In this connection, it is to be noted that the extra resonance energies of the substituted cyclohexadienyl radicals (III) simulating the transition state of the arylation at the meta position are calculated to be the same as those in the corresponding substrates (Table V, column 2), except for the case of the nitro group. Even in this case, however, the discrepancy is not serious, being 0.01 and 0.02 for $\delta=-0.5$ and -0.2, respectively. This result is very gratifying, since it means that the conjugative effect is nil for every substituent in accordance with the fact that the Hammett relation has been found to hold for the partial rate factors at the meta position.

Since the polar and the conjugative effect are separately taken into account above, the use of a substituent constant, such as σ_I[13], σ_p^o, or σ_p^n, which measures only the inductive effect, instead of σ_p, might seem more appropriate. The substitution of σ_I in Eq. 1, however, gives too large a value of τ_p for the nitrophenylation of chlorobenzene and anisole, and the use of σ_p^o or σ_p^n gives, although very slightly, too large a value of τ_p again for the nitrophenylation of chlorobenzene and anisole. On the other hand, Brown and Okamoto's σ^+ values[14] give negative values of τ_p for the nitrophenylation of anisole and toluene, indicating that in the *p*-nitrophenylation the electromeric electron-demand at the reaction centre is not so strong as to justify the use of σ^+. The fact that Hammett's σ_p gives the best constancy in τ_p values for each substituted benzene undoubtedly shows that the electromeric electron-demand at the reaction centre, even by an electrophilic radical such as *p*-nitrophenyl, is of so small a magnitude that the use of σ_p is suitable.

Experimental

Melting points are uncorrected.

Solvents.—Nitrobenzene, chlorobenzene, anisole, toluene and benzene were purified as described in Part VI[2].

Substituted Biphenyls Used as Carriers in Isotope Dilution Analysis.—2- and 3-Chlorobiphenyl were prepared according to Elks, Haworth and Hey's method[15] and were purified by chromatography on alumina in petroleum ether followed by recrystallization from methanol, m. p. 35°C and 19°C, respectively.

4-Chlorobiphenyl was prepared and purified as described in Part VI[2].

2- and 3-Methylbiphenyl were prepared by reaction of cyclohexanone with *o*- and *m*-tolylmagnesium bromide followed by dehydration and dehydrogenation, analogously to Hey and Jackson's preparation[16] of 3,4'-bitolyl, but with the use of twice the amount of sulphur in the dehydrogenation; they were then purified by repeated fractional distillations under reduced pressure. The boiling points are: 2-CH_3-, 126°C/13 mmHg (Found: C, 93.02; H, 7.12. Calcd. for $C_{13}H_{12}$: C, 92.81; H, 7.19%); 3-CH_3-, 135~136°C/13 mmHg (Found: C, 92.67; H, 7.21. Calcd. for $C_{13}H_{12}$: C, 92.81; H, 7.19%).

4-Methylbiphenyl was prepared by reaction of *N*-nitroso-*p*-acetotoluidide[17] with benzene and was recrystallized from methanol, m. p. 50.5°C.

4-Methyl-2'-nitrobiphenyl was prepared by reaction of *N*-nitroso-*p*-acetotoluidide[17] with nitrobenzene. After removal of the nitrobenzene, the residue was distilled with superheated steam and the distillate was fractionated by chromatography on alumina in petroleum ether-benzene (4:1) into an oily material and 4-methyl-4'-nitrobiphenyl, m. p. 140°C. The oil was fractionated under reduced pressure, and the distillate (b. p. 190~195°C/17 mmHg) was further purified by chromatography similar to the above to give 4-methyl-2'-nitrobiphenyl, m. p. 37~37.5°C (from methanol).

4-Methyl-3′-nitrobiphenyl was prepared according to Hey, Nechvatal and Robinson's method with some modification. Reduction of 4-methyl-4′-nitrobiphenyl (10 g.) with activated iron and water in benzene[18] followed by acetylation with acetic anhydride gave 4-acetamino-4′-methylbiphenyl (7.5 g.), m. p. 221°C. Into a mixture of this compound (1 g.), acetic acid (15 ml.) and concentrated sulphuric acid (1.6 ml.) maintained at 10°C, fuming nitric acid (d, 1.52; 0.25 g.) was gradually stirred. After 15 min., the mixture was poured into water to yield the 3-nitrated product (m. p. 164°C; 0.7 g.). The procedure for hydrolysis and deamination was the same as that described by Hey, Nechvatal and Robinson[19]. The final product was purified by recrystallization from methanol, m. p. 77.7°C.

The preparation of 4-methyl-4′-nitrobiphenyl was described in Part VII[3].

18) S. E. Hazlet and C. A. Dornfeld, *J. Am. Chem. Soc.*, **66**, 1781 (1944).

19) D. H. Hey, A. Nechvatal and T. S. Robinson, *J. Chem. Soc.*, **1951**, 2892.

2-Chloro-4'-methylbiphenyl was prepared as follows: (a) *N*-Nitroso-*p*-acetotoluidide[17] (157 g.) was allowed to decompose in chlorobenzene (3 l.). The product was isolated from the reaction mixture and fractionated by chromatography on alumina in petroleum ether, giving an oily material and a small amount of 4-chloro-4'-methylbiphenyl, m. p. 124°C. The oil was purified by repeating similar chromatography and distillation under reduced pressure to afford 22 g. of 2-chloro-4'-methylbiphenyl, b. p. 120~123°C/2 mmHg. (b) A mixture of *p*-iodotoluene (110 g.), *o*-iodochlorobenzene (40 g.), copper powder (150 g.), and clean sand (150 g.) was heated 6 hr. at 200~210°C. The reaction mixture was extracted with petroleum ether, and on removal of the solvent from the extract, the residue deposited crystals of 4,4'-bitolyl, which were then filtered off. The filtrate was purified in the same way as described under heading (a), b, p. 112~115°C/1 mmHg (yield, 7 g.). The specimens obtained by both method (a) and method (b) showed the same infrared spectrum (Found: Cl, 17.44. Calcd. for $C_{13}H_{11}Cl$: Cl, 17.48%).

Similarly, 3-chloro-4'-methylbiphenyl was prepared by the Ullmann reaction, m. p. 44~45°C (Found: Cl, 17.36. Calcd. for $C_{13}H_{11}Cl$: Cl, 17.48%).

The preparation of 4-chloro-4'-methylbiphenyl was described in Part VI[2].

2- and 3-Methoxy-4'-methylbiphenyl were prepared by the Ullmann reaction of *o*- and *m*-iodoanisole with *p*-iodotoluene. The experimental procedure was analogous to that mentioned above. Recrystallization of the crude products from methanol yielded the 2-isomer, m. p. 83°C (Found: C, 84.84; H, 7.17. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%) and the 3-isomer, m. p. 80°C. (Found: C, 84.72; H, 7.20. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%).

The preparation of 4-methoxy-4'-methylbiphenyl was described in part VII[3].

2,4'- and 3,4'-Bitolyl were prepared from 4-methylcyclohexanone and *o*- and *m*-bromotoluene according to Hey and Jackson's method[16] with some modification. The products were purified by repeated distillation under reduced pressure. The boilng points are: 2,4'-$(CH_3)_2$-, 149°C/20 mmHg (Found: C, 92.22; H, 7.87. Calcd. for $C_{14}H_{14}$: C, 92.26; H, 7.74%); 3,4'-$(CH_3)_2$-, 161~162°C/20 mmHg (Found: C, 92.22; H, 7.80. Calcd. for $C_{14}H_{14}$: C, 92.26; H, 7.74%), and the latter melts at 15°C.

4,4'-Bitolyl was prepared by the Ullmann reaction of *p*-iodotoluene and recrystallized from ethanol, m. p. 125°C.

Preparation of Labelled Compounds.—*N*-Nitroso-acet(anilide-^{14}C) (specific activity, 42.1±0.6 mc./mol.) was prepared by a method described elsewhere[20].

(*p*-Methyl-^{14}C)acetanilide was prepared from labelled toluene by acetylation and oximation followed by the Beckmann rearrangement. The detailed experimental procedure is described elsewhere[21].

N-Nitroso-(*p*-methyl-^{14}C)acetanilide was prepared by nitrosating (*p*-methyl-^{14}C)acetanilide (specific activity, 185.8±1.8 mc./mol.; 238 mg.) with nitrosyl chloride (2.6 ml. of a 10% solution in acetic anhydride) in a mixture of acetic acid (2.4 ml.) and acetic anhydride (0.6 ml.) in the presence of fused potassium acetate (0.67 g.) and a trace of phosphorus pentoxide according to the usual method (yield, 180 mg.).

Decomposition of Labelled *N*-Nitroso Compounds and Isotope Dilution Analyses. — The reactions were carried out in an equimolar binary or ternary mixture of aromatic solvents at 20.0°C (see Tables VI and VII); the general procedure for the analysis of the products was analogous to that described in previous papers, but the original reaction mixtures were diluted with acetone instead of benzene. The results of the isotope dilution analyses are summarized in Tables VI and VII.

Labelled biaryls recovered from the reaction mixtures were purified normally by recrystallization from methanol or ethanol until a constant specific activity was reached. The carbon-14 assay is described in Part V[4]. Biphenyl was recrystallized from methanol and finally sublimed. Since the following biaryls were difficult to purify enough for a correct carbon-14 assay, they were converted into suitable derivatives, which can be readily purified to afford specimens pure enough for the radioactivity measurement.

3-Chlorobiphenyl was nitrated by the method described in Part VII[3] to give 3-chloro-4'-nitrobiphenyl, which was purified by repeated recrystallization from methanol.

2- and 3-Methylbiphenyl and 2-chloro- and 2-nitro-4'-methylbiphenyl were converted, by oxidation with potassium permanganate in pyridine by a method similar to Dauben and Tanabe's method[22], into biphenyl-2-carboxylic acid, m. p. 110~111°C, biphenyl-3-carboxylic acid[23], m. p. 160°C, 2-chlorobiphenyl-4'-carboxylic acid, m. p. 247°C (Found: C, 66.95; H, 4.04; Cl, 15.44. Calcd. for $C_{13}H_9ClO_2$: C, 67.11; H, 3.90; Cl, 15.24%), and 2-nitrobiphenyl-4'-carboxylic acid, m. p. 251°C (Found: C, 64.30; H, 3.88; N, 5.92. Calcd. for $C_{13}H_9NO_4$: C, 64.20; H, 3.73; N, 5.76%), respectively. These acids were purified by recrystallizations from ethanol.

In experiments 4 and 5, the 4-methylbiphenyl recovered was nitrated by Grieve and Hey's method[24] to give 4-methyl-4'-nitrobiphenyl, which was then purified by recrystallization from methanol.

Similar nitration of the 2,4'-bitolyl recovered followed by reduction with hydrogen and a Raney nickel catalyst (W-7)[25] in ethanol and acetylation of the resulting amine with acetic anhydride gave monoacetamino-2,4'-bitolyl (Found: N, 6.02. Calcd. for $C_{16}H_{17}NO$: N, 5.85%), m. p. 166°C (from methanol). Similarly, the 3,4'-bitolyl recovered was converted into 4-acetamino-3,4'-bitolyl, m. p. 221°C (from ethanol).

Summary

N-Nitrosoacet(anilide-^{14}C) and *N*-nitroso-(*p*-methyl-^{14}C)acetanilide have been decomposed at 20.0°C in mixtures of benzene and monosubstituted benzenes, and the reaction products have been analyzed for biphenyl and substituted biphenyls by the isotope dilution method. From the results of these competitive experiments, the partial rate factors for the phenylation and *p*-methylphenylation have been calculated (Tables I and II).

The values of the partial rate factor for the meta position give a satisfactory Hammett plot with a slope of +0.05 for the phenylation and one with a slope of +0.03 for the *p*-methylphenylation, suggesting that the *p*-methylphenyl radical has little, if any, measure of polar character.

The correlation of the ρ values for various arylations with the inductive constant for the substituent group on the arylating radical indicates that the effect of the substituent group in the radical is purely inductive in nature.

The partial rate factor for the para position, k_p/k, is found to be related to Hammett's substituent constant by the following equation:

$$\log(k_p/k) = \rho\sigma_p + \tau_p$$

where ρ is the Hammett reaction constant for this arylation as determined from the Hammett plot of the partial rate factors of the meta position. τ_p is found to be tolerably constant for each substituted benzene, irrespective of the nature of the attacking aryl radical, and represents that part of the conjugative effect of the substituent which is independent of the polar nature of the attacking radical.

Molecular orbital calculations have given results which rationalize the trend found in the τ_p values.

The Photochemical Decomposition of α, α-Diphenyl-β-picrylhydrazyl (DPPH) in Solution. II. Products of the Photolysis and Its Reaction Mechanism

By Atuo SUZUKI*, Makoto TAKAHASI and Kengo SHIOMI

(Received March 27, 1963)

In the preceding paper of this series, the kinetic investigation of the photochemical decomposition of DPPH in solution was reported, and there was proposed a reaction mechanism which is compatible with the results of the kinetic experiments[1]. In order to obtain further detailed information on the decomposition mechanism, the reaction products were also investigated. In paper chromatographical analysis, the R_f values of the reaction products were determined; two of the products were found to be identical with those of α, α-diphenyl-β-picrylhydrazine (I) and α-phenyl-α-(*p*-nitrophenyl)-β-picrylhydrazine (II) respectively[2]. Further, by modifying the method of the photolysis, it became possible to obtain a large amount of the reaction products and to separate the reaction products in a relatively large amount on a cellulose column. Thus, two species of the reaction products were identified unequivocally as α, α-diphenyl-β-picrylhydrazine, and α-phenyl-α-(*p*-nitrophenyl)-β-picrylhydrazine by comparison with authentic specimens prepared by a different method.

The third component in the reaction products (III) (an experimental formula $C_{18}H_{10-11}\cdot N_3O_3$) has not yet been identified with any known compound, although a phenazine-type structure is presumed for it. On the basis of its structure and the previous kinetic results, however, it is presumed that this compound originates from excited DPPH; therefore, a reaction mechanism which involves the nitration of DPPH by the excited DPPH is herein proposed, a mechanism which is compatible with the findings of the previous kinetic experiment.

* Present address: Central Reaserch Institute, Teijin Limited, Hirayama, Hinomachi, Minamitama-gun, Tokyo.

1) Part I, This Bulletin, **36**, 644 (1963).

2) Until recently this compound was believed to be α, α-diphenyl-β-hydroxy-β-picrylhydrazine, but it has recently been demonstrated to be α-phenyl-α-(*p*-nitrophenyl)-β-picrylhydrazine by J. A. Weil, K. V. Sane and J. M. Kinkade, *J. Phys. Chem.*, **65**, 710 (1961).

Results and Discussion

Separation and Identification of the Reaction Products.—*Separation of the Products by Paper Chromatography.*—As a preliminary investigation, the reaction products were chromatographed on a filter paper. Porier[3] has described the separation of various hydrazyl derivatives by paper chromatography using several eluting solvents. In the present case, however, it was found that the most suitable solvent was a mixture of petroleum ether and carbon disulfide (1 : 1 by volume). The R_f values of the reaction products in the presence or absence of air shown in Tables Ia and Ib, which demonstrate that I and II have the same R_f values as those of α,α-diphenyl-β-picrylhydrazine and α-phenyl-α-(p-nitrophenyl)-β-picrylhydrazine respectively.

Table Ia. R_f-Values of reaction products
Decomposition was carried out at 25°C

Solvent	Condition of irradiation	Fraction A	B	C
Benzene	Air present	0.83	0.28	0.04
	Air absent	0.82	0.29	0.04
CCl_4	Air present	0.83	0.29	0.04
	Air absent	0.84	0.27	0.04

Table Ib. R_f-Values of reference substances

	I	II	DPPH
R_f-Value	0.83	0.27	0.84

I: α,α-Diphenyl-β-picrylhydrazine
II: α-Phenyl-α-(p-nitrophenyl)-β-picrylhydrazine

Isolation of the Reaction Products on a Cellulose Column.—Though the separation of the reaction products by paper chromatography is very convenient for the separation of a small amount of the products, it is necessary to obtain a large amount of the products in order to determine the structure of the product III. As a source of light for photolysis, sun-light was substituted for a tungsten lamp in order to complete the photolysis in a short time, and a cellulose column was used to separate a relatively large amount of the reaction products. Benzene was used as a solvent instead of carbon tetrachloride, since the reaction products by sun-light are found to be identical with those obtained under the controlled conditions described in the preceding paper. Three components are isolated on a cellulose column from the reaction products of DPPH, and I and II are confirmed unequivocally to be α,α-diphenyl-β-picrylhydrazine and α-phenyl-α-(p-nitrophenyl)-β-picrylhydrazine respectively by infrared spectra and by mixed melting point determinations with the authentic specimens. The structure of III will be discussed in detail later.

The Determination of the Ratios of the Reaction Products.—The method of the separation of the products on a cellulose column described above was also applied in the quantitative estimation of the reaction products. Known amounts of I, II and III were mixed and fractionated on a cellulose column, and the amount of the eluted products was determined by photometry. The visible and ultraviolet absorption spectra of DPPH, I, II and III are shown in Fig. 1, while the results of the quantitative determination of the reaction products are shown in Table II.

Table II. Fractionation of the three components on a powdered cellulose column

Eluting solvent	Petroleum ether+CS_2 (2 : 1)	Petroleum ether+CS_2 (1 : 1)	Benzene
Product	DPPH+I	II	III
Recovery (%)	99 104	103	98

I: α,α-Diphenyl-β-picrylhydrazine
II: α-Phenyl-α-(p-nitrophenyl)-β-picrylhydrazine
III: $(C_{18}H_{10-11}N_3O_3)_n$

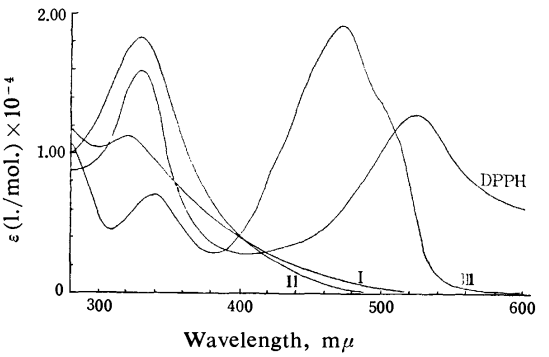

Fig. 1. Visible and ultraviolet absorption spectra of DPPH, α,α-diphenyl-β-picrylhydrazine (I), α-phenyl-α-(p-nitrophenyl)-β-picrylhydrazine (II), and unknown compound (III). ε of III is given by assuming its M.W. = 317.

The table shows that the method is satisfactory for the present purposes. The recovery of more than one hundred per cent of I and II might be due to errors in photometry caused by some impurities coming from the cellulose, which could not be completely removed even by extracting the adsorbent several times with benzene before its use.

Figure 2 gives the ratios of the reaction

3) R. H. Porier, E. J. Kahler and F. Benington, *J. Org. Chem.*, 17, 1437 (1952).

products in a benzene solution after various periods of the reaction time. Since the ratios of I, II and III do not vary markedly in the course of the decomposition, as is shown in Fig. 2, it may be concluded that no one of these three products is a precursor of the other. The total material balance at the final stage of the reaction may be approximated by saying that four moles of DPPH give approximately one mole of I (slightly more than one mole actually), two moles of II, and one mole of III (really slightly less than one mole). In a carbon tetrachloride solution, similar results were obtained, as is shown in Table III.

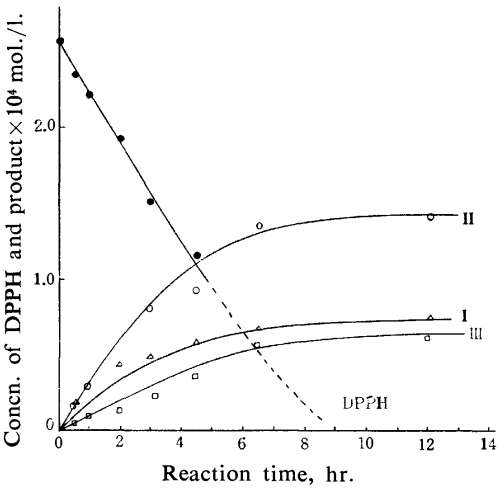

Fig. 2. Concentration-time curves of DPPH products in benzene solution.
I: α,α-Diphenyl-β-picrylhydrazine
II: α-Phenyl-α-(*p*-nitrophenyl)-β-picryl-hydrazine
III: Unknown compound

Investigation of the Structure of III.—*Physical Properties and Molecular Weight.*—The crude substance of III, which was isolated from the decomposition products of DPPH, gives orange-red needles when sublimed at a temperature between 230~250°C. It does not show a clear melting point, but decomposes gradually when heated above 280°C. In ordinary solvents it is sparingly soluble, but it is soluble in concentrated sulfuric acid or hydrochloric acid to give an orange solution without decomposition, indicating that it has basic property. Elemental analysis shows the chemical composition of $(C_{18}H_{10-11}N_3O_3)_n$. The determination of the molecular weight of III was attempted by various methods: the ebullioscopic method in dimethylformamide, the Rast method in camphor or camphor quinone, and the isothermal distillation method, but they produced no appreciable change in either boiling point or melting point within the possible upper limit of concentration, which is unfortunately very small in the available solvents, but the authors could nevertheless conclude that *n* should be more than three.

The Ultraviolet and Infrared Spectra of III.—The ultraviolet spectrum of III indicates a maximum absorption at $\lambda=470$ mμ, and it is

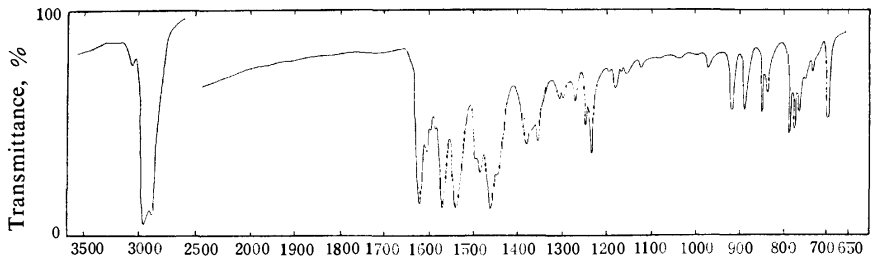

Fig. 3a.

TABLE III. AMOUNT OF THE REACTION PRODUCTS AT THE FINAL STAGE OF THE DECOMPOSITION IN mol./l.$\times 10^5$

Solvent	React. temp. °C	React. time hr.	Initial amount of DPPH*	Amount of products*				Total yield
				I	II	III	I+II+III	$\frac{\text{I+II+III}}{\text{DPPH}}\times 100$
Benzene	25	12	26.0	7.5	14.1	6.2	27.8	107
Benzene	45	12	26.0	7.7	13.2	6.3	27.2	105
CCl_4	25	17	27.7	8.1	14.3	6.0	28.4	103

* Concentration : mol./l.$\times 10^5$

to be noted that the maximum is located at longer wavelengths than those of I and II, suggesting that III has a larger conjugate system than I and II.

The infrared absorption spectrum of III, along with those of II, 10-phenyl-1, 3-diniro-9, 10-dihydrophenazine, phenazine and phenazine oxide as reference substances, are shown in Fig. 3.

No characteristic bands corresponding to the stretching vibration of N–H or O–H are observed in the 3000~3500 cm^{-1} region of the spectrum of III. The absorption bands at 1535 cm^{-1} and 1300 cm^{-1} are assigned to the nitro group. A band at 1235 cm^{-1} is difficult to assign to a unique vibration, but it might originate from the asymmetrical stretching vibration of the ether-type bond R–O–R if the supposed structure of III is accepted. α, α-Diphenyl-β-picrylhydrazine, 10-phenyl-1, 3-dinitro-9, 10-dihydrophenazine, and III have a strong band at 695 cm^{-1} in common, a band which is assigned to an out-of-plane bending vibration of the aromatic C–H of mono-substituted benzene. In mono-substituted benzene, we should expect another absorption band near 750 cm^{-1}; Fig. 3a shows two bands at 755 and 767.5 cm^{-1}, but it is not certain which of the two bands is to be assigned to this bending vibration. Figure 3a also shows bands at 835, 845, 882.5 and 915 cm^{-1}, indicating the presence of poly-substituted benzene nuclei in III.

The Reduction of III with Stannous Chloride.—The chemical formula $(C_{18}H_{10-11}N_3O_3)_n$ indicates the presence of one nitro group in one monomer unit, this combination being compatible with the infrared spectrum of III. In order to confirm the presence of this nitro group and simultaneously to investigate the possibility of the presence of any other reducible group or center, such as *N*-oxide or a free radical electron, the quantitative reduction of III with stannous chloride has been carried out. It has been found that three moles of stannous chloride were consumed per one mole of monomer unit of III, confirming the results of the infrared spectrum and elemental analysis. Further, this result shows that no other easily reducible group or center exists in the compound. The authors also concluded that the original hydrazine bond of DPPH is not left intact in the structure of III, since it is generally known that the usual hydrazine bond is split by stannous chloride to give amino compounds.

The Reaction of III with Hydroiodic Acid.—In order to explain the one extra atom of oxygen, in addition to the nitro group, in the chemical formula $C_{18}H_{10-11}N_3O_3$, the presence of ether-type oxygen was supposed, and the reaction of III with hydroiodic acid was carried out in attempt to open the supposed ether bond. When III was treated with hydroiodic acid, it gave a compound containing one atom of iodine for one unit of III, this compound does not, however, seem to be any simple salt nor molecular complex, because it does not liberate iodide ions when treated with alkali. The infrared spectrum of this compound is very different from that of III, but it does not show any band characteristic of N–H or O–H in the 3000~3500 cm^{-1} region. In spite of this finding, we could not, considering the general high resistivity of the aromatic ether bond to hydroiodic acid, discard the possibility of the presence of ether-type oxygen in III.

The Supposed Structure of III.—The whole of the available data described above is still not sufficient to establish the structure of III, particularly since its molecular weight is not yet known, but the following statements on the structure of III may be accepted at the present stage of knowledge:

(1) Three benzene skeletons are preserved, and one of them is of the mono-substituted type.

(2) One nitro group remains in a benzene nucleus which was originally the picryl group, but it is not known which one of the three nitro group (para or ortho) is thus preserved.

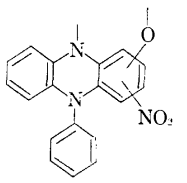
(3) The hydrazine-type $\rangle$N–N$\langle$ bond is split during the reaction to form a phenazine-type ring which is considered to be more stable than the hydrazine derivatives.

It is interesting that Wieland[4] found that the

4) H. Wieland, *Ber.*, **41**, 3478 (1908); **48**, 1078 (1915).

phenazine ring is formed from substituted tetraphenylhydrazines by the action of acid, although the present reaction conditions are different from these in Wieland's experiment.

Summarizing these results, a provisional presentation of the unit structure of III may be shown as follows:



The Material Balance of the Photolysis of DPPH.—According to the experiment determining the ratios of the reaction products, we propose the following stoichiometric relation:

$$4C_{18}H_{12}N_5O_6 \rightarrow C_{18}H_{13}N_5O_6 \text{ (I)} + 2C_{18}H_{12}N_6O_8 + C_{18}H_{10-11}N_3O_3 \text{ (III)}$$

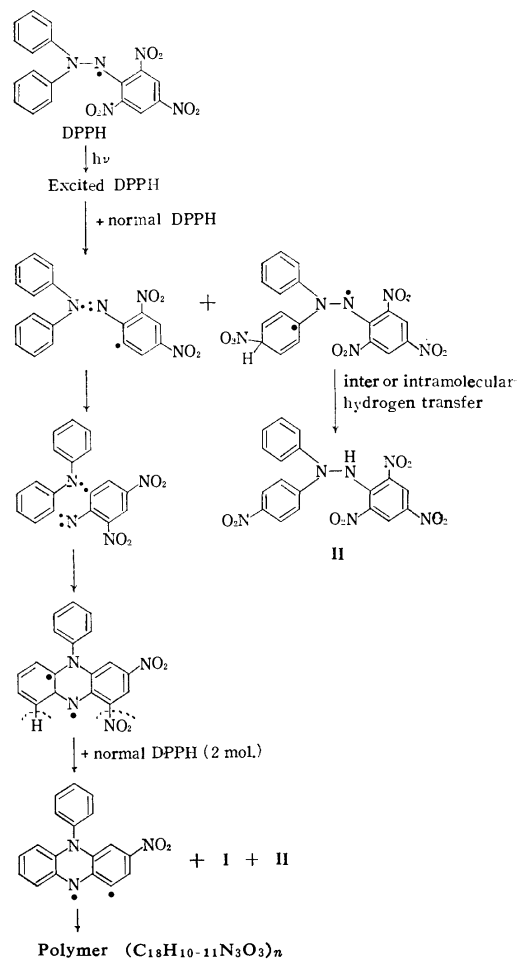
Although there is an excess atom of oxygen on the right hand side, the material balance seems to be fairly statisfactory, considering the accuracy of the quantitative estimation of the reaction products. No definite explanation of the unbalance in the number of oxygen atoms in the above equation is available at present, but it is possible that the oxygen atom is introduced from air or water during the treatment of the reaction products after the irradiation.

In spite of our efforts to find any other reaction product, gas chromatography failed to detect any such volatile substance as nitrobenzene which might be expected to result from the reaction of excited DPPH with the solvent benzene. It was found, however, that some nitrogen oxide existed in the reaction mixture. When the benzene mixture of the reaction products was extracted with water several times, the Gries test showed the presence of nitrous ions in the water extract, but the amount was very small (about one part to 80 parts of DPPH). Further, it was found that III itself produces some nitrogen oxide, most probably nitrogen dioxide, by irradiating its solution. It is presumed that nitrogen oxide comes from the nitro group of III by irradiation, although the detailed mechanism is not known. The nitrogen oxide found in the original reaction mixture of photolysis of III might be produced by the secondary decomposition of III.

The Reaction Mechanism of the Photolysis of DPPH.—In the absence of further data, it is premature to propose a complete scheme for photolysis of DPPH, but our kinetic investigation described in the preceding paper shows that the experimental rate expression fits the following reaction scheme:

$$\begin{aligned} D^* + h\nu &\longrightarrow D^* \\ D^* + (\text{solvent}) &\longrightarrow D \\ D^* + D &\longrightarrow D^*D \\ D^*D &\longrightarrow A + P_1 \\ P_1 + D &\longrightarrow B + P_2 \\ P_2 + D &\longrightarrow C + P_3 \end{aligned}$$

The products described here as A and B, are not directly related to the final products identified in the present work, but the authors assume that excited DPPH transfers its two nitro groups to normal DPPH to give α-phenyl-α-(p-nitrophenyl)-β-picrylhydrazine. The course through which the original excited DPPH is transformed to III is not yet clearly understood, and it might be difficult to describe the process completely in termes of a classical structure formula. The following scheme must be admitted to be rather speculative, but it is given to show some idea of the reaction mechanism:



Experimental

The Decomposition of DPPH in a Benzene Solution by Sun-light.—One gram of DPPH was dissolved in 1 l. of purified and dried benzene. In order to increase the surface area of the solution exposed to sun-light, the solution was divided into five glass tubes 2 cm. in diameter by 70 cm. in length, and each tube was sealed without evacuation, leaving air in the space above the surface of the solution. They were exposed to sun-light for about twenty days. By the time the decomposition was completed, the color of the solution had become brown red, giving a brown precipitate. The benzene was removed under reduced pressure, and the residue was fractionated by elution chromatography on a powdered cellulose column measuring 9.0 cm. in diameter by 40 cm. in length and containing 400 g. of adsorbent, using a solvent mixture of petroleum ether and carbon disulfide (2 : 1 by volume) as the eluting solvent. After the first fraction, which was α,α-diphenyl-β-picrylhydrazine (I), came out, the ratio of petroleum ether to carbon disulfide was varied from 2 : 1 to 1 : 1 by volume to elute α-phenyl-α-(*p*-nitrophenyl)-β-picrylhydrazine. The last component was eluted with benzene. Each component was readily distinguishable by the color of the zone. The eluting solvents were distilled off under reduced pressure, and the residue was purified in the following way: I was recrystallized from a mixture of chloroform and alcohol (1 : 1 by volume); 0.12 g. of brick-red crystals (m. p. 171~172°C) were obtained. II was purified by recrystallization from an ethyl acetate-alcohol mixture (1 : 2 by volume); brick-red crystals, (m. p. 152~153°C; weight, 0.21 g.) were obtained. I and II did not depress the melting points of admixture with authentic samples of α,α-diphenyl-β-picrylhydrazine and α-phenyl-α-(*p*-nitrophenyl)-β-picrylhydrazine respectively, and III (0.10 g.) was obtained as a brick-red powder.

The Quantitative Determination of the Reaction Products.—After known amounts of benzene solutions of DPPH, I, II and III were mixed, the solvent was removed by evaporating it under reduced pressure in the dark, and the residue was fractionated on a cellulose column by the method described in the preceding paragraph. The solvents of each fraction were evaporated up to dryness under reduced pressure in the dark, and the residues were dissolved in benzene. From the first fraction the amount of DPPH was determined colorimetrically by absorption at 520 mμ using $\varepsilon=1.28\times10^4$ l./mol., assuming $\varepsilon=0$ for I. The amount of I was obtained from the absorption at 320 mμ minus that of DPPH using $\varepsilon=1.13\times10^4$ l./mol., and $\varepsilon=1.83\times10^4$ l./mol. for I and DPPH respectively. The amounts of II and III were determined by the absorption at 330 mμ ($\varepsilon=1.83\times10^4$ l./mol.) and 470 mμ respectively. The number of moles of III was calculated by assuming its chemical formula to be $C_{18}H_{10}N_3O_3$.

The Determination of the Ratios of the Reaction Products in the Course of the Decomposition.—Fifty milliliters of a benzene solution of DPPH (2.60×10^{-4} mol./l.) was irradiated, and 2 ml. of the solution was pipetted out after various periods of time. Each component in the reaction mixture was determined by the method described in the preceding paragraph.

The Purification of the Product III.—The substance III, which was obtained by column chromatography, has a fairly high purity, but further purification can be achieved by sublimation, giving orange needles. A convenient apparatus for it is shown in Fig. 4.

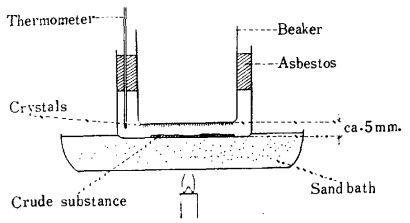


Fig. 4. Apparatus for sublimation of III.

The chemical composition and the visible and ultraviolet absorption spectra after sublimation were consistent with those obtained before sublimation.

Found: C, 68.28; H, 3.47; N, 13.28. Calcd. for $C_{18}H_{10}N_3O_3$: C, 68.35; H, 3.18; N, 13.28. $C_{18}H_{11}N_3O_3$: C, 68.13; H, 3.49; N, 13.24%.

After sublimation; C, 68.10; H, 3.50%.

The Estimation of the Molecular Weight.—The molal elevation constant (K) for dimethylformamide was found to be 18.9°C by using azobenzene. The elevation of the boiling point of the solution of III (0.0171 g.) in dimethylformamide (2.084 g.) was less than 0.10°C, indicating that the number of n is larger than 4.

Because of the low solubility of III in camphor or camphor quinone, as well as because of the coloring of the solutions, the determination of the molecular weight by Rast's method was unsuccessful. The depression of the melting point of a mixture of III (1.3 mg.) with camphor quinone (92.2 mg.) was scarcely observed. If the molecular weight of III is assumed to be about 320, the depression can be expected to be about 2°C in the concentration. When an isothermal distillation method[5] was also applied to III, using benzene as the solvent, the shift of meniscus was hardly noticeable.

The Quantitative Reduction of III with Stannous Chloride in Sulfuric Acid[6].—Nineteen milligrams of III purified by sublimation was suspended in 5 ml. of ethanol which had previously been freed from aldehyde by refluxing it for several hours in a rapid stream of carbon dioxide. When 2 ml. of dilute sulfuric acid (1 : 1 by volume) and 2 ml. of a standard stannous chloride solution (142.1 mg./ml.) were added, the color of III turned reddish violet. During the reduction, a slow stream of carbon dioxide was led into the flask, and the mixture was heated gradually on a water bath. When,

5) R. P. Linstead et al., "A Course in Modern Techniques of Organic Chmistry", Butterworths Scientific Publications, London (1955), p. 150.

6) A. Weissberger et al., "Organic Analysis II", Interscience Publishers, Inc., New York (1954), p. 77.

after half an hour, the reduction had been completed, the contents of the flask were rapidly cooled, diluted with 30 ml. of water, saturated with carbon dioxide, and rapidly titrated against a standard solution of iodine (35.98 mg./ml.), the end point being determined by a pH meter. The difference in the iodine solution between the amount of a blank test and that after the reaction was 1.27 ml., which corresponds to 34.7 mg. of stannous chloride. The theoretical amount of stannous chloride needed to reduce 19.0 mg. of III is 34.2 mg., assuming ing III to have only one nitro group per unit.

The Reaction of III with Hydroiodic Acid.— When a mixture of 10 mg. of III and 0.5 ml. of hydroiodic acid (52%) was heated on a water bath, reaction took place immediately, and the mixture turned black. After heating the mixture of ten minutes, the excess hydroiodic acid was filtered off and the residue was extracted with cold alcohol (95%) several times. The combined alcohol solution was diluted with water to give a dark precipitate which weighed 12.8 mg. when dried at 60°C/2 mmHg for 200 min. The free iodine accompanying the precipitate was completely eliminated in the drying procedure under vacuum.

The Molecular-weight Estimation of the Reaction Product. — When the reaction product (27.8 mg.) of III with hydroiodic acid was dissolved in bromoform (6.322 g.), the depression of the melting point was 0.005°C. As the molal depression constant for bromoform is 14.4°C, the molecular weight was calculated to be 1270, which means that III is a trimer of ($C_{18}H_{10}N_3O_3I$, mol. wt. 443). In such a a case, the depression should be not so large as to enable us to determine the molecular weight precisely, but it may be concluded that the number of n for $(C_{18}H_{10}N_3O_3I)_n$ is larger than 3.

The Determination of Nitrous Ions[7]. — DPPH (10.46 mg. 27 μ mol.) was dissolved in distilled dry benzene (100 ml.) and irradiated for 13 hr., according to the procedure described in the preceding paper, until the decomposition of DPPH had been completed. The reaction mixture was extracted several times with distilled water (in total 100 ml.) until the extract did not show the presence of nitrous ions. The extract was then brought to reaction with Griess' reagent and the amount of nitrous ion was determined colorimetrically, using a calibration curve obtained by an experiment with a known amount of sodium nitrite. The extract was found to contain 10^{-3} mg. of nitrous ions per 100 ml.

The benzene solution of the reaction mixture, which had been completely extracted with water and which was free from nitrous ion, was then divided into two parts; one of these was kept in the dark, and the other was irradiated for another 9 hr.

When the solutions were extracted with distilled water (in total 50 ml.), the one kept in the dark showed a scarcely positive Griess test, but the irradiated one contained 3.3×10^{-3} mg. (0.07 μmol.) of nitrous ions per 50 ml. of solution. The former was fractionated on a cellulose column into three components, and each component was then dissolved in benzene (50 ml.) as before. When these benzene solutions had been further irradiated for 9.5 hr., nitrous ions were detected only in the solution of III. The change in the absorption spectra of III before and after the irradiation was shown in Fig. 5.

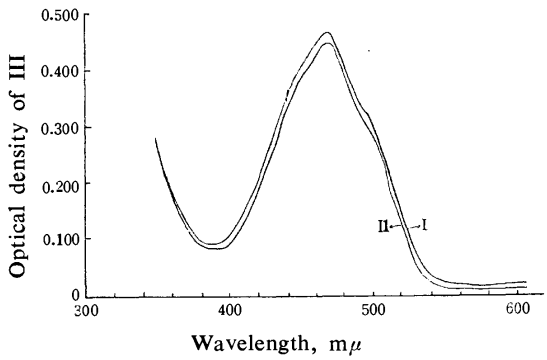

Fig. 5. Change in the absorption spectra of III before and after the irradiation.
I: Immediately after the isolation
II: After irradiation for 9.5 hr.

The other experiment, in which DPPH (10.50 mg.) (27 μ mol.) was dissolved in benzene (100 ml.) and irradiated for 22 hr., showed that the amount of nitrous ions was at most 17.25×10^{-3} mg. (0.37 μ mol.), which corresponds approximately to one part to twenty parts of III, assuming that III is produced in the yield of about 25 per cent from DPPH. Since the photochemical decomposition of III seems to be very slow, the low yield of nitrous ions and the high yield of III in the original reaction mixture of the photolysis of DPPH is understandable.

Summary

1. DPPH in a benzene solution was decomposed by sun-light on a relatively large scale in the presence of air, and the prducts were separated on a cellulose column. The products were identified as α,α-diphenyl-β-picrylhydrazine (I), α-phenyl-α-(p-nitrophenyl)-β-picrylhydrazine (II), and a third component (III) with a chemical composition of $(C_{18}H_{10-11}N_3O_3)_n$ (the n is greater than 3).

2. The method of separation by means of a cellulose column was applied in the quantitative estimation of the reaction products. The ratios of the products in the course of the decomposition were determined. From the ratio at the final stage, the over-all reaction can be written as follows:

$$4\ \mathrm{DPPH} \rightarrow \mathrm{I} + 2\,\mathrm{II} + \mathrm{III}$$

3. The physical and chemical properties of the third component have been described, and a possible structure for III has been proposed.

4. From the material balance and the

7) M. B. Shin, *Ind. Eng. Chem., Anal. Ed.*, 13, 33 (1941).

chemical compositions of the reaction products, it is presumed that the early stage of the decomposition of DPPH induced by light is an intermolecular nitration of DPPH.

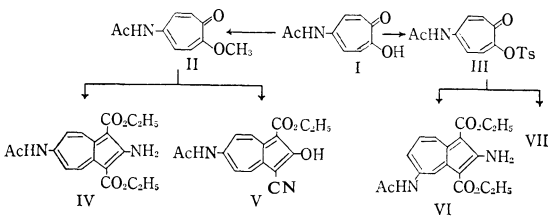
The Synthesis of 5- and 6-Aminoazulene Derivatives

By Tetsuo NOZOE, Kahei TAKASE and Masao TADA*

(Received February 25, 1963)

In our laboratory, we have made an effort to synthesize azulenes by the action of such active methylenes as malononitrile and ethyl cyanoacetate on troponoids[1-4]. Although this method, using substituted troponoids as the starting material, should provide a suitable method for the synthesis of azulenes with a functional group on the seven-membered ring, very few instances have been reported. We report herein the synthesis of 5- and 6-aminoazulene derivatives from 5-acetamidotropolone (I)[5].

The application of ethyl cyanoacetate, in the presence of one mole of sodium ethoxide, to 5-acetamido-2-methoxytropone (II) afforded two compounds, diethyl 6-acetamido-2-aminoazulene-1, 3-dicarboxylate (IV) and ethyl 6-acetamido-3-cyano-2-hydroxyazulene-1-carboxylate (V), while 5-acetamido-2-(*p*-tolylsulfonyloxy)tropone (III) afforded diethyl 5-acetamido-2-aminoazulene-1, 3-dicarboxylate (VI) and yellow crystals (VII) (m. p. above 270°C). The ultraviolet spectra of these compounds are shown in Figs. 1 and 2.



The structural proof of IV, V and VI was based on the analysis and on a comparison of the ultraviolet and infrared spectra with those of known compounds. The validity of the structures proposed was also supported by the well-established general concept that 2-halo- and 2-(*p*-tolylsulfonyloxy)tropones undergo condensation at the 1- and 7-positions of the troponoids, whereas 2-methoxytropones give rise to azulene derivatives derived by condensation at the 1- and 2-positions. The yellow compound (VII), $C_{14}H_{14}O_5N_2$, was shown by ultraviolet spectral evidence not to be an

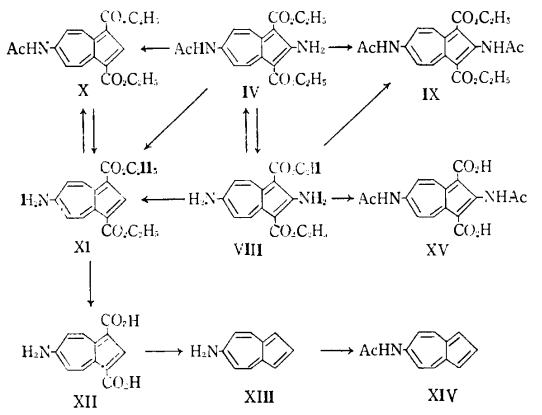
azulene derivative; its precise structure will be reported on in another paper.

The alkaline hydrolysis of IV afforded a dull brown 2, 6-diamino compound VIII, the acetamido group being predominantly attacked; acetylation of the latter, in turn, gave first IV and then diacetate IX, which was also obtained by the acetylation of IV. Mono Schiff's base was obtained from VIII by the action of benzaldehyde. The diazotization of IV was realized by isoamyl nitrite or sodium nitrite and an excess of sulfuric acid, and decomposition of the diazonium salt formed was carried out by either leaving it standing at room temperature or treating it with active copper and sodium hypophosphite. The reactions carried out in dioxane gave the deaminated product, diethyl 6-acetamidoazulene-1, 3-dicarboxylate (X), while these carried out in aqueous ethanol gave diethyl 6-aminoazulene-1, 3-dicarboxylate (XI), the hydrolysis product of the acetamido group. The acetylation of XI gave X, and the acidic hydrolysis of X afforded XI. XI was obtained also by deamination of the diamino compound VIII, which showing the greater basicity of C_2-amino between the two amino groups. 6-Amino compound XI gave, on alkaline hydrolysis, a dicarboxylic acid XII, the decarboxylation of which in pyridine furnished 6-aminoazulene (XIII) in the form of red prisms (ultraviolet spectrum Fig. 3). XIII is rather unstable and darkens on being left in air for a long time, while its blueish acetate XIV is quite stable (ultraviolet spectrum Fig. 3).



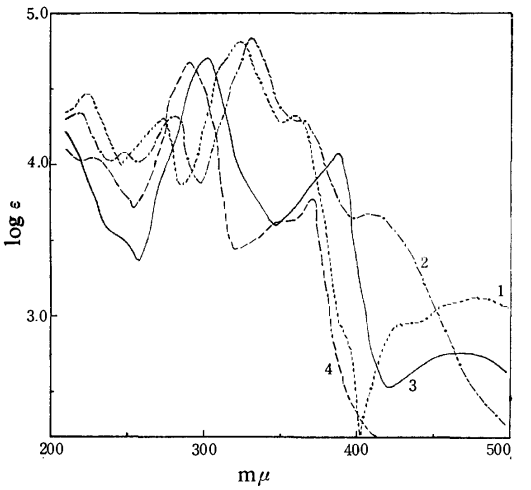


Fig. 3. Ultraviolet absorption spectra in methanol.
1 Diethyl 6-acetamidoazulene-1, 3-dicarboxylate (X)
2 Diethyl 6-aminoazulene-1, 3-dicarboxylate (XI)
3 6-Aminoazulene (XIII)
4 6-Acetamidoazulene (XIV)

In an attempt to derive 2, 6-diaminoazulene, the corresponding dicarboxylic acid XV was obtained from VIII. An attempt to decarboxylate XV on heating, however, resulted in a dark tarry material from which none of the desired product was isolated.

The preferential formation of a 6-acetamido derivative IV on the mild acetylation of 2, 6-diaminoazulene VIII, which contrasts with the preferential diazotization of the 2-amino group, can be explained by the operation of a steric hindrance caused by the presence of the two ethoxycarbonyl groups adjacent to the 2-amino group.

Experimental[6]

The Reaction of 5-Acetamido-2-methoxytropone (II) and Ethyl Cyanoacetate. — To a sodium ethoxide solution prepared from sodium (375 mg.) and absolute ethanol (30 ml.) were added ethyl cyanoacetate (3.6 g.) and then a suspension of II (3.12 g.) in absolute ethanol (50 ml.). The mixture was stirred for 4 hr. and then allowed to stand for 2 days at room temperature. The solvent was removed in vacuo, and water was added. The crystals which separated (2.5 g.) were recrystallized from ethanol to afford IV as yellow needles; m.p. 216~217°C.

Found: C, 62.95; H, 5.42; N, 8.28. Calcd. for $C_{18}H_{20}O_5N_2$: C, 62.78; H, 5.85; N, 8.14%.

λ_{max}^{MeOH} mμ (log ε): 245 (4.49), 280 (4.14), 335 (4.79), 420 (4.14), 462 (3.71). IR (Nujol): 3490, 3335, 1694, 1650, 1637 cm^{-1}.

The Picrate of IV.—M. p. 178~179°C (decomp.); black micro-prisms (from ethanol).

Found: C, 49.90; H, 4.09; N, 12.63. Calcd. for $C_{24}H_{23}O_{12}N_5$: C, 50.26; H, 4.04; N, 12.21%.

The aqueous mother liquor, after the separation of crystals, was extracted with benzene, by which a further crop of IV (0.20 g.) was obtained. The water layer was acidified with 6 N sulfuric acid, and the crystals (m. p. 220~230°C (decomp.)) thereby formed were collected by filtration and recrystallized from ethyl acetate to give V as yellowish brown micro-prisms; m. p. 234~236°C (decomp.); 70 mg.

Found: C, 63.70; H, 4.48; N, 9.02. Calcd. for $C_{16}H_{14}O_4N_2$: C, 64.42; H, 4.73; N, 9.39%.

λ_{max}^{MeOH} mμ (log ε): 232 (4.51), 330 (4.86), 395 (4.01), 420 (3.65) sh, 460 (3.35) sh. IR (Nujol): 3460, 2232, 1781, 1709, 1692 cm^{-1}.

The Reaction of 5-Acetamido-2-(*p*-tolylsulfonyloxy)tropone (III) and Ethyl Cyanoacetate.—The reaction and the working-up of the reaction mixture were carried out in exactly the same way as in the previous section, using sodium (85 mg.), absolute ethanol (12 ml.), ethyl cyanoacetate (0.75 g.) and III (1.00 g.) in absolute ethanol (20 ml.). The crystals which separated (400 mg.) were recrystallized from ethanol to give pale yellow leaflets (VII); m. p. above 270°C.

Found: C, 57.74; H, 5.07; N, 9.54. Calcd. for $C_{14}H_{14}O_5N_2$: C, 57.93; H, 4.86; N, 9.65%.

λ_{max}^{MeOM} mμ (log ε): 247 (4.25), 306 (4.49), 336 (4.23), 454 (3.13).

The mother aqueous liquor give a crystalline substance, 150 mg. of VI, which, after recrystallization from ethanol, gave yellow needles; m. p. 184~185°C.

Found: C, 62.74; H, 5.87; N, 8.06. Calcd. for $C_{18}H_{20}O_5N_2$: C, 62.78; H, 5.85; N, 8.14%.

λ_{max}^{MeOH} mμ (log ε): 263 (4.51), 336 (4.89), 392 (3.98), 450 (3.24) sh. IR (Nujol): 3500, 3370, 3220, 1669 cm^{-1}.

The Picrate of VI.—M. p. 150~151°C (decomp.); pale yellow crystals (from ethanol).

Found: N, 14.28. Calcd. for $C_{30}H_{26}O_{19}N_8$: N, 14.09%.

Diethyl 2, 6-Diaminoazulene-1, 3-dicarboxylate (VIII).—IV (200 mg.) was heated under reflux for 4 hr. with potassium hydroxide (200 mg.) in ethanol (12 ml.); by this procedure 100 mg. of brownish green crystals were precipitated. Recrystallization from benzene afforded VIII as dull brown plates with a metallic luster; m. p. 207~208°C.

Found: C, 63.76; H, 5.56; N, 9.20. Calcd. for $C_{16}H_{18}O_4N_2$: C, 63.56; H, 6.00; N, 9.27%.

λ_{max}^{MeOH} mμ (log ε): 224 (4.25), 262 (4.47), 296 (4.24), 346 (4.74), 430 (4.09), 472 (3.98). IR (Nujol): 3470, 3410, 3320, 3205, 1637 cm^{-1}.

VIII was acetylated to give IV by warming it in acetic anhydride on a water bath for 4 hr.

The Picrate of VIII.—M. p. 180~181°C (decomp.); black needles (from ethanol).

Found: C, 49.89; H, 3.88; N, 13.01. Calcd. for $C_{22}H_{21}O_{11}N_5$: C, 49.71; H, 3.99; N, 13.18%.

The Benzylidene Derivative of VIII.—A solution of VIII (90 mg.), a drop of acetic acid, and benzaldehyde (100 mg.) in ethanol (2 ml.) was warmed on a water bath for 15 min. After the solution had been allowed to stand overnight at room temperature, the crystals (70 mg.) deposited were recrystallized from benzene to recover 20 mg. of VIII. The filtrate was evaporated to dryness, and recrystallization from cyclohexane afforded a benzilidene derivative as orange prisms; m. p. 140~141°C, 15 mg.

Found: C, 70.97; H, 5.58; N, 7.25. Calcd. for $C_{23}H_{22}O_4N_2$: C, 70.75; H, 5.48; N, 7.18%.

IR (Nujol): 3500, 3370, 1686, 1664 cm^{-1}.

Diethyl 2, 6-Diacetamidoazulene-1, 3-dicarboxylate (IX).—A solution of IV in acetic anhydride, in the presence of pyridine, was refluxed on an oil bath for 3 hr. The crystalline residue produced by the evaporation of the solvent was recrystallized from ethanol to give IX as orange needles; m. p. 188~189°C.

Found: C, 62.66; H, 5.74; N, 7.27. Calcd. for $C_{20}H_{22}O_6N_2$: C, 62.16; H, 5.74; N, 7.25%.

λ_{max}^{MeOH} mμ (log ε): 345 (4.56), 316 (4.75), 327 (4.83), 378 (3.90), 398 (3.94), 470 (3.43). IR (Nujol): 3495, 3330, 1714, 1667 cm^{-1}.

The Deamination of IV.—*a) The Formation of Diethyl 6-Acetamidoazulene-1, 3-dicarboxylate (X).*— Into a solution of IV (200 mg.) and concentrated sulfuric acid (0.4 ml.) in dioxane (6 ml.) was added sodium nitrite (50 mg.) in water (2 ml.) with stirring. After the mixture had been stirred for a further 30 min., active copper powder (100 mg.) and sodium hypophosphite (0.8 g.) were added. The mixture was stirred for a further 3 hr. and then allowed to stand overnight at room temperature. The reaction mixture was diluted with water (200 ml.) and extracted with ethyl acetate, and the extract was passed through a column of alumina, yielding X (130 mg.). Recrystallization from ethanol formed orange leaflets; m. p. 221~221.5°C.

Found: C, 65.27; H, 5.57; N, 4.06. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.82; N, 4.25%.

λ_{max}^{MeOH} mμ (log ε): 227 (4.46), 276 (4.30), 329 (4.80), 366 (4.29), 475 (3.04). IR (Nujol): 3320, 1706, 1695, 1667 cm^{-1}.

6) All melting points are uncorrected. Shoulders in the UV spectral data are by sh.

b) The Formation of Diethyl 6-Aminoazulene-1, 3-dicarboxylate (XI).—i) Into a solution of IV (200 mg.) and concentrated sulfuric acid (1.2 ml.) in 60% aqueous ethanol (20 ml.), isoamyl nitrite (180 mg.) was added with stirring while the mixture was being ice-cooled. After the mixture had been stirred for a further 30 min., ethanol (8 ml.) was added and the mixture was allowed to stand overnight at room temperature. The mixture was extracted with ethyl acetate after the addition of water (200 ml.), and the extract was passed through a column of alumina to give XI (10 mg.). The water-layer was adjusted to a slightly alkaline state and extracted with ethyl acetate. By the same purification, XI (90 mg.) was obtained. Recrystallization from ethanol formed orange scales; m. p. 236~237°C, 85 mg.

Found: C, 66.98; H, 6.01; N, 4.87. Calcd. for $C_{16}H_{17}O_4N$: C, 66.88; H, 5.96; N, 4.88%.

λ_{max}^{MeOH} mμ (log ε): 225 (4.34), 252 (4.04), 284 (4.34), 335 (4.82), 365 (4.28), 410 (3.65). IR (Nujol): 3410, 3320, 3205, 1650 cm^{-1}.

The Picrate of XI.—M. p. 209~210°C (decomp.); orangish brown scales (from ethanol).

Found: C, 51.40; H, 4.17; N, 11.20. Calcd. for $C_{22}H_{20}O_{11}N_4$: C, 51.16; H, 3.90; N, 10.85%.

ii) To the diazotized solution of IV (200 mg.) with isoamyl nitrite (180 mg.), active copper powder (100 mg.) and sodium hypophosphite (0.8 g.) were added. The mixture was stirred for 2 hr. and then allowed to stand overnight at room temperature. After removal of the copper powder, the reaction mixture was treated as in i) to obtain XI (145 mg.).

iii) Into a solution of IV (200 mg.) in dioxane (8 ml.) and concentrated sulfuric acid (0.2 ml.), a solution of sodium nitrite (50 mg.) in water (2 ml.) was added with stirring while the mixture was being cooled. After the mixture had been stirred for 15 min., ethanol (5 ml.) and active copper powder (100 mg.) were added, and the mixture was warmed in a water bath for 1 hr. The solution was concentrated to half volume under a reduced pressure and treated as in i) to obtain XI (105 mg.).

The acetylation of XI with acetic anhydride by refluxing it for 10 min. gave X. The hydrolysis of X by refluxing it with 6 N sulfuric acid in ethanol gave XI.

The Deamination of VIII.—A solution of VIII (100 mg.) in 60% aqueous ethanol (10 ml.) and concentrated sulfuric acid (0.6 ml.) was diazotized with isoamyl nitrite (90 mg.) and treated as in the case of the deamination of IV, b-i); XI (20 mg.) was obtained.

6-Aminoazulene-1, 3-dicarboxylic Acid (XII).—A solution of XII (120 mg.) and potassium hydroxide (90 mg.) in 60% aqueous ethanol (15 ml.) was refluxed for 4 hr. The solution was concentrated to half volume under a reduced pressure, and this was then diluted with water (15 ml.) and acidified with 6 N sulfuric acid. The precipitate thereby formed was collected by filtration and repeatedly washed with water, by which process dicarboxylic acid (XII) was obtained as black crystalline powder; m. p. above 275°C; 80 mg.

6-Aminoazulene (XIII).—A solution of XII (80 mg.) in pyridine (2 ml.) was heated at 140~150°C to effect decarboxylation. The residue produced by evaporation of the excess of pyridine was dissolved in benzene and passed through a column of alumina, while the crude material obtained by the concentration of the effluent was recrystallized from ethanol to give XIII (m. p. 106~107°C; 10 mg.) as red scales.

Found: C, 84.12; H, 6.80; N, 9.32. Calcd. for $C_{10}H_9N$: C, 83.88; H, 6.34; N, 9.78%.

λ_{max}^{MeOH} mμ (log ε): 306 (4.70), 390 (4.07), 465 (2.70). in EtOH; 470 (2.71). IR (Nujol): 3420, 3330, 3200 cm^{-1}.

6-Acetamidoazulene (XIV).—A solution of XIII (20 mg.) in acetic anhydride was warmed on a water bath for 5 min. The crystalline residue produced by the evaporation of the solvent was recrystallized from ethanol to give XIV (10 mg.) as blue needles.

Found: C, 78.26; H, 6.07; N, 7.46. Calcd. for $C_{12}H_{11}ON$: C, 77.81; H, 5.99; N, 7.56%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.02), 291 (4.65), 355 (3.60), 374 (3.74). in EtOH; 570 (2.57). IR (Nujol): 3270, 1664 cm^{-1}.

2, 6-Diacetamidoazulene-1, 3-dicarboxylic Acid (XV).—A solution of VIII (20 mg.) and potassium hydroxide (100 mg.) in 60% aqueous ethanol (9 ml.) was refluxed for 7 hr. The solution was concentrated to 1/3 volume under a reduced pressure and diluted with water (20 ml.). The mixture was then extracted with ethyl acetate, and the extract was passed through a column of alumina. From the effluent, a reddish, oily substance was obtained. This was warmed with acetic anhydride on a water bath for 3 hr. The product was crystallized from aqueous ethanol to give XV as a violet brown powder (m. p. 212~213°C; 10 mg.).

Found: N, 8.05. Calcd. for $C_{16}H_{14}O_6N_2$: N, 8.48%.

IR (Nujol): 3470, 3290, 1669, 1650 cm^{-1}.

Expenses for the present series of experiments were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education. The infrared spectra in this paper were measured by using a Shimadzu infrared spectrophotometer IR-27 purchased by a grant-in-aid for Scientific Research from the Toyo Rayon Co., Ltd. The authors wish to express their deep gratitude for these contributions.

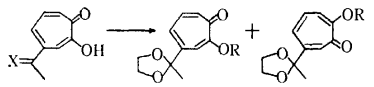
The Synthesis of 5- and 6-Acetylazulene Derivatives

By Tetsuo NOZOE, Kahei TAKASE and Masao TADA*

(Received February 25, 1963)

In a previous paper[1], we reported the synthesis of aminoazulenes from troponoid compounds as a part of a general scheme for the synthetic study of azulenes with the functional group on a seven-membered ring. In this paper, the synthesis of acetylazulenes is reported. The ethylene ketal (II)[2] of 4-acetyltropolone (I)[3] was converted to the corresponding methyl ethers (IIIa and IIIb) and *p*-toluenesulfonate (IVa and IVb), to which the general synthetic method[4-7] of the azulenic compound was then applied.



I: X=O IIIa: R=CH_3 IIIb: R=CH_3

II: X= IVa: R=Ts IVb: R=Ts

The reaction of a mixture of methyl ethers (IIIa and IIIb) with ethyl cyanoacetate yielded five azulenic products (ultraviolet spectra: Fig. 1): diethyl 2-amino-5-(1, 1-ethylenedioxyethyl)azulene-1, 3-dicarboxylate (V), ethyl 2-amino-5(or 7)-(1, 1-ethylenedioxyethyl)azulene-1-carboxylate (VI), 1, 3-dicyano-5-(1, 1-ethylenedioxyethyl)-2-hydroxyazulene (VII), ethyl 3-cyano-5(or 7)-(1, 1-ethylenedioxyethyl)-2-hydroxyazulene-1-carboxylate (VIII), and ethyl 3-cyano-7(or 5)-(1, 1-ethylenedioxyethyl)-2-hydroxyazulene-1-carboxylate (IX). The structural assignment of these compounds was based on their analyses, their infrared spectra, and a consideration of the general course of the azulene synthesis[4-7], although the exact locations of the ethoxycarbonyl and cyano groups in VI, VIII and IX with respect of the ethylenedioxyethyl group are not known.

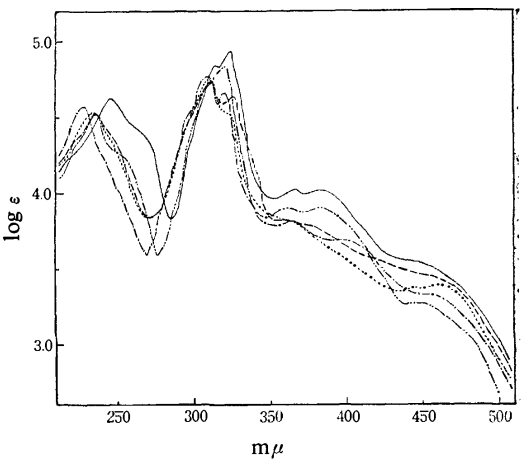


Fig. 1. Ultraviolet absorption spectra of V (——), VI (—·—), VII (—··—), VIII (— — —) and IX (·····) in methanol.

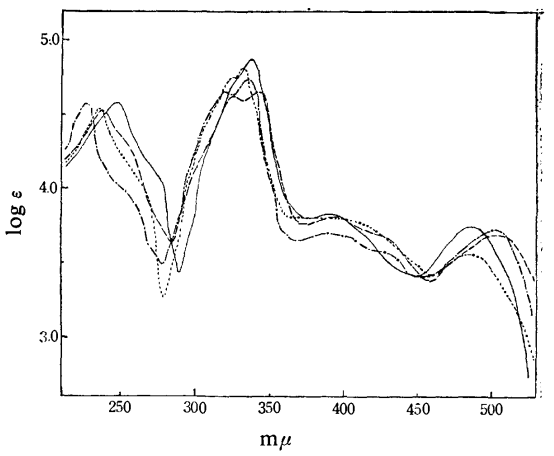

Fig. 2. Ultraviolet absorption spectra of X (——), XI (·····), XII (— — —), and XIII (—·—) in methanol.

When this condensation reaction was carried out in the presence of one molar equivalent of sodium ethoxide, V was obtained as a major product, together with a small amount of VII, VIII and IX, while the reaction with two molar equivalents of sodium ethoxide did not yield V but VII as the major product, accompanied by a small amount of VI. The mild acid hydrolysis of these compounds provoked a cleavage of the ethylene ketal ring to form

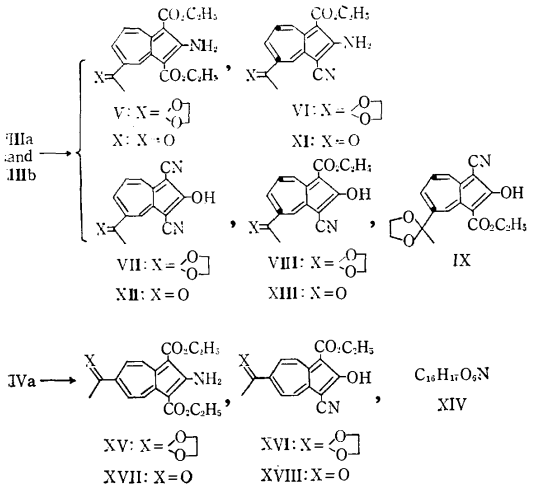
the corresponding acetyl compound; diethyl 5-acetyl-2-aminoazulene-1, 3-dicarboxylate (X) from V, ethyl 5(or 7)-acetyl-2-amino-3-cyanoazulene-1-carboxylate (XI) from VI, 5-acetyl-1, 3-dicyano-2-hydroxyazulene (XII) from VII, and ethyl 5(or 7)-acetyl-3-cyano-2-hyroxyazulene-1-carboxylate (XIII) from VIII. The ultraviolet spectra of these substances are shown in Fig. 2.



IVb → V

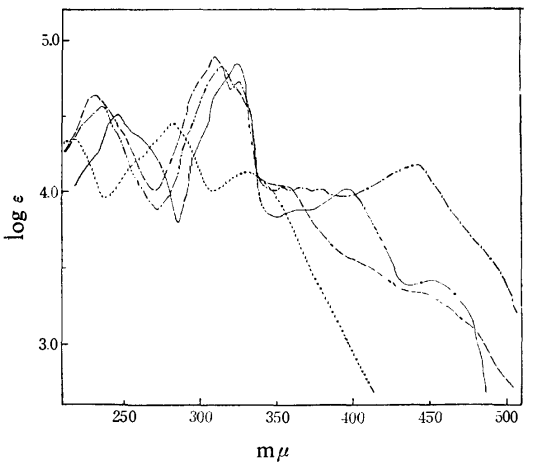


Fig. 3. Ultraviolet absorption spectra of XIV (——), XV (——), XVI (——) and XVIII (——) in methanol.

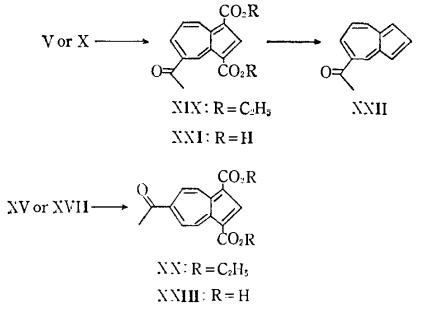
The reaction of ethyl cyanoacetate on 4-(1, 1-ethylenedioxyethyl)-2-(*p*-tolylsulfonyloxy)tropone (IVa) gave three products, all of which were different from those obtained from IIIa and IIIb. The analyses, the ultraviolet (Fig. 3) and infrared spectra, and the general conception of the nature of the reaction suggested that the first two products were diethyl 2-amino-6-(1, 1-ethylenedioxyethyl)azulene-1, 3-dicarboxylate (XV) and ethyl 3-cyano-6-(1, 1-ethylenedioxyethyl)-2-hydroxyazulene-1-carboxylate (XVI). The third compound XIV, the main product, was assumed not to be azulenic from its ultraviolet spectrum; it has properties similar to those of the substance obtained from 5-acetamido-2-(*p*-tolylsulfonyloxy)tropone[1]. The exact structure, however, can not be drawn. The hydrolysis of ethylene ketal in XV and XVI was effected by diluted acid to give their respective acetylazulenes, XVII and XVIII.

The reaction of ethyl cyanoacetate on the isomeric *p*-toluenesulfonate (IVb), 6-(1, 1-ethylenedioxyethyl)-2-(*p*-tolylsulfonyloxy)tropone, gave the azulene (V) in a low yield, besides the recovery of the starting material. The formation of the azulene (V), the product of the reaction at C_1 and C_2, may be due to the difficulty the reagent has in approaching the 7-position of the tropone because of the presence of the side chain at the 6-position.

The removal of substituents was carried out on ethylenedioxyethylazulenes (V and XV) and acetylazulenes (X and XVII); the diazotization reaction was accomplished by means of large excess of sulfuric acid and isoamyl nitrite or sodium nitrite, the amino group being notably unreactive compared with diethyl 2-aminoazulene-1, 3-dicarboxylate[5]. The decomposition of diazonium salts to yield the corresponding deamination products was achieved by letting the salts stand at room temperature or by warming them in the presence of copper or sodium hypophosphite. In the reactions of V and XV, ethylene ketal was hydrolyzed at the same time; thus, V and X gave diethyl 5-acetylazulene-1, 3-dicarboxylate (XIX), while XV and XVII yielded diethyl 6-acetylazulene-1, 3-dicarboxylate (XX). Dicarboxylic acid XXI obtained by the alkaline hydrolysis of XIX was submitted to thermal decarboxylation to form blue-violet 5-acetylazulene (XXII) ($\nu_{C=O}$ 1664 cm^{-1}), which, though its identify has not yet been established, is probably identical with the product (m. p. 39°C) obtained by Treibs and Quarg[8] by a



8) W. Treibs and M. Quarg, *Ann.*, **598**, 38 (1956).

ring expansion of indane with diazoketone. The similar hydrolysis of XX to the corresponding dicarboxylic acid XXIII and subsequent thermal decarboxylation yielded a pale green oil, but its small quantity did not allow the product to be characterized.

The alkaline hydrolysis of X and XVII afforded dicarboxylic acid XXIV and XXV respectively, the heating of which in pyridine caused decarboxylation which produced 5-acetyl-2-aminoazulene (XXVI) and 6-acetyl-2-aminoazulene (XXVII) respectively. XXVI was also obtained by the similar decarboxylation of the dicarboxylic acid XXVIII obtained from ethylene ketal V. The ultraviolet spectra of these 5-acetyl- and 6-acetylazulene derivatives are shown in Fig. 4 and Fig. 5. When alkaline hydrolysis of V was carried out in anhydrous ethanol, monocarboxylic acid XXIX was obtained; the decarboxylation of this in pyridine yielded monoester XXX. The acid hydrolysis of XXX gave ethyl 5(or 7)-acetyl-2-aminoazulene-1-carboxylate (XXXI) (ultraviolet spectra in Fig. 6). As the position of ethoxycarbonyl which had under gone alkaline hydrolysis could not be determined, no definite conclusion can be drawn at present concerning the position of the ethoxycarbonyl group in XXX and XXXI.

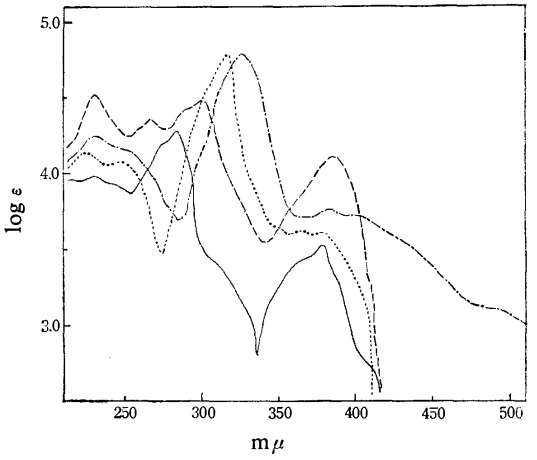


Fig. 4. Ultraviolet absorption spectra of XIX (——), XXII (——), XXVI (– – –) and acetate of XXVI (·····) in methanol.

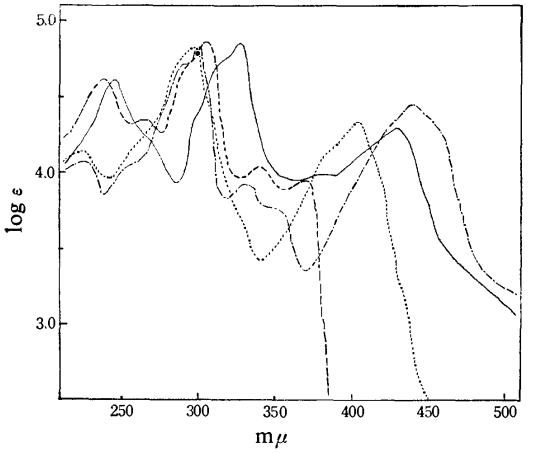

Fig. 5. Ultraviolet absorption spectra of XVII (——), XX (——), XXVII (·····) and acetate of XXVII (– – –) in methanol.

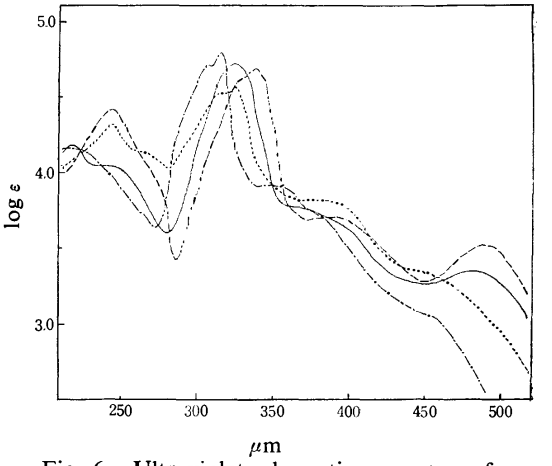

Fig. 6. Ultraviolet absorption spectra of XXIV (——), XXVIII (·····), XXX (——) and XXXI (——) in methanol.

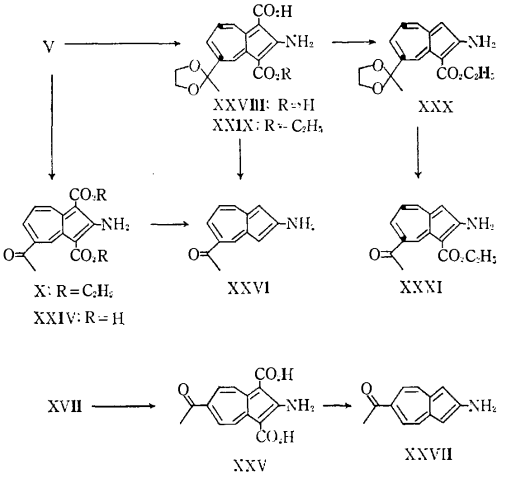

The reactions of these acetylazulene derivatives with ketonic reagents are being investigated and will be reported on in the future.

Experimental[9]

The Reaction of 4-(1, 1-Ethylenedioxyethyl)tropolone Methyl Ether (IIIa and IIIb) and Ethyl Cyanoacetate.—*a) With 1 mol. of Sodium Ethoxide.*—To a sodium ethoxide solution prepared from

9) All melting points are uncorrected. Shoulders in the UV spectral data are designated by "sh".

sodium (1.83 g., 0.036 mol.) and absolute ethanol (80 ml.), ethyl cyanoacetate (6.83 g.) was added. After this mixture had been allowed to stand for 30 min., a solution of methyl ether (a mixture of IIIa and IIIb) (6.9 g., 0.031 mol.) in absolute ethanol (30 ml.) was added, and the new mixture was allowed to stand overnight. The solvent was removed under reduced pressure, water was added, and the separated crystals (m. p. 104~109°C, 7.3 g.) were recrystallized from ethanol to afford V as yellow prisms (m. p. 112~113°C, 6.65 g.).

Found: C, 64.31; H, 6.90; N, 3.82. Calcd. for $C_{20}H_{23}O_6N$: C, 64.33; H, 6.21; N, 3.75%.

λ_{max}^{MeOH} mμ (log ε): 247 (4.88), 317 (5.08), 327 (5.20), 365 (4.25), 387 (4.24), 454 (3.29). IR: (KBr disk) 3445, 3328, 1668; (Nujol) 3460, 3350, 1650 cm^{-1}.

The Picrate of V: M. p. 124.5~126°C; orange needles (from ethanol).

Found: C, 51.70; H, 4.45; N, 9.40. Calcd. for $C_{26}H_{26}O_{13}N_4$: C, 51.82; H, 4.36; N, 9.30%.

The Acetate of V: This was obtained by refluxing V in acetic anhydride for 6 hr.; m. p. 122~123°C; reddish violet needles (from ethanol).

Found: C, 63.55; H, 5.87; N, 3.23. Calcd. for $C_{22}H_{25}O_7N$: C, 63.60; H, 6.07; N, 3.37%.

IR (Nujol): 3490, 3330, 1724, 1701, 1686 cm^{-1}.

From the aqueous mother liquor, crystals (m. p. 225~230°C, 0.20 g.) were obtained after the liquor had been left standing for 3 hr. Recrystallization from benzene formed VIII as yellowish orange silky needles; m. p. 234~237°C (decomp.).

Found: C, 66.56; H, 5.41; N, 4.36. Calcd. for $C_{18}H_{17}O_5N$: C, 66.05; H, 5.24; N, 4.28%.

The mother liquor was washed with benzene, the water layer was acidified with 6 N sulfuric acid, and the separated crystals (m. p. 225~230°C; 0.45 g.) were recrystallized from ethanol to afford VII as brownish yellow crystals (m. p. 238.5~239°C (decomp.), 0.26 g.).

Found: C, 67.69; H, 4.23; N, 9.70. Calcd. for $C_{20}H_{23}O_6N_2$: C, 68.56; H, 4.32; N, 10.00%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.58), 312 (4.76), 324 (4.65), 367 (3.80), IR (KBr disk): 3020, 2217 cm^{-1}.

The Acetate of VII: M. p. 215~216°C; pale brownish red needles (from ethyl acetate).

Found: C, 67.07; H, 4.38; N, 8.69. Calcd. for $C_{18}H_{14}O_4N_2$: C, 66.93; H, 4.07; N, 8.47%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.54), 303 (4.70), 366.5 (3.79), 480 (2.83). IR (Nujol): 2217, 1783 cm^{-1}.

The filtrate was extracted with benzene, and the crystals thus obtained were recrystallized from a mixture of ethanol and water to form IX, which appeared as pale brownish yellow silky needles (m. p. 214~215°C).

Found: C, 66.23; H, 5.23; N, 4.65. Calcd. for $C_{18}H_{17}O_5N$: C, 66.05; H, 5.24; N, 4.28%.

λ_{max}^{MeOH} mμ (log ε): 236 (4.51), 312 (4.74), 325 (4.52), 453 (3.36). IR (KBr disk): 3060, 2215, 1647 cm^{-1}.

b) With 2 mol. of Sodium Ethoxide.—To a sodium ethoxide solution prepared from sodium (0.18 g., 0.0078 mol.) and absolute ethanol (6 ml.), ethyl cyanoacetate (0.84 g.) was added. After the mixture had been left standing for 30 min., a solution of methyl ether (a mixture of IIIa and IIIb) (0.75 g., 0.0034 mol.) in absolute ethanol (6 ml.) was added, and the mixture was allowed to stand overnight. The solvent was removed under reduced pressure, water was added, and the separated crystals were collected by filtration; m. p. 108~134°C; 0.21 g. Recrystallization from ethanol afforded VI as orangish yellow needles (m. p. 180~182°C, 50 mg.).

Found: C, 65.82; H, 5.51; N, 8.54. Calcd. for $C_{18}H_{18}O_4N$: C, 66.24; H, 5.56; N, 8.56%.

λ_{max}^{MeOH} mμ (log ε): 239 (4.53), 325 (4.80), 368 (3.85), 388 (3.86), 446 (3.25). IR (Nujol): 3490, 3380, 2232, 1675 cm^{-1}.

The mother liquor was washed with benzene, and the aqueous layer was acidified with 6 N sulfuric acid, from which VII (m. p. 218~223°C; 0.52 g.) was obtained.

The Reaction of 4-(1, 1-Ethylenedioxyethyl)-2-(*p*-tolylsulfonyloxy)tropone (IVa) and Ethyl Cyanoacetate.—To a sodium ethoxide solution prepared from sodium (0.39 g.) and absolute ethanol (40 ml.), ethyl cyanoacetate (3.5 g.) was added. After this mixture had been left standing for 30 min., a suspended solution of IVa (5.04 g.) in absolute ethanol (20 ml.) was added, the mixture was stirred for 10 hr., and then it was allowed to stand for 2 days. After removal of the solvent under reduced pressure, water was added to the residue, and the separated crystals were collected (4.25 g.). The crystals were warmed with benzene, and the insoluble part (1.85 g., m. p. 250~256°C) was recrystallized from ethanol to give pale yellow needles of XIV (m. p. 258~259°C).

Found: C, 60.56; H, 5.43; N, 4.41. Calcd. for $C_{16}H_{17}O_6N$: C, 60.18; H, 5.37; N, 4.39%.

λ_{max}^{MeOH} mμ (log ε): 222 (4.34), 288 (4.44), 335 (4.29).

The benzene soluble part was passed through a column of alumina with benzene, and the crystals obtained (m. p. 141~145°C; 1.50 g.) were recrystallized from ethanol to give XV as orangish yellow needles (m. p. 154.5~155°C; 1.15 g.).

Found: C, 64.46; H, 5.62; N, 3.66. Calcd. for $C_{20}H_{23}O_6N$: C, 64.33; H, 6.21; N, 3.75%.

λ_{max}^{MeOH} mμ (log ε): 245 (4.51), 318 (4.71), 327 (4.82), 370 (3.87), 395 (4.00), 450 (3.40). IR (Nujol): 3450, 3345, 1675, 1647 cm^{-1}.

The Picrate of XV: M. p. 137~138°C; orange needles (from ethanol).

The aqueous mother liquor was extracted with benzene to give an oily substance containing a crystalline solid which was then recrystallized from ethanol to give XVI as yellowish orange needles (30 mg.; m. p. 205~206°C).

Found: C, 66.58; H, 5.18; N, 4.40. Calcd. for $C_{18}H_{17}O_5N$: C, 66.02; H, 5.24; N, 4.28%.

λ_{max}^{MeOH} mμ (log ε): 234 (4.61), 313 (4.79), 327 (4.55), 360 (4.12) sh, 450 (3.18) sh. IR (Nujol): 3150, 2222, 1667 cm^{-1}.

The Reaction of 6-(1, 1-Ethylenedioxyethyl)-2-*p*-tolylsulfonyloxy)tropone (IVb) and Ethyl Cyanoacetate.—A sodium ethoxide solution (30 mg. of sodium and 4 ml. of absolute ethanol), ethyl cyanoacetate (250 mg.), and a solution of IVb (360 mg.) in absolute ethanol were treated in the manner described above. After removal of the solvent, water was added and the crystals which had separated were recrystallized from ethanol to give recovered IVb (110 mg.) and the azulene derivative V (10 mg.).

The Hydrolysis of the Ethylene Ketal Group of V, VI, VII, VIII, XV and XVI.—A solution of ethylene ketal in ethanol (40 times) and 6 N sulfuric acid was refluxed for 30 min. and then allowed to cool, by which process a hydrolized compound was obtained, in a nearly quantitative yield.

a) Diethyl 5-Acetyl-2-aminoazulene-1, 3-dicarboxylate (X).—Obtained from V: M. p. 123~124°C; orange micro-prisms (from ethanol).

Found: C, 65.58; H, 5.65; N, 4.43. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.82; N, 4.25%.

λ_{max}^{MeOH} mμ (log ε): 246 (4.55), 328 (4.73), 340 (4.85), 389 (3.78), 490 (3.69). IR (Nujol): 3410, 3320, 1672 cm^{-1}.

The Acetate of X: Obtained by refluxing X in acetic anhydride for 8 hr.; m. p. 161~162°C; reddish violet leaflets (from ethanol).

Found: N, 3.81. Calcd. for $C_{20}H_{21}O_6N$: N, 3.77%.

IR (Nujol): 3380, 1724, 1695, 1686 cm^{-1}.

b) Ethyl 5(or 7)-Acetyl-2-amino-3-cyanoazulene-1-carboxylate (XI).—Obtained from VI; m. p. 199~200°C; orange prisms (from ethanol).

Found: C, 67.81; H, 4.87; N, 9.92. Calcd. for $C_{16}H_{14}O_3N_2$: C, 68.07; H, 5.00; N, 9.92%.

λ_{max}^{MeOH} mμ (log ε): 238 (4.51), 326 (4.63), 336 (4.67), 390 (3.78), 490 (3.51). IR (Nujol): 3470, 3370, 2217, 1686, 1664 cm^{-1}.

c) 5-Acetyl-1, 3-dicyano-2-hydroxyazulene (XII).—Obtained from VII; m. p. 223~225°C; pale brown prisms (from aqueous ethanol).

Found: C, 70.48; H, 3.50; N, 11.61. Calcd. for $C_{14}H_8O_2N_2$: C, 71.18; H, 3.41; N, 11.86%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.57), 324 (4.67), 339 (4.73), 400 (3.67), 504 (3.67). IR (KBr disk): 3010, 2218, 1672 cm^{-1}.

d) Ethyl 5(or 7)-Acetyl-3-cyano-2-hydroxyazulene-1-carboxylate (XIII).—Obtained from VIII; m. p. 204.5~206°C; dull yellowish orange leaflets (from ethanol).

Found: C, 67.25; H, 4.54; N, 5.10. Calcd. for $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63; N, 4.95%.

λ_{max}^{MeOH} mμ (log ε): 235 (4.48), 320 (4.56), 341 (4.63), 380 (3.73), 504 (3.67). IR (KBr disk): 2980, 2220, 1690 cm^{-1}.

The Acetate of XIII: Obtained by refluxing XIII in acetic anhydride; m. p. 169~170°C; brilliant red needles (from ethanol).

Found: C, 66.63; H, 4.61; N, 4.30. Calcd. for $C_{18}H_{15}O_5N$: C, 66.45; H, 4.65; N, 4.31%.

IR (Nujol): 2212, 1779, 1684 cm^{-1}.

e) Diethyl 6-Acetyl-2-aminoazulene-1, 3-dicarboxylate (XVII).—Obtained from XV: m. p. 139~140°C; orange needles (from ethanol).

Found: C, 65.89; H, 5.80; N, 4.38. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.82; N, 4.25%.

λ_{max}^{MeOH} mμ (log ε): 248 (4.60), 330 (4.84), 380 (3.98), 432 (4.30). IR (Nujol): 3510, 3340, 1692, 1669, 1656 cm^{-1}.

f) Ethyl 6-Acetyl-3-cyano-2-hydroxyazulene-1-carboxylate (XVIII).—Obtained from XVI; m. p. 196.5~198°C; pale red granules (from ethanol).

Found: C, 67.84; H, 4.52; N, 4.50. Calcd. for $C_{16}H_{13}O_4N$: C, 67.84; H, 4.63; N, 4.95%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.54), 318 (4.80), 330 (4.66), 357 (3.96), 375 (3.98), 440 (4.12). IR (Nujol): 3200, 2217, 1695, 1667 cm^{-1}.

Diethyl 5-Acetylazulene-1,3-dicarboxylate (XIX).—*a) The Deamination of V in Ethanol.*—To a solution of V (0.50 g.) in 50% aqueous ethanol (25 ml.), concentrated sulfuric acid (4.7 ml.) was added; isoamyl nitrite (2.4 g.) was then added into this mixture with stirring at room temperature. After having been stirred for 4 hr. and having been left standing overnight, the mixture was diluted with water and extracted with benzene. The benzene extract was passed through a column of alumina; from the first effluent, crude crystals of XIX (m. p. 106~109°C; 280 mg.) were obtained. Recrystallization from ethanol formed red needles (m. p. 116.5~117°C).

Found: C, 68.66; H, 5.75. Calcd. for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77%.

λ_{max}^{MeOH} mμ (log ε): 235 (4.54), 272 (4.36), 305 (4.48), 324 (3.94) sh, 395 (4.11), 508 (2.68). IR (Nujol): 1689 cm^{-1}.

From the second effluent, X (20 mg.) was obtained.

When sodium hypophosphite was used on the decomposition of the diazotized solution, XIX (60 mg.) was obtained from V (100 mg.).

b) The Deamination of V in Dioxane.—To a solution of V (100 mg.) in dioxane (3 ml.) and concentrated sulfuric acid (0.4 ml.), a solution of sodium nitrite (50 mg.) in water (0.2 ml.) was dropped in. After this mixture had been stirred for 30 min., active copper powder (100 mg.) was added, and the mixture was warmed on a water bath. The mixture was treated in the above-mentioned method to give XIX (35 mg.).

c) The Deamination of X.—A solution of X (100 mg.) in 50% aqueous ethanol (5 ml.) and concentrated sulfuric acid (4.5 ml.) was diazotized and treated as in a); XIX (30 mg.) was thus obtained.

Diethyl 6-Acetylazulene-1, 3-dicarboxylate (XX).—*a) The Deamination of XV in Ethanol.*—To a solution of XV (100 mg.) in 60% aqueous ethanol (5 ml.), concentrated sulfuric acid (0.6 ml.) was added, and to this mixture, isoamyl nitrite (0.44 g.) was added with stirring at room temperature. After having been stirred for 2 hr. and having been standing overnight, the reaction mixture was diluted with water (20 ml.) and extracted with benzene. The benzene extract was passed through a column of alumina, and from the first effluent, crude crystals

of XX (m. p. 105~106°C; 60 mg.) were obtained. Recrystallization from ethanol formed deep violet blue scales (m. p. 129~130°C).

Found: C, 68.61; H, 5.79. Calcd. for $C_{18}H_{15}O_5$: C, 68.78; H, 5.77%.

λ_{max}^{MeOH} mμ (log ε): 242 (4.62), 270 (4.26), 310 (4.77), 345 (3.93), 375 (2.82), 527 (2.49). IR (Nujol): 1686 cm^{-1}.

b) The Deamination of XV in Dioxane.—Into a solution of XV (200 mg.) in dioxane (6 ml.) and concentrated sulfuric acid (0.4 ml.), a solution of sodium nitrite (50 mg.) in water (2 ml.) was dropped. After this mixture had been stirred for 30 min., active copper powder (100 mg.) and a solution of sodium hypophosphite (0.8 g) in water (93 ml.) were added. After having been stirred an additional for 2 hr., the reaction mixture was treated as in a) From the first effluent, XX (60 mg.) was obtained; from the second effluent, XVII (60 mg.) was obtained.

c) The Deamination of XVII.—XVII (90 mg.) was diazotized and treated as in a); XX (30 mg.) was obtained.

5-Acetylazulene-1, 3-dicarboxylic Acid (XXI).—To a solution of potassium hydroxide (140 mg.) in 70% aqueous ethanol (5 ml.), XX (200 mg.) was added, and the mixture was refluxed for 4 hr. After it had cooled the solution was acidified with 6 N sulfuric acid to give XXI (140 mg.) as dark brown crystals (m. p. above 270°C; sparingly soluble in organic solvents).

5-Acetylazulene (XXII).—The decarboxylation of XXI was carried out under reduced pressure (15 mmHg) at 280~300°C, yielding a violet oil which was then passed through a column of alumina with petroleum ether (b. p. 40~60°C) to give a violet blue oil (XXII). IR (Nujol): 1664 cm^{-1}.

λ_{max}^{MeOH} mμ (log ε): 220 (3.97), 235 (3.98), 392 (4.25), 370 (3.40), 383 (3.50), 564, 584 sh, 612, 670 sh.

6-Acetylazulene-1, 3-dicarboxylic Acid (XXIII).—When XX (150 mg.) was treated as in the above experiment, XXIII (100 mg.) (brown crystals; m. p. above 260°C; sparingly soluble in organic solvents) was obtained. IR (Nujol): 1704 cm^{-1}.

5-Acetyl-2-aminoazulene-1, 3-dicarboxylic Acid (XXIV).—To a solution of potassium hydroxide (100 mg.) in 85% aqueous ethanol (3 ml.), X (100 mg.) was added, and the mixture was refluxed for 5 hr. After the solution had cooled, it was acidified with 6 N sulfuric acid to give XXIV (70 mg.) as a black crystalline powder (m. p. 203~204.5°C (decomp.); sparingly soluble in organic solvents).

Found: C, 60.78; H, 4.04; N, 4.75. Calcd. for $C_{14}H_{11}O_5N$: C, 61.54; H, 4.06; N, 5.13%.

λ_{max}^{MeOH} mμ (log ε): 243 (4.45), 339 (4.75), 385 (3.76), 494 (3.61). IR (KBr disk): 3439, 3325, 1657 cm^{-1}.

6-Acetyl-2-aminoazulene-1, 3-dicarboylic Acid (XXV).—When XVII (180 mg.) was treated as in the above experiment, XXV (130 mg.), (reddish brown crystals; m. p. 265°C (decomp.); sparingly soluble in organic solvents) was obtained.

λ_{max}^{MeOH} mμ (log ε): 246 (4.43), 329 (4.67), 378 (3.86), 434 (4.17). IR (Nujol): 3540, 3340, 1661 cm^{-1}.

2-Amino-5-(1, 1-ethylenedioxyethyl)azulene-1, 3-dicarboxylic Acid (XXVIII).—To a solution of potassium hydroxide (0.80 g.) in ethanol (6 ml.), V (1.00 g.) was added, and the mixture was refluxed for 4 hr. After the mixture had cooled, it was diluted with water and acidified with 6 N sulfuric acid to give XXVIII (0.71 g.) (dull yellowish orange crystals,; m. p. 174~175°C (decomp.); sparingly soluble in organic solvents).

Found: C, 61.71; H, 4.97; N, 4.73. Calcd. for $C_{16}H_{15}O_6N$: C, 60.56; H, 4.77; N, 4.41%.

λ_{max}^{MeOH} mμ (log ε): 345 (4.34), 315 (4.57), 326 (4.62), 380 (3.86) sh. IR (Nujol): 3430, 3340, 1658, 1642 cm^{-1}.

5-Acetyl-2-aminoazulene (XXVI).—*a) From XXIV.*—A solution of XXIV (300 mg.) in pyridine (2 ml.) was heated at 125~130°C to effect decarboxylation. The residue produced by the evaporation of the excess pyridine was dissolved in benzene, and the solution was passed through a column of alumina to give XXVI (m. p. 162~163°C; 130 mg.). Recrystallization from ethanol formed deep violet leaflets (m. p. 167~167.5°C; 110 mg.).

Found: C, 78.05; H, 5.93; N, 7.47. Calcd. for $C_{12}H_{11}ON$: C, 77.81; H, 5.99; N, 7.56%.

λ_{max}^{MeOH} mμ (log ε): 227 (4.25), 322 (4.79), 384 (3.75) 395 (3.72), 490 (3.11) sh. IR: (KBr disk) 3457, 3343, 3238, 1638, 1628; (Nujol) 3460, 3360, 3270, 1645, 1629 cm^{-1}.

Picrate: M. p. 166.5~167.5°C; brownish violet needles (from ethanol).

Found: C, 52.11; H, 5.54; N, 13.21. Calcd. for $C_{18}H_{14}O_8N_4$: C, 52.18; H, 5.77; N, 13.52%.

Acetate: M. p. 176~177°C; deep reddish violet needles (from ethanol).

Found: C, 74.42; H, 5.54; N, 6.16. Calcd. for $C_{14}H_{13}O_2N$: C, 73.99; H, 5.77; N, 6.16%.

λ_{max}^{MeOH} mμ (log ε): 224 (4.11), 250 (4.05), 315 (4.75), 380 (3.59). IR (Nujol): 3380, 1689, 1661 cm^{-1}.

b) From XXVIII.—When XXVIII (400 mg.) was dissolved in pyridine (2 ml.) and treated as in a), XXVI (80 mg.) was obtained.

6-Acetyl-2-aminoazulene (XXVII).—When a solution of XXV (150 mg.) in pyridine (2 ml.) was treated as in the above experiment, XXVII (m. p. 167~168°C; 20 mg.) was obtained. Recrystallization from ethanol formed brilliant brownish yellow scales (m. p. 168.5~169.5°C; 15 mg.).

Found: C, 77.89; H, 6.02; N, 7.50. Calcd. for $C_{12}H_{11}ON$: C, 77.81; H, 5.99; N, 7.56%.

λ_{max}^{MeOH} mμ (log ε): 225 (4.06), 290 (4.69), 301 (4.79), 335 (3.90), 340 (3.74) sh, 440 (4.43). IR (Nujol): 3460, 3340, 3270, 1642 cm^{-1}.

Picrate: M. p. above 270°C; fine black crystals (from ethanol).

Found: N, 12.00. Calcd. for $C_{18}H_{14}O_8N_4$-C_2H_5OH; N, 12.17%.

Acetate; M. p. 198~199°C; blacklish green micro-prisms (from methanol).

Found: C, 73.65; H, 5.97; N, 6.11. Calcd. for $C_{14}H_{13}O_2N$: C, 73.99; H, 5.77; N, 6.16%.

λ_{max}^{MeOH} mμ (log ε): 220 (4.12), 297 (4.83), 404 (4.33). IR (Nujol): 3340, 1704, 1675, 1661 cm^{-1}.

2-Amino-5-(1, 1-ethylenedioxyethyl)azulene-1, 3-dicarboxylic Acid Monoethyl Ester (XXIX).—To a solution of potassium hydroxide (140 mg.) in ethanol (5 ml.), V (400 mg.) was added, and the mixture was refluxed for 4 hr. After it had cooled, the solution was acidified with 6 N sulfuric acid to give XXIX (350 mg.) as brownish yellow crystals (m. p. 161~164°C (decomp.); sparingly soluble in organic solvents).

Found: C, 62.61; H, 5.44; N, 4.22. Calcd. for $C_{18}H_{19}O_6N$: C, 62.60; H, 5.55; N, 4.06%.

λ_{max}^{MeOH} mμ (log ε): 245.5 (4.49), 316 (4.70), 327 (4.80), 370 (3.85), 454 (3.43). IR (KBr disk): 3448, 3327, 1662 cm^{-1}.

p-Bromophenacyl Ester of XXIX.—In a solution of sodium hydroxide (200 mg.) in water (20 ml.), XXIX (100 mg.) was dissolved, and the solution was weakly acidified with 2 N hydrochloric acid. To this solution, a solution of *p*-bromophenacyl bromide (350 mg.) in ethanol (20 ml.) was added, and the mixture was refluxed for 2 hr. The reaction mixture was diluted with water (5 ml.), and the precipitate thereby formed was collected by filtration. Crude crystals of the ester of XXIX (m. p. 186~190°C; 100 mg.) were recrystallized from ethanol to form a pale brown crystalline powder (m. p. 214~215°C, 50 mg.).

Found: C, 58.40; H, 4.17; N, 3.06. Calcd. for $C_{26}H_{24}O_7NBr$: C, 57.57; H, 4.46; N, 2.58%.

Ethyl 2-Amino-5(or 7)-(1, 1-ethylenedioxyethyl)-azulene-1-carboxylate (XXX).—A solution of XXIX (260 mg.) in pyridine (1.5 ml.) was heated at 130~140°C to effect decarboxylation. The residue produced by evaporation of the excess pyridine was dissolved in benzene, and the solution was passed through a column of alumina. A reddish crude substance obtained from the effluent was recrystallized from ethanol to give reddish orange prisms (m. p. 144~145°C; 60 mg.).

Found: C, 67.74; H, 6.31; N, 4.65. Calcd. for $C_{17}H_{19}O_4N$: C, 67.76; H, 6.36; N, 4.65%.

λ_{max}^{MeOH} mμ (log ε): 216 (4.26), 306 (4.77), 316 (4.86), 357 (4.00), 380 (3.80) sh. IR (KBr disk): 3541, 3344, 3287, 1663 cm^{-1}.

Picrate: M. p. 138.5~139.5°C; orange prisms (from ethanol).

Acetate: M. p. 164~165°C; violet red micro-prisms (from ethanol).

Found: C, 66.53; H, 5.99; N, 3.95. Calcd. for $C_{19}H_{21}O_5N$: C, 66.46; H, 6.16; N, 4.08%,

λ_{max}^{MeOH} mμ (log ε): 244 (4.28), 306 (4.84), 316 (4.96), 356 (3.95), 370 (3.97). IR (Nujol): 3500, 1689, 1650 cm^{-1}.

Ethyl 5(or 7)-Acetyl-2-aminoazulene-1-carboxylate (XXXI).—A solution of XXX (50 mg.) in ethanol (2 ml.) and 6 N sulfuric acid (0.02 ml.) was refluxed for 20 min. The reaction mixture was diluted with water (3 ml.) to form XXXI (m. p. 130~132°C; 45 mg.), which was then recrystallized from ethanol to give brownish orange micro-prisms (m. p. 131~132°C; 40 mg.).

Found: C, 69.59; H, 5.49; N, 5.28. Calcd. for $C_{15}H_{15}O_3N$: C, 70.02; H, 5.88; N, 5.44%.

λ_{max}^{MeOH} mμ (log ε): 220 (4.22), 246 (4.10), 331 (4.73), 490 (3.41). IR: (KBr disk) 3313, 3254, 1664, 1612; (Nujol) 3380, 3280, 1656, 1603 cm^{-1}.

Expenses for the present series of experiments were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education. The infrared spectra in this paper were measured with a Shimadzu infrared spectrophotometer IR-27 purchased by a grant-in-aid for Scientific Research from the Toyo Rayon Co., Ltd. The authors wish to express their deep gratitude for these contributions.

The Reaction of 5- and 6-Acetylazulene Derivatives with Hydrazines. The Formation of Azuleno[4, 3-f]pyrazoles

By Tetsuo NOZOE, Kahei TAKASE and Masao TADA*

(Received February 25, 1963)

In a previous report[1], 5- and 6-acetylazulene derivatives were derived from 4-acetyltropolone. The present paper deals with the reaction of these acetylazulenes with various hydrazines and hydroxylamine. The reaction with unsubstituted hydrazine resulted in the formation of azulenopyrazoles.

The reaction of hydrazine hydrate with diethyl 5-acetylazulene-1, 3-dicarboxylate (I) yielded dull reddish crystals II. When II was heated with potassium hydroxide in ethylene glycol, deep violet crystals III were

* Present address: The Research Institute for Tuberculosis and Leprosy, Tohoku University, Sendai.

1) T. Nozoe, K. Takase and M. Tada, This Bulletin, **36**, 1010 (1963).

formed; III was also obtained by the alkaline hydrolysis of II and the subsequent decarboxylation in quinoline of the resultant dicarboxylic acid IV.

III contains nitrogen and shows a sharp N-H band at 3135 cm^{-1} which disappears upon acetylation to form *N*-acetate (V). The carbonyl frequency (1724 cm^{-1}) of the acetate indicated the attachment of an aromatic system or an electron-attracting group to the imino nitrogen[2]. These spectral observations reveal the structure of III to be that of a methylazulenopyrazole. The infrared spectra of II and its acetate VI exhibited ν_{NH} at 3230 cm^{-1} and ν_{NCOCH_3} at 1733 cm^{-1}, which facts suggest presence of the same ring system in both II and III. The conclusive evidence for the presence of a pyrazole ring was obtained by the alkaline permanganate oxidation of II, upon which 5-methylpyrazole-3, 4-dicarboxylic acid (VII) was obtained. The stability of II to chloranil indicated that II must be a pyrazole and not a pyrazoline derivative. Therefore, II can be formulated as IIa or IIb (see Chart I). Although definite evidence is lacking, we prefer IIa, that is, diethyl 3-methylazuleno [4, 3-f] pyrazole-5, 7-dicarboxylate, to IIb on the basis of the steric hindrance of ethoxycarbonyl at Position 3. Thus, the structures of 3-methylazuleno [4, 3-f] -pyrazole shown in Chart I were assigned to III and IV.

On hydrolysis with a limited amount of alkali, II yielded an ester acid VIII which, on heating in quinoline, gave a monoester IX, althougth the exact position of the ethoxycarbonyl group is not known.

The ultraviolet and visible absorption spectra of these 3-methylazuleno[4, 3-f]pyrazole derivatives are shown in Figs. 1 and 2.

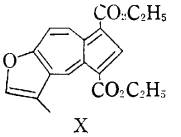
This rather unusual ring formation on an azulene nucleus (though such a formation is not without precedent[3], azulenofurane derivative (X)), can be rationalized by the electrophilic nature of the seven-membered ring in



X

azulene enhanced by the presence of the two ethoxycarbonyl groups at Positions 1 and 3, and by the facility of the dehydrogenation of dihydroazulene to azulene. This reaction path is shown in Chart II.

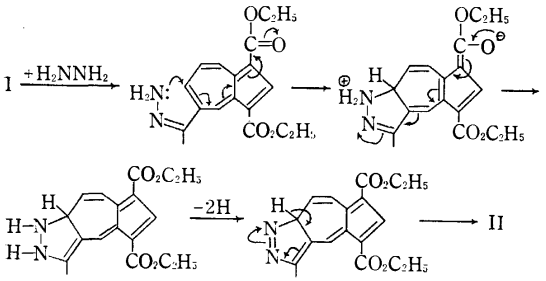

Chart II

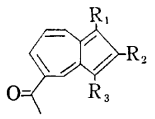
This interesting behaviour of I toward hydrazine prompted us to extend our study to other acetylazulenes and other reagents related to hydrazine.

Several experiments revealed that hydrazine is the only reagent to form pyrazole; thus, I gave a normal phenylhydrazone (ν_{NH} 3210 cm^{-1}), a normal *p*-tolylsulfonylhydrazone (ν_{NH} 3210 cm^{-1}) and a normal oxime (ν_{OH} 3350 cm^{-1}). Moreover, 2-amino (XI, XII), 2-acetamido (XIII) or 2-hydroxyl (XIV, XV) groups inhibit the ring formation, giving the normal ketonic derivatives (see the Experimental section). There seems to be no difference if the ethoxycarbonyl or the cyano groups



XI: $R_1=R_3=CO_2C_2H_5$; $R_2=NH_2$
XII: $R_1=CN$, $R_3=CO_2C_2H_5$ or $R_1=CO_2C_2H_5$, $R_3=CN$; $R_2=NH_2$
XIII: $R_1=R_3=CO_2C_2H_5$; $R_2=NHCOCH_3$
XIV: $R_1=CN$, $R_3=CO_2C_2H_5$ or $R_1=CO_2C_2H_5$, $R_3=CN$; $R_2=OH$

XVI: R=H
XVII: $R=NH_2$

occupy at Positions 1 and 3, inasmuch as electron-releasing amino or the hydroxyl group is situated at Position 2. Furthermore, it is a rather interesting difference that diethyl 6-acetylazulene-1, 3-dicarboxylate (XVI), the position isomer of I, gives only normal hydrazone. According to the SCF electron density calculation for the ground state of azulene[4], the density at Position 6 (0.938) is comparatively lower than that at Position 5 (1.034). The findings described above are consistent with the theoretical calculation.

Experimental[5]

Diethyl 3-Methylazuleno[4, 3-f]pyrazole-5, 7-dicarboxylate (II).—To a solution of diethyl 5-acetylazulene-1, 3-dicarboxylate (I) (130 mg.) in ethanol (2 ml.), 80% hydrazine hydrate (0.1 g.) was added, and the mixture was warmed for 30 min., by which process II (40 mg.) was obtained as dull red micro-prisms (m. p. 252~253°C, after recrystallization from ethanol).

Found: C, 65.99; H, 5.73; N, 8.56. Calcd. for $C_{18}H_{18}O_4N_2$: C, 66.24; H, 5.56; N, 8.58%.

λ_{max}^{MeOH} mμ (log ε): 232 (4.18), 218 (4.44), 307 (4.39), 339 (4.45), 384 (3.94), 460 (3.45). IR (Nujol): 3230, 1692, 1656 cm^{-1}.

Acetate (VI). — Reddish orange micro-prisms (from ethanol); m. p. 121~122°C.

Found: C, 65.46; H, 5.61; N, 8.04. Calcd. for $C_{20}H_{20}O_5N_2$: C, 65.46; H, 5.47; N, 7.61%.

λ_{max}^{MeOH} mμ (log ε): 255 (4.48), 275 (4.38), 328 (4.62), 404 (3.95), 480 (3.53). IR (Nujol): 1733, 1689, 1669 cm^{-1}.

3-Methylazuleno[4, 3-f]pyrazole-5, 7-dicarboxylic Acid (IV).—A solution of II (150 mg.) and potassium hydroxide (200 mg.) in 50% aqueous ethanol (8 ml.) was refluxed for 8 hr. After being cooled, the solution was acidified with 6 N sulfuric acid to give IV (110 mg.) as a brownish red crystalline powder (m. p. above 270°C) which is sparingly soluble in organic solvents.

Found: C, 59.55; H, 4.00; N, 8.90. Calcd. for $C_{14}H_{12}O_4N_2$-$2H_2O$: C, 59.78; H, 4.66; N, 9.96%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.25), 284 (4.54), 304 (4.41), 338 (4.56), 363 (3.82), 460 (3.53). IR (Nujol): 3155, 1661 cm^{-1}.

3-Methylazuleno[4, 3-f]pyrazole (III).—*i) From II.*—To a solution of potassium hydroxide (110 mg.) in ethylene glycol (3 ml.), II (180 mg.) was added, and the mixture was heated at 140~150°C for 6 hr. After being cooled, this solution was diluted with water (40 ml.) and extracted with benzene. Removal of the solvent from the extract gave III (50 mg.) (m. p. 185~186°C), which was recrystallized from aqueous ethanol in the form of purplish red needles (m. p. 186~187°C).

Found: C, 79.20; H, 4.91; N, 15.47. Calcd. for $C_{12}H_{10}N_2$: C, 79.09; H, 5.72; N, 15.38%.

λ_{max}^{MeOH} mμ (log ε): 280 (4.64), 352 (3.59), 370 (3.63), 390 (3.46), 430 (2.79), 500 (2.79). IR (Nujol): 3135, 1613 cm^{-1}.

Acetate (V).—Pale purple scales (from ethanol); m. p. 158~159°C.

Found: C, 75.46; H, 5.56; N, 12.70. Calcd. for $C_{14}H_{12}ON_2$: C, 74.99; H, 5.38; N, 12.49%.

λ_{max}^{MeOH} mμ (log ε): 300 (4.50), 316 (4.44), 359 (3.62),

4) A. Julg, *J. chim. phys.*, **52**, 377 (1955).
5) All melting points are uncorrected.

371 (3.67), 391 (3.55), 495 (2.64). IR (Nujol): 1724, 1684 cm^{-1}.

ii) From IV. — A mixture of IV (120 mg.) and quinoline (1 ml.) was heated at 230~250°C for 2 hr. to effect decarboxylation. The residue produced by the evaporation of the quinoline was dissolved in ethyl acetate and passed through a column of alumina to give III (10 mg.).

The Permanganate Oxidation of II. — Into a solution of II (400 mg.) in a 0.25 N potassium hydroxide solution (100 ml.), finely powdered potassium permanganate (2.32 g.) was added in small portions with stirring at room temperature; the mixture was then stirred a further 6 hr. and allowed to stand overnight. The excess permanganate was decomposed on the addition of methanol, and the precipitated manganese dioxide was filtered off. The filtrate was slightly acidified with 6 N hydrochloric acid and concentrated under a reduced pressure until crystal had begun to separate out. Acetone was added, and the inorganic salts thereby separated were filtered off. After the mother liquor was treated repeatedly in the same way as above, the combined acetone solution was evaporated to dryness; the subsequent addition of a small amount of water gave oxalic acid. From the water-soluble part, 5-methylpyrazole-3,4-dicarboxylic acid (VII) (20 mg.) was obtained (m. p., 233°C (decomp.)); this acid was identified as identical with an authentic specimen[6] by a comparison of the infrared spectra.

3-Methylazuleno[4,3-f]pyrazole-5,7-dicarboxylic Acid Monoethyl Ester (VIII). — To a solution of potassium hydroxide (150 mg.) in 75% aqueous ethanol (8 ml.), II (200 mg.) was added, and the mixture was refluxed for 4 hr. This solution was acidified with 6 N sulfuric acid to give VIII (150 mg.) as brownish red crystals (m. p. 247~250°C (decomp.)).

Found: C, 60.95; H, 4.92; N, 8.58. Calcd. for $C_{16}H_{14}O_4N_2$-H_2O: C, 60.75; H, 5.10; N, 8.86%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.19), 284 (4.55), 304 (4.37), 321 (4.42), 363 (3.79), 380 (3.86), 460 (3.51).

Ethyl 3-Methylazuleno[4,3-f]pyrazole-5 (or 7)-carboxylate (IX). — A mixture of VIII (100 mg.) and quinoline (1.5 ml.) was heated at 230~250°C for 2 hr. to effect decarboxylation. The residue, obtained by the evaporation of the quinoline, was dissolved in benzene and passed through a column of alumina to give red crystals (20 mg.) (m. p. 162~168°C) which were then recrystallized from benzene to form IX (15 mg.) as red prisms (m. p. 202~203°C).

Found: C, 71.03; H, 5.46; N, 10.71. Calcd. for $C_{15}H_{14}O_2N_2$: C, 70.85; H, 5.55; N, 11.02%.

λ_{max}^{MeOH} mμ (log ε): 235 (4.32), 286 (4.47), 302 (4.45), 315 (4.30), 333 (4.29), 373 (3.92), 390 (3.92), 484 (3.41). IR (Nujol): 3145, 1647 cm^{-1}.

Ketonic Derivatives of I.—*a) Phenylhydrazone.*— Violet brown micro-prisms (from ethanol); m. p. 181~182°C.

Found: C, 71.24; H, 5.90; N, 6.54. Calcd. for $C_{24}H_{24}O_4N_2$: C, 71.27; H, 5.98; N, 6.93%.

IR (Nujol) 3310, 1686, 1667 cm^{-1}.

b) p-Tolylsulfonylhydrazone.—Brown micro-prisms (from ethanol); m. p. 206~207°C.

Found: C, 62.16; H, 5.13; N, 5.67. Calcd. for $C_{25}H_{26}O_6N_2S$: C, 62.23; H, 5.43; N, 5.80%.

IR (Nujol): 3210, 1689 cm^{-1}.

Found: C, 62.60; H, 5.99; N, 10.80. Calcd. for $C_{20}H_{23}O_5N_3$: C, 62.32; H, 6.02; N, 10.90%.

IR (Nujol): 3350, 3250, 3100, 1724, 1675 cm^{-1}.

Picrate of Hydrazone Acetate: Deep red crystals (from ethanol); m. p. 252.5~253.5°C.

Expenses for the present series of experiments were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education. The infrared spectra in this paper were measured with a Shimadzu infrared spectrophotometer IR-27 purchased by a grant-in-aid for Scientific Research from the Toyo Rayon Co., Ltd. The authors wish to express their deep gratitude for these contributions.

The Infrared Spectra of Carbonyl Compounds in Alcohols

By Hiroshi MINATO*

(Received December 25, 1962)

The infrared spectra of carbonyl compounds in alcohols have not been studied extensively, but the shift due to the hydrogen bonding is regarded as rather small. Rasmussen et al.[1], for example, report that the carbonyl absorption of diacetone alcohol occurs at 1712 cm^{-1} despite the fact that the hydroxyl frequencies indicate the presence of strong hydrogen bonding. Grove and Willis[2] estimate the influence of hydrogen bonding on some ketones as being not greater than 10 cm^{-1}, and Searles et al.[3] have shown that the carbonyl shift in an equimolar mixture of carbon tetrachloride and methanol is about 8 cm^{-1} with esters, and 7 to 15 cm^{-1} with lactones, depending upon the ring size.

Becker[4] determined the infrared spectra of benzophenone in ethanol and in tetrachloroethylene, and in ethanol observed two bands of about equal intensity at 1666 cm^{-1} and

* Present address: Department of Chemistry, International Christian University, Mitaka, Tokyo.

4) R. S. Becker, *J. Molecular Spectroscopy*, **3**, 1 (1959).

1656 cm^{-1}, and, in tetrachloroethylene, a single band at 1668 cm^{-1}. It appears that this phenomenon has not been mentioned elsewhere, including the excellent reviews on hydrogen bonding recently published[5,6]. In order to obtain general knowledge about carbonyl absorption in alcohols and, particularly, to clarify the nature of the double peak, this investigation was undertaken.

Experimental

Materials.—Methyl *t*-butylperoxy carbonate was prepared by the drop-by-drop addition of a cooled sodium hydroxide solution to an equimolar mixture of *t*-butyl hydroperoxide and methyl chloroformate at −5°C. All the other chemicals were those of the best grade commercially available in the United States and were used without further purification.

Table I. Carbonyl bands in carbon tetrachloride and methanol

	In CCl_4 wave number ν_0	In CH_3OH wave number ν_1	ν_2	$\nu_2-\nu_1$	$\frac{(O.D.)_{\nu_2}}{(O.D.)_{\nu_1}}$

Ethyl salicylate	1684	1681[d]		3[c]	

a) This peroxycarbonate is exceptional in that it has two carbonyl bands, 1795 and 1764 cm^{-1} ($O.D._{1764}/O.D._{1795}=0.32$), even in carbon tetrachloride. Recently, Martin reported that di-*t*-butylperoxy carbonate possesses a split carbonyl band, with a high intensity peak at 1825 and a somewhat less intense peak at 1795 cm^{-1} (M. M. Martin, *J. Am. Chem. Soc.*, **83**, 2870 (1961)).
b) The wave numbers in parentheses are inaccurate due to the diffused nature of the bands.
c) These are $\nu_{MeOH}-\nu_{CCl_4}$, not $\nu_2-\nu_1$.
d) The band in methanol is a little broader than that in carbon tetrachloride.
e) These are the shoulders of stronger bands and are not accurate.

(The concentration of isopropyl acetate is 0.32 M.)

Infrared Spectra.—The infrared spectra of carbonyl compounds were determined in carbon tetrachloride, methanol or *t*-amyl alcohol by using calcium fluoride cells 0.2 mm. in thickness with a Perkin-Elmer Model 21 infrared spectrophotometer. The concentrations of the carbonyl compounds ranged from ca. 0.1 to 0.3 M, and were chosen so as to show the double peak clearly in alcohols.

Results

The infrared spectra of various carbonates, aldehydes, ketones, lactones and esters were determined in carbon tetrachloride and alcohols. The wave numbers of carbonyl bands in carbon tetrachloride (ν_0) and in alcohols (ν_1 and ν_2), together with the ratios of the optical density of the two bands in alcohols, are shown in Tables I, II, III and IV. The spectrum of the carbonyl absorption of isopropyl acetate in methanol is shown in Fig. 1; this will serve as an example of the doublet bands and also shows the independence of the relative band intensities of the concentration.

The results shown in Tables I—IV may be summarized as follows.

TABLE IV. CARBONYL BAND OF ISOPROPYL ACETATE OF THE VARIOUS CONCENTRATIONS IN METHANOL

Isopropyl acetate mol./l.	$\frac{(O.D.)_{\nu_2}}{(O.D.)_{\nu_1}}$
0.404	1.12
0.305	1.13
0.152	1.21
0.122	1.09
0.061	1.25

($\nu_2=1715$, $\nu_1=1736\,cm^{-1}$)

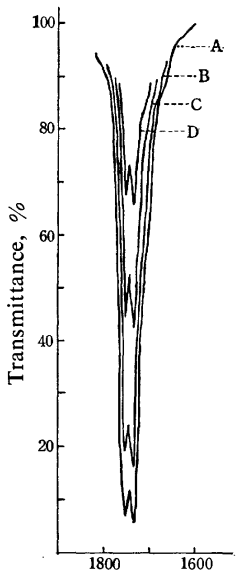

Fig. 1. Carbonyl band of isopropyl acetate in methanol.
Concentration of *i*-PrOAc; A, 0.404; B, 0.305; C, 0.122; D, 0.061 M. Spectral slit-width, 2 cm^{-1}.

1) Except for ethyl salicylate and methyl 3, 5-dinitrobenzoate, all the esters and carbonates appear to give two carbonyl bands in methanol, one at a wave number almost identical with the one in carbon tetrachloride, and the other lower by 15~27 cm^{-1}.

2) Carbonyl bands of aliphatic ketones shift by 9~15 cm^{-1} but do not give two bands in methanol. Benzophenone gives two bands, 11 cm^{-1} apart, while fluorenone seems

to give one broad band which may well in fact consist of two bands.

3) Diacetone alcohol, the carbonyl group of which is already hydrogen-bonded, suffers a further shift as much as 11 cm^{-1} in methanol, whereas the carbonyl absorption of triacetone alcohol is not affected by the change of solvents.

4) Aldehydes seem to give one broad band which may well in fact consist of two bands. The shift of the center of the band is 6~18 cm^{-1}.

5) Lactones gives one broad band in methanol, shifted by 15~19 cm^{-1}.

6) The (Optical density of ν_2)/(Optical density of ν_1) ratio increases as the alcohol is changed from methanol to *t*-amyl alcohol.

7) No significant change in the ratio of the band intensities was observed for various concentrations of isopropyl acetate in methanol.

Discussion

The infrared literature contains numerous examples of monocarbonyl compounds that exhibit two or more prominent bands between 1900 and 1650 cm^{-1}. In the absence of other acceptable explanations, both bands are usually assigned to vibrations involving the carbonyl groups. These doublet carbonyl peaks have been attributed to equilibria between conformational isomers, to Fermi resonance, or to some form of interaction between carbonyl compounds and solvents.

It is not possible to write pairs of stable, conformationally isomeric structures for the carbonyl compounds considered here. In order for the equilibria between conformational isomers to be the cause of the doublet carbonyl bands, it is necessary for the energy difference between two forms to be small enough to allow a significant concentration of the less stable form to exist in equilibrium at room temperature, and the inductive, mesomeric and field effects on the carbonyl group must differ sufficiently in the two forms to induce a significant displacement of the two carbonyl frequencies.

Next, the possibility of attributing these doublet carbonyl bands to Fermi resonance should be examined. Yates and his collaborators[7,8] found that some cyclopent-2-enones exhibited doublet carbonyl bands, the relative intensities of which were dependent on solvents. By a careful examination of the infrared spectra of 5,5-dimethylcyclopent-2-enone, deuterated cyclopent-2-enone and other substituted cyclopent-2-enones, they showed unambiguously that these doublet carbonyl bands arose from Fermi resonance between the carbonyl vibration and the out-of-plane bending vibration of the single ethylenic C–H bond. Angell et al.[9] attributed the double bands of cyclopentanone to the Fermi resonance.

However, the Fermi resonance does not seem to be an acceptable explanation for the doublet carbonyl bands of esters and carbonates in alcohols for the following reason. It is highly unlikely that an accidental degeneracy between the carbonyl stretching mode and an overtone or combination bands would occur through such a wide range of different types of structure. Although Jones et al.[10,11] reluctantly and tentatively attributed the doublet carbonyl bands of unsaturated lactones to Fermi resonance, they were not satisfied with their choice of explanation for the same reason. Yates and Williams[8] found that while 3,4-diphenylcyclopent-2-enone showed a doublet carbonyl absorption at 1718 and 1695 cm^{-1} due to the Fermi resonance with an overtone of the out-of-plane bending vibration of the single ethylenic carbon-hydrogen bond at 860 cm^{-1}, 3,4-diphenyl-5,5-dimethylcyclopent-2-enone showed a singlet carbonyl band since its ethylenic carbon-hydrogen absorption was at 873 cm^{-1}. It is utterly unlikely that the doublet carbonyl bands of all the compounds in Table I arose from an accidental degeneracy between the carbonyl stretching mode and an overtone or combination band, from, i.e., a Fermi resonance.

If these doublet carbonyl bands observed in alcohols cannot be attributed either to equilibria between conformational isomers or to a Fermi resonance, one is forced to believe that these doublet bands are due to some form of interaction between carbonyl compounds and solvents.

If these doublet carbonyl bands in alcohols are due to the hydrogen bonding between the carbonyl oxygen and solvent alcohols, the following three sets of species are conceivably responsible for the doublet bands: 1) non-hydrogen-bonded carbonyl and hydrogen-bonded carbonyl, 2) hydrogen-bonded carbonyl with monomeric alcohol and with polymeric alcohol, and 3) mono-hydrogen-bonded carbonyl and di-hydrogen-bonded carbonyl.

The first set of species does not seem acceptable because of the following two reasons.

7) P. Yates, N. Yoda, W. Brown and B. Mann, *J. Am. Chem. Soc.*, **80**, 202 (1958).
8) P. Yates and L. L. Williams, ibid., **80**, 5896 (1958).
9) C. L. Angell, P. J. Krueger, R. Lauzon, L. C. Leitch, K. Noack, R. J. D. Smith and R. L. Jones, *Spectrochim. Acta*, **11**, 926 (1959).
10) R. N. Jones, C. L. Angell, T. Ito and R. J. D. Smith, *Can. J. Chem.*, **37**, 2007 (1959).
11) R. N. Jones and B. S. Gallagher, *J. Am. Chem. Soc.*, **81**, 5242 (1959).

First, diacetone alcohol, the carbonyl group of which is already hydrogen-bonded, absorbs at 1712 cm^{-1} in carbon tetrachloride, while 2, 6-dimethylheptanone-4 absorbs at 1712 cm^{-1} and heptanone-4 absorbs at 1715 cm^{-1} in the same solvent, the latter two not being hydrogen-bonded. Second, the carbonyl absorption of diacetone alcohol, which is already hydrogen-bonded, is shifted as much as 11 cm^{-1} when its spectrum is taken in methanol.

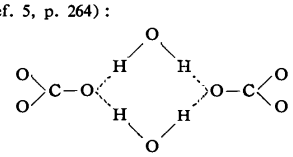
The second set was chosen by Becker[4] as responsible for the doublet bands of benzophenone in ethanol. He attributed the absorption at 1666 cm^{-1} to the carbonyl group hydrogen-bonded to the monomeric alcohol and the absorption at 1656 cm^{-1} to the carbonyl group hydrogen-bonded to the polymeric alcohol. However, it seems highly unlikely that the ethanol monomer can exist in pure ethanol. The oxygen of the ethanol molecule hydrogen-bonded to a carbonyl group is more basic and should be hydrogen-bonded to other molecules of ethanol.

Therefore, in the absence of other acceptable explanations, the most reasonable explanation for the double bands seems to be that carbonyl compounds in alcohols may exist as both a mono-hydrogen-bonded form and a di-hydrogen-bonded form[12,13]. In Tables I, II and III, ν_1 is attributed to the mono-hydrogen-bonded carbonyl and ν_2 is attributed to the di-hydrogen-bonded carbonyl. These assignments are made on the basis of the following observations: (a) The carbonyl absorption of diacetone alcohol occurs at 1712 cm^{-1} in carbon tetrachloride despite the fact that the hydroxyl frequencies indicate strong hydrogen-bonding (3484cm^{-1}), while 2, 6-dimethylheptanone-4 and heptanone-4 absorb in the same solvent at 1712 and 1715 cm^{-1} respectively, these latter two not being hydrogen-bonded. This fact indicates that the carbonyl absorption of a mono-hydrogen-bonded carbonyl compound occurs at nearly the same wave-number as that of a non-hydrogen-bonded carbonyl compound. (b) Triacetone alcohol, in which two intramolecular hydrogen bondings are possible, absorbs in carbon tetrachloride at 1698 cm^{-1} (compare this value with 1712 cm^{-1} of diacetone alcohol). The carbonyl absorption of triacetone alcohol does not suffer any shift at all when the solvent is changed from carbon tetrachloride to methanol. These facts indicate that a carbonyl absorption is shifted a great deal when the compound is subjected to a condition where di-hydrogen-bonding may take place, and that the carbonyl absorption of a di-hydrogen-bonded carbonyl compound is not affected at all by changing the solvent from carbon tetrachloride to methanol, while that of a mono-hydrogen-bonded carbonyl compound is shifted almost as much as that of a non-hydrogen-bonded carbonyl compound by changing the solvent from carbon tetrachloride to methanol.

It is an interesting question why mono-hydrogen-bonding gives only a small shift while di-hydrogen-bonding gives a rather large shift. A plausible explanation is that, since a carbonyl oxygen probably uses one of its p-orbitals in forming the σ-bond with carbon and another p-orbital in forming the π-bond, two unshared electron pairs are in the 2s and 2p orbitals. Therefore, the first hydrogen-bonding probably takes place by making use of the rich electron density of the unshared p-orbital. This hydrogen bonding probably will not affect the stretching frequency of a carbonyl bond very much. The second hydrogen bonding, however, may strongly affect the stretching frequency of the carbonyl bond, if use must be made of the electrons closer to the carbon-oxygen bond. In other words, extensive hybridization of oxygen orbitals would be required for the formation of two hydrogen bonds, whereas little hybridization would be required to form a single hydrogen bond.

Alkyl ketones are exceptional in that they show only one carbonyl band in methanol, one shifted by 8~12 cm^{-1}. They lack the conjugated π-system which is present in esters, carbonates and aryl ketones. The lack of conjugation and the presence of electron-releasing alkyl groups make alkyl ketones form di-hydrogen-bonds more easily than esters, carbonates or aryl ketones, in which the π-electrons of the carbonyl bond are somewhat spread to the conjugated π-system. In methyl 3, 5-dinitrobenzoate, the π-electrons of the carbonyl bond are strongly pulled to the benzene ring and di-hydrogen-bonded forms are present in a very small quantity, if at all. Methyl trichloroacetate and methyl trifluoroacetate, both of which are esters of strong acids, show only one band in methanol[14], presumably

12) The positions of two molecules of water in the crystalline structure of $Na_2CO_3 \cdot NaHCO_3 \cdot 2H_2O$ are as follows (Ref. 5, p. 264):



13) The oxygen atoms of water molecules are pictured as hydrogen-bonded to two hydrogens of other water molecules. See, for example, E. S. Gould, "Inorganic Reactions and Structure", Henry Holt and Co., New York (1955), p. 32.

14) T. G. Traylor, private communication.

due to the absence of the di-hydrogen-bonded carbonyl.

In the case of ethyl salicylate, the carbonyl π-electrons are completely spread to the quasi-six membered ring and are not available to form an additional hydrogen-bond. As may be seen in Table I, the carbonyl band of ethyl salicylate is not affected by changing the solvent from carbon tetrachloride to methanol. Its carbonyl band in carbon tetrachloride is at 1684 cm^{-1}, which is 40 cm^{-1} lower than that of ethyl benzoate in carbon tetrachloride and 20 cm^{-1} lower than that of ethyl benzoate in methanol.

Searles et al.[3] found that the shift of the carbonyl band by changing the solvent from carbon tetrachloride to an equimolar mixture of carbon tetrachloride and methanol is 7 cm^{-1} for β-propiolactone, 12cm^{-1} for γ-butyrolactone, and 15 cm^{-1} for δ-valerolactone. These are shifts of the centers of the broad band, and so the bigger shifts may mean a more di-hydrogen-bonded form. The carbonyl band of γ-butyrolactone is further shifted when its infrared spectrum is determined in pure methanol (15 cm^{-1}; see Table I).

The higher (Optical Density of ν_2)/(Optical Density of ν_1) ratio with *t*-amyl alcohol than with methanol may be explained by the fact that self-hydrogen-bonding is much weaker in *t*-amyl alcohol than in methanol[15]. Therefore, the equilibrium, self-bonded alcohol $\rightleftharpoons$ carbonyl-bonded alcohol, is shifted more to the right in the case of *t*-amyl alcohol, even though methanol is a stronger acid. It is presumably only as a hydrogen acceptor that *t*-amyl alcohol is ineffective; accordingly, we have a carbonyl compound able to compete with the oxygen of *t*-amyl alcohol in the hydrogen acceptor role, whereas the carbonyl oxygen cannot compete so well with the oxygen of methyl alcohol.

Summary

The infrared spectra of some esters, lactones, carbonates, ketones and aldehydes in methanol and *t*-amyl alcohol have been determined. With few exceptions, they showed either two carbonyl peaks separated by 15~27 cm^{-1} or a broad carbonyl peak shifted by 9~19 cm^{-1} from the wave number as determined in carbon tetrachloride. The relative intensities of the two bands are independent of the concentration. Some possible explanations for this phenomenon have been discussed, and as a result these doublet carbonyl bands have been attributed to the mono-hydrogen-bonded carbonyl and the di-hydrogen-bonded carbonyl.

The author would like to thank Professor Paul D. Bartlett of Harvard University for his encouragement to investigation these spectra as a side line to my Ph. D. thesis problem; Professor Teddy G. Traylor of the University of California for his stimulating discussions, and the Bell Telephone Laboratories for a predoctoral research fellowship (1959~1961).

The Phase Transition of Crystalline Potassium Thiocyanate, KSCN. I. Thermal and Infrared Studies

By Minoru SAKIYAMA, Hiroshi SUGA and Syûzô Seki

(Received January 31, 1963)

From the standpoint of the shape of ions, ionic crystals which consist of spherical cations and spherical anions may be the simplest case; there are found almost no materials of this type which undergo phase transition below their melting temperatures. Two exceptions are, however, silver[1] and cuprous[2] iodides. In those cases, the transitions are known to be due to the positional disorder of the cations in these crystalline lattices.

1) L. W. Strock, *Z. phys. Chem.*, **B25**, 441 (1931); **B31**, 132 (1936): S. Hoshino, *J. Phys. Soc. Japan*, **12**, 315 (1957).

2) J. Krug and L. Sieg, *Z. Naturforsch.*, **7a**, 369 (1952); S. Miyake, S. Hoshino and T. Takenaka, *J. Phys. Soc. Japan*, **7**, 19 (1952).

As the second simplest case, ionic crystals which consist of spherical cations and rod-shaped anions may be cited. They are known to undergo a phase transition which may be related to the change in the direction of the anions. Such ionic crystals include, for example, (1) hydrogen, sodium and potassium cyanides[3], (2) sodium, rubidium and cesium hydroxides[4], and (3) sodium, potassium and rubidium hydrosulfides and hydroselenides[5]. The material studied in this paper, potassium thiocyanate crystal, is known to belong to this category.

Another, simpler case may be the ionic crystals which are composed of spherical anions and radical cations. In this case the phase transition due to the orientational or rotational disorder of the cations is well known. Ammonium halides are the most common instances[6].

Beginning with the view just mentioned, we have studied the phase transition of potassium thiocyanate and ammonium thiocyanate crystals. In the present paper, however, we will confine ourselves to the findings concerning the former.

This crystal is known, by the phase diagram study of Wrzewnewsky[7], to undergo a phase transition at about 142°C. There have also been some crystallographic and structural chemical investigations by some workers.

The room temperature modification of this crystal has been found to belong to the orthorhombic system by Klug[8], while infrared studies of this modification by Jones[9] have shown that the absorption band due to the bending vibration of thiocyanate ions, which should be doubly degenerate, splits into doublets. Plester and Ubbelohde[10] have found in their dilatometric measurements that this substance melts accompanying an anomalously large premelting phenomenon, a phenomenon which they supposed due to the formation of a large number of lattice vacancies. However, our dilatometric study of the extremely purified sample did not show such an anomalous effect[11].

It seemed of interest to elucidate the mechanism of the phase transition of this substance on the basis of our knowledge of crystal structure and of the thermal and other properties. For this purpose, we have carried out differential thermal analysis, specific heat measurements from 0 to 165°C, and measurement of the temperature variation of the infrared absorption bands.

Experimental

Materials.—The potassium thiocyanate used for the present studies (extra pure grade reagent of the Wakō Pure Chemicals Co., Ltd.) was recrystallized twice from water and dried at 150°C under a high vacuum (10^{-5} mmHg).

Apparatus and Procedure.—The differential thermal analysis of this substance was carried out by using an automatically controlled recording apparatus, the details of which have already been reported on[12]. In order to determine the transition temperature accurately and in order to study the thermal behavior in more detail, specific heat measurements were also made in the temperature range from 0 to 165°C by using a conduction calorimeter[13], the heating rate being 0.2~0.3°C/min. A glass-made dilatometer was employed for the measurement of the thermal expansion. The confining liquid used was mercury. It was confirmed that mercury did not react with the sample, even above the melting point[11]. For the infrared measurements, an Hitachi infrared spectrophotometer EPI-2 with sodium chloride, calcium fluoride and potassium bromide prisms was used. Sample spectra were measured in Nujol mull or epitaxially-grown crystal from melt on a potassium bromide plate. The temperature was varied by an electrical heating device of the sample holder, and the temperature was measured by a copper-constantan thermocouple imposed in a hole drilled in a potassium bromide plate.

Results

Dilatometry.—The general trend of the results has been given in a previous paper[11]. The detailed behavior around the transition temperature is reproduced here on a large scale in Fig. 1. The curve does not show any of the discontinuity which is usually found in the first order phase transition. The volume thermal expansion coefficients given in Fig. 2 were calculated at each temperature from dilatometric data.

Differential Thermal Analysis.—The results are shown in Fig. 3. Measurements in the temperature range from −190 to 0°C gave no thermal anomaly, so those results are not reproduced here. The anomaly around 140°C is

due to the phase transition mentioned above, its shape suggesting again that the transition may be of the higher-order type. The higher temperature one at 175°C is ascribed to the melting. As may be seen in the figure, the sharp rise of this curve shows no evidence of the premelting phenomenon suggested by Plester and Ubbelohde[10]. All these results are in good agreement with the results of our dilatometric study[11].

Heat Capacity Measurements.—Heat capacities are tabulated in Table I, while their variation with the temperature is presented in Fig. 4. We can find from this figure that the phase transition is of the so-called "λ-type phase transition", accompanied by a sharp and remarkable rise just below the transition point. No hysteresis phenomenon was observed.

The following thermodynamic quantities were obtained:

Transition temperature: $T_{tr}=139.2°C$

Heat of transition: $\Delta H_{tr}=529.5\pm20$ cal./mol.

Entropy of transition: $\Delta S_{tr}=1.30\pm0.5$ e. u.

Infrared Measurements.—The absorption bands are assigned and the notation used is presented in Table II. Our results almost agreed with those by Jones[9] except in one point. We found a complex structure in the strong bands of the 2000 cm^{-1} region (Fig. 5) which is attributed to the stretching vibration (ν_1) of the C–N bond of SCN^- ions, when

we measured with a calcium fluoride prism with an epitaxially-grown sample from the melt.

When the sample was heated, gradual changes in the spectrum were observed. The most characteristic change was the apparent transformation of a doublet in the region of 480 cm^{-1}

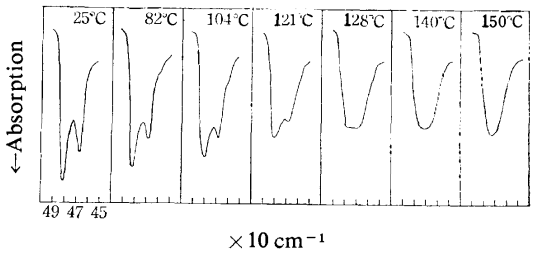

Fig. 6. Temperature variation of ν_{2a} and ν_{2b} bands of SCN^- ion in KSCN crystal.

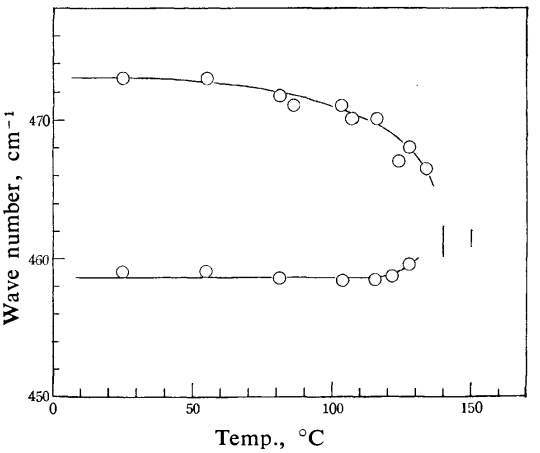

Fig. 7. Temperature dependence of the position of ν_{2a} and ν_{2b} bands of SCN^- ion in potassium thiocyanate crystal.

into a singlet. The behavior of and the variation in the positions of these bands are shown in Figs. 6 and 7. We can find that the 483 cm^{-1} band comes closer to the 469 cm^{-1} band as the temperature increases and the variation in wave number difference of these two bands as a function of the temperature accords with the progress of transition shown in molar volume or heat capacity change. Similar behavior was also observed in the position of the ν_3 band. As to the ν_1 band, little variation was found except for the thermal broadening and smearing of its fine structure.

Discussion

The crystal system of phase II (the room temperature phase) is orthorhombic, with $a=$ 6.66 Å, $b=7.58$ Å, $c=6.635$ Å, $Z=4$, and space group, $D_{2h}^{11}-Pcmb$[8]. The arrangement of ions is schematically given in Fig. 8. The thiocyanate ions lie on a crystallographic b-plane with specified orientations, while potassium ions are sandwiched between the thiocyanate layers.

The molecular symmetry of a "free" thiocyanate ion is $C_{\infty v}$. Three normal modes of vibration, one of which is doubly degenerate,

are those shown in Fig. 9. From the standpoint of site symmetry analysis, Jones[9] explained the splitting of the ν_2 band into a doublet in the crystalline state as the result of the anisotropy of the crystalline field that is brought about by the layer structure of crystal. The absorption bands at 483 and 469 cm^{-1} were assigned on the basis of the polarisation studies to the bending vibrations parallel with (ν_{2a}) and perpendicular to (ν_{2b}) the crystallographic b-plane respectively.

In the present study, a remarkable temperature shift of position was observed to take place in the ν_{2a} and ν_3 bands, both due to a in-plane vibration, while no such tendency was found in the ν_{2b} (out-of-plane) band. These experimental results suggest that phase transition takes place in such a way that the crystalline field parallel with the b-plane around a thiocyanate ion is much influenced in the course of phase transition. As is shown in Fig. 10, the thiocyanate ions in the b-plane are arranged in the closest packing way, so the overlapping of an electron cloud between atoms

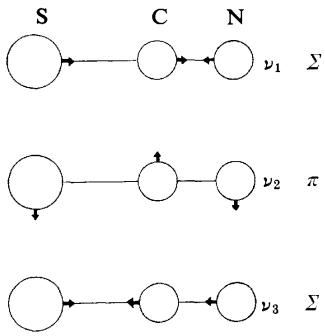

Fig. 9. Schematic representation of normal modes of vibration of SCN^- ion.

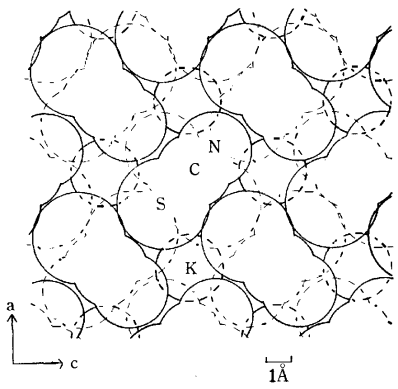

Fig. 10. Schematic representation of the packing of ions projected to b-plane. (phase II).

in the plane is more profound than that between the inter-layer atoms. The above-mentioned remarkable change in the ν_{2a} and ν_3 bands may be understandable by means of this line of explanation.

Now, we should like to proceed to the problem of the thermal properties of the crystal before entering into a discussion of the relationship between the spectroscopic results and the mechanism of phase transition. The molar volume and the thermal expansion coefficient versus the temperature curves reveal that this transition is of a higher order (see Figs. 1 and 2). This means that the crystal structure of the high temperature phase is nearly the same as the low temperature one, with no appreciable change in atomic arrangement. It is also found from the C_p vs. temperature curve that the transition is highly co-operative, as is evident from the sharp rise just below the peak. The amount of transition entropy, 1.30 ± 0.05 e. u., is nearly equal to $R\ln 2 = 1.38$ e. u. Combining these results of transition entropy and of dilatometry, it is strongly suggested that phase I maintains nearly the same arrangement of the centers of gravity of ions and obtains two opposite directions (S–C–N and N–C–S) in one and the same orientation (original to phase II) of anions in equal probability.

Recently, X-ray crystal structure analysis of phase I (the high temperature phase) has been carried out by Yamada and Watanabé[14], who found that the crystal in phase I belongs to the tetragonal system (space group, D_{4h}^{18}–I4/mcm, $Z=4$) and that the electron distribution map of a thiocyanate ion does not differentiate S and C atoms. This means that an averaged structure between two equilibrium directions (S–C–N and N–C–S) in one and the same orientation is obtained. These results are in good agreement with our results.

From these facts, we can conclude that the transition is of the order—disorder type for two directions of thiocyanate ions.

Next, we should like to discuss our spectroscopic results in connection with the mechanism of the phase transition.

As is shown in Figs. 2, 4 and 7, the volume thermal expansion coefficient, the molar heat capacity and the wave number of the infrared ν_{2a} band all start to change at nearly the same temperature, 70°C. These facts show that the temperature shift of the ν_{2a} frequency is intimately related to the progress of the phase transition.

As has been mentioned, the crystal in phase I belongs to the tetragonal system, but the layer structure of the thiocyanate ions is still maintained. Therefore, if the splitting of the ν_2 band observed in phase II is ascribed to the anisotropy of the crystalline field around a

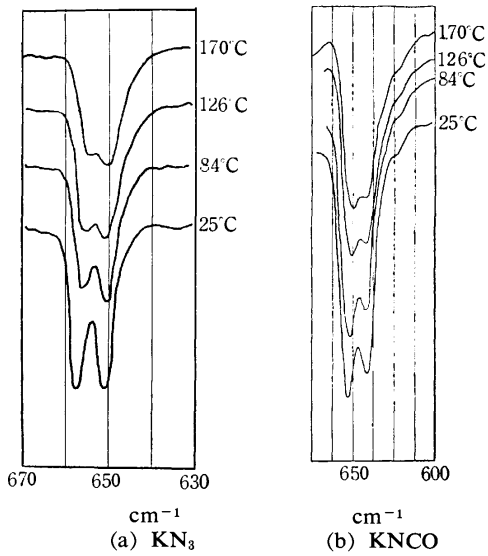

Fig. 11. Temperature variation of infrared ν_2 bands of KN_3 and KNCO crystals.

14) Y. Yamada and T. Watanabé, This Bulletin, 36, 1032 (1963).

thiocyanate ion, a similar ascription should hold also in phase I.

In this respect, we have taken infrared spectra of potassium azide, KN_3 and potassium cyanate, KNCO, crystals for reference. These crystals consist of linear triatomic anions and potassium cations and are quite isomorphous with potassium thiocyanate crystal in phase I (space group, $D_{4h}^{18}-I4/mcm$)[15,16]. In these two crystals the size of anions is the smaller and they are packed more closely, as is reflected in the lattice constants ($a=c=6.096$ Å, $b=7.056$ Å for KN_3 crystal; $a=c=6.07$ Å, $b=7.03$ Å for KNCO crystal), and the thermal motions mainly responsible for the reorientation occur with more difficulty because of their stronger interionic interactions, as is revealed by their higher melting points (355°C for KN_3 and ca. 700°C for KNCO). Spectra of these compounds in the ν_2 region at various temperatures above room temperature are presented in Fig. 11. As is evident from the figure, splitting may be observed at all the temperatures examined, accompanied by a slight shift of higher frequency bands*. From these facts, it is very plausible to assume that we can ascribe the transformation of a doublet into a singlet observed in the ν_2 band of the potassium thiocyanate crystal, not to the fact that this crystal belongs to the tetragonal crystal system in phase I, but rather to an excitation of violent torsional oscillation as well as to a flipping motion which leads to the dynamical directional disordering of the thiocyanate ions.

Inspection of the molecular packing in the potassium thiocyanate crystal of phase II (Fig. 10) shows that out-of-plane motions seem to occur more easily than in-plane motions. Furthermore, from X-ray studies by Yamada and Watanabé[14] it has been established that the expansion of the b axis of a unit cell at the end-point of phase transition is more remarkable than those along the a and c axes ($\Delta b/b\simeq 0.017$, $\Delta a/a\fallingdotseq\Delta c/c\simeq 0.008$). This fact is considered to reflect also the fact that interionic interactions along b-axis are weaker than those along the other two axes, so out-of-plane motions will be more frequently excited than in-plane motions. Although the torsional frequencies of thiocyanate ions are not known, the existence of a lattice frequency of 28 cm^{-1} has been reported by Jones[8]. In any case, it is quite plausible that torsional frequencies are of the order of one-tenth of the bending frequencies. The period of flipping motions from one equilibrium direction to another will be larger than or at least of the same order as those of the torsional oscillation. Therefore, in one period of torsional oscillation some ten cycles or so of bending vibration are possible. Such out-of-plane motions will diminish the repulsive potential, which affects in-plane bending vibration more seriously. Frequent excitation of such kinds of motion all over the crystal will work out to bring about operatively a considerable decrease in the crystalline field around the anions.

Summarizing these results, we may explain the temperature variation of the ν_{2a} band in the following way. When the temperature approaches the transition temperature, the out-of-plane torsional oscillation and the flipping motion of thiocyanate ions are more and more frequently excited; eventually, at the transition point the long-range directional order of thiocyanate ions will disappear completely. Parallel with the progress of the phase transition, the repulsive potential, as well as the anisotropy mentioned above, will be gradually decreased, resulting in the gradual shift of the ν_{2a} band.

Finally, we should like to comment briefly on the results of the factor group analysis of the molecular vibrations of thiocyanate ions in the potassium thiocyanate crystal (phase II). In this case a Bravais unit lattice coincides with a crystallographic unit cell, and there are four potassium cations and four thiocyanate anions in a unit cell. The analysis was performed following the ordinary method; the results are presented in Table III. If a thiocyanate ion is linear, $4\times(3\times3-5)=16$ inner vibrational modes will be present. Nevertheless, only twelve modes are found by this analysis. On the other hand, twelve modes are found for the rotational lattice vibration. If thiocyanate ions are strictly linear, there should be present only $4\times2=8$ rotational vibrational modes in a Bravais unit lattice. Thiocyanate ions are thus found by this analysis to be not strictly linear-shaped but slightly bending, even in the equilibrium configuration, under the influence of the intermolecular interaction. Of the twelve rotational lattice modes, four are out-of-plane modes, distributed among the A_{1u}, B_{1u}, B_{2g} and B_{3g} species. The out-of-plane bending vibration in the nomenclature of the site symmetry analysis corresponds to the rotational lattice modes which fall in B_{1u}.

16) L. K. Frevel, *Z. Krist.*, 94, 197 (1936); *J. Am. Chem. Soc.*, 58, 779 (1936).

* Infrared spectra of these two crystals have been reported by some authors. For KN_3, see P. Gray and T. C. Waddington, *Trans. Faraday Soc.*, 53, 901 (1957); H. A. Papazian, *J. Chem. Phys.*, 34, 1614 (1961). For KNCO, see T. C. Waddington, *J. Chem. Soc.*, 1959, 2499. These writers have, however, not made any comment regarding on the splitting of the ν_2 band nor have they presented a spectrum chart in which no doublet is observed. We should like to make a more detailed discussion of this point elsewhere in the near future.

As has been mentioned above, in phase I the direction of the thiocyanate ions is disordered. Since the space group of this phase represents the symmetry of the averaged structure, factor group analysis cannot be successfully applied to this phase. However, phase I belongs to the tetragonal system, and at least no positive reasons are available which oblige us to consider that thiocyanate ions bend in this phase. If so, the temperature shift of the ν_{2a} band may be accompanied by the change in molecular shape from slightly bending to strictly linear in the equilibrium configuration, but by no change in the mode of molecular motion. On the other hand, in the bending vibration which falls in the B_{3u} species, a change in the shape of the ions as well as a change in the mode of motion (from a rotational lattice one to a bending one) may be expected to occur, but no appreciable shift in the ν_{2b} frequency is observed.

Summary

The phase transition of the potassium thiocyanate crystal at ca. 140°C has been studied by thermal and infrared methods. The transition is of a higher-order type, accompanied by an entropy change of 1.30 ± 0.05 e. u., which is nearly equal to $R \ln 2$. The infrared band due to the in-plane bending vibration of a thiocyanate ion shifts to lower frequencies in the course of the phase transition. From these results, it has been concluded that the phase transition is connected with the dynamical disordering of the direction of thiocyanate ions in crystal, a disordering which is mainly brought about by the frequent excitation of the out-of-plane torsional oscillation and the flipping motion.

We wish to express our hearty thanks to Professor Isamu Nitta of Kwansei Gakuin University for his valuable advice and continued interest in this study, and also to Drs. Yasusada Yamada and Tatsuo Miyazawa of Osaka University for their kind discussions. This work was partly supported by Scientific Research Funds from the Ministry of Education.

The Phase Transition of Crystalline Potassium Thiocyanate, KSCN. II. X-Ray Study

By Yasusada YAMADA and Tokunosuké WATANABÉ

(Received April 27, 1963)

As has been illustrated in the foregoing paper[1], thermal and infrared absorption data suggest that the mechanism of the phase transition of potassium thiocyanate is described by a model of the order-disorder type transition for the orientation of the rod-shaped thiocyanate ion.

The aim of the present investigation is to confirm the above-mentioned mechanism of transition by the X-ray diffraction method, a proceeding based on the knowledge of the crystal structures below and above the transition temperature.

The crystal structure of the room temperature modification is known. According to Klug[2], potassium thiocyanate is isomorphous with D^{11}_{2h}–Pbcm, and its orthorhombic unit cell, containing four formula units, has the following dimensions:

$$a=6.66\,\text{Å},\ b=6.635\,\text{Å} \text{ and } c=7.58\,\text{Å}$$

Throughout this description, the axes (X, Y, Z) are derived from those of Klug (X', Y', Z') by a transformation: $X=Z'$, $Y=Y'$, $Z=X'$. A structure which gives a fairly good agreement between observed and calculated structure factors is obtained by putting atoms in the following equivalent positions given by D^{11}_{2h}–Pbcm.

4K:

$$u\ \frac{1}{4}\ 0,\ u\ \frac{1}{4}\ \frac{1}{2},\ \bar{u}\ \frac{3}{4}\ 0,\ \bar{u}\ \frac{3}{4}\ \frac{1}{2};$$

2) H. P. Klug, *Z. Krist.*, **85**, 214 (1933).

$$v\ w\ \frac{1}{4},\ \bar{v}\ \bar{w}\ \frac{3}{4},\ v\ \frac{1}{2}-w\ \frac{3}{4},\ \bar{v}\ \frac{1}{2}+w\ \frac{1}{4};$$

with $u(\mathrm{K})\approx\frac{3}{4}$, $v(\mathrm{S})=0.385$, and $w(\mathrm{S})=0.125$. The suggested parameters for nitrogen are $v(\mathrm{N})=0.080$ and $w(\mathrm{N})=0.400$; for carbon, $v(\mathrm{C})=0.205$ and $w(\mathrm{C})=0.280$. The arrangement of the thiocyanate ions in the unit cell is shown in Fig. 1. All the thiocyanate ions are lying on planes parallel to (0 0 1) and are oriented to the face diagonals, as Fig. 1 shows. The infrared absorption lines referred above correspond to the bending vibrations of the

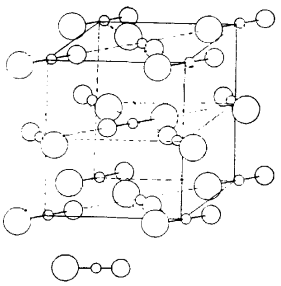

Fig. 1. The arrangement of thiocyanate ions in the low temperature phase.

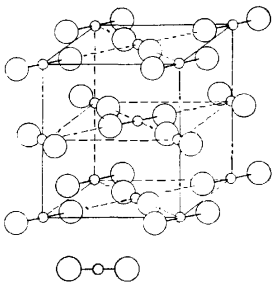

Fig. 2. The arrangement of thiocyanate ions in the high temperature phase.

thiocyanate ions in and out, respectively, of these planes.

The Crystal Structure of the High Temperature Phase

In order to investigate the crystal structure of the high temperature phase, X-ray diffraction experiments were carried out as follows:

The crystals used in the present experiments were obtained by slow evaporation from methanol solutions. In form they are thin rods elongated along [1 0 0]. By a preliminary test, it was found that the transition occurred in a single crystal. The crystals do not shatter on passing the transition temperature, and the process is almost completely reversible.

As the crystal is highly deliquescent, each sample was sealed in a thin, evacuated capillary. Hot air was blown in a constant stream over the capillary mounted on the goniometer in order to maintain the sample at a certain temperature between 160°C and room temperature. A thermocouple was placed at the nozzle of the jet. Before the crystal was set on the goniometer head, another thermocouple was mounted in place of the sample in order to estimate the temperature gradient in the hot air stream. As no appreciable difference was observed between the temperatures read by the two thermocouples, the temperature of the crystal was estimated by the thermocouple placed at the nozzle during the exposure.

Oscillation photographs were prepared by using [1 0 0] and [0 0 1] as the axes of rotation. Precession photographs for the $hk0$ and $hk1$ levels were also prepared.

The general appearance of the oscillation and precession photographs taken at 160°C was very like those taken at room temperature, indicating that the size of the unit cell and the arrangement of the constituent atoms do not change appreciably. However, the symmetry of the reciprocal lattice becomes ditetragonal and many of the weak reflections disappear, though the intensity of reflections from planes with the indices $hk1$ for $h+k+l$ even seems to be affected by the temperature factor alone. The lattice constants are found to be:

$$a=b=6.70\,\text{Å} \text{ and } c=7.73\,\text{Å} \text{ (at 160°C)}$$

To all the extinction rules observed for the room temperature modification, is now added hkl for $h+k+l$ odd. The space groups compatible with these rules are $C^{10}_{4v}-I4\,cm$, $D^{10}_{2d}-I\bar{4}c2$ and $D^{18}_{4h}-I4/mcm$.

Let us now try to derive a structure based upon these space groups, starting first with $C^{10}_{4v}-I4c2$. In this space group, there are two kinds of four-fold and one kind of eight-fold equivalent positions:

$$\left(0\,0\,0,\ \frac{1}{2}\ \frac{1}{2}\ \frac{1}{2}\right)+$$

4a: $0\,0\,z,\ \frac{1}{2}\ \frac{1}{2}\ z;$

4b: $\frac{1}{2}\ 0\ z,\ 0\ \frac{1}{2}\ z;$

8c: $x\ \frac{1}{2}+x\ z,\ \bar{x}\ \frac{1}{2}-x\ z,\ \frac{1}{2}+x\ \bar{x}\ z,$
$\frac{1}{2}-x\ x\ z$

Since there are four formula units in the unit cell, we have to find positions for four potassium, four carbon, four nitrogen and four sulfur atoms. Now, either 4a or 4b will give almost the same arrangement of potassium atoms as in the room temperature modification. However, the carbon, nitrogen and sulfur atoms cannot be placed on either 4a or 4b, because the length of the b-axis is too short to be accommodated with these atoms. Moreover, any one of these structures should give the natural decrease of intensities for $0k0$, e.g., $I_{020}>I_{040}>I_{060}>I_{080}$; this is not, however, the case. The only possibility of placing these atoms is to use 8c, with half a weight on each atom. If we place the potassium atoms on 4a, and the other atoms on 8c with appropriate parameters, we shall arrive at a structure which can easily be derived from the structure of the room temperature modification, the difference being that all the thiocyanate ions are here pointing statistically in two directions, namely, either [1 1 0] and $[\bar{1}\,\bar{1}\,0]$ or $[1\,\bar{1}\,0]$ or $[\bar{1}\,1\,0]$ (See Fig. 2). The same atomic arrangement can also be obtained either from $D^{10}_{2d}-I\bar{4}c2$ or $D^{18}_{4h}-I4/mcm$ by using 4a for potassium and 8h for the other atoms. If the origin of coordinates is shifted to $\frac{1}{4}\,\frac{3}{4}\,\frac{3}{4}$ from that given in International Table I, the positions of atoms can be given by:

$$\left(0\,0\,0,\ \frac{1}{2}\,\frac{1}{2}\,\frac{1}{2}\right)+$$

4K in 4a:

$$\frac{3}{4}\,\frac{1}{4}\,\frac{1}{2},\ \frac{3}{4}\,\frac{1}{4}\,0,\ \frac{1}{4}\,\frac{3}{4}\,0,\ \frac{1}{4}\,\frac{3}{4}\,\frac{1}{2};$$

4C, 4N, 4S in 8c:

$$x\,x\,\frac{1}{4},\ \frac{1}{2}-x\,\frac{1}{2}-x\,\frac{1}{4},\ \frac{1}{2}+x\,\bar{x}\,\frac{1}{4},$$

$$\bar{x}\,\frac{1}{2}+x\,\frac{1}{4},\ \frac{1}{2}+x\,\frac{1}{2}+x\,\frac{3}{4},\ \bar{x}\,\bar{x}\,\frac{3}{4},$$

$$x\,\frac{1}{2}-x\,\frac{3}{4},\ \frac{1}{2}-x\,x\,\frac{1}{4},$$

with half a weight on each.

Comparing these coordinates with those assigned to the atoms in the room temperature modification, it can easily be understood that the structure factor for the high temperature modification has the same expression as those for the room temperature modification with the indices $h+k+1$, even if u(K) is taken to be 3/4 and $w_i=1/2-v_1$. The differences in these three structures given by $C^{10}_{4v}-I4cm$, $D^{10}_{2d}-I\bar{4}c2$ and $D^{18}_{4h}-I4/mcm$ lie in the fact that the site symmetry of the positions of the centers of the mass of the constituent ions corresponds to the following:

	$C^{10}_{4v}-I4\,cm$	$D^{10}_{2d}-I\bar{4}c2$	$D^{18}_{4h}-I4/mcm$
K:	C_4-4	D_2-222	D_4-422
CNS:	$C_{2v}-mm$	D_2-222	$D_{2h}-mmm$

Since the thiocyanate ions are statistically disposed in two directions, or they flip from one direction to the reverse, there is no reason to assume that these thiocyanate ions have a symmetry lower than $D_{2h}-mmm$. The most probable space group is therefore, $D^{18}_{4h}-I4/mcm$. A fairly good agreement between observed and calculated structure factors was found with the following parameters: $x(C)=0.212$, $x(N)=0.110$, $x(S)=0.090$ and $B(\text{overall})=3.1\,\text{Å}^2$. Further refinement was not attempted because of the disordered structure. Though the crystal structure of potassium cyanate[3], KCNO, has not been worked out fully, it seems that it is isomorphous with the high temperature modification of potassium thiocyanate.

The Temperature Dependence of Ordering

It was observed that the intensity of the reflection from those crystal planes whose indices satisfy the relation, $h+k+l=2n+1$, decreases very rapidly as the temperature approaches the transition point. To investigate the temperature dependence of the intensity, the intensity of reflection (0 3 2) was measured at various temperatures by the scintillation-counter method, using monochromatized Mo-K_α radiation. The results are shown in Fig. 3, in which the scale of intensity is chosen arbitrarily. One of the reasons why this reflection was chosen for precise measurement is that there is only a negligible contribution

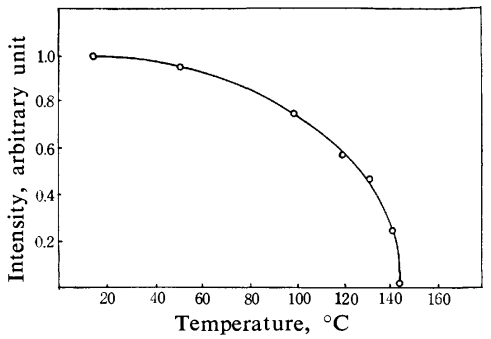

Fig. 3. Temperature dependence of intensity of (0 3 2) reflection.

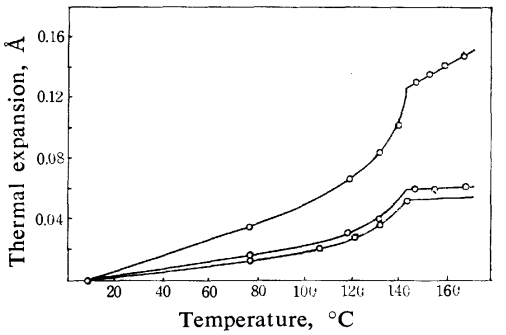

Fig. 4. Thermal expansion of lattice constants.

of the potassium atoms in its structure factor.

It was also observed that the lattice constants show an anomalous expansion near the transition temperature, a finding in accordance with dilatometric data given in the previous investigation. The results are shown in Fig. 4.

The temperature dependence of the reflected intensity directly gives information about the mechanism of the ordering of thiocyanate ions. If we call the arrangement of thiocyanate ions at room temperature " normal ", the high temperature phase can be described as containing an equal number of the normal and of the reverse arrangements of the thiocyanate ions. When the temperature of the crystal is raised, the reverse arrangement sets in and its fraction increases as the temperature rises; finally the crystal contains an equal number of the normal and reverse arrangements above the transition temperature.

Using the long range order parameter, S, which is defined by the relation: $p=1+S/2$, p being the probability that the thiocyanate ion takes in the normal position, we can now write the intensity of the reflection from the crystal planes $(h\,k\,l)$ whose indices satisfy the relation $h+k+l=2n+1$ in the following form:

$$I(hkl)\propto\{f^{r}-f^{w}\}^{2}S^{2}e^{-2M} \qquad (1)$$

where f^{r} represents the scattering amplitude of the thiocyanate ions in the normal position (the equillibrium position at room temperature), f^{w}, that of the same ion in the reverse position, and the factor e^{-2M}, the reduction factor called the Debye-Waller temperature factor. M can be written in the form:

$$M=8\pi^{2}\langle u^{2}\rangle\left(\frac{\sin\theta}{\lambda}\right)^{2}\equiv B(T)\left(\frac{\sin\theta}{\lambda}\right)^{2} \qquad (2)$$

where $\langle u^{2}\rangle$ is the mean-squared displacement of atoms perpendicular to the reflecting crystal plane.

Therefore, the temperature dependence of S relative to the order parameter, $S(T_0)$, at a certain temperature, T_0, can be given by observed intensities as follows:

$$R(T)\equiv\frac{S(T)}{S(T_0)}=\sqrt{\frac{I(T)}{I(T_0)}}\,e^{-M(T)+M(T_0)} \qquad (3)$$

Throughout this study the room temperature, 15°C, was chosen as T_0. To eliminate the $e^{-M(T)+M(T_0)}$ factor, we proceeded as follows. $M(T)$ for $T=160$°C and $T=15$°C were obtained by examining the observed structure factors $F(h\,k\,l)$ with $h+k+l=2n$, because these reflections are independent of the parameter, S, and the temperature dependence of their intensities mainly comes from the excitation of thermal vibrations. The experimental values of $B(T)$ are 3.1 Å^2 for $T=160$°C and 1.9 Å^2 for $T=15$°C. $M(T)$ at any temperature between $T=160$°C and $T=15$°C was obtained by a linear interpolation. The $e^{-M(T)+M(T_0)}$ factor for the (0 3 2) reflection using these values is 0.931 for $T=142$°C (transition temperature). Therefore, the maximum correction due to thermal vibrations is estimated to be about 7%. As $S(T_0)$ can not be obtained experimentally, it must be given more or less arbitrarily, except that the extrapolation of S to $T=0$°K should tend to unity $[S(0°K)=1]$, corresponding to the completely ordered state.

Discussion

Let us look into the mechanism of the ordering. We shall separate the whole lattice into two body-centered tetragonal lattices and assume that the ordering occurs independently in these two lattices. The interaction energy for one sublattice may then be expressed as:

$$U=-\sum_{i}\sum_{j}J_{ij}\mu_i\mu_j \qquad (4)$$

where μ_i is the dipole moment of the i'th ionic radical and can take only two values, $\pm\mu_0$, corresponding to the normal and reversed positions. Using the molecular field approximation, we replace μ_i's by an averaged value, $\langle\mu\rangle$, where

$$\langle\mu\rangle=\mu_0\frac{1+S}{2}-\mu_0\frac{1-S}{2}=\mu_0 S \qquad (5)$$

The interaction energy per ion may then be expressed as

$$U=-\mu_0^{2}\sum_{j}J_{0j}S^{2}\equiv -JS^{2} \qquad (6)$$

Following the usual thermodynamical calculations, we obtain the theoretical values of S versus temperatures which are given by the dotted line in Fig. 5. The open circles in the same figure represent experimental values obtained by Eq. 3, assuming $S(T_0)$ to be equal to the theoretical value. However, extrapolation of the experimental curve (solid line) to $T/T_c=0$ does not give $S=1$, which implies

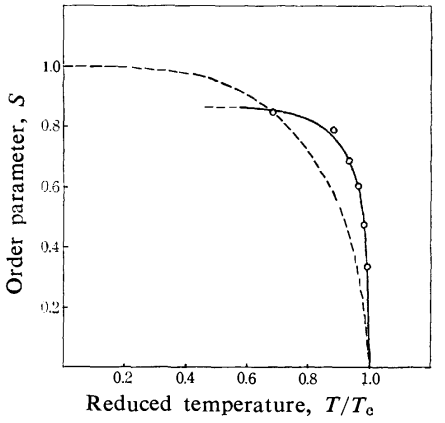

Fig. 5. Temperature dependence of order parameter. Dotted curve is for theoretical value by first approximation. Experimental value is normalized by $S=0.84$.

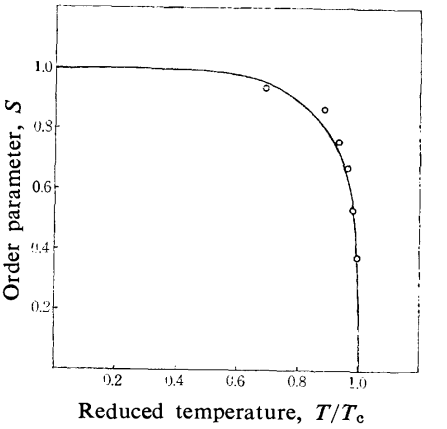

Fig. 6. Temperature dependence of order parameter. Observed values are normalized by $S=0.94$.

that ordering occurs more rapidly in the vicinity of the transition temperature.

As a second approximation, we shall take into account the effect of the volume dependence of the interaction energy, J[4]. If the gain of ordering energy by expansion overcomes the loss of elastic energy, the system will continue to possess the ordering accompanying the anomalous volume expansion near the transition temperature.

A simple calculation along these lines is performed in the Appendix. The results of the calculations give the temperature dependence of S as follows:

$$S=\mathrm{Tanh}\left[\frac{T_c}{T}S+A\frac{T_c}{T}S^3\right]$$
$$A=\frac{2v(\beta_c T_c)^2}{\kappa\alpha^2 k T_c} \qquad (7)$$
$$T_c=2J_0/k$$

where κ is the compressibility; β_c, the anomalous volume expansion coefficient; v, the ionic volume; J_0, the volume-independent part of interaction energy J; k, the Boltzman constant, and α, a parameter given by (A—9), T_c being the Curie temperature. A comparison of the experimental values of the long range order parameter and the values calculated by this equation is given in Fig. 6, where κ is assumed as:

$$\kappa=6.0\times10^{-12}\ \mathrm{cm^2/dyn.}$$

and the following experimental values are used:

$$T_c=142^\circ\mathrm{K}$$
$$\beta_c=4.4\times10^{-4}\ \mathrm{deg^{-1}}$$
$$v=167.5\times10^{-24}\ \mathrm{cm^3}$$

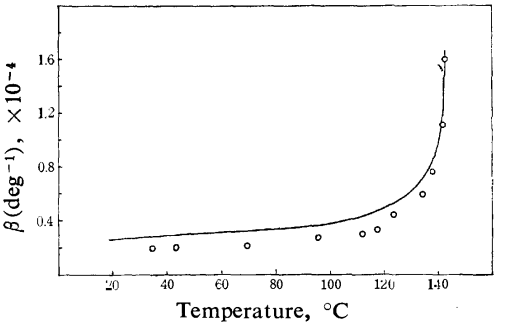

Fig. 7. Temperature dependence of volume expansion coefficient.

For these values,

$$A=0.30$$

As is illustrated in the Appendix, the value of A can not exceed 1/3 for the second order transition, regardless of the value of κ. A comparison of the experimental values of the anomalous volume expansion coefficient β_a and the values calculated by Eq. A—12 is also given in Fig. 7, in which part of the experimental values are given by a dilatation measurement[5].

Substantial accordances in both S and β_a seem to suggest that the transition mechanism is well described by the ordinary molecular field approximation if the volume dependence of the interaction energy is taken into account. The remaining discrepancies may be due to the effect of the excitation of lattice vibrations.

These investigations, however, do not yield any information about the dynamical properties of the flipping motion of the thiocyanate ions.

Summary

The phase transition of potassium thiocyanate has been investigated by the X-ray diffraction. It was confirmed that it is an order-disorder type transition with regard to the orientation of the thiocyanate ions. The temperature dependence of the ordering and the anomalous volume expansion near the transition temperature seem capable of being interpreted by the molecular field approximation if the volume dependence of the interaction energy is taken into account.

The authors wish to express their thanks to Professor Syūzō Seki for his kind suggestions for conducting this study. They are also indebted to Miss Takako Shinoda, who, kindly offered the dilatation data, and to Mr. Minoru Sakiyama of Osaka University for his helpful discussions in the course of this work.

Appendix

The free energy per ion concerning order, including elastic energy, is given by

$$F=\frac{1}{2\kappa}\frac{(\delta v_a)^2}{v}-JS^2+\frac{kT}{2}[(1+S)\ln(1+S)+(1-S)\ln(1-S)] \quad \text{(A—1)}$$

where κ is the compressibility, v is the ionic volume and δv_a is the anomalous part of the volume expansion. For small values of δv_a, we have

$$J=J_0+\frac{\partial J}{\partial v}\delta v_a \equiv J_0+J'\delta v_a \quad \text{(A—2)}$$

The equilibrium volume is determined by the energy minimum condition $\delta F/\delta v=0$, which gives:

$$\frac{\delta v_a}{v}=\kappa J' S^2 \quad \text{(A—3)}$$

The substitution of Eq. (A—3) back into (A—1) gives

$$F=-J_0S^2-\frac{\kappa v}{2}J'^2S^4+\frac{kT}{2}[(1+S)\ln(1+S)+(1-S)\ln(1-S)] \quad \text{(A—4)}$$

From the equilibrium condition $\delta F/\delta S=0$, the temperature dependence of S is now given by

$$\frac{4J_0}{kT}+S\frac{4\kappa vJ'^2}{kT}S^3=\mathrm{Tanh}^{-1}S \cong 2(S+\frac{1}{3}S^3+\cdots\cdots) \quad \text{(A—5)}$$

Using the asymptotic form of Tanh S for small S-values, we have an approximate expression for $S(T)$ near the transition temperature as follows:

$$S^2(T)=3\left(\frac{T_c}{T}-1\right)(1-6\kappa vJ'^2)^{-1} \equiv\alpha\frac{\Delta T}{T}\approx\alpha\frac{\Delta T}{T_c} \quad \text{(A—6)}$$

$$T_c=2J_0k$$

$$\alpha=\frac{3}{1-6\kappa vJ'^2}$$

which means that S^2 depends linearly on the temperature near T_c, the Curie temperature. The unknown parameter, J', is calculated by using the experimental value of the anomalous volume expansion coefficient at T_c as follows:

$$\beta_c=\left[\frac{\mathrm{d}\left(\frac{\delta v_a}{v}\right)}{\mathrm{d}T}\right]_{T=T_c}=\kappa J'\left[\frac{\mathrm{d}S^2}{\mathrm{d}T}\right]_{T=T_c} =\kappa J'\frac{\alpha}{T_c} \quad \text{(A—7)}$$

Therefore,

$$S^2=3\left(\frac{T_c}{T}-1\right)\left\{1-6\frac{v(\beta_cT_c)^2}{\kappa\alpha^2}\right\}^{-1} \quad \text{(A—8)}$$

where α is determined by the self-consistency condition:

$$\alpha=\frac{3}{1-\frac{6v(\beta_cT_c)^2}{\kappa\alpha^2}} \quad \text{(A—9)}$$

Finally, we can write the equations to determine S in the form:

$$S=\mathrm{Tanh}\,x \quad \text{(A—10)}$$

$$x=\frac{T_c}{T}S+\frac{T_c}{T}AS^3 \quad \text{(A—11)}$$

$$A=\frac{2v(\beta_cT_c)}{\kappa\alpha^2}$$

S is obtained by plotting S against x as given by (A—10) and (A—11) and looking for the intercept of the two curves. It should be noticed that S^2 as given by (A—8) is infinite for $A\geqq 1/3$, which implies that the asymptotic expansion of $\mathrm{Tanh}^{-1}S$ up to S^3 is invalid for $A\geqq 1/3$. It can be shown that, in this case, S^2 suddenly becomes zero from a finite value at T_c which corresponds to a first order transition.

Further, the anomalous volume expansion coefficient is calculated by the substitution of $S(T)$ in (A—3) as follows:

$$\beta_a=\frac{\mathrm{d}(\mathrm{d}v_a/v)}{\mathrm{d}T}=\kappa J'\frac{\mathrm{d}(S^2)}{\mathrm{d}T} \quad \text{(A—12)}$$

$$=\frac{1}{\alpha}\frac{\mathrm{d}S^2}{\mathrm{d}(T/T_c)}$$

*The Ion-exchange Equilibrium between Cesium and Phenol-sulfonic-acid-type Cation Exchange Resin**

By Hiroyuki TSUBOTA

(Received April 12, 1963)

Many researchers have investigated the specific adsorption of cesium on the phenol-sulfonic-acid-type cation exchange resin as a technique for analyzing cesium in various materials[1-4]. However, studies of the ion-exchange equilibrium with the resin have not yet been carried out, with the exception of one of the Cs^+-Na^+ exchange in a sodium hydroxide solution[5]. In this paper, the distribution coefficients of cesium between several basic solutions and the resin as measured by the batch method are reported. In addition, the phenomenon of the specific adsorption of cesium on the resin from an ammoniacal solution as compared to sodium hydroxide and potassium hydroxide solutions will be discussed.

Experimental

Chemicals.—Diaion BK (phenol-sulfonic-acid-type cation exchange resin) and Duolite C-3 of 60~80 mesh were used**. They were prepared as ammonium, sodium and potassium forms using basic solution of ammonium, sodium and potassium salts respectively. It was confirmed that about 90%, or more, of the phenolic-active groups were in NH_4^+-, Na^+- or K^+-forms. The exchange capacity of the active sulfonic group was 2.0 meq., and that of the phenolic group was 2.2 meq. for 1 g. of air-dried resin. The exchange capacities were determined by measuring the salt-splitting capacities and the exchange capacity in the basic solution.

Solutions of the following composition were used. Various amounts of cesium, with cesium-137 as the tracer, were added to ammoniacal solutions of various concentrations and pH values. The pH value was adjusted by adding ammonium formate. They were prepared in the range of 0.5~7.5 M of total concentration, a pH value of 10~12, and 0~100 mg. of cesium carrier for 50 ml. of solution. Sodium hydroxide plus sodium chloride and potassium hydroxide solutions were prepared in similar ways. All alkaline solutions were kept in CO_2-free air as far as possible.

Instruments.—The pH value of the ammoniacal solution was determined by a glass electrode pH-meter.

The β-activity was measured by a G. M. counter connected with an automatic sample changer. The γ-activity was measured for the photo-peak of 0.66 MeV. by using a well-type NaI(Tl) scintillation counter connected with a single-channel pulse height analyzer.

Measurements.—For each run, 50 ml. of the solution were shaken for 24 hr. with 0.500 g. of the dried ion-exchange resin in a constant temperature bath at 25°C. After an exchange equilibrium had been attained, 5 ml. of the solution were pipetted out, and the radioactivity or cesium concentration of the solution phase (C) was measured. From the C values and the cesium concentration in the initial solution (C_0), the distribution coefficients of cesium (K_d) under various conditions were obtained from the following equation. (Here, the volume decrease of the solution caused by the swelling of the ion exchanger is disregarded).

$$K_d = \{(C_0 - C)/C\}\{50/0.5\}$$
$$= 100 \cdot (C_0 - C)/C \qquad \text{(ml./g.)}$$

In the case of ammoniacal solutions, 2 ml. of the solution were put into a stainless steel counting dish, and the β-activity was measured after drying it under an infrared lamp. In the case of sodium or potassium solutions, 5 ml. of the solution were placed in a capsule and the γ-activity was measured. All measurements were made twice.

Results

$Cs^+-(NH_4^+ + NH_3)$ Exchange System.—The values of the distribution coefficients of cesium when the pH value of the outer solution was varied and the total concentration of the outer solution was kept constant are shown in Fig. 1. Straight lines, the slopes of which were nearly constant for various concentrations, were obtained, although they deviated slightly at both ends. The slopes are expressed as follows:

$$\left(\frac{\partial \log K_d}{\partial \text{pH}}\right)_{[NH_4^+ + NH_3]} = 1.0 \qquad (1)$$

Figure 2 shows the relationship between the distribution coefficients of cesium and the total

* A part of this work was read at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

** Similar results for distribution coefficients were obtained. The results for Diaion BK will be reported here.

concentration of the outer solution when the pH value of the outer solution was kept constant. They are expressed approximately by the following equation:

$$\left(\frac{\partial \log K_d}{\partial \log [NH_4^+ + NH_3]}\right)_{pH} = -1.6 \qquad (2)$$

where $[NH_4^+ + NH_3]$ denotes the total concentration of the solution.

From Eqs. 1 and 2, the following equation is obtained:

$$\log K_d = pH - 1.6 \log [NH_4^+ + NH_3] + C_1 \qquad (3)$$

where C_1 is the constant for the $Cs^+-(NH_4^+ + NH_3)$ exchange system.

The value when the salt-splitting capacity is 2.0 meq./g.* is as follows:

$$C_1 = -8.8$$

The Cs^+-Na^+ and Cs^+-K^+ Exchange Systems.—The relationship between the distribution coefficients of cesium and the pH value or the concentration of sodium hydroxide when the total sodium concentration in the outer solution was kept constant is shown in Fig. 3. The relation is expressed as follows:

$$\left(\frac{\partial \log K_d}{\partial \log [OH^-]}\right)_{[Na^+]} = 0.25 \qquad (4)$$

or

$$\left(\frac{\partial \log K_d}{\partial pH}\right)_{[Na^+]} = 0.25 \qquad (4')$$

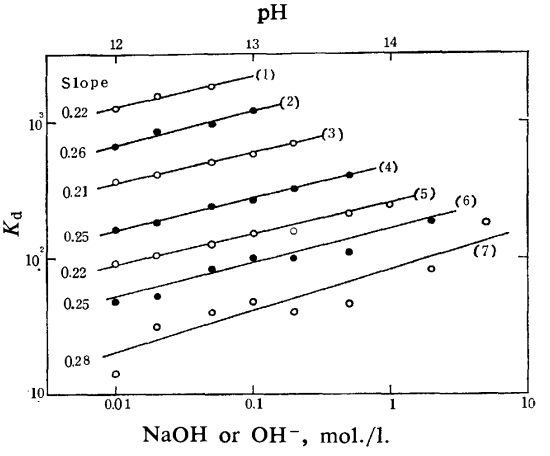

Fig. 3. Distribution coefficients of cesium in Cs^+-Na^+ exchange system.

Total sodium concn., mol./l.
(1) 0.05 (2) 0.1 (3) 0.2 (4) 0.5
(5) 1 (6) 2 (7) 5

Equation 5, which is obtained by rearranging the results shown in Fig. 3, gives the relationship between the distribution coefficients of cesium and the total sodium concentration when the pH value or the concentration of sodium hydroxide in the outer solution is kept constant.

$$\left(\frac{\partial \log K_d}{\partial \log [Na^+]}\right)_{pH} = -0.90 \qquad (5)$$

* Equations 1 and 2 can be formulated even when the quantities of the ion exchnger or the exchange capacities are varied because of the drying state of the resin. However, the value of C_1 in Eq. 3 changes. Therefore, all values of K_d and the constant C_1 are normalized when the salt-splitting capacity, which can be easily determined, is 2.0 meq./g.

From Eqs. 4 and 5, a formula for the Cs^+-Na^+ exchange system may be given with a good approximation as follows:

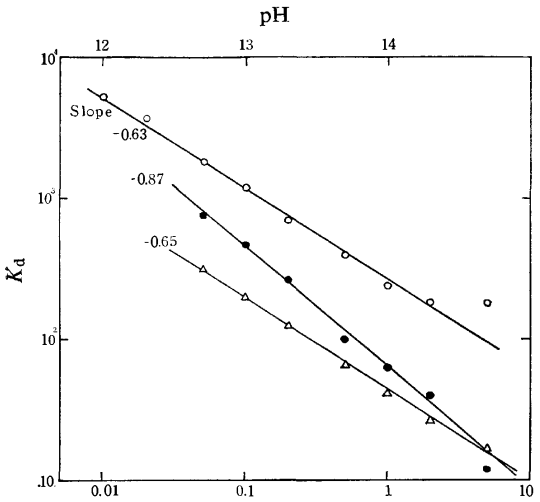
$$\log K_d = 0.25 \log [OH^-] - 0.90 \log [Na^+] + C_2 \quad (6)$$

where C_2 is the constant for the system, and

$$C_2 = 2.4$$

when the salt-splitting capacity is 2.0 meq./g.

Figure 4 shows the relations between the distribution coefficients of cesium and the



NaOH, KOH or NaCl, mol./l.

Fig. 4. Distribution coefficients of cesium in Cs^+-Na^+ and Cs^+-K^+ exchange system.
The outer solution:
○ Sodium hydroxide solution
● Sodium chloride solution
△ Potassium hydroxide solution

concentration of the outer solution when the outer solution contained only sodium hydroxide or potassium hydroxide, and neither sodium chloride nor potassium chloride. The following equation holds when the outer solution was a sodium hydroxide solution:

$$\log K_d = -0.63 \log [NaOH]_T + C_3 \quad (7)$$

where C_3 is a constant, and

$$C_3 = 2.4 = C_2$$

A similar equation is found when the outer solution was a potassium hydroxide solution:

$$\log K_d = -0.65 \log [KOH]_T + C_4 \quad (8)$$

where C_4 is a constant, and

$$C_4 = 1.7$$

When the outer solution is neutral, i.e., a sodium chloride solution, the distribution coefficients of cesium can be expressed by the following equation:

$$\log K_d = -0.87 \log [NaCl]_T + C_5 \quad (9)$$

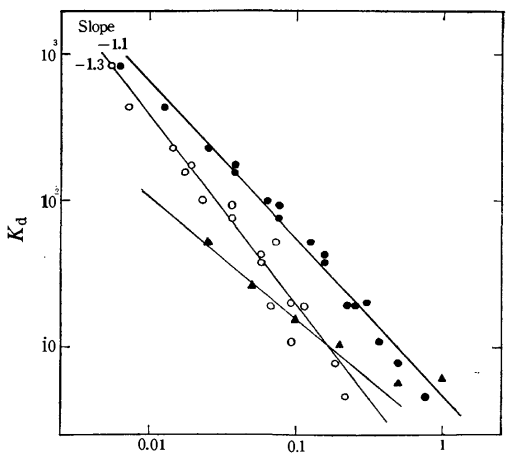
where C_5 is a constant, and

$$C_5 = 1.8$$

The $Cs^+-NH_4^+$ Exchange System.—It was very difficult to estimate the ammonium ion concentration in the outer solution exactly, but it was necessary for the rearrangement of the relation expressed by the Eq. 3 for the $Cs^+-(NH_4^+ + NH_3)$ exchange system to provide for the relation of the distribution coefficients of cesium to the ammonium ion concentration. Two ways were tried for the estimation of the ammonium ion concentration in the outer solution, 1) assuming that the ammonium ion concentration is equivalent to the quantities of ammonium formate added to the system, and 2) assuming that the ammonium ion concentration can be calculated by using the dissociation constant of ammonia water $pK = 4.74$ at 25°C[6]. When the ammonium ion concentration was kept constant, the relation between the distribution coefficients of cesium and the pH value of the outer solution can be expressed by the following equation:

$$\left(\frac{\partial \log K_d}{\partial \mathrm{pH}}\right)_{[NH_4^+]} = 0 \quad (10)$$

The relationship between the distribution coefficients and the ammonium ion concentration is shown in Fig. 5. The relationship



NH_4^+, mol./l.

is independent of the pH value and of the total concentration of outer solution, and can be expressed as follows:

$$\log K_d = -1.1 \log [NH_4^+] + C_6 \qquad (11)$$

where C_6 is a constant, and

$$C_6 = 0.62$$

The Variation of the Distribution Coefficients of Cesium with Variation in the Cesium Quantities. — The distribution coefficients of cesium when the cesium quantities in the exchange system were changed are shown in Fig. 6. No simple formula could be found for these variations.

Discussion

The observed values of the distribution coefficient of cesium are due to both the sulfonic group and the phenolic group of the resin. Therefore, the adsorption of cesium must be discussed by separating K_d into two functions: K_{dp}, which is due to the phenolic group, and K_{ds}, which is due to the sulfonic group.

$$K_d = K_{dp} + K_{ds} \qquad (12)$$

As the sulfonic acid group is strongly acidic, K_{ds} is probably a function only of the cation concentration in the outer solution $[M^+]$:

$$K_{ds} = B_s [M^+]^{m_s} \qquad (13)$$

where B_s and m_s are constants. Since the phenolic acid group is weakly acidic, however, K_{dp} may be a function of both the cation concentration and the pH value, or $[OH^-]$, of the outer solution:

$$K_{dp} = B_p [M^+]^{m_p} [OH^-]^{n_p} \qquad (14)$$

where B_p, m_p and n_p are constants.

Combining Eqs. 12, 13 and 14,

$$K_d = B_s [M^+]^{m_s} + B_p [M^+]^{m_p} [OH^-]^{n_p} \qquad (15)$$

Differentiating Eq. 15 with respect to $[M^+]$, when $m_s = m_p$,

$$\left(\frac{\partial \log K_d}{\partial \log [M^+]}\right)_{[OH^-]} = \text{const.} \qquad (16)$$

except when $B_s = 0$.

However, differentiating it with respect to $[OH^-]$, for every value of constants, B_s, B_p, B_s, m_p and n_p:

$$\left(\frac{\partial \log K_d}{\partial \log [OH^-]}\right)_{[M^+]} \neq \text{const.} \qquad (17)$$

Moreover, it should be considered that some of the metal ions are associated in the resin phase.

Thus, the results of the experiments cannot be generally expressed by the straight lines shown in Figs. 1—5, but they should be shown according to Eq. 15.

Because Eq. 15 cannot be generally solved, it has to be numerically evaluated. The variation of distribution coefficients, however, may be empirically discussed by assuming that the results are expressed by the straight lines in a limited range, even though it must be discussed more generally using Eq. 15.

The $Cs^+ - Na^+$ Exchange System.—Equation 7, obtained when the outer solution is sodium hydroxide, can be derived from Eq. 6. Sodium hydroxide is almost completely dissociated in an aqueous solution, so that:

$$[Na^+] = [OH^-] \simeq [NaOH]_T \qquad (18)$$

Substituting Eq. 18 in Eq. 6,

$$\log K_d = -0.65 \log [NaOH]_T + C_2 \qquad (6')$$

which is the same as Eq. 7. In the same manner, Eq. 8, obtained for the $Cs^+ - K^+$ exchange system, may be reduced as follows:

$$\log K_d = 0.25 \log [OH^-] - 0.90 \log [K^+] + C_4 \qquad (19)$$

Putting the condition of pH = 7, or $\log [OH^-] = -7$, into Eq. 6,

$$\log K_d = -0.90 \log [Na^+] + 0.65 \qquad (20)$$

The constant term of Eq. 20 is evidently different from that of Eq. 9, obtained when the outer solution is a sodium chloride solution. This fact shows that Eq. 6, which was obtained in the high pH range, cannot be applied in the neutral range*. K_d calculated with Eq. 6 must be larger than K_d calculated by Eq. 9, where the phenolic group plays a part in adsorbing the cesium: therefore,

$$\log K_d \ (6) > \log K_d \ (9)$$

Resolving the equation,

$$[OH^-] > 4.0 \times 10^{-3}$$

or

$$pH > 11.6 \qquad (21)^{**}$$

This shows that the specific adsorption of cesium caused by the phenolic group of the resin may be effective in the range of the pH value over 11.6 for $Cs^+ - Na^+$ exchange system. To increase the specific adsorption of cesium, the concentration of sodium hydroxide must be increased. Consequently, the total adsorption of cesium and K_d will decrease.

The $Cs^+ - (NH_4^+ + NH_3)$ Exchange System.— Equation 11, obtained for the $Cs^+ - NH_4^+$ exchange system, seemed to be inconsistent with the formula obtained for the $Cs^+ - Na^+$ and $Cs^+ - K^+$ exchange systems. This inconsistency can be interpreted as follows. The quantity of cesium A adsorbed on resin is a function of the concentration of the dissociated phenolic groups and of the cation concentration of the solution:

$$A = f\{[OH^-], \ [M^+]\} \qquad (22)$$

From the experimental results mentioned above, function f may be expressed by a power function:

$$A = k_1 [OH^-]^{n_1} [M^+]^{m_1}$$

or

$$K_d = k_2 [OH^-]^n [M^+]^m \qquad (23)$$

Equation 23 can be expressed in a logarithmic form:

$$\log K_d = n \log [OH^-] + m \log [M^+] + k_3 \qquad (24)$$

and for a $Cs^+ - NH_4^+$ exchange system, Eq. 24 is reduced to:

$$\log K_d = n \log [OH^-] + m \log [NH_4^+] + k_3' \qquad (24')$$

On the other hand, in an ammoniacal solution the following relation can be obtained:

$$\frac{[NH_4^+]\,[OH^-]}{[NH_3]} = K_b \qquad (25)$$

where K_b is the dissociation constant of ammonia water. Rearranging Eq. 25,

$$[OH^-] = K_b [NH_3] / [NH_4^+] \qquad (26)$$

As NH_3 may be kept constant before and after the exchange reaction,

$$[OH^-] = K' / [NH_4^+] \qquad (27)$$

Substituting Eq. 27 into Eq. 24',

$$\log K_d = -n \log [NH_4^+] + m \log [NH_4^+] + k_3' + n \log K' = (m-n) \log [NH_4^+] + k_4 \qquad (28)$$

Substituting the values of n and m ($n = 0.25$, $m = -0.90$) which were obtained for the $Cs^+ - Na^+$ and $Cs^+ - K^+$ exchange systems for n and m in Eq. 28 or 24, Eq. 29 can be obtained:

$$\log K_d = (-0.90 - 0.25) \log [NH_4^+] + k_4 = -1.15 \log [NH_4^+] + k_4 \qquad (29)$$

Substituting C_6 for the k_4 of Eq. 29, we can obtain Eq. 11 again. Thus, the tangent of Eq. 29 coincides with that of Eq. 11. This shows that the $Cs^+ - NH_4^+$ exchange is not different from the $Cs^+ - Na^+$ or $Cs^+ - K^+$ exchange.

Because in the $Cs^+ - (NH_4^+ + NH_3)$ exchange system the pH value of the outer solution is less than 11.6, which is the lower limit of pH value for a solution to adsorb cesium specifically with the phenolic group, it is necessary to verify whether or not the specific adsorption of cesium occurs. The distribution coefficients of cesium against NH_4^+ in the ammonium chloride solution shown in Fig. 5 can be attributed to the distribution coefficients caused by the sulfonic group. Because the estimated concentrations of NH_4^+ needed to plot Fig. 5 are uncertain, the results in an ammoniacal solution cannot be quantitatively compared with those in an ammonium chloride solution. The specific adsorption of Cs^+ by the phenolic group may occur in the pH range over 10.5~11, or in the concentration range of $[NH_4^+] < 0.1$ mol./l. In the $Cs^+ - (NH_4^+ + NH_3)$ exchange system, to increase total adsorption of cesium the concentration of NH_4^+ must be kept low and the pH value of the solution must be raised; consequently, the specific adsorption of cesium increases. This characteristic, which is different from that of the $Cs^+ - Na^+$ or $Cs^+ + K^+$ exchange system, is very

---

* This is evident from Eq. 15. Substituting $m_s = m_p = m$ in Eq. 15, the following equation can be obtained:

$$\log K_d = m \log [M^+] + \log\left\{1 + \frac{B_p}{B_s}[OH^-]^{n_p}\right\} + \log B_s$$

When

$$\frac{B_p}{B_s}[OH^-]^{n_p} \gg 1 \quad \text{(in high pH range)}$$

$$\log K_d \simeq m \log [M^+] + n_p \log [OH^-] + \log B_p$$

and when

$$\frac{B_p}{B_s}[OH^-]^{n_p} \ll 1 \quad \text{(in low pH range)}$$

$$\log K_d \simeq m \log [M^+] + \log B_s$$

** It was solved by substituting Eq. 9 as follows:

$$\log K_d = -0.90 \log [NaCl]_T + C_5$$

important in the application of ion exchange to the analysis of cesium.

Because Eq. 15 cannot be generally solved, it has to be numerically evaluated. The results of the numerical calculation of distribution coefficients caused by the adsorption of cesium by phenolic group (K_{d_p}) for the Cs^+-Na^+ exchange system, using the results shown in Figs. 3 and 4, are shown in Fig. 7. The K_{d_p} values for the $Cs^+-(NH_4^+ + NH_3)$ excange system are shown in Fig. 8.

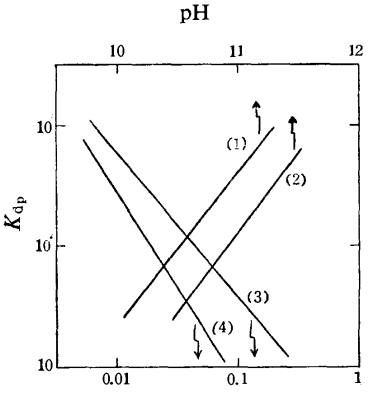

Fig. 8. Distribution coefficients of cesium due to phenolic group of the resin in $Cs^+-(NH_4^+ + NH_3)$ exchange system.

(1) Total concn., 0.5 mol./l.
(2) Total concn., 1 mol./l.
(3) When NH_4^+ is equivalent to the quantities of ammonium formate added.
(4) When NH_4^+ calculated using the dissociation constant of ammonia water.

Summary

1) In the $Cs^+-(NH_4^+ + NH_3)$ exchange system, the distribution coefficients of cesium can be approximately expressed as follows:

$$\log K_d = pH - 1.6 \log [NH_4^+ + NH_3] - 8.8$$

2) In the Cs^+-Na^+ and Cs^+-K^+ exchange systems, the distribution coefficients of cesium can be expressed with a good approximation by:

$$\log K_d = 0.25 \log [OH^-] - 0.90 \log [Na^+] + 2.4$$

and

$$\log K_d = 0.25 \log [OH^-] - 0.90 \log [K^+] + 1.7$$

In the $Cs^+-NH_4^+$ exchange system, the distribution coefficients of cesium can be expressed by:

$$\log K_d = -1.1 \log [NH_4^+] + 0.62$$

3) The specific adsorption of cesium by the active phenolic groups is observed when the pH value of the outer solution is above 12, and high selectivity is obtained above 13 for the Cs^+-Na^+ exchange system. For the $Cs^+-(NH_4^+ + NH_3)$ exchange system, the specific adsorption of cesium is observed above pH 11, and an extremely high selectivity can be obtained when the total concentration of the outer solution is below 1 mol./l.

The author wishes to thank Dr. Hidetake Kakihana and Dr. Terunosuke Nomura of the Tokyo Institute of Technology and Dr. Masami Izawa of the National Institute of Radiological Sciences for their helpful discussions and advice. Thanks are also due to Mr. Kazuo Watari for his assistance in the radioactivity measurements.

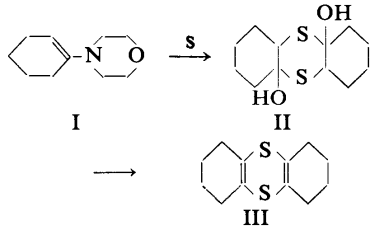
NOTES

Enamines. IV. The Reaction of 1-Morpholino-1-cyclohexene with Sulfur[1]

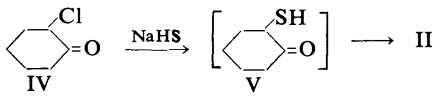
By Yujiro NOMURA and Yoshito TAKEUCHI

(Received April 11, 1963)

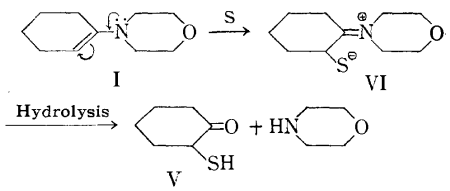
In a preceding paper of this series[2], the reaction of enamines with hydrogen sulfide was reported; in the present paper, the reaction of an enamine with elementary sulfur will be described. The heating of 1-morpholino-1-cyclohexene (I) with sulfur in the absence of a solvent gave an intractable yellow oil. By refluxing a mixture of I and sulfur in benzene, however, colorless crystals have been obtained and identified as 4a, 9a-dihydroxyperhydrothianthrene (II) by the infrared spectrum, by the elementary analysis and by the melting point test on an admixture with an authentic sample[3]. The assignment of the structure was supported by a successful conversion of II into 1, 2, 3, 4, 6, 7, 8, 9-octahydrothianthrene (III)[4] by the acid treatment.



This result may reasonably be explained by assuming the intermediate formation of 2-mercaptocyclohexanone (V), which dimerizes to a 1, 4-dithiane compound (II)[5], since Asinger et al.[3] obtained II by the reaction of 2-chlorocyclohexanone (IV) with sodium hydrogen sulfide.



It is postulated that 1-morpholino-1-cyclohexene was attacked by sulfur at the 2-position and that the resulting immonium compound (VI) was hydrolyzed to α-mercaptocyclohexanone as follows:



Such is actually the case with the Willgerodt reaction, in which Dauben et al.[6] also assumed an α-mercaptoketone as an intermediate.

II was recovered unchanged, even upon continued heating above its melting point. The OH-stretching frequency of II was observed at 3385 cm^{-1} in both Nujol and the KBr disk. Considering these facts and assuming that the 1, 4-dithiane ring is in the chair form[7], the most probable structure of II may be shown as follows (Fig. 1)*.

We expected that the 3385 cm^{-1} frequency would be shifted to the free OH region on dilution. The OH absorption of II in a carbon

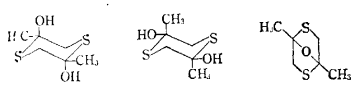
* Haberl et al.[8] isolated two isomeric forms of *trans*-2, 5-dihydroxy-2, 5-dimethyl-1, 4-dithiane (VII), the dimer of mercaptoacetone, one of which (VIIa) lost a molecule of water upon heating to give 2, 5-endoxy-2, 5-dimethyl-1, 4-dithiane (VIII), though the other VIIb was recovered unchanged.



They reported that the OH-strectching frequency of VIIa in Nujol or in the KBr disk was observed at 3300 cm^{-1} due to the intramolecular hydrogen bonding between OH and S, but the frequency of VIIb was observed at 3375 cm^{-1} due to the intermolecular hydrogen bond.

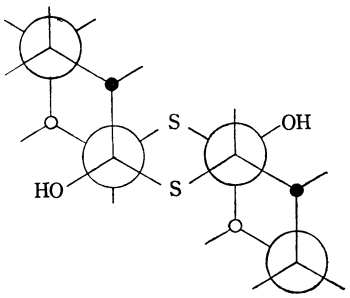

Fig. 1. Newman model of II.

tetrachloride solution, however, gradually disappeared and a strong absorption of $\nu_{C=O}$ appeared at 1710 cm^{-1}, though no absorption due to ν_{S-H} could be observed. II seems to dissociate into monomeric 2-mercaptocyclohexanone in a carbon tetrachloride solution, which has a disagreeable mercaptan-like odor.

Experimental

All melting points were uncorrected. The infrared spectra were determined on a Nihon Bunko Model Koken DS 301 spectrophotometer with a sodium chloride prism.

The Reaction of 1-Morpholino-1-cyclohexene (I) with Sulfur.—To a solution of 33.5 g. (0.2 mol.) of 1-morpholino-1-cyclohexene[9] in 100 ml. of benzene was added 4.8 g. (0.15 g. atom) of powdered stick sulfur. The mixture was heated under reflux for three hours. Refluxing was continued for two more hours after 100 ml. of 6 N hydrochloric acid had been added. The benzene layer was separated, and the aqueous layer was extracted with benzene. The combined benzene solution was washed twice with water, and the solvent was evaporated. The remaining oil was distilled in vacuo under a nitrogen atmosphere. After 1.7 g. of cyclohexanone had been distilled, 4.4 g. of a main fraction (b. p., 115~125°C/17 mmHg) was obtained; this soon solidified upon chilling. After repeated recrystallizations from 2-propanol, colorless crystals melting at 136~136.5°C (lit.[3] m. p. 135~136°C) were obtained. No depression of the melting point was observed on an admixture with authentic 4a, 9a-dihydroxy-perhydrothianthrene. Yield, 4.4 g. (25.1% based on sulfur used). IR ν_{O-H} 3385 cm^{-1} (Nujol, KBr).

Found: C, 54.92; H, 7.74; S, 24.00. Calcd. for $C_{12}H_{20}O_2S_2$: C, 55.34; H, 7.74; S, 24.63%.

A half gram of the material was heated above 160°C for two hours in an oil bath. After cooling, the almost-quantitatively recovered crystals melted at 136°C, and no depression of the melting point was caused by mixing with the initial material.

The Conversion of 4a, 9a-Dihydroxy-perhydrothianthrene (II) to 1, 2, 3, 4, 6, 7, 8, 9-Octahydrothianthrene (III).—To a solution of 0.5 g. of II in 5 ml. of 95% ethanol was added 1 ml. of concentrated hydrochloric acid, and the mixture was refluxed for three hours. After dilution with water, the acid was neutralized by sodium hydrogen carbonate. The resulting crystals were collected and recrystallized twice from 2-propanol. Yield, 0.22 g. (50% theoretical); m. p. 97~98°C (lit.[4] m. p. 97°C). IR $\nu_{C=C}$ 1610 cm^{-1} (Nujol).

Found: S, 28.58. Calcd. for $C_{12}H_{16}S_2$: S, 28.60%.

The Calculation of the Energy Levels of Acetaldehyde by a Semi-empirical Molecular Orbital Method Including the Hyperconjugation Effect

By Kōzō Inuzuka

(Received April 12, 1963)

It is well-known that the introduction of a methyl group into unsaturated bond system results in a spectral shift from the spectrum of the unsubstituted parent molecule. A molecular-orbital treatment for a molecule containing a methyl group has been developed by many workers[1]. In this paper, we will calculate the lowest (n, π^*) and (π, π^*) electronic state energies for acetaldehyde by a semi-empirical molecular orbital method[2,3] including a group orbital for the methyl group. The molecular structure of acetaldehyde is shown in Fig. 1[4].

A line combining two hydrogen atoms, H_a and H_b, is perpendicular to the molecular plane, and a third atom, H_c, is contained in its plane as Fig. 1 shows. From the point of view of the

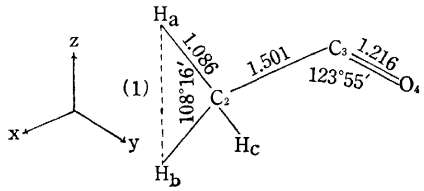

Fig. 1. A model of acetaldehyde molecule; (1) represents a quasi-atom.

molecular orbital method, the methyl group conjugates with the 2pπ orbital of the carbonyl group. For the methyl group, Mulliken[1] used the following group orbitals:

$$\phi_1=(h_a+h_b+h_c)/(3+6S)^{1/2} \qquad [\sigma]$$
$$\phi_2=(2h_c-h_a-h_b)/(6-6S)^{1/2} \qquad [\pi]$$
$$\phi_3=(h_a-h_b)/(2-2S)^{1/2} \qquad [\overline{\pi}]$$

Among these orbitals, the ϕ_3 orbital conjugates with the 2pπ orbitals of the carbonyl group. We assume the ϕ_3 orbital to be a quasi-2pπ orbital; the node is on the midpoint of a line connecting H_a with H_b, and it is separated by 1.086 Å from the neighboring carbon atom. The orbital energy of ϕ_3 is calculated by the following equation:

$$W(\phi_3)=\int \phi_3^* H \phi_3 \, d\tau$$

in which H is a Hartree-Fock type Hamiltonian[5]:

$$H=T+U_{H_3}$$
$$U_{H_3}=-1/r_a-1/r_b-1/r_c+(h_\sigma h_\sigma|+(h_\pi h_\pi|$$
$$-1/2(h_\sigma|h_\sigma-1/2(h_\pi|h_\pi$$

in which $-1/r_i$ is a potential force from a hydrogen nucleus i, and $(h_ih_i|$ and $(h_i|h_i$ are Coulomb and repulsion forces of the h_i electron respectively. For the 1s orbital energy of a hxdrogen atom, we use -13.595 eV., and the three center integrals are calculated by means of Sklar's approximation[6] and Kotani's table[7]. Paoloni proposed a relation between the effective nuclear charge, Z_μ, and one center Coulomb integral, $(\mu\mu|\mu\mu)=3.29_4 Z_\mu^8$. We use the above relation for calculating the effective nuclear charge of the quasi-2pπ orbital.

$$(\phi_3\phi_3|\phi_3\phi_3)=8.430 \text{ eV}.$$

Therefore, we obtain $Z_\mu=2.56$.

The nonbonding orbital for lone pair electrons on the oxygen atom can be approximately represented as follows:

$$\varphi_n=\chi_n$$

χ_n being the 2pπ AO of the oxygen atom, the nodal plane of which is perpendicular to the molecular plane and contains the CO axis. At any rate, we assume that the orbital of the H_3 group participates in hyperconjugation with the residual part of the molecule; the 2pπ group orbital has the effective nuclear charge of 2.56 and the valence state ionization potential of 8.804 eV. The interelectronic Coulomb integrals which appear in this calculation are evaluated according to Roothaan's table[9] for the case of $r>2.80$ Å and according to Pariser-Parr's method[2] for $r\leq2.80$ Å. Particularly, the empirical formula of the interelectronic Coulomb integrals $(H_3H_3|CC)$ is obtained as follows:

$$(H_3H_3|CC)=9.755-2.1680\,r+0.1551\,r^2$$

We use Kon's[10] formula for the calculation of the core integral, β_{CO}, between carbon and oxygen atoms. The core integral, β_{H_3-C}, between H_3 and the neighboring carbon atom, C, is substituted by β_{H_2-C}. β_{H_3-C} can be obtained by assumption of the proportionality relation, $\beta_{H_2-C}/\beta=S_{H_2-C}/S$, where β and S are core and overlap integrals respectively in a benzene molecule. The MO's of acetaldehyde have been obtained by the simple LCAO MO method

disregarding overlap integrals. As a methyl group has electron-donating property, it is known that its electronegativity is larger than that of a carbon atom. Accordingly, we adopt the following parameters[1]: $\alpha_{H_3}=\alpha-0.5\beta$, $\alpha_2=\alpha-0.1\beta$, $\alpha_3=\alpha$, $\alpha_4=\alpha+1.5\beta$, $\beta_{12}=2.92\beta$, $\beta_{23}=0.834\beta$, $\beta_{34}=2^{1/2}\beta$, in which α and β are Coulomb and resonance integrals for a benzene molecule. We obtained the following orbitals:

$e_1=-2.8919$

$\varphi_1=0.5547\chi_1+0.6443\chi_2+0.3693\chi_3+0.3753\chi_4$

$e_2=-2.1786$

$\varphi_2=0.3744\chi_1+0.3435\chi_2-0.3726\chi_3-0.7765\chi_4$

$e_3=0.8305$

$\varphi_3=0.2436\chi_1-0.0276\chi_2-0.8288\chi_3+0.5029\chi_4$

$e_4=3.3990$

$\varphi_4=0.7019\chi_1-0.6827\chi_2+0.1496\chi_3-0.0568\chi_4$

in which χ_i represents the $2p\pi$ AO of the ith atom shown in Fig. 1. The results of the calculation are summarized in Table I, together with observed data.

The Proton Magnetic Resonance Spectra of Some Anomeric Glycopyranosides

By Nobuo MORI, Satoshi OMURA, Osamu YAMAMOTO, Teruo SUZUKI and Yojiro TSUZUKI

(Received May 20, 1963)

The α- and β-anomers of glycopyranoses and their derivatives, such as acetates and glycosides, are generally identified on the basis of Hudson's rule of isorotation[1] as well as by infrared absorption spectroscopy[2]. In the latter method, however, there are some difficulties; for example, α-lactose and its acetate can not be distinguished from the corresponding β-anomers[3].

Recently, Lemieux and his co-workers[4] have employed high resolution proton magnetic resonance (NMR) spectroscopy (40 Mc.) for the identification of the anomers of fully-acetylated glycopyranoses and have found that the doublet signals characteristic of the anomeric hydrogens in the equatorial and axial orientaions generally appear around 1.2 and 1.7 p.p.m. (from the chloroform peak) with a splitting of ca. 3 and 8 c. p. s., respectively. However, this method has not yet been used to identify the anomers of other important derivatives, particularly simple alkyl glycosides.

In the present investigation, the NMR spectra in chloroform of some anomeric acetylated glycopyranosides as well as of acetylated lactoses and maltose were measured at room temperature at 60 Mc. and the signals for the anomeric hydrogens were observed. The spectra are shown in Fig. 1, along with those of some acetylglycopyranoses for the sake of comparison.

As far as the spectra of pentaacetyl-β-glycopyranoses (I and II) and the corresponding methyl tetraacetyl-β-glycopyranosides (V and VI) are concerned, it is to be noticed that a doublet signal at 1.65 p. p. m. in the former spectra, that of the anomeric axial hydrogen coupled with the adjacent axial hydrogen, is absent in the latter spectra. In the latter, however, a new doublet signal with a splitting of 6.3 or 7.8 c. p. s. appears at 2.93 p. p. m. This is to be assigned to the anomeric hydrogen in the glycosides. The position of the signal is not surprising, since it is well-known that the signals of the α-protons in etherified alcohols appear at a field higher by ca. 1$\sim$1.5 p. p. m. than those in the corresponding acetates[5] and this shift occurs regardless of the axial and equatorial orientation on a cyclohexane ring[6].

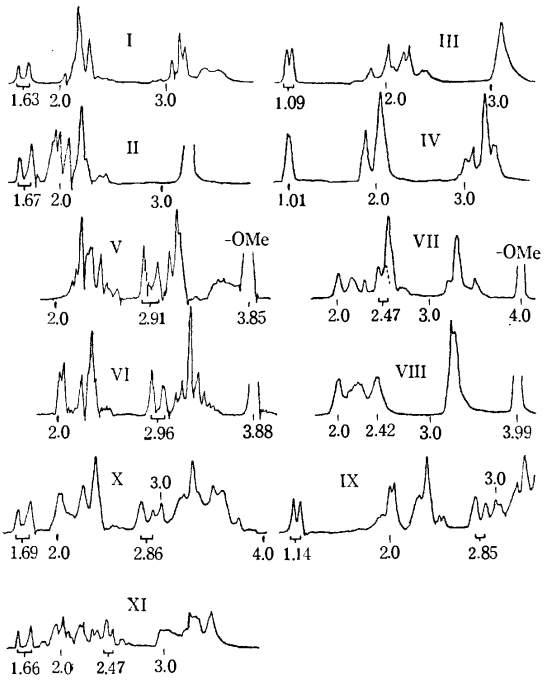

Fig. 1. NMR Spectra of acetylated sugars (in p. p. m. from $CHCl_3$).

Among the spectra of the corresponding α-anomers, a similar difference is observed. The spectrum of pentaacetyl-α-glucose (III) contains a doublet signal at 1.09 p. p. m. which is due to the anomeric equatorial hydrogen coupled with the adjacent axial hydrogen. In the spectrum of methyl tetraacetyl-α-glucoside (VII), the signal is absent, but a similar doublet signal with a splitting of 3 c. p. s. appears at 2.47 p. p. m., seemingly overlapping with a signal at 2.49 p. p. m. Similarly, with pentaacetyl-α-galactose (IV) a signal* which theoretically would be a doublet is present as a singlet at 1.01 p. p. m., while with methyl tetraacetyl-α-galactoside (VIII) a similar one appears at 2.42 p. p. m. Consequently, the signal at 2.45 p. p. m. in the α-glycosides, though not completely separated from other signals, seems to be that of the anomeric hydrogen.

In the spectra of the octaacetates of α- and β-lactose [4-*O*-β-D-galactopyranosyl-α- (IX) and -β-D-glucopyranose (X)], a doublet signal with a splitting of 6.3 or 7.4 c. p. s. appears at 2.86 p. p. m., in addition to the signal of the anomeric hydrogen in the α- or β-glucose unit. The former is of the anomeric axial hydrogen in the β-galactoside unit. In the case of the octaacetate of β-maltose (XI) [4-*O*-α-D-glucopyranosyl-β-D-glucopyranose], two characteristic signals are present, the one at 1.66 p. p. m. with a splitting of 6.7 c. p. s. being due to the anomeric hydrogen in the β-glucose unit and the other at 2.47 p. p. m. with a splitting of 3.5 c. p. s. due to that in the α-glucoside unit.

The above findings may be summarized as follows:

Pentaacetylglycopyranoses
α: 1.05 p. p. m. (J=3 c. p. s.)
β: 1.65 p. p. m. (J=7 c. p. s.)
Methyl tetraacetylglycopyranosides
α: 2.45 p. p. m. (J=3 c. p. s.)
β: 2.93 p. p. m. (J=7 c. p. s.)

Experimental

All compounds were prepared by the methods described in the literature cited; their melting points were as follows:

Pentaacetyl-D-glucopyranose[7], β(I) 131.5~132°C, α(III) 112~112.3°C

Pentaacetyl-D-galactopyranose[8], β(II) 143.5~143.7°C, α(IV) 96.5°C

Methyl tetraacetyl-D-glucopyranoside[7], β(V) 104~105°C, α(VII) 102°C

Methyl tetraacetyl-D-galactopyranoside[9], β(VI) 93~94.5°C, α(VIII) 86~87°C

Octaacetyllactose[10], β(X) 91~91.5°C, α(IX) 151.5°C

Octaacetylmaltose[11], β(XI) 162°C

All the spectra were measured in a 10~20% solution of the compound in chloroform using a Varian Model DP 60 NMR spectrometer equipped with a 60 Mc. r. f. unit. Tetramethylsilane was used in each case as an internal standard. Chemical shifts were obtained by the side-band method and are expressed in p. p. m. from chloroform to make them comparable with the data reported by Lemieux et al.[4]

SHORT COMMUNICATIONS

The Formation of Lysolecithin by Reductive Cleavage of Egg Yolk Lecithin with Lithium Aluminum Hydride

By Chieko URAKAMI and Kimiko YAMAGUCHI

(Received February 16, 1963)

The preparation of lysolecithins by controlled chemical reactions is of interest since they are utilized as the starting material for resynthesis of "mixed acid" lecithins (two different fatty acids being esterified). Recently, Marinetti[1] has reported that the treatment of lecithin with sodium methoxide at 0°C gives a mixture of α- and β-lysolecithin in a yield of 35%. This process is, however, accompanied by the formation of glycerylphosphorylcholine. Another disadvantage is that in such a polar solvent isomerization of the β-lysolecithin to the α-form and racemization of the β-carbon of the glyceryl moiety occur, though perhaps to only a small extent under the conditions employed. The optical purity of lysolecithin in the resynthesis of lecithins is of prime importance; our method of reductive cleavage of one acyl group of lecithin with lithium aluminum hydride in anhydrous ether is considered to meet this requirement since it has already been demonstrated that the product, glycerylphosphorylcholine formed, on removal of the two acyl groups from L, α-lecithin by the reducing agent retains the configuration of the latter[2]. A further advantage of this reaction is that lysolecithin may be the sole product, provided appropriate reaction conditions are found.

Purified egg yolk lecithin prepared by Hanahan's method[3] was treated with a dilute solution of lithium aluminum hydride in anhydrous ether according to the procedure described previously[2]. The reaction mixture was separated into the ether, aqueous, and inter-phase and the aqueous phase extracted with chloroform. The ether and chloroform solutions were analyzed for inorganic and organic phosphorus and examined by paper-chromatography[4].

Some typical examples of the results obtained are shown in Table I; substantial amounts of organic phosphorus are found in both organic solutions and insignificant amounts in the aqueous phase. Table II shows the R_f values of the products formed. The compound with R_f values higher than 0.2 is considered to be the unchanged lecithin since it was observed in separate experiments that an R_f value of 0.32~0.35 for pure lecithin became smaller, 0.25, when mixed with a large amount of the reduction products (supposedly containing considerable amounts of lysolecithin). The product with an R_f

value 0.10~0.14 is therefore considered to be lysolecithin. The detection of lysolecithin in the ether phase, however, is peculiar as it is generally regarded to be insoluble in ether. This may be explained by the fact that the unchanged lecithin makes lysolecithin soluble in ether, as has been observed by Lea[5]. No detectable amount of glycerylphosphorylcholine was found in the aqueous phase.

Accordingly, these results indicate that the method is promising for the preparation of optically pure lysolecithin, provided optimum reaction conditions are found. Further studies on a maximum extent of the cleavage and identification of the products are in progress.

The Synthesis of α-L-Aspartyl-L-serylglycine[1]

By Sidney W. Fox, Tadao Hayakawa and Kaoru Harada

(Received May 22, 1963)

The tripeptide residue, α-L-aspartyl-L-serylglycine, has been found as part of the active site of many esteratic enzymes[2]. The synthesis of this tripeptide is accordingly of interest for studies of catalytic activity *per se*, as a standard intermediate for syntheses of related substances, and as a copolymerized monomer in three-dimensional association with histidine residues in the polymers[3].

The ethyl ester of the tripeptide has been synthesized in this study. Other workers[4] have reported the synthesis of the ethyl ester of glycyl-α-L-aspartyl-L-serylglycine and of the L-aspartyl-*O*-acetyl-L-serylglycylglycine[5]. Attempts in this laboratory to saponify the tripeptide ester led to impure products. The *O*-acetylserine residue may also be subject to racemization when the acetate is removed by the usual treatment. The substituted aspartyl residue is also known to undergo alkaline decomposition easily[6]. The absence of the desired tripeptide from the literature, as well as informal reports of unsuccessful attempts at synthesis, can be explained by the reasons given.

We have devised a route which depends solely upon benzyl or carbobenzyloxy substituents which are entirely removable by hydrogenolysis. This route accordingly avoids any alkaline dederivatization. The sequence is:

$$\text{F-Ser(Bz)-OH (I)} + \text{H-Gly-OBz (II)} \xrightarrow[(90\%)]{\text{DCCD}}$$

$$\text{F-Ser(Bz)-Gly-OBz (III)} \xrightarrow[(71\%)]{} \text{H-Ser(Bz)-Gly-OBz (IV)}$$

$$\text{Z-Asp(OBz}(\beta)\text{)-OH (V)} + \text{IV} \xrightarrow[(47\%)]{\text{DCCD}}$$

$$\text{Z-Asp(OBz)-Ser(Bz)-Gly-OBz (VI)} \xrightarrow[\text{Pd-C}\ (55\%)]{H_2}$$

$$\text{H-Asp-Ser-Gly-OH (VII)}$$

F=Formyl; Z=Carbobenzyloxy; Bz=Benzyl

Except for II and V, none of these compounds were found in the literature. The aspartic acid and serine residues were L throughout.

The *N*-formyl-*O*-benzyl-L-serine was prepared by formylation of *O*-benzyl-L-serine[7], m. p. 133~134°C, $[\alpha]_D^{25} = +54.8°$ (*c* 2.75, ethanol). (Found: N, 6.23. Calcd. for $C_{11}H_{13}O_4N$: N, 6.28%). This substance was reacted with benzyl glycinate and *N*, *N'*-dicyclohexylcarbodiimide (DCCD) in dioxane to yield the formyldipeptide ester (III), m. p. 91~92°C, $[\alpha]_D^{25} = +2.2°$ (*c* 2.43, acetic acid) (Found: C, 65.02; H, 5.92; N, 7.53. Calcd. for $C_{20}H_{22}O_5N_2$: C, 64.85; H, 5.99; N, 7.56%). This compound

was deformylated by standing at room temperature in dioxane: benzyl alcohol: hydrochloric acid (5.5 ml.: 5.5 ml.: 1.0 ml. 12 N hydrochloric acid) in an amount equivalent in hydrochloric acid to the formyl ester, for 48 hr. to yield the hydrochloride of IV, which was hygroscopic and not analyzed as such. The hydrochloride had, however, $[\alpha]_D^{25}$ of approximately +8.3° (*c* 6.3, water). The hydrochloride was treated with an equivalent amount of triethylamine in dioxane in an ice bath and filtered from triethylammonium chloride. To the cold filtrate was added β-benzyl *N*-carbobenzyloxy-L-aspartate (V) and DCCD to give the substituted tripeptide (VI), m.p. 129~131°C, $[\alpha]_D^{25} = -4.7°$ (*c* 1.43, dioxane). (Found: C, 67.41; H, 5.99; N, 6.25. Calcd. for $C_{38}H_{39}O_9N_3$: C, 66.95; H, 5.77; N, 6.16%). All four substituents were simultaneously removed by hydrogenolysis with palladium-charcoal in methanol containing an equimolar amount of hydrochloric acid. The hydrochloride of the desired tripeptide (VII) was obtained. The hydrochloride was dissolved in absolute ethanol, the ethanolic solution was filtered from a small amount of insoluble impurity, and the filtrate was treated with an equivalent of pyridine. The free tripeptide (VII) separated immediately. It had d.p. 174~176°C, $[\alpha]_D^{25} = -7.3°$ (*c* 1.54, water). (Found: C, 38.93; H, 5.64; N, 15.20. Calcd. for $C_9H_{15}O_7N_3$: C, 38.99; H, 5.45; N, 15.16%). [Found; on automatic amino acid analyzer (following hydrolysis with 6 N hydrochloric acid at 110°C for 12 hr.): aspartic acid, 0.97; serine, 0.98; glycine, 1.00]. The final tripeptide was found to yield a single spot with ninhydrin when chromatographed on paper in a phenol $-H_2O$ (4:1) solvent, $R_f = 0.17$, with R_f of glycine standard = 0.38.

The tripeptide has little activity for the hydrolysis of *p*-nitrophenyl acetate, and this is additive with that of the free histidine when the two are tested together in solution. Now that the tripeptide is available, it can be included in various kinds of copolymerization with histidine for further tests.

The Effect of Water on the Equilibrium Pressure of Ammonium Carbamate

By Eugeniusz BŁASIAK and Andrzej BARAŃSKI

(Received May 30, 1963)

In what follows we are concerned with the effect of the initial amount of water on the equilibrium pressure of ammonium carbamate. We discuss this effect in the temperature range only, where the formation of urea is rather large.

There is some discrepancy between the effects observed by various authors. Kawasumi[1] claims that the pressure of ammonium carbamate does not depend of the amount of water included in the initial sample. On the other hand, Krase and Gaddy[2] and independently Błasiak[3] point out, that the pressure increases with the amount of water. We intend to show that this discrepancy does not exist so as in the reality the "water effect" depends strongly on the loading density.

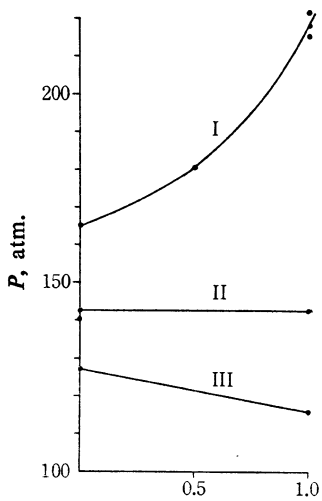

Fig. 1

1) S. Kawasumi, This Bulletin, **26**, 218 (1953).
2) N. W. Krase, V. L. Gaddy, *J. Ind. Eng. Chem.*, **14**, 611 (1922).
3) E. Błasiak, "Technologia związków azotowych (Technology of Nitrogen Compounds)", Vol. II, Collective Publication, Warsaw, P. W. T. (1956), p. 610.

In the figure we show our results obtained for the system $NH_4CO_2NH_2+wH_2O$ at various loading densities at 181°C. The curves I and III refer to the case $D'=0.92$ g./cm^3 and 0.30 g./cm^3 respectively, the curve II to the case $D=0.60$ g./cm^3.

The symbol D means here the initial loading density of ammonium carbamate and D' means the total loading density including the initial content of water. For a given system D, D' and the molar ratio of water to carbamate w, the equation $D'=D(1+0.2308\,w)$ is satisfied.

We see that curve II agrees with the results given by Kawasumi, $t=160$°C, $D=0.60$ g./cm^3, and that curve I agrees with the results obtained by Błasiak, $t=180$°C, $D'\approx 0.9$ g./cm^3. Krase and Gaddy gave no reference to the loading density.

We note that a similar effect was observed for the urea-water system[4].

The detailed discussion of our results will be published in "Chemia Stosowana".

A New Phenomenon of Storage Light Energy by Solution of Photochromatic 1,1'-Bi(2,4,5-triphenylimidazyl) at Low Temperatures

By Taro HAYASHI and Koko MAEDA

(Received May 30, 1963)

In a study of the mechanism of the chemiluminescence of 2,4,5-triphenylimidazole (lophine), 1,1'-bi(2,4,5-triphenylimidazyl) (I) (m. p. 199~201°C), was obtained as fine, pale yellow prisms. It exhibits both photochromism and thermochromism in a solution and in a solid state[1]. These phenomena were due to the reversible formation of a reddish purple free radical, 2,4,5-triphenylimidazyl-(II), by the dissociation of an N–N bond of compound I with irradiation or heating[2]. This communication deals with a new phenomenon which was found in solutions of this compound and its photochromatic substituted derivatives at low temperatures.

A pale yellow 10^{-3} M benzene solution of 1,1'-bi(2,4,5-triphenylimidazyl) (I) which had been prepared in the dark and sealed in a glass tube after removal of oxygen, was frozen at about −20°C in the dark to a nearly white solid, which soon became a pale yellow solution when kept at room temperature in the dark. The frozen solution did not acquire a reddish-purple color on being irradiated for several minutes with sunlight at −20°C. When this irradiated white solid was, immediately after irradiation, immersed in water at about 15°C in the dark, a reddish-purple color appeared as soon as the solid began to liquefy. In about 15 min. the irradiated frozen solid liquefied to be a deep reddish-purple solution, the color of which was nearly as deep as that acquired by an original pale yellow solution with irradiation at room temperature; it then gradually faded to the original pale yellow when kept in the dark at room temperature. A similar phenomenon was observed when the frozen solution was irradiated at −70°C. The reddish-purple color was attributed to the free radicals (II) produced by the splitting of the N–N bond of compound I, because the solution gave a strong electron spin resonance signal (g=2.003) and the free radical which gave the ESR signal was identified as 2,4,5-triphenylimidazyl (II) by a study of the absorption spectrum. It has, therefore, been concluded that light energy is stored in the frozen solution, to be used later for the splitting of the N–N bond. This phenomenon is a new effect of storage light energy by a frozen solution of the photochromatic compound. It was observed irrespective of the concentration of the solution and of the kind of solvent; it was found, for example, in a 10^{-2} or 10^{-4} M solution in benzene, cyclohexane or carbon tetrachloride.

A pale yellow 10^{-3} M toluene solution of compound I, which, unlike a benzene solution, did not freeze at −20°C, immediately acquired

1) T. Hayashi and K. Maeda, This Bulletin, **33**, 566 (1960); T. Hayashi, K. Maeda, S. Shida and K. Nakada, *J. Chem. Phys.*, **32**, 1568 (1960).

2) T. Hayashi and K. Maeda, This Bulletin, **35**, 2057 (1962).

a deep reddish-purple color when irradiated at about −20°C. From this fact the phenomenon of the storage of light energy seems to be characteristic of a frozen solution. However, the toluene solution did not acquire a reddish-purple color with irradiation at about −70°C. But it did begin to acquire a faint reddish-purple color when kept in a dark room at a temperature near −30°C, the color becoming deeper with a further rise in the temperature. Therefore, the storage of light energy can occur in both a frozen solution and a fluid solution. This phenomenon is primarily to be attributed to the photochromatic molecule in a solution cooled at a low temperature. A similar phenomenon was observed in a solution in *n*-heptane. The freezing of the solution seems to facilitate the storage at a higher temperature to some extent, because a frozen solution in benzene or cyclohexane did not acquire a reddish-purple color upon irradiation at about −20°C but stored light energy to split the N–N bond when the frozen solution liquefied in the dark.

A frozen toluene solution of compound I, which had been cooled at −195°C with liquid nitrogen in the dark, immediately acquired a faint reddish-purple color upon being irradiated at about −195°C. When the temperature rose to about −70°C in the dark or under irradiation, this solid lost its color and became a nearly colorless solution which began to acquire a reddish-purple color near about −30°C in the dark. A similar phenomenon was also observed near −195°C in a frozen solution in benzene, *n*-heptane, cyclohexane or EPA which trapped free radicals formed upon irradiation.

The duration of the storage of light energy by a frozen solution of compound I in benzene, irradiated at −20°C, was measured at −70°C and 0°C. It was found that light energy absorbed could be stored for 100 hr. or more at −70°C, whereas it was completely dissipated in about 6 hr. at 0°C. A fluid toluene solution was also found to be able to store light energy at −70°C for more than 100 hr.

A phenomenon of the storage of light energy, similar to that mentioned above, was also observed in solutions of substituted derivatives of compound I, such as 2-*p*-methylphenyl, 2-*p*-methoxylphenyl, 2-*p*-chlorophenyl, 2,4,5-tri-*p*-methylphenyl and 2,4,5-tri-*p*-chlorophenyl derivatives which were prepared by the method similar to that of compound I.

From the foregoing facts, the following is considered to be the mechanism of the storage of light energy at a low temperature. On irradiation in solution at a low temperature, 1,1'-bi(2,4,5-triphenylimidazyl) must be excited to an unusual metastable state, which is favorably affected by a low, ambient temperature or, especially, by the freezing of the solution. This state may be related to some peculiar state of the N–N bond or to a particular spatial disposition of the two imidazole rings which is related to the temperature. The light energy thus stored in the excited molecule, however, is a little insufficient for the splitting of the N–N bond; therefore, for the effective splitting of the bond, some thermal energy may have to be provided by an elevation of the temperature. The mechanism of the phenomenon observed at −195°C, which, considering from the preliminary investigation of the absorption spectrum, seems to be related to the spatial disposition of the imidazole rings and to that of the phenyl nuclei in the frozen solution, is unknown to us at the present time.

The Enhanced Effect of Anthracene on the Polarographic Maximum of Methyl-p-benzoquinone

By Kiyoko TAKAMURA

(Received June 1, 1963)

The author has been interested in the polarographic behavior of certain quinones in the presence of some polycyclic aromatic hydrocarbons. It is generally known that some polycyclic aromatic hydrocarbons have a suppressing effect on the polarographic maxima of some electroreducible substances[1]. It has been found in the present investigation that, on the other hand, these hydrocarbons are effective in inducing the maxima on the

1) C. E. Searle, *Nature*, **184**, 1716 (1959).

polarograms of some quinones. The results obtained with the methyl-*p*-benzoquinone (MQ)-anthracene (A) system are presented here.

As is shown in Fig. 1, a single wave having a typical maximum was obtained with 1.6×10^{-3} M of MQ in 2-methoxyethanol containing 0.25 M of lithium chloride at 25°C, but this maximum was suppressed by the addition of 0.004% methyl red. Contrary to this, the maximum was enhanced by the addition of A to the original solution. When A was added to the solution containing methyl red as a maximum suppressor, a pronounced maximum was observed to reappear.

The heights of the maxima were measured at varied concentrations of A with or without methyl red, keeping the concentration of MQ constant. In Fig. 2, the results obtained at 25°C are plotted against the concentration of A. Figure 2 shows that the maximum height increases with the increasing A concentration, but it seems gradually to reach to a limiting value. The maximum height obtained at given concentrations of MQ and A was observed to be lowered at higher temperatures and almost to disappear at 45°C.

Although the complete interpretation of the maximum is a very difficult problem, it may

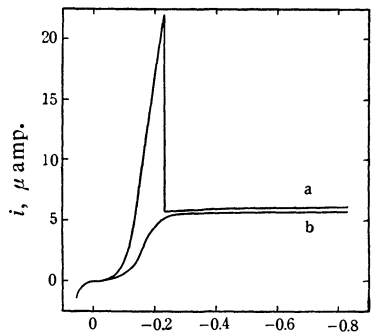

Fig. 1. Polarograms of 1.6×10^{-3} M of MQ obtained in 2-methoxyethanol solutions at 25°C in the absence (curve a) and in the presence of 0.004% methyl red (curve b).

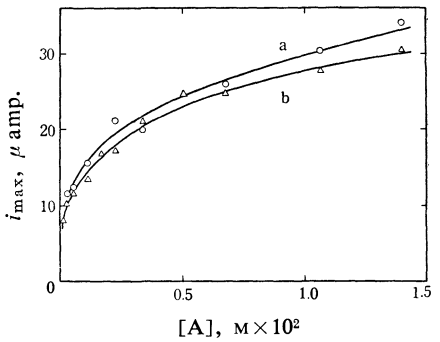

Fig. 2. Relation between maximum current (i_{max}) of MQ and concentration of A in 2-methoxyethanol solutions at 25°C in the absence (curve a) and in the presence of 0.004% methyl red (curve b).
Concentration of MQ is 1.3×10^{-3} M.

be suggested on the basis of the obtained results that the maximum may be attributed to the adsorption of MQ and A on the surface of the dropping mercury electrode. It can be considered that the maximum suppressing action of A is due to the preferential adsorption on the electrode surface. The adsorbed A molecules may prevent the adsorption of electroreducible substances. On the contrary, they should attract MQ and allow it to approach the electrode surface. It is possible that A reacts with MQ to form a charge-transfer complex[2]. Actually, some considerable changes were observed in the infrared spectrum of the mixture of A and MQ (KBr disk). On the assumptions that the complex formed between A and MQ is adsorbed on the electrode surface and that Langmuir's equation is applicable to this system, a consideration of the probable mechanism of the maximum is now in progress. The details will be published later.

The Infrared Spectra of Tributyl Phosphate Containing Extracted Salts

By Nobufusa SAITO and Akira YAMASAKI

(Received June 25, 1963)

Tri-*n*-butyl phosphate (TBP) is used as an useful extractant for a number of inorganic salts. In the case of extraction using TBP, some chemical evidence has been presented to indicate that the phosphoryl group of TBP plays an important role in the coordination with the extracted salts[1,2]. It has also been recognized that the extraction of inorganic salts brings about the shift of the phosphoryl stretching vibration band towards a lower frequency[3,4].

This study is concerned with the infrared spectra of TBP phases containing extracted chlorides, nitrates and some inorganic complexes. The infrared spectra of the TBP phases (10% benzene solution) were recorded with a Hitachi EPI-2 double-beam infrared spectrometer equipped with sodium chloride optics.

The maxima of the phosphoryl band which appear at 1285 and 1265 cm^{-1} in pure TBP were found to shift towards lower wave numbers upon extraction. It was observed that there were three groups of compounds producing phosphoryl band shifts of different magnitudes. The maximum of the shifted phosphoryl bands appeared at three different ranges of wave numbers: 1155~1175 cm^{-1} for group (I), 1195~1205 cm^{-1} for group (II) and 1260~1265 cm^{-1} for group (III). Some of the results obtained are summarized in Table I.

It has been reported that the compounds of group (I) form disolvates in TBP phase, whereas those of group (II) form trisolvates[1,2,5-8]. It seems likely to us that the magnitude of the phosphoryl band shift has some relationship with the number of TBP molecules coordinated with the extracted salts.

The compounds which are classified as group (III) in Table I exhibited only slight phosphoryl band shifts. These compounds are presumed to be extracted in the form of such complex acids as H_2TeCl_6[9].

The present results seem to indicate that the phosphoryl band shift depends on the degree of solvation of the extracted salts in the TBP phase as well as on the nature and strength of the bond between the phosphoryl group and the salts. Further investigation concerning this phenomenon is in progress.

Pure Quadrupole Resonance of Halogens in Potassium Hexahalorhenates(IV)

By Ryuichi IKEDA, Daiyu NAKAMURA and Masaji KUBO

(Received July 1, 1963)

Studies on the pure quadrupole resonance of chlorine in paramagnetic potassium hexachloroiridate(IV) and hexachloroosmate(IV)[1] have shown that metal-ligand bonds in these complexes involve π bond character, because the $d\varepsilon$ orbitals of iridium and osmium ions have one and two holes, respectively. This paper presents some preliminary results obtained for potassium hexachlororhenate(IV), hexabromorhenate(IV) and hexaiodorhenate(IV), rhenium ions in which have three electrons in their degenerate $d\varepsilon$ orbitals leaving three vacancies.

Resonance lines were observed by means of super-regenerative spectrometers described elsewhere[2]. At room temperature, potassium hexachlororhenate(IV) and hexabromorhenate(IV) show a single resonance line for each isotope of halogens. This is in conformity with the cubic structure of these crystals as determined by X-ray analysis[3,4]. On the other hand, the ν_1 as well as ν_2 signal of iodine in potassium hexaiodorhenate(IV) consists of three lines of equal intensity. This indicates the presence of at least three kinds of crystallographically nonequivalent iodine atoms in crystals. Orthorhombic symmetry has already been verified for the crystal structure[5], although detailed structural analysis has not been performed as yet. The observed resonance frequencies are shown in Table I.

Frequency measurements carried out between room and dry ice temperatures have revealed the existence of three transition points at about -4, -16 and -27°C for potassium hexabromorhenate(IV), whereas two transition points are reported to exist at -28 and -48°C from heat capacity[6].

TABLE I. PURE QUADRUPOLE RESONANCE FREQUENCIES OF ^{35}Cl, ^{79}Br AND ^{127}I IN POTASSIUM HEXAHALORHENATES(IV)

Compound		Temp., °C	Frequency, Mc./sec.
K_2ReCl_6		23.0	13.887±0.001
K_2ReBr_6		18.0	112.70±0.03
K_2ReI_6	ν_1	21.0	121.91±0.03 122.99±0.03 123.13±0.03
	ν_2	20.6	243.68±0.07 245.16±0.07 245.34±0.07

It is quite remarkable that the temperature coefficient of resonance frequencies of potassium hexachlororhenate(IV) and hexabromorhenate(IV) is positive (+0.13 and +2.8 kc. sec^{-1} deg^{-1} for K_2ReCl_6 and K_2ReBr_6, respectively, near room temperature), whereas in the majority of cases, the temperature coefficient of pure quadrupole resonance frequencies is negative. Only a few exceptions have ever been reported to this rule (WCl_6[7], $TiBr_4$[8] and $ThCl_4$[9]). No metal complexes have been known to show a negative temperature coefficient of the resonance frequencies. However, the rather abnormal value is not surprising, because the temperature coefficient (-1.0, -0.54, -0.22 and $+0.13$ kc. sec^{-1} deg^{-1} for K_2PtCl_6[2], K_2IrCl_6, K_2OsCl_6[1] and K_2ReCl_6, respectively) increases progressively with increasing electron defficiency in the $d\varepsilon$ orbitals of the central metal ions. It appears that some close parallelism exists between the temperature coefficient of the quadrupole resonance frequencies and the extent of π bond character of metal-ligand bonds. The detailed analysis of experimental results is now in progress and will be published shortly.

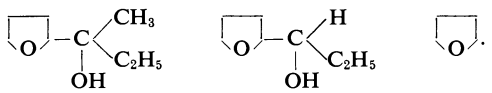
Studies of Photochemical Reaction. VI. The Synthesis of Methylethyl-α-tetrahydrofurylcarbinol and Ethyl-α-tetrahydrofurylcarbinol

By Kensuke SHIMA and Shigeru TSUTSUMI

(Received February 27, 1963)

In preceding papers[1,2] we have reported the synthesis of *t*-alcohols by means of the photochemical reaction of acetone in tetralin, dioxane and tetrahydrofuran. By these photoreactions, dimethyl-α-tetralylcarbinol, dimethyldioxanylcarbinol and dimethyl-α-tetrahydrofurylcarbinol were easily synthesized. In this paper, we wish to report the synthesis of methylethyl-α-tetrahydrofurylcarbinol (I) and ethyl-α-tetrahydrofurylcarbinol (II) by means of the photochemical reaction of ethyl methyl ketone and propionaldehyde in tetrahydrofuran.



(I) (II) (III)

In the photochemical reaction of ethyl methyl ketone in tetrahdrofuran, *s*-butyl alcohol, methylethyl-α-tetrahydrofurylcarbinol (I) and di-α-tetrahydrofuryl were obtained, as in the photoreaction of acetone in tetrahydrofuran. The new substance, methylethyl-α-tetrahydrofurylcarbinol (I), which can be prepared by other methods only with difficulty, was easily produced.

The photochemical reactions of aldehydes in a liquid phase have been widely studied. Leuschner and Pfordte[3] stated that α-diketones were formed when aldehydes were irradiated. Mayo et al.[4] reported that ethyl cyclohexyl ketone and ethyl-3-cyclohexenylcarbinol were obtained by the reaction of photoactivated propionaldehyde in cyclohexene. It may be predicted that the reactions of photoactivated aldehydes in hydrogen-donor solvents are more complex than those of photo-activated ketones because of the presence of active hydrogen in the aldehyde group. When propionaldehyde was irradiated in tetrahydrofuran, *n*-propyl alcohol and ethyl-α-tetrahydrofurylcarbinol were obtained, and di-α-tetrahydrofuryl was not produced. It was also confirmed that dioxanyldioxane was not produced in the photochemical reaction of propionaldehyde in dioxane. It is assumed that the α-tetrahydrofuryl radical (III), formed by the dehydrogenation of tetrahydrofuran by the photoactivated propionaldehyde, would abstract the hydrogen atom from propionaldehyde without dimerization. Ethyl-α-tetrahydrofurylcarbinol was identified by comparing it with an authentic sample which had been prepared by the following procedure:

4) P. de Mayo, J. B. Stothers and W. Templeton, *Proc. Chem. Soc.* (*London*), **1960**, 72; *Can. J. Chem.*, **39**, 488 (1961).

The reaction conditions and yields of the products are summarized in Table I.

Experimental

Materials.—Ethyl methyl ketone and propionaldehyde were purified by fractional distillation: ethyl methyl ketone, b. p., 79~80°C, n_D^{20} 1.3772; propionaldehyde, b. p., 49~50°C, n_D^{20}, 1.3733. Tetrahydrofuran was also purified by distillation over sodium: b. p., 66~67°C, n_D^{20}, 1.4052.

The Photochemical Reaction of Ethyl Methyl Ketone in Tetrahydrofuran.—A mixture of ethyl methyl ketone(48.7g., 0.676mol.)and tetrahydrofuran (194.8 g., 2.706 mol.) was placed in a 300 cc. reaction vessel and irradiated at 11°C in a nitrogen atmosphere for 10 hr. After this irradiation, the reaction product was fractionated to give the following fractions:

	B. p., °C	Weight, g.	n_D^{20}
(1)	64~68	144.5	1.4041
(2)	68~70	19.6	1.4029
(3)	70~81	11.2	1.3862
(4)	~35/13 mmHg	15.8	1.3943
(5)	35~59/13 mmHg	1.8	1.4223
(6)	60~84/13 mmHg	23.6	1.4512
(7)	85~87/13 mmHg	3.4	1.4530
(8)	87~97/13 mmHg	1.9	1.4504
(9)	Residue	18.9	

Fraction 4 was suspected to be *s*-butyl alcohol on the basis of gas chromatography, and it was identified as such by comparing its infrared spectrum with that of an authentic sample. The amounts of ethyl methyl ketone, tetrahydrofuran and *s*-butyl alcohol were estimated by gas chromatography: column, D. N. P. and Si DC 550; carrier gas, H_2, 0.32 kg./cm^2; bridge current, 160 mamp.; column temp., 47°C; retention time: ethyl methyl ketone, 8.5 min. (Si DC 550), 9.5 min. (D.N.P.); tetrahydrofuran, 10 min. (Si DC 550), *s*-butanol: 14 min. (D.N.P.).

It was established that fractions 6 and 7 were mainly composed of two components; they were separated by preparative gas chromatography. Fraction 1, n_D^{20}, 1.4518.

Found: C, 66.54; H, 11.12. Calcd. for $C_8H_{14}O_2$: C, 66.63; H, 11.18%.

The infrared spectrum is shown in Fig. 1. This fraction was confirmed to be methylethyl-α-tetrahydrofurylcarbinol by elemental analysis, study of its infrared spectrum, and comparison of it with the findings of a previous report[2].

The other fraction was di-α-tetrahydrofuryl.

The amounts of methylethyl-α-tetrahydrofurylcarbinol and di-α-tetrahydrofuryl were estimated by gas chromatography: column, Si DC 550, 3 m.; carrier gas, H_2, 0.3 kg./cm^2; bridge current, 160 mamp; column temp., 155°C; retention time: methylethyl-α-tetrahydrofurylcarbinol, 8.2 min.; di-α-tetrahydrofuryl, 11.4 min.

The Photochemical Reaction of Propionaldehyde In Tetrahydrofuran.—A mixture of propionaldehyde (41.0 g., 0.706 mol.) and tetrahydrofuran (203.6 g., 2.83 mol.) was irradiated at 12°C for 10 hr, and the reaction product was fractionally distilled under atmospheric and reduced pressure to give the following fractions:

	B. p., °C	Weight, g.	n_D^{20}
(1)	49~ 52	7.0	1.3710
(2)	52~ 64	5.4	1.3840
(3)	64~ 66	171.5	1.4063
(4)	~ 40/18 mmHg	11.2	1.3852
(5)	40~ 76/18 mmHg	0.7	1.4431
(6)	76~ 92/18 mmHg	20.0	1.4473
(7)	92~100/18 mmHg	2.2	1.4492
(8)	Residue	18.3	

Fraction 4 was assumed to be *n*-propyl alcohol on the basis of gas chromatography, and it was identified as such by means of a mixed melting point test of its 3, 5-dinitrobenzoate with an authentic sample.

Fraction 6 was purified by preparative gas chromatography: b. p., 71~72°C/11 mmHg, n_D^{20}, 1.4483.

The presence of the hydroxyl group was proved by the infrared spectrum. Its 3, 5-dinitrobenzoate was synthesized and recrystallized from ethanol; m. p., 81.2~82.2°C.

Found: C, 51.68; H, 5.10. Calcd. for $C_{14}H_{16}O_8N_2$: C, 51.85; H, 4.97%.

From the above results, this fraction was confirmed to be ethyl-α-tetrahydrofurylcarbinol.

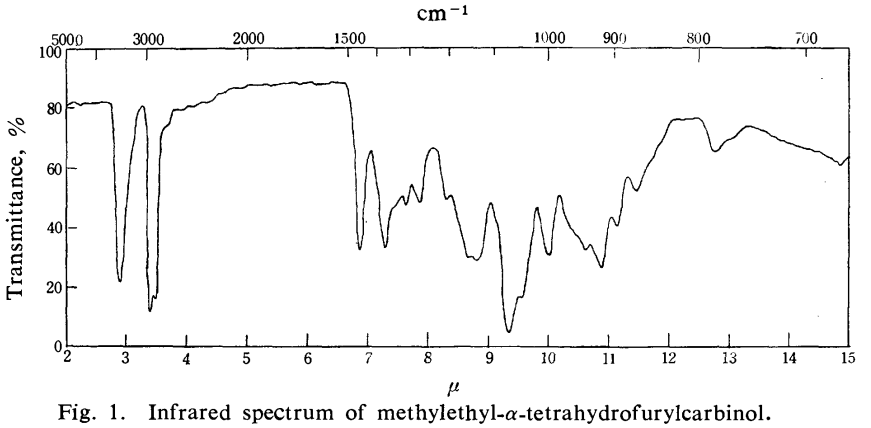

Fig. 1. Infrared spectrum of methylethyl-α-tetrahydrofurylcarbinol.

The Synthesis of Ethyl-α-tetrahydrofurylcarbinol.—Ethyl-α-furylcarbinol was prepared by the reaction of ethylmagnesiumbromide with furfural: b. p., 85~86°C/22 mmHg, n_D^{20}, 1.4763 (lit.,[5] 87~90°C/25mmHg). Ethyl-α-tetrahydrofurylcarbinol[6] was prepared by the hydrogenation of ethyl-α-furylcarbinol in the presence of an Adams catalyst: b.p., 85~95°C/19 mmHg, (lit.,[6] 182~186°C/745 mmHg, n_D^{20}, 1.4485).

Summary

The photochemical reaction of ethyl methyl ketone and propionaldehyde in tetrahydrofuran has been studied. Methylethyl-α-tetrahydrofurylcarbinol and ethyl-α-tetrahydrofurylcarbinol were easily obtained. In the photochemical reaction of propionaldehyde in tetrahydrofuran, di-α-tetrahydrofuryl was not produced, but it was observed to be produced in the photochemical reaction of acetone and ethyl methyl ketone in tetrahydrofuran.

The Reduction of Aquopentamminechromium(III) Ions at the Dropping Mercury Electrode

By Nobuyuki TANAKA, Yuichi SATO, Reita TAMAMUSHI and Gen SATÔ*

(Received March 14, 1963)

The polarographic behavior of hexamminechromium(III) ions has been reported by several authors.[1-5] In the recent papers by Tanaka and his coworkers,[4,5] the characteristics of the electrode processes of hexamminechromium(III) ions in neutral and acid aqueous solutions have been extensively discussed. In contrast, the polarographic behavior of aquopentamminechromium(III) ions has not been investigated in detail, though the half-wave potential in an acetate buffer has been reported by Friend and Smith.[2]

The present paper is concerned with the reduction of aquopentamminechromium(III) ions at the dropping mercury electrode in aqueous solutions. The study was undertaken in order to find the effect of the substitution of a water molecule for ammonia in the hexamminechromium(III) ion on the reduction at the electrode. The observations in the direct current and the alternating current polarography, including the measurements of Kalousek polarograms and current-time curves, will be presented, and the mechanism of the electrode processes will be discussed.

Experimental

Aquopentamminechromium(III) nitrate was prepared according to the method proposed by Mori[6] and was converted then into chloride.[7] Aquopentamminechromium(III) perchlorate, $[Cr(H_2O)(NH_3)_5](ClO_4)_3$, was precipitated from the solution of the chloride. After recrystallization from water, the complex was identified by measuring its absorption spectra and by determining the chromium and nitrogen contents. Absorption bands were observed at 480 mμ and 365 mμ by the use of a Hitachi *Model EPU-2 spectrophotometer*. The complex was oxidized to chromate with hydrogen peroxide in an alkaline solution, and the chromate content was determined by the spectrophotometric method. Nitrogen was determined by the conventional method.[8]

Found: Cr, 11.38; N, 14.83. Calcd. for $[Cr(H_2O)(NH_3)_5](ClO_4)_3$: Cr, 11.47; N, 15.44%.

This complex is stable for a few months when it is preserved in a silica-gel desiccator in darkness, but for only two or three hours in an acid solution. Gelatin or polyoxyethylene lauryl ether (LEO) was used as a maximum suppressor. All other chemicals used were of a guaranteed reagent grade and were used without further purification.

Direct current (d. c.) polarograms were recorded by a Yanagimoto PB-4 pen-recording polarograph. A Yanagimoto Galvarecorder Y-GR 2 was used to record alternating current (a. c.) polarograms. Kalousek polarograms were recorded with the same

circuit as previously described.[9] Current-time (i-t) curves were recorded by using a Rikadenki ER-J 1 recorder with an RLDC-201 preamplifier. A brown-colored cell of a simple beaker type was used in all measurements. The dropping mercury electrode (DME) used had an m value of 1.76$_6$ mg./sec. and a drop time, t_d, of 4.90 sec./drop, when measured in an air-free 1.0 M potassium nitrate solution at 25°C and −0.5 V. vs. SCE at 50 cm. of the height of mercury reservoir. The potential of the DME was measured against a saturated calomel electrode (SCE), which was connected to the electrolytic solution through a Hume and Harris-type salt bridge. When a. c. polarograms were measured, a platinum wire electrode of a large surface area was inserted in the electrolytic solution as the third electrode; this electrode was terminated at the SCE through a 100 μF capacitor in order to minimize the impedance of the cell. A Hitachi model EHP-1 pH meter was used for the measurement of pH of the solution.

All the measurements were carried out in a thermostat of 25±0.1°C, unless otherwise stated, and the dissolved oxygen in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution. The d. c. and Kalousek polarograms given in this paper were corrected for the residual current and the iR drop across the cell. The half-wave potentials were determined from the plots of log $\bar{i}(\bar{i}_d-\bar{i})$ versus potential.

Results

In the preliminary experiments, aquopentamminechromium(III) was found not to give a well-defined polarographic wave in neutral unbuffered solutions, but to give a well-defined wave in acetate buffers or acid solutions. Typical examples are shown in Fig. 1. In this paper, therefore, only the results obtained in acid solutions are presented.

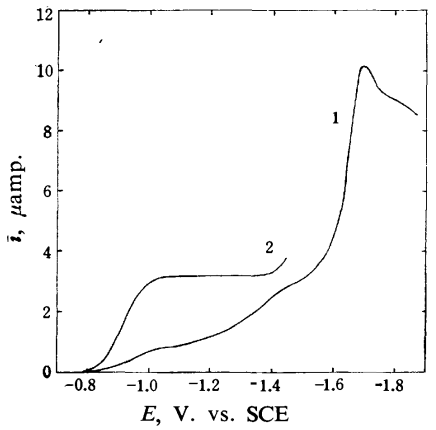

Fig. 1. Polarograms of 1.0 mM $[Cr(H_2O)(NH_3)_5](ClO_4)_3$: (1) in 1.0 M NaCl+0.005% gelatin; (2) in 0.1 M acetate buffer+0.9 M NaCl+0.005% gelatin (pH 4.46).

58.4	3.47	0.454
68.4	3.78	0.457

* Height of mercury reservoir corrected for the back pressure.

The current-potential curves were obtained at various concentrations of aquopentamminechromium(III) ions in 0.1 M acetic acid-sodium acetate buffers containing 0.9 M ammonium chloride and 0.005% gelatin. The limiting current, $\bar{i}_l$, was proportional to the concentration and the value of $\bar{i}_l/C$ was found to be 3.18 μ amp./mM in the concentration range from 0.2 to 2.0 mM. The half-wave potentials were found to be independent of the concentration of the complex. Table I gives the limiting currents measured at different heights of the mercury reservoir. These results clearly indicate that the limiting current is diffusion-controlled. A comparison of the diffusion coefficient of aquopentamminechromium(III) as calculated by the Ilkovič equation and those of hexamminechromium(III)[5] and hexacyanochromate(III)[10] suggests that the wave is of a one-electron reduction. The limiting currents were also measured at various temperatures, and the activation energy for the process controlling the limiting current was calculated according to the method proposed by Vlček[11] to be 5.0 kcal./mol.

Table II presents the diffusion currents, half-wave potentials and slopes of the log-plots which were obtained at 1.0 mM of the complex.

TABLE II. EFFECTS OF pH AND SUPPORTING ELECTROLYTE ON THE POLAROGRAM OF 1 mM $[Cr(H_2O)(NH_3)_5](ClO_4)_3$ IN SOLUTIONS CONTAINING 0.1 M ACETATE BUFFER AND 0.005% GELATIN

Polarograms of 1.0 mM aquopentamminechromium(III) were recorded at various concentrations of gelatin and LEO in 0.1 M acetate buffers containing 0.9 M ammonium chloride; examples are given in Table IV. The increase in the concentration of gealtin shifts the half-wave potential to more negative potentials. Current-time curves during the life of a mercury drop, which were recorded at −0.94 V. vs. SCE under the same conditions as in Table IV, are reproduced in Fig. 2. In this measurement, the first mercury drop after the initiation of electrolysis was used.[12] The *i-t* curve obtained in the presence of 2×10^{-6} M LEO is nearly the same as that obtained without a maximum suppressor, whereas the presence of gelatin decreases the current to a great extent. Current-time curves were also recorded at various potentials and at various concentrations of gelatin and LEO. The results showed that the addition of 2×10^{-6} M LEO gives satisfactory *i-t* curves. In the absence of a maximum suppressor, however, no satisfactory *i-t* curves were obtained at −1.2 V. vs. SCE.

TABLE IV. EFFECT OF SURFACE ACTIVE SUBSTANCE ON THE POLAROGRAM OF 1.0 M $[Cr(H_2O)(NH_3)_5](ClO_4)_3$ IN SOLUTIONS CONTAINING 0.1 M ACETATE BUFFER AND 0.9 M NH_4Cl

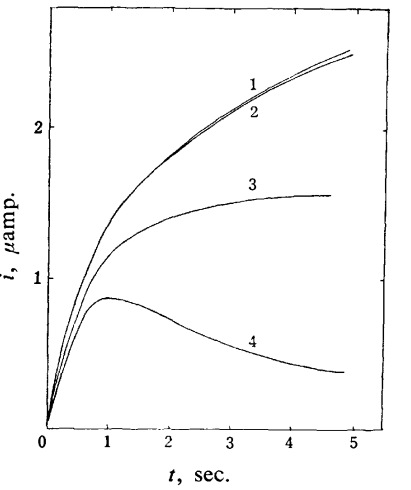

Fig. 2. Current-time curves of 1.0 mM $[Cr(H_2O)(NH_3)_5](ClO_4)_3$ measured at −0.94 V. vs. SCE in solutions containing 0.1 M acetate buffer and 0.9 M NH_4Cl in the absence (curve 1) and in the presence of 2×10^{-6} M LEO (curve 2), 0.005% gelatin (curve 3) and 0.01 % gelatin (curve 4).

Kalousek and a. c. polarograms were recorded to examine the polarographic reversibility of the reduction of the complex. A typical example of the Kalousek polarograms, which was obtained in a solution containing 0.1 M

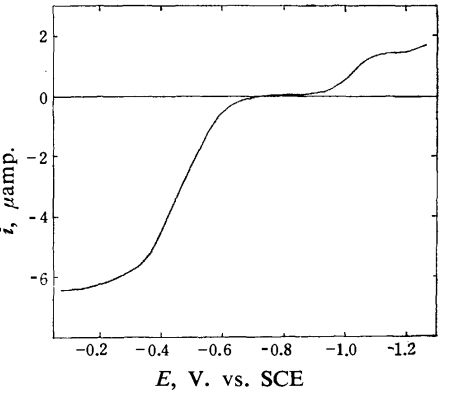

Fig. 3. Kalousek polarogram of 1.0 mM $[Cr(H_2O)(NH_3)_5](ClO_4)_3$ obtained at exchange frequency of 5 cycles/sec. in a solution containing 0.1 M acetate buffer, 0.9 M NH_4Cl and 0.005% gelatin. The potential is set up at −1.2 V. vs. SCE.

acetate auffer, 0.9 M ammonium chloride and 0.005% gelatin, is reproduced in Fig. 3.

Discussion

Aquopentamminechromium(III) gives no well-defined wave in neutral unbuffered solutions because it contains basic ligands and, when reduced, it forms an insoluble film on the surface of the electrode, as has already been reported in the case of the polarographic reduction of hexamminechromium(III).[4,5] In an acid solution, the ammonia molecules that the reduced chromium(II) species liberates are neutralized by hydrogen ions diffusing from the bulk of the solution; consequently, the formation of such an insoluble film is prevented.[4,5] The limiting current of the wave in acid media is diffusion-controlled in every respect; the value of 5.0 kcal./mol. obtained seems appropriate for the activation energy of the diffusion.

The fact that the half-wave potential was almost independent of the hydrogen ion concentration of the solution suggests that the hydrogen ions are not involved in the chemical reaction, if any, preceding the electron transfer (see Table II). Table III shows that the shift of the half-wave potential is due not to an increase in ammonium ion concentration but to an increase in total ionic concentration. It is suggested that no chemical reaction involving ammonium ions takes place prior to the electron transfer.

The reduction of aquopentamminechromium-(III) to chromium(II) species in an acid solution appears to be irreversible in the polarographic sense. A straight log-plot with a reciprocal slope of approximately 70 mV., which is somewhat greater than that expected for a reversible one-electron reduction wave, suggests the irreversible nature of the wave (see Tables II, III and IV). The value of $i_p/(n\bar{i}_d\sqrt{t_d})$, where i_p means the peak current of the a. c. polarogram, $\bar{i}_d$, the average diffusion current of the corresponding d. c. polarogram, and n, the number of electrons involved in the electrode process, represents the degree of polarographic reversibility of the electrode reaction.[13] In Table V, $i_p/(n\bar{i}_d\sqrt{t_d})$ values for the aquopentamminechromium(III) ion and other simple and complex ions are presented. The aquopentamminechromium (III) gives smaller values than that for nickel(II) in a potassium chloride solution, suggesting the complete irreversibility of the reduction of the complex. The irreversibility is supported also by the shape of the Kalousek polarogram (Fig. 3). The increase in exchange frequencies of the on-and-off switch from 5 cycl./sec. to 30 cycl./sec. showed no feature of reversibility.

The instantaneous current at constatnt potential during the life of a mercury drop is given as a function of time,

$$i = k\,t^{x} \qquad (1)$$

where k is a constant. The plot of log i against log t, therefore, should give a straight line with a slope of the value of x. In the case of the reduction of aquopentamminechromium(III), a straight line was obtained only when LEO was added as a maximum suppressor in a concentration of 2×10^{-6} M. The addition of gelatin was found to cause the

shape of the current-time curve to deteriorate and to give no linear plot of log i vs. log t. The values of x at various potentials, therefore, were determined in the presence of 2×10^{-6} M LEO. The plot of x vs. potential, as shown in Fig 4, varies from 0.55 to 0.23 with increasing negative potentials, suggesting that the electrode process is kinetic in nature at the foot of the wave, but diffusion-controlled at the limiting current plateau.

The results obtained from the d. c., the a. c. and the Kalousek polarograms and the current-time curves indicate that the reduction of aquopentamminechromium(III) to chromium-(II) proceeds irreversibly at the dropping mercury electrode and that its overall electrode process in an acid solution may be written as follows:

$$Cr(H_2O)(NH_3)_5^{3+} + e \rightarrow Cr(H_2O)(NH_3)_5^{2+} \quad (2)$$

$$Cr(H_2O)(NH_3)_5^{2+} + n\,H_2O + n\,H^+ \rightarrow Cr(H_2O)_{n+1}(NH_3)_{5-n}^{2+} + n\,NH_4^+ \quad (3)$$

When the electrode reaction is totally irreversible, the following equation holds:[14]

$$\ln\frac{\bar{i}_d-\bar{i}}{\bar{i}} = \ln\{1.13(\Lambda\sqrt{t_d})^{-1}\}+\frac{\alpha nF}{RT}(E-E_{1/2}^r)$$

$$\Lambda=\frac{k_s f_O^{\beta} f_R^{\alpha}}{(D_O^{\beta}D_R^{\alpha})^{1/2}} \qquad (\alpha+\beta=1) \quad (4)$$

where $E_{1/2}^r$ indicates the reversible half-wave potential, k_s, the standard rate constant, α, the transfer coefficient, and f_O and f_R, the activity coefficients of oxidized and reduced forms respectively. If f_O and f_R are assumed to be unity and D_O and D_R, equal to D, Eq. 4 can be simplified. When $\bar{i}$ equals $\bar{i}_d/2$, the equation,

$$\log k_f^\circ = \log 1.13 - \frac{1}{2}\log t_d + \frac{1}{2}\log D + \frac{2.303RT}{\alpha nF}E_{1/2} \quad (5)$$

is obtained, where k_f° indicates the forward rate constant at 0 V. In this paper, a saturated calomel electrode at the observed temperature was used for the reference.

The diffusion coefficients were obtained from the limiting currents with the aid of the Ilkovič equation. The values of log k_f° were determined at various temperatures, as Table VI shows. With these values, the heat of activation of the electrode process, $\Delta H^*_{E=0}$, was calculated to be 40.2 kcal./mol., being referred to the SCE.[15]

Table VI. Log k_f°'s of the reduction of $[Cr(H_2O)(NH_3)_5]^{3+}$ at various temperatures in solutions containing 0.1 M acetate buffer, 0.9 M NH_4Cl and 2×10^{-6} M LEO

Temp. °C	$E_{1/2}$ V. vs. SCE	α	$D^{1/2}\times10^3$ cm. $sec^{-1/2}$	t_d sec.	log k_f°
0.4	−0.972	0.89	1.89	4.40	−18.9
10.0	−0.951	0.88	2.19	4.34	−17.8
17.0	−0.935	0.85	2.46	4.23	−16.6
25.0	−0.918	0.83	2.83	4.12	−15.7
35.0	−0.893	0.83	3.25	4.02	−14.8

Although all experimental results support the irreversible electrode process of reaction 2 and although this irreversibilty seems to be attributed to the electronic rearrangement of aquopentamminechromium(III) from t_{2g}^3 to $e_g t_{2g}^2$,[16] there seems to be another possible mechanism. As has been reported in the case of hexamminechromium(III) ions,[5] reaction 2 may proceed reversibly in the polarographic sense, followed by the rapid aquation of the reduced species, aquopentamminechromium(II) ions. This mechanism would also explain the observations in the a. c. and the Kalousek polarograms. At the present moment, however, it seems not to be possible to decide by which mechanism the electrode reaction proceeds at the dropping mercury electrode.

Summary

The reduction of aquopentamminechromium-(III) ions at the dropping mercury electrode has been studied in acid solutions by means of the measurement of the direct current, the alternating current and the Kalousek polarograms and the current-time curves. The d. c. polarogram gives a well-defined wave corresponding to the one-electron reduction of chromium(III) to chromium(II). All polarograms, including the Kalousek ones, indicate the irreversibility of the reduction of aquopentamminechromium(III) ions. The heterogeneous rate constants at 0 V. vs. SCE at various temperatures have been presented, and the possible mechanisms for the electrode process have been discussed.

Dielectric Relaxation and Molecular Structure. I. Relaxation Time and Viscosity

By Kazuo CHITOKU and Keniti HIGASI

(Received March 22, 1963)

Stokes' simple formula for a rigid sphere rotating in a viscous liquid was assumed by Debye[1] to be applicable to a sphere of molecular dimensions surrounded by other molecules of a similar size:

$$\tau=\frac{4\pi\eta a^3}{kT} \tag{1}$$

in which η is the ordinary viscosity[2] of the liquid, a is the radius of the sphere, k is the Boltzmann constant, and T is the absolute temperature.

Equation 1 has been employed widely for thirty years;[3] it has been applied even in the analysis of the relaxation times of nuclear magnetic resonance absorption.[4] It was soon discovered, however, that the molecular radius a obtained from measurements of dielectric relaxation times, τ, in either a liquid or a solution by the use of Eq. 1 is usually only a fraction of the actual radius.[3] In addition, the relaxation time does not follow the increase in viscosity for highly viscous liquids. The concept of internal or microscopic viscosity has been developed[5] to account for this anomaly; however, one can not place much reliance on the estimation of this viscosity of an unmeasurable nature.[6,7]

The object of the present paper is to postulate an empirical relation between the viscosity and the relaxation time and to compare it with Eq. 1. The ordinary viscosity alone will be considered here, since it seems desirable to deal only with measurable quantities. The dielectric measurements in the present report have been limited to dilute solutions, because the relaxation time measured in the liquid state is accompanied with ambiguity because of the choice of an arbitrary conversion ratio from the macroscopic relaxation time to the microscopic relaxation time.[3,8]

Experimental

All the dielectric measurements reported below were made between 1×10^7 and 8×10^7 cycl./sec. (10 ~80 Mc./sec.) with a Hartshorn-Ward apparatus;[9] this measures the loss tangent ($\tan\delta=\varepsilon''/\varepsilon'$) in terms of the capacitance increment (ΔC) corresponding to the half-width of the voltage-resonance curve of the cell-containing circuit.[10] The loss tangents were measured up to 2×10^{-4}. The whole apparatus was kept in an air-thermostat maintained at 25°C.

Our general procedure was checked by measuring a standard substance, benzophenone, in various solvents: *n*-hexane, benzene, carbon tetrachloride and Nujol.

In dilute solutions, both Debye and Onsager equations become:[3]

$$\tan\delta=\frac{(\varepsilon'+2)^2}{\varepsilon'}\,\frac{4\pi n\mu^2}{27kT}\,\frac{\omega\tau}{1+\omega^2\tau^2} \tag{2}$$

where ε' is the dielectric constant of the solvent, n is the number of polar molecules per cubic centimeter, ω is the angular frequency, and τ is the relaxation time. When $\omega\tau\ll1$, this equation reduces to:

$$\tau=\frac{\tan\delta}{\omega c}\,\frac{6750\,kT}{\pi N\mu^2}\,\frac{\varepsilon'}{(\varepsilon'+2)^2} \tag{3}$$

where N is the Avogadro number and c is the molar concentration. The constancy of $\tan\delta/\omega$ over a wide frequency range provides a simple test of Eq. 3. Table I contains results for benzophenone in two solvents, those with the lowest and the highest viscosities. The $\tan\delta/\omega$ values were found constant in all the solvents employed. Using a mean value, $\tan\delta/\omega=6.9\times10^{-12}$, and $\mu=2.94$ D, one finds $\tau=14.7\times10^{-12}$ sec. (14.7 p. sec.) at 25°C in hexane. This is in good agreement with Fairweather's value, 14.3 p. sec.[11] The results are further compared in Table II.

As shown by the above example, the value of the dipole moment in the particular medium is necessary for calculation. Consequently, measurements of dipole moments were carried out by

the heterodyne-beat method and with the use of Halverstadt-Kumler's approximation.[16]

Materials.—All chemicals were of the best grade available and were purified before use; their m. p.'s or b. p.'s were checked against the values given in the literature.

Results

Table III summarizes the results of the present measurements. Mixed solvents were employed for substances which were not soluble in pure solvents. Viscosity values are recorded of the solvent itself and also of the dilute solution with which the measurement was carried out; the symbols η_{solv} and η_{solu} are used to mark the distinction between them.

Discussion

Plots of the observed relaxation times against the viscosities do not result in any satisfactory curve. On the other hand, when the logarithms of the relaxation times are plotted against the logarithms of the viscosities, an approximate linear relationship between $\log\tau$ and $\log\eta$ becomes noticeable, as may be seen in Figs. 1 and 2, in which plots are made in the logarithmic scale. For this reason, one can propose the following empirical equation:

$$\log\tau = A + x\log\eta \qquad (4)$$

where A and x are constants relating to the substance alone under a given temperature. In Table IV the A and x values determined by the present series of experiments are recorded.

Benzophenone	$\bar{1}0.301$	0.46
Benzil	$\bar{1}0.532$	0.51

* η_{solu} is employed instead of η_{solv}.

Alternatively, we may use η_{solu} instead of η_{solv} in examining the approximate linearity between $\log\tau$ and $\log\eta$. Pyridine in Fig. 1 and diphenyl ether in Fig. 2 show that Eq. 4 is equally valid for any case using either η_{solv} or η_{solu}. The values of A and x marked by an asterisk in Table IV and the broken lines in Figs. 1 and 2 refer to the examination by the use of η_{solu}.

The use of Eq. 2 requires that the dielectric absorption should be of the Debye type, which is not usually possible. In order to examine more fully the validity of Eq. 4, we have to refer to the results of the microwave measurements which account for the deviations from Debye's dispersion. In fact, this has been done by Higasi[7] and was repeated for the present work with equally satisfactory results. Table V records the values of A and x thus obtained.

Now we shall turn to the correlation between Stokes' formula and the new empirical equation. Equation 4 will become identical with Eq. 1 only when the following conditions are satisfied:

TABLE V. PARAMETER VALUES FROM THE LITERATURE

Substance	A	x	y	Ref.
2,2'-Dichloropropane	$\bar{1}2.529$	0.07	0.23	17
2,2'-Dinitropropane	$\bar{1}2.851$	0.16	0.28	17
t-Butyl chloride	$\bar{1}2.423$	0.09	0.21	18
Camphor	$\bar{1}1.190$	0.16	0.29	19,20
1,3-Dichlorobenzene	$\bar{1}1.373$	0.13	—	21
Isoquinoline	$\bar{1}1.591$	0.23	0.47	19,22
1-Chloronaphthalene	$\bar{1}1.712$	0.25	0.38	23
1-Bromonaphthalene	$\bar{1}1.839$	0.27	0.41	23
Acridine	$\bar{1}0.845$	0.69	1.1	19
4-Bromobiphenyl	$\bar{9}.193$	0.66	0.92	19,24

$$A = \log\frac{4\pi a^3}{kT}; \quad x = 1 \tag{5}$$

Tables IV and V both demonstrate that the x parameter is not unity but, rather, is distributed within a wide range: $0<x<1$. This suggests that Stokes' formula is not applicable to a sphere of molecular dimensions.

It is interesting to examine the values of parameter x in the light of molecular structure. For such rigid spherical molecules as 2,2'-dichloropropane and *t*-butyl chloride, one will notice that the x parameter is nearly zero; certainly, the Stokes spherical model is invalid. With an increase in distortion from sphericity, the parameter gradually increases: $x=0.24$ for nitrobenzene and $x=0.66$ for 4-nitrobiphenyl.

For molecules having freedom of internal rotation, the x parameter becomes smaller. This tendency is demonstrated in Fig. 2 in the comparison of diphenyl ether with benzophenone; in the latter kind of molecules, the rotation of the benzene rings does not affect the dipole moment of the molecule, while in the former the molecular moment changes its direction by means of internal rotation.[25] In connection with the internal motion of benzil,[26] it is interesting to find that the x parameter has the fairly large value of 0.46. This leads to a suggestion that benzil is practically a rigid molecule, which is in good agreement with the conclusions of the dipole work.[26]

26) K. Higasi, This Bulletin, 13, 158 (1938).

The trend of the x parameter is a quantitative description of what has been said qualitatively by Smyth and his co-workers.[27] That is, if the shape of the molecule undergoing dipole rotation departs slightly from that of a sphere, the relaxation time has little dependence upon the viscosity since it can rotate without any considerable displacement of the surrounding molecules. Further, if the molecule is asymmetrical in shape, its rotation must involve the displacement of neighboring molecules and so the relaxation time should depend markedly upon the viscosity of the medium. The concept of the displacement of solvent molecules belongs to a mechanism entirely different from the Newtonian flow on which the Stokes model is theoretically based.

The relation between viscosity and temperature can be expressed by:

$$\eta = B\exp(E_\eta/RT) \tag{6}$$

in which E_η can be called the molar activation energy of viscosity. Similarly, we can write for the time of relaxation,

$$\tau = C\exp(E_\tau/RT) \tag{7}$$

in which C is considered to be independent of the temperature and E_τ, the activation energy for relaxation.

If we take the ratio of E_τ to E_η and denote it by y:

$$y = \frac{E_\tau}{E_\eta} \tag{8}$$

then Eq. 6 will be transformed into:

$$\tau = C\exp(yE_\eta/RT) = (C/B^y)\cdot\eta^y$$

Or, we may write:

$$\log\tau = \log(C/B^y) + y\log\eta \tag{9}$$

Eq. 9 will become identical to Eq. 4, if

$$x = y \quad \text{and} \quad A = \log(C/B^y) \tag{10}$$

27) C. P. Smyth, Ref. 3, pp. 122–123.

The values of x obtained from various solvents using Eq. 4 are compared with the y values obtained for Nujol by Kalman and Smyth[19] from Eq. 8. It is impressive to find in Table V that these two parameters are roughly parallel to each other; $x \simeq y$ and $0 < y \leqslant 1$. The E_τ/E_η ratio is not independent of solvents, and the second condition of Eq. 10 is satisfied only very approximately. These points seem to be reflected in the observed differences between y and x values.

Lastly, we may refer to the frequency dependence of the viscosity. One might point out that the viscosity of Nujol at the frequency of 10~80 Mc./sec. might be different from its static viscosity and that, consequently, the observed relationship might need to be reconsidered. However, this suggestion is untenable. If that be the case, one can not explain why the molecular shape can produce such a considerable variation in x values.

Conclusions

(1) Stokes' formula for a rotating sphere in a viscous medium cannot be applied to a sphere of molecular dimensions.

(2) There exists an empirical relation between the relaxation time, τ, and the viscosity, η:

$$\log\tau = A + x\log\eta$$

in which the x parameter has a value $0 < x \leqslant 1$.

(3) Through the x parameter one can obtain some insight into the mechanism of rotation (internal rotation vs. overall rotation) or one can discuss the shape of the rotating unit.

*The Properties and Infrared Absorption Spectra of Nitrilotriacetate Chelates**

By Yuko TOMITA and Keihei UENO

(Received April 8, 1963)

The metal chelate-forming behavior of nitrilotriacetic acid (hereafter referred to as NTA) has been studied in terms of their properties in a solution,[1] but very few investigations have been undertaken into the NTA chelates in a solid state.[2] Extensive investigation into ethylenedinitrilotetraacetic acid (hereafter referred to as EDTA) chelates, both in a solution and in solid states have proved that the bonding between the EDTA and divalent metals is primarily ionic.[3] In those investigations, infrared absorption spectroscopy provided much information on the nature of the bonding between metal and ligand. For instance, the absorption band for the carbonyl bond of the carboxylate groups was found to shift to higher frequencies with the increasingly covalent character of the metal-carboxylate bond. This observation made it possible to determine whether the bonding in EDTA chelates is essentially ionic or covalent. At the same time, the infrared technique was utilized in differentiating coordinated and uncoordinated carboxyl groups.[4,5] However, this differentiating technique is not always successful; in those complexes whose bonding is primarily ionic, the absorptions of the COOM group and those of the uncoordinated COO^- group occur in the same region, so it is not possible to distinguish between these two cases.

This study, concerned with some of the properties and the infrared spectra of NTA and metal-NTA chelates, attempts to investigate the chelating behavior of NTA in a solid state as well as in a solution and to find a relationship between the carbonyl band and the nature of the metal-carboxylate bond.

Experimental

Infrared Spectra. — The infrared spectra of crystalline complexes were studied in mineral oil mulls and in potassium bromide disks. The solid complexes were pressed into disks, using 0.3~0.5 mg. of chelate mixed with 100 mg. of potassium bromide for each disk. The infrared spectra in aqueous solutions were also taken for those complexes which are soluble enough in water. The aqueous solutions were made with 99.5% D_2O at concentrations of approximately 3~15% by weight, and the spectra were observed using a cell with calcium fluoride windows. The measurements were made with a Nippon Koken model DS 301 double-beam spectrophotometer equipped with sodium chloride optics.

Reagents.—The inorganic salts used in preparing the complexes were reagent grade in all cases. The free acid of NTA (donated by Dojindo & Co.) was analytical grade and was used without further purification.

Preparation of NTA Chelates. Sodium Salt of NTA Chelates ($NaM^{II}Y$[6]).—The following metal carbonates were used in preparing solid chelates: $(MgCO_3)_4 \cdot Mg(OH)_2 \cdot 5H_2O$, $CaCO_3$, $SrCO_3$, $BaCO_3$, $CoCO_3 \cdot 3Co(OH)_2$, $NiCO_3 \cdot 2Ni(OH)_2 \cdot 4H_2O$, $CuCO_3 \cdot Cu(OH)_2 \cdot H_2O$, $(PbCO_3)_2 \cdot Pb(OH)_2$, $ZnCO_3$ and $CdCO_3$. The theoretical amount of inorganic salt was added to a warm suspension of 0.02 mol. of NTA in 50 ml. of water. After complete dissolution, the pH value of the solution was adjusted to 6~7 by adding a 0.01 M solution of sodium carbonate. The solution was heated almost to boiling. To this solution, 200~300 ml. of absolute ethanol was added until the precipitates began to appear, and the resulting solution was cooled in an ice-bath. After filtering the crystals, they were recrystallized from a small amount of water. The finished chelates were immediately placed in a vacuum desiccator for 24 hr.

Hydrogen NTA Chelates ($HM^{II}Y$).—These were prepared in a similar manner, but sodium carbonate was not added to the solution. The separated hydrogen NTA chelates were recrystallized from water and placed in a vacuum desiccator for 24 hr.

Analyses.—The chelates were analyzed for alkaline earths and divalent metals by the EDTA titration technique after the samples had been decomposed with concentrated nitric acid and hydrogen peroxide.[7] For the sodium salt of chelates, sodium was determined by precipitating it as sodium-zinc-uranyl-acetate from the decomposed solution,

followed by EDTA titration.[8,9] The results of the analyses are shown in Table I, along with the proposed formulae.

Results and Discussion

Spectra of Ligand.—In Table II, assignments and wave numbers are given for the important peaks of the NTA chelates of the alkaline earth metals (Mg, Ca, Sr, Ba), divalent metals (Cu, Ni, Zn, Co, Pb) and sodium salts of NTA. There is no significant absorption band between 4000 and 1800 cm^{-1} except for the bands in the 3000~2800 cm^{-1} region, which are assigned to the C-H streching vibration of the CH_2 groups.

The carboxyl group is known to give a strong band in the range between 1735 and 1550 cm^{-1} which is due to the C=O stretching vibration.[10] As it is believed, from the acid dissociation constant data, that NTA ligand acid has a zwitter ion structure, as in the case of EDTA, one may expect a band for carboxylate ion in the 1610~1550 cm^{-1} region for the acid form of NTA. However, no significant absorption band could be found in this region for the free ligand acid. Therefore, it is doubtful that NTA has a zwitter ion structure in the solid state. This situation will be made clearer if one could compare the spectra of the solid state with that of the solution state. However, the spectra of the aqueous solution could not be measured because of the poor solubility of the ligand acid. In this connection, it is noteworthy that a similar situation has been reported for EDTA ligand acid, where no clear band of carboxylate ions, could be found in the expected region. Therefore, the existence of a zwitter ion structure was thought to be doubtful[11] in the solid state, although a very weak shoulder at

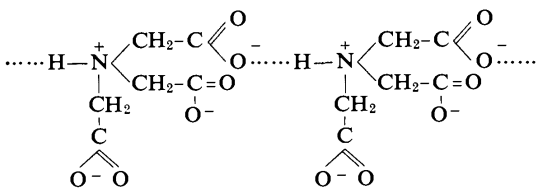
In solution			
	1720 cm^{-1} 1623 cm^{-1}	1625 cm^{-1}	1584 cm^{-1}
Solid			
1728 cm^{-1}		1678 cm^{-1} 1638 cm^{-1}	1580 cm^{-1}

1635 cm^{-1} has been assigned to carboxylate ions by one investigator.[12]

In contrast to the NTA free acid, its disodium and trisodium salts were easily soluble in water, so that their spectra were observed both in solid and in solution states. The two bands at 1678 cm^{-1} and 1638 cm^{-1} of disodium NTA in a solid state have been assigned to the $-COOH$ and $-COO^-$ groups respectively. However, in an aqueous solution, only one band, at 1625 cm^{-1}, is observed, indicating that all three carboxyl groups exist as $-COO^-$ and that the proton is attached to the nitrogen atom. This situation has been pointed out by Nakamoto, Morimoto and Martell.[13] Why this singlet carboxyl band splits into a doublet when one goes from a solution to a solid state can be explained in two ways. In one explanation, one of the carboxylate ions of NTA is bonded to the proton of neighboring NTA molecules in the solid state, as is schematically shown below (I). This intermolecular hydrogen bonding will not occur in a solution. The hydrogen-bonded carboxylate group gives rise to an absorption at 1678 cm^{-1}, whereas the free carboxylate group absorps at 1638 cm^{-1}. In



I

another explanation, the stretching vibration of the carboxylate carbonyl bonding will be influenced by the crystal field in the solid state, which will result in the splitting of the singlet band.

Trisodium NTA gives only one band, near 1580 cm^{-1}, both in a solid and in a solution, so it is clear that the three carboxyl groups exist as $-COO^-$, regardless of the state.

The shift of the band for the free carboxylate group from 1625 cm^{-1} in disodium salt to 1584 cm^{-1} in trisodium salt may be caused by the loss of a formal positive charge on the nitrogen atom, as has been discussed by Nakamoto.[13]

The Spectra of Metal Chelates.—It one assumes that NTA behaves as a tetradentate ligand, with all the carboxylate groups coordinated to the central metal ion, only one carboxyl band may be expected in this region for all metal-NTA chelates. However, the infrared spectra of NTA chelates of alkaline earth metals in a solid state show two carboxyl bands, as Table II indicates.

The first group of bands appears in the range between 1640 and 1600 cm^{-1} and can be found in the alkaline earth chelates but in neither free ligand acid nor sodium salts. Therefore, this band can be assigned to the coordinated carboxylate groups. The second group of bands appears in the range between 1600 and 1580 cm^{-1} and can be found in the trisodium salt of NTA as well as in the alkaline earth chelates. However, in the case of the hydrogen complexes and the free acid of NTA, this band has completely disappeared and a new band has appeared around 1700 cm^{-1}, where the absorption band of free carboxylic acid is expected. Therefore, it is quite probable that the band at 1600~1580 cm^{-1} is associated with the uncoordinated carboxylate ions. Similar spectral characteristics have been observed in EDTA chelates, where the coordinated carboxylate group, the uncoordinated carboxyl group and free carboxylic acid were assigned to the bands near 1650, 1750 and 1600 cm^{-1} respectively. From these observations, it is probable that, in the alkaline earth chelates, one of the three carboxyl groups does not coordinate with the central metal ion, but remains free carboxylic acid or carboxylate ions. This conclusion may not be extended to the chelating behavior of NTA in a solution, however, since the spectra were taken on solid samples only and no information on the spectra of the solution state could be obtained because of their poor solubility.

In the case of divalent metal ions other than alkaline earth metals, their chelates

12) D. T. Sawyer and P. J. Paslsen, *J. Am. Chem. Soc.*, **80**, 1597 (1958).
13) K. Nakamoto, Y. Morimoto and A. E. Martell, ibid., **84**, 2081 (1962).

showed a single band, with a shoulder in the carbonyl region. This suggests that NTA behaves as a tetradentate ligand, with all carboxylate groups coordinated with the central metal ion. This is also supported by the information obtained from the spectra of an aqueous solution, in which the shoulder of the carboxyl band disappears and the carboxyl band does not change when the hydrogen complex (HMY) is converted into a sodium complex (NaMY).

Regarding EDTA metal chelates, many papers have been published on the relationship between the carbonyl frequency of a coordinated carboxylate group and the covalent character of the metal-carboxylate bond. Sawyer and Paulsen[3] have summarized the previous data on the EDTA chelates and have concluded as follows: When the coordinated carboxylate band ($\nu_{C=O}$) appears in the 1610~1550 cm^{-1} region, the bonding is primarily ionic. When this band is in the 1650~1625 cm^{-1} region, the bonding is primarily covalent. When the band occurs between these two region, the bonding is probably partially ionic and partially covalent.

In the case of the NTA chelates investigated, the carbonyl bands are always found to occur in the same region, 1640~1600 cm^{-1}, where the carbonyl band of a so-called primarily or partially covalent character is expected to appear. The carbonyl frequencies, therefore, may not be related to the covalent character of the metal-carboxylate bond, and the general rule for judging the nature of the bonding in EDTA chelates cannot be applied to NTA chelates. However, in the case of alkaline earth chelates, the frequency of the carbonyl band in a solid state decreases in the order of calcium > magnesium > strontium > barium. Interestingly, this order is identical with the decreasing order of the chelate stability constant. The plots of the logarithms of stability constants against the wave numbers of the carbonyl bands show a straight line, as Fig. 1 shows. This parallel relationship in alkaline earth chelates can qualitatively be explained as follows. The increase in the stability of the NTA chelates is related to the increase in the covalent nature of the metal-ligand bond. Although the nature of this bonding is primarily ionic, the degree of the contribution of the covalent form II will be greater than that of the ionic form III; this effect results in an increase in the double-bond character of the carbonyl bond.

II III

As to the other divalent metal chelates, it is found that the frequency of the absorption band increases with the increasing stability constant, with the exception of nickel chelates. This relationship was observed in both the solid state and in an aqueous solution.

As has been stated previously, the frequency of the carboxylate band of NTA shifted from 1585 cm^{-1} to 1625 cm^{-1} when the nitrogen atom coordinated with a proton. This is understood to be due to the influence of the formal positive charge on the nitrogen atom. For the NTA chelates, in which the coordination of nitrogen atom with the central metal ion is strong, a similar influence on the carboxylate frequency may be expected. For the alkaline earth chelates, the *N*-metal bonding

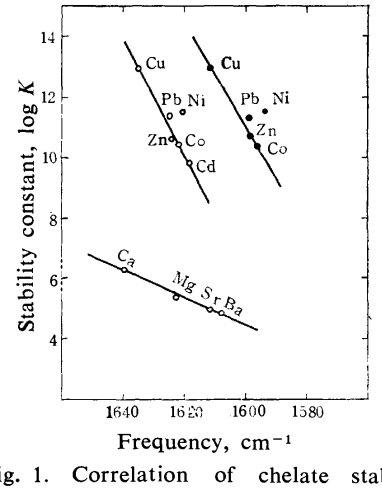


Fig. 1. Correlation of chelate stability constants with C=O absorption frequencies of the chelates.
-○- Hydrated crystal
-●- D_2O solution

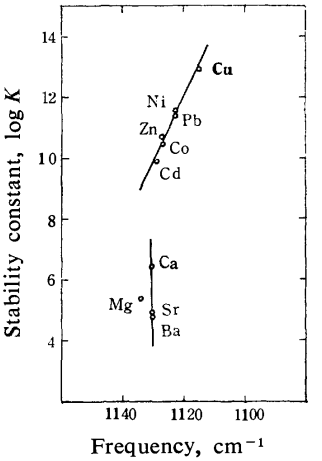

Fig. 2. Correlation of chelate stability constants with C-N absorption frequencies of the chelates.

may not be strong enough to influence the carboxylate frequency. In such a case, the carbonyl frequency must be discussed in relation with the chelate stability.

However, for the NTA chelates of other divalent metals which form more or less strong *N*-metal bonding, their carboxylate frequency will be influenced not only by the carbonyl-metal bonding, but also by the *N*-metal bonding. The coordination of nitrogen atoms to such metal ions is also supported by the shift of the C–N bond, as will be discussed later. Therefore, in this case, one must be careful not to correlate the carboxylate frequency with simply the chelate stability or the nature of the carbonyl-metal bonding.

Carboxylate ions are known to give rise to another peak in the 1420~1390 cm^{-1} region. Accordingly, the band at 1420~1390 cm^{-1} has been assigned to this group, as in Table II. The peak at 1420~1390 cm^{-1} shows some splitting, but no significant relationship between the frequencies of the peaks and the kind of metal ions can be found.

The absorption band in the 1410~1110 cm^{-1} region has been assigned to the C–N bond in NTA chelates.[10] The relationship between the chelate stability and the frequency of the C–N bond for NTA chelates is shown in Fig. 2. The alkaline earth chelates give rise to the peak in the same region, at 1130 cm^{-1}, with the exception of magnesium. On the other hand, the C–N bond of the other divalent metal chelates appears in the 1130~1110 cm^{-1} region, and their frequencies decrease with an increasing stability constant. The corresponding band of the trisodium salt of NTA is found at 1138 cm^{-1}. If one assumes that the coordination of nitrogen to the metal ion results in the lowering of the stretching frequency of the C–N bond, these observations indicate that the *N*-metal bond of alkaline earth chelates is relatively weak and is not sensitive to the metal ions, whereas the bond of other divalent metal chelates is relatively strong and is sensitive to the metal ions. This conclusion may be supported by the fact that these divalent metals form a relatively stable ammine complex, while alkaline earth metals do not form a stable ammine complex.

Summary

Infrared absorption spectra have been observed in NTA and its metal chelates, in solid states as well as in solution. The results indicate that NTA does not exist as zwitter ions in the solid state, that it behaves as a quadridentate ligand for such divalent metals as copper, nickel, cobalt, zinc, cadmium and lead, but that it behaves as a terdentate ligand for the alkaline earth metals. It is also found that the wave number of the $\nu_{C=O}$ band of the coordinated carboxylate group in the NTA chelates tends to shift to a higher value with an increasing chelate stability constant.

A Kinetic Study of the Isotopic Exchange of Indium in Indium N-2-Hydroxyethylethylenediamine-N, N', N'-triacetate Complex in Water

By Kazuo SAITO and Michiko TSUCHIMOTO

(Received April 13, 1963)

As an extension of the kinetic study of the isotopic exchange of co-ordination compounds of the d^{10} structure, the present authors have studied the kinetics of indium *N*-2-hydroxyethylethylenediamine-*N*,*N'*,*N'*-triacetate (henceforth written as EDTA–OH with a formula H_3Z) using indium 114 m as tracer. It was previously reported that the exchange rate is measurably slow in an acid solution of pH 2 to 4 but very fast in more acid solutions.[1] The exchange kinetics is quite different from that of the corresponding gallium complex,[2]

1) K. Saito and M. Tsuchimoto, This Bulletin, **35**, 368 (1962).

2) K. Saito and M. Tsuchimoto, *J. Inorg. Nucl. Chem.* **23**, 71 (1961).

and also from that of indium ethylenediamine-*N*,*N*,*N*',*N*'-tetraacetate (henceforth written as EDTA with a formula H_4Y).[3]

This paper gives the results of a kinetic study of the indium EDTA-OH complex $[InZ\cdot OH_2]\cdot H_2O$ with indium in neutral and basic media, and they are compared with the findings regarding the related complexes mentioned above.

Experimental

Preparation of the Complex. — Radioactive EDTA-OH complex of indium was prepared from indium 114 m. (Ammersham; specific activity: 10 μc. per mg.) and extra pure EDTA-OH (Dotite EDTA-OH).[1] The specific activity was 0.41 μc. per mg.

Procedure for Kinetic Runs and Measurement of Radioactivity. — The method was principally the same as that used in the previous work. Uncomplexed indium hydrolyses in aqueous solutions with a pH value of more than 4, and the kinetics was always studied in the presence of tartrate. In neutral solutions up to pH 8.0, 0.0035 M tartrate sufficed to keep 10^{-3} M indium in the aqueous phase, whereas as much as 0.05 M tartrate was required at pH 11. Since tartrate is present in a doubly de-protonated form in the pH region higher than 5, the given figures indicate the concentration of $C_4H_4O_6^{2-}$.

The reaction was very slow in neutral solutions at 25°C, and the kinetics was studied at 40°C. The separation with 8-quinolinol was effected with more ease at this temperature, the separation-induced zero-time exchange being negligible.

Results

The exchange constant, R, is expressed by McKay's formula:

$$R=-2.303\cdot\frac{ab}{a+b}\cdot\frac{\log(1-F)}{t}$$

where a and b are the molar concentrations of the uncomplexed indium and of the indium EDTA-OH complex respectively, t is the lapse of time, and F the fraction of reaction. The kinetics was entirely different in basic and in neutral media. The R values, however, are independent of a and are proportional to b, regardless of the pH value. Such relationships are graphically shown in Figs. 1 and 2. Hence, the reaction constant, k, is expressed by R/b and has a dimension of T^{-1} in the given concentration range.

Exchange in Basic Media.—The pH dependence of k in basic media buffered with various agents, including barbiturate, *p*-hydroxybenzoate and glycine, is shown in Fig. 3. The k values are proportional to the hydroxide ion concentration regardless of the kind of buffering agent, and the rate constant is expressed by $R=k'\cdot b[OH^-]$. The dependence of the k' value upon the concentration of tartrate and the buffering agents is shown in Table I for barbiturate and *p*-hydroxybenzoate solution and in Fig. 4 for glycine solution. The rate

error may be greater. In Fig. 6, the k values are plotted against the hydrogen ion concentration. At a given concentration of tartrate, the rate constant decreases with rise of pH value. The influence of tartrate ions is shown in Fig. 7. (see Discussion). The influence of the buffer and that of the ionic strength are tabulated in Table II. The k values do not appear to be affected significantly by these factors. On the other hand, the rate increases linearly with an increase in the concentration of glycine, as Fig. 8 shows. The temperature dependence of k, which is illustrated in Fig. 9, indicates that the Arrehenius activation energy is 19.2 kcal. per mol. in a tartrate solution, with or without barbiturate, and 24.7 kcal. per mol. in the presence of glycine.

Discussion

The kinetics of the exchange of the indium EDTA-OH complex is quite different from that of the indium EDTA, gallium EDTA or gallium EDTA-OH complex. In neutral solutions, the last three undergo isotopic exchange at an immeasurably slow rate, while the rate for the first-mentioned complex is measurable, although very small as compared with that in an acid or a basic solution. In basic solutions, k is proportional to the hydroxide ion concentration regardless of the kind of buffering agent used (see Table III).

The uncomplexed indium (initially non-radioactive) is present in solutions of a pH more than 4 in the form of a tartrate complex. However, the state of this indium species does not appear to be important in discussing the reaction mechanism because the exchange rate, R, is independent of the concentration of uncomplexed indium.

Exchange in Basic Media. — The indium EDTA-OH has a co-ordinated water, and the dissociation constant to give a proton is 3.6×10^{-6} at 25°C and 5.0×10^{-6} at 40°C. Hence, in basic solutions of pH higher than 8, most of the complex is present in the form of

TABLE III. COMPARISON OF KINETIC DATA FOR INDIUM EDTA AND EDTA-OH COMPLEX AT 25°C

Media		In-EDTA	In-EDTA-OH
	R	$k' \cdot b \cdot [H^+]^3$	$k' \cdot b \cdot [H^+]^1$
Acid	k'	4.3×10 l³/mol³/sec.	1.0×10^{-2} l./mol./sec.

	E_A	25 kcal./mol.	25 kcal./mol.

For simplicity values under representative conditions are given. Details of the experimental conditions are seen in other tables and figures.

hydroxo complex $[InZ \cdot OH]^-$. Since the exchange rate constant, k, is little affected by buffering agents with different structures, such as barbiturate, *p*-hydroxybenzoate and ammonia, the exchange in solutions containing these buffers appears to involve the exchange of the hydroxo complex. Thus, the exchange seems to proceed as follows:

$$[*InZ \cdot OH]^- + OH^- \rightleftarrows [*InZ \cdot O]^{2-} + H_2O$$

(equilibrium to form a conjugate base)

$$[*InZ \cdot O]^{2-} \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} [*InO \cdot aq.]^+ + Z^{3-}$$

$$\uparrow\downarrow$$

$$[In \cdot tart_x]^n$$

(rapid exchange of In)

These equations can be simplified as follows:

$$[*InZ \cdot O]^{2-} + [In \cdot tart_x]^n \underset{\text{fast}}{\overset{\text{slow}}{\rightleftharpoons}} [InZ \cdot O]^{2-} + [*In \cdot tart_x]^n$$

Such processes can be alternatively expressed in a somewhat different way as follows:

$$[*InZ \cdot OH]^- + OH^- \rightarrow [*InZ \cdot (OH)_2]^{2-}$$

(attack with hydroxide ions as the rate-determining step)

$$[*InZ \cdot (OH)_2]^{2-} + [In \cdot tart_x]^n \rightleftarrows [InZ \cdot (OH)_2]^{2-} + [*In \cdot tart_x]^n$$

(fast exchange)

Recently, Hoard, Smith and Lind[4] suggested that EDTA complexes of such tervalent metal ions as aluminum, chromium and iron have co-ordination number 7 in the crystalline state. Generally, EDTA–OH forms very similar complexes to EDTA with tervalent metal ions, so that it would not be unreasonable to assume a process involving the attack with hydroxide ions to form an intermediate with co-ordination number 7.

The formation of such an intermediate can also be postulated when it is assumed that the indium EDTA–OH complex has one other mole of co-ordinated water in an aqueous solution. The dissociation constant to give second proton would be so small as compared with that for the first proton that a labile dihydroxo complex is present only as an intermediate state in strongly basic solutions.

$$[*InZ \cdot (OH_2)_2] \rightleftarrows [*InZ \cdot OH_2 \cdot OH]^- + H^+$$

(dissociation of the first proton)

$$[*InZ \cdot OH_2 \cdot OH]^- + OH^- \rightleftarrows [InZ \cdot (OH)_2]^{2-} + H_2O$$

(equilibrium to form a labile dihydroxo complex (conjugate base) as a reaction intermediate)

Nevertheless, nothing decisive can be stated as to the validity of one of the alternative expressions.

Amidst other buffering agents, glycine increases the rate to a marked extent and k' is proportional to the glycine concentration. Such an observation suggests that the reaction mechanism is different from that mentioned above. Acceleration of the exchange reaction by glycine is also seen in the case of the indium EDTA complex, which gives quite different kinetics in the presence and in the absence of glycine.[3] The co-ordinated water in the $[InY \cdot OH_2]^-$ complex is rather easily replaced by other ligands, including halogens and ammonia. In a very similar complex, $[InZ \cdot OH_2]$, the water could also be replaced (although with more difficulty) and the following equilibrium is very likely established in aqueous solutions:

$$[*InZ \cdot OH_2] + NH_2CH_2CO_2H \rightleftarrows [*InZ \cdot NH_2CH_2CO_2H] + H_2O$$

4) J. L. Hoard, G. S. Smith and M. Lind, "Advances in the Chemistry of the Co-ordination Compounds," Ed. by S. Kirschner, McMillan Co., New York (1961), p. 296.

With rise of the pH value, the co-ordinated glycine will liberate a proton to give a complex anion, $[^*InZ\cdot NH_2CH_2CO_2]^-$, which predominates in the given pH region. This anionic complex would interact with hydroxide ions to give a conjugate base, and the exchange reaction would involve a dissociation of the conjugate base.

$$[^*InZ\cdot NH_2CH_2CO_2]^- + OH^- \rightleftarrows [^*InZ\cdot NHCH_2CO_2]^{2-} + H_2O$$

(equilibrium to form a conjugate base)

$$[^*InZ\cdot NHCH_2CO_2]^{2-} + [In\cdot tart_x]^n \overset{\text{slow}}{\underset{\text{fast}}{\rightleftarrows}} [InZ\cdot NHCH_2CO_2]^{2-} + [^*In\cdot tart_x]^n$$

The alternative expression, involving an intermediate with co-ordination number 7 can be similarly written.

Exchange in Neutral Solution. — In the pH region from 4 to 7, the rate constant is much less affected by the pH. In more acid solutions, k values are proportional to the hydrogen ion concentration;[1] this effect is observed at pH below 5. In the acid region, the rate increases in the presence of such acidic radicals as citrate and acetate, and a mechanism involving the replacement of the co-ordinated water by an acid radical was postulated.[1] In the pH region from 5 to 8, the dissociation of co-ordinated water is appreciable, and the effective concentration of the aquo indium EDTA-OH complex $[InZ\cdot OH_2]$ would be decreased to decrease the b value. If the observed k values were corrected on the basis of the effective b values calculated from the dissociation constant, the curves would be as those indicated by broken lines in Fig. 6; i. e., k is independent of the pH at a given concentration of tartrate.

The k vs. tartrate ($C_4H_4O_6^{2-}$, written as "tart" henceforth) concentration curve in Fig. 7 indicates that the corrected k value is proportional to the concentration of tartrate, regardless of the pH. Since the presence of such buffering agents as barbiturate, *p*-hydroxybenzoate and azide (except glycine) does not affect the k value, the replacement of co-ordinated water by tartrate could play an important role in exchange the mechanisms.

$$[^*InZ\cdot OH_2] + tart^{2-} \rightleftarrows [^*InZ\cdot tart]^{2-} + H_2O$$

(equilibrium to form a mixed complex)

If such species underwent isotopic exchange with uncomplexed indium at a measurable rate, the kinetics would be satisfactorily accounted for.

$$[^*InZ\cdot tart]^{2-} + [In\cdot tart_x]^n \overset{\text{slow}}{\underset{\text{fast}}{\rightleftarrows}} [InZ\cdot tart]^{2-} + [^*In\cdot tart_x]^n$$

Generally co-ordinated hydroxide ions are replaced by other ligands with much more difficulty than co-ordinated water, so that the formation of the tartrate complex $[^*InZ\cdot tart]^{2-}$ from the hydroxo complex would not be significant. Hence, the correction of the observed k values on the basis of the effective b values at pH 5 to 8 (broken lines in Fig. 6) would be legitimate. With rise of the pH value, such a species is overwhelmed by the hydroxo complex $[InZ\cdot OH]^-$, which undergoes isotopic exchange at a greater rate through the mechanism mentioned before. Throughout the whole pH range, barbiturate and *p*-hydroxybenzoate do not seem to participate in the exchange reaction.

Acceleration of the exchange reaction by glycine is also observed in the neutral region from pH 5 to 8. Since the rate is independent of the pH in this region, even in the presence of glycine and most glycine is present in an un-ionized form, the formula $[^*InZ\cdot NH_2CH_2\cdot CO_2H]$ would be feasible as an intermediate.

$$[^*InZ\cdot NH_2CH_2CO_2H] + [In\ tart_x]^n \overset{\text{slow}}{\underset{\text{fast}}{\rightleftarrows}} [InZ\cdot NH_2CH_2CO_2H] + [^*In\cdot tart_x]^n$$

With rise of the pH value, the co-ordinated glycine would lose a proton to give an anionic complex, $[InZ\cdot NH_2CH_2CO_2]^-$, which undergoes isotopic exchange through the formation of the conjugate base at a greater rate, as mentioned before.

As has been discussed in this and the preceding paper, the indium EDTA-OH complex is more labile than the indium EDTA complex, as Table III shows. No such difference was observed between the corresponding gallium complexes,[2] which give kinetics similar to that of the indium EDTA complex. Hence, the lability of the indium EDTA-OH complex is rather exceptional amidst similar complexes.

Summary

1) The kinetics of the isotopic exchange of the indium EDTA-OH complex with uncomplexed indium has been studied in neutral and basic solutions, with ^{114m}In as tracer.

2) The exchange rate is independent of the concentration of uncomplexed indium and proportional to that of the EDTA-OH complex, giving the relationship $R=k\cdot b$.

3) In a basic solution buffered by barbiturate, *p*-hydroxybenzoate, or ammonia, the k

value is proportional to the concentration of hydroxide ions and is little affected by the buffer. The Arrhenius activation energy is 25 kcal. per mol., and a mechanism involving the dissociation of hydroxo complex $[InZ \cdot OH]^-$ as the rate-determining step was postulated. The exchange is accelerated by glycine.

4) In a neutral solution with a pH value below 8, the rate is small but measurable. It is independent of the pH value and is little affected by barbiturate or *p*-hydroxybenzoate, and the activation energy is 19 kcal. per mol. The dissociation of a mixed complex containing tartrate as one of the ligands, $[InZ \cdot C_4H_4O_6]^{2-}$, appears to be the rate-determining step. Glycine accelerates the exchange reaction.

5) The feature of the isotopic exchange of the indium EDTA–OH complex is quite different from that of the EDTA complex; the former seems to be much more labile than the latter and similar gallium complexes.

Magnetic Study of Nitro Group

By S. SRIRAMAN, R. SABESAN and S. SRINIVASAN

(Received April 20, 1963)

Introduction of a substituent group for hydrogen in a benzene ring generally resulted a small but detectable change in various physical constants. But the nature of the effect depended much on the position of the group in the ring, and also on the substituting group itself. When a large group like that of the nitro group is substituted in the benzene ring, such changes are found to be large and detectable. Certain anomalous effects were also noticed by different workers, in the case of nitro group. Abe[1] found that *m*-dinitrobenzene showed the maximum absorption band at shorter wavelengths than nitrobenzene. Such a result was also confirmed by Semba.[2] He also measured the equilibrium constants of isomeric nitroanilines and found that the meta compound had a very high value compared with other two isomers. These differences were attributed to the meta-directing property of the nitro group. The resonance structures of the nitro group was also found to contribute largely to the observed changes in the ultraviolet spectrum. Jatkar and Phansalker[3] from their measurements of dipole moments of the nitro-substituted compounds confirmed that the meta directing inductive effect of the nitro group had a considerable influence on the dipole moment.

Bhatnagar and his collaborators[4] detected a variation in the diamagnetic susceptibility depending on the position of the substituting group in the benzene ring, ortho showing a maximum value. Later Cabrera and Fahlenbrach[5] found that in nitrotoluenes the meta compound had a higher value of χ_M than the other two isomers. French,[6] after studying a large number of compounds, noticed an anomalous effect in the case of nitro-substituted compounds. This anomaly was explained by Baddar and Mikhail[7] and later by Mikhail[8], as arising from the contribution of the quinonoid structures of the nitro group to the normal structure. The contribution of the nitro group to the diamagnetic susceptibility was found to vary from 1.45 to 11.74 by Shah et al.[9] But Sriraman and Sabesan[10] found that the behavior of the nitro group, when substituted in the benzene ring, fell generally in line with the observations made by Mikhail,[8] and no serious irregularities were noticed by them. The large changes reported by Shah et al.[9] could not be explained

* The symbols used in column 4 are based on Yang's[16] paper.

satisfactorily, and therefore it was believed that a careful examination of the diamagnetic contribution of the nitro group, taking some more compounds also, might be of interest.

Experimental

The investigations were carried out with a Curie balance.[11] A. R. benzene dried over sodium and distilled over phosphorus pentoxide was used as standard. Its specific susceptibility was taken as -0.702×10^{-6} units. Liquids and solids were purified by standard methods and the purification was continued till specimens of constant susceptibility were obtained. The purified substance was filled in thin-walled glass bulbs, the remaining portion of the bulb being completely evacuated. The solids are powdered and then filled up in the bulb to eliminate orientation effects.

Results

Magnetic susceptibilities of seventeen substances are given in Table I. The observed values are the mean of eight very closely agreeing values, the maximum deviation being shown in the same table. The last column refers to the χ_M values recorded by other workers and is given for the sake of comparison. The theoretical values were calculated by taking atomic and bond values as given by Ingold.[12]

Discussion

In all the nitro compounds studied it is seen that in all cases the meta compound has a higher χ_M value than the other two isomers. Such a result is normally expected as already explained by Sriraman and Sabesan[10]. Also the difference between the experimental values of χ_M and theoretically calculated values are less than two units in most cases and for only a few compounds $\Delta\chi_M$ exceeds three units. This definitely shows that there is no large irregularity in the behavior of the nitrosubstituted compounds and these small differences are explicable by taking into account the inductive and resonance effects[10].

The Contribution of the Group $(NO_2)^{1+}$.— Sriraman and Shanmugasundaram[15] calculated the contribution of the $(NH_2)^{1+}$ value to the diamagnetic susceptibility by treating the shared electrons of the covalent bond as ionic as suggested by Yang[16]. A similar attempt is made to calculate the contribution of $(NO_2)^{1+}$ by taking Angus' modified ionic value[17].

It has been found that the contribution of $(NO_2)^{1+}$ group to the diamagnetic susceptibility, when substituted in the meta position is about eight units and the average contribution is 6.7 units. The atomic contribution of nitro group in organic nitrates was found to be 5.6 by Voiget[18] but in organic nitro compounds he obtained a value of 8.7 units. But the present value of 6.7 units (on the average) for $(NO_2)^{1+}$ is in accordance with the value given by Yang[16] (6.57 units).

The χ_M value of CH_2 when it combined with O^{2-} was taken by Yang as 10.78 units. It is worthy to note that in our present investigation, (χ_M nitroanisole $-\chi_M$ nitrophenol) in ortho and para isomeric compounds are 11.01 and 10.64 respectively, making an average of 10.83, a value very similar to the one obtained by Yang. This arguement cannot be substantiated at this stage until more work is done in this direction.

Summary

The magnetic susceptibilities of several disubstituted aromatic nitro compounds were determined by Curie retorsion method. The contribution of the $(NO_2)^{1+}$ to the diamagnetic susceptibility was evaluated by the method suggested by Yang, taking Angus' modified ionic values.

The Crystal Structure of trans-Dichloro-bisethylenediamine-cobalt(III) Nitrate, $[Co\,en_2\,Cl_2]NO_3$

By Shun'ichiro Ooi and Hisao Kuroya

(Received April 1, 1963)

In the last decade, we have carried out the X-ray crystallographic determination of the structures of various *trans*-dihalogeno-bisethylenediaminemetal(III) complexes ("ethylenediamine-praseo salts") having the general formula $[M\,en_2\,X_2]\,Y$, where M is Co or Cr, and X is Cl or Br.[1-3] It has thus been proved that the complex ion is of the centrosymmetrical configuration; namely, i) the two halogen atoms are coordinated to the central metal ion, M, definitely in the trans positions; ii) the ethylenediamine molecule is of the puckered or "gauche-type" structure, which possesses only a two-fold axis of rotation in symmetry, giving a molecular disymmetry to the ligand molecule fixed to M, while, however, iii) the two ethylenediamine molecules are constantly present in the form of an enantiomorphric pair. With the purpose of seeing if any structual changes may be brought to the complex ion in the case of the replacement of Y by the nitrate ion, an attempt has now been made to determine the crystal structure of ethylenediamine-praseo nitrate, $[Co\,en_2\,Cl_2]\,NO_3$. It is well-known that this compound is one of the few slightly soluble nitrates. We have been interested also in this peculiarity.

Experimental

The crystals of $[Co\,en_2\,Cl_2]\,NO_3$ were obtained by slowly adding a dilute solution of nitric acid to an aqueous solution of $[Co\,en_2\,Cl_2]\,Cl\cdot HCl\cdot 2H_2O$. These crystals are green scale-like tablets and are slightly soluble in water. They belong to the monoclinic system, and the unit cell dimensions were found to be:

$a=6.33$ Å, $b=9.25$ Å, $c=10.62$ Å, $\beta=114.5$

The space group was determined to be $P2_1/c$ from the systematic extinctions. The unit cell contains two formula units ($\rho_{obs}=1.75$ and $\rho_{calcd}=1.72$ g. cm^{-3}). Ni$K\alpha$ radiation (1.659 Å) was used, and a multiple film technique was employed in taking Weissenberg photographs about the principal axes. All intensities were measured visually by comparison with a standard scale. The usual correction factors were applied to the observed intensities, and a set of relative $|F_o|$ values was obtained.

Determination of the Structure

In the determination of the structure, $(h\,0\,l)$ and $(0\,k\,l)$ reflections on the Weissenberg photographs were used. As the unit cell contains two formula units, the cobalt atoms and the nitrogen atoms of the nitrate ions must occupy two among the four sets of two-fold special positions, all having point symmetry $\bar{1}$; the cobalt atoms may therefore be placed arbitrarily at the sets of (0 0 0) and (0 1/2 1/2). On the other hand, the nitrate ions are to be located centrosymmetrically on one of the other three sets; in short, a nitrate ion should be in some disordered arrangement, the central nitrogen atom lying on or around the special position referred to above, since the ion has no center of symmetry in its well-known, normal form. Similar disordered structures of the nitrate ion were found in the crystals of bis(glutaronitrilo) and bis(adiponitrilo)copper(I) nitrates and in bis(dimethylglyoximato)-diamminecobalt(III) nitrate.[4-6]

The Patterson projections, $P(UW)$ and $P(VW)$, gave fairly simple patterns, and the approximate position of the chlorine atom could be derived without any trouble. Then, on the basis of the coordinates of cobalt and chlorine atoms only, the structure amplitudes were calculated; in turn, these were found rather consistent with the observed values. Consequently, the signs of all but weak reflections were assumed to be available. From the first Fourier projections, $\rho(XZ)$ and $\rho(YZ)$, we could obtain the approximate position of the ethylenediamine molecule, but not that of the nitrate ion. At this stage, our attempt to pack together the complex cations and nitrate anions, with a view of the $\rho(YZ)$, led us to

the deduction that the center of the nitrate ion lies close to (0 1/2 0).

Fourier refinements were made as usual. In the case of the a-axis projection, residual electron density due to other components than the complex ion gave a diffuse peak around (X 1/2 0). On the other hand, in the case of the b-axis projection, the residual electron density showed up as a peak around (0 Y 0); however, because of the overlapping of the nitrate ion with the complex ion, the exact coordinates of the nitrate ion could not be elucidated from the Fourier peak.

Taking account of the shape of peak around (X 1/2 0) in the a-axis projection, a model of the disordered structure of the nitrate ion was presented; in this model the ion occupies two different positions in the neighborhood of (0 1/2 0), each of them having a weight of one-half, as shown in Figs. 1, 2 and 3; in these figures, the positions of the two nitrate ions of different orientations are indicated by the

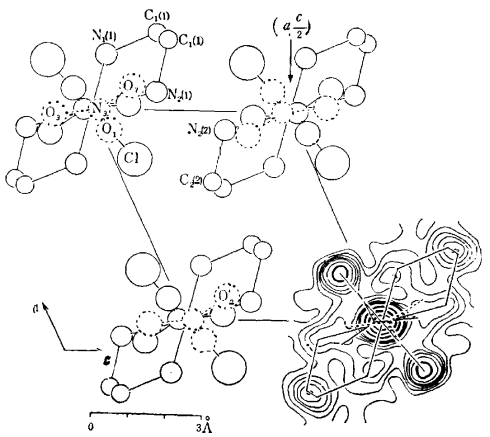

Fig. 1. Structure and electron density projected along b-axis. Contours are drawn at intervals of 2 and 10 e. Å^{-2}, starting at two and twenty electron levels for thin and thick lines, respectively.

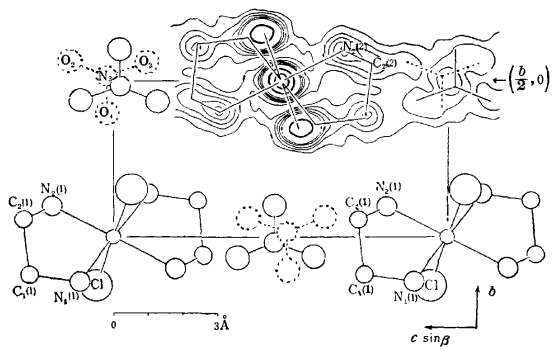

Fig. 2. Structure and electron density projected along a-axis. Contours are drawn in the same manner as Fig. 1.

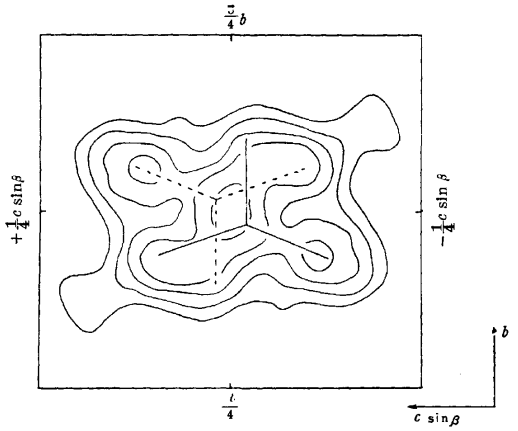

Fig. 3. Residual electron density due to a disordered structure of the nitrate ion projected along a-axis. Contours are drawn at intervals of 1 e. Å^{-2}, starting at two electron level.

dotted and full lines, being related by $\bar{1}$ to one another. Thus, the nitrate ion may take up one of these positions in an asymmetric unit, while the equivalent or the opposite position in any other asymmetric unit may be assumed with quite equal probability; the probability of finding one orientation of the nitrate ion in an asymmetric unit is equal to that of finding another. No unreasonable interatomic distances have been detected in this structure. Possibly, there might be another plausible model which could account for the peak mentioned above. However, no further study was attempted, since the object of the present work was mainly to study the stereochemical configuration of the complex ion.

Table I. Atomic coordinates

Atom	x/a	y/b	z/c
Co	0	0	0
Cl	−0.235	−0.149	0.052
N_1	0.260	−0.133	0.100
N_2	0.083	0.096	0.183
C_1	0.358	−0.112	0.250
C_2	0.322	0.055	0.270
N_3	0.000	0.508	0.017
O_1	−0.100	0.399	0.021
O_2	0.110	0.563	0.129
O_3	−0.023	0.562	−0.096

The atomic coordinates are given in Table I; they gave reliability indices of 0.157 and 0.148 for (0 k l) and (h 0 l) respectively, with the exception of the (1 0 0) reflection, which would be influenced critically by, for instance, extinction effect. Isotropic temperature factors, 4.0 Å^2 for (0 k l) and 3.5 Å^2 for (h 0 l), were used in usual manner.

Results

The geometry of the complex ion herein determined is not significantly different from those reported before. The cobalt atom is surrounded by the four nitrogen atoms of the two ethylenediamine molecules and the two chlorine atoms at the trans-position, forming an octahedral configuration elongated in the Cl–Co–Cl direction. The two ethylenediamine molecules are of the gauche type and are enantiomorphous with one another. The ion has the approximate symmetry of C_{2h}, the two-fold axis of which passes through the central metal atom and bisects the C–C bonds of the ethylenediamine molecules coordinated.

The interatomic distances and bond angles are listed in Table III. The bond length of Co–Cl, 2.26 Å, is a little shorter than the value, 2.33 Å, found in $[Co\,en_2\,Cl_2]\,Cl\cdot HCl\cdot 2H_2O$[1] and $[Co(NH_3)_3H_2O\,Cl_2]\,Cl$,[7] but it ts comparable to that of 2.27 Å in $[Co(NH_3)_5Cl]\,Cl_2$[8] and that of 2.29 Å in $[Co\,pn_2\,Cl_2]\,Cl\cdot HCl\cdot 2H_2O$.[9] The nitrate ion appears to deviate

from D_{3h} symmetry, but our measurements are not accurate enough for the shape of the ion to be discussed in detail. The short distances, 2.77, 2.76, 3.02 and 3.07 Å, between the oxygen atoms of the nitrate ion and the nitrogen atoms of the ethylenediamine molecules may be indicative of the presence of hydrogen bonds of the N–H···O type between them.

Recently, a new type of coordination of the ethylenediamine molecule was reported on the crystal of [Hg en Cl_2],[10] where the ethylenediamine molecule is coordinatively bound to two different Hg atoms with its $-NH_2$ radicals in the trans form, thereby forming a $(-Hg-en-)_\infty$ chain, to which the insolubility of this compound in water and alcohol could more or less be attributed. However, as is evident from the findings presented above, no remarkable structual peculiarity to which the slight solubility of the ethylenediamine-praseo nitrate would be even partially due, was found in the present work.

Summary

The crystal structure of *trans*-[Co en_2 Cl_2] · NO_3 has been determined by means of X-ray analysis. The space group is $P2_1/c$ with two formula units in a cell of the dimensions of $a=6.33$ Å, $b=9.25$ Å, $c=10.62$ Å, and $\beta=114.5°$. The crystal is composed of [Co en_2 Cl_2]$^+$ and NO_3^-. The geometry of the complex ion herein determined is not significantly different from those reported before. It has been proposed that the nitrate ion is in a disordered arrangement.

Part of the cost of this investigation was defrayed from the Fund for Scientific Research Expenditure of the Ministry of Education, to which the authors' thanks are due.

*The Crystal Structure of Tetramethylenediammonium Chloride**

By Tamaichi ASHIDA and Sakutaro HIROKAWA

(Received May 11, 1963)

There have been fewer published structural investigations of tetramethylenediamine (TDA) in the crystals than of the homologous compounds, ethylenediamine (EDA)[1-5] and hexamethylenediamine,[6-8] both of which are the nearest to TDA in the even-membered series of polymethylenediamines. Recently, the present authors reported a gauche-form of the TDA ion in the crystal of its adipate,[9,10]

though they had expected a planar (trans-) configuration of the ion. Although no investigations so far published have shown the planar configuration of TDA in the crystals, a planar configuration as the cases of EDA[1] and hexamethylenediamine[6-8] may be expected for TDA. Thus, a trans-gauche stereoisomerism like that of EDA is possible for TDA. Tetramethylenediammonium chloride (TDA · Cl) was chosen to be studied in order to elucidate this aspect of the problem. The structural analysis of TDA·Cl may be interesting because the crystal structures of both ethylenediammonium chloride (EDA·Cl)[1] and hexamethylenediammonium chloride[6] have been reported. The present study will show a crystal structure analogous to that of EDA·Cl, and some comparisons between the present crystal and that of EDA·Cl will be made.

Experimental

Tetramethylenediammonium chloride, $H_3N(CH_2)_4NH_3 \cdot 2Cl$, was obtained as white precipitates from ethanol solutions of the components in a stoichiometric molar ratio. The crystals were grown from ethanol-water solutions. The three principal axes of the crystals were designated by referring to those of EDA·Cl.[1] Some of these crystals were obtained as needles elongated along the b-axis, and others, as plates, the main face being (1 0 0). A perfect cleavage perpendicular to the c-axis was found. The crystal belongs to the monoclinic system, and the unit cell dimensions were obtained from the Weissenberg photographs of $(h\,0\,l)$ and $(h\,k\,0)$ by overlapping the powder patterns of aluminum as a standard; they are:

$a=10.73\pm0.01$ Å $\quad b=8.35\pm0.01$ Å

$c=4.60\pm0.01$ Å $\quad \beta=92.5\pm0.3°$

The space group was found to be $P2_1/a$ from the systematic absences of the following spectra: $(0\,k\,0)$ for $k=2n+1$, and $(h\,0\,l)$ for $h=2n+1$. The density, 1.30 g.cm^{-3}, observed by the flotation method corresponds to two formula units in a unit cell; the calculated density is 1.30 g.cm^{-3}.

Weissenberg photographs were taken around the b- and c-axes using CuK_α radiation. The multiple-film technique was used, and the intensities of $(h\,0\,l)$, $(h\,k\,0)$ and a part of the $(h\,k\,1)$ reflections were estimated visually, comparing them with a standard scale. Corrections for polarization and Lorentz factors were made. The linear absorption coefficient of the crystal for CuK_α is rather large ($\mu=64.0$ cm^{-1}). However, the shapes of the crystals used in the experiments were irregular, and no absorption corrections were made.

Structure Determination

Since the crystal belongs to the $P2_1/a$ space group and since the number of formula units in the unit cell is two, the TDA ion has to occupy a center of symmetry of the unit cell. The position of the chloride ion was determined from the projections of the Patterson function along the b- and c-axes. The projections of the electron-density functions along the two principal axes were synthesized by using the structure factors whose phases were assigned by the coordinates of the chloride ion. The maps thus obtained showed the positions of the carbon and nitrogen atoms. The coordinates of the atoms were then refined by successive (F_o-F_c) syntheses. In the course of these refinements, it was found that the contributions of the hydrogen atoms to the structure factors were not negligible; the number of electrons which belong to the hydrogen atoms amount to 16% of the total number of electrons in the crystal. Then, the coordinates of all the hydrogen atoms were calculated geometrically, using the coordinates of the heavier atoms, and these calculations were confirmed on the $(\rho_o-\rho_c)$ maps. These hydrogen atoms were used in the further refinements of the structures, and the *R* factors of the two zones decreased by about 0.02. In these procedures, it was found that if the hydrogen atoms lying near the heavier atoms were disregarded, the coordinates of the heavier atoms cannot be improved by (F_o-F_c) syntheses. In fact, significant shifts in the positions of the atoms, especially carbon and nitrogen, were observed when the hydrogen atoms were included in the calculations. The

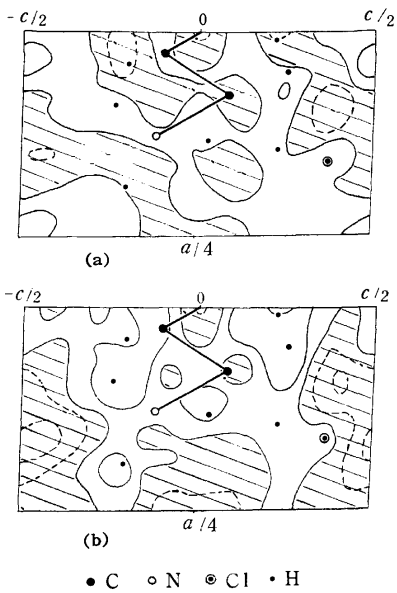

Fig. 1. Final $(\rho_o-\rho_c)$ projected on (0 1 0). (a): ρ_c includes all the atoms; (b): ρ_c does not include any hydrogen atoms. Contours at intervals of 0.4 e. Å^{-2}, broken lines represent negative contours, and negative areas are shaded.

final $(\rho_o-\rho_c)$ maps of $(h\,0\,l)$ are shown in Fig. 1, where significant changes due to the inclusion or exclusion of the hydrogen atoms are observed, not only at the positions of the hydrogen atoms but almost everywhere.

The final atomic coordinates and the temperature factors of the heavier atoms are listed in Table I. Each absolute value of the temperature factors listed in Table I may not have a rigid meaning, however, because no absorption corrections for the intensities were made. The comparisons between the observed and calculated structure factors are shown in Table II. The final R factors are 0.058 and 0.075 respectively for $(h\,0\,l)$ and $(h\,k\,0)$, excluding a few reflections which showed marked

extinction effects (these are shown with asterisks in Table II).

Discussion of the Results

Some of the important interatomic distances and bond angles in this crystal are shown in Table III and in Fig. 2. Because the TDA ion

occupies a center of symmetry, the four carbon atoms are completely coplanar. The terminal N atoms are also in the plane and join with the carbon atoms to make a coplanar zigzag chain; the displacement of the N atom from the plane of the four carbon atoms is found to be less than 0.001 Å. Thus, in the crystals, the TDA ion was found to have either a trans- or gauche-configuration, depending on the structures of the crystals.

The crystal structure projected on the (001) and the (0 1 0) planes is shown in Figs. 3 and 4. The nitrogen atom has four nearest neighbors among the chloride ions (Cl(1), Cl(2), Cl(3) and Cl(4) in Figs. 3 and 4), the N-Cl distances being 3.19, 3.28, 3.28 and 3.28Å respectively. Such N-Cl lengths are comparable to the values of 3.10~3.30Å found in EDA·Cl,[10] hexamethylenediammonium chloride[6] and several other crystals.[11,12] These four short contacts correspond to the N-H···Cl hydrogen bond distance. However, three of these four contacts, excluding the 'bifurcated' type, may be hydrogen bonds. The C(1)-N-Cl(4) angle (164.4°) is so large that N-Cl(4) may be excluded. The $(\rho_o-\rho_c)$ maps seem to support this view. In the $(\rho_o-\rho_c)$ projected on the

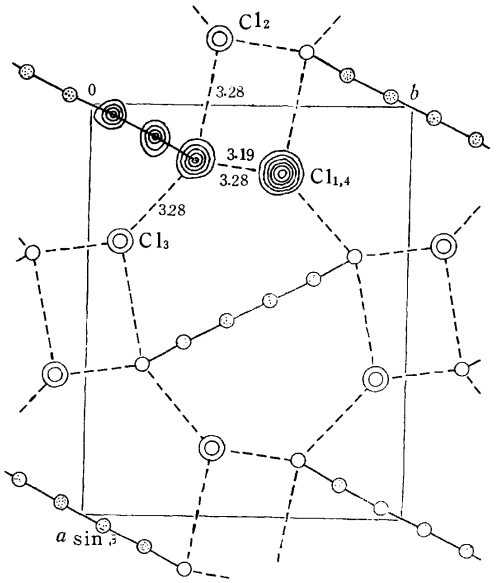

Fig. 3. The structure of TDA·Cl projected on (0 0 1). Broken lines represent hydrogen bonds. In a part of the electron-density function, contours are drawn at an arbitrary equal interval, except at Cl^-, where an interval is three times of that for lighter atoms.

(0 0 1) plane, Cl(1) and Cl(4) occupy the same position, and hydrogen atoms were found around the nitrogen atom pointing to Cl(1) or Cl(4), Cl(2) and Cl(3) respectively. On

12) W. Fuller, *J. Phys. Chem.*, **63**, 1705 (1959).

the other hand, in the $(\rho_o - \rho_c)$ maps shown in Fig. 1, no hydrogen atom can be found between N and Cl(4), although in the three other short contacts hydrogen atoms are found to be present. Thus, Cl(1), Cl(2) and Cl(3) are considered as being hydrogen-bonded from the nitrogen atom. Another short contact between N and Cl(4) may be ionic in character; similar short contacts which are not hydrogen bonds have been reported in triazolo-pyrimidine hydrochloride, 3.29 and 3.31 Å.[13] Thus, in this crystal, the three N-H···Cl hydrogen bonds link the organic ions and the chloride ions and make two-dimensional, infinite networks parallel to the (0 0 1) plane. The forces which combine these layers along the c-axis may be van der Waals forces, together with electrostatic forces, if any. These facts explain the perfect cleavage parallel to the (0 0 1) plane.

A Comparison between TDA·Cl and EDA·Cl. —It may be worthwhile to make some comparisons between the structure of this crystal and that of EDA·Cl.[1] The similarity between these two crystals may be interesting if we consider the differences in the dimensions of the organic ions in the two crystals. There are considerable differences between the crystal structure of TDA·Cl and that of hexamethylenediammonium chloide, though the dimensions of the two organic ions differ from each other in just the same way as has been described above.

TABLE IV. CRYSTALLOGRAPHIC DATA OF EDA · Cl AND TDA · Cl

* Symmetry of the organic ion
** Cleavage parallel to

The crystallographic data of both EDA·Cl and TDA·Cl crystals are listed in Table IV. The a- and b-axes of TDA·Cl are a little longer than those of EDA·Cl because of the necessity to accommodate a larger organic ion. Only the crystal habits are different from each other.

The modes of packing of the ions in the crystals or of the hydrogen bonds are said to be, in effect, the same. This was one of the reasons why the possibility of a hydrogen bond between the nitrogen atom and Cl(4) was rejected in the present crystal. These situations may be understood if we compare Figs. 3 and 4 of this paper with Figs. 2 and 3 of the paper on EDA·Cl.[1] In Fig. 3 of this paper, if N is taken out and C(1) is changed to N, the figure thus obtained corresponds roughly to the structure of EDA·Cl projected on the (0 0 1) plane shown in Fig. 2 of Ref. 1. The coordinates of the atoms in both crystals (by Å unit) are listed in Table V for the sake of comparison. The inversions of the signs of the *z*-coordinates of the organic ions are inevitable in order to obtain the same packing. By considering these coordinates of the atoms, the differences in the unit cell dimensions of the two crystals may be elucidated. The equations of the planes of the zigzag chains of the organic ions are:

$$0.901X - 0.434Y + 0.030Z = 0$$

and

$$0.895X - 0.448Y - 0.020Z = 0$$

for TDA·Cl and EDA·Cl respectively, where $X = ax \sin\beta$, $Y = by$, and $Z = cz + ax\cos\beta$. Thus, the orientations of the organic ions to the principal axes are also not very far from each other.

Summary

The crystal structure of tetramethylenediammonium chloride has been determined by the two-dimensional Fourier method. The crystal belongs to the monoclinic system, with $a=10.73$ Å, $b=8.35$ Å, $c=4.60$ Å and $\beta=92.5°$, and the space group is $P2_1/a$. The tetramethylenediammonium ion has been found to possess a center of symmetry of the unit cell, and the carbon and the nitrogen atoms in the ion, make a coplanar (trans-) zigzag chain. Thus, the tetramethylenediammonium ion has been found to have either a trans- or a gauche-configuration, depending on the structures of the crystals. There are four short approaches

13) P. G. Owston and J. M. Rowe, *Acta Cryst.*, **15**, 231 (1962).

between nitrogen and chloride ions with lengths of 3.19～3.28Å ; three of them have been concluded to be hydrogen bonds. These hydrogen bonds make two-dimensional networks of the ions perpendicular to the c-axis. The structure of this crystal is similar to that of ethylenediammonium chloride, and some comparisons between them have been given.

The Effect of Tri-, Tetra-, Penta- and Hexaphosphate on the Crystallization of Strontium Sulfate

By Masaji MIURA, Sadaichi OTANI, Yasuhiro ABE and Chikako FUKUMURA

(Received June 7, 1963)

It is a well-known fact that a very small amount of various condensed phosphates exhibits a striking effect on the stabilization of supersaturated solutions of various inorganic salts, especially those of sparingly soluble calcium salts.[1] In many papers emphasis has been laid on the superior of effect of "hexametaphosphate," a mixture many homologues of polyphosphates, but no work seems to have been done with its individual constituents.

In our previous works,[2,3] the effect of ortho-, pyro-, tri- and trimetaphosphate on the crystallization of strontium sulfate has been investigated in relation to the adsorption of these phosphates on the crystals of strontium sulfate. The purpose of the present work is to study the effect of the higher homologues of polyphosphates, which are the main constituents of the "hexametaphosphate."

Experimental

Radioactive tri-, tetra-, penta- and hexaphosphate were separated by anion-exchange chromatography from a "hexametaphosphate glass" prepared by pyrolysis from a mixture of sodium dihydrogen phosphate and disodium hydrogen phosphate containing ^{32}P.[4] Since these phosphates are gradually hydrolyzed in a solution,[4] all measurements were made with solutions newly prepared and stocked in a cold place. The other reagents used were the same as those used in the previous works.[2,3] The strontium sulfate crystals used as the adsorbent were prepared in a way similar to that used in a previous work,[3] but the crystal size of the product was somewhat larger than that used before.

The effect of the phosphates on the crystallization rate of strontium sulfate was examined by measuring the conductivity decrease in equivalent mixtures of strontium chloride and potassium sulfate solutions containing various amounts of the phosphates. The techniques employed in measuring the conductivity and the adsorption of the phosphates on strontium sulfate have been described in the previous papers.[2,3]

Results and Consideration

The effect of the four kinds of phosphates on the crystallization rate of strontium sulfate is represented by the conductometric data shown in Fig. 1—4. The ordinate of these graphs represents the percentage decrease in the specific conductivity with reference to the total decrease when no phosphate is added.

Figure 5 shows the adsorption isotherms obtained at 25°C and pH 7. This figure shows that the number of moles adsorbed per gram of strontium sulfate decreases with the increase in the chain length of polyphosphate.

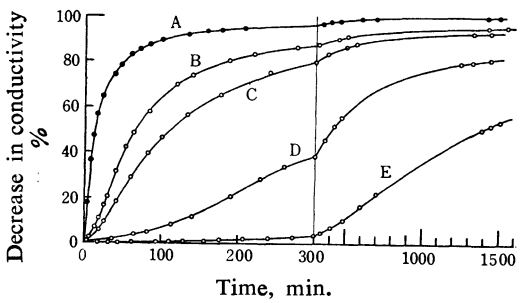

Fig. 1. Decrease in conductivity of 0.01 M $SrSO_4$ solutions containing (A) none, (B) 7×10^{-7}, (C) 1×10^{-6}, (D) 2×10^{-6} and (E) 3×10^{-6} M of triphosphate.

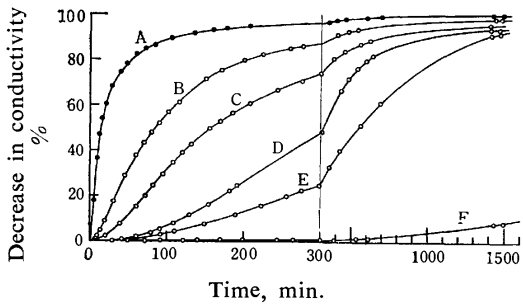

Fig. 3. Decrease in conductivity of 0.01 M $SrSO_4$ solutions containing (A) none, (B) 5×10^{-7}, (C) 7×10^{-7}, (D) 1×10^{-6}, (E) 1.5×10^{-6} and (F) 2×10^{-6} M of pentaphosphate.

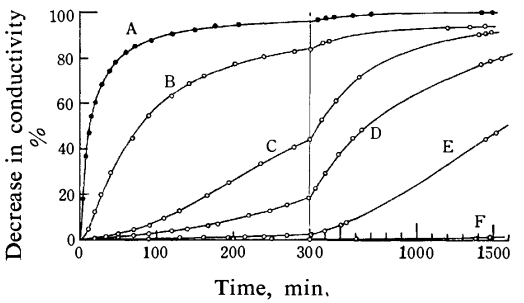

Fig. 4. Decrease in conductivity of 0.01M $SrSO_4$ solutions containing (A) none, (B) 5×10^{-7}, (C) 1×10^{-6}, (D) 1.25×10^{-6}, (E) 1.5×10^{-6} and (F) 2×10^{-6} M of hexaphosphate.

If, however, we represent the same data in terms of the monomer unit, as in Fig. 6, the adsorbed amounts of these phosphates can be illustrated by a common curve almost within the range of experimental error. This fact shows that a tetrahedral PO_4 unit of the polyphosphates adsorbed always occupies, on the average, about the same area of the crystal faces, independent of the chain length of the phosphates examined.

As has been mentioned previously,[3] the average area occupied per triphosphate ion

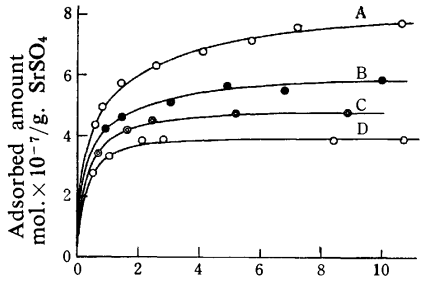

Fig. 5. Adsorption isotherms of tri- (A), tetra- (B), penta- (C) and hexaphosphate (D) at 25°C, pH 7.

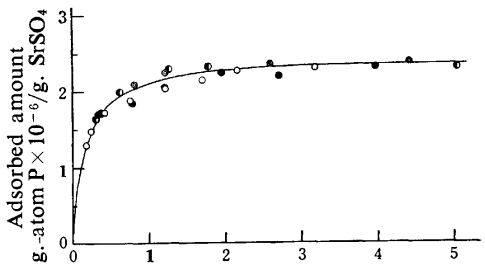

Fig. 6. Adsorption isotherms expressed in terms of the monomer unit.
○ Tri ● Tetra ◎ Penta ◐ Hexa

adsorbed on strontium sulfate is 37Å^2 ; hence, we can estimate the area occupied per PO_4 tetrahedral unit of the phosphates as roughly 12Å^2, independent of their chain length. On the other hand, the areas occupied per ion pair of strontium sulfate on the (1 0 0), (0 1 0) and (0 0 1) faces of its crystal (celestine) were found to be 18.4, 28.7 and 22.4Å^2 respectively.[5] Since the adsorption of phosphates is considered to be caused by some bonding between phosphate anions and Sr^{2+}cations on the crystal face, the above-mentioned data suggest that more than one PO_4 tetrahedral unit may be bound to an Sr^{2+} ion on the crystal faces.

As has been discussed in previous papers,[2,3] the inhibition of the crystallization of strontium sulfate due to the phosphates added may be caused by their adsorption on the crystal nuclei or growing crystals of strontium sulfate. From the similar behavior of the four phosphates in their adsorption on strontium sulfate, their effect on the crystallization rate may be expected to be nearly equivalent in all cases. That this is true may readily be realized if the phosphate concentrations are expressed in monomer units and Figs. 3—6 are then compared with one another. Independent of the

5) S. Otani and M. Miura, *J. Sci. Hiroshima Univ., Ser. A-II*, 27, 11 (1963).

chain length of the phosphates, each monomer exhibits almost the same effect on the crystallization rate. The effects of these phosphates on the habit of the crystals deposited are also similar to one another; spherulites having a nearly spherical shape were obtained from 0.01 M strontium sulfate solutions containing $(5\sim9)\times10^{-6}$ g.-atom P/1. of each phosphate.

In so far as the present work is concerned, "hexametaphosphate" can not be expected to exhibit a far greater effect on the crystallization of strontium sulfate if there is no cooperative effect among the individual constituents.

*The Electronic State and Dipole Moment of Diazine Mono-N-oxide**

By Tanekazu KUBOTA** and Haruyuki WATANABE

(Received June 7, 1963)

In previous studies undertaken as part of a programme of physicochemical investigations of various heterocyclic *N*-oxides, one (T. K.) of the present authors has calculated simple molecular orbitals (SMO) and anti-symmetrized molecular orbitals taking into account configuration interactions (ASMO-CI) to elucidate their electronic structures and electronic spectra.[1,2] These results have been compared with these of some physicochemical experiments, such as electronic spectra, dipole moments, infrared spectra, reactivities, etc. As a result, the following set of parameters have been found to be most reasonable for SMO calculation:[3]

$$\alpha_{N^{\delta+}} = \alpha + 1.6\beta,\ \alpha_{O^{\delta-}} = \alpha + 0.8\beta,\ \rho_{NO} = 1$$

where $\alpha_{N^{\delta+}}$, $\alpha_{O^{\delta-}}$ and α are the Coulomb integrals of nitrogen, oxygen and carbon atoms respectively; β is the usual exchange integral between two carbon atoms in benzene; and ρ_{NO} represents the exchange integral of the N–O bond in the β unit. The exponential decrease of inductive effect due to the $N^{\delta+}$ atom, which is the same form as in Jaffé's procedure,[4] was taken into account:

$$\text{Inductive effect} = (1/3)^n \times 1.6\beta$$

where n is the number of bonds between the nitrogen atom and the carbon atom in question.

Further, it was shown that the SMO's and ASMO-CI's calculated under these conditions can reasonably explain the above physicochemical and chemical properties of basic such heterocyclic *N*-oxides[1,2,5] as pyridine *N*-oxide, and quinoline *N*-oxide. Now, as a further extension of these studies, the present authors have investigated the electronic state and the dipole moments of three diazine mono-*N*-oxides, which are convenient in confirming the adequacy of these parameters, from experimental and theoretical (SMO calculation under the conditions described above) points of view.

Experimental

The measurements of dipole moments were carried out at 25°C on dilute solutions in benzene. The dielectric constants were measured by means of a heterodyne beat apparatus provided with a platinum cell.[6] For each solute, determinations were made on solutions of four different concentrations, appropriately chosen below 3 weight per cent. The graphical plot of the dielectric constant, as well as the density of solutions against the concentration in weight per cent, gave a linear dependence within the range of experimental error. The slopes of these straight lines were evaluated by the least-squares method. The molar polarization of the solute was calculated by a method similar to that introduced by Halverstadt and Kumler[7]; it differed, however, in that densities were used rather than the specific volumes. The deformation polarization of each compound was assumed to be 1.05 times the molar refraction approximated with the sum of

4-Methyl-pyrimidine 1-oxide	13.26	0.22	314.0	29.2	3.72
Pyridazine 1-oxide	31.02	0.35	581.3	24.8	5.21

atomic refractions for the D line. Since the values of moments are great, no serious errors are introduced by this assumption, the probable errors being estimated at less than 0.05 D.

The results are shown in Table I, in which α and β denote the changes in the dielectric constant and in the density of the solutions with the weight fraction of the solute; the other notations have their usual meanings. The samples of pyrazine mono-*N*-oxide,[2] 4-methylpyrimidine mono-*N*-oxide[2] and pyridazine mono-*N*-oxide (hygroscopic colorless crystal of m. p. 38~39°C)[8,9] used in this investigation were the same as those reported in detail in previous papers.[2,9] Here, we have employed 4-methylpyrimidine mono-*N*-oxide instead of pyrimidine mono-*N*-oxide because of the difficulty of preparing the latter. Moreover, although the position of the N–O group in 4-methylpyrimidine *N*-oxide has not yet been established, Position 1 in Fig. 2 was inferred to be the most plausible.[10]

MO Calculations and Discussion

The electronic structures of pyrazine mono-*N*-oxide, pyrimidine mono-*N*-oxide and pyridazine mono-*N*-oxide have been calculated by using a simple LCAO-MO (SMO) method, disregarding overlap integrals and electronic interactions.

The various parameters necessary to carry out the calculation are the same as those described at the beginning of this paper, except for the Coulomb integral of pyridine-type nitrogen, which was taken to be the $\alpha+0.4\beta$ derived by Hameka et al.[11] on the basis of the theoretical treatment of the dipole moment of the compounds like pyridine and which was added to the Coulomb potential due to the inductive effect of the $\rangle N^{\delta+}$-group.

In this calculation, pyrazine mono-*N*-oxide was reasonably assumed to belong to the point group C_{2v}. The SMO's of the other two molecules, however, were directly obtained from the original secular equations.

The molecular diagrams thus obtained are shown in Figs. 1, 2 and 3, along with the numbering of atoms. Providing that the benzene heterocyclic ring of these molecules consists of a regular hexagon, with a bond length of 1.38 Å,[12] and that the N–O distance is 1.28 Å,[1,2,13] we have calculated the π-moments on the basis of the π-electron densities given in Figs. 1, 2 and 3. The results are demonstrated in each of the above figures. As in the case of basic heterocyclic *N*-oxides, it is clear from Figs. 1, 2 and 3 that the direction of the π-moment in each diazine mono-*N*-oxide indicates the π-electron transfer from the oxygen atom to the ring, the magnitude of which is greater than that (0.76 D) of pyridine *N*-oxide[2] to be discussed below. This fact is in good agreement with the accepted general tendency; that is, the replacement of one ring carbon atom by a nitrogen atom, which is a more electronegative element than carbon, brings about a greater charge transfer from the N→O group to the ring.

TABLE II. THE VALUES OF EMPLOYED σ-MOMENTS (D)
(See text)

Bond	Condition 1	Condition 2
$\overset{(+)\ (-)}{N\rightarrow O}$	4.55	4.30**
N—O	0.40	0.40
$\rangle N^*$:	1.0	—
C—N	O[C(sp^2)—N(sp^2)]	0.45

* The moment due to the unshared electron pair. See text.

** This value was cited from Smyth's table. C. P. Smyth: "Dielectric Behaviour and Structure," McGraw-Hill Book Co., New York (1955), p. 244.

It is especially noteworthy to point out that in pyrazine mono-*N*-oxide, a considerable amount of π-electron density is accumulated on the nitrogen atom at position 4, which is furthest apart from the N→O group. On the other hand, the fact that in the case of pyrimidine mono-*N*-oxide the contribution of the meta nitrogen atom to the increase of the π-moment is relatively small shows that the electron migration ability to the meta (3-) N-atom is weak, as is expected from the usual electronic theory. Assuming the mutual interaction between π- and σ- (the moments due to each of the localized bonds) moments to be negligible, we calculated the total dipole moments by means of the vector summation of π- and σ-moments, the latter values of which are listed in Table II. Here the necessary estimation of σ-moments is important. Our estimations were made under two conditions:

Condition 1: In this case we explicitly took into account the moment due to the unshared electron pair (the lone pair moment) on the nitrogen atom in the ring. Recently, Sheibe et al.[14] have reported the NMR chemical shift of pyrimidine in detail, showing that the lone pair moment of the nitrogen atom is, semi-experimentally, 1.2 D by connecting of above chemical shift data with the MO calculation results concerning pyrimidine under the following reasonale conditions: the SMO parameters of the N-atom are 0.5 or 0.4, the C(sp^2)–N(sp^2) σ-moment is nearly zero, as was suggeted by Hameka and Liquori,[11] and the usual C–H σ-moment was adopted. However, since the C–H moment, 0.6 D, adopted by them was somewhat larger than the normal value, we applied 0.4 D[15] to their data to obtain the N-lone pair moment of 1.0 D.

The σ-moment of the N→O bond was assigned as 4.55 D so as to reproduce the observed moment of pyridine *N*-oxide by using the π-moment (0.76 D) estimated experimentally and theoretically by us[1,2] and by other workers[16] and by using the C–N and C–H σ-moments as stated above and as listed in Conditon 1 in Table II.

Condition 2: We have applied the same σ-moments as those employed by Orgel et al.[15] to analyze the dipole moments of many heterocyclic compounds theoretically.[17]

As may be seen from Table III, the agreement between the observed total moments and the calculated ones is relatively good. However, Condition 1 seems to be more reasonable in view of the reproducibility of the observed value and from the theoretical point of view.

Now, the SMO-parameter for aromatic-*N*-oxides, derived previously by us, seems to be suitable to explain the electronic dipole moments for these compounds, including diazine mono-*N*-oxides.

Table IV gives the frontier electron densities of the compounds studied here as defined by Fukui et al.,[19] densities which were successfully applied hitherto to explain the chemical reactivities of the various *N*-oxides.

The chemical reactivity of pyridazine mono-*N*-oxide, which was recently studied in detail by Ogata and Kano,[20] showed that position 4 in the molecule (the para position to the N→O bond) is very active; for example, substituent reaction by a nitrating agent leads to a 4-nitro derivative. These facts agree well with the theoretical prediction inferred

16) A. R. Katritzky, E. W. Randall and L. E. Sutton, *J. Chem. Soc.*, 1957, 1769.

17) The values of many σ-moments have recently been given by R. Daudel et al.[18] on the basis of the theoretical treatment of a σ-bond like C-H, the $\overset{(+)\ (-)}{C\rightarrow H}$ and $\overset{(+)\ (-)}{C\rightarrow N}$ moments being assigned as 0.40 and 1.15 D respectively. It should be noted that the C→N bond moment is very large and that it partly contains the contribution from the lone pair moment of the N-atom, which was prorated to each of the σ-bonds bonded with the N-atom. It seems that the above C→N σ-moment, etc., can not be applied to the C→N bond in the *N*-oxides, because the N-atom in the $\rangle N\rightarrow O$ bond has no lone pair electron. Formally, however, we could explain the observed values with a better accuracy than that of "Condition 2" in Table II by using the σ-moments given by the above authors.

Moreover, although the direction of the C–H bond moment under conditions 1 and 2 is in the direction opposite to that expected theoretically,[18a,b] it should be pointed out that, in the case of Condition 1, the sum of "the lone pair moment of the N-atom" and "the C–H bond moment located at the para-position to the N-atom" is 1.40 D, the value and the direction of which are nearly of the same order as the 1.33 D obtained theoretically by Hameka and Liquori.[11]

from Table IV, in which the frontier electron density on the carbon atom located at position 4 is largest.

Summary

The dipole moments of pyrazine 1-oxide, 4-methylpyrimidine 1-oxide and pyridazine 1-oxide have been measured in benzene solutions and found to be 1.66, 3.72, and 5.21 D respectively. A comparison of these values with those obtained by the SMO calculation, in which the necessary parameters have been theoretically evaluated in detail by us in previous papers,[1,2] shows that the agreement between the observed and calculated values is good.

The authors are grateful to Professor Saburo Nagakura, of the Institute for Solid State Physics, The University of Tokyo, for his kind discussions; and to Mr. Masato Yoshikawa and Dr. Choichiro Asano for their advice on employing an electronic computer in our calculations.

The Photosensitized Oxidation of Leuco-uranine. III. The Kinetics of an Acridine-sensitized Photoöxidation in an Aerated Solution

By Kengo UCHIDA

(Received March 20, 1963)

In previous papers[1-3] the author and his co-workers have studied some properties of leuco-uranine and the kinetics of the acridine-sensitized photoöxidation of leuco-uranine in a deaerated solution. Leuco-uranine prepared by reducing uranine with sodium amalgam was photoöxidized to the colored form by adding some suitable sensitizer to the solution and then by irradiating it with the light appropriate to the sensitizer. In the case of the deaerated solution, leuco-uranine attacked by the triplet state of a sensitizer, i. e., acridine, was transformed into the oxidized form via semiquinone and perhaps with the evolution of molecular hydrogen. The evolved hydrogen, however, could not be successfully detected because of its small quantity.

Now in an aerated solution the rate of the photosensitized oxidation of leuco-uranine is more than ten times slower and the recovery of uranine is less quantitative than in a deaerated solution under suitable conditions. The purpose of the present report is to clarify kinetically the mechanism of this sensitized oxidation in the aerated solution by investigating quantitatively the concentration effect of the dissolved oxygen. The conclusions may be summarized as follows: oxygen rapidly reacts with the triplet state of acridine and produces between them perhaps a molecular complex, which may be similar to that proposed by Schenck.[4] It decomposes mostly into oxygen and acridine, only a little portion participating in the oxidation of leuco-uranine. Therfore, when the concentration of dissolved oxygen is low, oxygen prohibits the formation of uranine, while in the high concentration, the oxidation of leuco-uranine takes place via a different mechanism from that of the deaerated solution which has been elucidated before.[3]

Experimental

Material. — *Leuco-uranine.* — The method of preparation has already been reported in detail.[1] Uranine was reduced with sodium amalgam in an aqueous alkaline solution and recrystallized from ethanol a few times. The crystal was desiccated in a high vacuum.

Acridine.—Tokyo Kasei's acridine was recrystallized twice from a water-ethanol mixture.

Sodium Hydroxide. — The saturated solution was prepared from a G. R. reagent of the Wako Junyaku Co., and the supernatant solution was diluted to the desired concentration.

Disodium Hydrogen Phosphate and Potassium Dihydrogen Phosphate.—G. R. Reagents of the Wako Junyaku Co. were recrystallized three times from an aqueous solution.

Oxygen. — Air was used, and it was purified by removing moisture and carbon dioxide by the use of soda lime, calcium chloride and a trap cooled with dry ice.

Procedure.—Usually the stock solution of leuco-uranine 9.5×10^{-5} M was diluted ten times. In most experiments, the concentration of the acridine used as a sensitizer was about 1.5×10^{-4} M. For the control of the pH value of the solution, a phosphate buffer (about M/30) and sodium hydroxide (for the region of the higher pH values) were used. The pH value was measured with a Hitachi pH meter (model EHP-1).

The concentration of oxygen was controlled in the following way: the sample solution was sufficiently evacuated, repeatedly melted and refrozen in vacuo, and then saturated with oxygen of a definite pressure at 30°C. The oxygen concentration in the solution was calculated with a Bunsen-coefficient, 0.026 at 30°C.[5]

The reaction apparatus was described in detail in the previous paper.[3] The light source was a high-pressure mercury lamp (Matsuda SHL-100 UV), and a specially-designed interference filter transmitting near 490 and 375 mμ was used. This mercury lamp was used as the exciting light (at 365 mμ) and also as the monitoring light (at 490 mμ) with which the absorbance of the solution was measured. From the change of absorbance, the rate of the formation of uranine may easily be evaluated. The reaction cell made of Terex glass is $1\times1\times4$ cm. and has a side arm for evacuation along the long axis. To change the light intensity, the distance between the lamp and the reaction cell was changed, and each time the intensity was measured with a potassium ferrioxalate actinometer.[6] All experiments were performed at 30°C.

Results

Determination of the Order of the Reaction with Respect to Leuco-uranine. — The initial rate of the formation of uranine as a function of the initial concentration of leuco-uranine, $[L]_0$, was investigated. A slight variation in the concention of acridine, [A], and in the light intensity, I_0, was standardized by dividing the initial rate by the quantity of absorbed light, since, as will be described later, the rate is proportional to the absorbed light. The

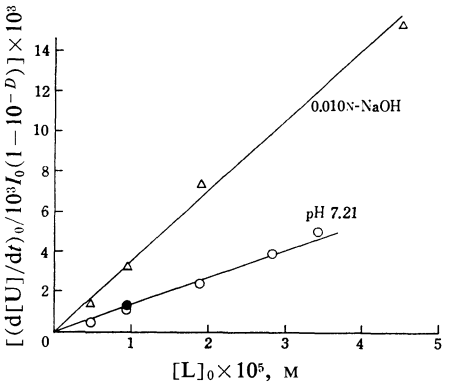

Fig. 1. Dependence of the initial rate on $[L]_0$.
$I_0\sim8\times10^{-8}$ mol. cm^{-2} min^{-1}
$[A]\sim1.3\times10^{-4}$ M
●: Uranine is beforehand added to 5×10^{-6} M (pH 7.21).

results are shown in Fig. 1. It is apparent that the rate is proportional to $[L]_0$. Thus, the rate may be represented as follows:

$$\left(\frac{d[U]}{dt}\right)_0 = k_0'[L]_0 \qquad (1)$$

$$\frac{(d[U]/dt)_0}{10^3 I_{abs}} = \frac{(d[U]/dt)_0}{10^3 I_0(1-10^{-D})} = k_0[L]_0 \qquad (2)$$

where $(d[U]/dt)_0$, [U] and k_0 are the initial rate of the formation of uranine, the concentration of uranine, and the rate constant respectively. I_{abs} is the number of photons (in mol.) absorbed (cm^{-2} min^{-1}) and is represented as $I_0(1-10^{-D})$, where I_0 is the incident light intensity and D, the absorbance of acridine at 365 mμ.

As the initial rates are obtained from the tangent of the plot [U] vs. time t, some error may be inevitable and k_0 may not be entirely accurate. The values of k_0 obtained are 353 l. mol^{-1} for a 0.010 N aqueous alkaline solution and 136 l. mol^{-1} at pH 7.21.

The Effect of the Concentration of Oxygen. —The oxidation of leuco-uranine in a deaerated solution proceeds about ten times faster than in an air-saturated solution. In order to investigate how oxygen behaves in the reaction,

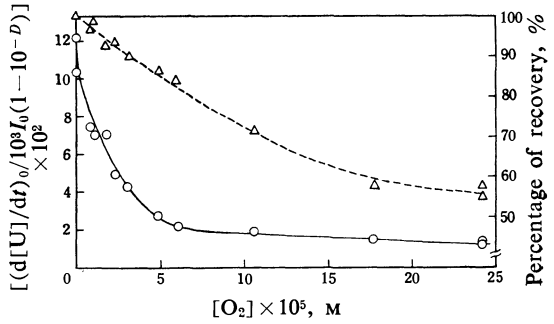

Fig. 2. Effects of $[O_2]$.
0.11 N-NaOH
$I_0=(4.9\sim5.5)\times10^{-8}$ mol. cm^{-2} min^{-1}
$[A]=(1.8\sim2.0)\times10^{-4}$ M
○: $\dfrac{(d[U]/dt)_0}{10^3I_0(1-10^{-D})}$
△: Percentage of the recovery of uranine

the concentration effect of oxygen on the reaction rate was examined. The results are shown in Fig. 2, in which the initial rate is plotted against the concentration of oxygen, $[O_2]$. In the lower concentration region, the rate decreases rapidly with the concentration of oxygen, but the slope of the curve lessens near $[O_2]\sim5\times10^{-5}$ M, and from this concentration up to $[O_2]\sim24\times10^{-5}$ M (air-saturated solution) the rate declines very slowly. From the above results, it is obvious that oxygen suppresses the oxidation, which takes place in vacuo. Judging from a very large retarding effect at the low concentration of oxygen, the rate ought to be negligible in a concentration as high as that in the air saturated solution. However, the fact is that the reaction actually proceeds at an appreciable rate, even in the air-saturated solution. This leads to the conclusion that oxidation of a different mechanism, involving oxygen, is taking place. The percentage of the recovery of uranine after the reaction also decreases with the concentration of oxygen. The results are shown in Fig. 2 with a dashed line.

The Rate Formula. — Let us now discuss a rate formula for each run in the air-saturated solution. Although the total reaction consists of the formation of uranine and the decomposition of the dye, the rate formula for only the former will be considered. It was found that the next equation holds satisfactorily. The interpretation of this equation will be given in the discussion.

$$\frac{d[U]}{dt} = k'([U]_\infty - [U]) \qquad (3)$$

From this,

$$\ln[U]_\infty - \ln([U]_\infty - [U]) = k't \qquad (4)$$

where $[U]_\infty$ is the concentration of uranine at

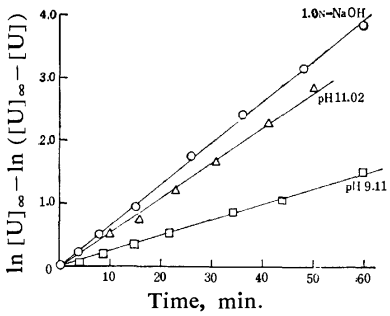

Fig. 3. Plots of $\{\ln [U]_\infty - \ln ([U]_\infty - [U])\}$ against time for typical examples.
$[L]_0 = 9.5\times10^{-6}$ M, $[A] \sim 1.4\times10^{-4}$ M
$I_0 \sim 5.5\times10^{-8}$ mol. cm^{-2} min^{-1}

the end of the reaction and k' is a rate constant. Some examples are shown in Fig. 3.

In the range of lower pH values, however, this equation fails, and when the pH value is lower than 8, the reaction at the initial stage appears to be rather of approximately the zeroth order with respect to the concentration of leuco-uranine. Examples in the range of lower pH values are shown in Fig. 4. Thus the order of the reaction obtained from each run is quite different from that which is obtained from the dependence of the initial rate on the concentration of leuco-uranine, which maintains the first order, as has been mentioned already. This discrepancy suggests that the reaction might be promoted by some reaction products. The problems will be considered in the discussion.

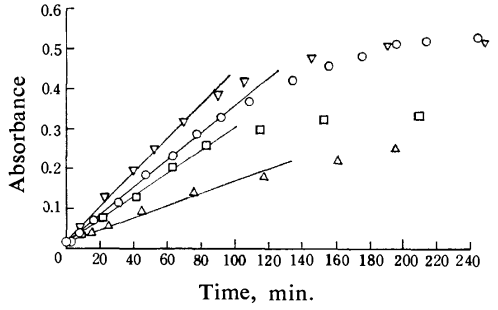

Fig. 4. Dependence of absorbance on the irradiation time.
$[L]_0 = 9.5\times10^{-6}$ M, $[A] = 1.4\times10^{-4}$ M
○: pH 7.2, ▽: pH 6.9, □: pH 6.2,
△: pH 7.2 ($[L]_0 = 4.75\times10^{-6}$ M)

Next, the effects of various factors upon the k' values of the air-saturated solution were examined.

The Effect of Light Intensity. — The results are shown in Fig. 5. As the concentration of acridine differs slightly from sample to sample, the quantity of the absorbed light is used as an abscissa instead of the incident light intensity, I_0. It is calculated from $10^3 I_0(1-10^{-D})$. Figure 5 shows the plot of k' against this quantity. It is apparent that k' increases in proportion to the light intensity.

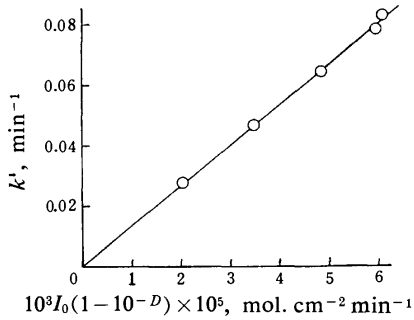

Fig. 5. Plot of k' against I_0.
$[L]_0 = 9.5\times10^{-6}$ M, $[A] = (1.27\sim1.42)\times10^{-4}$ M
$[NaOH] = 0.010$ N

The Effect of the Concentration of Acridine. —The results obtained in region [A] from 0 to 2.06×10^{-4} M are listed in Table I. Since the quantity of the absorbed light is given by $I_0(1-10^{-D})$ and since the k' values are proportional to I_0, as has been mentioned above, it is convenient to plot the value of k'/I_0 against $(1-10^{-D})$ as in Fig. 6. From Fig. 6 it is certain that the values of k' are proportional to the absorbed light under these conditions. Thus, Eq. 3 can be written as follows:

$$\frac{d[U]}{dt} = 10^3 k I_0 (1-10^{-D})([U]_\infty - [U]) \qquad (5)$$

where k is a new rate constant. The value of

Table I. The effect of the concentration of acridine

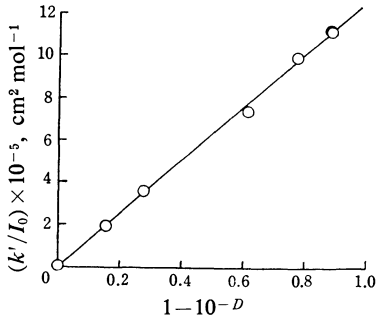

Fig. 6. Plot of k'/I_0 against $(1-10^{-D})$.

$k([U]_\infty-[U])$ gives the quantum yield for the formation of uranine. This is not affected by the concentration of acridine, as Table I shows.

The Effect of the pH Value. — The rate of the formation of uranine varies with the pH value of the solution. The results are listed in Table II. Mention will be made later of the column under $\varphi k_8/k_7$ and $\varphi k_9/k_7$ in Table II. Above a 2 N sodium hydroxide solution, the solubility of acridine is less than 1.5×10^{-4} M, at which value the usual experiments were performed. In the region between pH values of 14 and 11, the k values are almost constant. Below pH 11, they begin to decrease, and at pH~8, Eq. 4 fails; thus the reaction proceeds approximately in the zeroth order respect to the concentration of leuco-uranine at the initial stage. The further decrease of pH seems to increase the rate. The relation between pH values and k values is shown in Fig. 7 by a solid line. It is to be added that the k values in a lower pH region are tentative, since they were obtained from the tangent

at time zero on the plot of the left side of Eq. 4, $\{\ln[U]_\infty-\ln([U]_\infty-[U])\}$, against time. Although the quantity of the produced uranine at the end of the reaction seems to be affected by a very small difference in the experimental conditions and although the reproducibility is not very good, the recovery of uranine at the end of the reaction is about 40~55% at the higher pH values. The percentage begins to increase near pH~11 and approaches 100% at pH~6. The results are shown in Fig. 7 with a dashed line.

In order to make clear why the recovery of the dye is incomplete in high alkalinity, the solution after the reaction was evacuated and again irradiated, but no recovery of uranine was observed. Since the recovery of uranine should take place perfectly in a deaerated solution, the above results show that uranine is partially decomposed irreversibly. The absence of leuco-uranine in the thoroughly irradiated solution was further substantiated by means of paper chromatography.[1] From these results, it is obvious that photolysis of the dye takes place, accompanied by the formation of uranine. This decomposition reaction decreases in magnitude below pH 11.

Since uranine has a pK value of about 7 for the dissociation of univalent into divalent anions,[7] the concentration of univalent anions becomes appreciable below pH 8. As the univalent anions of uranine have absorption maxima at 455 and 475 mμ and as the molar extinction coefficient at 490 mμ is smaller than that of dianions, it is naturally expected that the rise of absorbance at 490 mμ is far less than that in high alkalinity, even when the recovery of the dye really occurs to the same

7) V. Zanker and W. Peter, *Chem. Ber.*, **91**, 572 (1958); L. Lindqvist, *Arkiv. Kemi.*, **16**, 79 (1960).

extent. The recovery of the dye in this pH region was definitely confirmed, however, by adding one drop of an alkaline solution to the thoroughly irradiated solution. Below pH 6, moreover, the neutral molecule of uranine exists in the solution, which has an absorption maximum at 437 mμ, but its extinction coefficient (particularly at 490 mμ) is so much smaller that the absorption can not be recognized at the concentration of 10^{-5} M. Therefore, the experiment below pH 6 cannot be performed for the usual concentration used in the present experiment. However, it was qualitatively confirmed, by a test analogous to that mentioned above, that even with such low pH values uranine is photochemically recovered.

Discussion

In the case of the deaerated solution, leuco-uranine reacts with the triplet state of acridine and becomes an oxidized form via a semi-quinone form. The details of this mechanism have been reported on in a previous papers.[2,3] In the case of the aerated solution, it is clear from the effect of dissolved oxygen that oxygen retards the oxidation reaction. However, if oxygen were to behave only as a retarder, it would be expected that the reaction should be completely suppressed at such a high oxygen concentration as in an air-saturated solution. The experimental results are contrary to the above expectation. Thus, although the rate decreases rapidly with the concentration of oxygen in the lowest region, the decrease becomes less and less near $[O_2] \sim 5 \times 10^{-5}$ M, and even in the air-saturated solution the reaction proceeds at an appreciable rate. These results would imply that the oxidation of leuco-uranine of another type, one involving oxygen, also occurs in addition to the oxidation which involves no oxygen.

From spectroscopic and paper-chromatographic analyses, there is no doubt that the photoöxidized product in the air-saturated solution is uranine[1] and that the acridine acting as a sensitizer does not change at all.

Next, the retardation of the reaction by oxygen will be considered. It is plausible that oxygen attacks and chiefly deactivates the triplet state of acridine. This was confirmed by the following supplementary experiments.

When acridine in an aqueous solution (10^{-4} M in a phosphate buffer of pH 7.3) was irradiated by the light of 365 mμ from a mercury lamp, acridine was photolysed; the quantum yield of the photolysis is 2×10^{-4} in the aerated solution. From the fact that the quantum yield is very small, it is certain that most of the excited state of acridine is deactivated, only a small portion of it being decomposed by the oxygen. When the concentration of oxygen is decreased, the rate of decomposition begins to fall at about $[O_2] \sim 3 \times 10^{-5}$ M. If one assumes that the reaction between an excited molecule and oxygen takes place so fast that the diffusion is the rate-determining process, the above finding implies that oxygen attacks a fairly long-lived excited species, since the dependence of the rate on the concentration of oxygen becomes apparent at such a low concentration. Thus, it is probable that oxygen attacks the triplet state of acridine rather than the singlet excited state. The existence of leuco-uranine in the system would not alter the situation essentially. Now, however, the triplet state of acridine reacts with not only oxygen but also with leuco-uranine at similar rates in this case. Hence it is expected that the concentration effect of oxygen will appear in a somewhat higher concentration. This expectation conforms well to the experimental results, confirming again that oxygen reacts with the triplet state of acridine and not with the excited singlet state. Besides, this is supported by the fact that no quenching of the fluorescence of acridine by oxygen is observed. As for the reaction between oxygen and the triplet state, Schenck[4] has studied many examples of photosensitized oxidation and has proposed that a loosely-bound molecular complex between oxygen and a triplet state of a sensitizer is formed in the course of the photosensitized oxidation. On the basis of Schenck's scheme, it can be considered that the intermediate between oxygen and the triplet state of acridine, $(A^t \cdots O_2)$, is formed during the photosensitized oxidation when acridine is used as a sensitizer, and that most of it may decompose into the original acridine and oxygen and only a little part participate in the recovery of uranine or the irreversible decomposition of the dye.

We will now consider how the decomposition reaction interferes with the recovery of the dye. From the fact that the formation of uranine can be treated satisfactorily with Eqs. 3 and 4, it seems likely that not only is the rate of the formation of uranine (noted below as process [8]) proportional to the concentration of leuco-uranine, as has been shown above, but also the decomposition (noted below as process [9]) is proportional to the concentration of leuco-uranine. Therefore, the relation between the concentration of leuco-uranine and that of uranine may be represented as follows:

$$\{[L]_0 - [L]\}\frac{k_8}{k_8 + k_9} = [U]$$

$$[L] = [L]_0 - \frac{k_8+k_9}{k_8}[U]$$

$$= \frac{k_8+k_9}{k_8}\{[U]_\infty - [U]\} \quad (6)$$

where k_8 and k_9 are the rate constants of processes [8] and [9] respectively. Thus, the fact that the experimental results are satisfactorily analysed by Eq. 3 implies that the decomposition of the dyes occurs simultaneously with the formation of uranine and at a rate proportional to the concentration of leuco-uranine. The ratio of the quantity of uranine formed to that of the dye decomposed at any time is given by the ratio of k_8 to k_9.

Such relations, however, seemingly do not hold at a low pH value, perhaps due to the promotion of the oxidation of leuco-uranine by a certain reaction product. To examine if uranine acts as such a product, the effect of the addition of uranine was examined. As Fig. 1 (a solid circle) shows, the result is that the addition of as much as about 5×10^{-6} M of uranine has no effect on the rate beyond the range of experimental error. Another possibility is that hydrogen peroxide which may be formed during the oxidation of leuco-uranine maintains its existence at a lower pH value and oxidizes leuco-uranine to uranine. It is natural to consider that the formation of hydrogen peroxide is accompanied by the oxidation of leuco-uranine, since this has already been confirmed in the case of the oxidation of the leuco form of thiazine dyes.

Summing up all the processes described above, the next scheme can be proposed:

$$A \xrightarrow{h\nu} A^* \quad [0]$$

$$A^* \rightarrow A \quad [1]$$

$$A^* + OH^- \rightarrow A + OH^- \quad [2]$$

$$A^* \rightarrow A^t \quad [3]$$

$$A^t + OH^- \rightarrow A + OH^- \quad [2']$$

$$A^t \rightarrow A \quad [4]$$

$$A^t + L \rightarrow U + A + H_2 \quad [5]$$

$$A^t + O_2 \rightarrow A^t\cdots O_2 \quad [6]$$

$$A^t\cdots O_2 \rightarrow A + O_2 \quad [7]$$

$$A^t\cdots O_2 + L \rightarrow U + A + (H_2O_2) \quad [8]$$

$$A^t\cdots O_2 + L \rightarrow \text{Decomposition of the dye} \quad [9]$$

where A* is the excited singlet state of acridine and A^t, the triplet state of acridine. Processes [2] and [2'] are observed only in very high concentration of hydroxyl ions.

The application of the steady state method leads to the following equation:

$$\frac{d[U]}{dt} = 10^3 I_0(1-10^{-D})\varphi\left\{\frac{k_5[L]}{k_4+k_5[L]+k_6[O_2]} + \frac{k_6[O_2]}{k_4+k_5[L]+k_6[O_2]}\times\frac{k_8[L]}{k_7+(k_8+k_9)[L]}\right\} \quad (7)$$

where

$$\varphi = \frac{k_3}{k_1+k_3(+k_2[OH^-])}$$

when $[O_2]$ is small, the second term of the right side of this equation can be disregarded. Therefore,

$$\frac{d[U]}{dt} = 10^3 I_0(1-10^{-D})\varphi\frac{k_5}{k_4+k_5[L]+k_6[O_2]}[L] \quad (8)$$

whence

$$\frac{10^3 I_0(1-10^{-D})}{d[U]/dt} = \frac{1}{\varphi}\times\frac{k_4+k_5[L]}{k_5[L]} + \frac{1}{\varphi}\times\frac{k_6}{k_5[L]}[O_2] \quad (9)$$

In agreement with Eq. 9, the plot of the left side of this equation against $[O_2]$ gives a straight line in the region of small $[O_2]$ values, as Fig. 8 shows. From the inclination and the intercept, the values of k_6/k_5 and k_6/k_4 can be evaluated as 1.3 and $(2.2\pm0.5)\times10^5$ l. mol^{-1} respectively. As the value of φ which gives the fraction of the excited singlet state of acridine that goes to the triplet state, the value, 0.24, evaluated in a previous paper[3] was used.

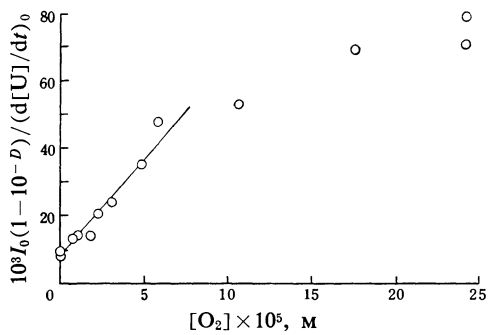

Fig. 8. Plot of $\frac{10^3 I^0(1-10^{-D})}{(d[U]/dt)_0}$ against $[O_2]$.

When the $[O_2]$ value is high, the $k_6[O_2]$ term is so much greater than the $k_5[L]$ term that the first term of Eq. 7 can be disregarded in favor of the second term. From the fact that the overall rate is proportional to [L] up to 4.5×10^{-5} M, one may assume

$$k_7 \gg (k_8+k_9)[L] \quad (10)$$

Thus, the rate of the formation of uranine

may be approximately represented as follows:

$$\frac{d[U]}{dt}=10^3 I_0(1-10^{-D})\varphi\frac{k_6[O_2]}{k_4+k_5[L]+k_6[O_2]}\times\frac{k_8}{k_7}[L] \quad (11)$$

When $[O_2]$ is great, one may put

$$k_6[O_2]\gg k_4+k_5[L] \quad (12)$$

and Eq. 11 is reduced to

$$\frac{d[U]}{dt}=10^3 I_0(1-10^{-D})\varphi\frac{k_8}{k_7}[L] \quad (13)$$

Applying the relation of Eq. 6 to Eq. 13, one gets

$$\frac{d[U]}{dt}=10^3 I_0(1-10^{-D})\varphi\frac{k_8+k_9}{k_7}([U]_\infty-[U]) \quad (14)$$

A comparison of Eq. 14 with Eq. 5 leads to

$$k=\varphi\frac{k_8+k_9}{k_7} \quad (15)$$

The values of $\varphi k_8/k_7$ and $\varphi k_9/k_7$ can easily be obtained from $[U]_\infty$, $[L]_0$, as can the ratio of the quantity of the produced uranine to that of the decomposed dye, i. e., k_8/k_9. The values listed in Table II were obtained in this way. Figure 9 gives the plot of $\varphi k_n/k_7$ ($n=8$ or 9) against pH. Alternatively, the values of $\varphi k_8/k_7$ can also be evaluated from the relation between the initial rate and the initial concentration of leuco-uranine. The agreement between them is rather satisfactory in view of some errors in both values due to the poor reproducibility of the fraction of the produced uranine for the former and the rather inexact procedure of drawing the tangent to the absorbance—time curve at the initial time for the latter.

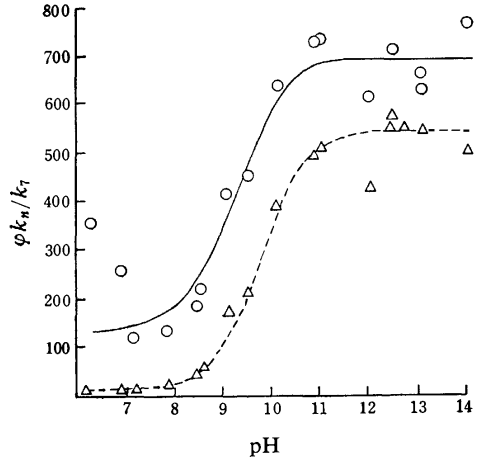

Fig. 9. Plots of $\varphi k_n/k_7$ against the pH value.
○: $\varphi k_8/k_7$ △: $\varphi k_9/k_7$

The pH dependence of the rate in the air-saturated solution is curious at first sight. However, the results can satisfactorily be interpreted in the same way as in the deaerated solution, i. e., on the basis that the various ionic forms of leuco-uranine have different reactivities and, accordingly, have different rate constants. Thus, the next scheme can be written on this basis:

$A^t\cdots O_2 + L^{3-} \rightarrow U$ [i]

$A^t\cdots O_2 + L^{2-} \rightarrow U$ [ii]

$A^t\cdots O_2 + L^{-} \rightarrow U$ [iii]

$A^t\cdots O_2 + L \rightarrow U$ [iv]

$A^t\cdots O_2 + L^{3-} \rightarrow$ Decomposition of the dye [i']

$A^t\cdots O_2 + L^{2-} \rightarrow$ Decomposition of the dye [ii']

$A^t\cdots O_2 + L^{-} \rightarrow$ Decomposition of the dye [iii']

$A^t\cdots O_2 + L \rightarrow$ Decomposition of the dye [iv']

where k_I, k_{II},$\cdots$, k_{Iv}' are the rate constants for each process.

The rate can be approximately given as follows by the use of Eq. 13:

$$\frac{d[U]}{dt}=10^3 I_0(1-10^{-D})\frac{\varphi}{k_7}\times(k_I[L^{3-}]+k_{II}[L^{2-}]+k_{III}[L^{-}]+k_{Iv}[L]) \quad (16)$$

This equation can be rewritten as follows by using the successive dissociation constants of leuco-uranine (K_1, K_2 and K_3):

$$\frac{d[U]}{dt}=10^3 I_0(1-10^{-D})\frac{\varphi}{k_7}\times\frac{(k_{Iv}[H^+]^3+k_{III}K_1[H^+]^2+k_{II}K_1K_2[H^+]+k_IK_1K_2K_3)}{[H^+]^3+K_1[H^+]^2+K_1K_2[H^+]+K_1K_2K_3}[L]_s \quad (17)$$

where $[L]_s$ is the analytical concentration of leuco-uranine. Equation 17 can be changed further as follows by using Eq. 13 again:

$$\frac{\varphi k_8}{k_7}\{[H^+]^3+K_1[H^+]^2+K_1K_2[H^+]+K_1K_2K_3\} \quad (=S)$$

$$=\frac{\varphi}{k_7}\{k_{Iv}[H^+]^3+k_{III}K_1[H^+]^2+k_{II}K_1K_2[H^+]+k_IK_1K_2K_3\} \quad (18)$$

The left side of this equation can now be evaluated, since K_1, K_2 and K_3 have already been determined.[1,3]

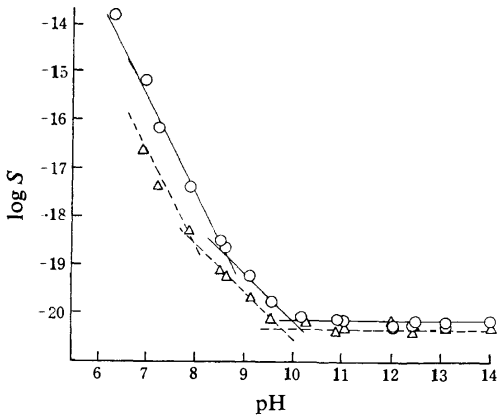

Fig. 10. Plots of $\log S$ against the pH value.
○ : Formation of uranine
△ : Decomposition of the dye

Plotting $\log S$ against pH, it is expected that in the region where the pH value is so small that the first term of the right side overwhelms the other terms, the curve will be a straight line with a slope of -3. As the pH value increases, the straight line gradually curves and joins another straight part having a slope of -2 and then one of 0. Extrapolating each straight line to a pH value of zero, $\varphi k_{\rm I}/k_7$, $\varphi k_{\rm II}/k_7$ and $\varphi k_{\rm III}/k_7$ can be evaluated. The relations are shown in Fig. 10; the following results were obtained:

$$\varphi k_{\rm I}/k_7 = 700 \text{ l. mol}^{-1}$$
$$\varphi k_{\rm II}/k_7 = 400 \text{ l. mol}^{-1}$$
$$\varphi k_{\rm III}/k_7 = 130 \text{ l. mol}^{-1}$$

The value of $\varphi k_{\rm IV}/k_7$ can not be given in the pH region tested in the present experiment. It is to be noted that below pH 8, a slight deviation from the straight line becomes apparent. The values of $\varphi k_8/k_7$ calculated by the use of these values are plotted in Fig. 9 as a solid line. At pH values lower than 8, a deviation from this line is again observed, the experimental values being appreciably larger than the calculated ones. This deviation may be attributed to a somewhat different scheme in the lower pH region, such as the promoting effect of a product which is marked in this pH region.

The values of $\varphi k_9/k_7$ which are related to the decomposition of the dye have been examined in the same manner as was the value of $\varphi k_8/k_7$. The results obtained are as follows:

$$\varphi k_{\rm I}'/k_7 = 550 \text{ l. mol}^{-1}$$
$$\varphi k_{\rm II}'/k_7 = 100 \text{ l. mol}^{-1}$$
$$\varphi k_{\rm III}'/k_7 = 10 \text{ l. mol}^{-1}$$

The values of $\varphi k_9/k_7$ at each pH values were calculated reversely from the above results; the broken curve in Fig. 9 gives the resultant plot. It is seen that this curve fits the experimental values fairly well.

From the above results, it is concluded that the value of $\varphi k_{\rm III}'/k_7$ is much smaller than the values of $\varphi k_{\rm I}'/k_7$ and $\varphi k_{\rm II}'/k_7$, in contrast to the case in the deaerated solution, in which the values of $\varphi k_n/k_{\rm t}$ are not very different from each other.[3] In other words, the univalent anions of leuco-uranine are more stable to the oxidation than the di- and trivalent anions. It is remarkable that the values of $\varphi k_n/k_7$ are very much smaller than those corresponding to the deaerated solution. It will be interesting to investigate whether this difference is due to the difference in the rate constants pertaining to the oxidation of leuco-uranine or to that between the rate constants of the deactivation of the triplet state of acridine and that of the molecular complex, $A^{\rm t}\cdots O_2$; however, this point can not be discussed in the present state of research.

Summary

The mechanism of an acridine-sensitized photoöxidation of leuco-uranine in an aerated solution has been elucidated. The oxidation takes place in a different manner from that in a deaerated solution. That is, oxygen attacks the triplet state of acridine very rapidly and presumably forms a kind of loosely-bound molecular complex. Most of this decomposes into the original acridine and oxygen, so that oxygen suppresses the oxidation of leuco-uranine occurring in the deaerated solution. Denoting the rate constants of the reactions between the triplet state of acridine and leuco-uranine and oxygen, respectively, as k_5 and k_6, the value of k_6/k_5 is given as 1.3. On the other hand, the oxidation of leuco-uranine by oxygen becomes apparent in a high oxygen concentration, such as an air-saturated solution. Namely, the molecular complex consisting of the triplet state of acridine and oxygen reacts with leuco-uranine, and the oxidation of the latter takes place. If one writes the rate constant of this reaction as k_8 and that of the reaction in which the molecular complex decomposes into acridine and oxygen as k_7, one can evaluate the ratio of $\varphi k_8/k_7$ from the experimental results, where the value of φ is the transition probability in which acridine goes to the triplet state from the excited singlet state. An irreversible decomposition of the dye also competes with the above reactions. Putting its rate constant as k_9, the value of $\varphi k_9/k_7$ has been evaluated. The variation of the ratios of $\varphi k_8/k_7$ and $\varphi k_9/k_7$ with the variation in pH values has been interpreted on the basis

that the reactivities of leuco-uranine are different in each ionic species. With the higher values of pH, the quantum yield becomes greater. The quantum yields of the formation of uranine and the irreversible decomposition of the dye have been evaluated as 0.0070 and 0.0055 respectively, yields which are about one thirtieth that in the deaerated solution. In the region of pH values lower than 8, a promoting action of a certain reaction seems to take part in the reaction and the reaction approaches the zeroth order.

The author wishes to express his deep thanks to Professor Masao Koizumi for his cordial encouragement and many helpful discussions throughout this work. He also desires to thank heartily Dr. Shunji Kato for his much valuable advice and Mr. Shigeya Niitsuma for his assistance.

Appendix

The Confirmation of the Hydrogen Evolution.— In Part I of this series, it was tentatively concluded, on the basis of the results of various kinds of scrutinizing experiments, that the evolution of hydrogen would occur, along with the photosensitized oxidation of leuco-uranine, in the deaerated condition. However, in spite of great effort, we could not succeed at that time in gathering and identifiying the evolved gas, and so the most direct evidence for the hydrogen evolution was lacking. Now, by increasing the quantity of the sample to be irradiated to several times the amount used in the previous paper, the author has succeeded in confirming that hydrogen is evolved. Thus, sample solutions which were about twice as concentrated and the volumes of which were two or four times as great as previous ones were prepared, and the gas evolved during the irradiation was gathered and analysed. As a sensitizer, uranine was used because there is no possibility for the sensitizer itself to be reduced by the evolved hydrogen. It is to be noted, however, that the reproducibility in the feature of the reaction seemed to be rather poor, perhaps because of the use of uranine as a sensitizer. 175~200 ml. of the sample solution ($[L]=9\times10^{-5}$ M, $[U]=(4\sim13)\times10^{-6}$ M and $[NaOH]=2\times10^{-3}$ N) was divided into several portions, each 25~50 ml. in volume, and they were evacuated carefully. After irradiation, all the evolved gas non-condensable at the liquid air temperature was gathered by the use of a small mercury diffusion pump and a Toepler pump. Two similar experiments were then performed; the results obtained are shown in Table III.

Table III. Quantity of gas evolved after irradiation

Exp. no.	Quantity of oxidized leuco-uranine mol.	Volume of gas obtained (reduced to STP*), ml.	Quantity of gas, mol.
I	5.2×10^{-6}	0.149	6.7×10^{-6}
II	5.1×10^{-6}	0.049	2.2×10^{-6}

* Standard temperature (0°C) and pressure (1 atm.)

The gas thus obtained was passed through a tube containing copper(II) oxide at 297°C, and the oxidation product was condensed in a trap cooled by liquid air. The volumes of the non-condensable gases at −183°C, −75°C and at room temperature were determined separately. The results are shown in Table IV.

It is concluded that gas C is water vapor, because water-like mist condensed on the wall when the gas was compressed into a small measuring vessel by the use of a Toepler pump; moreover, its vapor pressure was nearly the same as that of water. The quantity of gas A in Exp. no. I is unexpectedly large; this is perhaps due to the leakage of air during the procedure.

Furthermore, 95% of gases B and C in Exp. no. II disappeared when they were passed through a tube containing sodium hydroxide pellets and were condensed in a trap cooled at about −75°C; so gas B must be carbon dioxide. No organic substance which is not captured by liquid air but which is oxidized into water and carbon dioxide over copper oxide at about 300°C is likely to be produced from leuco-uranine in the reaction.

From the above results, most of the gas evolved in the reaction can be concluded to be hydrogen, but there seems to be some possibility that carbon monoxide might also be produced. The production of the latter might be due to the photochemical reduction of carbonate ions by the hydrogen evolved in the oxidation of leuco-uranine. If one assumes that the equimolar hydrogen is consumed in the reduction of carbonate ions, the quantity of hydrogen initially produced corresponds to 95 and 40% of the oxidized leuco-uranine in the above two experiments. Although the quantitative agreement

Table IV. Quantity of gas after passing through a heated CuO-tube

(Volumes of gases are reduced to STP)

Exp. no.	Gas A Non-condensable at −183°C Volume, ml. (mol.)	Gas B Non-condensable at −75°C Volume, ml. (mol.)	Gas C Non-condensable at room temperature Volume, ml.
I	36×10^{-3} (16×10^{-7})	1.9×10^{-3} (0.9×10^{-7})	($\sim110\times10^{-3}$)
II	1.9×10^{-3} (0.9×10^{-7})	22×10^{-3} (9.6×10^{-7})	($\sim25\times10^{-3}$)

is rather poor in the two experiments, it can be concluded from the above results that the evolution of the hydrogen gas is the main process in the photoöxidation of leuco-uranine in the deaerated solution. It is interesting that carbon monoxide seems to be produced under some conditions; this is perhaps due to the photochemical reduction of carbonate ions.

An NMR Study of Acetaldehyde Methanol Solutions

By Yuzuru FUJIWARA and Shizuo FUJIWARA

(Received April 26, 1963)

Aqueous solutions of acetaldehyde have been investigated utilizing the technique of nuclear magnetic resonance (NMR). The heat of hydration, the equiliblium constants, the chemical shifts, the spin-spin coupling constants, the relative relaxation times and the activation energies for Brownian motions of the molecules have been determined. The probable electronic structures and proton exchange between water and hydrated acetaldehyde have been discussed.[1)]

NMR posseses a considerable advantage for the investigation of the states of such chemically unstable substances as hemiacetal, which forms when acetaldehyde and methanol are mixed. Hemiacetal is difficult to detect by means of other than NMR.

In the present investigation solutions of methanol and acetaldehyde were compared with solutions of water and acetaldehyde. Where no catalyst is used, the rates of the formation of hemiacetal and acetal are so low that measurement of the equilibrium constants for the systems of aldehyde-hemiacetal and aldehyde-acetal are precluded, while the rates of formation are measurable.

Experimental

NMR spectra were obtained at 60 Mc./sec., using a Varian Associates spectrometer. Chemical shifts were measured by the side-band method from the methyl proton signal of free acetaldehyde. Concentrations of various species of hydrogen were determined by measuring the area under the curves with consideration of the power saturation. Acetaldehyde was prepared by the decomposition of commercial para-aldehyde, using sulfuric acid as a catalyst, and by redistillation.

Results and Discussion

It is well known that acetaldehyde and methanol react as follows:

$$CH_3CHO + CH_3OH \rightarrow CH_3CH(OH)(OCH_3)$$

$$CH_3CH(OH)(OCH_3) + CH_3OH \rightarrow CH_3CH(OCH_3)_2 + H_2O$$

The NMR spectra of these solutions are shown in Fig. 1, where the signals for all species of hydrogen appear at separate positions and are unambiguously assigned to their respective curves through such NMR features as fine structure, chemical shift, line width, the concentration dependence of the line intensity, and a comparison of these spectra with the spectra of pure and aqueous solution of dimethylacetal. Three kinds of methoxy methyl hydrogen appear separately in acetal, hemiacetal, and methanol, and three kinds of methyl hydrogen also appear separately in acetal, hemiacetal and acetaldehyde. These phenomena can be explained in terms of the electron density and the long-range magnetic shielding of the C–C and C–O bonds. The anisotropic magnetic effect of C=O on the shift of the methine proton is estimated to be 5.0 p.p.m. on the basis of the difference between the shift of free and that of solvated acetaldehyde; this is not so different from the value of 4.6 p.p.m. obtained from an aqueous solution of acetaldehyde.[1)]

Three kinds of OH hydrogen in water, methanol and hemiacetal form a single broad line in a 60 mol. % solution; its position depends on the concentration (cf. Fig. 2). This suggests a rapid hydrogen exchange, the shift corresponding to the variation of the concentration of each component. In a 10 mol. % solution, these OH hydrogens are separated and have different line widths, i. e., 5.8 c. p. s. for water, 5.3 c. p. s. for hemiacetal, and 6.8 c. p. s. for methanol. If we assume that exchanges are slow[2)] and that the ratios

Meiboom[3] shows that the corresponding value obtained in this laboratory is 0.63 times that of Meiboom. Since his data refer to solutions catalyzed by acid or base, a correction was made to adjust the concentration for this comparison. This can be regarded as a good agreement; the slight discrepancy may be attributed to the role of diffusion due to the different concentration of water. In the present

3) S. Meiboom, *J. Chem. Phys.*, **34**, 375 (1961).

case, the diffusion is somewhat a rate determinant. Arnold[4] has also reported a hydrogen exchange rate for pure ethanol which was about one-third of the value obtained in the present investigation for the exchange between methanol and methanol. This difference undoubtedly results from differences in molecular size.

Molecular motion can be investigated by the measurement of relaxation time, since it depends on the correlation time of the Brownian motion of the molecule. In this case the relative relaxation times were measured by the power saturation method (Fig. 3), assuming an extremely narrow case.[5] The results are shown in Table II, where the temperature dependence of relaxation times is also given. From these data, estimation of the activation energies for the molecular motions was made. Hemiacetal has the largest activation energy; this may be attributed to the restricted motion resulting from the hydrogen bonding with other OH's and is consistent with the case of hydrated acetaldehyde. Hydrated acetaldehyde has a larger value than hemiacetal; this may be explained by the greater tendency of hydrated acetaldehyde to undergo hydrogen bonding than hemiacetal. The activation energy for free acetaldehyde in a methanol solution is estimated to be 1.3 kcal./mol., which agrees quite well with that in an aqueous solution (1.27 kcal./mol.). The small temperature dependence of dimethylacetal may be ascribed to its spherical molecular shape, which hinders rotation very little, to the molecular structure, which has no group which can interact strongly with the surrounding molecules, and to the intermolecular motion, which may considerably contribute to the relaxation.

TABLE II. RELATIVE RELAXATION TIMES

Temp.	Relative relaxation time			E_{ac} kcal./mol.
	+86°C	+30°C	−16°C	
CH_3CHO	1.3	1.0	0.74	1.3
$CH_3CH\langle^{OH}_{OCH_3}$	1.3	0.91	0.51	2.2
$CH_2CH(OCH_3)_2$	1.1	0.91	1.0	~0

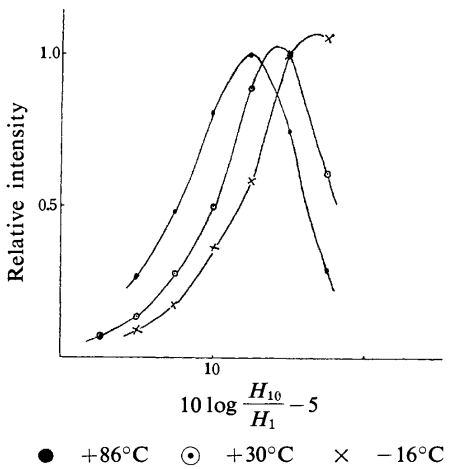

Fig. 3. Power saturation of $CH_3CH(OH)(OCH_3)$

The formation of hemiacetal and acetal from the mixture of acetaldehyde and methanol is very slow when the system is free from a catalyst such as acid or salt. Nevertheless, measurements of their formation rates were made in the case where no catalyst was added. This was necessary in order to avoid the possible disturbance to the system which might be caused by the catalyst and to ascertain the direct interaction of aldehyde with alcohol. The values in Table III were calculated on the assumption that the reverse reactions are negligible and that the methanol content does not vary appreciably during the reaction. The validity of the first assumption was confirmed by observing that the reaction proceeds more rapidly and more extensively in the presence of a catalyst. That of the second was confirmed by measuring the methanol concentration before and after the reaction, which proceeded for 70 days. The agreement of the values obtained at various concentrations is satisfactory and suggests that the calculation based on the above assumption is correct.

TABLE III. REACTION RATE OF AcH-MeOH

Concn., mol./l. AcH	MeOH	$k_1 \times 10^5$* l./mol./hr.	$k_2 \times 10^5$* l./mol./hr.
14.4	6.2	9.0	1.9
12.8	8.5	8.1	2.4
9.2	13.7	8.1	1.9
4.7	18.1	8.7	0.30
Average		8.5 ± 1	2.1 ± 0.5

* $CH_3CHO + CH_3OH \xrightarrow{k_1} CH_3-CH(OCH_3)-OH$

$CH_3-CH(OCH_3)-OH + CH_3OH \xrightarrow{k_2} CH_3-CH-(OCH_3)_2$

Summary

By the NMR method, the methanol solution of acetaldehyde was studied; in this solution all the species of hydrogen of each molecule are measurable, and a kinetic study of the system was readily performed. This could be

4) J. T. Arnold, *Phys., Rev.*, **102**, 136 (1956).
5) N. Bloembergen, E. M. Purcell and R. V. Pound, ibid., **73**, 672 (1948).

compared with any other conventional methods, by which some of the species usually present in the system are directly measured. The formation rates of hemiacetal and acetal were measured as $(8.5 \pm 1) \times 10^{-5}$ and $(2.1 \pm 0.5) \times 10^{-5}$ l./mol./hr., respectively, in the absence of a catalyzer. The hydrogen exchange rates for three kinds of OH's were also obtained. When compared with the related values in the literature, agreement is satisfactory. The relaxation times show a difference in the molecular motion corresponding to molecular structure and in the interaction with surrounding molecules.

The authors wish to thank Mr. Osamu Yamamoto of the Government Chemical Industrial Research Institute and Mr, Naohiro Hayakawa of the Japan Atomic Energy Institute for their aid in obtaining NMR spectra which have been presented in this paper.

The Electronic Spectra and Structures of s-Triaminobenzenium and Some Related Ions

By Noboru MATAGA

(Received February 27, 1963)

It has been shown by Köhler and Scheibe[1] that *s*-triaminobenzene (TAB), *s*-triaminoanisol, *s*-triaminoxylene, *s*-triaminomesitylene and phloroglucine trianion (TOB) seem to be easily protonated on the ring carbon in an aqueous solution. When *m*-phenylenediamine is singly protonated, the absorption spectrum of the protonation product is almost the same as that of aniline, and the spectrum of singly protonated aniline is very close to that of benzene. However, the spectrum of singly protonated TAB is quite different from that of *m*-phenylenediamine, and intense band appears at a much longer wavelength. This remarkable change in the spectrum has been ascribed[1] to the formathin of $TABH^+$ protonated on the ring carbon.

In the case of the methyl derivatives of TAB, the wavelength of this intense band is a littler larger than in the case of TAB.

These facts are quite interesting from the viewpoint of the conjugation power of the amino group. The study of the electronic structure and spectrum of $TABH^+$ may be somewhat interesting also in view of the recently developed chemistry[2] of the aromatic hydrocarbons protonated in strongly acidic media.

On the other hand, we have been making some theoretical studies of the electronic spectra and electronic structures of such amino-substituted benzenes as aniline, phenylenediamines and TAB and such amino-substituted nitrogen heterocycles as amino pyridines.[3]

Using the results of these studies, we have attempted to interpret theoretically the electronic spectra and structure of $TABH^+$ and also to give a theoretical basis to the observed stability of the protonated TAB and TOB.

In the following, we shall report the results of these theoretical calculations, together with some discussion.

Theoretical Method

The semiempirical ASMO CI method[4] was used for the calculation of the electronic spectra. The necessary Hückel MO's were calculated by assuming appropiate parameters; that is, all resonance integrals were taken to be the same and equal to β, the Coulomb

parameter for amino nitrogen, to be 1.2,[5] and that for O^- of TOB, 0.8.*

For the protonation products, the localization model was assumed. That is, if there are $2m$ π-electrons in the framework of n cores of the neutral molecule, then there are $2(m-1)$ π-electrons moving in the framework $n-1$ cores in the protonation product.

Thus, the effect of hyperconjugation[2b,c] with the CH_2 group is not explicitly taken into account in the present treatment. However, its effect on the stabilty of the protonation product will be examined, in an approximate way, in the latter part of this paper.

The procedures for the calculation of the electronic spectra of TAB and $TABH^+$ and the stabilities of the protonated aminobenzenes and TOB were as follows.

A) The Stabilities of the Protonation Products.—As a measure of the stabilities of the protonated species, the so-called localization energies[5-9] were calculated.

In the present case, if the π-energy of the neutral molecule is $2m\alpha+M\beta$, that of the localized system is $2(m-1)\alpha+M_r{}^+\beta$ where the proton is attached at position "r."

The localization energy is given by the difference between the π-energies of the neutral molecule and of the localized system, or by $(M-M_r{}^+)$. If all changes in the σ-bond caused by protonation are treated as being effectively constant throughout a series of aminobenzenes, we can anticipate a correlation[2a,c,8,9] between the calculated localization energies and the experimental basicities.

B) The Electronic Spectra.—The orbital energy of the i-th MO, ε_i, may be written formally:

$$\varepsilon_i=\langle\phi_i|F|\phi_i\rangle=\sum_{\mu,\nu}C_{i\mu}C_{i\nu}\langle\phi_\mu|F|\phi_\nu\rangle$$
$$=\sum_{\mu,\nu}C_{i\mu}C_{i\nu}F_{\mu\nu} \quad (1)$$

where F is the Fock Hamiltonian and ϕ_i is the LCAO MO, for which the Hückel MO's are used in the present calculation:

$$\phi_i=\sum_{\mu}^{n}C_{i\mu}\phi_\mu. \quad (2)$$

The matrix elements of the Fock Hamiltonian in terms of $2p\pi$ AO's may be written as follows:

$$F_\mu=\langle\phi_\mu|F|\phi_\mu\rangle=-I_\mu+(1/2)\cdot P_{\mu\mu}\gamma_\mu+\sum_{\kappa\neq\mu}(P_{\kappa\kappa}-Z_\kappa)\gamma_{\kappa\mu} \quad (3)$$

$$F_{\mu\nu}=\langle\phi_\mu|F|\phi_\nu\rangle=\beta_{\mu\nu}-(1/2)\cdot P_{\mu\nu}\gamma_{\mu\nu} \quad (4)$$

$$\gamma_{\mu\nu}=\langle\phi_\mu(1)\phi_\nu(2)|G_{12}|\phi_\mu(1)\phi_\nu(2)\rangle \quad (5)$$
$$G_{12}=e^2/r_{12}$$

$$P_{\mu\nu}=2\sum_{i}^{\text{occ.}}C_{i\mu}C_{i\nu} \quad (6)$$

In Eqs. 3—5, I_μ is the ionization potential of the μ atom in the appropriate valence state, Z_κ is the core charge of the κ core, $\beta_{\mu\nu}$ is the core resonance integral, and r_{12} in the two electron-operator G_{12} is the inter-electronic distance.

The excitation energy of the $i\rightarrow k$ transition, $E(\chi_{ik})=\langle\chi_{ik}|\mathscr{H}|\chi_{ik}\rangle-\langle\chi_0|\mathscr{H}|\chi_0\rangle$, and the interconfigurational matrix element, $\langle\chi_{ik}|\mathscr{H}|\chi_{jl}\rangle$, may be calculated by the following equations:

$$E({}^1\chi_{ik})=(\varepsilon_k-\varepsilon_i)-\langle\phi_i(1)\phi_k(2)|G_{12}|\phi_i(1)\phi_k(2)\rangle+2\langle\phi_i(1)\phi_k(2)|G_{12}|\phi_k(1)\phi_i(2)\rangle \quad (7)$$

$$\langle{}^1\chi_{ik}|\mathscr{H}|{}^1\chi_0\rangle=\sqrt{2}\langle\phi_k|F|\phi_i\rangle \quad (8)$$

$$\langle{}^1\chi_{ik}|\mathscr{H}|{}^1\chi_{il}\rangle=\langle\chi_k|F|\chi_l\rangle-\langle\phi_i(1)\phi_k(2)|G_{12}|\phi_i(1)\phi_l(2)\rangle+2\langle\phi_i(1)\phi_k(2)|\underset{k\neq l}{G_{12}}|\phi_l(1)\phi_i(2)\rangle \quad (9)$$

$$\langle{}^1\chi_{ik}|\mathscr{H}|{}^1\chi_{jk}\rangle=-\langle\phi_j|F|\phi_i\rangle-\langle\phi_k(1)\phi_j(2)|G_{12}|\phi_k(1)\phi_i(2)\rangle+2\langle\phi_k(1)\phi_j(2)|\underset{i\neq j}{G_{12}}|\phi_i(1)\phi_k(2)\rangle \quad (10)$$

$$\langle{}^1\chi_{ik}|\mathscr{H}|{}^1\chi_{jl}\rangle=-\langle\phi_j(1)\phi_k(2)|G_{12}|\phi_i(1)\phi_l(2)\rangle+2\langle\phi_j(1)\phi_k(2)|\underset{i\neq j,\ k\neq l}{G_{12}}|\phi_l(1)\phi_i(2)\rangle \quad (11)$$

For ${}^3\chi$'s, the third terms in Eqs. 7, 9 and 10 and the second term in Eq. 11 vanish.

In the ASMO CI method used here, the wave function Ψ for an electronic state is approximated by a linear combination of χ_0 and χ_{ik}'s.

5) H. Baba, This Bulletin, 34, 76 (1961).

* In order to determine the Coulomb parameter for O^-, proportionality between α and the valence state ionization potential was assumed, taking the sp^2 hybridized carbon as a reference; i. e., $\delta_O-/\delta_N=(\alpha_O--\alpha)/(\alpha_{N^+}-\alpha)=(I^\pi{}_O\ (\mathrm{tr}^2\mathrm{tr}^c\mathrm{tr}\pi)-I^\pi{}_C)/(I^\pi{}_{N^+}\ (\mathrm{tr}\ \mathrm{tr}\ \mathrm{tr}\pi)-I^\pi{}_C)$, where tr indicates the trigonal hybrid orbital (sp^2).
Using $I^\pi{}_C=11.16$ eV., $I^\pi{}_O=17.7$ eV., $I^\pi{}_{N^+}=28.72$ eV. (J. Hinze and H. H. Jaffé, *J. Am. Chem. Soc.*, **84**, 540 (1962)) and $\delta_N=1.2$, δ_O- was calculated to be 0.45. If we use for $I^\pi{}_{N^+}$ the VESCF value (25.772 eV.) obtained by Brown and Heffernan for pyrrole (Ref. 13), δ_O- can be calculated to be 0.54. Thus, δ_O- seems to be close to 0.5. This value was used at first. However, the electronic spectrum of $TOBH^+$ calculated with this Hückel MO was in poor agreement with the observed data. (S. Mataga and N. Mataga, unpublished.)
Therefore, other values of δ_O- were examined, and it was found that $\delta_O-=0.8$ gave what appeared to be a reasonable result for the spectrum of $TOBH^+$.

9) A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemist," John Wiley & Sons, New York (1961), p. 335.

The oscillator strength, f, is calculated by the method described by Mulliken and Rieke:[10]

$$f=1.085\times10^{11}\omega_{0\alpha}\sum_{r=x,y,z}[M^{r}_{0\alpha}]^{2} \qquad (12)$$

where $\omega_{0\alpha}$ is the frequency in cm^{-1} of the transition from the ground state, Ψ_0, to an excited state, Ψ_α. The necessary fromulas for the calculation of $M^{r}_{0\alpha}$ are given elsewhere.[4b]

C) The Semiempirical Evaluation of Integrals in the ASMO CI Calculation.—The molecular integrals which arise have been evaluated by a semiempirical procedure.

$Z_\mu=1$ for the carbon core and $Z_\kappa=2$ for the core of amino nitrogen which contributes two electrons to the π-system. The I_μ value for carbon was taken to be 11.42 eV., and that for the amino nitrogen, 28.85 eV.[11]

$\gamma_{\mu\nu}$'s were evaluated by the same procedure as before,[12,4c,11] using the valence state ionization potential, I_μ, and the electron affinity, A_μ:

$$\gamma_{\mu\nu}=14.3949/(a+R_{\mu\nu}) \text{ (eV.)} \qquad (13)$$

where $R_{\mu\nu}$ is the distance between the μ and ν atom (in Å). In a homonuclear case,

$$\gamma_\mu=14.3949/a=I_\mu-A_\mu \qquad (14)$$

Thus, $a_C=1.328$Å and $a_N=0.868$Å. For the case of heteronuclear two centers, i. e. carbon and nitrogen, the value of a is the harmonic mean of a_C and a_N. Therefore, $a_{CN}=1.049$Å.

The empirical parameter, $\beta_{\mu\nu}$, was taken into account only for the nearest neighbors and neglected for more distant neighbors: $\beta_{CC}=-2.388$ eV.[12,4c] and $\beta_{CN}=-3.6$ eV.[3a] All C–C bond distances were assumed to be 1.39 Å, and C–N distances, 1.36 Å. D_{3h} and C_{2v} symmetries were assumed for TAB and $TABH^+$ respectively.

The values of F_μ's for the amino nitrogens calculated by Eq. 3 using 28.85 eV. for I_μ, which is the ionization potential of the $2p\pi$ electron of N^+ in the trigonal hybrid state, seem to be too large. For a more refined calculation, the VESCF method[13] proposed by Brown and Heffernan may be useful. Actually, we have calculated the electronic spectra and electronic structure of *p*-phenylenediamine[3a] by the VESCF method and have obtained an improved result compared with that obtained by the ASMO CI calculation similar to the one described above.

However, in the present study, we have not attempted such a refined calculation but have used only a simple procedure which gives appropriate values for the F_μ's of amino nitrogen. That is,

$$\langle F_\mu\rangle_N=\langle F_C\rangle_{AV}+\delta_N\cdot\langle F_{CC}\rangle_{AV} \qquad (15)$$

where $\langle F_C\rangle_{AV}$ is the simple arithmetic mean of F_μ's for carbons, $\langle F_{CC}\rangle_{AV}$ is the same quantity of $F_{\mu\nu}$'s for the nearest neighbor carbon-carbon bonds, and δ_N is the Hückel MO parameter for the Coulomb integral of nitrogen, 1.2.

When $\langle F\rangle_N$ instead of F_N was used, the most suitable value of the core resonance integral, β_{CN}, was -2.399 eV.[3a] the value of β_{CC} being the same as before. Using $\langle F\rangle_N$ and $\beta_{CN}=-2.399$ eV., we have calculated the electronic spectra of some amino-substituted benzenes such as aniline and phenylenediamines and obtained a very good agreement with the observed.[3a]

Results and Discussion

The Hückel MO's and MO energies of TAB, $TABH^+$ (protonated on carbon), TOB and $TOBH^+$ (protonated on carbon) are given in the appendix. The numbering of the atoms in these compounds is given in Fig. 1.

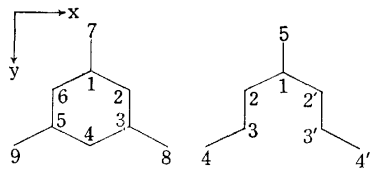

Fig. 1. The numbering of atoms in the base molecule and the corresponding carbonium ion.

A) Comparison of the Calculated Spectra with the Observed.—Using these MO's, the electronic spectra of TAB and $TABH^+$ were calculated by the method described in "Theoretical Method." The calculated spectra are given in Table I together with the observed, and the state functions and energies, taking the energy of the ground configuration, $E(\chi_0)$, as zero, are collected in Table II. The calculated values of such matrix elements as the formal orbital energies, $\langle\psi_i|F|\psi_i\rangle$'s, excitation energies and interconfigurational elements are given in the appendix.

Owing to the D_{3h} symmetry, the transitions to the lowest and the second excited singlet states of TAB respectively are electronically forbidden. These calculated spectra correspond quite well to the very weak absorption bands

in the observed spectra of TAB. Such weak transitions do not exist in the observed spectra of TABH$^+$, and the calculated transition energies are in satisfactory agreement with the observed values. These facts seem to support the assumed structure for TABH$^+$.

B) Calculation of Electronic Spectra with Other Models for TABH$^+$.—Although the results of the calculation described in A agree quite well with the observed spectra of TABH$^+$, we shall examine other models for TABH$^+$.

One of the possible structures of TABH$^+$ is a kind of π-complex,[14] in which the proton is situated on the molecular plane of TAB.

Because of the existence of the proton on the molecular plane, the electronic states of TAB might be considerably changed. The cause of the perturbation in this case will be the electrostatic potential of the proton or the charge-transfer interaction between the π-MO's of TAB and the proton.

We have tried some perturbation calculations using a model in which the proton is situated at the center of and 1.7 Å (half of the interplane distance in graphite) above the molecular plane.

In this model, the perturbing electrostatic potential due to the proton may be written[11] as:

$$\mathscr{H}^p{}_j=-\frac{Z_{H^+}e^2}{r_{pj}} \tag{16}$$

where r_{pj} is the distance between the proton and the j-th electron and $Z_{H^+}e$ is the effective charge of the proton. The formal orbital energy, ε_i, may be modified to ε_i' due to this perturbation.

$$\begin{aligned}\varepsilon_i' &= \varepsilon_i+\langle\phi_i(j)|\mathscr{H}^p{}_j|\phi_i(j)\rangle \\ &\quad+\sum_n\frac{(\langle_i\underline{\phi(j)}|\mathscr{H}^p{}_j|\phi_n(j)\rangle)^2}{\varepsilon_i-\varepsilon_n} \\ &=\varepsilon_i+\sum_\mu C^2{}_{i\mu}\langle\phi_\mu(j)|\mathscr{H}^p{}_i|\phi_\mu(j)\rangle \\ &\quad+\sum_n\frac{(\sum_\mu C_{i\mu}C_{n\mu}\langle\phi_\mu(j)|\mathscr{H}^p{}_j|\phi_\mu(j)\rangle)^2}{\varepsilon_i-\varepsilon_n}\end{aligned} \tag{17}$$

The integral, $V_\mu=\langle\phi_\mu(j)|\mathscr{H}^p{}_j|\phi_\mu(j)\rangle$, was calculated by a formula[15] using Slater AO's with the values of the orbital exponents, $\zeta_C=1.018$, $\zeta_N=1.212$.[11] The second order terms in Eq. 17 were very small compared with those of the first order and were accordingly disregarded as a first approximation.

Therefore, the values of ε_i' necessary for

TABLE III. STATE FUNCTIONS AND ENERGIES CALCULATED WITH THE ELECTROSTATIC POTENTIAL DUE TO PROTON

E, eV.		
−0.0985	$^1A_1$	$0.9899\chi_0+0.1418(^1\chi_{68}+{}^1\chi_{57})/\sqrt{2}$
3.7596	$^1A_2$	$(^1\chi_{67}-{}^1\chi_{58})/\sqrt{2}$
4.7018	$^1A_1$	$0.1418\chi_0-0.9899(^1\chi_{68}+{}^1\chi_{57})/\sqrt{2}$
5.2782	^1E	$\begin{cases}(^1\chi_{67}+{}^1\chi_{58})/\sqrt{2}\\(^1\chi_{68}-{}^1\chi_{57})/\sqrt{2}\end{cases}$

the calculation of the electronic spetra were calculated as follows:

$$\left.\begin{aligned}\varepsilon_6'=\varepsilon_5'=\varepsilon_5+(0.6972)V_C+(0.3026)V_N\\ \varepsilon_8'=\varepsilon_7'=\varepsilon_7+(0.9074)V_C+(0.0926)V_N\end{aligned}\right\} \quad (18)$$

With the V_μ values, $V_C=-6.8649$ eV., $V_N=-4.4321$ eV. and the interconfigurational matrix elements, $\langle\chi_0|\mathscr{H}^{p_j}|^1\chi_{68}\rangle=\langle\chi_0|\mathscr{H}^{p_j}|^1\chi_{57}\rangle=\sqrt{2}(0.4072)$ eV. The state functions and energies were calculated as shown in Table III.

We can obtain a little red shift of the spectrum in this model of $TABH^+$ also. However, the molecular symmetry of this $TABH^+$ is C_{3v}, and in this symmetry the transition to $^1A_2$ is electronically forbidden and that to $^1A_1$ is polarized perpendicular to the molecular plane. Therefore, we cannot interpret the observed strong band at 3.4 eV. by means of this model. Even if we take into account the charge-transfer interaction between the π-MO's of TAB and the proton, the calculated results will be similar to those of the electrostatic model as long as the proton is situated on the principal axis of the C_3 symmetry.

If the proton is moved to the periphery of TAB, the perturbation will become larger and all π-MO's of TAB will be mixed with each other. Thus, the electronic structure is considerably changed, and the electronic spectra will approach the observed data. However, such interactions may finally lead to the localization or to the hyperconjugation model as the most stable equilibrium form.

Accordingly, the theoretical calculation supports the structure of $TABH^+$ protonated on the ring carbon. The structures of $TABH^+$ similar to the π-complex discussed above may probably be realized in the course of the protonation reaction as an intermediate (outer complex), and the system will shifts to the localized one (inner complex).[14b]

Of course, the reaction involving the movement of the proton in an aqueous solution is very rapid, and the equilibrium between TAB and $TABH^+$ will be realized instantaneously.

C) Effect of Methyl Substitution on the Electronic Spectrum of $TABH^+$.—Although we have calculated here only the electronic spectra of TAB and $TABH^+$ from among the compounds examined by Köhler and Scheibe,[1] a similar interpretation will hold also for other compounds.

The transition energies to the lowest excited singlet states of *s*-triaminoxylenium ($TAXH^+$) and *s*-triaminomesitylenium ($TAMH^+$) ions are smaller by ca. 0.34 eV.[1] than that of $TABH^+$.

The effects of methyl substitutions on the electronic spectra of protonated benzene[16,17] have been discussed by means of both the localization model and the hyperconjugation model.[2c,16]

Calculations and an interpretation similar to those by Morita[2c] may be possible in the present case also. However, we shall make a more simplified explanation as follows.

The lowest excited singlet state of $TABH^+$ is almost completely contributed by $^1\chi_{56}$, as is shown in Table II; that is, the excitation energy to this state is essentially determined by the transition from the highest occupied to the lowest vacant orbitals.

If we assume an inductive model of methyl substitution by taking the Coulomb integral of the substituted carbon to be $\alpha+\delta\cdot\beta$, the orbital energy differences, $\Delta\varepsilon=\varepsilon_6-\varepsilon_5$, for TAB^+ and $TAXH^+$ may be calculate as follows using the MO's given in appendix.

$$\left.\begin{aligned}TABH^+\quad \Delta\varepsilon=-1.0764\,\beta\\ TAXH^+\quad \Delta\varepsilon=-1.0764\,\beta+(0.5531)\delta\cdot\beta\end{aligned}\right\} \quad (19)$$

The value of δ averaged for various methyl substituted aromatics seems to be ~-0.5.[9] If we put $0.34=-(0.5531)\delta\cdot\beta$, assuming $\beta\sim-3$ eV., δ is estimated to be ~-0.2. This value is a little different from the ordinary value, -0.5; nevertheless, the observed bathochromic shift by methyl substitution is, at least qualitatively, well understood by means of this simplified calculation.

D) Similarity of the Electronic Spectrum of $TABH^+$ to Those of Benzenium Ion and Methyl-substituted Benzenium Ions. — As has been discussed in the previous section, the methyl substitution affects the spectrum of $TABH^+$ rather remarkably.

3.4941	$^1B_1$ $0.9991{}^1\chi_{23}-0.0419{}^1\chi_{14}$	0.26
5.2930	$^1A_1$ $0.1028\,\chi_0-0.9106{}^1\chi_{13}-0.4002{}^1\chi_{24}$	0.12
7.0331	$^1A_1$ $0.0380\,\chi_0-0.3896{}^1\chi_{13}+0.9202{}^1\chi^{24}$	1.02
8.1188	$^1B_1$ $0.0419{}^1\chi_{23}+0.9991{}^1\chi_{14}$	1.35

In the case of the substitution for the neutral aromatic hydrocarbon molecules, the amino group affects the spectra to a far greater extent than does the methyl group. Therefore, one might expect that the spectrum of $TABH^+$ is very different from that of benzenium ions or methyl-substituted benzenium ions. However, this is not the case for either the observed spectra or for the calculated spectra. The observed excitation energies to the lowest excited singlet states of benzenium, methyl-substituted benzenium, *s*-triaminobenzenium, methyl-substituted *s*-triaminobenzenium ions, and $TOBH^+$ are not very different from one another and lie approximately between 3.0~3.6 eV. In order to interpret this fact, it will be necessary to compare the MO's and state functions of $TABH^+$ with those of benzenium ion.

The electronic spectrum of benzenium ion has been studied in detail by Morita[2c] using the semiempirical SCF MO CI method. However, for purposes of comparison, the results of theoretical calculations with similar approximations for both compounds may be more reasonable. Accordingly, we have calculated the electronic spectrum of benzenim ion with the same approximations as for $TABH^+$. The calculated energies, state functions and oscillator strengths of transitions from the ground state to the excited states are given in Table IV.

Although the method of calculation used here is less elaborate than that used by Morita, the present results are rather close to Morita's. As is shown in Table IV, the lowest excited singlet state of benzenium ion is almost completely contributed by $^1\chi_{23}$, just as the lowest excited singlet state of $TABH^+$ is almost exclusively contributed by $^1\chi_{56}$. Furthermore, an analogous circumstance holds for other states of both compounds. That is, each excitation energy is essentially determined by the transition from one of the occupied orbitals to one of the vacant orbitals. This may be a remarkable example of the change from the "*round field*" spectra[17] in benzene and TAB (where the configuration interaction is quite strong) to the "*long field*" spectra[17] caused by protonation.

Thus, we have seen the similarity of the state functions of $TABH^+$ to those of benzenium ions, a similarity which corresponds to the resemblance of the observed spectra of these compounds.

Next, we shall show the similarity of the MO's of $TABH^+$ to those of benzenium ions. We can transform the MO's of $TABH^+$ into the following equivalent forms:

$$\left.\begin{aligned}
\phi_4&=0.4084(\phi_2+\phi_{2'})+0.3332(g_3{}^4+g_{3'}{}^4)+0.6665\,g_1{}^4\\
\phi_5&=0.5259(\phi_2-\phi_{2'})+0.4725(g_3{}^5-g_{3'}{}^5)\\
\phi_6&=\qquad\qquad 0.5773(g_3{}^6-g_{3'}{}^6)-0.5773\,g_1{}^6\\
\phi_7&=0.4255(\phi_2-\phi_2')-0.5646(g_3{}^7-g_{3'}{}^7)
\end{aligned}\right\} \tag{20}$$

In these MO's, g is the normalized group orbital for C–NH_2, which can be written as:

$$\left.\begin{aligned}
g^4&=0.3418\phi_C-0.9398\phi_N,\quad g^5=0.5678\phi_C-0.8233\phi_N\\
g^6&=0.8702\phi_C-0.4926\phi_N,\quad g^7=0.9247\phi_C-0.3810\phi_N
\end{aligned}\right\} \tag{21}$$

where, in the same ϕ, $g_3=g_{3'}=g_1$.

The corresponding MO's of benzenium ion are given by:

$$\left.\begin{aligned}
\phi_1&=0.5000(\phi_2+\phi_{2'})+0.2887(\phi_3+\phi_{3'})+0.5773\phi_1\\
\phi_2&=0.5000(\phi_2-\phi_{2'})+0.5000(\phi_3+\phi_{3'})\\
\phi_3&=\qquad\qquad 0.5773(\phi_3+\phi_{3'})-0.5773\phi_1\\
\phi_4&=0.5000(\phi_2-\phi_{2'})-0.5000(\phi_3-\phi_{3'})
\end{aligned}\right\} \tag{22}$$

Thus we can see that the transformed MO's of $TABH^+$ are apparently similar to those of benzenium ion. Of course, the two sets of MO's are not exacty the same but are different from each other to some extent. However, we have described the above transformation of the MO's in order to demonstrate the *geometrial* or *topological* nature of the MO's.

If we transform the base set for the Hückel MO's of $TABH^+$ from $(\phi_1\cdots\phi_8)$ to

$$\left\{\begin{aligned}
&g_1{}^a,\ (g_3{}^a+g_3{}^a)/\sqrt{2},\ g_1{}^b,\ (g_3{}^b+g_{3'}{}^b)/\sqrt{2},\\
&(\phi_2+\phi_{2'})/\sqrt{2},\ (g_3{}^a-g_{3'}{}^a)/\sqrt{2},\\
&(g_3{}^b-g_{3'}{}^b)/\sqrt{2},\ (\phi_2-\phi_{2'}/\sqrt{2}
\end{aligned}\right\}$$

where the group orbitals for C–NH_2 are given by:

$$\begin{aligned}
g^a&=0.870\phi_C-0.493\phi_N\\
g^b&=0.493\phi_C+0.870\phi_N
\end{aligned} \tag{23}$$

then the energy matrix for the Hückel MO's can be written in the following form;

for b_2 species

$$\begin{pmatrix} g_1^a & (g_3^a+g_{3'}^a)/\sqrt{2} & g_1^b & (g_1^b+g_3^b)/\sqrt{2} & (\phi_2+\phi_2)/\sqrt{2} \\ (\alpha-0.5667\beta) & 0 & 0 & 0 & 2(0.87)\beta \\ & (\alpha-0.5667\beta) & 0 & 0 & 2(0.87)\beta \\ & & (\alpha+1.7662\beta) & 0 & 2(0.493)\beta \\ & & & (\alpha+1.7662\beta) & 2(0.493)\beta \\ & & & & \alpha \end{pmatrix}$$

for a_2 species

$$\begin{pmatrix} (g_3^a-g_3^a)/\sqrt{2} & (g_3^b-g_{3'}^b)/\sqrt{2} & (\phi_2-\phi_2)/\sqrt{2} \\ (\alpha-0.5667\beta) & 0 & 2(0.87)\beta \\ & (\alpha+1.7662\beta) & 2(0.493)\beta \\ & & \alpha \end{pmatrix}$$

TABLE V. LOCALIZATION ENERGIES OF SOME AMINOBENZENES AND TOB (in units of β)

Mode of protonation	A. Carbon	B. Amino group
Aniline	2.2498 a)	2.8054
m-Phenylenediamine	1.9562 b)	2.8058
TAB	1.8294	2.8060
TOB	1.6861	—

a) Protonation on para-carbon.
b) Protonation of the carbon atom at ortho-position to both amino groups.

Accordingly, g_a and g_b of each C–NH_2 group are mixed to some extent; that is, the g^i's in (21) can be written as $g^i=c_a{}^i g_a+c_b{}^i g_b$, but $g_1{}^i=g_3{}^i=g^i$ because,

$$\langle g_1^a|\mathscr{H}|(\phi_2+\phi_{2'})/\sqrt{2}\rangle= \langle(g_3^a+g_{3'}^a)/\sqrt{2}|\mathscr{H}|(\phi_2+\phi_{2'})/\sqrt{2}\rangle$$

and

$$\langle g_1^b|\mathscr{H}|(\phi_2+\phi_{2'})/\sqrt{2}\rangle= \langle(g_3^b+g_{3'}^b)/\sqrt{2}|\mathscr{H}|(\phi_2+\phi_{2'})/\sqrt{2}\rangle$$

The calculated spectra of $TABH^+$ and benzenium ion in Tables I and IV respectively indicate that the excitation energy to the lowest excited singlet state of $TABH^+$ is a little smaller than that of benzenium ion. However, this is not the case indeed, the order is just reversed in the observed spectra. This indicates that the present semiempirical ASMO CI method cannot reproduce such a small difference between the observed spectra,** although the calculated excitation energies themselves are close to the observed values.

On the other hand, the difference between the Hückel MO energies of the lowst vacant orbital and the highest occupied orbital can reproduce the observed excitation energy to the lowest excited singlet state quite well, as is described below.

If we assume the inductive parameter for methyl substitution to be ~-0.2, as has already been established, the orbital energy differences may be evaluated as: $-\beta$, -1.0764β, and -1.1β for benzenium ion, $TABH^+$ and mesitylenium ions respectively. The observed excitation energies are 3.1 eV., 3.4 eV. and 3.5 eV. for these ions respectively. Thus, the calculated results agree, at least qualitatively, very well with the observed spectra.

E) The Basicities of TAB and TOB in Comparison with Other Aminobenzenes and Aromatic Hydrocarbons.—As has been described in the "Theoretical Method" section, localization energies due to protonation were calculated as a measure of the stabilities of the protonated species. Calculated results for the protonation of some aminobenzenes and TOB are collected in Table V, where the localization energy is given by $(M-M_r{}^+)$.

As is shown in Table V, the destabilization energy of the π system becomes considerably smaller from aniline to TAB and TOB ($pK\sim9.7$) in mode A, whereas it is almost constant or even slightly increases in mode B. This result is in accordance with the observed data.

Although the effect of hyperconjugation with CH_2 group was not taken into account

** In the present calculation, we have used the same value of the nearest-neighbor core resonance integral for the carbon-carbon bond (β_{CC}) in both $TABH^+$ and benzenium ion. However, there are twice as many π-electrons of $TABH^+$ as those of benzenium ion, whereas the dimension of the core framework of the former is not so large compared with that of the latter. Accordingly, the effective core charge for π-electrons seems to be smaller in $TABH^+$ than in benzenium ion, resulting in the larger overlapping between AO's and, thus, the larger core resonance integrals in the former than in the latter. Moreover, the value of β_{CC} was the same as that used for the neutral aromatic hydrocarbons. Because the effective core charge is larger in benzenium ion than in benzene, a little smaller value of β_{CC} may be more reasonable for benzenium ion.
In general, the calculated spectrum shifts to blue when the values of the core resonance integrals are increased, while a red shift occurs when they are decreased. Therefore, the calculated spectra of $TABH^+$ and benzenium ion will approach the observed values if one adjusts the β_{CC} value in the way described above.

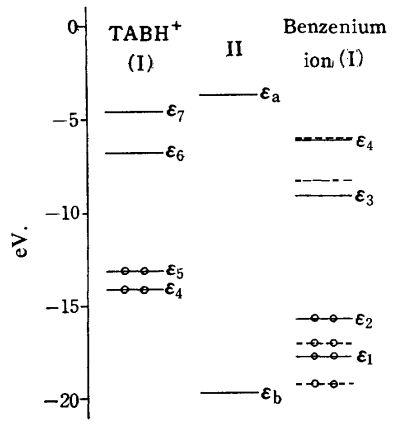

Fig. 2. MO energies for the local systems of $TABH^+$ and benzenium ion, respectively.
In the local system I of benzenium ion, - - - represents the SCF MO energies calculated by Morita.[2c]

either in the calculation of the electronic spectra or in the calculation of the stabilities of the protonated species, it may be examined in some qualitative or semi-quantitative manner.

In the case of $TABH^+$, owing to the presence of the three amino groups, the higher occupied orbitals of the local system I which is indicated in Fig 1b (II is the CH_2 group) may be much more elevated than the highest-occupied orbital of the corresponding local system of benzenium ion.

Actually, this is the case, as is shown in Fig. 2, where the approximate orbital energies for $TABH^+$ and the corresponding quantities for benzenium ion calculated by the present method are indicated, together with the energies of the bonding and antibonding π-orbitals of the CH_2 group as calculated by Morita.[2c] In Fig. 2, the SCF MO energies[2c] for the local system I of benzenium ions are also given for purposes of comparison.

Therefore, the excitation energies from the higher-occupied orbitals of I to the antibonding π-orbital of II(ϕ_a) may not be very large in the case of $TABH^+$. Employing the Pariser-Parr approximation[4a] for the evaluation of the electron repulsion integrals (γ's) between AO's of I and II, the approximate charge transfer (CT) excitation energies in $TABH^+$ were estimated as follows: $E(^1\chi_{5a})\sim4.5$ eV. and $E(^1\chi_{4a})\sim6.4$ eV., where $^1\chi_{5a}\subset B_1$, $^1\chi_{4a}\subset A_1$. Thus, it may be possible that the interactions between these CT configurations and the ground configuration χ_0 stabilize the protonated species.

Mackor et al.[2a] demonstrated an approximate linear relation between the localization energy and log K, where K is the relative basicity constant, in the case of the protonation of many aromatic hydrocarbons.

Although there are only two points for TAB and TOB, the relation between the pK values and the localization eneregies in the present calculation seems to be parallel with that between the values of log K and the localization energies for some aromatic hydrocarbons, as is shown in Fig. 3.

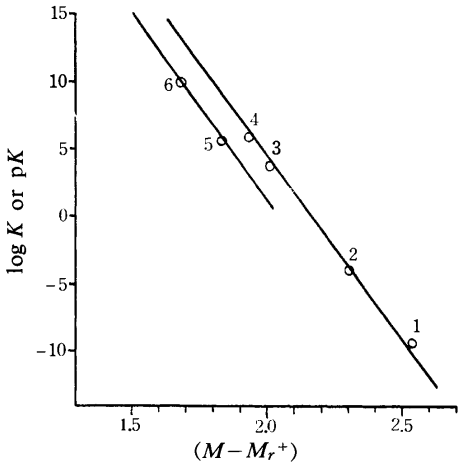

Fig. 3. Relation between the observed basicities and localization enegies.
1. Benzene, 2. Naphthalene, 3. Anthracene, 4. Naphthacene, 5. TAB, 6. TOB.
Localization energies for the polyacene series were taken from Ref. 2a.

Concluding Remarks

The results of the theoretical calculations herein described have revealed that the extraordinarily large proton affinities of TAB and TOB are consistent with the ordinary MO concept of the π-electron system and with the great conjugation power of amino group, and that $TABH^+$ and $TOBH^+$ are carbonium ions similar to the protonation products of benzene and methyl-substituted benzenes. Nevertheless, it is necessary to make a more direct experimental confirmation of the structure of $TABH^+$ by, for example, NMR spectral measurement.

Summary

The electronic spectra and electronic structure of TAB and $TABH^+$ have been studied by the MO method. The calculated spectra agree satisfactorily with the observed values. The stabilities of the protonation products of various aminobenzenes have been studied by Hückel MO calculations. The results of these calculations give an interpretation of the observed facts[1] that TAB in an aqueous solution is easily protonated on the ring

carbon (pK ~5.5), although no such protonation occurs in the case of aniline or *m*-phenylenediamine, where the amino group is protonated. The stability of the protonation product of TOB has also been studied.

It has been pointed out that the spectum of $TABH^+$ is rather similar to that of benzenium ion, although the basicity of the former is much larger than that of the latter. This fact has been explained theoretically.

Further, it has been observed that a relation between the calculated localization energy and the observed basicity constant for the protonation similar to those of many aromatic hydrocarbons approximately holds for TAB and TOB.

The author wishes to express his gratitude to Professor Saburo Nagakura of The University of Tokyo and Dr. Toshifumi Morita of Tokyo Metropolitan University for their thought-provoking discussions. He is also thankful to Dr. Shizuyo Mataga for her assistance in the numerical computations.

The Infrared Spectra of Troponoid Compounds. VI. The Infrared and Raman Spectra of Tropolone, 3- and 4-Isopropyltropolones

By Yusaku IKEGAMI

(Received March 30, 1963)

In Part IV[1] of this series, the infrared and Raman spectra of tropone (I) and their vibrational assignments were described. Analyses of the infrared spectra of many troponoids can be made on the basis of these findings. Yet, however, for the analyses of the infrared spectra of many tropolones, it is desirable to know the characters and the assignments of the infrared and Raman spectra of some typical tropolones. In the present paper, the Raman spectra of tropolone (II), 4-isopropyltropolone (hinokitiol) (III) and 3-isopropyltropolone (α-thujaplicin) (IV) will be measured in carbon tetrachloride, and the vibrational assignments of these spectra will be discussed, together with their infrared spectra. All these tropolones are colorless crystals and are soluble in organic solvents suitable for the measurement of Raman spectra. Although the Raman spectra of II and III in benzene have been reported on already by Imanishi and Ito,[2,3] more detailed results were obtained in the present measurements.

Measurements

Raman spectra were measured with a Shimadzu automatic-grating Raman spectrometer, type GRS-750, using the Hg-e line (4358 Å) from the Toronto-type mercury lamp as the exciting line. A solution containing ethyl violet and *p*-nitrotoluene in denatured alcohol was used as the filter for the light source.[1] Each sample was measured in carbon tetrachloride (25~35% conc.) by the use of a Raman tube 8 mm. in inner diameter. As the three tropolones are easily colored on exposure to light, the purified samples were preserved in a dark place and caution was taken to shorten the time required for the measurement. Relative intensities in each spectrum (Tables I—III) are given, taking the peak intensity of the most intense line, around 1500 cm^{-1}, as the standard.

Infrared spectra were measured with a Perkin-Elmer model 21 infrared spectrophotometer, using calcium fluoride, sodium chloride and potassium bromide prisms.

Tropolone (m. p. 51°C), 4-isopropyltropolone (m. p. 52°C) and 3-isopropyltropolone (m. p. 34°C) were purified several times by recrystallization and vacuum distillation.

Results and Discussion

Characteristic Features Appearing in the Raman Spectra of Four Troponoids.—The Raman lines observed on three tropolones are shown in Fig. 1, together with those of tropone measured earlier.[1] All these spectra exhibit the most intense line around 1500 cm^{-1}. Further, some strong lines were found which correspond well in their wave numbers and relative intensities to the intense lines of the

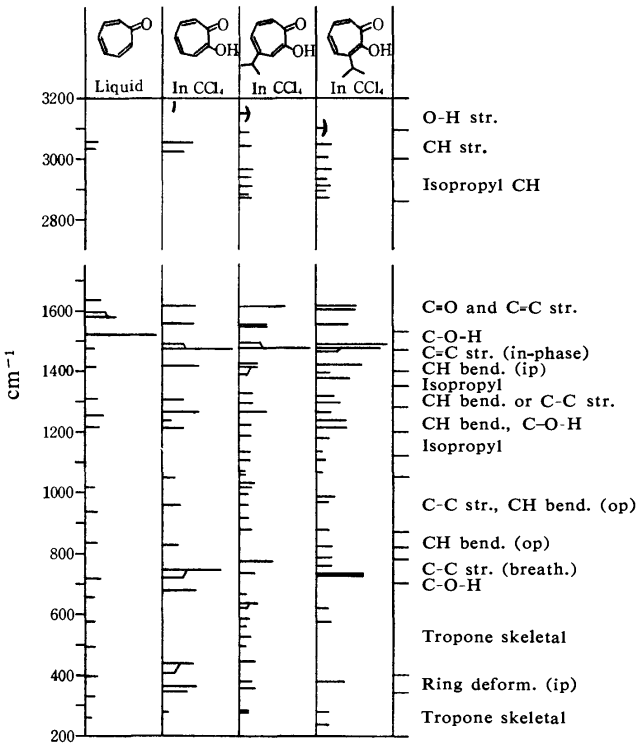

Fig. 1. Raman spectra of four troponoids.

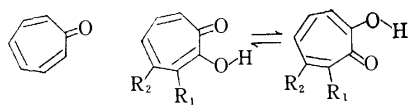
tropone spectrum. Since these characteristic lines in the four troponoids are related to the vibrations of the tropone skeletal part, tentative assignments can be made with reference to the assignments for the spectra of tropone[1] and tropolone[4], as Fig. 1 shows.

The following features in the spectra are illustrated in Fig. 1.

(1) The Raman lines of the three tropolones corresponding to the vibrations belonging to



I a b

II: $R_1=R_2=H$
III: $R_1=H$, $R_2=$isopropyl
IV: $R_1=$isopropyl, $R_2=H$

A_1 species of tropone are strong in general. The Raman line due to the C=C in-phase stretching vibration in each spectrum is most intense, but not so strong as that of tropone in the relative intensity.

(2) In a spectrum of 3-isopropyltropolone, it is noticeable that the line due to the C=C in-phase stretching vibration is separated into two lines, at 1489 and 1476 cm^{-1}, with a similar intensity. This fact suggests two possible tautomeric forms, IVa and IVb, for the structure of 3-isopropyltropolone. In the other region, also, some of the Raman lines are found to form pairs, such as 1618 and 1604, 1318 and 1295, 1263 and 1239, 985 and 965, 785 and 758, 728 and 724, and 275 and 234 cm^{-1}.

The existence of similar tautomeric forms must be considered also for 4-isopropyltropolone, and some paired lines, such as 1554 and 1549, 1426 and 1412, 1328 and 1293, 772 and 731, and 280 and 272 cm^{-1}, are pointed out. On the intramolecular hydrogen bonding of tropolone, it has been suggested that a highly mobile tautomeric hydrogen is located by the two equivalent potential minima.[5] Accordingly, it is natural to interpret the vibrational spectra of tropolones on the basis of a consideration of the tautomerism, except for those cases, such as the 5-monosubstituted tropolones, in which two tautomeric forms have the same structural model.

(3) The vibrations due to the C–O–H group are generally strong in the infrared spectra,[4,6,7] but weaker or indistinct in the Raman spectra.

a) The region of 3600~2000 cm^{-1} was measured by using a calcium fluoride prism. The spectrum was measured in carbon tetrachloride (4000~900 cm^{-1} range) and in carbon disulfide (900~400 cm^{-1}).

b) Refs. 4 and 6. c) Ref. 9.

Therefore, it is fairly difficult to distinguish the vibrations of the tropone skeletal part in the infrared spectra, especially in the finger-print region, because of the overlap with the strong and broad absorptions due to the C-O-H group. On the contrary, almost all of the skeletal vibrations are observed distinctly in the Raman spectra.

(4) In the spectra of 4- and 3-isopropyltropolones, the Raman lines due to the isopropyl group[8] are found in the 2968~2872, 1393~1375 and 1188~1132 cm^{-1} regions.

On the basis of these features, the following

remarks can be made concerning the assignments for the observed frequencies of tropolone, 4- and 3-isopropyltropolones.

Tropolone.—The observed frequencies of tropolone and their assignments are summarized in Table I. The infrared spectra of tropolone in the solid, liquid and vapor states and the assignments regarding the C–O–H group, the CH-stretching and some of the CH-bending vibrations have already been described in Parts II[6] and III[4].

In the 1650～1450 cm^{-1} region, the most intense Raman line, at 1473 cm^{-1}, may easily be assigned to the totally symmetric stretching vibration of three C=C bonds. The two bands at 1618 and around 1555 cm^{-1} may be explained as resulting from the participation of both C=O and C=C stretching vibrations, as has been described in the preceding paper.[9] These frequencies are considerably lower than those of the corresponding bands in tropone as a result of the conjugated chelation in a tropolone structure.

When the Raman spectrum in the 1450～1000 cm^{-1} region is compared with that of tropone, the following lines corresponding to each other in frequency and relative intensity are found:

Tropone; 1412 (0.3), 1309 (0.4), 1254 (1.3), 1217 (0.6), 1017 cm^{-1} (0.2).
Tropolone; 1418 (4.2), 1304 (1.9), 1265 (4.2), 1211 (1.9), 1049 cm^{-1} (0.5).

The vibrational frequencies due to the tropone skeletal part in tropolone are not greatly different from those of tropone. Therefore, the above frequencies can be assigned to the same vibrational modes as those of tropone, as is indicated in Table I. The band at 1265 cm^{-1} is assumed to be related to the vibration of the C–O–H group,[4] and thus this band may be considered the overlap of two bands. The band at 1444 cm^{-1} is assumed to correspond to the band at 1473 cm^{-1} of tropone.

The infrared absorptions at 767 and 726 cm^{-1} are assigned to the CH and OH out-of-plane bending vibrations respectively.[4] Of the remaining frequencies in the 1000～700 cm^{-1} region, the two bands at 957 and 744 cm^{-1} can be assigned to the C–C stretching vibrations, since these bands are strong in the Raman spectrum and correspond well to the vibrations belonging to A_1 species of tropone. The latter was also assigned similarly by Imanishi and Ito.[2,3] The other frequencies observed in this region are assumed mainly to be due to the CH bending vibrations, as indicated in Table I.

The bands in the region lower than 700 cm^{-1} are assigned to the deformation vibrations of the tropone skeleton. Of these, the distinct Raman lines at 678, 360 and 342 cm^{-1} are probably due to vibrations similar to the bands at 653, 396 and 329 cm^{-1} of the tropone spectrum.[1]

4-Isopropyltropolone.—The observed frequencies, obtained from the infrared spectra in the

a) The region higher than 2000 cm^{-1} was measured by using a calcium fluoride prism.

solid, liquid, solution and vapor states[10] and from the Raman spectrum, are shown in Table II, together with their possible assignments. The OH and CH-stretching absorptions have already been discussed in Part II.[6] Frequencies in the 1650~1470 cm^{-1} region are due to the tropone skeletal stretching and C–O–H group vibrations, as in the case of tropolone.

The bands in the 1460~1442, 1389~1360 and 1188~1130 cm^{-1} regions are assigned, respectively, to the CH_3 degenerate deformation, the symmetric deformation and the skeletal vibrations of the isopropyl group.[8,11] These bands are very weak in both infrared and Raman spectra. The assignments of the remaining bands in the 1470~1000 cm^{-1} region were given with reference to those of tropolone and after consideration of the variation of absorptions according to the changes of state.[4] The Raman lines at 1030 and 1014 cm^{-1}, as well as those at 1426 and 1412 cm^{-1}, are considered to be doublets due to the existence of two tautomeric forms, IIIa and IIIb.

It is possible to assign the intense Raman lines at 878 and 772 cm^{-1} to the ring C–C stretching, and the absorption bands at 950, 820 and 790 cm^{-1},[12] to the CH out-of-plane bending vibrations, which are expected to have a strong intensity. The broad absorption band at 735 cm^{-1} is the OH out-of-plane vibration. The weak bands at 998 and 951 cm^{-1} are probably assigned to the CH out-of-plane vibrations, which are to be expected in this region. The weak absorptions at 1997 and 1900 cm^{-1} can be explained as the overtones of these vibrations.

3-Isopropyltropolone.—The observed frequencies and their possible assignments are summarized in Table III. The bands observed in the 2967~2865 and 3049~3007 cm^{-1} regions belong to the CH stretching vibrations, and their frequencies differ little from those of 4-isopropyltropolone. The broad infrared absorption in 3450~3095 cm^{-1} is assigned to the OH stretching vibration, and the corresponding Raman lines are very weak. This OH absorption, which is strongest at 3170 cm^{-1} in liquid, shifts to 3095 cm^{-1} and its intensity decreases in carbon tetrachloride. The direction of the shift of absorption caused by the change of state agrees with that in the case of tropolone, but the frequencies in each state are lower by about 50 cm^{-1} than those of many tropolones. Such lower frequencies are also observed in the spectra of 3,7-dibromotropolones[13] and 3-quinonyltropolone (3090 cm^{-1}),[14] all of which have a bulky substituent at the 3-position of the tropolone ring.

Frequencies in the 1650~1470 cm^{-1} region are assigned in the same manner as in the case of 4-isopropyltropolone. The Raman line at 1463 cm^{-1} is assigned to the CH_3 degenerate deformation vibration, and the corresponding infrared band shows a strong intensity because of the overlap with the strong and broad absorption due to the C–O–H group. Two bands in 1395~1375 cm^{-1}, one shoulder at 1345 cm^{-1} and two band in 1183~1130 cm^{-1} are all assigned to the vibration due to the isopropyl group. Of these, the strong intensity of the infrared absorption band at 1394 cm^{-1} indicates the overlapping with the ring CH bending absorption, as its to be expected from the fact that 3-bromotropolone shows the absorption band at 1375 and 1353 cm^{-1} (in carbon tetrachloride).

The broad absorption band at 1233 cm^{-1} in the liquid spectrum appears to be related to the C–O–H group. In carbon tetrachloride, this band shifts to the higher wave number side, merging around 1254 cm^{-1}, as in cases of tropolone and 4-isopropyltropolone.[6] The remaining bands in the 1470~1000 cm^{-1} region have been assigned with reference to the assignments for the spectra of tropolone and 4-isopropyltropolone.

As may be seen in Fig. 1, a line at 877 cm^{-1} and two paired Raman lines at 985 and 965 cm^{-1} and at 728 and 724 cm^{-1} are assigned to the ring C–C stretching vibrations. The broad absorption band, strongest at 742 cm^{-1} in the liquid spectrum, shifts to 739 cm^{-1} in carbon tetrachloride; this is assigned to the OH out-of-plane vibration. Among the remaining bands in the 1000~700 cm^{-1} region, those which are strong in the infrared spectrum and weak in the Raman spectrum are probably to be assigned to the CH out-of-plane bending vibrations, as Table III indicates. The two Raman lines at 785 and 758 cm^{-1} are assumed to be due to the isopropyl group.[8] The Raman lines at 618 and 376 cm^{-1} and the paired ones at 275 and 234 cm^{-1}, which are all distinct in the Raman spectrum, are probably to be assigned to the same vibrations as those of tropone at 653, 396 and 259 cm^{-1} respectively.

The author wishes to express his deep gratitude to Professor Susumu Kinumaki, Professor

Molecular Vibrations and Structures of High Polymers. V.[*1] *The Infrared Active Normal Vibrations of Isotactic Polypropylene, Poly(propylene-2-d), Poly(propylene-1, 1-d_2) and Poly(propylene-3, 3, 3-d_3) in the 1500 ~ 650 cm^{-1} Region*

By Tatsuo MIYAZAWA and Yoshiko IDEGUCHI

(Received May 25, 1963)

Isotactic polypropylene $[-CH_2-CH(CH_3)-]_n$ is structurally typical of a large number of isotactic polymers. Detailed infrared studies of isotactic polypropylene would provide the basic knowledge necessary for vibrational analyses and structure studies of other isotactic polymers. The infrared spectra of isotactic polypropylene and its deuterated derivatives have been measured, and empirical vibrational assignments have been made.[1-6] The effect of isotopic substitutions of the CH, CH_2, and CH_3 groups upon the infrared spectra have been found to be quite complicated. Except for the bands arising from the CH_3 symmetric or asymmetric deformation vibrations or for the bands due to the CH_2 bending vibrations, all the infrared bands in the 1500~650 cm^{-1} region have been found to shift more or less upon the deuterium substitution of any of the CH, CH_2, and CH_3 groups. Therefore, from empirical analyses of the observed isotope effects, all these bands have been considered to be due to hybridized modes of the CH, CH_2, and CH_3 groups.[4] Accordingly, the normal coordinate analyses are indispensable in elucidating the nature of the infrared bands observed for polypropylene and deuterated derivatives.

In our previous studies, general methods were worked out for treating normal vibrations of infinite helical polymers belonging to dihedral groups[7] (for example, polyethylene glycol) or those belonging to cyclic group[8] (for example, isotactic polypropylene). The infrared active normal vibrations of isotactic polypropylene were calculated[8] by the use of the modified Urey-Bradley potential function,[9,10] where the potential constants were transferred from aliphatic hydrocarbons.[11]

The polarized far-infrared spectra of isotactic polypropylene were measured in the 600~280 cm^{-1} region[8] and also in the 400~80 cm^{-1} region, and all the low-frequency infrared active normal vibrations were observed.[12] The normal vibrations of isotactic polypropylene were calculated by the use of the modified Urey-Bradley force field as supplemented by the internal rotation potential about the axial and equatorial C–C bonds and the C-methyl bonds,[13] and the nature of the low-frequency infrared bands were elucidated.[12]

Unfortunately, however, the far-infrared spectra of the deuterated derivatives of isotactic polypropylene have not yet been published. In the present study, therefore, vibrational analyses were made of the infrared bands of isotactic polypropylene and deuterated derivatives observed in the 1500~650 cm^{-1} region.

Normal Coordinate Treatment

The normal vibrations of isotactic polypropylene, $[-CH_2-CH(CH_3)-]_n$; poly(propylene-2-d), $[-CH_2-CD(CH_3)-]_n$; poly(propylene-1,1-d_2), $[-CD_2-CH(CH_3)-]_n$; and poly(propylene-3,3,3-d_3), $[-CH_2-CH(CD_3)-]_n$ were treated in the present research. The high-frequency C–H stretching modes of the CH, CH_2, and CH_3 groups were separated in a manner described previously.[8] The internal rotation modes about the C–C bonds were not taken into account since the contributions of the internal rotation potential are not appreciable for the vibrations of polypropylene lying above 650 cm^{-1}. An NEAC model 2101 digital computer (Nippon Electric Company, Ltd., Tokyo) was used for the numerical computations involved in the normal coordinate treatment. The $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices[14] for the degenerate normal vibrations of isotactic polypropylene were constructed and diagonalized according to a method described previously.[8]

The internal coordinate (or local symmetry coordinate) vectors, R_n, of the n-th repeating unit are,

where Δr's are the stretching coordinates for which the numbering of carbon and hydrogen atoms are shown in Fig. 1. The elements of the vector $\phi(CH)_n$ in Eq. 1, are; $\Delta\phi(2,n-1;1,n;3,n)$, $\Delta\phi(2,n-1;1,n;5,n)$, $\Delta\phi(2,n-1;1,n;2,n)$, $\Delta\phi(3,n;1,n;5,n)$, $\Delta\phi(3,n;1,n;2,n)$, and $\Delta\phi(5,n;1,n;2,n)$. The elements of the vector $\phi(CH_3)_n$ in Eq. 3 are; $\Delta\phi(1,n;3,n;7,n)$, $\Delta\phi(1,n;3,n;8,n)$, $\Delta\phi(1,n;3,n;9,n)$, $\Delta\phi(8,n;3,n;9,n)$, $\Delta\phi(9,n;3,n;7,n)$, and $\Delta\phi(7,n;3,n;8,n)$. The elements of the vector $\phi(CH_2)_n$ in Eq. 5 are; $\Delta\phi(1,n;2,n;4,n)$, $\Delta\phi(1,n;2,n;6,n)$ $\Delta\phi(1,n;2,n;1,n+1)$, $\Delta\phi(4,n;2,n;6,n)$, $\Delta\phi(4,n;2,n;1,n+1)$, and $\Delta\phi(6,n;2,n;1,n+1)$, where $\Delta\phi$'s are the angle-bending coordinates for which the numbering of the atoms are shown in Fig. 1.

For the CH group of polypropylene, there are two CH bending modes. The CH bending

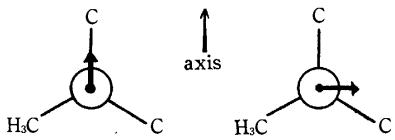

Fig. 2. The axial and equatorial CH bending modes.

mode in the axial direction (CH bend.^{ax}) and the bending mode in the equatorial direction (CH bend.^{eq}) (perpendicular to the helix axis) are given in Eq. 1 and are shown in Fig. 2. For the CH_3 group, there are two asymmetric deformation modes and two rocking modes. The asymmetric deformation mode in the axial direction (CH_3 δ_a^{ax}) and that in the equatorial direction (CH_3 δ_a^{eq}) and the rocking modes in the axial direction (CH_3 rock.^{ax}) and in the equatorial direction (CH_3 rock.^{eq}) are given in Eq. 3 and are shown in Fig. 3.

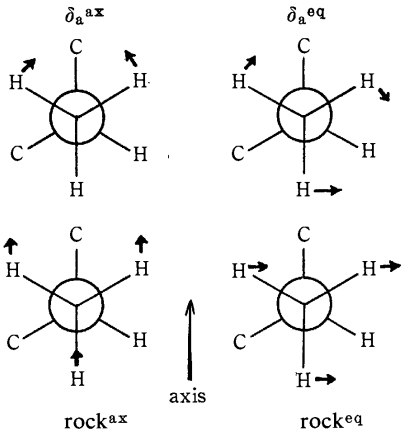

Fig. 3. The axial and equatorial CH_3 asymmetric deformation modes and rocking modes.

In deriving the potential energy matrix, $\boldsymbol{F}$, the modified Urey-Bradley force field[9] was used; the trans-coupling potential[10,11,15] for pairs of C–C–H bond angles in the trans arrangement, the gauche-coupling potential[11] for pairs of C–C–H angles in the gauche arrangement, and the l(C–C–H) angle interaction potential[10,11,16] for the CH_2 group were added as correction terms to the Urey-Bradley force field.[17]

The Urey-Bradley potential constants (in mdyn./Å) of K(C–H) = 3.90 (CH group), K(C–H) = 4.05 (CH_2 group), K(C–H) = 4.05 (CH_3 group), F(H–C–H) = 0.080 and F(H–C–C) = 0.540 were used in correcting for the potential-energy interactions with high-frequency C–H stretching modes.[8]

The C–C stretching constants for the C-methyl bond and the main chain C–C bonds, the H–C–H bending constants for the CH_2 and CH_3 groups, the C–C–H bending constants for the CH, CH_2, and CH_3 groups, the C–C–C bending constant, the C···(C)···C repulsive constants, the intramolecular tension for the CH, CH_2, and CH_3 groups, the trans- and gauche-coupling constants and the angle-interaction constant (l) were adjusted by the

*1 Observed in previous studies (Refs. 8 and 12). Only the frequencies above 250 cm^{-1} are listed for comparisons.

*2 δ^s and δ^a, the symmetric and asymmetric deformations, respectively, of the CH_2-$CH(CH_3)$-CH_2 group; δ, the C-CH_2-C deformation.

method of least squares.[18] The initial set of these constants as transferred from ethane, propane, and isobutane[11] have been described previously[8]. All the fundamental frequencies of $[-CH_2-CH(CH_3)-]_n$, $[-CH_2-CD(CH_3)-]_n$, $[-CD_2-CH(CH_3)-]_n$, and $[-CH_2-CH(CD_3)-]_n$ observed by Peraldo and Farina[1] in the 1500~650 cm^{-1} region and the skeletal frequencies of $[-CH_2-CH(CH_3)-]_n$[8,12] (A species: 456, 398 and 251 cm^{-1}; $E(2\pi/3)$ species: 528, 460 and 321 cm^{-1}) were used for the adjustment of potential constants. The potential constants thus obtained are shown in Table I. A common stretching constant K(C-C) was used for the axial C-C bond and for the equatorial C-C bond since the arrangements of the carbon and hydrogen atoms adjacent to these C-C bonds are the same, as Fig. 4 shows. In the adjustments of the potential constants, the elements of Jacobian matrices (derivatives of frequencies with respect to potential constants) were calculated by means of an equation reported previously.[19]

The trans-coupling ($T=0.104$) and gauche-coupling ($G=-0.044$) constants of polypropylene agree closely with the corresponding constants for polyethylene ($T=0.100$ and $G=-0.033$) and for ethane ($T=0.107$ and $G=-0.025$).[9] It is interesting to note that the gauche constant is nearly equal to $-T/2$.

The frequencies calculated with the final set of potential constants may be compared

* For the notation of the symmetry coordinates, see *3 of Table II.

with the observed frequencies in Tables II—X and in Fig. 5. Except for the unobserved fundamentals, the r. m. s. frequency deviations for the vibrations lying in the 1500~650 cm^{-1} region are: $[-CH_2-CH(CH_3)-]_n$: 1.0%, $[-CH_2-CD(CH_3)-]_n$: 1.1%, $[-CD_2-CH(CH_3)-]_n$: 1.0%, and $[-CH_2-CH(CD_3)-]_n$: 1.2%, and the overall deviation is 1.1%. In view of the small number (a total of 16) of potential constants as compared with the large number (a total of 108) of observed frequencies, a frequency deviation as small as this indicates that these potential constants may now be used for the elucidation of the nature of observed fundamental vibrations. Therefore, the potential energy distributions ($F_{ii}L_{ip}^2/4\pi^2c^2\nu^2$) were also calculated as shown in Tables II–X for the A and E($2\pi/3$) vibrations of polypropylene and the deuterated derivatives. Only the terms greater than 15% are listed in Tables II–X.

For nondegenerate vibrations, the normal modes may be expressed by the elements of the L matrix. When the p-th normal vibration is excited, the i-th internal coordinate (or local symmetry coordinate) of the n-th repeating unit is given by

$$R_{i,n} = (1/N)^{1/2} L_{ip} Q_p \qquad (7)$$

where Q_p is the normal coordinate for the p-th vibration and $(1/N)^{1/2}$ is the normalization factor. On the other hand, for degenerate vibrations of a helical molecule associated with the phase difference of δ, the normal modes may be expressed by the amplitude factor $L_{ip}(\delta)$ and the phase angle $\varepsilon_{ip}(\delta)$. When the p-th degenerate vibration is excited, the i-th internal coordinate of the n-th unit is given by:

$$R_{i,n} = (2/N)^{1/2} L_{ip}(\delta)\{Q_{pa}(\delta)\cos[n\delta + \varepsilon_{ip}(\delta)] + Q_{pb}(\delta)\sin[n\delta + \varepsilon_{ip}(\delta)]\} \qquad (8)$$

where $Q_{pa}(\delta)$ and $Q_{pb}(\delta)$ are the p-th pair of normal coordinates with the phase difference of δ.[8] The L matrix elements [in units of 1/10·Å·(atomic weight)$^{1/2}$] for the A vibrations of isotactic polypropylene are listed in Table XI. The amplitude factor [in units of 1/10·Å·(atomic weight)$^{1/2}$] and the phase angle (in degrees) for the E($2\pi/3$) vibrations are listed in Table XII, where the phase angles were taken in the range of $+90°\sim-90°$ with the result that the values of a number of L_{ip}'s were taken to be negative.

CH_2 Bending Vibrations

The band of polypropylene at 1435 cm^{-1} is also observed for $[-CH_2-CD(CH_3)-]_n$ and $[-CH_2-CH(CD_3)-]_n$, but not for $[-CD_2-CH(CH_3)-]_n$. This band is assigned to the CH_2 bending vibration.[1,4] As is shown in Tables II—V, VIII and IX, the potential energy of this vibration is almost exclusively associated with the CH_2 bending mode.

For $[-CH_2-CH(CD_3)-]_n$, the bands due to the A and E components have been resolved at 1440 (parallel: ∥) and 1438 cm^{-1} (perpendicular: ⊥), respectively.[1] The infrared

*1 Phase angles are listed in parentheses. *2 For the notation of the symmetry coordinates, see *3 of Table II.

intensity ratio for these CH_2 bending vibrations has been calculated to be A : E = 1.8 : 1,[21] where the C-C-C bond angle has been assumed to be 114.5°.*2 In fact, the parallel peak at 1440 cm^{-1} has been found to be slightly stronger than the perpendicular peak at 1438 cm^{-1} (Fig. 4f of Ref. 1).

For neither $[-CH_2-CH(CH_3)-]_n$ nor $[-CH_2-CD(CH_3)-]_n$ has the band at 1435 cm^{-1} been resolved into two components. Furthermore, the calculated frequencies of the A and E CH_2 bending vibrations are essentially the same. Accordingly, the strong $\perp$ dichroism of the band at 1435 cm^{-1} indicates that the E vibration is appreciably stronger than the A vibration; the observed ratio (A : E) is very different from the ratio estimated from the spatial structure or from the ratio observed for $[-CH_2-CH(CD_3)-]_n$. Since the spatial structure of isotactic polypropylene will not change much upon isotopic substitution, the appreciably weak relative intensity of the A component is possibly associated with the normal mode (or hybridization). It may be seen in Tables XI and XII that the hybridization of the methyl asymmetric deformation mode is greater for the CH_2 bending vibration (ν_9) of the A species than the corresponding ν_9 vibration of the E species. For $[-CH_2-CH(CH_3)-]_n$ and $[-CH_2-CD(CH_3)-]_n$, the asymmetric deformation frequencies of the methyl group lie within 30 cm^{-1} of the CH_2 bending frequency and so slight hybridization may well be expected, even though the methyl group is separated from the CH_2 group by the CH group. The slight coupling of the CH_2 bending mode and the CH_3 asymmetric deformation modes is also suggested from the higher frequency shift of the CH_2 bending band upon the deuteration of the CH_3 group.

CH_3 Deformation Vibrations

Asymmetric Deformation Modes. — The $\parallel$ band at 1454 cm^{-1} and the $\perp$ band at 1460 cm^{-1} of polypropylene are also observed for $[-CH_2-CD(CH_3)-]_n$ and $[-CD_2-CH(CH_3)-]_n$, but not for $[-CH_2-CH(CD_3)-]_n$. These bands are assigned to the asymmetric deformation vibrations of the CH_3 group.[1,4,6] The calculated A and E frequencies (ν_7 and ν_8) are nearly the same. Neither the band at 1460 nor that at 1454 cm^{-1} has been resolved into two components, and the dichroism is not strong. Apparently, the 1460 cm^{-1} ($\perp$) band due to the E vibration is overlapped by the corresponding $\parallel$ band due to the A vibration, and the 1454 cm^{-1} ($\parallel$) band due to the A vibration is overlapped by the corresponding $\perp$ band due to the E vibration.

Symmetric Deformation Modes. — The $\perp$ band of $[-CH_2-CH(CH_3)-]_n$ at 1377 cm^{-1} is also observed for $[-CH_2-CD(CH_3)-]_n$ and $[-CD_2-CH(CH_3)-]_n$ but not for $[-CH_2-CH\cdot(CD_3)-]_n$.*3 This band is assigned to the CH_3 symmetric deformation vibration. The frequencies calculated for the corresponding A and E vibrations are essentially the same. Accordingly, the perpendicular dichroism of the band at 1377 cm^{-1} indicates that the perpendicular band due to the E vibration is stronger than the parallel band due to the A vibration. The intensity ratio of the A and E bands has been estimated by Krimm[21] to be 0.4 : 1.0, a figure in good agreement with the observed intensity ratio.

The Normal Vibrations of Polypropylene $[-CH_2-CH(CH_3)-]_n$

In our previous study, the normal vibrations of isotactic polypropylene were treated by the use of potential constants as transferred from other hydrocarbons[8]. In the present study, the gauche-coupling potential and the l(C-C-H) potential were introduced, and the potential constants were refined by the method of least squares. Therefore, the potential energy distributions calculated in the present study differ somewhat from the previous ones. In the following discussions, the nature of the normal vibrations will be discussed, referring to the potential energy distributions as listed in Tables II—IX and to the normal modes as listed in Tables XI and XII.

CH_2 Wagging and Twisting Modes and CH Bending Mode.—In the region between 1370 and 1200 cm^{-1}, four parallel bands (1365, 1326, 1304, and 1254 cm^{-1}) and four perpendicular bands (1360, 1330, 1296, and 1220 cm^{-1}) have been observed for $[-CH_2-CH(CH_3)-]_n$. Similar spectra have also been observed for $[-CH_2-CH(CD_3)-]_n$, but not for either $[-CH_2-CD(CH_3)-]_n$ or $[-CD_2-CH(CH_3)-]_n$. As is shown in Tables II, III, XI, and XII, these bands of $[-CH_2-CH(CH_3)-]_n$ arise from the hybridized vibrations of the CH_2 wagging and twisting modes and from those of the axial and equatorial CH bending modes.

Upon the deuteration of the CH group, two parallel bands (at 1342 and 1291 cm^{-1}) and two perpendicular bands (1334 and 1273 cm^{-1}) have been observed for $[-CH_2-CD(CH_3)-]_n$.

21) S. Krimm, *Fortschr. Hochpolymer.-Forsch.*, 2, 51 (1960).

*2 If the C-C-C bond angle is assumed to have the tetrahedral value, the intensity ratio is derived as A : E = 1 : 1.

*3 As will be discussed later, the parallel band of $[-CH_2-CH(CD_3)-]_n$ at 1379 cm^{-1} is assigned to the ν_8^A vibration (see Table VIII).

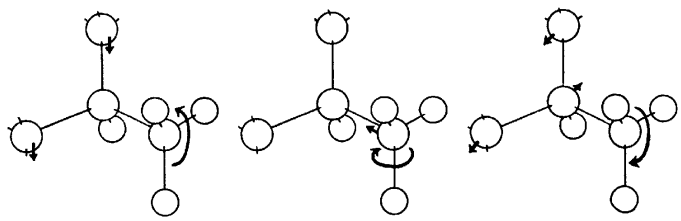

Fig. 6. Schematic representations of the normal modes of the ν_{15}, ν_{17} and ν_{18} vibrations (A species) of isotactic polypropylene.

These bands are due to the CH_2 wagging and twisting modes, which are not hybridized with the CH bending modes (Tables IV and V). On the other hand, for $[-CD_2-CH(CH_3)-]_n$, two parallel bands (1327 and 1313 cm^{-1}) and two perpendicular bands 1325 and 1303 cm^{-1}) have been observed[1] (Tables VI and VII). These bands arise from the CH bending modes (axial and equatorial), which are not hybridized with either the CH_2 wagging or twisting modes. It is interesting to note that the 'intrinsic' CH_2 wagging and twisting frequencies observed for $[-CH_2-CD(CH_3)-]_n$, as well as the 'intrinsic' CH bending frequencies observed for $[-CD_2-CH(CH_3)-]_n$, all lie in the narrow region of 1350~1270 cm^{-1}. Naturally the CH_2 wagging and twisting modes and the CH bending modes are extensively hybridized for the molecule of $[-CH_2-CH(CH_3)-]_n$.

In our previous study, the weak ∥ band at 1254 cm^{-1} and the weak ⊥ band at 1220 cm^{-1} were considered to arise primarily from the CH_2 twisting modes. Actually, however, these frequencies are much lower than the 'intrinsic' CH_2 twisting frequencies as observed for $[-CH_2-CD(CH_3)-]_n$. The A vibration at 1254 cm^{-1} is due to the CH_2 twisting mode as coupled with the CH bending mode in the H–C–methyl plane, whereas the E vibration at 1220 cm^{-1} is due to the CH_2 twisting mode as coupled with the CH bending mode perpendicular to the H–C–methyl plane.

CH_3 and CH_2 Rocking Modes and C–C Stretching Modes.—In the region between 1200 and 900 cm^{-1}, five strong parallel bands due to the A vibrations and five perpendicular bands due to the E vibrations are observed. As Tables II, III, XI, and XII show, these bands of polypropylene arise from the hybridized vibrations of the axial and equatorial CH_3 rocking, the axial and equatorial C–C stretching, the C–methyl stretching, and the CH_2 rocking modes.*5

The parallel bands at 1168, 998, 973 and 842 cm^{-1} are the strongest peaks of polypropylene. As Table II shows, all these bands are associated with the methyl rocking modes. However, the hybridization of the C–C stretching modes is appreciable for these vibrations. Thus, the band at 1168 cm^{-1} is primarily associated with the axial C–C stretching mode as coupled with the axial methyl rocking mode. The band at 1045 cm^{-1} is due to the asymmetric stretching mode of the C-methyl bond and the equatorial C–C bond. The band at 998 cm^{-1} is due to the equatorial rocking mode coupled with the C-methyl bond, whereas the band at 973 cm^{-1} is due to the axial rocking mode as coupled with the antisymmetric stretching mode of the axial and equatorial C–C bonds. The band at 842 cm^{-1} is associated with the methyl rocking mode in the H–C-methyl plane coupled with the symmetric stretching mode of the C-methyl and the equatorial C–C bonds. The hybridizations of the C–C stretching modes and the methyl rocking modes are schematically shown in Fig. 6 for the A vibrations at 1168, 998 and 973 cm^{-1}.

It might be anticipated that the intensities of the parallel bands at 1168 and 973 cm^{-1} are due to the methyl rocking modes in the axial direction. However, the intensity of the band at 998 cm^{-1} is as strong as those of the bands at 1168 or 973 cm^{-1}, although the vibration at 998 cm^{-1} is largely associated with the equatorial methyl rocking mode. Apparently more extensive studies are necessary for a detailed discussion of the intensities of bands arising from much hybridized modes.

*4 The assignments by Liang et al.[4] were: 1360 (⊥), 1330 (⊥), CH_2 wag.+CH bend.; 1304 (∥) and 1296 (⊥), CH_2 twist.+CH and CH_3 bend.; 1255 (∥) and 1220 cm^{-1} (⊥), CH bend.+CH_2 rock.+CH_3 rock. The assignments by McDonald and Ward[6] were: 1360 (⊥), 1304 (∥), 1254 (∥), and 1220 (⊥), CH bend.; 1330 (⊥), CH_2 wag.; and 1296 cm^{-1} (⊥), CH_2 twist.

*5 The assignments by Liang et al.[4] were: 1168 (∥) and 1155 (⊥), CH_3 rock.+CH_2 and CH bend.; 1103 (⊥), 1045 (∥), 998 (∥), 941 (∥) and 899 (⊥), r_{CC}; 973 (∥), CH_3 rock.+CH_2 and CH rock.; 840 (∥) and 809 (⊥), CH_2 rock.+CH and CH_3 rock. The assignments by McDonald and Ward[6] were: 1168 (∥), CH_3 rock.+r_{CC}; 1103 (⊥), 941 (⊥), 899 (⊥) and 809 (⊥), CH bend.+r_{CC}; 1045 (∥), r_{CC}+CH_3 rock.; 998 (∥), r_{CC}+CH_3 rock.+CH_2 rock.; 973 (∥), CH_3 rock.+CH_2 rock.+r_{CC}; 842 (∥), CH_2 rock.+CH_3 rock.+r_{CC}.

The perpendicular band of polypropylene at 1155 cm^{-1} has also been observed in the Raman effect[22]. This band corresponds to the calculated ν_{15}^{E} frequency of 1156 cm^{-1}. Although the ν_{15}^{E} perpendicular band and the ν_{15}^{A} parallel band lie close to each other, these vibrations are quite different from each other. Thus the ν_{15}^{E} vibration is primarily associated with the C-methyl stretching mode as coupled with the CH bending modes modes in the axial and equatorial directions, but it is not much associated with the methyl rocking modes. On the other hand, the three perpendicular bands at 1103, 941 and 899 cm^{-1} are due to the methyl rocking modes, where the contributions of the axial or equatorial C–C stretching modes are also appreciable.

The band at 1103 cm^{-1} is due to the methyl rocking mode in the axial direction ($\varepsilon=0°$), the rocking mode in the equatorial direction ($\varepsilon=25°$), and the axial C–C stretching mode ($\varepsilon=10°$), with small phase angle differences among them. The band at 941 cm^{-1} is due to the axial methyl rocking mode ($\varepsilon=0°$), the equatorial rocking mode ($\varepsilon=-30°$), the axial C–C stretching mode ($\varepsilon=-20°$), and the equatorial C–C stretching mode ($\varepsilon=65°$). The axial and equatorial C–C stretching modes for this vibration are almost 90° out-of-phase. The band at 899 cm^{-1} is due to the equatorial methyl rocking mode ($\varepsilon=0°$), the equatorial CH bending mode ($\varepsilon=-15°$), and the CH_2 rocking mode ($\varepsilon=40°$), all of which take place in the equatorial direction. The methyl rocking mode and the CH bending mode are almost in phase for this vibration.

The perpendicular band at 809 cm^{-1} is due to the CH_2 rocking mode ($\varepsilon=0°$), coupled with the C-methyl stretching mode ($\varepsilon=-35°$) and the equatorial C–C stretching mode ($\varepsilon=25°$). On the other hand, the ν_{20}^{A} vibration calculated at 819 cm^{-1} is primarily due to the the CH_2 rocking mode. The displacements of the hydrogen atoms associated with this rocking mode are nearly perpendicular to the helix axis; this vibration has not, however, yet been located in the infrared absorption.

The Normal Vibrations of Poly(propylene-2-d) $[-CH_2-CD(CH)_3-]_n$

CH_2 Wagging and Twisting Modes.—As has been discussed before, the CH_2 wagging and twisting modes of $[-CH_2-CH(CH_3)-]_n$ are coupled with the CH bending modes. However, the CH_2 wagging and twisting modes of $[-CH_2-CD(CH_3)-]_n$ are almost free from the coupling with the CD bending modes, since the "intrinsic" CD bending frequencies are much lower than the 'intrinsic' CH_2 wagging and twisting frequencies. As Tables IV and V show, the parallel band of $[-CH_2-CD(CH_3)-]_n$ at 1342 cm^{-1} and the perpendicular band at 1334 cm^{-1} are associated almost exclusively with the CH_2 wagging mode. The parallel band at 1291 cm^{-1} and the perpendicular band at 1273 cm^{-1} are associated with the CH_2 twisting modes in accordance with the assignment made by Liang et al.[4]*6

The CH_2 wagging and twisting frequencies of propane are 1336 and 1278 cm^{-1} respectively.[11] These vibrations of propane are also free from much coupling with other modes. Therefore, the 'intrinsic' CH_2 wagging and twisting frequencies may be taken to be about 1335 cm^{-1} and 1280 cm^{-1} respectively.

CD Bending, CH_3 and CH_2 Rocking, and C–C Stretching Modes.—For $[-CH_2-CD(CH_3)-]_n$, eight parallel bands and seven perpendicular bands are observed[1] in the 1250~650 cm^{-1} region; all these bands arise from the hybridized vibrations of the CD bending, CH_3 rocking, CH_2 rocking, and C–C stretching modes. (No single band is due to a 'pure' mode.) All these modes have their intrinsic frequencies in the 1100~800 cm^{-1} region. For highly symmetric molecules, symmetry elements (such as twofold axes or planes of symmetry) impose restrictions upon the couplings among those vibrational modes, even though their 'intrinsic' frequencies lie in the same frequency region. However, the molecular chain of isotactic polypropylene does not have such symmetry elements, and all those vibrational modes of $[-CH_2-CD(CH_3)-]_n$ are subject to extensive hybridization.

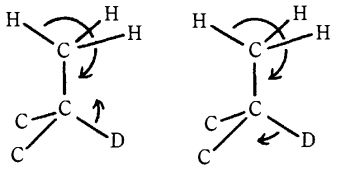
The bands at 1060 (∥) and 1091 cm^{-1} (⊥) have been assigned to the C–D bending mode.[6] However, to judge from the normal coordinate analysis, these bands are not very much associated with the CD bending modes. Rather, the A vibration at 1060 cm^{-1} is due to the equatorial methyl rocking mode coupled with the CH_2 rocking mode, while, on the other hand, the E vibration at 1091 cm^{-1} is due to the equatorial methyl rocking mode coupled with the C-methyl stretching mode.*7

The parallel bands at 981, 969 and 790 cm^{-1} are the strongest peaks in the 1250~650 cm^{-1} region. The ν_{16}^{A} vibration is associated with the C-methyl stretching mode, the axial methyl rocking mode, and the axial CD bending

22) M. C. Tobin, *J. Opt. Soc. Am.*, 49, 850 (1959).

*6 McDonald and Ward[6] also have assigned the bands at 1334 (⊥) and 1291 cm^{-1} (∥) to the CH_2 wagging and twisting modes respectively.

*7 Weak bands were observed at 1049 (∥) and 1016 cm^{-1} (⊥) and were assigned to CD bending modes.[6] These bands, however, are not identified in the spectra reported by Peraldo and Farina (Fig. 2b of Ref. 1).



(a) (b)

Fig. 7. Schematic representations of the A vibrations of isotactic poly(propylene-2-d) at 790 cm^{-1} (a) and 1145 cm^{-1} (b).

mode. The ν_{17}^{A} vibration is associated with the methyl rocking mode perpendicular to the D-C-methyl plane as coupled with the axial C-C stretching mode.

The medium intensity band at 1210 cm^{-1} (‖) has been considered to be due to the coupling of the methyl rocking mode and the C-C stretching mode.[8] However, as Table IV shows, this band is due to the antisymmetric stretching mode of the axial and equatorial C-C bonds as coupled with the CD bending mode perpendicular to the D-C-methyl plane.

The strong parallel band at 790 cm^{-1} is due to the coupling of the CD bending mode and the CH_3 rocking mode (both in the D-C-methyl plane), as is schematically shown in Fig. 7a. On the other hand, the medium intensity band at 1145 cm^{-1} is primarily due to the other hybridization of the CD bending and methyl rocking modes, as shown in Fig. 7b. This vibration is, therefore, the counterpart of the A vibration at 790 cm^{-1}.

The CH_2 rocking mode (A species) of $(-CH_2-CD(CH_3)-]_n$ is strongly coupled with the CD bending mode (nearly perpendicular to the D-C-methyl plane). This band appears to be much stronger than the corresponding A vibration of $[-CH_2-CH(CH_3)-]_n$ calculated at 819 cm^{-1}. This is possibly due to the greater coupling of the CH_2 bending mode with the CD bending mode.

It is noteworthy that the perpendicular bands of $[-CH_2-CD(CH_3)-]_n$ are much weaker than the parallel bands observed in the 1250 ~650 cm^{-1} region although these E vibrations are also due to the hybridizations of the CD bending, CH_3 and CH_2 rocking, and C-C stretching modes, as are the A vibrations (Tables IV and V).

The Normal Vibrations of Poly(propylene-1, 1-d_2), $[-CD_2-CH(CH_3)-]_n$

CH Bending Modes.—As has been discussed before, the CH bending modes of $[-CH_2-CH(CH_3)-]_n$ are coupled with the CH_2 wagging and twisting modes. However, the CH bending modes of $[-CD_2-CH(CH_3)-]_n$ are almost free from couplings with the CD_2 wagging or twisting modes. As Tables VI and VII show, the parallel bands at 1327 and 1313 cm^{-1} and the perpendicular bands at 1325 and 1303 cm^{-1} are almost exclusively due to the CH bending modes. The CH bending displacements of the ν_{10}^{A} and ν_{11}^{E} vibrations are perpendicular to the H-C-methyl plane, whereas the CH bending displacements of the ν_{11}^{A} and ν_{10}^{E} vibrations are in the H-C-methyl plane.

The CH bending vibration of isobutane, which is observed at 1330 cm^{-1}, is not much coupled with other vibrational modes. Taking into account the CH bending frequencies of isobutane as well as of $[-CD_2-CH(CH_3)-]_n$, the 'intrinsic' CH bending frequency may be taken as ca. 1320 cm^{-1}.

CD_2 Rocking Modes.—The parallel band of $[-CD_2-CH(CH_3)-]_n$ at 691 cm^{-1} is primarily due to the CD_2 rocking mode, as Table VI shows. The intensity of this band is much stronger than the corresponding band (ν_{20}^{A}) of $[-CH_2-CH(CH_3)-]_n$. The perpendicular band at 716 cm^{-1} is due to the CD_2 rocking mode, coupled with the C-methyl stretching mode and the equatorial C-C stretching mode.

CD_2 Bending.—The perpendicular band at 1051 cm^{-1} corresponds to the calculated ν_{15}^{E} frequency of 1042 cm^{-1}, and this band is considered to be due to the CD_2 bending mode (Table VII). On the other hand, the strong parallel band at 1058 cm^{-1} appears to correspond to the ν_{15}^{A} vibration calculated at 1048 cm^{-1} or to the ν_{14}^{A} vibration calculated at 1082 cm^{-1}. The ν_{15}^{A} vibration is associated with the CD_2 bending mode, coupled with the equatorial methyl rocking mode. The ν_{14}^{A} vibration is associated with the hybridization of the axial methyl rocking mode and of the antisymmetric stretching mode of the C-methyl and C-C bonds.

CD_2 Wagging and Twisting Modes, CH_3 Rocking Modes, and C-C Stretching Modes.—The parallel band at 1134 cm^{-1} is due to the methyl rocking mode (in the H-C-methyl plane) coupled with the CD_2 twisting mode. The perpendicular band at 1110 cm^{-1} corresponds either to the ν_{14}^{E} vibration calculated at 1103 cm^{-1} or to the ν_{13}^{E} vibration calculated at 1128 cm^{-1}. The ν_{14}^{E} vibration is associated with the CD_2 wagging mode and the methyl rocking mode in the H-C-methyl plane.

The parallel band at 1184 cm^{-1} is due to the axial C-C stretching mode, coupled with the CD_2 wagging mode, whereas the perpendicular band at 1170 cm^{-1} is due to the equatorial C-C bond, coupled with the CD_2 bending mode. The nature of the infrared bands of poly(propylene-1, 1-d_2) in this region of the spectrum are too complicated for empirical analyses based on the isotope shifts.

The parallel bands at 894 and 868 cm^{-1} are due to the methyl rocking modes, coupled with the CD_2 wagging or twisting modes, as Table VI shows. The methyl rocking motion of the ν_{17}^A vibration (calculated at 900 cm^{-1}) is nearly perpendicular to the H-C-methyl plane, whereas the rocking motion of the ν_{18}^A vibration (calculated at 878 cm^{-1}) is nearly in the H-C-methyl plane. The parallel band at 1013 cm^{-1} arises from the antisymmetric stretching mode of the C-methyl and equatorial C–C bonds, coupled with the CD_2 wagging and methyl rocking mode.

The perpendicular band at 896 cm^{-1} is due to the methyl rocking mode (perpendicular to the H-C-methyl plane), coupled with the axial C–C stretching mode. The band due to the ν_{18}^E vibration is possibly overlapped by the strong parallel band at 868 cm^{-1}. The methyl rocking mode of the ν_{18}^E vibration is nearly in the H-C-methyl plane.

The weak parallel band at 764 cm^{-1} and the perpendicular band at 811 cm^{-1} are primarily due to the CD_2 twisting modes, as Table VI and VII show.

The Normal Vibrations of Poly(propylene-3, 3, 3-d_3), $[-CH_2-CH(CD_3)-]_n$

CH_2 Wagging and Twisting Modes and CH Bending Modes. — For isotactic $[-CH_2-CH\cdot(CD_3)-]_n$, four parallel bands and four perpendicular bands are observed in the 1400～1200 cm^{-1} region.[1] The absorption spectra in this region are very similar to the spectra of $[-CH_2-CH(CH_3)-]_n$. These bands arise from the coupling of the CH_2 wagging, CH bending, and CH_2 twisting modes, as Tables VIII and IX show*8. It may be seen that the A vibrations of $[-CH_2-CH(CD_3)-]_n$ at 1379, 1334, 1305 and 1239 cm^{-1} closely correspond to the A vibrations of $[-CH_2-CH(CH_3)-]_n$, except for a slight hybridization of the methyl symmetric deformation mode. Also the E vibrations of $[-CH_2-CH(CD_3)-]_n$ at 1361, 1333, 1293, and 1206 cm^{-1} correspond to the E vibrations of $[-CH_2-CH(CH_3)-]_n$ at 1360, 1330, 1296, and 1220 cm^{-1} respectively.

CD_3 Asymmetric Deformation Modes. — The strong parallel band at 1051 cm^{-1} corresponds to the ν_{14}^A and ν_{15}^A vibrations (calculated at 1049 and 1045 cm^{-1} respectively), and the strong perpendicular band at 1054 cm^{-1} corresponds to the ν_{15}^E and ν_{16}^E vibrations (calculated at 1044 and 1040 cm^{-1}, respectively). As Tables VIII and IX show, these bands are associated almost exclusively with the asymmetric deformation modes of the CD_3 group.

Liang et al. have assigned the bands at 1051 and 1054 cm^{-1} to the overlapped A and E components of all the asymmetric and symmetric deformation modes of the CD_3 group.[4] On the other hand, McDonald and Ward have assigned the strong bands at 1051 (∥) and 1145 cm^{-1} (⊥) to the symmetric and asymmetric deformation modes, respectively, of the CD_3 group.[6] As for the bands due to the symmetric modes, the present normal coordinate analysis favors the assignment made by Liang et al.

CD_3 Symmetric Deformation Mode.—The CD_3 symmetric deformation modes are strongly coupled with the C–C stretching modes. The weak parallel band at 1115 cm^{-1} appears to correspond to the ν_{13}^A vibration calculated at 1083 cm^{-1}. This vibration arises from a strong coupling between the CD_3 symmetric deformation mode and the C-methyl stretching mode. The perpendicular band at 1081 cm^{-1} corresponds either to the ν_{13}^E vibration calculated at 1079 cm^{-1} or to the ν_{14}^E vibration calculated at 1061 cm^{-1}. The ν_{13}^E vibration is associated with the axial and equatorial C–C stretching modes, coupled with the CD_3 symmetric deformation mode, whereas the ν_{14}^E vibration is primarily due to the CD_3 symmetric deformation mode, coupled with the asymmetric deformation mode. The parallel band at 989 cm^{-1} corresponds to the ν_{16}^A vibration and is due to the equatorial C–C stretching mode and the CD_3 symmetric deformation mode.

CD_3 Rocking Mode.—The parallel bands of $[-CH_2-CH(CD_3)-]_n$ at 791 and 703 cm^{-1} and the perpendicular bands at 759 and 743 cm^{-1} are associated almost exclusively with the CD_3 rocking modes, as Tables VIII and IX show.*9 The 'intrinsic' CD_3 rocking frequency appears to be much lower than the intrinsic frequencies of the CH_2 wagging and twisting modes or the C–C stretching mode. For the A vibration at 791 cm^{-1} and the E vibration at 759 cm^{-1}, the CD_3 rocking mode is nearly perpendicular to the H-C-methyl plane, whereas for the A vibration at 703 cm^{-1} and the E vibration at 743 cm^{-1} the CD_3 rocking mode is nearly parallel to the H-C-methyl plane.

CH_2 Rocking Mode and C–C Stretching Modes. —The parallel band at 807 cm^{-1} and the perpendicular band at 821 cm^{-1} are primarily due to the CH_2 rocking modes, coupled with the

*8 The bands at 1305 (∥) and 1293 (⊥) were assigned by Liang et al.[4] to the CH_2 twisting modes. The assignments by McDonald and Ward[6] were: 1379 (∥) and 1333 (⊥), CH_2 wag; 1293 (⊥), CH_2 twist; 1361 (⊥), 1305 (∥), 1239 (∥), and 1206 cm^{-1} (⊥), CH bend.

*9 The bands at 1081 (⊥), 909 (∥), and 791 cm^{-1} (∥) have been considered to be due in part to the CD_3 rocking modes.[6]

C-methyl or equatorial C–C stretching modes.*[10] The parallel band at 909 cm^{-1} is due to the symmetric stretching mode of the C-methyl and equatorial C–C bonds (coupled with the equatorial CD_3 rocking mode and the CH_2 twisting mode). On the other hand, the strong perpendicular band at 1145 cm^{-1} is due to the C–methyl stretching mode and the CH bending mode.

The Liquid Spectra of Isotactic Polypropylene and Its Deuterated Derivatives

On the basis of the potential energy distributions as well as on that of the normal modes calculated for the crystalline spectra, one may also assign the bands observed in the liquid spectra of isotactic polypropylene and its deuterated derivatives.

Localized Modes.—The effect of melting upon the infrared spectra of isotactic polypropylene[23,24] and its deuterated derivatives[1] have been studied, and several absorption bands have been found to persist upon melting. For example, strong bands are observed at 1380 cm^{-1} and 1460 cm^{-1} for $[-CH_2-CH\cdot(CH_3)-]_n$, $[-CH_2-CD(CH_3)-]_n$, and $[-CD_2-CH(CH_3)-]_n$, but not for $[-CH_2-CH(CD_3)-]_n$. These peaks are assigned to the symmetric and asymmetric deformation modes, respectively, of the methyl group. Similarly, for $[-CH_2-CH(CD_3)-]_n$ in the liquid state, a strong band is observed at 1052 cm^{-1}. This band corresponds to the strong bands at 1054 ($\parallel$) and 1051 cm^{-1} ($\perp$) in the crystalline state and is assigned to the asymmetric deformation modes of the CD_3 group in the liquid state.

The strong band at 1446 cm^{-1} is observed for $[-CH_2-CH(CD_3)-]_n$ and is assigned to the CH_2 bending mode. For $[-CH_2-CH(CH_3)-]_n$ and $[-CH_2-CD(CH_3)-]_n$ in the liquid state, the band due to the CH_2 bending mode is overlapped by the strong band arising from the asymmetric methyl deformation modes. For $[-CD_2-CH(CH_3)-]_n$, a medium intensity band is observed at 1057 cm^{-1}. This band appears to correspond to the ν_{15}^{A} (1058 cm^{-1}) and ν_{15}^{E} vibration (1051 cm^{-1}) and is assigned to the CD_2 bending mode.

The frequencies of the symmetric and asymmetric deformation vibrations of the CH_3 group or the bending vibrations of the CH_2 group do not shift essentially upon melting. As Tables II–IX show, the potential energy of these vibrations is concentrated in one vibrational mode, while the atomic displacements are localized in the methyl or the methylene groups. Therefore, even though the main chain of isotactic polypropylene carries out internal-rotation rearrangements above the melting point, these localized vibrations of the methyl or the methylene groups are not very much influenced by the thermal motions of the backbone chain. The bands arising from localized vibrations in the liquid state may be as strong and sharp as the corresponding bands in the crystalline state.

CH_2 Wagging and Twisting Modes.—On the basis of these considerations, it would be anticipated that the bands due to 'localized' vibrations in the liquid state will be stronger and more well-defined as the localization becomes higher. In fact, for $[-CH_2-CD(CH_3)-]_n$, a strong band is observed at 1333 cm^{-1}; this band is assigned to the CH_2 wagging mode in the liquid state. As has been discussed before, the CH_2 wagging vibration of this molecule is free from coupling with other modes, and its vibrational displacements are much localized in the $C-CH_2-C$ group. The frequency of this band agrees closely with the 'intrinsic' CH_2 wagging frequency taken at 1335 cm^{-1}. In the crystalline state, the CH_2 wagging frequencies ($\nu_{11}^{A}=1342$ cm^{-1} and $\nu_{11}^{E}=1334$ cm^{-1}) are split by 8 cm^{-1}.

The liquid band of $[-CH_2-CD(CH_3)-]_n$ at 1282 cm^{-1} corresponds to the 'intrinsic' CH_2 twisting frequency of 1280 cm^{-1} and is assigned to the CH_2 twisting mode in the liquid state. As has been discussed before, the twisting mode of this molecule is also free from much coupling with other vibrational modes, and the vibrational displacements are greatly localized in the $C-CH_2-C$ group. In the crystalline state, the twisting frequencies are split into the A component at 1291 cm^{-1} and the E component at 1273 cm^{-1}.

CH Bending Modes.—For $[-CD_2-CH(CH_3)-]_n$, a strong band is observed at 1318 cm^{-1} in the liquid state. This band corresponds to the 'intrinsic' CH bending frequency of 1320 cm^{-1}. The CH bending vibrations of this molecule are not much coupled with other vibrational modes.

For $[-CH_2-CH(CD_3)-]_n$ in the liquid state, four bands are observed[1] at 1358, 1326 (shoulder), 1293, and 1235 cm^{-1}. These peaks arise from the CH_2 wagging and twisting modes and the CH bending modes in the liquid state. These frequencies, however, are shifted slightly but distinctly from the 'intrinsic' frequencies of the CH_2 wagging, twisting and CH bending modes, indicating vibrational couplings among these modes, even in the liquid state. Vibrational couplings among these

*[10] The parallel band at 710 cm^{-1} was assigned to the CH_2 rocking mode by McDonald and Ward.[6]

23) G. Natta, *J. Polymer Sci.*, 16, 143 (1955).

24) K. Abe and K. Yanagisawa, ibid., 36, 536 (1959).

modes should depend upon the internal-rotation conformations about the axial and equatorial C–C bonds. Therefore, theoretical analyses of these couplings will be useful for conformation studies of isotactic polypropylene chains in the liquid state.

CD_3 Rocking Modes. — For $[-CH_2-CH\cdot(CD_3)-]_n$ in the liquid state, two medium-intensity bands are observed at 790 and 709 cm^{-1}. The band at 790 cm^{-1} corresponds to the $\nu_{19}{}^A$ (791 cm^{-1}) and $\nu_{19}{}^E$ vibrations (759 cm^{-1}) of the crystalline state, vibrations which are associated with the CD_3 rocking mode perpendicular to the H–C-methyl plane. On the other hand, the liquid band at 709 cm^{-1} corresponds to the $\nu_{20}{}^A$ (703 cm^{-1}) and $\nu_{20}{}^E$ vibrations (743 cm^{-1}), which are associated with the CD_3 rocking mode in the H–C-methyl plane. As Tables VIII and IX show, these vibrations of the crystalline state are associated exclusively with the CD_3 rocking modes, and the vibrational displacements are localized, at least in the CD_3–$CH\langle^{C}_{C}$ group. These CD_3 rocking modes involve the vibrational displacement of the main-chain carbon atoms and, in fact, the A and E frequencies of the ν_{19} or ν_{20} vibrations are split by 30~40 cm^{-1}. These splittings are reduced upon melting when the main chain conformations are not rigid. On the other hand, the internal rotation conformation of the CD_3–$CH\langle^{C}_{C}$ group does not change upon the rearrangement of the CD_3 group from one staggered form to another. Therefore, the CD_3 rocking modes are not influenced by the internal rotation of the CD_3 group, and well-defined bands due to the CD_3 rocking modes may well be expected, even in the liquid state. Accordingly, the liquid band at 790 cm^{-1} is assigned to the CD_3 rocking mode perpendicular to the H–C-methyl plane, whereas the band at 709 cm^{-1} is assigned to the CD_3 rocking mode in the H–C-methyl plane.

The CD_3 rocking frequencies of perdeuterated ethane, C_2D_6, are observed at 970 cm^{-1} (E_g) and 594 cm^{-1} (E_u). Since the splitting of these rocking frequencies arises from the trans- and gauche-coupling potential term,[9,11] the 'intrinsic' CD_3 rocking frequency may be taken to have an average value of about 780 cm^{-1} [~(970+594)/2]. The CD_3 rocking vibration of $[-CH_2-CH(CD_3)-]_n$ at 790 cm^{-1} corresponds to the intrinsic frequency derived from deuteroethane.

CH_3 Rocking and C–C Stretching Modes.— For $[-CH_2-CH(CH_3)-]_n$ two strong bands are observed at 1151 cm^{-1} and 971 cm^{-1} in the liquid state. These liquid bands are possibly associated with 'localized' vibrational modes of the CH_3–$CH\langle^{C}_{C}$ group modes, which are not influenced by the internal rotation rearrangements, at least of the CH_3 group.

The intrinsic CH_3 rocking frequency may be estimated at about 1000 cm^{-1} [~(1190+821)/2] from the CH_3 rocking frequencies (E_g: 1190 cm^{-1} and E_u: 821 cm^{-1}). The liquid band of $[-CH_2-CH(CH_3)-]_n$ at 971 cm^{-1} corresponds to this intrinsic frequency and is considered to be associated primarily with the CH_3 rocking modes in the liquid state. On the other hand, the contributions of the C–C stretching modes are possibly greater for the liquid band at 1151 cm^{-1} than that of the methyl rocking mode. Since the degenerate C–C stretching vibration of isobutane,[11] CH_3–$CH\langle^{CH_3}_{CH_3}$, is observed at 1166 cm^{-1}, the liquid band of polypropylene at 1151 cm^{-1} is possibly associated with the asymmetric stretching mode, coupled with the methyl rocking mode of the CH_3–$CH\langle^{C}_{C}$ group. Naturally, these tentative assignments should be examined further by means of theoretical treatment of the liquid spectra. Nevertheless, these considerations are supported by the observation of a corresponding strong band at 1140 cm^{-1} in the liquid spectra of $[-CH_2-CH(CD_3)-]_n$, a band which may not be ascribed to the methyl rocking mode. More extensive analyses of the liquid spectra of isotactic polypropylene and deuterated derivatives will be important for conformation studies of the isotactic polymeric chain, and, accordingly, theoretical developments in the treatment of the liquid spectra of flexible polymeric chains are highly desirable.

Summary

The infrared active normal vibrations of isotactic polypropylene and its deuterated derivatives in the crystalline state have been treated by the general method derived previously.[8] The modified Urey-Bradley force field has been used; the trans- and gauche-coupling potential terms for the H–C–C angles and the angle-interaction terms for the methylene group have been added to the Urey-Bradley force field. A total of 16 potential constants have been adjusted by the method of least squares, and a total of about 100 infrared-active frequencies have been calculated with the r. m. s. frequency deviation as small as 1.1%. The potential energy distributions have been calculated, together with the normal modes, and the nature of the inferred bands observed in the 1500~650 cm^{-1} region

have been elucidated. Vibrational assignments for the well-defined liquid bands of isotactic polypropylene and its deuterated derivatives have also been made.

The authors wish to thank Professor Takehiko Shimanouchi of the University of Tokyo for his encouragement and his stimulating discussions and Dr. Kunio Fukushima of Osaka University and Dr. Takaharu Ohnishi and Dr. Hiroaki Takahashi of the University of Tokyo for their helpful discussions.

The Electron Spin Resonance of o-Substituted Benzophenone Ketyls

By Kazuhiro MARUYAMA,*1 Rikuhei TANIKAGA and Ryozo GOTO

(Received April 20, 1963)

Previous papers[1,2] in this series have shown that ketyls of those benzophenone derivatives which consist of non-substituted phenyl groups and ortho-substituted phenyl groups (i. e., 2-methylbenzophenone, 2, 6-dimethylbenzophenone, 2, 6-dimethyl-4-*t*-butylbenzophenone, 2, 4, 6-trimethylbenzophenone and 2-methylcyclohexyl phenyl ketone—group I) give extremely different ESR spectra from those of the ketyls of benzophenone and para-substituted benzophenone derivatives (i. e., 4-methylbenzophenone, 4, 4'-dimethylbenzophenone, 4-*t*-butylbenzophenone, 4, 4'-di-*t*-butylbenzophenone, 4-methoxybenzophenone, 4, 4'-dimethoxybenzophenone and 4-ethylbenzophenone—group II). That is, although the ketyls of group II give well-resolved spectra, the ketyls of group I give less well-resolved spectra consisting of four broad lines. We have speculated that these four broad lines might be caused by a larger accumulation of free electron spin on a non-substituted phenyl group — especially an accumulation at two ortho- and para-positions. In order to confirm this hypothesis, the ESR spectrum of the ketyl of d_5-phenyl 2-methylphenyl ketone was studied. Two other pieces of experimental evidence were also obtained in support of the authors' view.

Results and Discussion

The Ketyl of the d_5-Phenyl 2-Methylphenyl Ketone.[*2] — The ESR spectra of the ketyls of the d_5-phenyl 2-methylphenyl ketone (I) and of the phenyl 2-methylphenyl ketone (II) are shown in Fig. 1. ESR measurement was done in a dilute solution of the ketyl in tetrahydrofuran (THF). When these two spectra are compared, the difference is quite clear. II gives four broad lines with a total width of 21.7 gauss, while I gives a single line with a smaller total width of 18.5 gauss. Since the

nuclear spin of deuterium is one, seven lines should be observed if the free electron spin is accumulated exclusively into two ortho- and para-positions of the non-substituted phenyl group. However, line broadening is caused by the thermal motion of the ortho methyl on the other phenyl group (time-dependent local field change), as is evident from the previous paper and from the following experimental results. The nuclear magnetic moment of deuterium is one-seventh that of protium. The results obtained above are, therefore, reasonable.

The Ketyl of the 2-Methylphenyl 4'-*t*-Butylphenyl Ketone. — The ESR spectrum of the ketyl of the 2-methylphenyl 4'-*t*-butylphenyl ketone was obtained in a dilute solution of THF (Fig. 2). The spectrum consists of three broad lines. The intensity ratio of the lines is 1 : 2 : 1. This fact also shows that the free electron spin is exclusively accumulated at two ortho-positions of the 4'-*t*-butyl-substituted phenyl group.

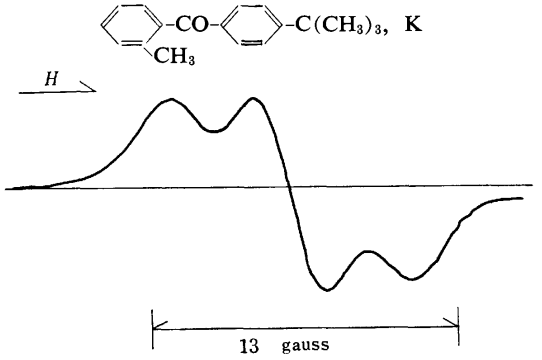

Fig. 2

The Ketyl of the 2-Methylphenyl 3'-Chlorophenyl Ketone. — The ESR spectrum of the ketyl of the 2-methylphenyl 3'-chlorophenyl ketone was observed in a dilute solution of THF (Fig. 3). The spectrum consists of four broad lines. The intensity ratio of the spectrum lines is nearly 1 : 3 : 3 : 1. This result shows that the free electron spin density of the meta positions of the non-ortho-substituted phenyl group is nearly zero or, at least, very small.

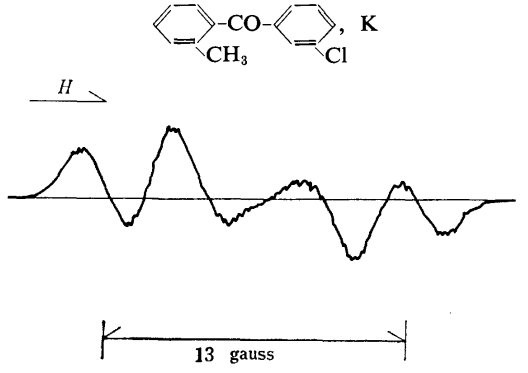

Fig. 3

Discussion

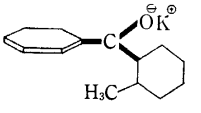
All the results so far obtained show that the free electron spin of the ketyl of the benzophenone derivative which is constructed form the non-ortho-substituted phenyl and the ortho-substituted phenyl is delocalized mainly on a non-ortho-substituted phenyl of the two phenyl groups. If we could assume that the splitting parameter for aromatic hydrocarbons (23 gauss) is also applicable to these ketyls, we could say that about fifty per cent of the free electron spin is located on the non-substituted phenyl group, since the splitting between the four broad lines is about five gauss in almost all cases. The rest of the free electron spin will reside on the $\cdot\dot{C}-OK$ group. The structure of the ketyl has been the subject of extensive investigations.[3-8] Recently Hirota[9] showed the possibility of the existence of paramagnetic dimers due to the dimerization of monomer ion pairs. The simplest representation of ketyl structure, however, is III.

$$C_6H_5-\dot{C}(O^{\ominus}K^{\oplus})-C_6H_4X$$

III

X=*o*-, *m*-, *p*-, CH_3, CH_3O, $C(CH_3)_3$, Cl, etc.

From the said results, the spatial arrangement of the ketyl which consists of the non-ortho-substituted phenyl group and the ortho-substituted phenyl group is to be represented by IV.



IV

That is to say, the ortho-substituted phenyl group is bent out of the plane of the three central bonds because of the steric hindrance

of the ortho methyl group. Deguchi[10] reported recently that the diphenyl nitric oxide derivative, which has an ortho substituent, gave an extraordinarily broad ESR spectra although the other derivatives gave a well-resolved hyperfine structure. He was inclined to consider that most of the electron spin densities must be delocalized on nitrogen and on the ortho methyl group. However, this may be far from the truth. The same explanation as has been presented for ketyls may apply.

Experimental

The Preparation of the Ketyl and Measurement. — Ketyls were produced by the reduction of the corresponding ketones with a potassium metal. The measuring apparatus of the ESR was a usual vacuum vessel. THF was dried over K-Na alloy.

Synthesis of Material. — d_5-Phenyl 2-methylphenyl ketone was synthesized from d_6-benzene (99.5 atom%) and *o*-toluyl chloride using the usual Friedel-Crafts reaction (b. p. 131°C/2 mmHg). d_6-Benzene was synthesized by the exchange reaction between benzene and D_2SO_4 (concn. 50 mol. %). D_2SO_4 was made by mixing D_2O and anhydrous SO_3 (γ-form).

The physical constants of the other ketones are as follows:

	Boiling point
2-Methylphenyl 4'-*t*-butylphenyl ketone	160°C/2.0 mmHg
2-Methylphenyl 3'-chlorophenyl ketone	144~148°C/ 3.5 mmHg

10) Y. Deguchi, This Bulletin, **35**, 260 (1962).

Summary

The ESR spectra of the potassium ketyls of d_5-phenyl 2-methylphenyl ketone (I), phenyl 2-methylphenyl ketone (II), 2-methylphenyl 4'-*t*-butylphenyl ketone and 2-methylphenyl 3'-chlorophenyl ketone have been measured in a tetrahydrofuran solution.

II gave four broad lines, and I, a single line with a smaller total width. It is considered that the ortho-substituted phenyl group is bent out of the plane of the three central bonds because of the steric hindrance of the ortho methyl group, and that then the free electron spin is accumulated at a non-substituted phenyl group — especially at the ortho- and para-positions.

The findings on the other ketyls support the above hypothesis.

A part of this work was done at the laboratory Professer S. I. Weissman at Washington University. The authors would like to express their sincere gratitude for his valuable discussion and for the use of his apparatus. Synthetic Studies of the Derivatives of Nitroacetic Acid. I. The Preparation of Nitroacetic Ester and the Synthesis of α, β-Unsaturated α-Nitrocarboxylic Esters

By Sumio UMEZAWA and Shonosuke ZEN

(Received April 30, 1963)

The Steinkopf method[1] for the preparation of nitroacetic ester has been modified, and it has been found that, when dipotassium nitroacetate is esterified with ethanol and hydrogen chloride in the presence of a dehydrating agent such as magnesium sulfate, the yield of ethyl nitroacetate is greatly raised, to 78%, probably because the decomposition of nitroacetic acid by the Nef reaction[2] is prevented by the dehydrating agent.

α, β-Unsaturated α-nitroesters have been prepared by the reactions shown in Chart 1.

This is a general synthesis of α, β-unsaturated α-nitroesters. Although the literature contains some examples[3] of the preparation of α, β-unsaturated α-nitroesters, esters of the sort form a relatively unknown class of compounds and are expected to be extraordinary reactive.

Chart 1

Ethyl β-hydroxy-α-nitrocarboxylates (I and II) were prepared by the general method used by Rodionov and Belikov.[4]

The condensation of sodium ethyl formylacetate with ethyl nitroacetate in aqueous sodium carbonate gave diethyl β-hydroxy-α-nitroglutarate (III), which is a potential intermediate to β-hydroxyglutamic acid.

The acetylation of ethyl β-hydroxy-α-nitrobutyrate (I) with acetic anhydride in the presence of a small quantity of sulfuric acid gave ethyl β-acetoxy-α-nitrobutyrate (IV). Ethyl β-acetoxy-α-nitrocaproate (V) and diethyl β-acetoxy-α-nitroglutarate (VI) were prepared from ethyl β-hydroxy-α-nitrocaproate (II) and diethyl β-hydroxy-α-nitroglutarate (III) by an analogous procedure.

The treatment of the ethyl β-acetoxy-α-nitrocarboxyrates with anhydrous sodium carbonate in benzene at room temperature resulted in deacetylation and dehydration, giving ethyl α,β-unsaturated α-nitrocarboxylates; ethyl α-nitrocrotonate (VII) and ethyl 2-nitro-2-hexenoate (VIII) have been obtained by this procedure from IV and V respectively (Table I).

4) K. M. Rodionov and V. M. Belikov, *Chem. Abstr.*, **49**, 1550 (1955). The preparation of ethyl β-hydroxy-α-nitrobutyrate (I) and of ethyl β-hydroxy-α-nitrovalerate is described.

Compound	Ester CO	C=C	C—NO_2
VII	1742	1667	1542, 1346
VIII	1742	1660	1544, 1347
IX*	1750	1659	1588, 1310

* Carbon tetrachloride

The treatment of diethyl β-acetoxy-α-nitroglutarate (VI) with sodium carbonate by the procedure described above failed to produce the corresponding α,β-unsaturated α-nitroester. The condensation of sodium ethyl formylacetate[5] (1.0 mol.) with ethyl nitroacetate (2.0 mol.) in the presence of an amine such as n-butylamine or diethylamine (1.0 mol.) gave diethyl α-nitroglutaconate (IX) by the reactions shown in Chart 2.

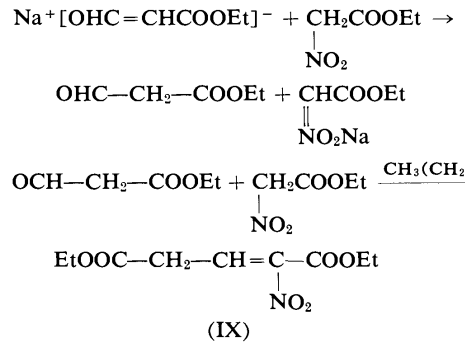

Chart 2

Experimental

Ethyl Nitroacetate.—A mixture of powdered dipotassium nitroacetate (50 g., 0.27 mol.) and anhydrous magnesium sulfate (10 g.) in absolute ethanol (300 g.) was stirred and cooled −8~−10°C, and dry hydrogen chloride was passed into the mixture. After the mixture absorbed 42 g. (1.15 mol.) of hydrogen chloride, the mixture was stirred

5) M. Cogan, *Bull. soc. chim. France*, [5] **8**, 125 (1941); S. M. McElvain and R. L. Clake, *J. Am. Chem. Soc.*, **69**, 2657 (1947); W. Deuschell, *Helv. Chim. Acta*, **35**, 1587 (1952).

for an additional hour and allowed to stand overnight at room temperature. The inorganic salt which separated was removed by filtration, and the ethanol was evaporated under reduced pressure at about 30°C. The residue was dissolved in benzene (100 ml.), and the solution was washed with a small quantity of a 5% sodium carbonate solution to neutralize the reaction product. After drying with anhydrous magnesium sulfate, followed by the evaporation of the solvent, the product was distilled under reduced pressure to give ethyl nitroacetate, b. p. 102~105°C/23 mmHg, yield 30.2 g. (78.2%).

Ethyl β-Hydroxy-α-nitrocaproate (II).—A solution of anhydrous sodium acetate (0.107 g.) in water (1.1 ml.) was added to a solution of *n*-butyraldehyde (8.48 g., 0.118 mol.) in ethanol (11.3 ml.) at below 10°C. To this solution ethyl nitroacetate was added drop by drop (14.1 g., 0.118 mol.), while the temperature was maintained at 8~14°C. Stirring was continued for 3.5 hr. to give a clear, pale-yellow solution. After the removal of the solvent under reduced pressure, the residue was dissolved in ether (200 ml.) and the solution was acidified with 10% hydrochloric acid and washed with a small quantity of water. The ethereal solution was dried with anhydrous magnesium sulfate and evaporated. The resulting residue was distilled under reduced pressure to ethyl β-hydroxy-α-nitrocaproate, b. p. 102~114°C/3 mmHg, n_D^{20} 1.4479, yield 14 g. (64.2%).

Found: C, 46.76; H, 7.45; N, 7.26. Calcd. for $C_8H_{15}O_5N$: C, 46.80; H, 7.37; N, 6.83%.

Diethyl β-Hydroxy-α-nitroglutarate (III).—Ethyl nitroacetate (7.5 g. 0.054 mol.) was added to a solution of concentrated hydrochloric acid (4.5 ml.) in water (7 ml.) below −10°C. Into this mixture was added sodium ethyl formylacetate (7.2 g., 0.05 mol.) rapidly under vigorous stirring. The solution was strongly acidic. Then a 5% aqueous sodium carbonate (about 45 ml.) which had been cooled to about 5°C was added to the reaction mixture to make pH 7.2~7.6, and the mixture was stirred at about 0°C for 1 hr. After the mixture had been made acidic (pH 1~2) by the addition of concentrated hydrochloric acid (about 4.5 ml.) under cooling in an ice-bath, the mixture was extracted with benzene. The benzene extract was dried over anhydrous sodium sulfate, and then the solvent was removed by evaporation, giving a yellow sirup. This product was subjected to fractional distillation under reduced pressure in the usual way. After small fore-runs of unchanged ethyl nitroacetate and triethyl trimesate, diethyl β-hydroxy-α-nitroglutarate distilled at 120~123°C/0.08 mmHg, n_D^{20} 1.4616; yield 3.5 g. (26%); infrared spectrum (liquid): 3480 (OH), 1750 (ester CO), 1565 and 1375 cm^{-1} (C-NO_2).

Found: C, 44.87; H, 5.63; N, 5.71. Calcd. for $C_9H_{15}O_7N$: C, 43.37; H, 6.07; N, 5.62%.

The agreement between the found and calculated values of analysis was not very good, probably because the sample was accompanied with a trace of triethyl trimesate, the removal of which by distillation was difficult. However, acetylation gave an analytically pure sample of the acetate of III, as will be described below.

Ethyl β-Acetoxy-α-nitrobutyrate (IV).—A mixture of ethyl β-hydroxy-α-nitrobutyrate (I) (9.0 g., 0.05 mol.), acetic anhydride (5.7 g., 0.056 mol.) and concentrated sulfuric acid (0.04 ml.) was stirred at 60°C for 30 min. After the removal of acetic acid and acetic anhydride by distillation under reduced pressure, the residue was subjected to fractional distillation to give the title compound; yield, 5.9 g.

Ethyl α-Nitrocrotonate (VII).—To a solution of ethyl-β-acetoxy-α-nitrobutyrate (IV) (5.0 g. 0.023 mol.) in dry benzene (2.5 ml.) anhydrous sodium carbonate (1.21 g., 0.0114 mol.) was added; the mixture was stirred at about 60°C for about 5 min. until the evolution of carbon dioxide ceased. When the temperature of the mixture had fallen to room temperature, additional dry benzene was added and the mixture was stirred. The benzene-layer was dried with anhydrous sodium sulfate, and the solvent was removed by distillation. The residue was fractionated under reduced pressure to give a colorless oil, b. p. 72~76°C/3 mmHg, yield 2.27 g. Repeated distillation gave an analytically pure sample of ethyl α-nitrocrotonate.

Diethyl α-Nitroglutaconate (IX).—To a mixture of sodium ethyl formylacetate (6.0 g., 0.04 mol.) and ethyl nitroacetate (11.6 g., 0.086 mol.) in absolute ethanol, *n*-butylamine (3.2 g., 0.04 mol.) was added, and the mixture was refluxed on a water bath for 8 hr. After the mixture had stood overnight at room temperature, the precipitate of sodium ethyl nitroacetate was removed by filtration and the reddish brown filtrate was concentrated by evaporation. To the concentrate dry benzene (90 ml.) was added to precipitate additional sodium ethyl nitroacetate, this was removed again by filtration. After cooling to about 10°C, the benzene solution was washed with a small quantity of 20% acetic acid and with water. The benzene solution was dried over anhydrous sodium sulfate overnight, and filtered, and the solvent was removed, going an oily residue. This residue was fractionated under reduced pressure to give a crude product of diethyl α-nitroglutaconate; b. p. 144~158°C/0.1~0.5 mmHg, yield 3.0 g. (29.8%). When the product was allowed to stand, a small quantity of crystalline triethyl trimesate separated. After removal of this trimesate, the oily product was repeatedly fractionated.

Synthetic Studies of the Derivatives of Nitroacetic Acid. II. The Synthesis of Isoxazolecarboxylic Acids from α, β-Unsaturated α-Nitroesters[1,2]

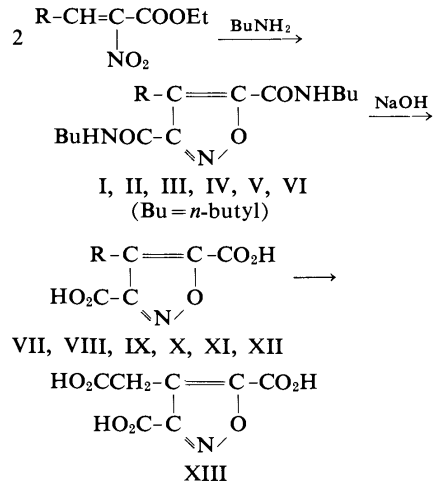
By Shonosuke ZEN and Sumio UMEZAWA

(Received April 30, 1963)

In a preliminary communication[3] we have shown that the treatment of α, β-unsaturated α-nitroesters with *n*-butylamine in ligroin or absolute ethanol gives derivatives of isoxazole-3, 5-dicarboxylic acid. In the present paper, we report a more detailed study of the new synthesis of isoxazole compounds.

When an excess of *n*-butylamine was added to a solution of diethyl α-nitroglutaconate,[4] it was found that considerable heat was evolved and, after the solution was allowed to stand at room temperature, crystals of 3, 5-bis(*n*-butylcarbamoyl)-4-(*n*-butylcarbamoylmethyl)-isoxazole (I) were deposited in almost a quantitative yield.

Moreover, we have found that the cyclization reaction is generally applicable to the synthesis of 4-substituted isoxazole-3, 5-dicarboxylic acids. The treatment of ethyl α-nitrocrotonate[4] with an excess of *n*-butylamine in absolute ethanol, followed by refluxing for several hours, gave 4-methyl-3, 5-bis(*n*-butylcarbamoyl)-isoxazole (II); 4-*n*-propyl-3, 5-bis(*n*-butylcarbamoyl)isoxazole (III), 4-phenyl-3, 5-bis(*n*-butylcarbamoyl)isoxazole (IV), 4-(*p*-chlorophenyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole (V) and 4-(*p*-nitrophenyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole (VI) have been obtained from ethyl 2-nitro-2-hexenoate,[4] ethyl α-nitrocinnamate,[5] ethyl *p*-chloro-α-nitrocinnamate[5] and ethyl 4, α-dinitrocinnamate[5] respectively by the same general procedure (Table I).



I, VII: R=BuHNOCCH$_2$; II, VIII: R=CH$_3$; III, IX: R=*n*-C$_3$H$_7$; IV, X: R=C$_6$H$_5$; V, XI: R=(*p*)Cl-C$_6$H$_4$; VI, XII: R=(*p*)NO$_2$-C$_6$H$_4$

Chart 1

By mild alkaline hydrolysis with 10% sodium hydroxide in 50% aqueous ethanol, the above-mentioned butylamides of isoxazolecarboxylic acids have been converted into the corresponding free acids of 4-substituted isoxazoles. Thus, 4-methylisoxazole-3, 5-dicarboxylic acid (VIII), 4-(*n*-propyl)isoxazole-3, 5-dicarboxylic acid (IX), 4-phenylisoxazole-3, 5-dicarboxylic acid (X), 4-(*p*-chlorophenyl)isoxazole-3, 5-dicarboxylic acid (XI) and 4-(*p*-nitrophenyl)isoxazole-3, 5-dicarboxylic acid (XII) have been obtained in high yields. The hydrolysis of 3, 5-bis(*n*-butylcarbamoyl)-4-(*n*-butylcarbamoylmethyl)isoxazole (I) at about 60°C gave 4-(*n*-butylcarbamoylmethyl)isoxazole-3, 5-dicarboxylic acid (VII), while more drastic hydrolysis achieved by refluxing for about seven hours with 10% sodium hydroxide in 50% aqueous ethanol afforded 3, 5-dicarboxyisoxazole-4-acetic acid (XIII) (Table II).

Evidence for the structures of the above-mentioned isoxazole derivatives could be deduced from the hydrolysis products. It has been known that isoxazoles are cleaved at the N–O and C=C bonds or C–C bond by drastic hydrolysis with alkali.[6] The drastic alkaline hydrolysis of 4-phenyl-3, 5-bis(*n*-butylcarbamoyl)isoxazole (IV) resulted in the formation of phenylacetic acid (IV') and oxalic acid. Moreover, the hydrolysis of 4-(*p*-dimethylaminophenyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole (XIV)[7] by an analogous treatment afforded *p*-dimethylaminophenylacetic acid (XIV') and oxalic acid. The above hydrolysis of IV and

XIV can be easily explained by the reaction sequence shown in Chart 2.

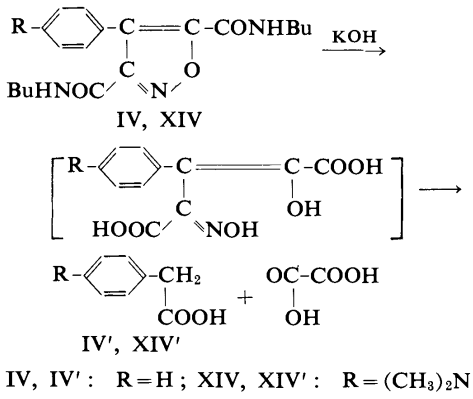

Chart 2

Reaction Mechanism.—The formation of isoxazole derivatives described above suggests that a key intermediate in the reaction sequence may be an addition compound (XIX) formed by the addition of nitroacetate to an α,β-unsaturated α-nitroester. Therefore, it seems reasonable to suggest that the initial step involves the base-catalyzed cleavage of α,β-unsaturated α-nitroester to liberate the nitroacetic ester moiety, which may be in equilibrium with the original unsaturated nitroester, followed by the addition of the former to the latter to give the above-mentioned key intermediate. It then cyclize to form an isoxazole derivative (XX) by the elimination of its water and nitrous acid.

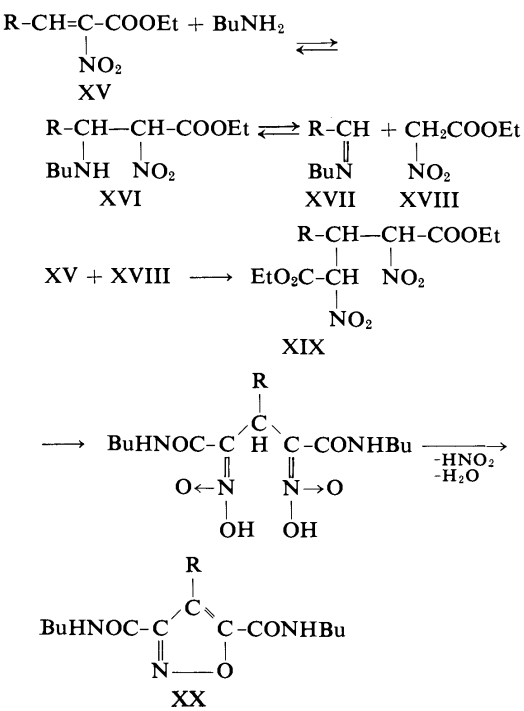

Chart 3

Fortunately, we could isolate a Schiff base (XVII), benzylidene-*n*-butylamine, from the mother liquor of the 4-phenyl-3, 5-bis(*n*-butylcarbamoyl)isoxazole (IV) which is obtained from ethyl α-nitrocinnamate by refluxing it with *n*-butylamine in absolute ethanol. Evidently, the initial reaction involves the addition of butylamine to an α,β-unsaturated α-nitroester (XV), while the adduct (XVI) generates nitroacetic ester (XVIII), which adds to the α,β-unsaturated α-nitroester in the presence of a basic catalyst (*n*-butylamine) in a way similar to that of the Michael reaction to give the key intermediate (XIX), as is outlined in Chart 3.

As was expected, the addition of ethyl nitroacetate to the above reaction-systems resulted in a significant increase in the yields of isoxazole derivatives.

Experimental

3, 5-Bis(*n*-butylcarbamoyl)-4-(*n*-butylcarbamoylmethyl)isoxazole (I). — Into a mixture of diethyl α-nitroglutaconate[4] (0.50 g., 0.0022 mol.) in ligroin (2 ml.) was added *n*-butylamine (1.0 g., 0.013 mol.) under stirring. During this period considerable heat was evolved, and the color of the solution changed to a yellowish brown. When the solution was left standing at room temperature, there were deposited crude crystals of I, which were then collected and washed with a small quantity of ethanol; m. p. 176~178°C, yield 0.41 g. (nearly quantitative). Recrystallization from ethanol gave an analytically pure sample.

4-Methyl-3, 5-bis(*n*-butylcarbamoyl)isoxazole (II). —(An example of procedure A) A mixture of ethyl α-nitrocrotonate[4] (1.0 g., 0.0063 mol.), absolute ethanol (2 ml.) and *n*-butylamine (2.75 g., 0.038 mol.) was refluxed for 3 hr. After standing at room temperature overnight, the solvent was removed by distillation to give a reddish brown sirup, which was then taken in hot ligroin, filtered, and cooled to give colorless needles of the title compound; m. p. 82~85°C; yield 0.035 g. (5.5%). Recrystallization from ligroin gave an analytically pure sample.

(An example of procedure B) By the addition of ethyl nitroacetate.—A mixture of ethyl α-nitrocrotonate (1.06 g., 0.0066 mol.), ethyl nitroacetate (0.88 g., 0.0066 mol.) and *n*-butylamine in absolute ethanol was refluxed for 10.5 hr. After the solution had been left standing at room temperature overnight, the solvent was removed by distillation to give a deep yellow residue, which was then recrystallized from ligroin (yield, 0.19 g.). The product was found to be identical with the product prepared by procedure (A) above by undepressed m. p. and infrared spectra.

8) A. R. Katritzky and A. J. Boulton, *Spectrochimica Acta*, 17, 238 (1961).

4-(*n*-Butylcarbamoylmethyl)isoxazole-3, 5-dicarboxylic Acid (VII).—(An example of procedure C) A mixture of 3,5-bis(*n*-butylcarbamoyl)-4-(*n*-butylcarbamoylmethyl)isoxazole (1.14 g.) and 10% sodium hydroxide in 50% aqueous ethanol (110 ml.) was warmed at 50~55°C for 2 hr. while being stirring. After the removal of the ethanol by distillation under reduced pressure, the aqueous solution was acidified with hydrochloric acid and then extracted with ether. The extract was dried over anhydrous sodium sulfate, filtered, and evaporated to give a powdery residue (yield 0.74 g.). Recrystallization gave colorless needles of the title compound.

3, 5-Dicarboxylsoxazole-4-acetic Acid (XIII).—A mixture of 3,5-bis(*n*-butylcarbamoyl)-4-(*n*-butylcarbamoylmethyl)isoxazole (I) (0.80 g.) and 10% sodium hydroxide in 50% aqueous ethanol (25 ml.) was refluxed for 7 hr. After the removal of the ethanol by distillation, aqueous solution was acidified with hydrochloric acid and extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate, filtered and evaporated to give a pale-yellow powder (yield 0.44 g.). Recrystallization gave colorles needles of the titlec ompound.

4-Methylisoxazole-3, 5-dicarboxylic Acid (VIII).—(An example of procedure D) A mixture of 4-methyl-3,5-bis(*n*-butylcarbamoyl)isoxazole (II) (0.82 g.) and 10% sodium hydroxide in 50% aqueous ethanol (33 ml.) was refluxed for 2 hr. and worked up as has been described in the preparation of XIII (yield, 0.47 g.).

The Ring Opening of 4-Phenyl-3, 5-bis(*n*-butylcarbamoyl)isoxazole.—A mixture of 4-pheny-3,5-bis(*n*-butylcarbamoyl)isoxazole (1.0 g.) and 28.5% potassium hydroxide in 50% aqueous ethanol (55 ml.) was refluxed for about 4 hr. After the ethanol had been removed by distillation, the aqueous solution was cooled to about 5°C, acidified with hydrochloric acid, and extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate, filtered, and evaporated to give a crystalline residue (yield 0.55 g.). The product was then extracted with benzene.

The soluble part obtained by the evaporation of the benzene extract was washed with petroleum ether to give crystals of phenylacetic acid, m. p. 74~77°C; yield 0.25 g. (64%). Mixed m. p. with an authentic specimen of phenylacetic acid was undepressed.

The insoluble part in benzene was recrystallized from dioxane-chloroform to give colorless crystals of oxalic acid dihydrate, m. p. 97.5~99°C; yield 16 mg. Mixed m. p. with an authentic sample of oxalic acid dihydrate was undepressed.

The Ring Opening of 4-(*p*-dimethylaminophenyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole.—A mixture of 4-(*p*-dimethylaminophenyl)-3,5-bis(*n*-butylcarbamoyl)isoxazole[7] (0.5 g.) and 10% sodium hydroxide in 50% aqueous ethanol (10 ml.) was refluxed for 2 hr. After the ethanol had been removed by distillation, the aqueous solution was acidified to pH 5.4~5.6 with hydrochloric acid and extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate, filtered and evaporated to give a crystalline residue, yield 0.12 g. (51.6%). Recrystallization from ligroin gave colorless plates of *p*-(dimethylamino)phenylacetic acid, m. p. 109.5~110.5°C.[9]

Found: C, 67.46; H, 7.21; N, 7.50. Calcd. for $C_{10}H_{13}O_2N$: C, 67.02; H, 7.31; N, 7.82%.

Paperchromatography of the mother-liquor which remained after extraction with ether showed the presence of oxalic acid.

The Isolation of Benzylidene-*n*-butylamine from the Reaction Mixture Obtained from Ethyl α-Nitrocinnamate and *n*-Butylamine.—A mixture of ethyl α-nitrocinnamate (1.0 g., 0.0048 mol.), *n*-butylamine 1.32 g., 0.019 mol.) and absolute ethanol (4 ml.) was refluxed for 8 hr. After the solution had been left standing at room temperature, the resulting crystals of 4-phenyl-3,5-bis(*n*-butylcarbamoyl)-isoxazole (IV) was collected by filtration. Concentration of the filtrate gave the second crop; the total yield of IV was 0.187 g. (23.5%). The mother liquor which separated from the second crop was distilled under reduced pressure to give a colorless liquid boiling at 95~112°C/12 mmHg.

The product was extracted with benzene. The removal of benzene by evaporation, followed by vacuum distillation, gave benzylidene-*n*-butylamine, b, p. 110~111°C/13 mmHg., yield 92 mg., which was found by infrared spectra to be identical with an authentic specimen.

Summary

1) α,β-Unsaturated α-nitroesters react with *n*-butylamine to give 4-substituted isoxazole-3, 5-carboxylic butylamides. This is a new synthesis of isoxazole derivatives.

2) The mechanistic features of the above reaction have been explained.

3) The mild alkaline hydrolysis of the above butylamides gave 4-substituted isoxazole-3, 5-dicarboxylic acids.

This work has been supported in part by a grant from the Kawakami Memorial Foundation, to which the authors' thanks are due. The authors are also indebted to Mr. Saburo Nakada of this Laboratory for the microanalytical data.

Synthetic Studies of the Derivatives of Nitroacetic Acid. III. The Synthesis of Isoxazole-3, 5-dicarboxylic Acids from Schiff Bases and Nitroacetic Ester[1]

By Sumio UMEZAWA and Shonosuke ZEN

(Received April 30, 1963)

The authors have previously reported[2] that dibutylamides of 4-substituted isoxazole-3, 5-dicarboxylic acids were obtained when α, β-unsaturated α-nitrocarboxylates were treated with an excess of *n*-butylamine in an anhydrous solvent; they also presented the reaction mechanism of the new synthesis.

If the mechanism presented by the authors is valid, one should be able to obtain the derivatives of isoxazole-3, 5-dicarboxylic acids by the reaction of Schiff bases (1) with nitroacetic ester (2) in the presence of basic catalysts by means of the scheme outlined in Chart 1.

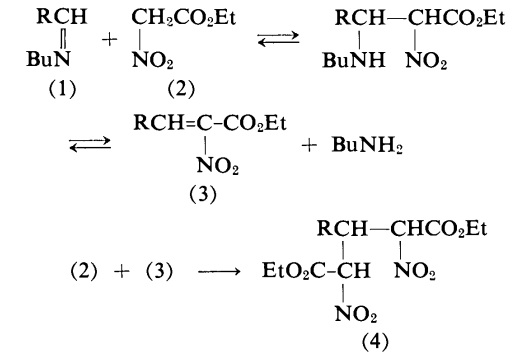

Chart 1

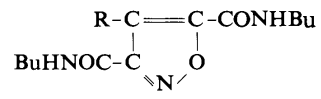
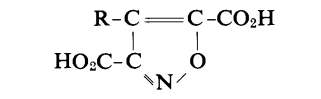
The authors have already mentioned, in a previous paper,[2] the sequel of the path from (4) to the isoxazole derivatives.

This expectation has now been realized. When an excess of *n*-butylamine (about five moles) was added to a mixture of Schiff base (one mole) and ethyl nitroacetate (two moles) in absolute ethanol, an exothermic reaction occurred. After refluxing for several hours, the mixture was concentrated to give a crystalline solid of 3, 5-bis(*n*-butylcarbamoyl) derivatives of isoxazole.

By this general procedure the following compounds, I—XVII, have been prepared from the corresponding Schiff bases and ethyl nitroacetate:



I—XVII



VI', IX'*, XI', XIII'*, XIV', XVII'

Aliphatic series:

R

I: CH_3
II: n-C_3H_7
III: $(CH_3)_2C{=}CH(CH_2)_2{-}CHCH_2$ (with CH_3 on the last CH)

Aromatic series:

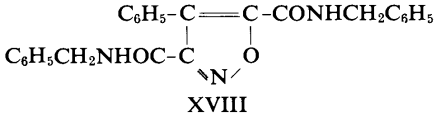
XVI: 2-Pyridyl
XVII, XVII': 3-Indolyl

Citronellylidene-*n*-butylamine failed to give isoxazole compounds, whereas citronellylidenebenzylamine gave 4-(2, 6-dimethyl-2-octenyl)-3, 5-bis(benzylcarbamoyl)isoxazole (III) by means of a reaction with ethyl nitroacetate in the presence of an excess of benzylamine. Indole-3-aldehyde and *n*-butylamine failed to give a Schiff base; however, 3-indolylidenaniline could be used to give 4-(3-indolyl)-3, 5-bis-(*n*-butylcarbamoyl)isoxazole (XVII) by means of the general procedure.

1) Presented in part before the Division of Organic Chemistry of the 14th and 15th Annual Meetings of the Chemical Society of Japan, Tokyo, April, 1961, and Kyoto, April, 1962. Preliminary communication: S. Zen and S. Umezawa, This Bulletin, 34, 890 (1961).
2) S. Zen and S. Umezawa, This Bulletin, 36, 1146 (1963).

* Dimethyl ester were caused to crystallize.

As an example using a primary amine other than *n*-butylamine the treatment of benzylidenebenzylamine with ethyl nitroacetate in the presence of an excess of benzylamine by analogous reaction conditions gave 4-phenyl-3,5-bis(benzylcarbamoyl)isoxazole (XVIII) in 84% yield.



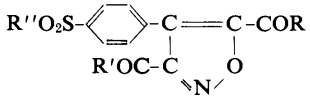
XVIII

XIX

The di-*n*-butylamine Schiff base of terephthalaldehyde, namely, *p*-xylylidene-di(*n*-butylamine), also gave a diisoxazolyl derivative of benzene (XIX) upon the treatment of one mole of the Schiff base with four moles of ethyl nitroacetate and an excess of *n*-butylamine.

An alternative method, in which aldehydes and an primary amine are used instead of a Schiff base, also gave a 4-substituted isoxazole-3,5-dicarboxylic acid. However, the yield by this alternative method have been found to be generally lower than corresponding yields by the first-mentioned method.

4-(*p*-Sulfamoylphenyl)-3(or 5)-(*n*-butylcarbamoyl)-5(or 3)-(ethoxycarbonyl)isoxazole (XX) was obtained by the alternative procedure in good yield.



XX: R, R'=BuHN, C_2H_5O or vice versa; R''=NH_2

XX': R, R', R''=OH

The above amide derivatives of isoxazole-3,5-dicarboxylic acid have been hydrolyzed mildly with sodium hydroxide in aqueous ethanol by the procedure described in a proceding paper[2] to give the corresponding 4-substituted isoxazole-3,5-dicarboxylic acids. In general, the derivatives substituted for aliphatic groups at the 4-position gave better yields when the reaction mixture was refluxed, while the derivatives substituted by aromatic or heterocyclic groups at the same position gave better yields when the reaction mixture was warmed at 50~60°C for several hours.

The hydrolysis of 4-(*p*-acetamidophenyl)-3,5-bis(*n*-butylcarbamoyl)isoxazole (IX) and 4-(2-furyl)-3,5-bis(*n*-butylcarbamoyl)isoxazole (XIII) failed to give crystalline products of free acids; their methyl ester have, however, been crystallized.

Experimental

4-Methyl-3,5-bis(*n*-butylcarbamoyl)isoxazole (I). —(A typical example of the general method).— Into a solution of ethylidene-*n*-butylamine[3] (1.50 g., 0.015 mol.) in absolute ethanol (5 ml.) was added ethyl nitroacetate (4.03 g., 0.03 mol.) under stirring. During this period considerable heat was evolved; the temperature of the reaction mixture rose to 60°C from 18°C. *n*-Butylamine (5.53 g., 0.076 mol.) was then added to the mixture. When the exothermic reaction had subsided, the reaction mixture was gently refluxed for 5 hr. After the solution had been left standing at room temperature, the solvent was removed by distillation to give a reddish brown sirup, which was allowed to stand in a refrigerator to give crystals of the title compound, yield 0.46 g. (10.9%) which were then recrystallized from ligroin to give feathery crystals, m. p. 84~86°C. The product was found by undepressed mixed melting point and infrared spectra to be identical with the authentic specimen[2] prepared from ethyl α-nitrocrotonate.

II-XI, XIV, XVI and XIX were prepared by the general procedure (Tables I and II).

4-(9-Anthryl)-3,5-bis(*n*-butylcarbamoyl)isoxazole (XII).—The reaction mixture obtained from 9-anthrylidene-*n*-butylamine (2.09 g.), ethyl nitroacetate (2.31 g.) and *n*-butylamine (2.92 g.) was refluxed for 9 hr. After the mixture had cooled to room temperature, water (about 10 ml.) was added to give a crude crystalline solid. The product was dissolved in ethanol (11 ml.), and the solution was diluted with water (6 ml.) to give a crystalline solid. This was again dissolved in benzene (7.3 ml.) and diluted with ligroin, whereupon there separated analytically pure crystals of the title compound (yield 0.34 g.); UV (methanol): 255 mμ (ε, 235000).

4-(2-Furyl)-3,5-bis(*n*-butylcarbamoyl)isoxazole (XIII). — The reaction mixture obtained by the general method from 2-furylidene-*n*-butylamine[5] (7.55 g.), ethyl nitroacetate (13.3 g.) and *n*-butylamine (18.5 g.) was refluxed for 9 hr. and allowed to stand, whereupon it gave a crude solid (yield 5.60 g.) The mother liquor was concentrated, and the residue was extracted with hot cyclohexane. When the cyclohexane extract was cooled, the second crop was obtained; (yield 3.64 g.; total 55.5%). Recrystallization from cyclohexane gave colorless feathery crystals (UV (methanol): a shoulder at 246 mμ (ε, 16000), 308 mμ (ε, 10700)).

4-(2-Pyrrolyl)-3,5-bis(*n*-butylcarbamoyl)isoxazole (XV).—The reaction mixture obtained by the general procedure from 2-pyrrolylidene-*n*-butylamine (1.0 g.), ethyl nitroacetate (1.8 g.) and *n*-butylamine

(2.45 g.) was refluxed for 14 hr., and the solvent was removed by distillation to give a tarry residue, which was then extracted with benzene. The benzene solution was evaporated to give again a tarry residue. This residue was again extracted with hot *n*-hexane (30 ml.), and the hexane extract was cooled to give crystals of the title compound; yield 0.072 g.; recrystallized from *n*-hexane to give slightly violet needles; UV (methanol): 247~255 mμ (ε, 7900).

4-(3-Indolyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole (XVII). — The reaction mixture obtained by the general procedure from indolylidenaniline[6] (1.0 g.), ethyl nitroacetate (1.2 g.) and *n*-butylamine (1.7 g.). was refluxed for 6.5 hr. and evaporated to give a dark red tar, which was then caused to crystallize by treatment with aqueous ethanol (yield 0.77 g.) Repeated recrystallization from 50% ethanol gave yellow needles (UV (methanol): a shoulder at 281 mμ (ε, 8510) and 288 mμ (ε, 7400)).

4-Phenyl-3, 5-bis(benzylcarbamoyl) isoxazole (XVIII).—To a mixture of benzylidenebenzylamine (1.95 g.) and ethyl nitroacetate (2.66 g.) benzylamine (5.35 g.) was added, and the mixture was refluxed for 2 hr. After the mixture had stood at room temperature, the resulting solid was collected by filtration; yield 3.46 g. (84%) recrystallized from ethanol to give colorless needles of the title compound, m. p. 199.5~200°C.

Found: C, 72.98; H, 4.99; N, 10.30. Calcd. for $C_{25}H_{21}O_3N_3$: C, 72.98; H, 5.14; N, 10.21%.

The hydrolysis of the product with 10% sodium hydroxide in 50% ethanol at 50~60°C for 2 hr. gave 4-phenylisoxazole-3,5-dicarboxylic acid[2] in 69% yield.

The Alternative Method Using Aldehydes and Primary Amine Instead of Schiff Bases. — To a mixture of an aldehyde (1.0 mol.) and ethyl nitroacetate (2.0 mol.) in absolute ethanol *n*-butylamine (6 mol.) was added; the mixture was refluxed for 5 hr. and worked up in a manner similar to that described in the preparation of the above-described 4-substituted isoxazole-3,5-dicarboxylic dibutylamides. Yields by the alternative method are shown in comparison with those obtained through Schiff bases in Table II.

** Recrystallized from aqueous ethanol ; yellow needles

a procedure similar to that described in the preceding paper.[2] Hydrolysis was carried out at 50~60°C for 2 hr.; yield 0.52 g.; recrystallized from ether-ligroin to give colorless plates.

A sample free from crystalline water was analyzed.

XI' XIV' and XVII' were prepared by a similar procedure (Tables III and IV).

Dimethyl 4-(*p*-Aminophenyl)isoxazole-3, 5-dicarboxylate (IX').—A mixture of 4-(*p*-acetamidophenyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole (IX) (10.6 g.) and 10% sodium hydroxyde in 50% aqueous ethanol (430 ml.) was refluxed for 2 hr. After the mixture had stood at room temperature, a small quantity of an insoluble matter was removed by filtration, and then ethanol (1.0 l.) was added to the filtrate to give disodium salt of the title compound; yield 5.27 g. (68.1%); m. p.>300°C. A sample of the salt (0.36 g.) was suspended in absolute methanol (11 ml.), and the mixture was saturated with hydrogen chloride gas while being cooled. After standing at room temperature overnight, the solution was evaporated to dryness. The residue was dissolved in water, and the solution was made alkaline with a 5% sodium carbonate solution to pH 8.7~9.0, followed by extraction with methylene chloride.

The extract was dried over anhydrous sodium carbonate and evaporated to give an yellow solid yield 0.10 g. (28%); recrystallization from ethyl acetate-ligroin gave yellow needles of the title compound, m. p. 163~166°C.

Found: C, 57.01; H, 4.10; N, 10.27. Calcd. for $C_{15}H_{12}O_5N_2$: C, 56.52; H, 4.38; N, 10.14%.

Dimethyl 4-(2-Furyl)isoxazole-3, 5-dicarboxylate (XIII').—A mixture of 4-(2-furyl)-3, 5-bis(*n*-butylcarbamoyl)isoxazole (1.67 g.) and 10% sodium hydroxide in 50% ethanol (20 ml.) was warmed at 55~60°C for 1 hr. The dark brown mixture thereby obtained was evaporated under reduced pressure to remove the ethanol, acidified with hydrochloric acid, and extracted with ether. Evaporation of the ethereal extract gave a dark brown sirup (1.22 g.) which failed to crystallize. A part of the residue (0.9 g.) was dissolved in absolute methanol (40 ml.); the solution was then saturated with dry hydrogen chloride gas and left to stand at room temperature. After the removal of the methanol by distillation, the resulting sirup with dissolved in chloroform (30 ml.) and washed with a 5% sodium carbonate solution and water. The chloroform solution was dried over anhydrous sodium sulfate and evaporated to give a dark brown sirup, which was caused to crystallize, giving needles yield, 0.1 g. (10%); recrystallized from *n*-hexane; colorless needles, m. p. 63~64.5°C.

Found: C, 52.44; H, 3.62; N, 5.80. Calcd. for $C_{11}H_9O_6N$: C, 52.59; H, 3.61; N, 5.58%.

4-(*p*-Sulfophenyl)isoxazole-3, 5-dicarboxylic Acid (XX'). — A mixture of 4-(*p*-sulfamoylphenyl)-3(or 5)-(*n*-butylcarbamoyl)-5(or 3)-(ethoxycarbonyl)isoxazole (XX) (0.30 g.) and 10% sodium hydroxide in 50% aqueous ethanol (20 ml.) was warmed at about 60°C for 2 hr. while being stirred. After removal of the ethanol, the aqueous solution was acidified with hydrochloric acid to pH 2.0 and extracted with ether. The extract was dried over anhydrous sodium sulfate, filtered, and evaporated to give a yellow powder (0.22 g.), which was a partially hydrolized product. A part (0.1 g.) of the product was dissolved in 10% aqueous sodium hydroxide (2.0 ml.), and the solution was refluxed for 1 hr. After acidified with hydrochloric acid to pH 4.0, the solution was extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate, filtered, and evaporated to give a yellow powder (0.1 g.). Recrystallization from dioxane-chloroform gave colorless needles.

Schiff Base (Table V). — Prepared by a general procedure illustrated by the following examples.

n-Butylidene-n-butylamine.—A mixture of *n*-butylaldehyde (5.04 g., 0.07 mol.) and *n*-butylamine (5.11 g., 0.07 mol.) in benzene (15 ml.) was refluxed for 30 min. After the mixture had been dried over anhydrous sodium sulfate, the benzene was removed and the residue was distilled under reduced pressure to give the Schiff base, b. p. 113.5~114°C/20 mmHg, yield 4.10 g. (46.1%).

Citronellylidene-n-benzylamine. — A mixture of citronellal (5.0 g.) and benzylamine (3.8 g.) in benzene (30 ml.) was stirred and allowed to stand for 1 hr. The benzene layer was then separated and dried over anhydrous sodium sulfate. After the removal of the benzene, the residue was distilled under reduced pressure to give the Schiff base, b. p. 150~151.5°C/5.5 mmHg, yield 4.76 g. (60.3%).

Found: N, 5.86. Calcd. for $C_{17}H_{25}N$: 5.76%.

Summary

1) Schiff bases react with ethyl nitroacetate in the presence of *n*-butylamine or benzylamine to give 4-substituted isoxazole-3, 5-dicarboxylic amides. This is a new synthesis of isoxazole derivatives.

2) Twenty kinds of 4-substituted isoxazole-3, 5-dicarboxylic amides, including aliphatic, aromatic and heterocyclic derivatives, have been prepared.

3) Seven of the above-mentioned amides have been hydrolyzed to give the corresponding 4-substituted isoxazole-3, 5-dicarboxylic acids.

4) Some Schiff bases have been described.

This work has been supported in part by a grant from the Kawakami Memorial Foundation, to which the authors' thanks are due. The authors are also indebted to Mr. Saburo Nakada of this Laboratory for the microanalytical data.

*Corundum α-Al_2O_3 Formation from the Dehydration of Boehmite γ-AlOOH under Hydrothermal Conditions. I. Factors Determining the Grain Size of Corundum and a Proposal for the Formation Mechanism**

By Goro YAMAGUCHI and Hiroaki YANAGIDA

(Received May 22, 1963)

The fact that aluminum hydroxides are transformed into corundum through dehydration in a relativery low temperature range near 400°C under hydrothermal conditions has been noted by Laubengayer and Weisz,[2] Ervin and Osborn[3] and Kennedy,[4] while the temperature of transformation by calcination in air is usually above 1000°C. Using this reaction, the present authors obtained grains consisting of separated single crystals of corundum of a uniform size and habit of hexagonal plate or column ;[5] the grains showed excellent qualities as abrasive material.[6] It is worth clarifying the mechanism of this reaction as an approach to the investigation of the processes of solid phase formation. The solubilities of corundum and boehmite under the condition of corundum formation from boehmite have been discussed in a previous paper.[7] In the present paper, the grain size of corundum crystals obtained under various hydrothermal conditions with such varying factors as reaction temperature, hydrothermal pressure and quantity of the seed crystals of corundum, has been measured to provide other information for a discussion of the formation mechanism.

Experimental

Procedure.—Aluminum hydroxide, boehmite or gibbsite is weighed and laid in a Bridgeman-sealed Morey-type reactor with an aqueous solution of alkali. The reactor is then heated to an appointed temperature within 15 min. in an electric furnace and kept at the temperature for enough hours to convert the boehmite completely into corundum. The hydrothermal pressure is calculated from the relation among the pressure, volume and temperature of the water after the table of Kennedy.[8] The reactor is quenched to room temperature, also within 15min. and the corundum residue is washed out with pure water into a glass beaker.

Grain Size Determination. — The grain size of corundum is measured by the sedimentation method using Shimadzu's sedimentograph. Glycerol diluted with pure water is used as a sedimentation medium. The viscosity of the medium is calculated from the relation among the viscosity, density and temperature of glycerin diluted with water.[9]

Results

1) The Effect of Reaction Temperature.— The grain size of corundum crystals obtained when the pressure was 1000 atm., the solvent was a 0.1 N sodium hydroxide solution, and the temperature was 460 to 550°C was measured. The results are shown in Fig. 1, while the appearance of the corundum crystal is shown in Fig. 2. The shape of the corundum crystal is scarecely at all similar to that of boehmite,

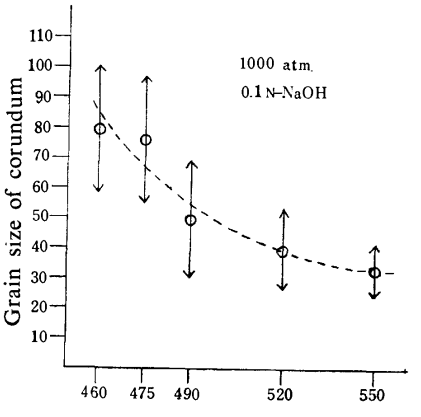

Fig. 1. Relation between grain size of corundum and hydrothermal temperature.

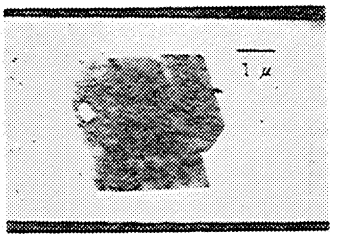

Fig. 3. Boehmite as starting material.

the starting material, as Fig. 3 shows. This suggests that the reaction of corundum formation under the conditions of the present section is due to a dissolution-precipitation process. The activation energy of the nucleation process of corundum should be larger than that of crystal growth judging from the fact that the grain size of corundum is decreased with the rise of temperature.

2) The Effect of Hydrothermal Pressure.—The grain size of corundum obtained when the temperature was 500°C, the solvent was a 0.1 N sodium carbonate solution, and the hydrothermal pressure was 250 to 1500 atm. was also measured. The results are shown in Fig. 4. The appearance of the crystals of corundum are shown in Figs. 5 and 6. The figures show that corundum obtained under lower hydrothermal pressure has a less perfect shape than that obtained under higher pressure. The former seems to be composed of aggregates of small crystals. This phenomenon is closely related to that of boehmite formation from gibbsite under various hydrothermal pressure.[1] In that case, boehmite was formed in its own rhombic tabular shape, as is shown in Fig. 3, when the nucleus of boehmite was formed and grew practically in a free hydrothermal solvent, while boehmite was formed as an aggregate of fine crystals with the original shape of gibbsite when the processes took place within the original grain. In the present case of corundum formation from boehmite, the nucleus formation and the crystal growth of corundum seem to occur practically in a free hydrothermal solvent not enclosed within boehmite grain when the hydrothermal pressure is higher, and so when the solvent is rich and dence, whreas the processes seems to occur within the grain when the pressure is lower, and so when the solvent is poor in outer free space.

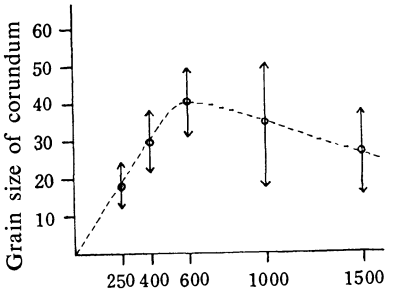

Fig. 4. Relation between grain size of corundum and hydrothermal pressure.

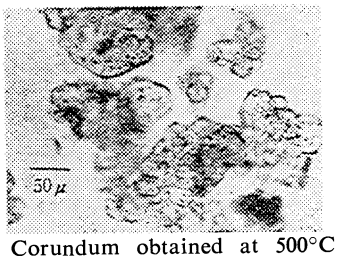

Fig. 5. Corundum obtained at 500°C under 250 atm.

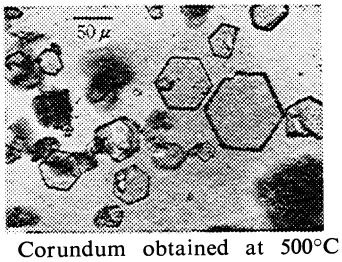

Fig. 6. Corundum obtained at 500°C under 1000 atm.

3) The Effect of the Addition of Seed Crystals of Corundum.—Corundum was formed from boehmite hydrothermally above 440°C when no seed crystal of corundum was added.[2,5,7] The equilibrium point between boehmite and corundum, however, should be 370°C under 1000 atm.[10-12] An equilibrium relation between two species must be discussed for the condition when the two co-exist, if the reaction of the formation of the more stable phase is of great activation energy of nucleation.[11] By the addition of seed crystals of corundum, the induction period before the initiation of corundum formation can be considerably

TABLE I. EFFECT OF ADDITION OF SEED CRYSTAL OF CORUNDUM UPON THE GRAIN SIZE OF NEWLY FORMED CORUNDUM IN 0.01 N NaOH SOLUTION UNDER 1000 ATM. AT 450°C

Addition of seed crystals of corundum			Newly formed corundum
		Surface area	
μ	g.	cm^2	μ
—	—	—	55.0±16.0
2.1	0.5	2.5×10^3	2.8± 1.1
2.1	1.0	5.0×10^3	1.8± 1.2
47.0	0.5	100	29.2± 7.5
500	0.1	2.0	34.2±10.4

shortened,[11,12] as Table I shows, the grain size of the newly-formed corundum is decreased. The results was obtained when the temperature was 450°C, the solvent was a 0.01 N sodium hydroxide solution, and the pressure was 1000 atm. with the addition of various quantities, of seed crystals of corundum. The larger the surface area of the seed crystals of corundum, the finer the size of the newly-formed corundum. It is supposed, therefore, that the crystal as seed promotes the nucleus formation. Since the effect was also observed when the seed crystal was far separated from boehmite grain in the reactor, the nucleation process must also take place in outer free space, not enclosed within the original boehmite grain, when some seed crystals are present. The seed crystal grew a little and the boehmite grain was converted into corundum even when boehmite existed metastably without any addition of corundum seed crystals. Moreover, the corundum crystal newly obtained from boehmite behaves as new seed. Just after the initiation of corundum formation when no seed crystals of corundum were added, as has been in preseding sections, therefore, the corundum behaved as seed and the nucleation process and the growth took place in the free space instead.

Summary of the Results and Some Suggestions.—The results may be summarized as follows; (1) The corundum crystal in most cases is in the shape of hexagonal plate (the habit modification is discussed in another paper)[13] except when the hydrothermal pressure is lower and the solvent is poor. (2) The grain size of corundum decreases with the rise of the reaction temperature. (3) By the addition of seed crystals of corundum, the grain size of newly-formed corundum can be decreased. These findings suggest that; (a) the reaction of corundum formation is closely related to that of boehmite formation from gibbsite; (b) according to the first finding, the reaction is carried out through a hydrothermal dissolution-precipitation process; (c) the nucleation process is of a higher activation energy than the growth; (d) the nucleus is formed both within the original boehmite grain and in the free space of a solution (the latter contribution becomes larger if the solvent is rich enough or if some corundum seed crystals have formerly been added); (e) after the initiation of corundum formation, the newly-formed corundum acts as new seed, and (f) the process of crystal growth takes place practically always in the free space of a solution, not within the original boehmite grain; the growth within it is noticeable when the outer solvent is poor, as when hydrothermal pressure is low.

Conclusion

A Proposal for the Mechanism of Corundum Formation under Hydrothermal Conditions. — Considering these results, the present authors propose the reaction schema shown in Fig. 7 for the formation mechanism of corundum under hydrothermal conditions. This schema

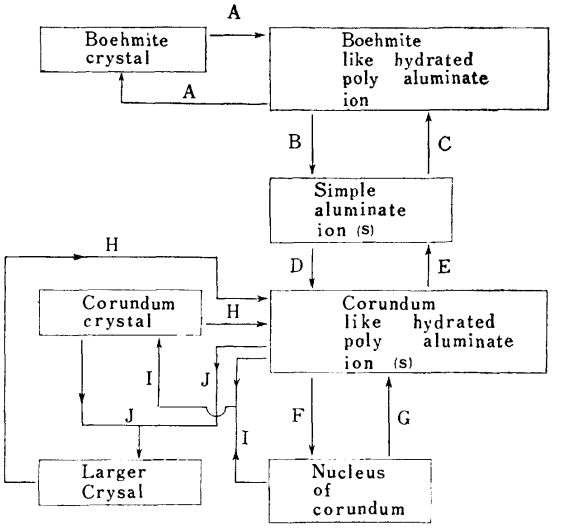

Fig. 7. Reaction schema for corundum formation.

is closely related to that of boehmite formation from the dehydration of gibbsite.[1] In that schema, gibbsite and boehmite were in the positions of boehmite and corundum respectively in the present schema. The most important hypothesis of these proposals is the existence of certain hydrated polyions whose structure is like the corresponding crystal lattice. Process A in Fig. 7 involves the dissolution of boehmite to boehmite-like hydrated polyions and process A', the precipitation of boehmite.

Process A′ is more complex in fact and is carried out through a cycle similar to that of the F, G, H and I processes; it is, however, written here in a simplified way. Process B indicates the dissociation of boehmite-like hydrated polyions into such simpler ones as $Al(OH)_4^-$ or $Al(H_2O)_2(OH)_4^-$, and C, the process of their association. The dissolution equation of aluminas in the previous paper[7] shows that an equilibrium among A, B, C and D has already been attained when the reaction temperature reaches above 400°C. Process D indicates the association of the simpler aluminate ions into corundum-like hydrated poly-aluminate ions, and E, the process of the dissociation. Process D, the present authors propose, is of high activation energy and it becomes the rate-determining one when the poly ions are not present at all. The seed crystals of corundum, whether added formerly or newly formed, supply the polyions according to Process H. The corundum-like hydrated poly aluminate ions are characterized by the structure of the two nearest aluminum ions being jointed through three oxygen atoms as in corundum lattice, while that of the boehmite-like one is of the nearest two aluminum ions being jointed through one or two oxygen atoms as in boehmite lattice. Process F indicates the nucleus formation of corundum crystal through the polymerization of the corundum-like polyions and G, the process of its depolymerization. Further polymerization results in the precipitation of corundum crystals according to Process I. The corundum crystals grows through Process J and at the same time supplies the polyions through the Process H.

Explanation of the Results According to the Reaction Schema.—The results in the present work can be explained with this reaction schema as follows. Finding (1) in the summary of the results in the preceding section is due to the reaction schema of a dissolution-precipitation process; Finding (2) is interpreted as meaning that the activation energy of the nucleation of corundum, Processes D and F, especially D at the early stage of the reaction, when any corundum seed crystals are not added, is larger than that of crystal growth J, and Finding (3) is due to the fact that the addition of corundum seed crystals makes it possible to initiate Process F and to promote Process D through Process H, and (e), therefore, is due to the fact that newly-formed corundum supplies the polyions through the Process H.

A reaction mechanism of corundum formation under hydrothermal condition has been discussed on the basis of the findings that the grain size of corundum varies with the hydrothermal conditions of temperature, pressure, and the addition of corundum seed crystals. The present authors have proposed a reaction schema by adapting the conception of hydrated poly aluminate ions with crystal lattice structure as proposed in the previous paper.[1] The reaction schema will be discussed also in a later paper[12] in connection with the results concerned with the reaction velocity of corundum formation under various hydrothermal conditions.

The Crystal Structure of Purpureo Salt, $[Co(NH_3)_5Cl]Cl_2$

By Yoshihiko SHIGETA, Yoshimichi KOMIYAMA and Hisao KUROYA

(Received May 25, 1963)

A series of monoacido-pentaammine-cobalt-(III) complexes of the $[Co(NH_3)_5L]X_2$* type have been extensively investigated with respect to their light absorptions, their substitution reactions, and so on. However, there have been few reports on their crystal structures. In 1935, West determined the crystal structure of the chloro-pentaamine-rhodium(III) chloride, $[Rh(NH_3)_5Cl]Cl_2$[1] and, furthermore, found, by means of the powder photographic method, that the corresponding cobaltic salt is isotype to this rhodium(III) compound; he did not, however, give any details of the structure of the former.

Therefore, in order to determine exactly the way of packing in the crystalline state, the chloro-pentaammine-cobalt(III) chloride or "purpureo salt," $[Co(NH_3)_5Cl]Cl_2$, was taken up, and an X-ray analysis of its crystal structure was attempted. It should be noted that this compound is one of the most fundamental of the Werner complexes.

Experimental

Purpureo-cobaltic salt was prepared by Jörgensen's method.[2] The crystals for our X-ray work were grown slowly at room temperature from an aqueous solution as concentrated as possible. They are orthorhombic-bipyramidal, showing a pseudo-regular octahedral shape.

Ni$K\alpha$ radiation (1.659 Å) was used, and a multiple-film technique was employed in taking Weissenberg photographs about the three principal axes. The dimensions of the unit cell, the space group, and other crystallographic data were found to be as follows:

$a=13.34\pm0.03$, $b=10.33\pm0.03$, $c=6.73\pm0.02$ Å;

Puma-D_{2h}^{16}, $Z=4$,

$\rho_{obs}=1.77$ g. cm^{-3} (25°C), $\rho_{calcd}=1.79$ g. cm^{-3}

The relative intensities were estimated visually by comparison with a standard scale. The usual correction factors were applied by means of the chart given by Cochran,[3] while no correction for absorption was made.

* L denotes any univalent acid-radical working as a ligand.

Determination of the Structure

Possibly, this compound is isostructural with the corresponding rhodium(III) compound, as has already been suggested by West. Therefore, the first trial model, based on the structure of the corresponding rhodium(III) compound, was immediately set up, the bond lengths and bond angles being properly adjusted. The agreement was fairly good between the observed structure amplitudes and those calculated for this model.

Then, all the parameter values were refined by the usual procedure of successive approximations. The final parameters are listed in Table I, while the final electron density projection along the b-axis is shown in Fig. 1. The observed structure factors are compared with the calculated ones in Table II. The atomic scattering factors used for calculating the structure factors were those listed in the International Tables. An overall temperature factor was used in the form of $\exp(-B\sin^2\theta/\lambda^2)$, where B has the value of 2.0 Å^2.

TABLE I. ATOMIC COORDINATES

Atom	x/a	y/b	z/c
Co	0.395	0.250	0.176
Cl(1)	0.528	0.250	−0.033
N_1	0.283	0.250	0.353
N_2	0.303	0.250	−0.055
N_3	0.487	0.250	0.407
N_4	0.395	0.059	0.176
N_5	0.395	0.441	0.176
Cl(2)	0.148	0.000	0.158

The $R=\sum||F_o|-|F_c||/\sum|F_o|$ reliability factors are 0.104, 0.073 and 0.121 for ($hk0$), ($0kl$) and ($h0l$) respectively. The weighted mean value of R is 0.109 for the observed reflections up to $\sin\theta/\lambda=0.590$.

Description of the Structure

The structure projected upon a plane normal to the b-axis is shown in Fig. 2, which corresponds to Fig. 1. Evidently, the crystal is composed of complex cations, $[Co(NH_3)_5Cl]^{2+}$, and chloride anions in an arrangement of the CaF_2-type; thus, the compound is essentially ionic.

The interatomic distances and bond angles, calculated on the basis of the atomic parameters in Table I, are listed in Table III.

The cobalt atom is surrounded by four nitrogen atoms at the corners of a square (Co–$N_{2\sim5}$, 1.97 Å), with one more nitrogen atom (Co–N_1, 1.91 Å) and one chlorine atom (Co–Cl (1), 2.27 Å) just below or above,

completing a slightly distorted octahedral coordination. One remarkably shorter distance between Co and $NH_3(1)$, which is in trans-position to Cl, has been found also in the case of $[Co(NH_3)_3(NO_2)_2Cl]$.[4] The other Co-N bonds are normal in length, as in $[Co(NH_3)_6]^{3+}$, where the nitrogen atoms are all equidistant from the cobalt atom (Co–N, 2.02 Å or so).

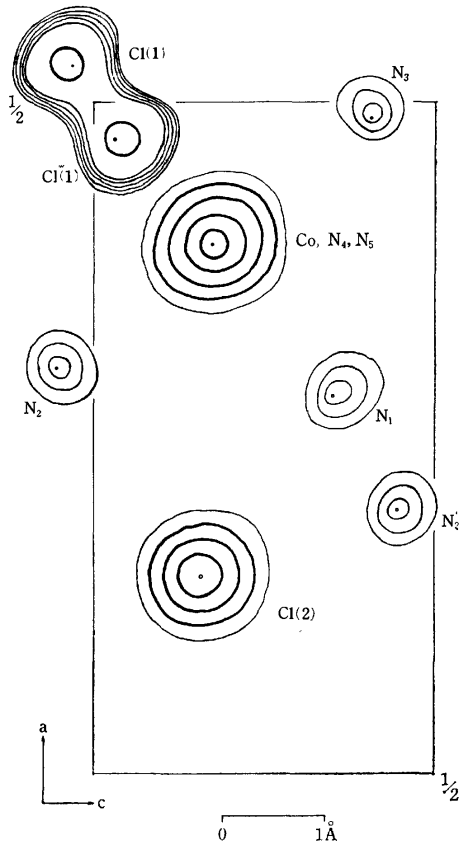

Fig. 1. Contours are drawn at intervals of 2e. $Å^{-2}$, starting at two electron level. Contours above 10e. $Å^{-2}$ are drawn at 10e. $Å^{-2}$ with thick lines.

The occurrence of one significantly shorter Co–NH_3 bond is to be noted. This may be because, working as a strongly electronegative ligand, the chlorine atom exerts its influence, if any, most effectively upon a ligand lying in the trans position to it, since to a first approximation the chlorine atom and the ligand can be regarded as bound to one another through the d_{z^2}, p_z and s orbitals of the central cobalt atom.

According to West, there is no distinction between the five Rh–NH_3 bonds involved in $[Rh(NH_3)_5Cl]^{2+}$. This might be shown not to be the case, however, if the structure of this rhodium(III) compound* were more refined.

* However, our recalculation based on the atomic coordinates reported by West revealed that the four NH_3-groups are not exactly in a plane normal to the N-Rh-Cl axis (see Fig. 3).

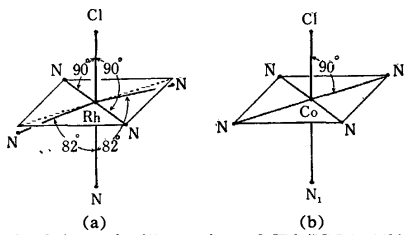

Fig. 3. Schematic illustration of $[Rh(NH_3)_5Cl]^{2+}$ (a) and $[Co(NH_3)_5Cl]^{2+}$ (b) ion.

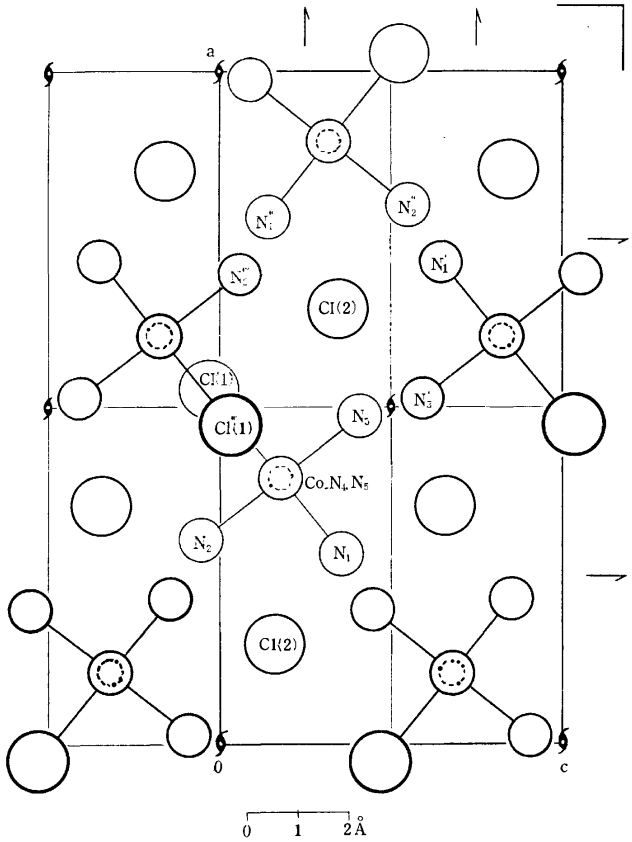

Fig. 2. Projection of the structure along the b-axis.

A chloride anion Cl(2) in the outer atmosphere is surrounded by fourteen NH_3 groups at distances ranging from 3.29 Å to 3.61 Å, as well as by two coordinated chlorine atoms at distances of 3.95 Å and 4.06 Å. Considerations of the distances of $NH_3\cdots Cl(2)$, the angles of Co–N···Cl(2) and the way of packing lead us to the view that the hydrogen bonding is not unfavorable for the following four links of N–H···Cl(2):

	N···Cl(2)	∠Co–N···Cl(2)
N_3—H···Cl(2)	3.39 Å	107.0°
N_5'—H···Cl(2)	3.35	100.0
N_4''—H···Cl (2)	3.36	101.5
N_2'''—H···Cl (2)	3.29	111.5

Summary

The crystal structure of $[Co(NH_3)_5Cl]Cl_2$ has been determined by the two-dimensional Fourier method. The orthorhombic unit cell has dimensions of $a=13.34$, $b=10.33$ and $c=6.73$ Å, and it contains four formula units. The space group is Pnma–D_{2h}^{16}.

The shape and the size of a complex ion were found to be approximately similar to those of the crystal of the corresponding rhodium(III) compound.

One NH_3 group is co-ordinated to the central cobalt atom in the trans position to the chlorine atom; the Co–N(1) distance is 1.91 Å, rather shorter than the four other Co–N distances, 1.97 Å.

Part of the cost of this study has been defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

X-Ray Diffraction Studies of the Molecular Complexes of Tetracycline Salts

By Shigeharu INOUYE and Yoichi IITAKA

(Received April 22, 1963)

In addition to the usual 1 : 1 type of molecular compounds formed by an antibiotic tetracycline with such other substancs as γ-butyrolactone,[1] urea,[2] or methanol,[3] tetracycline sulfate forms a series of complexes with the general formula: [2 tetracycline] sulfate·complexing agent·10 water, where "complexing agent" denotes a second molecule, such as an aliphatic carboxylic acid or a derivative of urea, having a rather smaller molecular volume. In a dry atmosphere, however, the decahydrate readily loses 4 molec. of water to form a relatively stable hexahydrate, while the crystal lattices are simultaneously rearranged. The latter dehydrated sulfate-complexes have been the subject of previous investigations,[4,5] and from the close resemblance of their X-ray diffraction powder patterns, a clathrate-like structure has been suggested for them. The formation of similar sulfate-complexes has been observed with oxytetracycline, but not with chlorotetracycline.[6]

This communication is concerned with a crystallographic investigation of the decahydrated sulfate-complexes, together with a classification of the powder patterns of various salt-complexes, including fluosilicate-, hydrochloride-, and nitrate-complexes, as well as of sulfate-complexes.

Experimental

Preparation.—Neutral hydrated tetracycline or oxytetracycline (1 mmol.) is dissolved in water (3~5 ml.) by the addition of strong acid (1~1.5 mequiv.). The complexing agent (2.5 mmol.) is dissolved in the solution under gentle heating. Removing unsoluble compounds by filtration, the solution is cooled to obtain the salt-complexes as crystallites. When guanidine sulfate, dimethylglyoxime or glyoxal, for example, is added to the solution as a complexing agent, crystals are obtained in which water molecules are enclosed in place of guanidine sulfate, etc.

Most of the salt-complexes were obtained as fine crystalline powders. However, when the supersaturated solution was kept in a refrigerator without shock for several days, some of the sulfate-complexes grew in a form of needles elongated along the b-axis, showing {001} as the principal face and often twinned on {001}. The single crystals are yellow in color and show a marked pleochroism.

When the salt anion is sulfate or fluosilicate, the salt-complexes usually crystallize as decahydrates. Hexahydrates of these salt-complexes are prepared by storing the original decahydrates over silica gel at room temperature overnight. Most of the hydrochloride- and nitrate-complexes, as well as a few of the sulfate- and fluosilicate-complexes, crystallize from an aqueous solution directly as hexahydrates. In Table I, the hexahydrates that crystallize directly are distinguished by an asterisk.

Analysis.—The chemical analyses of the composition of the salt-complexes have been reported in previous papers.[4-7] The specific gravity of a single crystal was determined by flotation in a mixture of carbon tetrachloride and chloroform at 20°C. The values given in Table II, however, are not expected to be more accurate than $\pm$ 0.02, since the crystals were subjected to dehydration.

X-Ray Measurement.—X-Ray diffraction powder patterns were taken by means of CuK_α radiation using a Norelco diffractometer. The powder patterns of the decahydrates were measured using undried specimens, for they are readily converted into partially dehydrated forms when exposed to dried air.

Single crystal X-ray photographs of oscillation, rotation, and Weissenberg were taken by means of CuK_α radiation. The unit cell parameters recorded in Table II were calculated mainly from the oscillation and (*h*0*l*) Weissenberg photographs about the b-axis. The mean errors for the monoclinic cell dimensions are *a*, $\pm$ 0.04; *b*, $\pm$ 0.02; *c*, $\pm$ 0.04 Å, and β, $\pm$ 0.2°, whilst for orthorhombic cells, they are $\pm$ 0.04, $\pm$ 0.03, and $\pm$ 0.05 Å for the a, b, and c-axes respectively. In the case of the dehydrated sulfate-complexes, the errors may exceed the above values, since the reflections consist of diffuse spots. A comparison among the intensities of corresponding X-ray reflections was made mainly on the (*h*0*l*) and (*h*1*l*) Weissenberg photographs for the 11 different salt-complexes of the *d*α form shown in Table II.

Results and Discussion

Table I shows a classification of the salt-complexes according to their powder patterns. Many of the salt-complexes belong to one of four distinct groups, that is, the *dα*, *dβ*, *hγ*, *hδ* forms, in which *dα* and *dβ* are the crystal forms found in decahydrates, and *hγ* and *hδ* are those found in hexahydrates. Figure 1 illustrates their typical powder patterns. Besides these, several other variations of the above forms are also recognized; these are shown in Table I as "other salt-complex," but they are not mentioned further in this paper.

The general characters of each of these four forms are set out below.

The *dα* Form.—*Sulfate-complexes.*—To this group belong most of the sulfate-complexes of decahydrate, namely, 19 members so far examined. Since all of them show striking

TABLE II. UNIT CELLS AND SPECIFIC GRAVITIES OF SALT-COMPLEXES

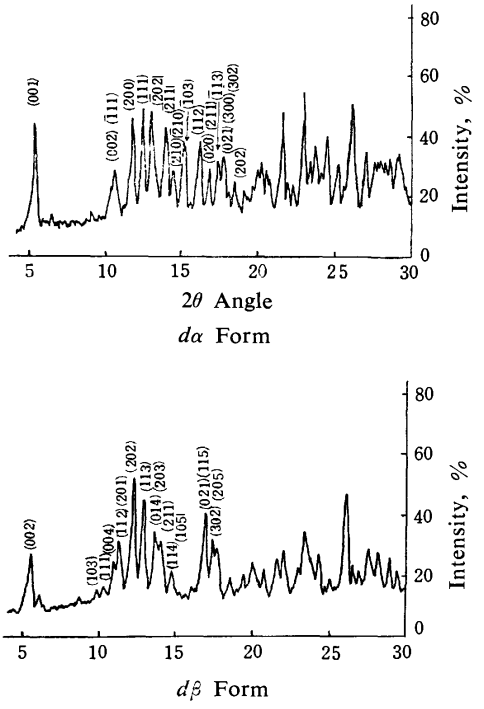
similarities in their powder patterns, it was assumed that they possess essentially the same unit cell dimensions and symmetry. In order to confirm this point, X-ray single crystal patterns of 9 different kinds of sulfate-complexes were examined; it was, indeed, found that the unit cell dimensions are nearly



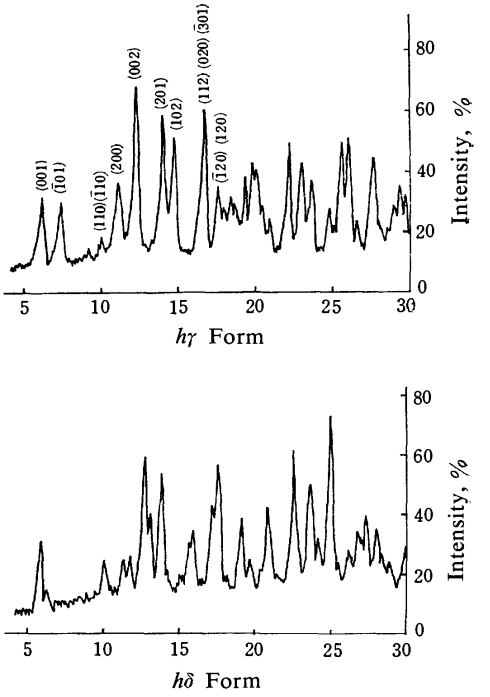


Fig. 1. X-Ray diffraction powder patterns of the four crystal forms.

the same in all of them, as Table II shows. Generally, the cell dimensions are in the range a=15.7~15.9, b=10.5, c=17.3~17.5 Å, and β=108~109°. Taking into consideration the optically-active character of the tetracycline

melecule coupled with the systematic absence, $(0\,k\,0)$ when k is odd, the space group of the $d\alpha$ form was determined as $P2_1$. In nearly every case, there are [2 molec. of tetracycline], one sulfate, one molecule of a complexing agent, and 10 molec. of water in each asymmetric unit, as calculated from the cell volume and the density given in Table II.

Fluosilicate-complexes. — Seven of the fluosilicate-complexes so far examined gave powder patterns very similar to those of the corresponding sulfate-complexes. The isomorphous series of sulfate-complexes, therefore, seems to be extended to include the fluosilicate-complexes. In fact, the monoclinic cell parameters of the fluosilicate-monochloroacetic acid complex were found to be $a=15.91$, $b=10.49$, $c=17.50$ Å and $\beta=109°00'$, figures are indistinguishable from those of its sulfate-complex.

Oxytetracycline Sulfate-complexes.—In addition to the oxytetracycline sulfate-acetic acid complex, whose cell parameters were $a=15.79$, $b=10.50$, $c=17.40$ Å, and $\beta=108°12'$, two more members (sulfate-propionic acid and -monochloroacetic acid complexes) are found to belong to the $d\alpha$ form.

The above results, together with the similar compositions of the salt-complexes, indicate that the molecular packings within the isomorphous salt-complexes of the $d\alpha$ form are very similar. No influence of the complexing agent was observed in determining the crystal structure. Molecules so chemically diverse as water, formic acid, oxalic acid, hydantoin, and dicyanodiamide are considered to be interchangeable in the $d\alpha$-type unit cell without any considerable enlargement or contraction of the cell dimensions.

In the isomorphous molecular compounds, which contained such a variety of chemical compounds, it does not seem likely that the binding force arises primarily from ion-dipole interactions as in the case of the tetraethylammonium bromide succinimide complex.[8] The formation of such a co-ordination compound is subjected to restriction not only by a charge distribution of the complexing agents but also by dimensional factors, so that even chemically-analogous substances may not form similar co-ordination compounds.[9] Therefore, it seems reasonable that the crystal strcutures of the $d\alpha$ form consist of an almost identical framework of the tetracycline (or oxytetracycline) molecules enclosing spaces capable of containing a complexing agent, just as those observed in inclusion compounds.

Further sppport for this point comes from a consideration of the restricted size (50~120 Å^3) and shape (co-planarity) of the complexing agent, as has been discussed previously,[7] and particularly from a detailed comparison of the X-ray diffraction intensities as a whole. Among the $d\alpha$-type sulfate-complexes given in Table II, there is a notable intensity resemblance when due allowance is made for the differences in absorption effect. For example, the difference in intensity between the sulfate-monobromoacetic acid and -propinic acid complexes of tetracycline is less than the difference between two sulfate-acetic acid complexes of tetracycline and oxytetracycline. Since the crystal structures of these complexes are isomorphous, it is to be expected that the differences in intensity of the corresponding reflections are due largely to the different scattering contributions of the complexing agents. However, the above finding suggests that they make only a small contribution. This may be explained, as in the case of the β-quinol clathrate,[10] by the freedom of motion or the statistical disorderness of the complexing agents in the cavities.

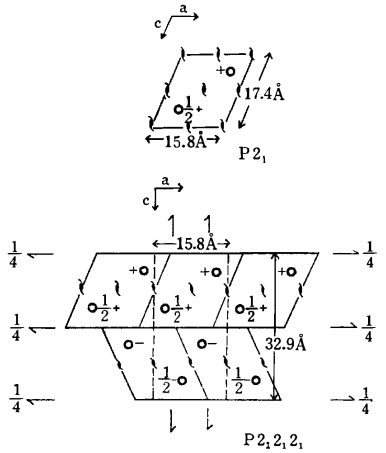

Fig. 2. Relationship between the $d\alpha$ type monoclinic cell ($P2_1$) and the $d\beta$ type orthorhombic cell ($P2_12_12_1$) (projection along [010]).

The $d\beta$ Form.—The $d\beta$ from is found in a few decahydrated sulfate-complexes, that is, sulfate-malonic acid, -glutaric acid, -parabanic acid and ascorbic acid complexes. Since sulfate-malonic acid complex also crystallizes in the $d\alpha$ form, the $d\beta$ form is evidently a polymorphic modification of the $d\alpha$ form. The crystals of the $d\beta$ form are orthorhombic, with the space group $P\,2_12_12_1$ and with cell dimensions of $a=16.0$, $b=10.5$, $c=32.1$~32.4 Å ; there are 4 units in a cell, each unit consisting of [2

tetracycline] sulfate, one complexing agent and 10 water molecules. A comparison of these parameters with those of the $d\alpha$ form reveals that a and b are almost identical with those of the $d\alpha$ form, whilst c corresponds to $2c_{d\alpha}\sin\beta$. If two monoclinic cells of the $d\alpha$ form are twinned, as in Fig. 2, where the twinning axis is the twofold screw axis lying at $y=1/4$ or 3/4 in the (001), the newly-formed orthorhombic cell has cell dimensions and a space group which are nearly identical with those of the $d\beta$ form. It is, therefore, possible that the $d\beta$ form is really a monoclinic substance submicroscopically twinned, thus exhibiting orthorhombic symmetry.* If so, the molecular packing must be essentially the same in both the $d\alpha$ and $d\beta$ forms, in spite of the apparent differences in unit cell dimensions and symmetry.

In this connection, it is interesting to note that the monoclinic crystals of the $d\alpha$ form are often twinned on a plane parallel to (001), giving apparent orthorhombic symmetry on the $h0l$ reflections. However, a careful examination of the Weissenberg photographs shows that they are, in fact, made up of the superposition of the sets of reflections from each of the untwinned crystals. In this case, therefore, each component part of the twinned crystal is large enough compared with a coherent region of X-rays.

The $h\gamma$ Form.—The $h\gamma$ form is found in the hexahydrates produced by the partial dehydration of the decahydrated sulfate-complexes: about one-half of the $d\alpha$-type sulfate-complexes fall into the $h\gamma$ form on dehydration. When a single crystal of the $d\alpha$-type sulfate-oxalic acid or -water complex was kept in dried air for a few minutes, diffuse spots due to the partial dehydrates appeared on the X-ray photograph, superposed on the normal diffraction spots. From the oscillation and ($h0l$) Weissenberg photographs about the b-axis of the dehydrated crystals, the approximate monoclinic cell dimensions of the $h\gamma$ form were found to be $a=16.0$, $b=10.5$, $c=14.7$ Å and $\beta=102°$ (Table II). The reliability of the proposed parameters may be judged further from the indexing of the powder pattern shown in Table III, in which there is no significant discrepancy between the observed and calculated diffraction angles.

Since all the powder patterns belonging to the $h\gamma$ form are very similar, it is reasonable, as in the case of the $d\alpha$ form, to assume the existence of the same essential framework among the $h\gamma$-type sulfate-complexes. It is to be noted, however, that, unlike the $d\alpha$ and $h\delta$ forms, where other salt-complexes besides sulfate-complexes are isomorphous members, the formation of the $h\gamma$ form is limited to the sulfate-complexes, insofar as we have been able to determine. This suggests that a sulfate anion plays an important part in determining the common framework of the $h\gamma$ form.

Table III. Indexing and Comparison of the Observed and Calculated Diffraction 2θ Angles for the Powder Patterns of the $d\alpha$ and $h\gamma$ Forms

$d\alpha$ Form			$h\gamma$ Form		
hkl	Calcd.	Found	hkl	Calcd.	Found
001	5.35°	5.35°	001	6.1 °	6.1 °
002, $\bar{1}11$	10.7	10.7	$\bar{1}01$	7.4	7.3
			$\bar{1}10$	10.15	10.05
200	11.9	11.9	200	11.3	11.3
111	12.5	12.5	002	12.3	12.3
$\bar{2}02$	13.25	13.2	201	14.0	14.0
$\bar{2}11$	14.2	14.1	102	14.6	14.6
210	14.6	14.6	112, 020, $\bar{3}01$	16.9	16.8
$\bar{1}03$	15.3	15.3			
112	16.2	16.2	120	17.8	17.7
020	16.9	16.9			
$\bar{1}13$	17.5	17.5			

As may be seen from a comparison of the cell parameters of the $d\alpha$ and $h\gamma$ forms, it is apparent that the escape of 8 mol. of water from the the $d\alpha$-type unit cell causes a decrease in the c-axis length (2.7 Å) and in the β angle (7°). According to an infrared analysis,[11] the lattice deformation probably corresponds to the approach of a complexing agent to a sulfate anion. In contrast to the $d\alpha$ form, where the sulfate anion holds tetrahedral symmetry as a whole, in the $h\gamma$ form a splitting of the sulfate bands is observed, this can be reasonably interpreted as a lowering of the T_d symmetry caused by interaction between a complexing agent and a sulfate anion.

The $h\delta$ Form.—The $h\delta$ form is a polymorphic modification of the $h\gamma$ form, for some of the hexahydrates, for example, sulfate-acetic acid or -monochloroacetic acid complex, crystallize in both of these forms. Though its unit cell dimensions were not determined, many hexahydrates of the sulfate-, nitrate-, hydrochloride-, and hydrobromide-complexes belong to this group (Table I).

A particularly interesting phenomenon observed in this group is that the powder patterns of 4 different kinds of salt-complexes, namely, the hydrochloride-oxalic acid, hydrobromide-oxalic acid, nitrate-oxalic acid and

* Such submicroscopic twinning is often found in minerals (T. Ito, "X-Ray Studies on Polymorphism," Maruzen, Tokyo (1950)).

11) S. Inouye, *Chem. Pharm. Bull.*, in press (1963).

sulfate-methyl hydrogenoxalate complexes, are quite similar to one another, suggesting the isomorphous replacement of Cl^-, Br^-, NO_3^- and SO^{2-} anions among these crystals.

Summary

An examination of the salt-complexes of tetracycline and oxytetracycline by the X-ray powder method has shown the presence of at least four different kinds of crystal structures, i. e., the *dα*, *dβ*, *hγ*, and *hδ* forms. Among them, the *dα* form has been studied in detail by the use of single crystals. The monoclinic unit cell dimensions of the *dα* crystals do not vary much either with a salt anion or with a complexing agent, and the intensities of the various reflections so far examined are very similar. On the basis of these findings, it is suggested that the crystal structures of the *dα*-type salt-complexes consist of an almost identical framework of tetracycline or oxytetracycline molecules which encloses spaces capable of containing complexing agents of various types. The orthorhombic *dβ* form is a polymorphic modification of the *dα* form, probably arising from submicroscopically polysynthetic twinning of the latter.

The authors wish to express their gratitude to Professor Toshihiko Okamoto and Professor Masamichi Tsuboi of the University of Tokyo, and to Dr. Hiroshi Ogawa of this laboratory, for their interest and encouragement. Thanks are also due to Dr. Kazuhiko Ohta and Messrs. Katsumi Hamano and Tomoya Ogawa for the use of their X-ray facilities.

A Consideration of the Q-e Scheme. IV. A Theoretical Approach to Price-Alfrey's Polarity Term

By Nariyoshi KAWABATA, Takayuki FUENO, Teiji TSURUTA and Junji FURUKAWA

(Received April 24, 1963)

Part I of this series[1] described a revised pattern of Price-Alfrey's *Q-e* scheme[2] which assumed the *e*-value of styrene to be equal to zero. In Part II,[3] we tried to give some theoretical background for this scheme. We divided the conjugation-stabilization energy between the monomer and the attacking radical, E_{RM}, into four terms by means of the following equation:

$$E_{RM} = E_{RoMo} + E_R + E_M + E'_{RM} \quad (1)$$

Here, E_{RoMo} is the stabilization energy between the polyethylene radical and the ethylene monomer, and E_R and E_M are the increments in the stabilization energy over E_{RoMo} as the standard introduced by the substituents in the polymer radical and in the monomer molecule respectively. E'_{RM} is the surplus increment in the stabilization energy introduced by the substituents of the radical and the monomer. We proposed relations 2 to 4 for the *P*-, *Q*- and *e*-terms:

$$P \propto \exp(E_R/\boldsymbol{RT}) \quad (2)$$

$$\ln Q_1 - \ln Q_2 = (E_{M_1} - E_{M_2})/\boldsymbol{RT} \quad (3)$$

$$e_R e_M = -E'_{RM}/\boldsymbol{RT} \quad (4)$$

The classical interpretation of the *P*-, *Q*- and *e*-terms is obviously different from ours, especially in the explanation of the polarity term. According to the classical interpretation,[2b] *e* is proportional to the charge on the end group of the radical or the monomer. Both of the two interpretations correlate with experimental facts; therefore, some theoretical interrelation may exist between them. The electronic charge on the end group of the radical or the monomer seems to be introduced mainly by heteroatoms. Therefore, we tried to investigate the effect of heteroatoms on the *Q-e* terms.

The Effect of Heteroatoms on the Conjugation-stabilization Energy. — In Part II of this series,[3] we proposed relations 2—4 for the *P*-, *Q*- and *e*-terms. Therefore, we would like now to investigate the effect of heteroatoms on the stabilization energy in order to examine their effect on the *Q-e* terms.

The conjugation-stabilization energy, E_{RM}, was calculated by the following equation.[3-5]

$$E_{RM}=2\left(\sum_{i}^{occ}\sum_{j}^{unocc}-\sum_{j}^{occ}\sum_{i}^{unocc}\right)\frac{(C_r^j)^2(C_m^i)^2}{E_j-E_i}(\Delta\beta)^2+\left(\sum_{i}^{occ}-\sum_{i}^{unocc}\right)\frac{(C_r^h)^2(C_m^i)^2}{E_h-E_i}(\Delta\beta)^2 \quad (5)$$

where C_r^j and C_m^i are the coefficients of the rth and the mth atomic π-orbitals in the jth and the ith molecular orbitals belonging to the eigenvalues E_j and E_i in the radical and the monomer respectively. E_h and C_r^h are the energy of the half-occupied orbital of the radical and the coefficient of the rth π-orbital in this MO respectively. $\sum^{occ}$ and $\sum^{unocc}$ imply summation over all the occupied (except the half-occupied) and all the unoccupied molecular orbitals. When the r'th atom of the radical and the m'th atom of the monomer are replaced with the heteroatoms Y and X respectively, E_j, E_i, $(C_r^j)^2$ and $(C_m^i)^2$ will become,[6] respectively:

$$E_i+\delta E_i=E_i+(C_m^i)^2\delta X \quad (6)$$

$$E_j+\delta E_j=E_j+(C_{r'}^j)^2\delta Y \quad (7)$$

$$(C_m^i)^2+\delta(C_m^i)^2=(C_m^i)^2+2C_m^iC_{m'}^i\sum_{p\neq i}\frac{C_m^pC_{m'}^p}{E_i-E_p}\delta X+\lambda_m(\delta X)^2 \quad (8)^*$$

$$(C_r^j)^2+\delta(C_r^j)^2=(C_r^j)^2+2C_r^jC_{r'}^j\sum_{q\neq j}\frac{C_r^qC_{r'}^q}{E_j-E_q}\delta Y+\lambda_r(\delta Y)^2 \quad (9)^*$$

where δX and δY are the respective increments of the Coulomb integrals for the heteroatoms X and Y. E_{RM} then becomes

$$E_{RM}=2\left(\sum_{i}^{occ}\sum_{j}^{unocc}-\sum_{j}^{occ}\sum_{i}^{unocc}\right)\times\frac{\{(C_m^i)^2+\delta(C_m^i)^2\}\{(C_r^j)^2+\delta(C_r^j)^2\}}{(E_j+\delta E_j)-(E_i+\delta E_i)}(\Delta\beta)^2+\left(\sum_{i}^{occ}-\sum_{i}^{unocc}\right)\times\frac{\{(C_m^i)^2+\delta(C_m^i)^2\}\{(C_r^h)^2+\delta(C_r^h)^2\}}{(E_h+\delta E_h)-(E_i+\delta E_i)}(\Delta\beta)^2 \quad (10)$$

Therefore, when, by the use of Eq. 11, we separate the stabilization energy into four terms in order to investigate the effect of the heteroatoms, the E_r, E_m and E'_{rm} terms can be given by Eqs. 12—14.[7] Here, E_r and E_m are the increments in the stabilization energy introduced by the heteroatom of radical Y and by that of monomer X respectively. E'_{rm} is the surplus increment in the stabilization energy introduced by the heteroatoms of the radical and the monomer.

$$E_{RM}=E_{r_0m_0}+E_r+E_m+E'_{rm} \quad (11)$$

$$E_r=C_r(\delta Y)^2 \quad (12)^*$$

$$E_m=C_m(\delta X)^2 \quad (13)^*$$

$$E'_{rm}=-C'_{rm}(\delta X)(\delta Y) \quad (14)$$

C_m, C_r and C'_{rm} are positive constants characteristic of a series of monomers having a same skeletal structure, in which only the r'th atom of the radical and the m'th atom of the monomer are replaced by various heteroatoms.

A Theoretical Approach to Price-Alfrey's Polarity Term. — In Part II of this series,[3] we proposed relations 2—4. According to Price and Alfrey,[2] the rate constant of the propagation step, k_p, is expressed by:

$$k_p=PQ\exp(-e_Re_M) \quad (15)$$

Here, the polarity term is the product of e_R and e_M. Further, $e_{R_1}=e_{M_1}$ is assumed for the radical and the monomer of type 1. In these two points, Eq. 4 does not conform to the concept of Price and Alfrey. However, for each series of isoelectronic monomers having a same skeletal structure, in which a fixed

* $\lambda_m=(C_{m'}^i)^2\left(\sum_{p\neq i}\frac{C_m^pC_{m'}^p}{E_i-E_p}\right)^2+2C_m^iC_{m'}^i\sum_{l\neq i}\sum_{p\neq i}\frac{C_m^lC_{m'}^l(C_{m'}^p)^2}{(E_i-E_l)(E_i-E_p)}-2C_m^i(C_{m'}^i)^3\sum_{l\neq i}\frac{C_m^lC_{m'}^l}{(E_i-E_l)^2}$

$\lambda_r=(C_{r'}^j)^2\left(\sum_{q\neq j}\frac{C_r^qC_{r'}^q}{E_j-E_q}\right)^2+2C_r^jC_{r'}^j\sum_{n\neq j}\sum_{q\neq j}\frac{C_r^nC_{r'}^n(C_{r'}^q)^2}{(E_j-E_n)(E_j-E_q)}-2C_r^j(C_{r'}^j)^3\sum_{n\neq j}\frac{C_r^nC_{r'}^n}{(E_j-E_n)^2}$

* When the reference monomer and the reference radical are alternant hydrocarbons, the 1st order terms cancel after summation. Therefore, Eqs. 12 and 13 are free from 1st order terms. When the reference monomer or the reference radical is a non-alternant hydrocarbon, Eqs. 12 and 13 may not be correct, although such a case is of rare occurrence.

carbon atom of a reference monomer (ethylene, butadiene, styrene or another neutral monomer) is replaced by such a heteroatom as oxygen, nitrogen, etc., the surplus energy term, E'_{RM}, seems to satisfy the concept. For these series of monomers, Eqs. 2−4 can, respectively, be reduced to

$$P \propto \exp(E_r/\boldsymbol{RT}) \tag{16}$$

$$\ln Q - \ln Q_0 = E_m/\boldsymbol{RT} \tag{17}$$

$$e_R e_M = -E'_{rm}/\boldsymbol{RT} \tag{18}$$

Here, Q_0 is the *Q*-value of the reference monomer of a monomer series. From Eqs. 12, 13 and 14, Eqs. 16, 17 and 18 can, respectively, be reduced to:

$$P \propto \exp\{(C_r/\boldsymbol{RT})(\delta Y)^2\} \tag{19}$$

$$\ln Q - \ln Q_0 = (C_m/\boldsymbol{RT})(\delta X)^2 \tag{20}$$

$$e_R e_M = (C'_{rm}/\boldsymbol{RT})(\delta X)(\delta Y) \tag{21}$$

Here, C_r, C_m and C'_{rm} are constants characteristic of a series of monomers having a same skeletal structure. As can be seen in Eq. 21, the polarity term may reasonably be separated into two terms, e_R and e_M, for such a monomer series.

$$e_R = -\sqrt{C'_{rm}/\boldsymbol{RT}}(\delta Y) \tag{22}$$

$$e_M = -\sqrt{C'_{rm}/\boldsymbol{RT}}(\delta X) \tag{23}$$

The assumption by Price and Alfrey that $e_{R_1} = e_{M_1}$ for the radical and the monomer of type 1 also seems to be reasonable for a monomer series of the same skeletal type.

Revised *Q-e* Values. — On the basis of the copolymerization data collected by Young,[8] we calculated the revised *Q-e* values by assuming the *e*-value of styrene to be equal to zero. These values are given in Table I.

We also calculated the $e_R e_M$ values as the

8) L. J. Young, *J. Polymer Sci.*, 54, 411 (1961).
9) K. Chikanishi, unpublished finding.
10) Irl. N. Duling and C. C. Price, *J. Am. Chem. Soc.*, 84, 578 (1962).
11) N. Kawabata, T. Tsuruta and J. Furukawa, *Makromol. Chem.*, 48, 106 (1961).

products of the relevant e-values given in Table I. These $e_R e_M$ values were compared with the e_{RM} values.[1] For each series of isoelectronic monomers having a same skeletal structure, the average deviation of $e_R e_M$ from e_{RM} was about 7%. However, for other pairs of radical and monomer, the average error was nearly 35%. This finding shows the validity of our conclusion that the expression by Price and Alfrey is reasonable for a series of monomers having a same skeletal structure.

An Electrostatic Interpretation of the Polarity Term.—According to the classical interpretation,[2b] e is proportional to the charge on the end group of the radical or the monomer. In fact, a linear relation was observed between $q_R q_M$ and $e_R e_M$.[3] That is,

$$e_R e_M \propto q_R q_M \tag{24}$$

Here, q_R and q_M are π-electronic charges on the end groups of the radical and the monomer respectively. According to Price,[12] it would be a reasonable speculation to write

$$e_R e_M = \varepsilon_R \varepsilon_M / rDkT \tag{25}$$

Here, ε_R and ε_M are actual charges on the end groups of the radical and the monomer respectively. D is the effective dielectric constant, and r is the distance of separation in the activated complex. However, there has often been proposed a different opinion that the electron transfer from a donor radical to an acceptor monomer, or vice versa, in the activated complex may account for the alternation tendency.[3,13-18] For a series of monomers having a same skeletal structure, q_R and q_M can be expressed as follows on the basis of Eqs. 8 and 9:

$$q_R = -2\sum_{j}^{occ} \delta(C_r^j)^2 e - \delta(C_r^h)^2 e = C_R(\delta Y) \tag{26}$$

$$q_M = -2\sum_{i}^{occ} \delta(C_m^i)^2 e = C_M(\delta X) \tag{27}$$

Here, C_R and C_M are negative constants characteristic of the series of monomers. From Eqs. 22 and 26,

$$e_R = -(\sqrt{C'_{rm}/\boldsymbol{RT}}/C_R)q_R \tag{28}$$

From Eqs. 23 and 27,

$$e_M = -(\sqrt{C'_{rm}}/\boldsymbol{RT}/C_M)q_M \tag{29}$$

The correlation of the polarity term with the product of π-electronic charges (Eq. 24) seems to be ascribable to the relations 28 and 29.

Summary

Previously, we pointed out the correlations of the P-, Q- and e-terms with the components of the conjugation-stabilization energy between monomers and attacking radicals. In the present paper, the effect of heteroatoms on the components of the stabilization energy was investigated. For each series of isoelectronic monomers, in which a fixed carbon atom of a reference monomer (ethylene, styrene, butadiene or another neutral monomer) is replaced by a heteroatom (oxygen, nitrogen, etc.), we obtained the relations: $\ln Q - \ln Q_0 = (C_m/\boldsymbol{RT})(\delta X)^2$, $P \propto \exp(C_r/\boldsymbol{RT})(\delta Y)^2$, $e_R = -\sqrt{C'_{rm}/\boldsymbol{RT}}(\delta Y)$ and $e_M = -\sqrt{C'_{rm}/\boldsymbol{RT}}(\delta X)$. Here, C_m, C_r and C'_{rm} are positive constants characteristic of the monomer series, while δX and δY are the Coulomb integral increments of the heteroatoms (relative to a carbon atom) in the monomer X and the radical Y respectively. Q_0 is the Q-value of the reference monomer of the series. The e-values of the reference monomers were all assumed to be zero. The opinions of Price and Alfrey that the polarity term is the product of e_R and e_M and that $e_{R_1} = e_{M_1}$ for the radical and the monomer of type 1 seem to be not only convenient but also reasonable for a series of monomers having a same skeletal structure. The π-electronic charges, q_R and q_M, on the end groups of the radical and the monomer seem to be correlated with e_R and e_M in such a manner that $e_R = -(\sqrt{C'_{rm}/\boldsymbol{RT}}/C_R)q_R$ and $e_M = -(\sqrt{C'_{rm}/\boldsymbol{RT}}/C_M)q_M$. Here, C_R and C_M are negative constants characteristic of the series of monomers. The correlation of the polarity term with the electrostatic interaction between the charges of the radical and the monomer seems to be ascribable to these relations.

The C-H Stretching Spectra and Intensities of Dihalogenomethanes and Intermolecular Interaction

By Utako KANBAYASHI

(Received April 17, 1963)

Many experiments and theoretical considerations concerning the vibrational spectra of dihalogenomethanes have been carried out.[1-7] Regarding the C–H stretching bands of each compound in the condensed phase, a band existing between 2970 and 3000 cm^{-1} was assigned to ν_1 (a symmetric stretching vibration) and another between 3040 and 3070 cm^{-1}, to ν_6 (an antisymmetric stretching vibration).

In the C–H stretching region of the infrared spectrum of dichloromethane vapor, there is found only a doublet centered at 2995 cm^{-1}. In the dilute solution state, a band of weak intensity appears on the high frequency side (3048 cm^{-1} in the case of the carbon tetrachloride solution), whereas none is observed in the vapor state. As the concentration of the solute increases, the absorptivity* of this band also increases, while that of the band of low frequencies (2983 cm^{-1} in the carbon tetrachloride solution) decreases. In the pure liquid, the former is much stronger than the latter, as Josien et al.[8] have indicated.

In ordinary cases, where the existence of intermolecular interaction, rotational isomerism, etc. can be ignored, neither the frequency nor the absorptivity of an infrared band changes appreciably as a function of the concentration in a non-polar solvent. Considering this well-known fact, it is very interesting to find such experimental results as have been presented above.

Experimental

The commercial products of dichloromethane, chlorobromomethane, dibromomethane, and diiodomethane were purified by distillation. Dimethoxymethane-d_6 was prepared at the author's laboratory.[9] The purity of these compounds was checked by means of gas chromatography.

The infrared spectra in the C–H stretching region were obtained by means of a Perkin-Elmer model 12 C spectrophotometer equipped with a lithium fluoride prism. The recording of spectra in the vapor state was made in cells with path lengths of 10 cm. and 100 cm. on dichloromethane and chlorobromomethane, 100 cm. on dibromomethane, and 10 cm. on dimethoxymethane-d_6, all at a total pressure of 1 atm. The recording of spectra in solution was made with carbon tetrachloride and carbon disulfide as the solvents, and at the following volume percentage concentrations: dichloromethane—50% (cell thickness, 0.10 mm.), 10% (0.2 and 0.5 mm.) and 1.0% (0.5 and 1.0 mm.); chlorobromomethane—50% (0.05 and 0.1 mm.), 10% (0.2 and 0.5 mm.) and 2% (0.5 and 1.0 mm.); dibromomethane—50% (0.01, 0.03 and 0.05 mm.), 10% (0.2 mm.) and 2% (1.0 mm.); diiodomethane—50% (0.03 and 0.05 mm.), 10% (0.2, 0.5 and 1.0 mm.), 5% (1.0 mm.) and 2% (1.0 and 5.0 mm.); and dimethoxymethane-d_6 (in carbon tetrachloride solution only)—25% (0.15 mm.). In the pure liquids spectral, measurements were made in cells 0.05 and 0.03 mm. thick for dichloromethane and chlorobromomethane, 0.03 and 0.014 mm. thick for dibromomethane and diiodomethane, and 0.014 mm. thick for dimethoxymethane-d_6.

Spectra were also obtained with a Perkin-Elmer model 21 spectrophotometer equipped with a sodium chloride prism on the compounds in the vapor state, in solution (solvent: carbon tetrachloride and carbon disulfide) and as pure liquids. Especially on dichloromethane, the variation in intensity and frequency with concentration was observed minutely with varied concentrations—the CH_2 bending vibration* (1425 cm^{-1}) and the CH_2 rocking vibration (895 cm^{-1}) in carbon tetrachloride solution, and the CH_2 wagging vibration (1154 cm^{-1}) and the C–Cl stretching vibrations (740 and 707 cm^{-1}) in carbon disulfide solution.

As for the Raman spectra, observation was made by means of a Cary model 81 spectrophotometer on dichloromethane, chlorobromomethane and dibromomethane in pure liquid and in carbon tetrachloride solution (50, 20 and 10% by volume). On the compounds in pure liquid, the qualitative degrees of depolarization were measured by alternately wrapping the Raman tube with two types of polarizing cylinders.

* In pure liquid, dichloromethane has a band at 1425 cm^{-1} and a very weak shoulder at 1445 cm^{-1}. When it is diluted with carbon tetrachloride, the intensity at 1445 cm^{-1} becomes larger, but that at 1425 cm^{-1} becomes a bit smaller.

Results

Variation of the Relative Intensities.—*Infrared Spectra.*—The ratio of the absorbance of ν_6 to that of ν_1 (D_6/D_1) was computed from the observed spectra of the dihalogenomethanes and dimethoxymethane-d_6 by means of the base-line method.* In the cases of carbon tetrachloride and carbon disulfide solutions, plots of the observed values of D_6/D_1 against the concentration yield straight lines (see Figs. 2 and 3). If these straight lines are extended to zero concentration, the values of D_6/D_1 at

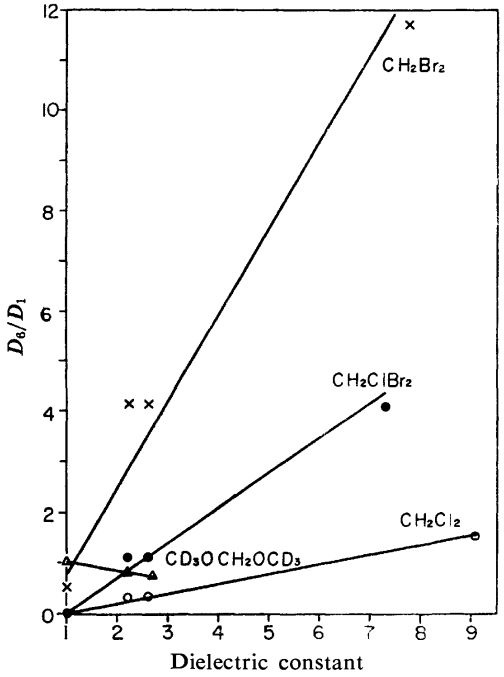

Fig. 4. Plot of D_6/D_1 vs. the dielectric constant of the medium for CH_2Cl_2 (○), CH_2ClBr (●), CH_2Br_2 (×) and CD_3OCH_2O-CD_3 (△).

infinite dilution in carbon tetrachloride and carbon disulfide solutions are obtained. Then, in the cases of chlorobromomethane, dibromomethane and dimethoxymethane-d_6, if the values of D_6/D_1 are plotted against the dielectric constants of the media (vapor, carbon tetrachloride, carbon disulfide and pure liquid), they fall on a straight line. (Fig. 4) Moreover, in the case of dichloromethane, if the values of D_6/D_1 in pure liquid and in carbon tetrachloride and carbon disulfide solutions are plotted against the dielectric constants of the media, the value of D_6/D_1 obtained by setting the dielectric constants at one (vapor) by extrapolation is nearly zero. This agrees well with the author's interpretation that, in vapor, the intensity of ν_6 is extremely weak. Details of this interpretation are given below.

As Fig. 4 shows, the value of D_6/D_1 increases with the dielectric constant in the cases of dichloromethane, chlorobromomethane and dibromomethane, but decreases in the case of dimethoxymethane-d_6.

In the case of dichloromethane, the variations in the band intensities with the concentration in the sodium chloride prism region, were observed to be smaller than those in the C-H stretching region.

Raman Spectra.—The relative intensity of ν_1 and ν_6 were estimated in the cases of dichloromethane, chlorobromomethane and dibromomethane in the pure liquid and in carbon tetrachloride solutions of various concentrations. The ratio of the peak intensity of ν_6 to that of ν_1 (h_6/h_1) shows no variation beyond the range of experimental errors. The values of h_6/h_1 are 0.16～0.18 for dichloromethane, 0.17～0.18 for chlorobromomethane, and 0.28～0.29 for dibromomethane.

Frequency Shifts.—When the compound is in a solution, the frequency shifts of ν_1 and ν_6 are linear functions of the concentration in both the infrared and Raman spectra. The slope varies with the kind of compound as well as with the kind of band and solvent. The frequencies shown in Table I for carbon tetrachloride and carbon disulfide solutions were obtained by extrapolation to zero concentration. When the compound is in a vapor, carbon tetrachloride solution or carbon disulfide solution, the relation between $(\nu_{vapor}-\nu_{solution})/\nu_{vapor}$ and $(\varepsilon-1)/(2\varepsilon+1)$ is approximately linear. However, the value in the case of a pure liquid is not on the same line.

Discussion

Assignment of C-H Stretching Vibrations of the Dichloromethane Molecule in Vapor. — In the infrared spectra of dichloromethane in the condensed phases, single bands are observed at about 2980 and 3050 cm^{-1}. However, in the vapor, only a doublet centered at 2995 cm^{-1} is found, and no band is observed in the vicinity of 3050 cm^{-1}. Straley[1] has reported the doublet as being due to a partial overlapping of ν_1 and ν_6. However, the present author has concluded, on the basis of the following considerations, that the doublet at 2995 cm^{-1} corresponds to ν_1, showing P and R branches, and that ν_6, which may exist in a higher frequency region, is not observed because of its very weak intensity (see Fig. 1). This result is in good agreement with Kagarise's.[10]

(1) In the infrared spectrum of chlorobromomethane vapor, a band of weak intensity is observed at 3065 cm^{-1} in addition to the doublet centered at 3000 cm^{-1}. These two bands, which are also observed in the condensed phase, can reasonably be assigned to ν_6* and ν_1 respectively. In the case of dibromomethane, the bands at 3005 and 3077 cm^{-1} in the vapor are also observed in the condensed phase and can be reasonably assigned to ν_1 and ν_6 respectively. In both cases, the difference in frequency between ν_1 and ν_6 is 60～80 cm^{-1} irrespective of the phase. Assuming that

10) R. E. Kagarise, *Spectrochim. Acta* (in press).

* The asymmetric C-H stretching vibration in the cases of chlorobromomethane and dimethoxymethane-d_6 molecules is also represented by ν_6.

Straley's assignment is correct in the case of dichloromethane, the difference in frequency in the vapor is 14 cm^{-1}, while that in the condensed phase is 60~70 cm^{-1}. This frequency difference of 14 cm^{-1} in the vapor is abnormally small when compared with the other dihalogenomethanes.

When the compounds are in vapor, the intensity of ν_6 is much weaker than that of ν_1 in the case of chlorobromomethane but not very different in the case of dibromomethane. When the compounds are in the condensed phase, the intensity of ν_6 compared with that of ν_1 increases in the order of: dichloromethane → chlorobromomethane → dibromomethane. If the same tendency exists in vapor, it must be expected that the intensity ratio of ν_6 to ν_1 is smaller in the case of dichloromethane than in the case of chlorobromomethane.

(2) The dichloromethane molecule is a nearly prolate symmetric top* and ν_1 is a type-B band, while ν_6 is a type-C band. It is inferred from the band contours of the other fundamental bands, overtones and combination bands[11] of dichloromethane that the type-B bands lack a Q branch, while the type-C bands have a relatively strong Q branch. The doublet of dichloromethane centered at 2995 cm^{-1} does not exhibit a prominent Q branch; therefore, it is reasonably regarded as a type-B band.

In the case of a nearly prolate symmetric top, the approximate value of the separation of the maxima of P and R branches is given as follows;

$$\Delta\nu = \sqrt{\frac{8kT}{hc}} \cdot \frac{B+C}{2}$$

As estimated by this formula, $\Delta\nu$ is 13 cm^{-1} in the case of dichloromethane, a value which is in good accordance with the observed separation of 14 cm^{-1}, between the maxima of the doublet at 2995 cm^{-1}.

Variation of the Infrared Intensities of the C–H Stretching Bands and Intermolecular Interaction.—The intensities of the C–H stretching bands of dihalogenomethanes vary extraordinarily with the dielectric constant of the medium, as is shown in Fig. 4, but the frequency shifts are comparatively small, as Table I shows. According to Josien et al.,[8] in the case of dichloromethane the ratios between the integrated intensities in a dilute carbon tetrachloride solution (0.15 mol./l.) and in pure liquid are 1 : 0.6 for ν_1 and 1 : 2.4 for ν_6.

According to Polo et al.,[12] the ratio of the infrared intensity in the condensed phase to that in vapor hinges solely on the refractive indices of the media as estimated by the Debye model. In other words, the ratio between the intensities in vapor is identical with the ratio in the condensed phase.

If Polo's theory were valid, the intensity of any band in the carbon tetrachloride solution would be nearly equal to that in pure liquid, since the refractive index of dichloromethane (1.42) is nearly equal to that of carbon tetrachloride (1.46). Nevertheless, it is observed that the absorptivities of ν_1 and ν_6 vary markedly with the concentration of both in carbon tetrachloride and carbon disulfide solutions. Such variation cannot be explained by the simple model mentioned above, rather, it suggests the existence of some intermolecular interaction, as Polo indicated. Caldow et al.[13,14] have made an experimental study of the effect of solvents on the absorption bands of hydrogen cyanide. They have concluded that the observed solvent effects in the case of hydrogen cyanide result from the superposed contributions of both bulk dielectric effects and intermolecular interaction between a solute molecule and a solvent molecule. It is considered reasonable, therefore, that the remarkable concentration effect on the infrared intensities of ν_1 and ν_6 in the case of dichloromethane result from intermolecular interaction. In this case the interaction between solute molecules (dichloromethane) is more predominant than the interaction between a solute molecule and a solvent molecule (carbon tetrachloride or carbon disulfide); it is observed that the intensity ratio between ν_1 and ν_6 in solution approaches the ratio in vapor as the solution is diluted (see Fig. 4). Kagarise concluded also that dichloromethane forms a complex with aceton.[10]

Hydrogen bonding generally causes not only a large variation in the intensity of the stretching band, but also a remarkable lowering of its frequency. In such cases, the effect of intermolecular interaction has more influence on the intensity than on the frequency. Therefore, to presuppose the existence of intermolecular interaction in the case of dichloromethane seems not to contradict the experimental finding that the frequency shift is comparatively small. In chlorobromomethane and dibromomethane, a similar variation is also observed; therefore, a similar interaction

* $I_A = 2.6\times10^{-39}$, $I_B = 25.6\times10^{-39}$ and $I_C = 27.7\times10^{-39}$ g.cm²

is presupposed. Again, in the case of dimethoxymethane-d_6, where such an interaction seems negligible, the variation in the ratio of intensities (D_6/D_1) is smaller than in the cases of dihalogenomethanes, and its slope against the dielectric constants of media is opposite to the slope in dihalogenomethanes (see Fig. 4).

The author wishes to express her thanks to Dr. Kenkichi Nukada for the opportunity given to perform this research and for his helpful advice and critical remarks, and to Dr. Shinnosuke Saeki, for their valuable suggestions.

The author is also grateful to Dr. Kazuo Amaya and Mrs. Kazuko Sasaki for their measuring of the dielectric constant of chlorobromomethane.

For aid in completing this English manuscript, acknowledgement is due to Professor R. E. Kagarise and Mr. Norizo Maeda.

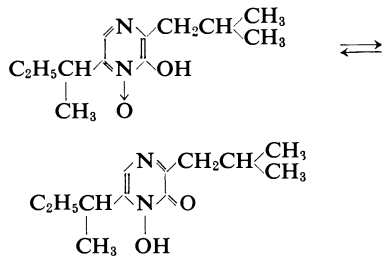
Synthese von 3,6-Disubstituierten 2-Hydroxypyrazinen

Von Mitsuo MASAKI und Masaki OHTA

(Eingegangen am 27. April, 1963)

Die Untersuchungen über Aspergillsäure, ein von dem Moder, *Aspergillus flavus*,[1] produziertes Antibiotikum, zogen den Schluss,[2] dass die Substanz 3-Isobutyl-6-*sek*.-butyl-2-hydroxypyrazin-1-oxyd oder tautomere Hydroxamsäure (I) darstellt.



(I)

Zwei Methoden zur Synthese von 2-Hydroxypyrazinen, welche an 3 und 6 Stellungen zwei ungleiche Substituenten aufweisen, sind bereits von Spring et al. berichtet worden. Die erste Synthese geht von dem aus α-Oximino-aldehyd mit α-Amino-nitril erhaltenen 3,6-disubstituierten 2-Aminopyrazin-1-oxyd aus, das bei der Reduktion mit Natriumdithionit den Deoxykörper ergibt, der durch Behandlung mit salpetriger Säure zu 3-Isobutyl-6-*sek*.-butyl-2-hydroxypyrazin umgewandelt wurde.[2] Die zweite Synthese beruht auf der Dehydratisierung von DL-Leucyl-DL-isoleucinanhydrid mit Phosphorylchlorid zu 3-*sek*.-Butyl-6-isobutyl-2-hydroxypyrazin.[3]

In der vorliegenden Arbeit beschreiben wir, dass man durch die direkte Cyclisierungsreaktion zu 3,6-disubstituierten 2-Hydroxypyrazinen gelangen kann, indem man einen *N*-(2-Keto-alkyl)-aminosäureester (IV) mit Ammoniak in Methanol kondensiert.

Kürzlich berichteten wir,[4] dass durch die Umsetzung von α-Halo-oxim mit Aminosäureester in ätherischer Lösung *N*-(2-Oximinoalkyl)-aminosäureester (II) leicht zugänglich ist, der bei Hydrolyse mit Alkali die entsprechende Carbonsäure liefert. Verbindungen vom Typus IV liessen sich durch Verseifung

	R	R′

2) G. T. Newbold, W. Sharp und F. S. Spring, *J. Chem. Soc.*, **1951**, 2679. vgl. J. D. Dutcher, *J. Biol. Chem.*, **171**, 321 (1947).
3) J. J. Gallagher, G. T. Newbold, W. Sharp und F. S. Spring, *J. Chem. Soc.*, **1952**, 4870.
4) M. Masaki und M. Ohta, Dieses Bulletin, **36**, 922 (1963).

der Oximinogruppe der *N*-(2-Oximino-alkyl)-aminosäuren, und durch die anschliessende Veresterung der entstandenen *N*-(2-Keto-alkyl)-aminosäure (III), erhalten.

In der Gegenwart von Benzaldehyd[5] wurde *N*-(2-Oximinopentyl)-leucin mit Salzsäure in 60 proz. Ausbeute zur *N*-(2-Keto-pentyl)-leucin (III-a) verseift, welche mit Methanol und Chlorwasserstoff *N*-(2-Keto-pentyl)-leucin-methylester-hydrochlorid (IV-a) lieferte. Dieses Ester-hydrochlorid gab durch Behandlung mit Ammoniak in Methanol bei Zimmertemperatur 3-Isobutyl-6-propyl-2-hydroxypyrazin (V-a), dessen Konstitutionsbeweis durch Elementar-Analyse und Ultraviolet-spektrum erreicht wurde. Die letzte Stufe der Synthese ist die Oxydation, die in den meisten Pyrazin-synthesen allgemein ist.

Durch dieses Verfahren konnten wir weiter 3, 6-Diisobutyl-2-hydroxypyrazin ("Flavacol") (V-b)[6] und 3-Isobutyl-6-phenyl-2-hydroxypyrazin (V-c), ausgehend von den entsprechenden *N*-(2-Oximino-alkyl)-leucinen, synthetisieren.

Zur Synthese von 2-Hydroxypyrazin-1-oxyd oder tautomerer Hydroxamsäure dürfte der durch die oben erwähnte Methode zugänglich gewordene *N*-(2-Keto-alkyl)-aminosäureester (IV) als Zwischenprodukt erwartet werden.[7]

Beschreibung der Versuche

***N*-(2-Keto-pentyl)-leucin (III-a).** — Eine Lösung von 2 g *N*-(2-Oximinopentyl)-leucin[4] in 20 ccm 3N Salzsäure wurde mit 2 g Benzaldehyd und 20 ccm Methanol versetzt und die klare Lösung wurde bei Zimmertemperatur stehengelassen. Nach 3 Tagen wurde die Lösung unter vermindertem Druck auf ca. 10 ccm eingeengt, dann 2 mal mit Äther gewaschen und mit Natriumcarbonat neutralisiert, wobei sich die Keto-aminosäure ausschied, die 2 mal mit Wasser nachgewaschen wurde. Rohausb. 1.2 g. Farblose Nädelchen vom Schmp. 184~186°C (aus Methanol).

Gef.: C, 61.27; H, 9.64; N, 6.59. Ber. für $C_{11}H_{21}O_3N$: C, 61.36; H, 9.83; N, 6.51%.

Bei der Einwirkung von Hydroxylamin auf dieses Keton wurde das Oxim quantitativ erhalten.

***N*-(2-Keto-pentyl)-leucin-methylester-hydrochlorid (IV-a).**—Eine Suspension von 0.6 g III-a in 15 ccm Methanol wurde unter Durchleitung von trockenem Chlorwasserstoff 2 Stdn am Rückfluss gekocht und die erhaltene Lösung wurde über Nacht stehengelassen. Der beim Eindampfen des Lösungsmittels hinterbliebene Rückstand wurde unter vermindertem Druck über Kaliumhydroxyd getrocknet und aus Essigester umkristallisiert. Ausb. 0.6 g. Farblose Nadeln vom Schmp. 90~91.5°C (Sintern bei 70~74°C).

Gef.: N, 5.08. Ber. für $C_{12}H_{23}O_3N \cdot HCl$: N, 5.29%.

3-Isobutyl-6-propyl-2-hydroxypyrazin (V-a).— Eine Lösung von 0.5 g IV-a in 12 ccm Methanol sättigte man mit Ammoniak und liess die Lösung bei Zimmertemperatur stehen. Nach 2 Tagen wurde die Lösung unter vermindertem Druck eingeengt und der Rückstand wurde in Essigester mit Aktivkohle behandelt, und wieder wurde die Lösung unter vermindertem Druck abgedampft. Der ölige Rückstand wurde mit 3 N Salzsäure extrahiert, dann der Extrakt mit Aktivkohle behandelt und unter vermindertem Druck zur Trockene eingedampft. Der kristallinische Rückstand wurde mit Natriumbicarbonatlösung und dann mit Wasser gewaschen. Rohausb. 0.3 g. Farblose Nadeln vom Schmp. 136.5~137°C (aus Äthanol). UV-Spektrum in Äthanol: λ_{max} 2280 A(ε=7400) und 3260 A(ε=7400).

Gef.: C, 67.91; H, 9.00; N, 14.64. Ber. für $C_{11}H_{18}ON_2$: C, 68.00; H, 9.34; N, 14.42%.

***N*-(2-Keto-isohexyl)-leucin (III-b).**—Eine Lösung von 3 g *N*-(2-Oximino-isohexyl)-leucin[4] in 20 ccm 3 N Salzsäure versetzte man mit 2 g Benzaldehyd und 18 ccm Methanol, liess die erhaltene Lösung 3 Tagen bei Zimmertemperatur stehen und arbeitete dann weiter auf wie beim III-a. Rohausb. 1.9 g. Farblose Nädelchen vom Schmp. 178~179°C (aus Methanol).

Gef.: C, 62.59; H, 10.19; N, 6.05. Ber. für $C_{12}H_{23}O_3N$: C, 62.85; H, 10.11; N, 6.11%.

3, 6-Diisobutyl-2-hydroxypyrazin (V-b). — Wie beim IV-a wurde 0.6 g III-b mit Methanol und Chlorwasserstoff verestert, wobei 0.7 g rohes *N*-(2-Keto-isohexyl)-leucinmethylester-hydrochlorid (IV-b) erhalten wurde. Eine Lösung von 0.55 g IV-b vom Schmp. 114~116°C (aus Benzol-Äther) in 20 ccm Methanol wurde mit Ammoniak gesättigt und nach 2 tägigem Stehenlassen bei Zimmertemperatur wurde das Reaktionsgemisch wie beim V-a aufgearbeitet, dabei wurde 0.25 g rohes V-b erhalten. Umkristallisierung aus Äthanol ergab farblose Kristalle vom Schmp. 149~151°C (Gef.: N, 13.33%. Lit.[6] Schmp. 144.5~147°C). UV-Spektrum in Äthanol: λ_{max} 2290 A(ε=6700) und 3250 A(ε=7400).

Salzsäuresalz von *N*-Phenacyl-leucin (III-c).— Man löste 5 g *N*-(2-Phenyl-2-oximinoäthyl)-leucin[4] in 40 ccm 3 N Salzsäure auf und liess bei Zimmertemperatur stehen. Bald fing ein farblose Niederschlag (Salzsäuresalz von III-c) sich auszuscheiden an. Nach 24 stdg. Stehen wurde der Niederschlag abgesaugt. Rohausb. 5 g. Farblose Nadeln vom Schmp. 194°C (aus 3N Salzsäure).

Gef.: C, 58.79; H, 6.91; N, 4.89. Ber. für $C_{14}H_{19}O_3N \cdot HCl$: C, 58.84; H, 7.01; N, 4.90%.

***N*-Phenacyl-leucin-methylester-hydrochlorid (IV-c).**—Eine Suspension von 0.9 g Salzsäuresalz von III-c in 20 ccm Methanol wurde wie beim IV-a aufgearbeitet. Farblose Prismen vom Schmp. 133~135°C (aus Essigester). Ausb. 0.6 g.

Gef.: N, 4.61. Ber. für $C_{15}H_{21}O_3N \cdot HCl$: N, 4.67%.

Freie Base: Leicht zersetzliche, farblose Nadeln vom Schmp. 53°C (aus Petroläther).

6) G. Dunn, G. T. Newbold und F. S. Spring, *J. Chem. Soc.*, **1949**, 2586.

7) Tatsächlich erhielten wir schon durch Behandlung des Keto-amino-ester mit Hydroxylamin eine Spur Substanz, die mit Eisenchlorid eine deutliche Farbreaktion zeigt. Wir untersuchen dies jetzt und werden bald davon Mitteilung machen.

3-Isobutyl-6-phenyl-2-hydroxypyrazin (V-c).— Man löste 0.5 g IV-c in 20 ccm Methanol auf, leitete Ammoniak bis zur Sättigung und liess dann die Lösung bei Zimmertemperatur stehen. Nach 2 Tagen wurde die Lösung unter vermindertem Druck eingedampft, der ölige Rückstand wurde in Essigester aufgelöst und nach der Entfernung des unlöslichen Ammoniumchlorides wurde die Lösung wieder eingedampft, inzwischen wurde ein Luftstrom durch die Lösung eingeleitet, um die Luftoxydation zu vervollständigen. Der ölige Rückstand wurde mit 6 N Salzsäure extrahiert und nach Behandlung mit Aktivkohle der Extrakt mit 2 N Natronlauge neutralisiert, wobei sich ein brauner Niederschlag (0.16 g) ausfiel, der aus Äthanol umkristallisiert wurde. Gelbe Nadeln vom Schmp. 167~168.5°C. UV-Spektrum in Äthanol: λ_{max} 2390 A(Schulter $\varepsilon=6800$), 2500 A($\varepsilon=8000$) und 3280 A($\varepsilon=13000$).

The Luminescence Spectra of Triply-ionized Dysprosium and Terbium in Alkaline Earth Fluorides

By Eiichi IWASE and Seijiro NISHIYAMA

(Received May 14, 1963)

The three principal luminescence bands of the samarium(III) ion, which is embedded in alkaline earth fluorides, show, according to Tomaschek,[1] a blue shift as the matrix is changed in the sequence of calcium fluoride, strontium fluoride and barium fluoride. Here the blue shift refers to the displacement of bands towards the larger frequency side of the spectrum. Yoshimura[2] verified this regularity of the blue shift with a much greater number of bands of samarium(III) luminescence appearing in the sequence of matrices just mentioned. Furthermore, Evert[3] studied the luminescence of another rare earth ion, namely, the praseodymium(III) ion, embedded in sulfides as well as in oxides of alkaline earth elements, and put forward two suggestions, though they did not explicitly concern the luminescence in the matrices of alkaline earth fluorides. One of his suggestions was that a blue shift may also occur in the luminescence spectrum of the praseodymium(III) ion embedded in the sequence of alkaline earth fluorides with ascending lattice-constants; the other suggestion is that, with this sequence of matrices, there may be seen the "contraction of the luminescence spectrum," i.e., the decrease occurs in the frequency-intervals of the luminescence bands of the praseodymium(III) ion. This paper presents the results of investigations of the luminescence spectra of dysprosium(III) and terbium(III) ions embedded in the matrices of calcium fluoride, strontium fluoride and barium fluoride; this investigation was undertaken for the purpose of ascertaining what the effects of the crystal-field strength of these matrices on the f-f transitions of the said triply-ionized rare earths are really like.

Experimental

By means of the reactions between alkaline earth nitrates and hydrofluoric acid in aqueous solutions, precipitates of calcium fluoride, strontium fluoride and barium fluoride were prepared; they were then soaked with a nitrate solution of either dysprosium(III) or terbium(III) and calcined at about 900°C for 30 min. These rare earths were made by the Lindsay Chemical Division, the American Potash & Chemical Corporation, and were of 99.9% purity. The concentration of the rare earth ions in the matrix is always made to be about 0.1%.

The excitation to the luminescence is done in a small Urbain tube by cathode-ray bombardment at room temperature, and the luminescence thus provoked is spectrographically investigated by employing a glass-prism spectrograph of Feuss.

In the matrix-sequence of calcium fluoride, strontium fluoride and barium fluoride, the intensity of the luminescence generally decreases so markedly that, in order to make sure of a proper and detailed comparison among the luminescence spectra, the duration of the exposure to the photographic plate had to be varied, for instance,

several minutes for the luminescence in the calcium fluoride matrix and several hours for that in the barium fluoride matrix.

Results and Discussion

Figures 1—3 are, respectively, the schematic representations of the luminescence spectra of dysprosium(III) and terbium(III) ions which are embedded in the calcium fluoride, strontium fluoride and barium fluoride matrices.

In a comparatively recent work by Chatterjee[4] on the luminescence spectra of dysprosium(III) and terbium(III) ions, calcium fluoride was selected as their matrix. From our experiments on the luminescence spectra, it is now confirmed that a fairly great number of the bands observed by him should be ascribed to the presence of praseodymium, samarium and either terbium or dysprosium as impurities in the dysprosium and terbium preparates.

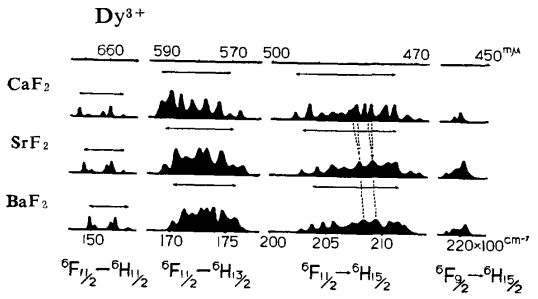

Fig. 1

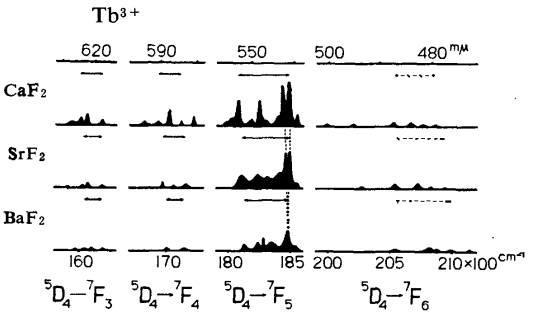

Fig. 2

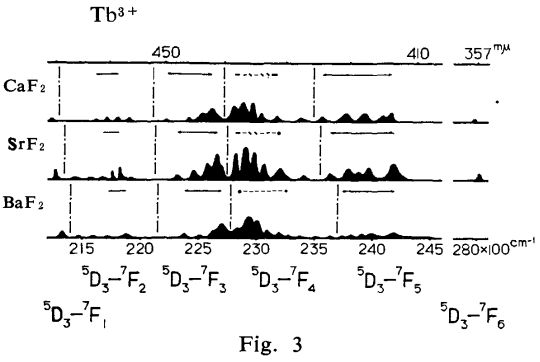

Fig. 3

Our measurements cover the frequency regions 14800~21200 cm^{-1} and 15900~26300 cm^{-1} for the luminescence of dysprosium(III) and terbium(III) ions respectively. As is shown in Table I, the total number of observed bands of the dysprosium(III) ion is 28, 26 and 27 for the luminescence found in the calcium fluoride, strontium fluoride and barium fluoride matrices respectively. Similarly, that of the terbium(III) ion is 46, 42 and 40 for the luminescence found in the calcium fluoride, strontium fluoride and barium fluoride matrices respectively.

TABLE I

	Total number of observed bands			Number of bands showing blue shift	
	CaF_2	SrF_2	BaF_2	$CaF_2 \rightarrow SrF_2$	$SrF_2 \rightarrow BaF_2$
Dy^{3+}	28	26	27	25	22
Tb^{3+}	46	42	40	35	33

The four systems of the bands of dysprosium(III) ions around 15100, 17300, 20800 and 22000 cm^{-1} are assigned, respectively, to the 6F11/2→6H11/2, 13/2, 15/2 and 6F9/2→6H15/2 transitions. To make these assignments of bands, the data given by Dieke and others,[5] are referred to.

Ten band-groups of the terbium(III) luminescence around 16100, 17100, 18300, 20700, 21300, 21800, 22500, 23200, 23900 and 26200 cm^{-1} are, respectively, assigned to the 5D4→7F3, 4, 5, 6 and 5D3→7F1, 2, 3, 4, 5, 6 transitions. To make these assignments of bands, the data given by Gobrecht[6] and Dieke and others[5] are taken into consideration.

The outermost electron-shell of all the triply-ionized rare earths is, as is well known, of a configuration having two 5s and six 5p electrons. Because of the shielding of this electronic structure of the closed-shell type, the f-f transitions of these ions would not be very much affected by an external force, and when these ions are embedded in various matrices, all the observed luminescence bands due to the f-f transitions are sharp and the proper correspondences between them may be ascertained comparatively easily.

When the matrix is restricted to alkaline earth fluorides with a comparatively simple structure of cubic fields (O_h^5), the lattice-constant is increased in the successive order of

calcium fluoride, strontium fluoride and barium fluoride. Accordingly, the effects of crystal-field strength on a foreign cation embedded in the site of alkaline earth ions may be decreased in this order.

The detailed and comparative studies of the luminescence spectra of triply-ionized rare earths embedded in these alkaline earth fluorides imply the elucidation of the effects on the f—f transitions under the application of different crystal-field strengths. From the measurements described above, three items of interest may generally be settled. The first is the displacement of bands caused by changing the matrix. The second is the relative values of overall crystal-field splittings observed in the transitions with the definite total angular momentums of J an J'. The third is the determination of the splitting of certain individual bands under the influence of more intense crystal fields.

Concerning the first item, the following facts should be mentioned. If the matrix is changed in a sequence of increasing lattice-constants, namely, calcium fluoride → strontium fluoride, then 25 bands of the dysprosium(III) ion are found to follow the regularity of the blue shift as is shown in Table I. Similarly, this is the case with the 22 bands of the dysprosium(III) ion for the matrix-sequence strontium fluoride→barium fluoride. As to the luminescence of the terbium(III) ion, the blue shift is observed with 35 bands on changing the matrix calcium fluoride→strontium fluoride, and with 33 bands for the change of matrix strontium fluoride→barium fluoride.

Concerning the second item, Table II indicates that, with the decrease in the lattice-constant of the matrix in the successive order

of barium fluoride, strontium fluoride and calcium fluoride, each of the overall crystal-field splittings of the 6H11/2, 13/2, and 15/2 levels of the dysprosium(III) ion is increased. Here ν and ν' are the wave number of the bands. This effect may be assumed to occur almost directly proportionately to the crystalfield strength of the matrices. In other words, if the matrices are arranged in the order of descending crystalfield strength, namely, in the sequence of calcium fluoride, strontium fluoride and barium fluoride, it can then be called a "contraction of spectrum" using Evert's term. Tables III—IV demonstrate how the relation of the socalled contraction of spectrum also holds generally for the band-systems of terbium(III) luminescence. However, there are exceptions for the two band-systems belonging to the 5D4→7F6 and 5D3→7F4 transitions, in which is seen, on the contrary, an "expansion of spectrum."

Finally, it is note worthy that the splitting of some individual bands under the influence of a more intense crystalfield is found in the luminescence spectra of dysprosium(III) and terbium(III) ions. The two intense bands at 20830 and 20940 cm^{-1} observed in the barium

			18430 18480	50

fluoride matrix are ascribed to the 6F11/2→6H15/2 transition, and these bands correspond to the two bands in the strontium fluoride matrix appearing at 20780 and 20900 cm^{-1}. On changing the matrix strontium fluoride→calcium fluoride, the band at 20780 cm^{-1} observed in strontium fluoride is found to split into two components of 20690 and 20750 cm^{-1} ($\Delta\nu=60\,cm^{-1}$) in the more intense crystalfield of calcium fluoride, while the other band of 20900 cm^{-1} in strontium fluoride similarly splits into two, of 20820 and 20880 cm^{-1} ($\Delta\nu=60\,cm^{-1}$), in calcium fluoride. It should be mentioned that the magnitude of each of these $\Delta\nu$ splittings is 60 cm^{-1}. The most intense band of terbium(III) luminescence is ascribed to a 5D4→7F5 transition and is observed at 18480 cm^{-1} in the barium fluoride matrix. In the more intense crystalfield of the strontium fluoride matrix, it splits into two components of 18460 and 18490 cm^{-1} ($\Delta\nu=30\,cm^{-1}$), while in the most intense crystalfield of the calcium fluoride matrix, it splits into components of 18430 and 18480 cm^{-1} ($\Delta\nu=50\,cm^{1}$). It should be emphasized that the magnitude of these splittings, namely 30 and 50 cm^{-1}, may be taken as the approximate measure of the relative strength of the crystalfield for the matrices of barium fluoride, strontium fluoride and calcium fluoride.

Summary

(i) The luminescence spectra of dysprosium(III) and terbium(III) ions have been measured in the cubic field (O_h^5) of calcium fluoride, strontium fluoride and barium fluoride under excitation by cathode-ray-bombardment.

(ii) The displacement of the luminescence bands of dysprosium(III) ion has been studied with relation to the matrices mentioned above, a blue shift being observed, with 25 and 22 bands as the matrix was changed in successive sequences of calcium fluoride to strontium fluoride and strontium fluoride to barium fluoride respectively. Similarly, this was the case with 35 bands of the terbium(III) luminescence when, the matrix was changed from calcium fluoride to strontium fluoride, and with 33 bands for that from strontium fluoride to barium fluoride.

(iii) The magnitude of the relative crystalfield splittings $\Delta\nu$ of the luminescence bands of dysprosium(III) and terbium(III) ions was reported in relation to the increasing strength of the crystal field, i. e., in the sequence of matrices barium fluoride, strontium fluoride and calcium fluoride. For the dysprosium(III) luminescence, the crystalfield splittings observed in the 6F11/2→6H11/2, 6F11/2→6H13/2 and 6F11/2→6H15/2 transitions had a tendency to increase in the matrix-sequence barium fluoride, strontium fluoride and calcium fluoride. In the case of the terbium(III) luminescence, variations similar to that found in the dysprosium(III) luminescence took place in the crystalfield splittings of the 5D4→7F3, 5D4→7F4,

5D4→7F5, 5D3→7F2, 5D3→7F3 and 5D3→7F5, transitions, while the reverse was the case with the 5D4→7F6 and 5D3→7F4 transitions.

(iv) It was found that the band appearing at 18480 cm^{-1} in the luminescence spectrum of the terbium(III) ion embedded in barium fluoride splits into its respective two components when the terbium ion was embedded in matrices of strontium fluoride and calcium fluoride with a more intense crystalfield strength. The magnitudes of these splittings, 30 and 50 cm^{-1} as observed in strontium fluoride and calcium fluoride respectively, are presumably proportional to the differences between the crystalfield strength for barium fluoride, strontium fluoride and calcium fluoride.

The authors wish to thank Professor S. Nagakura, Professor S. Sugano and Professor S. Shionoya of the Institute for Solid State Physics, the University of Tokyo, for their interest and helpful discussions.

The Luminescence Spectra of Triply-ionized Rare Earths in the Calcination Products of Some Magnesium Compounds

By Eiichi IWASE and Seijiro NISHIYAMA

(Received May 14, 1963)

According to Tomaschek,[1] the luminescence spectra of samarium(III) ions embedded in the matrices of magnesium oxide, which are derived from the thermal treatment of magnesia usta, magnesium sulfate and magnesium chloride, are different from one another, although these matrices have the same X-ray diffraction diagram.

From the chemical point of view, the thermal decomposition of magnesium compounds does not always give rise to a simple and high-quality magnesium oxide, and the few fragments of the starting magnesium compounds remaining in the calcination products may be expected, in some cases, to have a remarkable effect on the luminescence spectra of the triply-ionized rare earths embedded therein. These effects would be detectable in variations of relative intensity, spectral position and sharpness of the luminescence bands. Therefore, measurements have been made of the luminescence spectra of the europium(III), terbium(III), and dysprosium(III) as well as of the samarium(III) ions embedded in calcination products derived from three kinds of magnesium compounds. This paper will present the experimental results obtained and some interpretations relating to them.

1) R. Tomaschek and O. Deutschbein, *Ann. Physik*, [5] **16**, 943 (1933); R. Tomaschek, *Acta Phys. Polon.*, **5**, 405 (1936).

Experimental

High-quality crystals of $Mg(NO_3)_2 \cdot 6H_2O$, $MgSO_4 \cdot 7H_2O$ and $MgCl_2 \cdot 6H_2O$ are soaked with a nitrate solution of one of the rare earths just mentioned, and then subjected to a calcination at about 900°C for 30 min. Some portions of these calcination products are then further heated in a flame of town gas mixed with oxygen at about 1800°C for 5 min. The concentration of the rare earth added is made to be 0.1 % of the matrix. The excitation to the luminescence is done in a small Urbain tube by cathode-ray bombardment at room temperature, and the luminescence thus yielded is spectrographically investigated by employing the glass-prism spectrograph of Feuss.

Results and Discussion

Figures. 1—4 are the schematic representations of luminescence spectra of, respectively, the samarium(III), europium(III), terbium(III) and dysprosium(III) ions which are embedded in the calcination products derived from $Mg(NO_3)_2 \cdot 6H_2O$, $MgSO_4 \cdot 7H_2O$ and $MgCl_2 \cdot 6H_2O$ at 900 and 1800°C. The most intense bands in each of the luminescence spectra are shown in Table I. Comparing the results obtained on the matrix calcined at 900°C with those calcined at 1800°C, there will be found either a simple displacement of the band of maximum intensity or a simple interchange of intensity with another band. The former situation is

Fig. 4

seen in the case of the samarium(III) luminescence in the $Mg(NO_3)_2 \cdot 6H_2O$-derived and $MgSO_4 \cdot 7H_2O$-derived matrices, while the latter situation is seen in the cases of the samarium(III) luminescence in the $MgCl_2 \cdot 6H_2O$-derived matrix, the europium(III) luminescence in the $MgSO_4 \cdot 7H_2O$-derived matrix, the terbium(III) luminescence in the $MgCl_2 \cdot 6H_2O$-derived matrix and the dysprosium(III) luminescence in the $MgSO_4 \cdot 7H_2O$-derived as well as the $MgCl_2 \cdot 6H_2O$-derived matrices. In some cases, circumstances are more complicated and a variation in the number of bands with the maximum intensity is seen. For instance, in the case of the terbium(III) luminescence given by the $Mg(NO_3)_2 \cdot 6H_2O$-derived matrix, one of three bands having equal maximum intensity remains unchanged in its intensity, while the other two are weakened. Thus, the bands with maximum intensity decrease in number. On the other hand, an increase in the number of bands with maximum intensity is seen, for instance, in the cases of the europium(III) luminescence given by the $MgCl_2 \cdot 6H_2O$-derived matrix and of the dysprosium(III) luminescence given by the $Mg(NO_3)_2 \cdot 6H_2O$-derived matrix, where the original band of maximum intensity is displaced and another band is intensified up to an intensity equal to that of the original one, while in the terbium(III) luminescence given by the $MgSO_4 \cdot 7H_2O$-derived matrix, the original band of maximum intensity is weakened and the other four bands tend to have an intensity equal to that of the original band. Thus, the bands of maximum intensity increase in number.

On the right of Figs. 1—4 are indicated the total number of observed bands of samarium(III), europium(III), terbium(III) and dysprosium(III) ions. When the calcination-temperature is elevated, the total number of bands of samarium(III) and europium(III) ions decreases on the contrary, that of terbium(III) ions increases with the exception of the case of the $Mg(NO_3)_2 \cdot 6H_2O$-derived matrix. Here the total number of bands remains almost unchanged. In the case of the luminescence of dysprosium(III) ions, the total number of bands increases when the calcination temperature is raised.

Generally speaking, calcination at a different temperature causes a comparatively small change in the total number of luminescence bands given by the $MgCl_2 \cdot 6H_2O$-derived matrix.

So far as the matrix calcined at 900°C is concerned, the total number of observed luminescence bands of the triply-ionized rare earths embedded in the $MgCl_2 \cdot 9H_2O$-derived matrix is much larger than in the $Mg(NO_3)_2 \cdot 6H_2O$-derived and $MgSO_4 \cdot 7H_2O$-derived matrices.

When the samarium(III), europium(III), terbium(III) and dysprosium(III) ions embedded in the matrices of magnesium compounds calcined at 900°C are subjected to further heat treatment at 1800°C, the total intensity of luminescence is changed. It is interesting to note that the magnitude of the intensity-variation of luminescence can be arranged in the sequence of increasing atomic number of these rare earths; the most marked decrease in the total intensity of luminescence is effected for samarium(III) ions, whereas the most marked increase is for dysprosium(III) ions. For europium(III) and terbium(III) ions a moderate decrease and a moderate increase in the total intensity of luminescence are observed respectively.

As the result of the elevation of the calcination temperature, the relative intensity of luminescence bands appearing side by side in the spectrum is sometimes reversed in order. For the europium(III) luminescence, this is the case with the band-couple of 15880 and 15950 cm^{-1} in the matrix derived from $Mg(NO_3)_2 \cdot 6H_2O$ and with those of 15360 and 15400 cm^{-1}, as well as with 15840 and 15920 cm^{-1} in the matrix derived from $MgCl_2 \cdot 6H_2O$. For the terbium(III) luminescence a similar reversal of intensity is observed in the bands of 15920, 16000 and 16060 cm^{-1} in the matrix derived from $Mg(NO_3)_2 \cdot 6H_2O$.

In the case of $Mg(NO_3)_2 \cdot 6H_2O$, thermal conversion to magnesium oxide goes forward so smoothly that the luminescence spectrum of each of the triply-ionized rare earths embedded in magnesium oxide is obtained in its pure form. As was expected, the thermal decomposition to magnesium oxide does not proceed easily for $MgSO_4 \cdot 7H_2O$. Turbidimetric analyses of SO_4^{2-} as barium sulfate sol (Table II, upper line) show that about 2/3 of the starting material is decomposed to magnesium oxide by calcining at 900°C for 30 min. in an electric furnace and that about 1/4 of the sulfate component still remains in a product subjected to further heating in a flame of town gas mixed with oxygen at 1800°C for 5 min. Due to the sulfate component remaining in the matrix calcined at 900°C, a number of characteristic diffuse bands and their conglomeration are

Table II. Examples of chemical analyses of remaining components in calcined products

Starting substances	900°C 30 min.	1800°C 5 min.
$MgSO_4 \cdot 7H_2O$	25.66%	19.52%
$MgCl_2 \cdot 6H_2O$	0.000147	0.000038

seen. When further decomposition occurs following heat treatment at 1800°C, the feature of the luminescence spectrum approaches that in pure magnesium oxide. Although the thermal decomposition to magnesium oxide is readily obtainable with $MgCl_2 \cdot 6H_2O$, the luminescence spectrum of each of the triply-ionized rare earths embedded therein has an appearance considerably different from the luminescence spectrum obtained in the $Mg(NO_3)_2 \cdot 6H_2O$-derived matrix; these rare earth ions give intense and sharp luminescence bands peculiar to the respective chloride-derived matrix. Examples of turbidimetric analyses as silver chloride sol (Table II, lower line) show 147 p.p.m. of chlorine content for a product calcined at 900°C for 30 min. and 38 p.p.m. of chlorine content for that calcined at 1800°C for 5 min. The quantity of chlorine ions existing in the matrix corresponds to about 64 and 17 mol. % of that of the rare earth ions respectively. It should be mentioned that even such a minute quantity of chlorine ions found in the matrix would have quite remarkable effects over the whole luminescence spectrum of the rare earth ions existing therein.

If it can be assumed that the luminescence spectrum of each of the triply-ionized rare earths embedded in either the $MgSO_4 \cdot 7H_2O$-derived or $MgCl_2 \cdot 6H_2O$-derived matrix is composed of two kinds of bands (one, the kind of bands observed in pure magnesium oxide and the other, the kind of bands characteristic of the matrix with either a sulfate or chloride component remaining therein), the composition of the luminescence spectrum, as well as the mixing ratio of these two kinds of luminescence bands, would be such as shown in Table III.

Table III. Mixing ratio of bands characteristic of magnesium sulfate- or chloride-derived matrix and those due to pure magnesia in luminescence spectrum of triply-ionized rare earth

Starting matrix	Sm^{3+}	Eu^{3+}	Tb^{3+}	Dy^{3+}
$MgSO_4 \cdot 7H_2O$	11/11	9/9	16/37	4/2
$MgCl_2 \cdot 6H_2O$	17/10	12/8	29/39	14/14

Table IV gives the frequency of some principal luminescence bands of samarium(III), europium(III), terbium(III) and dysprosium(III) ions, which is considered to be inherent in the matrices derived from $MgSO_4 \cdot 7H_2O$ and $MgCl_2 \cdot 6H_2O$ by the calcination at 900°C.

Table IV. Principal luminescence bands of triply-ionized rare earth characteristic of the sulfate-derived and chloride-derived matrices
(Calcination temp. 900°C)

Starting matrix	Sm^{3+} cm^{-1}	Eu^{3+} cm^{-1}	Tb^{3+} cm^{-1}	Dy^{3+} cm^{-1}
$MgSO_4 \cdot 7H_2O$				16990
	16460	15520	18150	17150
	16640	15700	18460	17310
		15980		17560
$MgCl_2 \cdot 6H_2O$	16130	16050	16010	17360
	17540	16100	18090	
		16180	18260	

Summary

(i) The luminescence spectra of samarium(III), europium(III), terbium(III) and dysprosium(III) ions embedded in the calcination products of $Mg(NO_3)_2 \cdot 6H_2O$, $MgSO_4 \cdot 7H_2O$ and $MgCl_2 \cdot 6H_2O$ have been studied under excitation by cathode-ray bombardment at room temperature. The calcination of these ions was carried out either at about 900°C for 30 min. or by further heating at about 1800°C for 5 min.

(ii) The luminescence spectrum of each of the rare earth ions in magnesium oxide matrix was obtained in its pure form in the case of the calcination products derived from $Mg(NO_3)_2 \cdot 6H_2O$. A number of distinguishing diffuse luminescence bands were observed arising from the sulfate component remaining in the calcination products derived from $MgSO_4 \cdot 7H_2O$. Calcination products derived from $MgCl_2 \cdot 6H_2O$ had a composition very near that of magnesium oxide and contained only a small amount of chlorine. When the triply-ionized rare earths here investigated were embedded in these calcination products, several intense and sharp luminescence bands were found which cannot be ascribed to those observed in pure magnesium oxide, but presumably result from their chlorine content.

(iii) The luminescence spectra of these triply-ionized rare earths embedded in the matrices derived from the calcination of $MgSO_4 \cdot 7H_2O$ and $MgCl_2 \cdot 6H_2O$ were considered to be constituted of the bands observed in the matrix of pure magnesium oxide and those characteristic of a matrix containing either a sulfate- or chloride-component. The frequencies of some of the principal bands characteristic of the presence of sulfate- and chloride-components have been given for each of the triply-ionized rare earths investigated here.

(iv) As to the intensity of the luminescence of samarium(III), europium(III), terbium(III) and dysprosium(III) ions embedded in the matrices of calcined magnesium compounds, the magnitude of variation arising from heat treatment at elevated temperatures may be arranged

in the order of rare earth ions with increasing atomic numbers 62~66, the most marked decrease being seen in the luminescence of samarium(III) ions with the smallest atomic number (62), and the most marked increase, in that of dysprosium(III) ions with the largest atomic number (66).

The Structure of Bromoemimycin

By Chihiro TAMURA

(Received June 10, 1963)

The purpose of this investigation was to elucidate the molecular structure of emimycin by means of X-ray crystal analysis. Emimycin is an antibiotic which is obtained from Streptomyces griseochromogenes.[1] It has a partial inhibition against various species of bacteria and some yeasts. The chemical formula $C_8H_8N_4O_4$ was assigned to emimycin on the basis of the chemical analysis and molecular weight determination. When we started our crystal structure analysis of emimycin, nothing was known of its structure except that it had one hydroxyl group. By the direct bromination of emimycin with aqueous bromine, a bromine derivative was obtained in a form of crystals suitable for X-ray analysis. To this compound as used in this investigation, a compound which we call bromoemimycin, the formula $C_8H_6N_4Br_2O_4$ was assigned.

Experimental

Crystals of bromoemimycin were obtained by letting an aqueous solution stand for a week in a refrigerator. They are colorless long needles elongated along the c-axis. The crystal was found to be orthorhombic. The dimensions of the unit cell were obtained using higher order reflections on oscillation photographs:

$$a = 8.68 \pm 0.03\,\text{Å}$$
$$b = 11.84 \pm 0.05\,\text{Å}$$
$$c = 5.35 \pm 0.02\,\text{Å}$$
$$\text{Volume} = 549\,\text{Å}^3$$

The systematic absences were found to be $(0\,k\,l)$ for $k+l$ odd, and $(h\,0\,l)$ for h odd. Therefore, the space group was determined to be $Pna2_1$ or Pnam. These space groups require four or eight molecules in the unit cell. The density, as measured by the floatation method using a mixture of carbon tetrachloride and tetrabromoethane, was 2.25 g.cm^{-3}. From the volume of the unit cell and the density of the crystal thus obtained, the molecular weights are calculated to be 186 or 93, which are approximately one-half or one-quarter of the expected value. However, the latter value is unlikely, because the total atomic weights of the chemical formula requires 191 as the least value. This suggests that the true moleular formula should be $C_4H_3N_2BrO_2$, which gives a calculated density of 2.31 g.cm^{-3}, compatible with the observed value.

Intensities were obtained by the multiple-film technique, using an integrated Weissenberg camera. Filtered CuK_α radiation was used throughout. Three-dimensional intensity data were collected for $(h\,k\,l)$ l up to 3, for $(h\,k\,l)$ h up to 3, and for $(h\,0\,l)$ and $(h\,1\,l)$. The intensities were visually estimated using a standard calibrated strip.

Correction for the Lorentz and polarization factors were made in the usual way. Absorption correction was not made, since the cross-sections of the specimens used are 0.03×0.05 mm. for the c-axis and 0.02×0.05 mm. for the b-axis.

The structure factors were put on an approximately absolute scale by Wilson's method.[2] The temperature factor for all those atoms were taken as 2.2 Å^2, except for the bromine atom. McWeeny's f-curves[3] were employed for the light atoms, while that of Thomas[4] was used for the bromine atom.

Determination of the Structure

Since the c-axis is the shortest, it was expected that the projection of the structure on the (0 0 1) plane would show the maximum resolution of the molecular structure. This projection belongs to the same plane group pgg, no matter whether the space group is $Pna2_1$ or Pnam. Patterson syntheses were carried out using intensities of both the ordinary and modified types, the latter having been described by Takaki et al.[5]

Fig. 1. Patterson projection on the (0 0 1) plane, ordiary type, $P(UV)$.

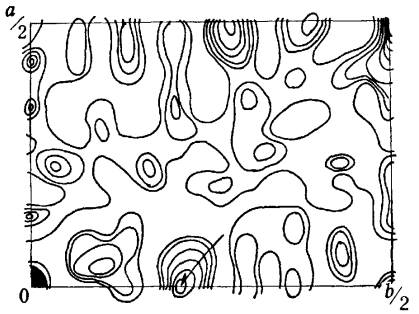

Fig. 2. Patterson projection on the (0 0 1) plane, modified type, $P'(UV)$, as $b=3$.

$$P'(UV)=\sum\sum F^2(1-e^{-b(\sin\theta/\lambda)^2})^2 \times\cos 2\pi hx\cdot\cos 2\pi ky$$

These projections showed that the bromine-bromine vector lay very close to the b-axis. The approximate coordinates of the bromine atom was found to be:

$$x=0.0$$
$$y=0.1$$

Modified Fourier projections of the structure on the (0 0 1) plane were calculated, using the signs derived from the position of the heavy atom alone.

$$\rho'(xy)=\sum\sum F(1-e^{-b(\sin\theta/\lambda)^2}) \times\cos 2\pi hx\cdot\sin 2\pi ky$$

It was prepared with 56 terms (47% of the total reflection), using cosine terms only, as the assumed position of the bromine atom was on the b-axis.

Several models of the molecular structure fit the Fourier projection. However, it contains false peaks because all the sine terms were disregarded. Closer examination showed that the bromine atom was situated slightly out of the b-axis. By the trial and error method, the coordinates of the bromine atom were assigned to the following positions:

$$x=0.010$$
$$y=0.105$$

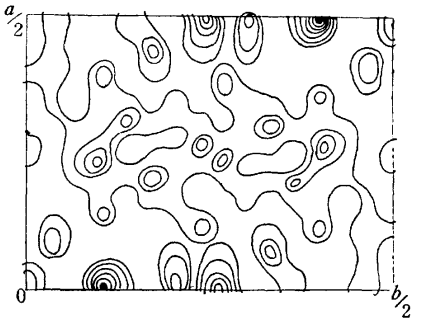

Fig. 3. Modified Fourier projection on the (0 0 1) plane.

A modified Fourier map was synthesized based on the new coordinates of the bromine atom, terms of doubtful sign being omitted. The number of terms used in this calculation was 107 out of a total of 121 observed reflections.

This Fourier projection indicates that the molecule has a six-membered ring system, with the replacements at the 1, 2 and 3 position and with position 2 taking the bromine atom, although it was not possible to distinguish carbon, nitrogen and oxygen atoms. The contribution of the light atoms were then included to determine the phases of the sturcture factors. In this calculation, all the atoms except bromine were treated as nitrogen atoms. The temperature factors for all those light atoms were taken as 2.2 Å^2, and that of bromine, as 1.5 Å^2.

In the second Fourier map, the locations of the oxygen atoms were easily recognized from the peak heights in the electron density distribution. This was also supported by the R-factor, when oxygen atoms were placed at positions 1 and 3. The six compounds listed below were considered (Fig. 4.), which are the six-membered ring systems of the meta substituents for the oxygen atoms. Compound III is already known,[6] and compound IV is difficult to fit because of its chemical properties.

$D(x, y)$ differential syntheses were calculated for the refinements of the atomic coordinates and for the distinction between carbon and nitrogen atoms. The mean value of the scattering factors of carbon and nitrogen was used for all the atoms in the pyrazine ring. These projections clearly showned the presence of anisotropy in the thermal vibrations of the bromine atom in the direction of the maximum amplitude lying almost parallel to the a-axis. The reliability factor became 18% when a correction of anisotropic temperature factors

6) G. W. Kenner, B. Lythgoe, A. R. Todd and A. Topham, *J. Chem. Soc.*, 1943, 388.

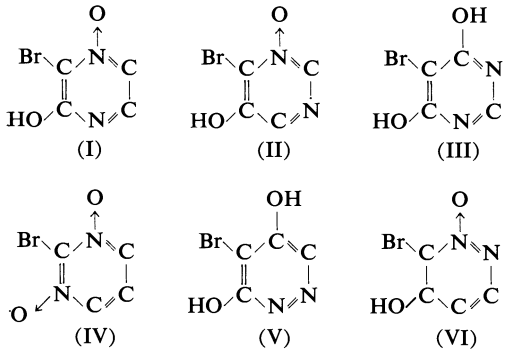

Fig. 4. Six possible structure formulae, as expected.

to bromine was made. To distinguish nitrogen from carbon atoms, $D(x, y)$ syntheses were carried out four times (Fig. 5). One can see that positions 1 and 4 have higher electron densities than those at positions 2, 3, 5 and 6. This suggests that positions 1 and 4 are occupied by nitrogen atoms. Furthermore, we have made structure factor calculations based on the following models:

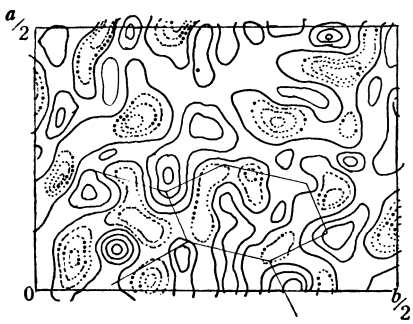

Fig. 5. Differential synthesis, on the (0 0 1) plane.

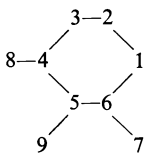
TABLE I. *R*-FACTOR CALCULATIONS FOR FOUR ESTIMATED MODELS

Model No.	Br	O	N	C	*R*-Factor %
1	9	7,8	1,2	3,4,5,6	17.5
2	9	7,8	1,3	2,4,5,6	17.7
3	9	7,8	1,4	2,3,5,6	15.9
4	9	7,8	2,4	1,3,5,6	16.9



From these calculations also, the best model is found to be the one in which nitrogen atoms occupy positions 1 and 4.

The peak heights of electron density in the final Fourier synthesis is shown to be seven electrons per Å^2 for positions 1 and 4, and six electrons per Å^2 for positions 2, 3, 5 and 6. Thus, from these three results, we concluded that nitrogen atoms occupy positions 1 and 4. The final reliability factor reached 12.3% for $(h\,k\,0)$.

The systematic absences required as a possible space group $Pna2_1$ or Pnam. However, the fact that four molecules in the unit cell combined with the following face, suggested that the space group in $Pna2_1$. If it is Pnam, molecules are required to lie on the mirror planes, which are 2.67Å appart. Judging from the (0 0 1) projection, it seems very unlikely for the molecules to have such an arrangement. Furthermore, Wilson's test revealed that the space group has no center of symmetry. The space group was confirmed later by structrure factor calculations.

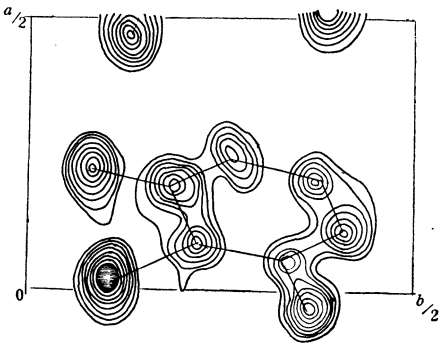


Fig. 6. Final Fourier map of bromoemimycin contours are drawn at intervals of 1 eÅ^2 except for bromine.

Now that the y-coordinate of the bromine atom was obtained by the (0 0 1) projection, and since the space group of the crystal $Pna2_1$ allowed the z-coordinate of this atom to be given at 0, we carried out Fourier analysis $\rho(x, y)$ based on the phases given by bromine. Although this projection contained overlappings of the molecule, it was possible to assign the z-coordinates of the light atoms by referring to the y-coordinates already obtained by the (0 0 1) projection. Two cycles of $D(y, z)$ syntheses were carried out for the refinements. The reliability factor for $(0\,k\,l)$ became 14.3%.

The observed and calculated structure factors are shown in Table II for $(h\,k\,0)$, and in Table III for $(0\,k\,l)$.

The final coordinates of the carbon, nitrogen, oxygen and bromine atoms are shown in Table IV.

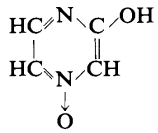
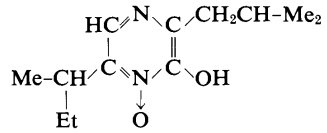
C_4	0.203	0.381	0.516

Discussion of the Results

From the coordinates of the atoms obtained, the molecular structure of bromoemimycin was determined to be 2-bromo-3-hydroxy-pyrazine-*N*-oxide-1. Therefore, the emimycin should have the structure 3-hydroxyl-pyrazine-*N*-oxide-1.



It is interesting to see that the structure of emimycin resembled that of the antibiotic aspergillic acid.[7] The molecular formula of aspergillic acid is:



The pyrazine ring of the bromoemimycin is planar, and the equation of the best plane as determined by the methods of least squares is:

$$0.222x+y-0.820z-0.524=0$$

The displacements of the atoms within the ring and O_1, O_2 and Br from this plane are shown in Table V.

The molecule can be described as a planar

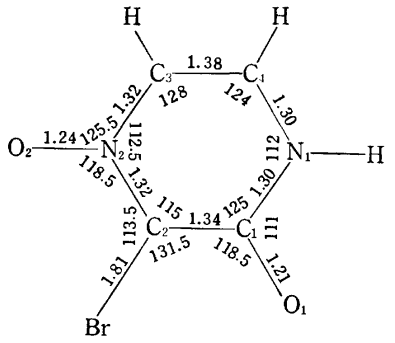

Fig. 7. The bond lengths and angles of the bromoemimycin.

pyrazine ring, but the oxygen of *N*-oxide is about 0.4Å apart from the pyrazine ring plane. The other oxygen and the bromine atom departed slightly from its plane.

The bond lengths and bond angles are given in Fig. 8.

The C_1–O_1 bond length 1.21Å, appears to be significantly shorter than the reported value, 1.39Å, for the ⩾C–OH bond in β-naphthol.[8] This might mean that the ⩾C=O bond here has a strong double bond character, so that the hydrogen atom may be attached to N_1. It may form a hydrogen bond with the carbonyl oxygen atom. It is expected that a keto-enol tautomerism similar to that found in the case of α-pyridone occurs.[9] The N_2–O_2 bond length is found to be 1.24Å, which is the same as that reported[10] for the N–O bond in phenazine-5, 10-*N*-oxide. The C–Br bond length is 1.81Å, which is considerably shorter than the reported value, 1.88Å,[11] for *o*-bromo-benzoic acid. This suggests that the C–Br bond is associated with a double bond character. The C–N bonds within the pyrazine ring are considerably shorter than those reported for those in pyrazine, 1.334Å,[12] and in pyrazinamide, 1.348Å.[13] The C–C bonds are also shorter than the mean value for benzene, 1.39Å.

The molecular arrangements are shown in Fig. 8 and Fig. 9.

The closest intermolecular interatomic distances occur between O_1 of molecule A and O_2' and N_2' of molecule B. The distances

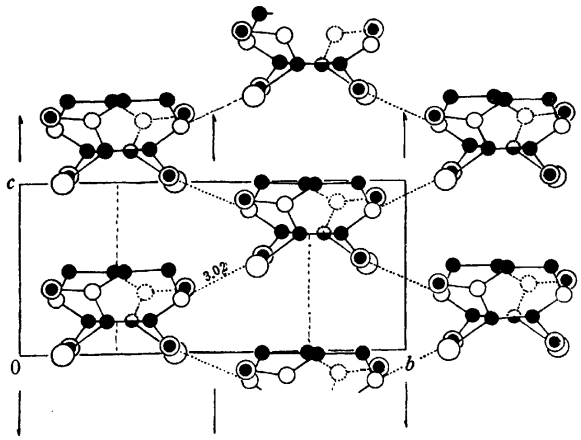

Fig. 9. The projection on (0 1 0), the hydrogen bonds are indicated by dotted lines.

are 2.81Å for $O_1 \cdots O_2'$ and 2.92Å for $O_1 \cdots N_2'$, and one might expect hydrogen bonds between those atom. However, there are no hydrogen atoms associated with these atoms, and the interatomic distances mentioned above may well be explained by the van der Waals contacts.

Another short interatomic distance, 3.02Å, is found between N_1 of molecule A and O_1'' of molecule C. It appears that a hydrogen bond would exist between these atoms. If the tautomerism occurs, as has been suggested earlier, the molecular chain along the screw axis may be stabilized by the synchronized oscillation of the hydrogen atoms.[14]

The distance between O_2 and Br', 3.08Å, is considerably shorter than the accepted value of the van der Waals radii sum, 3.48Å. It may not be possible to discuss this contact because of the inaccurate z-coordinates. Though we do not know the electronic state of the oxygen atom of the *N*-oxide group, nor the van der Waals radius of the atom in question, however, one might also suggest that this shortening is due to the charge-transfer effect.[15]

Another shorter intermolecular contact, 3.14Å, occurs between the O_2 atom of the *N*-oxide group and the ring C_4 atom; this distance does not differ significantly from the reported value in *N*-oxyphenazine, 3.11Å.[16]

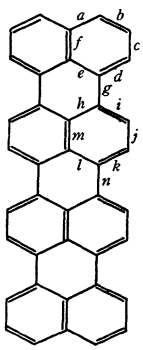
Electronic Properties of Quaterrylene, $C_{40}H_{20}$

By Yusei MARUYAMA, Hiroo INOKUCHI and Yoshiya HARADA

(Received June 25, 1963)

Experimental studies of the electrical and optical behaviour of organic semiconductors have been carrried out for a number of materials.[1] In the polycyclic aromatic hydrocarbon series quaterrylene, $C_{40}H_{20}$ (Fig. 1), with eleven benzene rings, is one of the largest molecules ever studied as an organic semiconductor.



Average lengths

$a=1.392\pm0.009$ Å
$b=1.374\pm0.007$

Fig. 1. Quaterrylene ($C_{40}H_{20}$).

Quaterrylene was synthesized by Clar et al.[2] and also by Zinke and his coworkers.[3] Though there is some confusion between them it generally seems to be true that it is synthesized by a condensation of perylene. The crude material applied in the work was provided by Rütgerswerke-Aktiengeselschaft A. G., Germany, and was regarded as "Clar's quaterrylene" on the basis of its optical absorption spectra.

The crystal and molecular structure of quaterrylene (Clar's quaterrylene) was studied by Shrivastava and Speakman[4] in connection with X-ray analysis. They found that quaterrylene is isotypic with perylene; it crystallizes in the monoclinic system with $a=11.25$ Å, $b=10.66$ Å, $c=19.31$ Å, $\beta=100.6°$ and with four molecules per unit cell, while the space group is $P2_1/a$. The molecule lies with its greatest length almost exactly perpendicular to the ab plane. The bond lengths are shown in Fig. 1; the mean length of the peri-bonds connecting the naphthalenic residues is assessed at 1.53 ± 0.01 Å.

An aromatic compound with a larger molecular size would have a higher electrical conductivity. Therefore, it is expected that reliable results concerning semiconductive behaviour would be found when this hydrocarbon is applied for the observations of Shrivastava and Speakman. In this article, we are presenting a more quantitative figure of organic semiconductors obtained through a study of the electronic properties of quaterrylene.

Further, the simple molecular orbital calculation for this molecule will in due course enable the present authors to explain its spectroscopical data.

Experimental Procedures

Purifications.—The microcrystals of quaterrylene were dark green, but its thin films were violet. The hydrocarbon was extraordinarily stable, as it could be heated to about 500°C without decomposition and without melting. Since they were virtually insoluble in all solvents at room temperature, ordinary methods for the purification of organic compounds, for recrystallization and for chromatography could not be applied. Therefore, sublimation was the most useful technique for purification and also for making single crystals in this case.

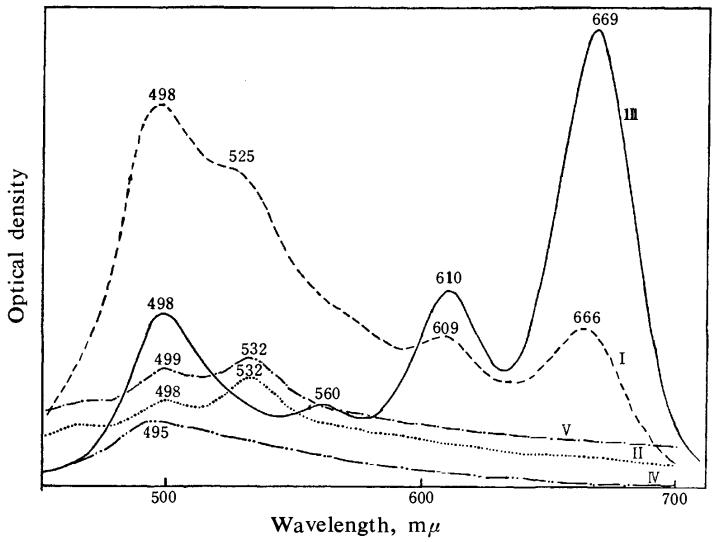

Fig. 2. The optical absorption spectra in the course of purification.

Impurities included in the matrix were soluble in trichlorbenzene. Therefore, the filtration technique was also employed for purification. Before filtration, the hydrocarbon was sublimed three times in vacuum of 10^{-5} mmHg at about 450°C. The compound was also dark green-coloured microcrystals. A suspension of quaterrylene in trichlorobenzene possessed no absorption peaks in a visible region because of its insolubility at room temperature. It was rather soluble in that solvent at about 100°C; the solution was blue at that temperature. The absorption spectrum for this step is shown as curve I in Fig. 2. When the hot solution was cooled, its colour changed to a light reddish violet from blue and dark green powders were precipitated. This spectrum is shown as II in Fig. 2. The powders which were filtered off from the solution were suspended again in cold trichlorobenzene. No absorption peaks could be found in the spectrum at room temperature, but at about 100°C several peaks appeared on the spectral response curve. The spectrum is shown as III in the figure.

A remarkable difference between curves I and III is the disappearance of the peak of 525 mμ in the latter spectrum. When the solution was cooled, only the peak of 495 mμ survived (curve IV). On the other hand, the filtered solution possessed 499 mμ and 532 mμ absorption peaks (curve V), and no considerable change in spectra was obtained by means of heating and cooling.

In order to examine the solvent effect on the absorption spectra, α-methylnaphthalene was employed in place of trichlorobenzene. This spectrum is illustrated as curve VI, which corresponds to curve I. Since no noticeable difference could be found between them, it can be concluded that the solvent effect is to be neglected.

When III and V are compared, it seems that the 530 mμ peak originates in impurities which are soluble in cold trichlorobenzene. On the basis of these results, the typical absorption spectrum of quaterrylene is possibly curve III: this agrees with the finding of Clar.[2]

The absorption spectrum of the evaporated thin film is shown in Fig. 3, along with that of the solution.

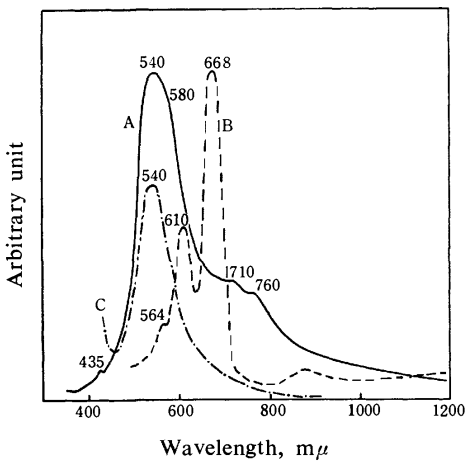

Fig. 3. The optical absorption spectra of thin film (A) and of solution (B) of quaterrylene. Curve C shows the spectral response of photo-emf.

In ordinary aromatic hydrocarbons, the positions of their absorption peaks for the solid state only shift to the long wave length side compared with those for the solution state. For quaterrylene, however, this was not the case, and, further, no correspondence between their absorption peaks and the intensity ratios of both their spectra was found.

Preparation of Single Crystals.—Because of the insolubility of quaterrylene for any solvent, it was difficult to obtain a single crystal sufficient in size to measure the resistivity by deposition from a

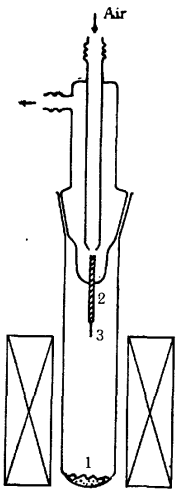

Fig. 4. The sublimation vessel used to make single crystals.

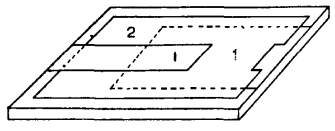
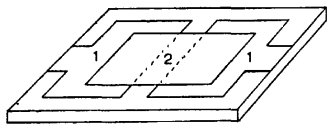
solution or by cooling the molten material. Thereby, a slow sublimation of quaterrylene in a vacuum vessel, as is shown in Fig. 4, was applied to make a single crystal. The bottom (1) of a glass tube which had been evacuated to a pressure of 10^{-5} mmHg was heated by a surrounding electric furnace. Before starting the sublimation, a tiny needle-like single crystal (3) to be used as a nucleus was stuck on the top of the tungsten rod (2), which is cooled with circulated air. Upon being heated at 350°C for a long period, the single crystal grew to a fairly large one, 0.2 mm.×0.2 mm.× 5.0 mm. The direction of the long axis of the crystal was b.

Preparation of Conductivity Cells.—The cells of the thin film of quaterrylene were prepared by the method of vacuum evaporation. When the evaporation speed was controlled to be slow, the prepared films were lustrously violet and very stable. They seemed to be better-oriented films than those of other aromatics. Thin aluminium or silver films which had also been evaporated in vacuo were employed for the electrodes of cells, as is shown in Fig. 5.

The powdered specimens compressed in an insulating cylinder were also applied measured for resistivity.



(1) Sandwich-type



(2) Surface-type

Fig. 5. The electrode arrangement of cells. Electrodes (1) and quaterrylene (2).

Preparation of the Single Crystals for a Polarized Light Absorption.—In the course of the vacuum evaporation of quaterrylene, when a substrate, a glass plate, was heated to the proper temperature from the back by an electrical heater, fairly large single crystals grew on the film. In fact, the evaporation had to proceed very slowly in this case; it took several hours to accomplish it under a pressure of 10^{-5} mmHg.

For that duration, the substrate was kept at about 250°C, and the evaporation gun, at about 450°C. Following this method, one or two flat single crystals 50 $\mu\times100\,\mu\times100$ Å (thickness) could be found on the film under a polarization microscope, and, as they showed oblique extinction, the crystal faces were possibly ac plane. It is expected that the polarized light absorption spectra of these crystals will probably show dichroism and "Davydov Splitting."

Experimental Results

The measurements of the electrical resistivity were made with a Cary vibrating-reed electrometer, model 31, for four types of specimens; compressed powders, single crystals, sandwich-type films, and surface-type films. For the last two types of cells, the photoconductivity measurements were also made using a Hitachi photo-electric spectrometer, model EPU-2, or a projector lamp as the light sources. Their dark resistivities are listed in Table I.

Table I. The electrical resistivity, ρ_{15} of quaterrylene $\rho=\rho_0\exp(\Delta\varepsilon/2kT)$

Type of specimen	ρ_{15}, Ωcm.	$\Delta\varepsilon$, eV.
Powder	10^{10}	0.6
Single crystal	10^{6}	—
Sandwich-type	10^{13}	0.6
Surface-type	10^{5}	0.6

From the results of the two types of film cells, a substantial anisotropy of the resistivity was found by a factor of $10^{7}\sim10^{8}$; 10^{5} Ωcm. for the surface-type cell and 10^{13} Ωcm. for the sandwich-type cell.[5] The $\Delta\varepsilon$ values listed in the same table were calculated from the temperature dependence of the resistivity in the range of 15~150°C in air.

Quaterrylene was very stable against an applied electric field; the hydrocarbon could be subjected to a very high voltage, $10^{6}\sim10^{7}$ V./cm. The relation between the dark current and their applied potential is given in Fig. 6.

In the sandwich-type cell, a photovoltage appeared when it was illuminated by a visible light. As the photoelectromotive force (abbreviated as photo-emf.) originates in the

5) H. Inokuchi, H. Kuroda and H. Akamatu, This Bulletin, 34, 749 (1961).

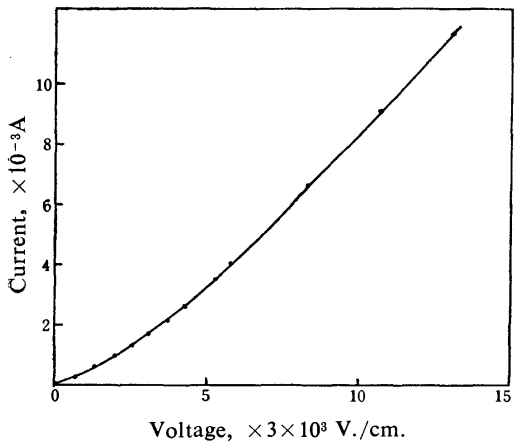


Fig. 6. The dark current versus the applied potential for the sandwich-type cell.

contact layer between the metal and the aromatics, the surface conditions of both are essential to this effect. Therefore, during the preparation of the cell and also during the measurement of the voltage, it must be kept in vacuo.* The apparatus which is convenient for such treatments is in preparation; therefore, the following data concerning photo-emf. are tentative.

In the present experiment the photovoltaic cell was made of a quaterrylene thin film sandwiched between two aluminium films on a glass plate. However, it was exposed to air for only a few minutes needed to place it in the other vessel for measurement. The photovoltage attained the maximum value of 135~270 mV. when the light intensity was 40 μW/cm^2. The cells were sensitive to a very weak light;* the dependence on the light intensity is shown in Fig. 7. The spectral response of photo-emf. is in Fig. 3 compared with the optical absorption spectrum for the film.

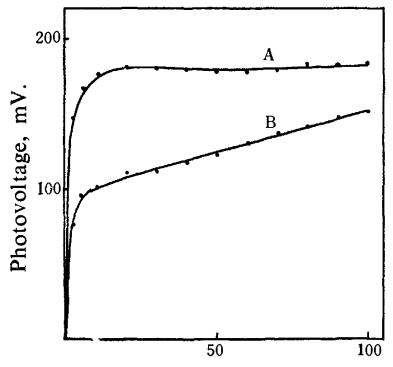

Fig. 7. The photovoltage versus the light intensity. Curve (A) is illuminated from the front of the cell and (B), from the back.

Photoconductivity measurements were also made for the surface-type and the sandwich-type cells; the former was less sensitive than the latter. The rectifying effect of the photoconduction was scarcely recognized; therefore, it could not be determined by this method whether the sign of the predominant charge carrier is plus or minus.

Pulsed photoconductivity measurement was applied to the evaporated films because of the impossibility of gaining single crystals sufficiently large to find the sign of the charge carrier and the charge mobility. The evaporation of quaterrylene was made onto a "Mylar" sheet, and then the film was covered with another Mylar sheet. The film thickness was several microns. A short light pulse, approximately a few μsec. long, was applied to the film through the conducting glass electrode, which was held against the back face of one Mylar sheet.** The applied electric field varied from about 1×10^6 V./cm. to 2×10^6 V./cm. The photocurrent was fairly small in comparison with that for anthracene;[6] therefore, a large electric field was necessary in order to obtain photocurrent enough for the detector, a Tektronix oscilloscope, type 545 A. The mobility of the charge carriers was calculated from the $\mu = d^2/Vt$ relation, where μ is the mobility; d, the film thickness; V, the voltage applied and t, the time between the light pulse and the saturation point in the charge pulse. The transit time, t, was very small and comparable to the light pulse duration; therefore, its estimation was rather difficult. The mobility was in the order of 10^{-3} cm^2/V. sec. and was very low in comparison with that of anthracene.[6] The scattering of the charge carriers at the crystalline boundaries in the film specimen may be partly responsible for this low value.

The ionization potential of solid quaterrylene was found from the photoemission

* When the surfaces of the specimens were in direct contact with air during the preparation of the cell, the photovoltaic behaviour was rather irregular. For example, the glass plate, which was exposed to air after the evaporation of the aluminum electrode (the front-side electrode) on the substrate in a vacuum vessel, was placed in another vessel to make a thin film of the aromatics. After the aromatics had been evaporated, the cell was removed to the former vessel and the electrode(the back-side electrode) was evaporated on the aromatic film. The photovoltaic cell showed a photo-emf. of the same sign when it was illuminated from either side of the electrode. In this case, it was supposed that the contact layer between the aromatics and the back-side electrode was responsible for the induced photo-emf. because the surface of the front electrode was poisoned with air.

* The measurement had to be made in a dark room because it was affected by stray room light.

** The details of the apparatus will be appear elsewhere.

spectrum of the evaporated film. The evaporated film on a glass plate was placed on a centre of a glass vessel, the inner-surface of which had been coated entirely with colloidal graphite as an electron collector, excepting a quartz window for introducing a light. When a monochromatic light was introduced into the vacuum photoemission cell of quaterrylene, a fairly strong photoelectric current was found. The threshold value of its spectral response, as is illustrated in Fig. 8, was around 250 mμ, 4.9 eV.

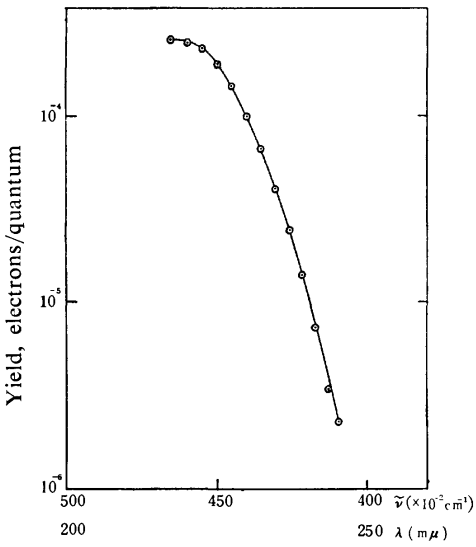

Fig. 8. The quantum yield of the photoemission of quaterrylene.

Discussion

Because the semiconductivity of quaterrylene is fairly high, its numerical values may be employed in further quantitative considerations. This is also true for the photovoltaic effect.

When contact is made between semiconductive material and metal, it is believed that the potential barrier corresponding to the contact potential difference is established. In the case of quaterrylene, such a model was employed to interpret its photovoltaic effect. Supposing the band-type model for the organic semiconductors, the following schematic diagram may be introduced for the system of quaterrylene and aluminium. In the diagram, the band gap, 0.6 eV., is based on the results of the temperature dependence of semiconduction, and the ionization potential, 4.9 eV., is based on the photoemission data. The potential barrier height which is essential for this case is $\Delta\varepsilon/2$ (half of the band gap). When the contact layer is illuminated by a light which has enough energy to excite electrons from the filled band to the conduction band excited electrons are driven to the metal by the electric field which has been built in that layer. (Holes may flow in the opposite direction.) This flow of charge carriers can be detected as photocurrents by the electrometer when the circuit is closed. In the case of an open circuit condition (in the experiment, the insulating resistance of the apparatus was greater than 10^{15} Ω), the driven carriers accumulate to build a field which prevents the further flow of the carriers. At last, equilibrium is achieved when the Fermi level of quaterrylene is lowered by the amount of the barrier height in dark. Therefore, the photovoltage, which is measured by the electrometer, is the difference between the Fermi level of aluminium and that of quaterrylene, that is, $\Delta\varepsilon/2$.[7] On this basis, the experimental data for photovoltage, 100$\sim$300 mV., seemed rather reasonable, since the $\Delta\varepsilon/2$ is about 0.3 eV.

The optical absorption spectra of quaterrylene have several interesting points, and the observation of the polarized light absorption of the single crystals made by the method previously described has been made preliminarily. The work of quantitative assignment is in progress.

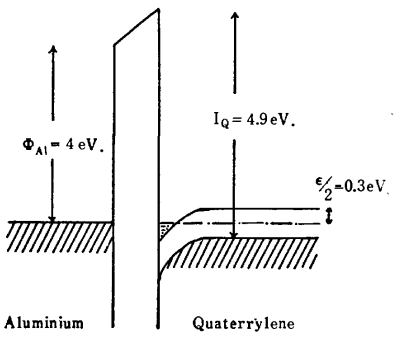

Fig. 9. A schematic energy diagram for the system of quaterrylene in contact with aluminium.

Summary

Quaterrylene ($C_{40}H_{20}$) is a dark green-coloured aromatic hydrocarbon and is extraordinarily stable, as it can be heated to over 500°C without decomposition. The semiconduction of the aromatic hydrocarbon possesses a substantial anisotropy by a factor of $10^7\sim10^8$; the resistivity in the direction parallel to the b axis is 10^6 Ωcm. (for a single crystal) or 10^5 Ωcm. (for a surface-type cell) and that perpendicular to the b axis is 10^{13} Ωcm.

7) H. Inokuchi, Y. Maruyama and H. Akamatu, This Bulletin, **34**, 1093 (1961).

However, their energy gaps are around 0.6 eV.

From its pulsed photoconduction of the thin film, a drift mobility has been estimated in the order 10^{-3} cm^2/V. sec. However, the rectifying effect of the photoconduction can scarcely be recognized; that is to say, it seems that the mobilities of the holes and electrons in crystal are almost the same.

Further, its photovoltage between aluminium and quaterrylene has a value of 0.1~0.3 V., while the ionization potential of the hydrocarbon is 4.9 eV. judging from the threshold value of the spectral response of the photoelectric emission.

From these results, a energy level diagram has been introduced for the system of the aromatic hydrocarbon-aluminium contact when a band-type model is employed as the organic semiconductor.

*The Structure of Todomatuic Acid. The Synthesis of (±)-Dihydro-desoxo-todomatuic Acid**

By Masao NAKAZAKI and Sachihiko ISOE

(Received February 25, 1963)

The chemical investigation of todomatuic acid (I) was initiated by Tuchihashi and Hanzawa,[1] who isolated an acid on the hydrolysis of the high boiling fraction (b. p. 207~210°C/12 mmHg) of an oil which had been obtained as a by-product when *Abies sachalinensis* MAST. (todo matu) was digested with sulfite in the pulp industry. They described the sesquiterpene acid, todomatuic acid (m. p. 58.5°C; b. p. 200~215°C/3 mmHg; n_D^{50} 1.4891, d_4^{50} 1.0233, $[\alpha]_D^{32.5}$ +85.84°) and suggested the formula of $C_{15}H_{24}O_3$. They also established the presence of a carbonyl group by preparing various carbonyl derivatives: semicarbazone (m. p. 193°C), thiosemicarbazone (m. p. 149~150°C), and *p*-nitrophenylhydrazone (m. p. 154~155°C). That this compound was a ketone rather than an aldehyde was assumed as a results of its negative Schiff and Legal tests. Furthermore, the natural compound absorbed one mole of hydrogen over a palladium-on-carbon catalyst to give dihydrotodomatuic acid (b. p. 182~183°C/3 mmHg).

These facts, together with other evidence (the molecular formula, the molecular refraction index, etc.) led them to conclude correctly that this natural product is an unsaturated monocyclic sesquiterpene carboxylic acid with one keto group. Some further observations on the structure of todomatuic acid, observations which eventually led to its correct structure assignment, are due to Momose.[2] He found that, on oxidative degradation with potassium permanganate, I gave oxalic acid and an acyclic saturated ketodicarboxylic acid, $C_{13}H_{22}O_5$ (semicarbazone, decomp. p. 185~186°C). The further oxidation of $C_{13}H_{22}O_5$ with nitric acid gave isovaleric acid (IV) and racemic β-(α-carboxyethyl)glutaric acid (V), which was found to be identical with a synthetic specimen.[3]

These findings indicate that the acyclic saturated ketodicarboxylic acid $C_{13}H_{22}O_5$ could be either IIIa or IIIb, corresponding to structure I or II respectively for todomatuic acid. The structure formula I was Momose's choice, because I is compatible with the isoprene rule and several sesquiterpenes[4] (see Fig. 4) can be found posssesing the same carbon skeleton (bisabolene type) as I; of these, atlantone[5] (VI) is especially noteworthy, for in it the keto group and the endocyclic double bond are located in the same place as in I.

It seems desirable, however, to provide more convincing evidence to prove unambiguously[6]

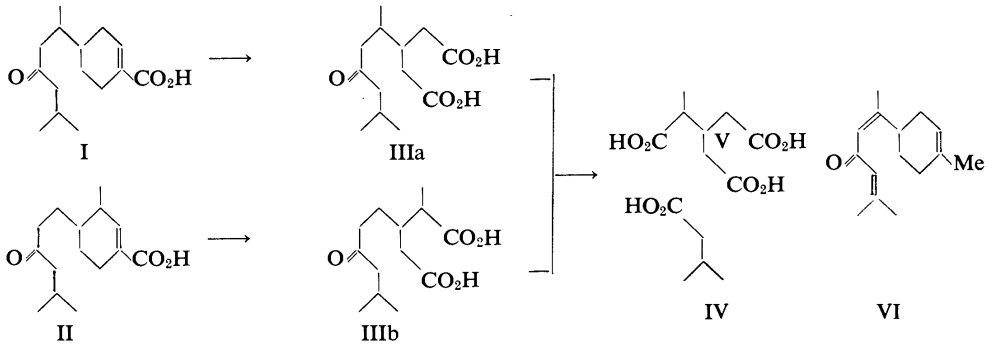

Fig. 1

the structure of this unusual monocyclic sesquiterpene carboxylic acid, preferably by a synthetic approach. In this paper, the synthesis of (±)-dihydro-desoxo-todomatuic acid and the establishment of the absolute configuration of todomatuic acid will be reported.

First we wanted to ascertain the exact location of the carboxyl group on the cyclohexene ring by means of Barbier-Wieland degradation, hoping that a cyclohexanone derivative, our prime objective, would prove to be a useful key substance for structure determination as well as for a synthetic approach.

The Wolff-Kishner reduction of todomatuic acid yielded desoxy-todomatuic acid (VIIa) (Fig. 2) (m. p. 59~60°C), which was esterified with diazomethane to afford the methyl desoxo-todomatuate (VIIc) (b. p. 130~131°C/1 mmHg). The catalytic hydrogenation of VIIc over an Adams catalyst gave methyl dihydro-desoxo-todomatuate (VIIIa) (b. p. 117~119°C/1 mmHg), which gave the carbinol VIIIc with phenylmagnesium bromide. The unsaturated compound VIIId, obtained from VIIIc on dehydration by boiling with acetic anhydride and pyridine, was ozonolyzed. After the ozonide had been decomposed with zinc powder, the neutral fraction boiling at 100~110°C/1 mmHg was purified by chromatography on alumina. An oil which showed infrared absorption at 1704 cm^{-1} (six-membered cyclic ketone) was converted directly into semicarbazone (m. p. 151~152°C). If the structure of todomatuic acid is represented correctly by I, this ketone should be 2-(4-oxocyclohexyl)-6-methylheptane (IX). Our next project was, therefore, the synthsis of this compound.

p-Anisyl-isohexylketone (Xa) (Fig. 3), obtained by the Friedel-Crafts reaction of anisol

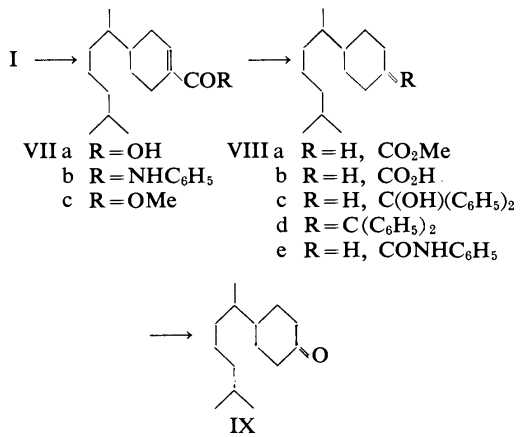

Fig. 2

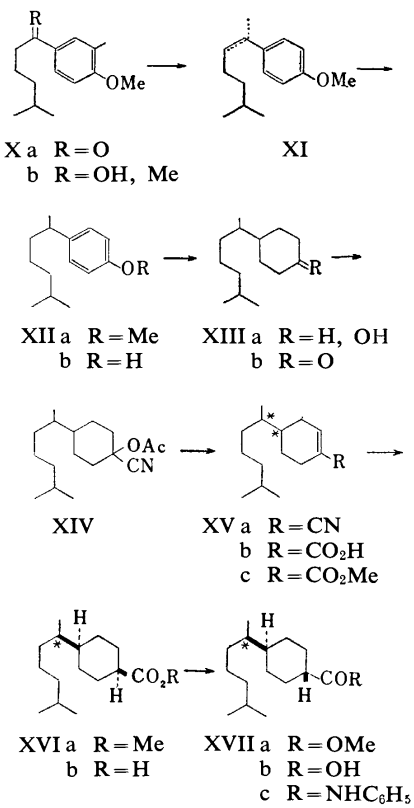

Fig. 3

and 5-methylhexanoyl chloride, was converted into the carbinol Xb with methylmagnesium bromide, and then Xb was dehydrated by boiling it with acetic anhydride to afford the unsaturated phenol ether XI. The catalytic hydrogenation of XI gave XIIa, which was hydrolyzed by boiling it with hydroiodic acid in an acetic acid solution to afford the phenol XIIb. The high pressure catalytic hydrogenation of XIIb (Raney nickel 130 atms., 140~150°C) yielded the alcohol XIIIa, which was oxidized with potassium dichromate in sulfuric acid to (±)-2-(4-oxocyclohexyl)-6-methylheptane (XIIIb) (b. p. 113~114°C/1 mmHg, semicarbazone, m. p. 149~150°C), whose infrared absorption spectrum was found superimposable on that of the ketone IX from the natural product. These findings firmly established the structure of todomatuic acid (I). Our attention was next directed to introduce a carboxyl group to the C_1 position of the ketone XIIIb in order to synthesize (±)-dihydro-desoxo-todomatuic acid (VIIIb).

The ketone XIIIb was heated with potassium cyanide in acetic anhydride to give the cyanohydrin acetate XIV, which was pyrolyzed at 1 mmHg by passing it through a heated Pyrex tube (600°C) packed with ceramic Rashig rings to afford the unsaturated cyanide XVa, which was then hydrolyzed to the unsaturated acid XVb (b. p. 163~165°C/1 mmHg). Although two racemic forms[7] were expected for the structure XVb because of the presence of two asymmetric carbon atoms, the infrared absorption spectrum of the synthetic XVb was found identical with that of (+)-desoxotodomatuic acid (VIIa).

In order to provide more unambiguous evidence, it seemed desirable to compare compounds with only one asymmetric center. The synthetic XVb was esterified with diazomethane, and the methyl ester thus obtained was catalytically hydrogenated on an Adams catalyst, affording the saturated methyl ester XVIa, probably the cis form predominantly. Equilibration of the methyl ester XVIa by boiling it with sodium ethoxide yielded the more stable trans methyl ester XVIIa, which was then saponified to (±)-*trans*-2-(4-carboxycyclohexyl)-6-methylheptane (XVIIb) (b. p. 152~155°C/1 mmHg; n_D^{18} 1.4723); its anilide XVIIc melted at 105~106°C. In order to compare the above mentioned synthetic XVIIb with the saturated acid VIIIb obtained from the natural product, it is necessary to convert VIIIb to the trans form; this was accomplished by the equilibration of the methyl ester VIIIa by boiling it with sodium ethoxide. Saponification of the optically active trans methyl ester thus prepared gave (+)-*trans*-dihydro-desoxo-todomatuic acid (XVIIb), b. p. 150~153°C/1 mmHg; $[\alpha]_D^{27}$ +14.1°; n_D^{18} 1.4723 (the anilide, m. p. 115~116°C), whose infrared spectrum was found to be superimposable on that of the synthetic XVIIb in every detail.

Having thus accomplished the synthesis of (±)-dihydro-desoxo-todomatuic acid, let us now proceed to discuss the absolute configuration of todomatuic acid. As can be seen from the structure formula of todomatuic acid (I) (Fig. 4; the molecular rotations are shown below the structure formula of the relevant compounds), it has two asymmetric centers (C_4 and C_7). The absolute configuration around C_4 will be discussed first. Since todomatuic acid (I) and desoxo-todomatuic acid (VIIa) show almost equal rotation values ($[M]_D$ +233° and $[M]_D$ +224° respectively), the keto groups on the side chains seem to have little effect on the optical rotations. The same is true for the asymmetric center at C_7; dihydro-desoxo-todomatuic acid XIXa, lacking the asymmetric center at C_4, exhibits very little rotation, showing a predominant contribution of the asymmetric center at C_4 to the optical rotation of the unsaturated compounds I and VIIa.

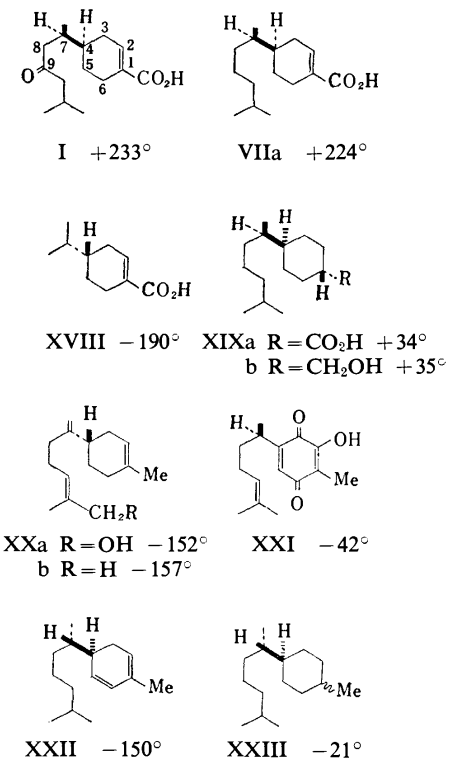

Fig. 4

7) Pyrolysis at 600°C can hardly be stereo-specific, and the products, XVa, XVb and XVc, may be a mixture of two racemic forms.

Therefore, it is safe to compare todomatuic acid (I) and desoxo-todomatuic acid (VIIa) with (−)-phellandric acid (XVIII) ($[M]_D$ −190°),[8] despite the fact that I and VIIa have extra asymmetric centers in the side chains. One of Mills' empirical rules[9] tells us that I and VIIa have the (R)-configuration opposite natural (−)-phellandric acid (XVIII) at the C_4 center. Among the four bisabolene type sesquiterpenes whose absolute configurations have been established (lancerol (XXa),[10] bisabolene (XXb),[11] perezone (XXI)[12] and zingiberene (XXII)[13]), is particularly suitable to compare zingiberene's asymmetric center in the side chain with that of todomatuic acid (I). Hexahydrozingiberene (XXIII) ($[M]_D$ −21°),[14] which has only one asymmetric center in the side chain, can be compared with (+)-dihydro-desoxo-todomatuic acid (XIXa), since the substitutions at C_1 are too remote from the asymmetric centers on C_7 to affect the signs of rotation in both compounds. A more relevant comparison is that of XXIII with the alcohol XIXb, $[M]_D$ +35°, prepared from XIXa by lithium aluminum hydride reduction. Since the hydroxymethyl group has almost the same polarizability as the methyl group,[15] the fact that XIXb and XXIII show opposite rotations of about the same order indicates that these compounds have opposite configurations in the side chains. This deduction assigns the (R)-configuration to the asymmetric center, C_7, of todomatuic acid. Although the specific rotation[5] reported for atlantone (VI) is very small (+1∼+6°),[16] it is very interesting to note that todomatuic acid and atlantone are the only two sesquiterpene ketones of the bisabolene type with a positive optical rotation so far isolated from conifers.

These facts are of interest in connection with the taxonomy of conifers,[17] suggesting the same absolute configuration at the C_4 asymmetric centers in both compounds.

Experimental*

Todomatuic Acid (I). — Crude todomatuic acid (80 g.), obtained from the hydrolysis of the high boiling fraction of sulfite oil, was recrystallized from petroleum ether (b. p. 35∼60°C) to give 41 g. of a pure compound, m. p. 57∼59°C, $[\alpha]_D^{13}$ +92.50° (*c* 1.2 in ethanol) (lit.:[1] m. p. 58.5°C, $[\alpha]_D$ +85.84° (in ethanol)).

Found: C, 71.56; H, 9.57. Calcd. for $C_{15}H_{24}O_3$: C, 71.38; H, 9.57%.

The semicarbazone prepared from I was recrystallized from diluted ethanol decomp. p. 190°C (lit.:[1] decomp. p. 193.2∼193.7°C).

Found: C, 61.92; H, 8.83; N, 13.42. Calcd. for $C_{16}H_{27}O_3N_3$: C, 62.09; H, 8.80; N, 13.59%.

(+)-Desoxo-todomatuic Acid (VIIa).—In a copper flask, 12 g. of sodium was dissolved in 230 cc. of diethylene glycol, and a mixture of 21 g. of todomatuic acid and 20 cc. of hydrazine (prepared from commercially available 80% hydrazine hydrate by azeotropic dehydration with toluene) was then added. The reaction mixture was heated at 180∼190°C, and the generated water was co-distilled with excess hydrazine. Heating was continues for 24 hr., and then 15 cc. of hydrazine was added. The reaction mixture was heated for another 24 hr. and then poured into ice water. After the aqueous solution was made acidic with concentrated hydrochloric acid, this was extracted with benzene. The benzene extract was dried over anhydrous magnesium sulfate. Removal of the solvent gave a viscous residue which distilled at 164∼166°C/1 mmHg to give 13.8 g. of a viscous oil. After this oil had stood at room temperature, the product crystallized. Recrystallization from diluted methanol gave crystals which melted at 50∼60°C, $[\alpha]_D^{27}$ +94.3° (*c* 1.18 in ethanol).

Found: C, 75.90; H, 11.18. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

The anilide VIIIb was prepared by the usual procedure and recrystallized from petroleum ether and then from diluted methanol; m. p. 78∼79°C.

Found: C, 80.36; H, 10.15; N, 4.77. Calcd. for $C_{21}H_{31}ON$: C, 80.46; H, 9.97; N, 4.47%

(+)-*trans*-Dihydro-desoxo-todomatuic Acid (XVIIb).—To 40 cc. of an ether solution of diazomethane prepared from 4 g. of *N*-nitrosomethylurea, a solution of 2 g. of desoxo-todomatuic acid in 50 cc. of ether was added. After being kept at room temperature for 2 hr., the excess diazomethane was decomposed with acetic acid. After the mixture had been washed with water and dried over anhydrous magnesium sulfate, the solvent was removed

* The analyses were performed in the microanalytical laboratory of the Institute of Polytechnics, Osaka City University.

to afford a liquid which was distilled to give 1.9 g. of methyl desoxo-todomatuate (VIIc) (b. p. 130~131°C/1 mmHg). The catalytic hydrogenation of 1.9 g. of VIIc in 30 cc. of ethanol with 0.5 g. of an Adams catalyst gave 1.7 g. of methyl dihydro-desoxo-todomatuate, (VIII) (b. p. 117~119°/1 mmHg). To a sodium ethoxide solution prepared from 0.2 g. of sodium and 11 cc. of absolute ethanol, 1.7 g. of methyl dihydro-desoxo-todomatuate (VIIIa) was added. After the solution had been refluxed for 1 hr., the methyl ester was saponified by boiling it with 1 g. of potassium hydroxide and 5 cc. of water. After the ethanol had been distilled off, the reaction mixture was refluxed for 4 hr. and then diluted with 20 cc. of water. The alkaline solution was washed with ether and was made acidic with concentrated hydrochloric acid. After this solution had been extracted with ether and dried over anhydrous magnesium sulfate, the solvent was removed to give a viscous oil which distilled at 150~153°C/1 mmHg, affording 1.6 g. of an oil. $[\alpha]_D^{27}$ +14.1° (*c* 1.77 in ethanol), n_D^{18} 1.4723. The anilide prepared from XVIIb was recrystallized from ethanol, m. p. 115~116°C.

Found: C, 80.14; H, 10.62; N, 4.49. Calcd. for $C_{21}H_{33}ON$: C, 79.94; H, 10.54; N, 4.44%.

The Wieland-Barbier Degradation of Methyl (+)-Dihydro-desoxo-todomatuate (VIIIa).—To a Grignard solution prepared from 4 g. of magnesium, 30 g. of bromobenzene and 100 cc. of ether, a solution of 4 g. of the methyl ester VIIIa in 30 cc. of ether was added. After the solution had been refluxed for 15 min., the ether was removed and replaced by 50 cc. of benzene; then the reaction mixture was heated in an oil bath (110°C) for 12 hr. The Grignard complex was decomposed with cold diluted hydrochloric acid and extracted with ether. After being dried over anhydrous magnesium sulfate, the ether extract was concentrated to give an oil which was distilled to yield 4.5 g. of the tertiary alcohol VIIIc (b. p. 200~205°C/1 mmHg). The tertiary alcohol VIIIc (8.8 g.) was dehydrated by heating it with 200 cc. of acetic anhydride and 40 cc. of pyridine for 4 hr. The reaction mixture was poured into ice water and extracted with ether. The ether extract was washed with diluted hydrochloric acid and a 5% sodium carbonate solution successively and then dried over anhydrous magnesium sulfate. Removal of the solvent gave an oil which was then distilled to afford 7.2 g. of the unsaturated compound VIIId (b. p. 205~210°C/1 mmHg). To a solution of 7.2 g. of the unsaturated compound VIIId in 75 cc. of chloroform, a stream of ozone (2%) was passed for 1 hr. The ozonide was decomposed with 8 cc. of acetic acid and 6 g. of zinc powder. After being freed from the zinc powder, the chloroform solution was washed with a diluted sodium carbonate solution and then concentrated. The residue was distilled at 1 mmHg to give two fractions: 1. b. p. 100~110°C. 1 g; 2. b. p. 190~210°C. 5.4 g. The higher boiling fraction was shown to be recovered unsaturated compound VIIId by examination of its infrared spectrum; it was then ozonolyzed again to afford 0.7 g. of the low boiling fraction (b. p. 110~120°C/1 mmHg). The combined low boiling fractions were dissolved in 20 cc. of petroleum ether and passed through a column containing 35 g. of alumina. Elution with petroleum ether-ether (10 : 1) gave 0.2 g. of an oil which exhibited an absorption at 1704 cm^{-1} infrared spectrum; this was directly converted into semicarbazone. The semicarbazone was recrystallized from diluted ethanol, m. p. 151~152°C.

Found: C, 67.38; H, 11.02; N, 15.97. Calcd. for $C_{15}H_{29}ON_3$: C, 67.37; H, 10.93; N, 15.72%.

***p*-Anisyl-isohexylketone (Xa).**—A mixture of 44.3 g. of 5-methylhexanoic acid and 35 cc. of thionyl chloride was heated on a water bath for 30 min. After the excess thionyl chloride had been removed, the residue was distilled to yield 45 g. of 5-methylhexanoyl chloride (b. p. 70~71°C/1 mmHg). To a stirred mixture of 53.4 g. of aluminum chloride and 150 cc. of carbon disulfide, 45 g. of the acid chloride was added over a 10 min. period under cooling. After 36.7 g. of anisole had been added over a 30 min. period, stirring was continued for another 30 min.; then the temperature of the reaction mixture was gradually brought to room temperature. The reaction mixture was decomposed with ice and extracted with ether. The ether extract was washed with water, a 10% sodium hydroxide solution and water successively, and then dried over anhydrous magnesium sulfate. Removal of the solvent gave a residue which distilled to yield 56.6 g. of Xa, b. p. 131~133°C/1 mmHg.

Found: C, 76.27; H, 9.34. Calcd. for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%.

The semicarbazone prepared from Xa was recrystallized from ethanol to give prisms, m. p. 124~125°C.

Found: C, 65.11; H, 8.54; N, 15.10. Calcd. for $C_{15}H_{23}O_2N_3$: C, 64.95; H, 8.36; N, 15.5%.

2-*p*-Anisyl-6-methylheptane (XIIa).—To a suspension of 18 g. of magnesium in 250 cc. of ether, a stream of methyl bromide was passed until the magnesium was consumed. A solution of 56 g. of the ketone Xa in 100 cc. of ether was added to the Grignard solution for over 1 hr., and the reaction mixture was refluxed for 2 hr. After diluted hydrochloric acid had been added to decompose the Grignard complex, the reaction mixture was extracted with ether. Removal of the solvent gave the crude alcohol Xb, which was refluxed with 150 cc. of acetic anhydride for 3 hr. The solution was concentrated at reduced pressure and the residual oil was distilled, giving 47.8 g. of the unsaturated compound XI (b. p. 107~113°C/1 mmHg). Two grams of Raney nickel were added to a solution of 47.8 g. of the unsaturated compound XI in 30 cc. of ethanol and hydrogenated in a steel bomb at 25 atm. of hydrogen at 30~40°C. The product boiled at 107~113°C/1 mmHg and weighed 47.5 g.

Found: C, 81.95; H, 11.13. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

2-(4-Hydroxyphenyl)-6-methylheptane (XIIb).—A mixture of 42 g. of XIIa, 115 cc. of hydroiodic acid (b. p. 127°C), 40 cc. of acetic anhydride and 1 g. of red phosphorus was refluxed for 2 hr. After 60 cc. of acetic anhydride had been added, heating

was resumed for another 2 hr. The reaction mixture was then poured into ice water and extracted with benzene. The benzene extract was washed with water and dried over anhydrous magnesium sulfate. Removal of the solvent and distillation gave 38 g. of XIIb, b. p. 127~128°C/1 mmHg.

Found: C, 80.42; H, 10.80. Calcd. for $C_{14}H_{22}O$: C, 81.50; H, 10.75%.

2-(4-Hydroxycyclohexyl)-6-methylheptane(XIIIa).—The phenol (38 g.) XIIb was catalytically hydrogenated in 70 cc. of ethanol with 2 g. of Raney nickel in a steel bomb (140~150°C, 130 atm. of hydrogen) for 3 hr. After being freed from the catalyst, the product was distilled to give 37.5 g. of the cyclohexanol derivative XIIIa, b. p. 120~121°C/1 mmHg.

Found: C, 79.75; H, 12.19. Calcd. for $C_{14}H_{28}O$: C, 79.18; H, 13.29%.

2-(4-Oxocyclohexyl)-6-methylheptane (XIIIb).—To a solution of 18.5 g. of potassium dichromate in 142 cc. of water, 16.3 cc. of concentrated sulfuric acid was added. To the stirred dichromate solution, 37.0 g. of the alcohol XIIIa was added at 57~58°C. The mixture was then stirred for 20 min., cooled to room temperature and extracted with ether. The ether extract was washed with water and with a 5% sodium hydroxide solution successively, and then dried over anhydrous magnesium sulfate. Removal of the solvent and distillation gave 27.5 g. of XIIIb (b. p. 113~114°C/1 mmHg).

Found: C, 79.96; H, 12.91. Calcd: for $C_{14}H_{16}O$: C, 79.93; H, 12.46%.

The semicarbazone prepared from XIIIb was recrystallized from diluted ethanol, m. p. 149~150°C. The mixed melting point with the semicarbazone (m. p. 151~152°C) of IX from todomatuic acid was 149.5~150°C, and their infrared spectra in a Nujol mull or carbon disulfide were superimposable in every detail.

Found: C, 67.53; H, 10.78; N, 15.73. Calcd. for $C_{15}H_{29}ON_3$: C, 67.37; H, 10.93; N, 15.72%.

2-(4-Cyano-4-acetoxycyclohexyl)-6-methylheptane (XIV).—A mixture of 20 g. of the ketone XIIIb and 22.8 g. of acetic anhydride was added slowly to a chilled solution of 14.6 g. of potassium cyanide in 145 cc. of water and then stirred for 13 hr. at room temperature. The reaction mixture was neutralized with a sodium carbonate solution and extracted with ether. The ether extract was washed with water and dried over anhydrous magnesium sulfate. When the solvent was removed at reduced pressure, the cyanohydrin began to decompose. The crude cyanohydrin was directly acetylated by heating it with 10 cc. of acetic anhydride and 1.3 g. of acetyl chloride for 1 hr. After concentration at reduced pressure, the residue was distilled to give 3.5 g. of XIV, b. p. 145~147°C/1 mmHg. The ketone XIIIb was recovered from a low boiling fraction.

2-(4-Carboxycyclohex-3-enyl)-6-methylheptane (XVb).—Five grams of the acetate XIV were passed through a heated Pyrex tube (600°C) packed with ceramic Rashing rings at reduced pressure (1 mmHg) over 1.5 hr. The decomposition products were collected in a trap chilled in a dry ice-acetone bath. After being diluted with ether, the product was washed with water and dried over anhydrous magnesium sulfate. The solvent was removed, and the residue was distilled to give 2.11 g. of the unsaturated cyanide XVa (b.p. 130~132°C/1 mmHg). The cyanide XVa (2.0 g.) was hydrolyzed by heating it with a solution of 1.5 g. of potassium hydroxide in 13 cc. of water with 15 cc. of diethylene glycol for 30 hr. After being made acidic with concentrated hydrochloric acid, the mixture was extracted with benzene. Removal of the solvent gave a residue which was hydrolyzed further by refluxing it with an ethanolic sodium ethoxide solution (prepared from 0.5 g. of sodium and 20 cc. of ethanol). The reaction mixture was diluted with water and washed with benzene. The unsaturated acid XVb precipitated by adding diluted hydrochloric acid was extracted with ether. Removal of the solvent gave an oil which distilled to afford 1.5 g. of XVb, b. p. 163~165°C/1 mmHg. The infrared spectrum was found superimposable on that of (+)-desoxo-todomatuic acid (VIIa).

Found: C, 75.34; H, 10.99. Calcd. for $C_{15}H_{26}O_2$: C, 75.58; H, 11.00%.

***trans*-2-(4-Carboxycyclohexyl)-6-methylheptane (XVIIb).**—The unsaturated acid XVb (1.2 g.) was dissolved in 50 cc. of ether and esterified with a diazomethane ether solution prepared from 2.4 g. of nitrosomethylurea. After the reaction mixture had been allowed to stand at room temperature for 3 hr., the excess diazomethane was decomposed with a small amount of acetic acid. The mixture was washed with a diluted sodium cabonate solution and then water. After being dried over anhydrous sodium sulfate, the solvent was removed to give an oil which distilled at 128~130°C/1 mmHg. The yield was 1.2 g. The methyl ester XVc was dissolved in 20 cc. of ethanol and catalytically hydrogenated with 80 mg. of an Adams catalyst for 12 hr. Removal of the catalyst and the solvent gave 1.1 g. of an oil which was distilled, b. p. 117~120°C/1 mmHg. The saturated ester (XVIa) (1.1 g.) was added to an ethanolic sodium ethoxide solution prepared from 0.1 g. of sodium and 5 cc. of ethanol, and the solution was refluxed for 1 hr. After a solution of 0.7 g. of sodium hydroxide in 8 cc. of water had been added, the mixture was refluxed for 8 hr. The solution was acidified with diluted hydrochloric acid and extracted with ether. Removal of the solvent and distillation of the residue gave an oil (1.0 g.) (b. p. 152~155°C/1 mmHg; n_D^{18} 1.4723) whose infrared absorption spectrum was found superimposable in every detail on that of natural (+)-*trans*-dihyro-desoxo-todomatuic acid. The anilide prepared from XVIIb was recrystallized from diluted methanol to give needles, m. p. 105~106°C. The mixed melting point with the anilide from natural (+)-*trans*-dihydro-desoxo-todomatuic acid (m. p. 115~116°C) was 103~104°C.

Found: C, 80.42; H, 10.76; N, 4.64. Calcd. for $C_{21}H_{33}ON$: C, 79.94; H, 10.54; N, 4.44%.

The Lithium Aluminum Hydride Reduction of Methyl (+)-*trans*-Dihydro-desoxo-todomatuate (XVIIa).—To a slurry of 0.57 g. of lithium aluminium hydride and 10 cc. of ether, a solution of 2.0 g. of the optically active methyl ester XVIIa in 10 cc. of ether was added over a 45 min. period.

After the reaction mixture had been refluxed for 1.5 hr. and then cooled in an ice bath, the excess lithium aluminum hydride was decomposed with ethyl acetate. Twenty cubric centimeters of 2 N hydrochloric acid were added, and the reaction mixture was extracted with ether. The ether extract was washed with water and dried with anhydrous sodium sulfate. Removal of the solvent gave a viscous oil which was then distilled to afford 1.5 g. of a liquid, b. p. 152~155°C/4 mmHg; n_D^{31} 1.4663, $[\alpha]_D^{31}$ +15.5° (*c* 30.4 in chloroform).

This work was partially supported by a grant-in-aid for fundamental scientific research from the Ministry of Education, to which the author's thanks are due. They also are very grateful to Mr. Yoshio Ohta for his technical assistance and to Mr. Sohei Sato, Dai Shyowa Pulp Ind. Co., for generously supplying them with crude todomatuic acid.

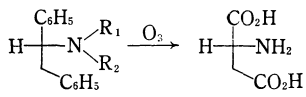
On the Absolute Configuration of threo-1, 2-Diphenyl-2-hydroxyethylamine

By Masao NAKAZAKI

(Received February 25, 1963)

The (R)-configuration of (−)-1, 2-diphenylethylamine (Ia) has been established[1] by the degradation of its (+)-*N*-acetyl derivative Ib to D-aspartic acid (II), and the analgesic property of (−)-*N*, *N*-dimethyl-1, 2-diphenylethylamine (Ic), derived from Ia, has been attributed to its configuration similar to that of (−)-morphine (Fig. 1).



Ia $R_1=R_2=H$ II
b $R_1=Ac$, $R_2=H$
c $R_1=R_2=Me$

Fig. 1

However, this assignment of the absolute configuration to Ia has been found to be inconsistent with the findings of La Manna and his collaborators,[2] who obtained (+)-Ia (the enantiomer of Ia) from (+)-*threo*-1, 2-diphenyl-2-hydroxyethylamine (VIIa) by replacing the hydroxyl group with a chlorine atom with phosphorus pentachloride and by the subsequent hydrogenolysis of the chloro derivative (Fig. 2). The L-configuration* had been assigned to the (+)-*threo* isomer VIIa by Weijlard et al.,[3] who reported that they had converted the *N*-formyl derivative IVb of the D(−)-*erythro* isomer IVa, whose absolute configuration had been proved unambiguously,[4] into the (+)-*threo* isomer VIIa by treating it with thionyl chloride, which is believed to allow only the hydroxyl group to epimerize.[5]

Once this assignment of the L-configuration of the (+)-*threo* isomer VIIa is accepted as correct, it is more than natural that La Manna et al. were led to give the (R)-configuration to (+)-1, 2-diphenylethylamine instead of to the (−)- isomer Ia. However, a very curious situation arose when they found that the D(−)-*erythro* isomer IVa afforded (−)-Ia by the same treatment applied to the (+)-*threo* isomer VIIa.

2) P. Pratesi, A. La Manna and L. Fontanella, *Il Farmaco (Pavia), Ed. Sci.*, **10**, 673 (1955); *Chem. Abstr.*, **50**, 10057 (1956).

* The configurations of the formulations in this paper are in accord with Fischer's convention referring to the asymmetric center at C_2 (Figs. 2 and 3).

3) J. Weijlard, K. Pfister. 3rd, E. F. Swanezy, C. A. Robinson and M. Tishler, *J. Am. Chem. Soc.*, **73**, 1217 (1951).

4) A. McKenzie and D. J. C. Pirie (*Ber.*, **69**, 876 (1936)) correlated the configuration at C_2 of IVa with D(−)-mandelic acid (IIIa) via D(−)-benzoin (IIIb) and D(−)-benzoin oxime (IIIc) (Fig. 2). (Cf. also A. McKenzie and H. Wren, *J. Chem. Soc.*, **93**, 309 (1908).) The erythro configuration of IVa was established by J. Reed and I. G. M. Campbell (ibid., **1930**, 2377) and by A. Weissberger and H. Bach (*Ber.*, **64**, 1094 (1934); **65**, 63 (1935)). On the predominant formation of the erythro derivative IVa by the reduction of benzoin oxime (IIIc), see D. J. Cram and F. A. Abd Elhafez, *J. Am. Chem. Soc.*, **74**, 5824 (1952).

5) A mechanism involving the intermediate stages V and VI had been suggested. There is ample evidence to support the idea of the epimerization at the center carrying the hydroxyl group (Cf. D. F. Elliot, *J. Chem. Soc.*, **1950**, 62; G. Fodor, V. Bruckner, J. Kiss and G. Óheggi, *J. Org. Chem.*, **14**, 337 (1949),). Weijlard et al.[3] cites much relevant literature.

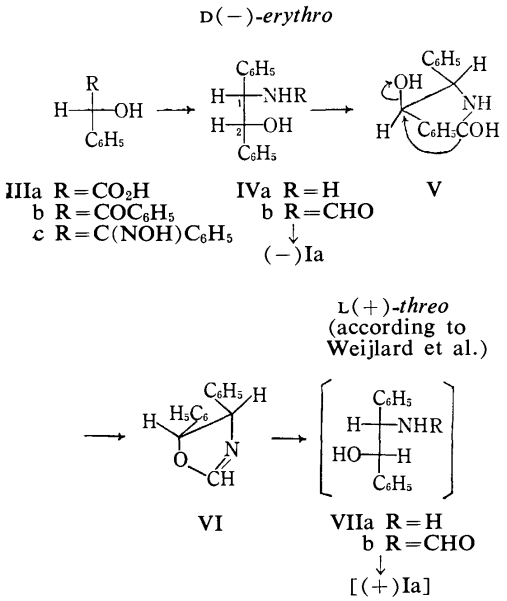

Fig. 2

Since, according to Weijlard et al.,[3] the D(−)-*erythro* isomer IVa and the (+)-*threo* isomer VIIa both have the same configuration at C_1 (the carbon atom carrying amino group) (Fig. 2), both compounds may be expected to give the same optically-active 1, 2-diphenylethylamine. To circumvent this difficulty, La Manna and his collaborators suggested that "the replacement of the hydroxyl group (of D(−)-*erythro* isomer IVa) by a chlorine atom by means of phosphorus pentachloride may involve inversion of the configuration at the C_1 center (the carbon atom bearing amino group) which is not directly concerned in the replacement."[2]

Since the absolute configuration of (−)-1, 2-diphenylethylamine (Ia) was unambiguously determined[1] by correlating it directly to D-aspartic acid (II), one is forced to assume, contrary to the suggestion of La Manna et al.,[2] that it must not be the D(−)-*erythro* isomer IVa but the (+)-*threo* isomer VIIa which epimerizes at the center of C_1 while the hydroxyl group is replaced at C_2 with phosphorus pentachloride.

However, the awkwardness has still remained, demanding some reasonable mechanism to explain this curious epimerization at C_1; no relevant parallel to which could be found in the literature. This contribution is primarily concerned with the revision of the absolute configuration of *threo*-1, 2-diphenyl-2-hydroxyethylamine (VIIa) originally proposed by Weijlard et al.,[3] so as to avoid the awkward circumstance mentioned above.

A survey of the literature reveals that

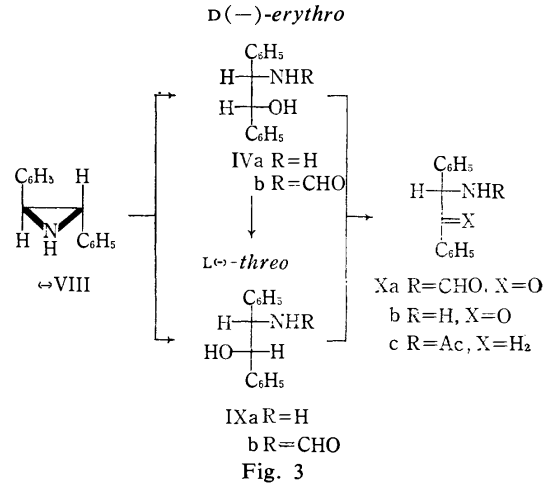

Fig. 3

Weissberger and Bach[6] performed an experiment (Fig. 3) which indicated clearly that (−)-*erythro* isomer IVa and (−)-*threo* isomer IXa have the same configuration at C_1; in this experiment they obtained these two optically-active diastereoisomers from (−)-*trans*-1, 2-diphenylethyleneimine (VIII)[7] on hydrolysing it with diluted sulfuric acid. Because the (−)-*erythro* isomer IVa resulted from the *trans*-opening of the (−)-*trans* ethyleneimine, VIII has been shown to have the D-configuration by correlating it with D(−)-mandelic acid IIIa[4] (Fig. 2); the (−)-*threo* isomer which is formed by the cis-opening of the VIII, differing from IVa only at the configuration of C_2 must have the L-configuration, contrary to the conclusion of Weijlard et al., as Fig. 3 shows. This deduction[8] was further supported by the conversion of the *N*-formyl derivatives of both D(−)-*erythro*- (IVb) and L(−)-*threo*- 1, 2-diphenyl-2-hydroxyethylamine (IXb) to the same (R)(+)-desylamine hydrochloride (Xb)[9] by sodium

6) A. Weissberger and H. Bach, *Ber.*, 65, 631 (1932).

7) Since the absolute configuration of D(−)-*erythro*-1, 2-diphenyl-2-hydroxyethylamine (IVa) has been established, (−)-*trans*-1, 2-diphenylethyleneimine is shown to be 1(S), 2(S)-diphenylethyleneimine (VIII).

8) P. Pratesi, A. La Manna and G. Vitali (*Il Farmaco (Pavia) Ed. Sci.*, 15, 387 (1960); *Chem. Abstr.*, 54, 24472 (1960)) reached the same conclusion by obtaining the same optically-active (+)-*N*-acetyl-1, 2-diphenylethylamine (Ib) m. p. 164~165°C, $[\alpha]_D$ +14° by hydrogenolysis of the *N*, *O*-diacetyl derivatives of IVa and IXa.

9) This finding also confirms the absolute configuration of (S)(−)-desylamine (the enantiomer of Xb) and the retention of the configuration in the conversion of (S)(−)-desylamine to D(−)-benzoin (IIIb) reported by A. McKenzie and D. J. Cruickshank (*Ber.*, 69, 876 (1936)), although their deduction of these facts was not complete until the compounds, m. p. 141~142°C ($[\alpha]_D$−10° from (D)-benzoin oxime, $[\alpha]_D$+10.4° from (+)-desylamine)) were shown to be of the erythro form of 1, 2-diphenyl-2-hydroxyethylamine.[4] This has been pointed out by C. K. Ingold (1951) in his personal communication to the editor of Beilstein, "Handbuch der Organischen Chemie." (IV Auflage, Bd. 14, zweites Ergänzungswerk, Springer, Berlin (1951), p. 62).

dichromate oxidation, followed by hydrolysis of the resulting *N*-formyldesylamine (Xa).[10]

These results are in harmony with La Manna's finding mentioned above that the (+)-*threo* isomer (now known to be of the D-configuration, the enantiomer of IXa) and the D(−)-*erythro* isomer IVa gave optically-active 1,2-diphenylethylamines with opposite rotations; hence it is not necessary to assume a rather incredible epimerization at C_1 in the replacement reaction of the hydroxyl group at C_2 of the erythro isomer IVa with phosphorus pentachloride.

Let us turn now to the conversion of the *N*-formyl derivative IVb of the D(−)-*erythro* isomer IVa into the (+)-*threo* isomer (now known to have the D-configuration; the enantiomer of IXa) with thionyl chloride reported by Weijlard et al. In order to accommodate their finding to the established absolute configurations (vide supra) of *erythro*- and *threo*-1,2-diphenyl-2-hydroxyethylamine, it seems inevitable, although improbable, to assume the epimerization at C_1 against overwhelming evidence which support the epimerization at the carbon atom C_2 carrying the hydroxyl group under these reaction conditions. On duplicating their isomerization experiment of the *N*-formyl derivative IVb of the D(−)-*erythro* isomer with thionyl chloride, it was found that the *threo* isomer showed, rather surprisingly, $[\alpha]_D -122°$, which has been shown to have the L-configuration IXa (vide supra); this is contrary to the finding of Weijlard et al.

This finding also indicates that the isomerization follows the usual, well-established path, affording an isomer which differs in the configuration of the carbon atoms carrying the hydroxyl groups (V→VI, in Fig. 2).

This error in the measurement of the optical rotation has been responsible for creating a chaos of puzzling phenomena, confusing La Manna and his collaborators in their determination of the absolute configuration of 1,2-diphenylethylamine (Ia).

It may be worthwhile to mention here another attempt to determine the absolute configuration of 1,2-diphenylethylamine (Ia), an attempt which eventually led to a conclusion opposite to ours.[1] Lyle[11] suggested the (R)-configuration for (+)-1,2-diphenylethylamine (the antipode of Ia) because its positive plain rotatory dispersion curve is very close the summation curve of (R)(+)-α-methylbenzylamine and (S)(+)-amphetamine which she considered to be the components of (+)-1,2-diphenylethylamine molecule. The reason why she was led to the wrong conclusion must be sought in her failure to take account of the phenyl-phenyl interaction and of the hydrogen bond between the phenyl groups and the amino groups, as well as the conformational asymmetry emphasized by Brewster.[12]

Experimental

(±)-*erythro*-1,2-Diphenyl-2-hydroxyethylamine ((±)-IVa).—To a solution of 5.7 g. of benzoin-α-oxime in 60 cc. of 90% ethanol was added 0.5 g. of 10% palladium-charcoal catalyst, together with 6 cc. of 5.5 N ethanolic hydrochloric acid; this mixture was then shaken at 40°C in an atmosphere of hydrogen for 6 hr. After the catalyst had been filtered out, the filtrate was concentrated to about 1/3 of the original volume. The crystals (1.1 g.) which were deposited upon the addition of water were recrystallized from benzene to afford hydrobenzoin, m. p. 135~136°C. The aqueous solution was made basic with concentrated aqueous ammonia to yield 3.97 g. of racemic IVa, m. p. 152~158°C. Recrystallization from methanol raised the m. p. to 157~160°C (lit.:[3] m. p. 163°C).

The Hydrochloride.—To a solution of 1 g. of racemic IVa in 10 cc. of ethanol was added 1.2 cc. of 5.5 N ethanolic hydrochloric acid, followed the addition of 10 cc. of ether to precipitate the hydrochloride of IVa (1.1 g.), m. p. 228°C (lit.:[3] m. p. 219~220°C).

***N*-Formyl-(±)-*erythro*-1,2-diphenyl-2-hydroxyethylamine** ((±)-IVb).—One gram of the hydrochloride of racemic IVa was dissolved in 3 cc. of formamide, and the mixture was heated at 150°C for 15~20 min. After being cooled to room temperature, the reaction mixture was diluted with 20 cc. of water to precipitate crystals which were then collected and washed with water to yield 0.61 g. of racemic IVb. Recrystallization from ethanol gave needles which weighed 0.61 g. and which melted at 180~182°C (lit.:[3] m. p. 179~181°C).

(±)-*N*-Formyldesylamine ((±)-Xa) from (±)-IVb.—A solution of 0.21 g. of racemic IVb in 3 cc. of acetic acid was added to a stirred solution of 0.27 g. of sodium dichromate dihydrate in 4 cc. of acetic acid at 10°C over 1/2 hr. The solution was then brought slowly to room temperature (10°C) and allowed to stand overnight. After being heated at 50°C for 20 min., the reaction mixture was diluted with 70 cc. of water and kept in a refrigerator overnight; 76 mg. of prismatic crystals (m. p. 199~120°C) precipitated. Recrystallization from benzene-petroleum ether did not raise the melting point. An infrared spectrum in Nujol indicated major peaks at 3360 (NH), 1685, and 1660 cm^{-1} (CO).

Found: C, 75.2; H, 5.6; N, 6.0. Calcd. for $C_{15}H_{13}O_2N$: C, 75.30; H, 5.48; N, 5.85%.

(±)-Desylamine ((±)-Xb) Hydrochloride from (±)-Xa.—After a mixture of 86 mg. of racemic

10) Optically-active *N*-formyldesylamine could not be obtained in a crystalline state, but the racemic variety was in prism form, m. p. 119~120°C.

11) G. G. Lyle, *J. Org. Chem.*, 25, 1779 (1960).

12) J. Brewster, *J. Am. Chem. Soc.*, 81, 5475 (1959).

Xa and 4 cc. of 2 N hydrochloric acid had been refluxed for 2 hr., the solution was evaporated to dryness in a vacuum. The crystalline residure was dissolved in 5 cc. of water and treated with Norit. The filtrate was then concentrated to about 0.5 cc., and 1 cc. of concentrated hydrochloric acid was added. The mixture was allowed to stand in a refrigerator to precipitate fine needles, which were then collected and washed with concentrated hydrochloric acid. The (±)-desylamine hydrochloride, after being dried in a desiccator over sodium hydroxide pellets, decomposed at 220~225°C and weighed 40 mg. (lit.:[3]) the optically active hydrochloride, m. p. 230°C).

(±)-*threo*-1,2-Diphenyl-2-hydroxyethylamine ((±)-IXa).—A mixture of racemic IVb and 3.0 cc. of thionyl chloride was stirred at 0~5°C for 20 min., and the reaction mixture was brought slowly to room temperature over a 1 hr. period. After the excess thionyl chloride had been decomposed with 20 g. of ice, the reaction mixture was refluxed for 2 hr. After being cleared with Norit, the solution was made basic with a 3 N sodium hydroxide solution to precipitate the racemic IXa, which was then washed with water and dried to yield 1.1 g. of crystals, m. p. 128°C. Recrystallization from ethanol gave 0.9 g. of prisms, m. p. 129~130°C (lit.:[3]) m. p. 126~128°C).

The hydrochloride (decomp. p. 205~210°C) was prepared following the procedure described for the erythro isomer IVa. The yield was quantitative (lit.:[3]) decomp. p. 200~201°C).

***N*-Formyl-(±)-*threo*-1, 2-diphenyl-2-hydroxyethylamine ((±)-IXb).**—Following the procedure described for the erythro isomer IVb, a mixture of 0.83 g. of the hydrochloride of racemic IXa and 3 cc. of formamide was heated to give 0.65 g. of racemic IXb, m. p. 146~149°C after recrystallization from diluted ethanol (lit.:[3]) m. p. 145~146°C).

(±)-Desylamine ((±)-Xb) Hydrochloride from (±)-IXb.—A solution of 0.60 g. of the racemic IXb in 7 cc. of acetic acid was added gradually to a stirred solution of 0.81 g. of sodium dichromate dihydrate in 12 cc. of acetic acid at 10°C over a 1/2 hr. period. After being allowed to stand over-night at room temperature, the mixture was heated at 50°C for 1/2 hr. This mixture was diluted with 200 cc. of water, saturated with sodium chloride, and then extracted with ether. The ether extract was washed with a dilute sodium hydrogen carbonate solution and then with a saturated sodium chloride solution. The ether extract was dried over anhydrous magnesium sulfate and was concentrated to give 0.42 g. of a viscous residue (the odor of benzaldehyde was noticed) which was then hydrolyzed by boiling it with 10 cc. of 2 N hydrochloric acid for 2 hr. The solution was concentrated under reduced pressure to give a crystalline mass, which was washed with benzene. The residue was dissolved in a small amount of water and concentrated again after treatment with Norit. To the clear solution (about 1 cc.) 3 cc. of concentrated hydrochloric acid was added to precipitate (±)-desylamine hydrochloride, which decomposed at 225~230°C and which weighed 0.12 g.

Found: N, 5.5. Calcd. for $C_{14}H_{14}ONCl$: N, 5.66%.

D(−)-*erythro*-1,2-Diphenyl-2-hydroxyethylamine (IVa).—A mixture of 11.1 g. of racemic IVa and 7.9 g. of L-glutamic acid was dissolved in 330 cc. of 50% ethanol and was kept in a refrigerator to precipitate the L-glutamate of the (−)-amine IVa as fine needles, which were then recrystallized from 50% ethanol. The L-glutamate melted at 213°C with decomposition. $[\alpha]_D^{20}$ −50.0° (*c* 0.42 in water) (lit.:[3]) decomp. p. 215°C, $[\alpha]_D^{25}$ −50.3° (*c* 0.65 in water)). The L-glutamate (6.63 g.) was dissolved in 100 cc. of water, and the D(−)-*erythro* base IVa was precipitated by adding concentrated aqueous ammonia. The base was collected and washed with water to give 3.5 g. of crystals, which melted at 141~144°C after recrystallization from ethanol. $[\alpha]_D^{24}$ −6.4° (*c* 1.25 in ethanol) (lit.:[3]) m. p. 143°C, $[\alpha]_D^{25}$ −10.1° (*c* 0.59 in ethanol)).

The hydrochloride which was prepared following the procedure for the racemic compound decomposed at 215°C, $[\alpha]_D^{21}$ −59.0° (*c* 1.0 in water) (lit.:[3]) decomp. p. 213.5~214.5°C, $[\alpha]_D^{25}$ −69.5° (*c* 0.65 in water)).

Found: N, 5.2. Calcd. for $C_{14}H_{16}ONCl$: N, 5.61%.

***N*-Formyl-D(−)-*erythro*-1,2-diphenyl-2-hydroxyethylamine (IVb).**—The *N*-formyl derivative IVb, which was prepared following the procedure for the racemic erythro amine, melted at 201~202°C after recrystallization from ethanol, $[\alpha]_D^{22}$ +2.6° (*c* 0.45 in ethanol).

Found: C, 74.4; H, 6.3; N, 5.8. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%.

(+)-Desylamine (Xb) Hydrochloride obtained by the Oxidation of IVb.—A solution of 0.411 g. of IVb in 8 cc. of acetic acid was added to a stirred solution of 0.56 g. of sodium dichromate dihydrate in 6 cc. of acetic acid over a 15 min. period at 0°C. After being stirred for 1 hr. at 0°C, the solution was allowed to stand overnight at room temperature. The reaction mixture was then poured into 200 cc. of water and extracted with ether. The ether extract was washed with a dilute sodium hydrogen carbonate solution and then with a saturated sodium chloride solution. After drying over anhydrous magnesium sulfate, the solvent was removed to give crude *N*-formyl-(+)-desylamine (an oil, $[\alpha]_D^{22}$ +227° (*c* 1.4 in ethanol)), which was hydrolyzed directly by boiling it with 10 cc. of 2N hydrochloric acid for 2 hr. The solution was concentrated under reduced pressure to give a crystalline residue which was dissolved in a small amount of water and treated with Norit. The filtrate freed from Norit was concentrated again to 3 cc., and then 6 cc. of concentrated hydrochloric acid was added to precipitate (+)-desylamine hydrochloride, which decomposed at 225°C and which weighed 60 mg., after drying in a vacuum desiccator over sodium hydroxide pellets., $[\alpha]_D^{21}$ +189° (*c* 1.0 in water) (lit.:[13]) $[\alpha]_D^{16}$ +223.2° (*c* 2.54 in water)).

Found: C, 68.0; H, 5.7. Calcd. for $C_{14}H_{14}ONCl$: C, 67.87; H, 5.69%.

The Isomerization of *N*-Formyl-D(−)-*erythro*-1,2-diphenyl-2-hydroxyethylamine (IVb) to L-(−)-*threo* Isomer IXa.—A mixture of 1.5 g. of *N*-formyl-D(−)-*erythro* amine IVb and 3 cc. of thionyl chloride was stirred at 0°C for 5 min., and then the temperature of the mixture was gradually raised to room temperature (15°C) over a 45 min. period. The solution was poured onto 100 g. of ice to decompose the excess thionyl chloride, and the reaction mixture was refluxed for 2 hr. The solution was cleared with Norit and was made basic with a 4 N sodium hydroxide solution to precipitate 1.4 g. of L(−)-*threo* amine IXa, which was collected and washed with water. The amine was recrystallized from ethanol to give needles which melted at 114~116°C, $[\alpha]_D^{22}$ −122° (*c* 1.0 in ethanol) (lit.:[3] m. p. 115.2~115.8°C $[\alpha]_D^{24}$ −123.7° (*c* 1.2 in ethanol) for the "D(−)-*threo*" isomer).

Found: C, 78.8; H, 7.1; N, 6.4. Calcd. for $C_{14}H_{15}ON$: C, 78.84; H, 7.09; N, 6.57%.

The hydrochloride which was prepared following the procedure for the racemic threo compound decomposed at 230°C, $[\alpha]_D^{18}$ −122° (*c* 1.2 in ethanol). (lit.:[3] decomp. p. 220~221°C, $[\alpha]_D^{23}$ +84.7° (*c* 0.01 in water) for the hydrochloride of the "L(+)-*threo*" isomer).

***N*-Formyl-L(−)-*threo*-1,2-diphenyl-2-hydroxyethylamine (IXb).**—The *N*-formyl-L(−)-*threo* isomer IXb which was prepared following the procedure used for the racemic compound melted at 116~119°C after recrystallization from 50% ethanol, $[\alpha]_D^{18}$ +11.3° (*c* 1.2 in ethanol).

Found: C, 74.2; H, 6.2; N, 5.9. Calcd. for $C_{15}H_{15}O_2N$: C, 74.66; H, 6.27; N, 5.81%.

(+)-Desylamine (Xb) Hydrochloride from IXb. Following the procedure used for the oxidation of IVa, 0.469 g. of IXb was oxidized with 0.58 g. of sodium dichromate dihydrate in acetic acid to give 70 mg. of (+)-desylamine hydrochloride, which decomposed at 225°C, $[\alpha]_D^{23}$ +130° (*c* 0.51 in water). Its infrared spectrum was found superimposable on that of (+)-desylamine hydrochloride derived from IVa (in a Nujol mull).

The author is very grateful to the Nitto-kasei Co. for its financial support. He is also indebted to Drs. Tetsuo Shiba (Osaka University) and Setsuji Sakurai (Ajinomoto Co.) for their generous gifts of L-glutamic acid. A part of the expense of this research was defrayed by the grant-in-aid for fundamental scientific research from the Ministry of Education, to which the author's thanks are due.

*Studies on the Absorptiometric Determination of Microamounts of Boron. V. The Necessity of Methyl or Ethyl Oxalate in the Color Reaction of Boric Acid with Curcumin**

By Masatoshi MIYAMOTO

(Received May 4, 1963)

The color reaction of boric acid with curcumin, whereon the most sensitive method for absorptiometric determination of boron is based, is well-kown, but it has not yet been clearly revealed although when Schulemberger[1] first studied the reaction in 1866. Spicer and Strickland[2] have, however, contributed valuable information on the reaction product. The present paper deals with facts concerning the color reaction overlooked for a long time. The study has been initiated with the purpose of extracting an effective product from a curcumin-oxalic acid reagent solution sufficiently aged by refluxing;[3] thus, it is hoped, a stable and reliable reagent for instant use can be obtained.

Results and Discussion

The Effects of Various Acids on Color Reaction.—It has been reported that the presence of oxalic,[4] tartaric[5] and salicylic[6] acids intensify the color resulting from the reaction between

curcumin and boric acid. The author's results in the 4th column of Table I show that the presence of oxalic acid is effective for the color reaction under the conditions stated in the experimental section below, whereas those of hydrochloric, malonic, tartaric, *o*-phthalic and salicylic acids are ineffective (cf. Nos. 2 to 7). The slight effect of malonic acid may possibly be attributed to small amounts of oxalic acid contaminating the malonic acid used (cf. "Effect of various esters" below). No correlation is observed between the effects and the first dissociation constants of the acids added to a curcumin solution. The effect of oxalic acid on the reaction is unique.

A comparison of the results shown in the 5th column, Nos. 1 and 2, shows that the presence of hydrochloric acid promotes the color reaction in the presence of oxalic acid. This may be attributed to the effect of hydrochloric acid (hydrogen ions) on the aging reaction of a reagent solution, whereby aging reaction proceeds during evaporation for the color reaction. However, the aging reaction does not proceed enough during the evaporation, as is revealed by a lower result of No. 2, 5th column, than that of No. 3, 4th column. In either cases, both oxalic and hydrochloric acids were present at the evaporation stage; a curcumin-oxalic acid solution aged fairly enough by 4 hours' refluxing[3] was used in the latter case. Tartaric and *o*-phthalic acids are not only ineffective but also interfere with the color reaction in the presence of oxalic acid, as is shown in the 5th column. This may be attributed to the formation of borate

complexes* with the acids.

When acetone is used as the solvent in preparing a reagent solution, the reagent solution gives an intense color only in the presence of hydrochloric acid (cf. Nos. 8 and 9). A reagent solution prepared with diethyl ketone as the solvent gave a little coloration (cf. No. 10). However, because of insufficient data, no conclusion was possible except that the solution might not have a strong color-developing power, if, indeed, it has any.

The foregoing results indicate that the presence of oxalic acid is necessary in the color reaction between boric acid and curcumin when ethanol is used as the solvent in preparing a reagent solution and that the presence of both of hydrochloric and oxalic acids is required when acetone is used as the solvent. These facts suggest a close relation between the color reaction and the solvent of the reagent solution used.

The Aging Reaction of the Curcumin-Oxalic Acid Reagent.—*Absorption Spectrum.*—The aging phenomenon of a curcumin-oxalic acid reagent solution is pronounced in an ethanol medium. However, no interpretation of this phenomena has been made thus far. The structure[8,9] of curcumin reveals no possibility of a reaction whereby curcumin reacts with either oxalic acid or ethanol in the solution or is converted to a compound effective in the coloration of boric acid. The structure was confirmed by absorption spectroscopic studies. The infrared and near-ultraviolet absorption curves obtained by the author are shown in Figs. 1 and 2, respectively. The infrared absorption bands of a purified curcumin in the solid

I, Fig. 2). Only a little decrease in the absorbancy of a curcumin-oxalic acid reagent solution at 430 mμ was observed after it had been refluxed for 6 hr., indicating a good stability[3] of the reagent solution (cf. curves I and II). A decrease of about 10% was also observed after allowing reagent solution to stand at room temperature for 29 days. However, no appreciable change in the shape of the absorption curve was observed in either case.

A comparison of curve I, obtained for a curcumin solution, with curve II obtained for an aged reagent solution leads to curve V, analogous to the absorption curve of the ethyl oxalate (curve IV) but different from that of oxalic acid (curve VII). Seemingly this implies that the aging reaction may simply be the esterification reaction of oxalic acid with the ethanol used as a solvent rather than a reaction with which curcumin is concerned. This expectation was substantiated by the facts that a fresh curcumin solution to which ethyl oxalate has been added develops the color with boric acid as much as a sufficiently aged reagent solution does and that this is also the case when a refluxed ethanolic solution of oxalic acid has been added instead of the ester. On the contrary, a very weak coloration takes place with a refluxed ethanolic curcumin solution to which a fresh ethanolic solution of oxalic acid has been added. The results obtained are shown in Tables III and IV.

Diethyl	Acetone	0.404
Di-*n*-butyl	Ethanol	0.003
Di-*n*-butyl	*n*-Butanol	0.002

The Effects of Various Esters.—As Table IV shows, a curcumin solution to which diethyl oxalate has been added develops the color with boric acid independently of the solvent used in preparing the reagent solution. Dimethyl oxalate acts as does diethyl oxalate. Dibutyl oxalate (presumably any higher ester of oxalic acid than propyl oxalate) and esters other than that of oxalic acid do not contribute to the color reaction at all. These facts indicate the unique and important role of dimethyl oxalates in the color reaction.

Acetone has been frequently used as a solvent in place of ethanol in preparing a curcumin-oxalic acid reagent solution. It is dimethyl or diethyl oxalate but not oxalic acid which enables the reagent solution to develop the color with boric acid. The ester should be formed from alcoholic impurities in any acetone used. This will be seen from the fact that the purer the acetone, the lower the intensity of the resulting color, as Table V shows. No difference in the shape of the absorption curve was observed between the colored product obtained from an acetonic curcumin-oxalic acid solution and that obtained from an ethanolic curcumin-diethyl oxalate solution (cf. curves II and III, Fig. 3). It has been

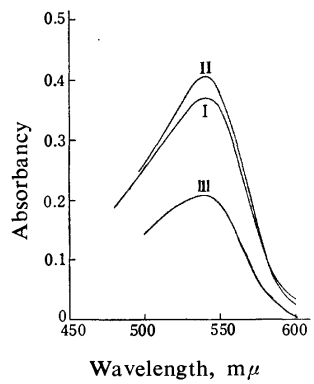

Fig. 3. Absorption spectra of ethanolic solutions of colored products.
Reagent solutions used are:
I: Curcumin-dimethyl oxalate as a methanolic solution
II: Curcumin-diethyl oxalate as an ethanolic solution
III: Curcumin-oxalic acid as an acetonic solution refluxed for 8 hr.

said[13] that commercial acetone some times contains methanol as an impurity. The author observed strong absorption bands at 206.5 and 214 mμ and around 1.9 μ which may be attributed to such impurities as water and alcohols present in commercial acetones.

With this view, the role of hydrochloric acid in the color reaction, whereby an acetonic reagent solution is able to develop a strong color with boric acid with the aid of hydrochloric acid (cf. Table I), may be understood as that of an acid catalyst in the esterification which occurs during evaporation for the color reaction. The presence of insufficient amounts of either of the esters in the reaction mixture may cause low and scattered results. For this reason,* the amounts of aqueous sample solutions assigned to the color reaction should be regulated[3] in order to retain ethyl oxalate against hydrolysis. The fact that an insufficiently aged reagent solution or a reagent solution containing relatively small amounts of oxalic acid results in low and scattered results[14] may also be attributed to insufficient amounts of ethyl oxalate formed in the reagent solutions. Seemingly, for the same reason, highly precise results may hardly be expected by using an acetonic reagent solution prepared with a commercially available acetone containing even relatively small amounts of alcoholic impurities, even if a working curve is renewed for a particular reagent solution prepared with a particular lot of acetone as the solvent.

The Composition of the Colored Product. — The composition of the colored product has been studied by Schulemberger[1] and by Clarke and Jackson.[15] Spicer and Strickland[2] have presented a structure for a red complex, rosocyanin,** formed in the presence of hydrochloric acid; they have found the boron curcumin ratio to be 1 to 2. They have also stated that another red complex, rubrocurcumin, having a 1 to 1 to 1 composition of boron, curcumin, and oxalic acid is formed when the reaction takes place in the presence of oxalic acid, and they have presented a structure for this complex. However, the foregoing discussion reveals that further studies of the colored products, especially of rubrocurcumin, are necessary.

No distinct difference in absorption maximum and shape was observed between absorption curves of ethanolic solutions of the colored product obtained in the presence of methyl and ethyl oxalate respectively (cf. curves I and II, Fig. 3). This might imply that the same product is obtained in the presence of either of the esters. The author leaves uncovered such problems as the role of the esters in the reaction mechanism and the composition of colored product, merely indicating that methyl or ethyl oxalate is necessary for the color reaction between curcumin and boric acid.

Experimental

The chemicals, such as curcumin, oxalic acid, ethanol and hydrochloric acid, the apparatus, the procedure of color development, and the method of measuring color intensity are the same as in the previous reports.[8,14,16] The other chemicals used were of JIS special or guaranteed grade. The methanol, acetone, and diethyl ketone used as solvents for preparing curcumin-oxalic acid solutions had been purified by distillation with a quartz apparatus after having been dried with anhydrous sodium carbonate. Variations will be indicated for particular cases.

The Effect of Various Acids on Color Development. — A boric acid solution containing 1.00 μg. of boron associated with either one of the other substances, 2.00 mg. (3.2 meq.) of oxalic acid, or 1 meq. of hydrochloric acid was subjected to the color reaction with a curcumin solution containing one of the various acids to be tested. The curcumin solution was prepared by dissolving 40.0 mg. of curcumin and 80.0 meq. of hydrochloric, oxalic, malonic, tartaric, *o*-phthalic or salicylic acid in 100 ml. of ethanol, acetone, or diethyl ketone. This mixture was refluxed for 4 hr. in order to promote an aging reaction such as might take place in the case of an ethanolic curcumin-oxalic acid solution. The refluxing was continued for 8 hr. in the case of an acetonic solution because of the low boiling point of acetone. The reaction product was extracted by ethanol, and the absorbancy was measured at 550 mμ. Blank tests gave absorbancies less than 0.033. The results are shown in Table I.

Absorption Spectra. — The infrared absorption spectrum of curcumin was obtained with a recording spectrophotometer, Hitachi Model EPI-2, a pellet consisting of 0.5 mg. of curcumin and 200 mg. of potassium bromide being used. The curcumin was purified by recrystallization[14] from ethanol until a constant melting point, 173°C, was obtained. The results are shown in Fig. 1. For obtaining the absorption spectra of the various solutions shown in Fig. 2, a manual spectrophotometer, Hitachi Model EPU-2, equipped with 1 cm. cells was used, the reference liquids being the same

13) T. Kuwata, "Yozai," Maruzen Co., Tokyo (1940), p. 258.

* The hydrolysis of the resultant colored product during evaporation for the reaction may not be a principal reason for regulating the volume of the aqueous sample solution to be taken. The coloration is observed at the end of the evaporation, and it proceeds further by baking.[3]

** Rosocyanin, so called by these workers, should be distinguished from the "rosocyanine" of the previous workers.[1,15]

14) M. Miyamoto, *Japan Analyst (Bunseki Kagaku)*, **12**, 115 (1963).

15) L. Clarke and C. L. Jackson, *Am. Chem. J.*, **39**, 696 (1908).

16) M. Miyamoto, *Japan Analyst (Bunseki Kagaku)*, **12**, 120 (1963).

as the solvents of the sample solutions. Ethanolic solutions of curcumin-oxalic acid, curcumin, oxalic acid, and diethyl oxalate were diluted with ethanol to an appropriate concentration just before the measurements so as to give appropriate absorbancies, although their concentration was originally 40.0 mg./100 ml. and 0.400 M as to the curcumin and oxalic acid equivalent respectively. For obtaining the absorption spectra of reaction products extracted by ethanol, a recording spectrophotometer, Hitachi Model EPS-2, and 1 cm. celles were used, the reference liquid being ethanol. The results are shown in Fig. 3.

Color Development with a Curcumin and an Oxalic Acid Solutions Prepared Independently.—An ethanolic solution of curcumin, 80.0 mg./100 ml., and one of 0.800 M oxalic acid were prepared. Two milliliter portions of the solutions were mixed together just before use, and the color-developing power of the mixed solutions was tested by using 1.00 μg. of boron. The test was also carried out after the solutions had been independently subjected to refluxing for 2 hr. The results are shown in Table III.

The Effects of Various Esters.—A reagent solution containing 40.0 mg. of curcumin and 40.0 mmol. of the various esters to be tested was prepared by dissolving the respective substances in methanol, ethanol, acetone, or *n*-butanol. The color-developing power of the solution was tested by using 1.00 μg. of boron. The esters tested were dimethyl, diethyl, and di-*n*-butyl oxalates. The results are shown in Table IV. When *n*-butanol was the solvent, two layers were formed by adding the reagent solution to a boric acid solution, and the system was not dried by the evaporation at 55°C leaving the solvent because of its high boiling point. In this case, it was assumed that drying completed when the aqueous layer had disappeared. None of the color-developing power was observed when the oxalate esters were replaced by any of the following esters: the dimethyl and diethyl esters of acetic, malonic, and *o*-phthalic acids, and methyl and ethyl salicylates.

Color Development with Curcumin and Oxalic Acid Dissolved in Various Purity Grades of Acetone.—Curcumin-oxalic acid solutions were prepared by using various purity grades of acetone as a solvent. Immediately after the preparation, the color-developing power of the solutions was tested by using 1.00 μg. of boron, to which 1.00 meq. of hydrochloric acid had previously been added. The test was also carried out after the solutions had been refluxed for 8 hr. The results are shown in Table V. Of the various grades of acetone, a spectroscopic-grade aceton was that of Eastman Kodak, and a purified acetone was obtained by the following procedure: acetone, JIS first grade, was stirred in the presence of powdered potassium permanganate for 3 days, then double distilled after dehydration with anhydrous sodium carbonate.

Summary

The coloration of microamounts of boric acid with an ethanolic solution takes place in the presence of oxalic, but not in that of other acids. Near-ultraviolet, visible, and infrared absorption spectroscopic studies have revealed that the aging reaction of an ethanolic curcumin-oxalic acid reagent solution is simply the esterification of the oxalic acid with the solvent used. The resulting diethyl oxalate is necessary to the color reaction. The role of the ester has not been interpreted yet; however, it is so unique that it can be performed only by dimethyl oxalate, not by the other esters. The esterification of oxalic acid in an acetonic reagent solution may be attributed to the presence of alcoholic impurities present in aceton used. The composition of the colored reaction product, rubrocurcumin, presented by Spicer and Strickland[2] has not been substantiated yet in relation to the necessity of the esters to the color reaction.

Studies of the Pyrimidine Derivatives. XXV. The Reaction of Alkoxycarbonylthiocyanates and Related Compounds with the Sodium Salt of Thiamine*

By Akira TAKAMIZAWA, Kentaro HIRAI and Keiko MATSUI

(Received May 22, 1963)

In previous papers of this series,[1,2] the syntheses of many *S*-alkoxycarbonylthiamine (I) and *O*,*S*-bis(alkoxycarbonyl)thiamine (II) derivatives have been reported. It has also been shown that *O*,*S*-bis(ethoxycarbonyl)thiamine (DCET) (IIa) has a thiamine activity approximately equivalent to that of thiamine hydrochloride (III) that it is highly absorbed when administered orally, and that the high thiamine level is maintained for a longer time than that of III.[3] In an attempt to obtain a reagent which can introduce the alkoxycarbonyl group into thiamine under mild conditions, the present authors first took up alkoxycarbonylthiocyanate (IV).

Dixon and Taylor[4] reported that potassium thiocyanate reacted with ethyl chloroformate and with acylchloride in acetone solutions to give ethoxycarbonylisothiocyanate (Va) and acylisothiocyanate (VIII) respectively. We reinvestigated the reaction of ethyl chloroformate with potassium thiocyanate and obtained two oily substances with b. p. 25.5~26.7°C/1.8 mmHg and b. p. 41.2~41.9°C/2.0 mmHg. The elementary analyses of both substances agreed with the formula $C_4H_5O_2SN$, and it was suggested that they were the isomeric each other. The infrared spectrum of the former showed absorptions at 1960~1990 cm^{-1} for the -N=C=S group and at 1750 cm^{-1} (C=O)

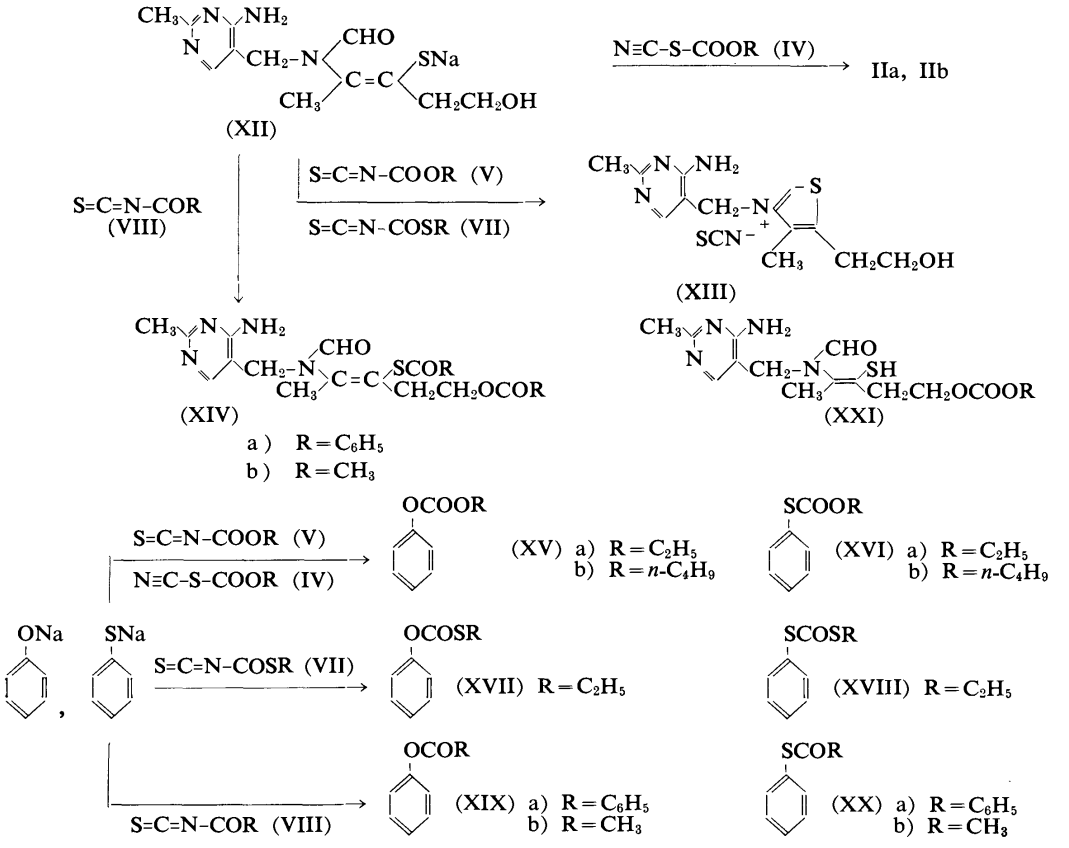

Chart 2

and at 1220~1260 cm^{-1} (C–O) respectively for the –N–C–O– group (Fig. 1). The spectrum of the latter showed the –C≡N band at 2190 cm^{-1}, and C=O and C–O bands at 1770 cm^{-1} and 1140~1190 cm^{-1} respectively for the –S–C–O– group (Fig. 4). From these results, the former should be ethoxycarbonyl isothiocyanate (Va), and the latter, ethoxycarbonylthiocyanate (IVa). These structures were also confirmed by their ultraviolet spectra. Hosoya, Tanaka and Nagakura[5] have shown that the ultraviolet spectrum of thioacetamide has the absorption maximum characteristic of the C=S group at 318 mμ (ε, 60). The ultraviolet spectrum of the former substance (isothiocyanate) showed the absorption maximum at 325 mμ (ε, 61.9). On the other hand, no absorption was found in the latter substance (thiocyanate) (Fig. 5).

3. After 45 min. at room temperature (—·—·)

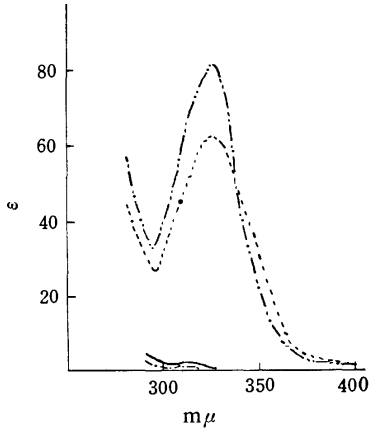

Fig. 5. Ultraviolet spectra of IVa (——), IVb (------), Va (—·—·—) and Vb (··—··—).

As it was interesting that two isomers were obtained in this reaction, investigations on analogous compounds were carried out. The reaction of butyl chloroformate with potassium thiocyanate gave two isomers, buthoxycarbonylthiocyanate (IVb) and butoxycarbonyl isothiocyanate (Vb), whose structures were confirmed by their infrared and ultraviolet spectra. The infrared spectrum of Vb showed the -N=C=S band at 1970~1990 cm^{-1}, the C=O band at 1750 cm^{-1} and the C–O band at 1240~1250 cm^{-1} for the $-\overset{}{N}-\overset{O}{\overset{\|}{C}}-O-$ group (Fig. 2), while that of IVb showed the -C≡N band at 2190 cm^{-1}, the C=O band at 1765 cm^{-1} and the C–O band at 1155~1165 cm^{-1} for the $-S-\overset{O}{\overset{\|}{C}}-O-$ group (Fig. 3). Moreover, although the ultraviolet spectrum of Vb exhibited the absorption maximum at 323 mμ (ε, 81) no maximum was observed with IVb (Fig. 5).

Further, the reaction of potassium thiocyanate with thioethoxycarbonylchloride (VI) gave only one product, the isothiocyanate (VII). Similarly, benzoylchloride and acetylchloride did not give the thiocyanates, but only the respective isothiocyanates, VIIIa[4,6] and VIIIb[4]. Their structures were confirmed by infrared

and ultraviolet spectra. When allyl chloroformate (IX) was used, however, besides a small amount of allyloxycarbonyl isothiocyanate (XI), allylisothiocyanate (X) was afforded, along with decarboxylation. X was identified by the infrared spectra of the product obtained by the reaction of allyl bromide with potassium thiocyanate in dimethylformamide.[7] These results are listed in Table I.

Next, the behaviors of these thiocyanate and isothiocyanate derivatives in relation to the sodium salt of thiamine (XII) were investigated. The reaction of alkoxycarbonylthiocyanate (IV) with thiamine sodium salt (XII) produced *O*,*S*-bis(alkoxycarbonyl)thiamine (II). However, when alkoxycarbonyl isothiocyanate (V) was used, a small amount of thiamine thiocyanate (XIII) was obtained as the only product. On the other hand, benzoylisothiocyanate (VIIIa) and acetylisothiocyanate (VIIIb) gave *O*, *S*-dibenzoylthiamine (XIVa)[8,9] and *O*, *S*-diacetylthiamine (XIVb)[8] respectively.

Analogously, IV or V reacted with simple phenol and thiophenol to give alkoxycarbonyl phenol (XV) and alkoxycarbonylthiophenol (XVI) respectively. Similarly, thioalkoxy carbonyl isothiocyanate (VII) gave thioalkoxycarbonyl phenol (XVII) or thioalkoxycarbonyl

7) S. Yoneda, H, Kitano and K. Fukui, *J. Chem. Soc. Japan, Ind. Chem. Soc.* (*Kogyo Kagaku Zasshi*), **65**, 1816 (1962).

8) T. Matsukawa and H. Kawasaki, *J. Pharm. Soc.* (*Yakugaku Zasshi*), **73**, 705, 709 (1953).

9) S. Yoshida, ibid., **74**, 993 (1954).

thiophenol (XVIII), and acylisothiocyanate (VIII) gave acylphenol (XIX) or acylthiophenol (XX). From these facts, it became clear that these thiocyanate or isothiocyanate derivatives can be used for alkoxycarbonylation or acylation reactions. These results are summarized in Table II.

Acyl- or alkoxycarbonylphenol and thiophenol are obtained in better yields than diacyl- and bis(alkoxycarbonyl)-thiamine respectively, possibly because phenol and thiophenol are much more reactive than the thiol-type thiamine. Thiocyanates gave a better yield than isothiocyanates. From Table II, the power of acylation and alkoxycarbonylation may tentatively ranked as follows:

$$RCOCl \geq (RCOSCN) > ROCOCl \geq RCONCS \geq ROCOSCN > ROCONCS$$

In the reaction with thiamine, it was noticed that IV, having reactive carbonyl, could react with thiamine, which has a relatively weak activity, and that at the first step, *S*-alkoxycarbonylthiamine (I) was formed and then a S→O rearrangement of the alkoxycarbonyl group occurred to give *O*-alkoxycarbonylthiamine (XXI) in the presence of alkali. The SH group of (XXI) was further alkoxycarbonylated to yield *O*,*S*-bis(alkoxycarbonyl)thiamine (II).[2]

While V seemed to have no carbonyl reactive enough to interact with the SH group of thiamine, VIII was much more active and reacted with XII to give *O*,*S*-diacylthiamine (XIV).

When a 2.5 molar equivalent of alkyl chloroformate was used in the reaction with potassium thiocyanate, IV and V were given in ratio of 1 : 1; this ratio was not changed by the increase of the mole of alkyl chloroformate. When an equimolar equivalent of alkyl chloroformate was used, however, V was given predominantly. Ethoxycarbonylthiocyanate (IVa) was thermally stable and did not change upon being boiled in ethanol in the presence of acetic acid. When a small amount of potassium thiocyanate or potassium acetate was added, however, IVa was readily converted into Va, even at room temperature. This conversion was traced by the infrared spectrum of this reaction mixture. As is shown in Fig. 4, the N=C=S and N–C–O bands increased with the decrease in the C≡N and S–C–O bands. It was considered that IV would convert into V by the reaction with potassium thiocyanate.

The mechanism of these reactions may be explained as follows: In an acetone solution the thiocyanato ion takes the form of an ion pair, and the S site or N site of this ion attacks the carbonyl carbon of acylchloride to give acylthiocyanate (XXII) and acyl isothiocyanate (VIII) as the respective transient products. Since XXII was considered to be the powerful acylation agent, however, it reacted with the thiocyanato ion to yield the stable acylisothiocyanate (VIII).

In the same manner, the reaction between the thiocyanato ion and alkyl chloroformate gives alkoxycarbonylthiocyanate (IV) and isothiocyanate (V). However, as the activity of IV is considerably weaker, the excess of alkyl chloroformate consumes the thiocyanato ion and IV is not able to participate in the reaction with the thiocyanato ion. As a result, IV and V are isolated in the reaction mixture.

Experimental

Ethoxycarbonylthiocyanate (IVa) and Ethoxycarbonylisothiocyanate (Va).—Into a solution of 244 g. (2.5 mol.) of potassium thiocyanate in 2.5 l. of acetone was added 633 g. (5.75 mol.) of ethyl chloroformate dropwise with stirring at room temperature. After the solution had been stirred for 4 hr. at room temperature, the separating potassium chloride was filterd off and the filtrate was concentrated. Distillation of the residue yielded 200.5 g. of the liquid with a b. p. of 43~58°/6.0 mmHg. The fractional distillation of this liquid (119.1 g.) gave 32.1 g. of IVa and 26.5 g. of Va.

IVa; b. p. 25.5~26.7°C/1.8 mmHg. $n_D^{25.3}$ 1.4930.
Found: C, 36.79; H, 4.06; N, 10.40; S, 24.07. Calcd. for $C_4H_5O_2NS$: C, 36.63; H, 3.84; N, 10.68; S, 25.21%.

Va: b. p. 41.2~41.9°C/2.0 mmHg.*1 $n_D^{25.3}$ 1.4570.
Found: C, 36.86; H, 4.33; N, 10.13. Calcd. for $C_4H_5O_2NS$: C, 36.63; H, 3.84; N, 10.68%. λ_{max}^{EtOH} 325 mμ (ε, 61.9).

Butoxycarbonylthiocyanate (IVb) and Butoxycarbonylisothiocyanate (Vb).—To a solution of 9.8 g. (0.1 mol.) of potassium thiocyanate in 100 cc. of acetone 27.2 g. (0.2 mol.) of butyl chloroformate was added dropwise. Treating it as above gave 8.7 g. of the liquid with a b. p. of 38~74°C/4~5 mmHg. The fractional distillation of this liquid (35 g.) gave 10 g. of VIb and 6.0 g. of Vb.

IVb: b. p. 54.0~55.5°C/2.0 mmHg. $n_D^{24.5}$ 1.4545.
Found: C, 44.87; H, 5.96; N, 8.66. Calcd. for $C_5H_9O_2SN$: C, 45.25; H, 5.69; N, 8.79%.

Vb: b. p. 59.0~61.0°C/6.0 mmHg. $n_D^{24.5}$ 1.4820.

Found: C, 42.87; H, 3.81; N, 9.57. Calcd. for $C_5H_5O_2NS$: C, 41.95; H, 3.52; N, 9.78%.

***O*, *S*-Bis(ethoxycarbonyl)thiamine (IIa) Hydrochloride.**—Into the suspension of 3.6 g. (0.01 mol.) of the sodium salt of thiamine[10] (XII) in *n*-propyl alcohol was added 3.3 g. (0.025 mol.) of IVa dropwise with stirring. During this reaction, the reaction mixture was maintained at pH 8.8～9.0 by the addition of alcoholic sodium ethoxide. After stirring for 2 hr. at room temperature, *n*-propyl alcohol was removed by vacuum distillation. Residue was dissolved in 20% hydrochloric acid and after being washed with ether, extracted with chloroform thoroughly. This chloroform extract was dried over anhydrous magnesium sulfate, and the chloroform was removed. The sirup obtained was induced to crystallize by treating it with ether and then recrystallized from the mixture of ethyl acetate and ethanol to give 1.26 g. (26.2%) of IIa hydrochloride in the form of colorless prisms m.p. 121～123°C. This product was identified with an authentic sample of IIa hydrochloride[1] by infrared spectra.

***O*, *S*-Bis(butoxycarbonyl)thiamine (IIb) Hydrochloride.**—This was prepared from 3.6 g. (0.01 mol.) of the sodium salt of thiamine (XII) in EtOH and 3.2 g. (0.02 mol.) of IVb as described above. The yield of IIb hydrochloride was 1.1 g. (21.2%); m. p. 86～88°C. The infrared spectrum of this product was identical with that of an authentic sample of IIb hydrochloride.[2]

Thiamine Thiocyanate (XIII).—This compound was obtained in a trace amount from XII by the reaction of either Va, Vb, or VII after treating it as above. It was then recrystallized from water to give colorless prisms, m. p. 180～181°C (decomp.). The infrared spectrum of this product was identical with that of an authentic sample of XIII.

***O*, *S*-Dibenzoylthiamine (DBT) (XIVa).**—To a suspension of 2.8 g. (0.06 mol.) of XII in ethanol 2.5 g. (0.15 mol.) of VIIIa was added dropwise as described above for the preparation of II. After the removal of ethanol, the residue was dissolved in ethyl acetate and washed with water and a diluted sodium hydroxide aqueous solution. After being dried over anhydrous magnesium sulfate, ethyl acetate was removed to give colorless crystals. Recrystallization from diluted ethanol gave 0.98 g. (25.5%) of colorless prisms; m. p. 172°C. The infrared spectrum was identical with that of the sample obtained by the other method.[8,9]

Found: C, 63.58; H, 5.43; N, 11.24; S, 6.62. Calcd. for $C_{26}H_{26}O_4N_4S$: C, 63.65; H, 5.34; N, 11.42%.

***O*, *S*-Diacetylthiamine (DAT) (XIVb).**—To a suspension of 3.9 g. (0.11 mol.) of XII in ethanol 2.2 g. (0.22 mol.) of VIIIb was added dropwise as described above for the preparation of II. After the removal of ethanol, the residue was dissolved in water and extracted with benzene. This benzene extract was shaken with 3% acetic acid, and the acetic acid layer was thoroughly extracted with chloroform. The chloroform extract was dried over anhydrous magnesium sulfate, and the chloroform was removed. The residual sirup was treated with ether to give colorless crystals; yield 1.35 g. (34.0%). Recrystallization from benzene-petroleum benzine gave colorless prisms (m. p. 118～119.5°C), whose infrared spectrum was identical with that of the sample obtained by the other method[8].

Found: C, 52.44; H, 6.12; N, 15.00. Calcd. for $C_{16}H_{22}O_4N_4S$: C, 52.44; H, 6.05; N, 15.29%.

The Acylation and Alkoxycarbonylation of Phenol and Thiophenol.—To a suspension of 0.03 mol. of dry sodium salt of phenol or thiophenol in ethanol 0.03 mol. of various alkoxycarbonylthiocyanates, isothiocyanates or acylisothiocyanates were added. After the mixture had been stirred for 2 hr. at room temperature, the ethanol was removed ether was added to the residue, and the separated sodium thiocyanate was filtered off. The esher solution fractionally distilled.

The Infrared Spectral Change of Ethoxycarbonyl Thiocyanate (IVa) in the Presence of

NOTES

Selective Reduction of Phosphatides with Lithium Aluminum Hydride. II. Reductive Cleavage of Phosphatidic Acid

By Chieko URAKAMI and Mitsuko OKADA

(Received February 20, 1963)

In a previous paper[1] we had reported that the reductive cleavage of lecithin with lithium aluminum hydride in anhydrous ether gave rise to L, α-glycerylphosphorylcholine, a finding which was later confirmed by De Haas and Van Deenen[2] by the resynthesis of L, α-lecithins and L, α-lysolecithins from L, α-glycerylphosphorylcholine prepared by our method. A similar cleavage of the two acyl groups of the phosphatidic acid molecule may be attained by controlling reaction conditions so as to give L, α-glycerylphosphoric acid if no further reduction of the phosphate moiety occurs.

The method described by Kates[3] was followed for the preparation of the sodium salt of phosphatidic acid by subjecting purified (by column chromatography) egg yolk lecithin to the action of the lecithinase C of carrot roots and for the liberation of the free acid. The analytical results, the examination by paper chromatography,[4] and analyses for phosphorus and ester bond[5] indicate that the product so obtained consisted of approximately 70% phosphatidic acid and of some such as impurities fatty acids and their esters.

Difficulty was experienced in purifying the sample because phosphatidic acid is known to be highly labile; it is hydrolyzed even on exposure to moist air* or its ethanol solution is allowed to stand at room temperature.[6]

Since phosphatidic acid is a monoester of orthophosphoric acid, an extra mole of the hydride reagent would be required to compensate its acidity in addition to the one mole needed for the cleavage of the two fatty acid residues. Therefore, mole ratios higher than 1 : 2 (phosphatidic acid : lithium aluminum hydride) were considered in the present study; the reaction time was varied from 10 to 30 min. within a temperature range of 8~15°C. The procedure employed for reduction of the free acid in anhydrous ether with lithium aluminum hydride was essentially the same as that described earlier.[1] The aqueous phase separated from the reaction mixture was passed through a small column of Amberlite IR-112 and

the eluate and the ethereal phase initially separated from the reaction mixture were analyzed for phosphorus, α-glycerylphosphoric acid-phosphorus[7,8] and ester bond.[5] The best conditons found from these studies appeared to be a mole ratio of phosphatidic acid to the hydride reagent of 1 : 2, at 10°C, and for 20 min; a typical example of the results obtained is shown in Table I.

TABLE I. RECOVERY OF PHOSPHORUS IN THE AQUEOUS AND ETHEREAL PHASES

Reaction conditions:		
Rhosphatidic acid : $LiAlH_4$ = 1 : 2, 10°C, 20 min.		
Sample wt., 18.2 mg. (equivalent to 492 μg. of α-GP-P)		
Reaction products:		
Aqueous phase	P_i, μg.	0.0
	α-GP-P, μg.[a]	456 ± 6
	%	92.6 (97.9)
	α-GP-P, μg.[b]	473 ± 2
Ethereal phase	Ester[c]	trace
	Total P	—

P_i stands for inorganic phosphorus, α-GP-P α-glycerylphosphoric acid-phosphorus.

a) Burmaster's method.[7]

b) Voris' method.[8]

c) The quantitative method[5] was employed; a trace amount detected may be due to the presence of fatty acid esters. The figures in parentheses are corrected for a loss of phosphorus during the course of elution through a column of Amberlite IR-112, the average recovery of the lithium salt of glycerylphosphoric acid being 94.5%.

An attempt to isolate the reaction product in the aqueous phase according to the method of Long and Maguire[9] was made with 200 mg. of the phosphatidic acid, but an amount of the barium salt of glycerylphosphoric acid obtained was so small that its rigorous purification could not be attained. Consequently, examination of its optical rotation was not possible (its specific rotation is known to be small, $[\alpha]_D = -1.2$[10]). However, the analytical results revealed that the sample isolated contained 77% α-glycerylphosphoric acid, the chief impurity being barium carbcnate; the amount of periodate consumed was equivalent to the content of α-glycerylphosphoric acid-phosphorus determined by Burmaster's method,[7] and no β-glycerylphosphoric acid-phosphorus was detected.

The fact that L, α-lecithin when treated similarly with the hydride reagent, gives rise to L, α-glyceylphosphoric acid[1] provides the reasonable assumption that the α-glycerylphosphoric acid obtained here retains the L-configuration of the natural acid. Further work is indicated, of course, but this method, involving a single-step reaction appears, to be preferable for the structural determination of naturally-occurring phosphatidic acids to the diazomethanolysis recommended by Baer,[11] which requires hydrogenation previous to interaction with diazomethane.

A Study of the Structure of Pyridine Extracts from Coals by High Resolution Nuclear Magnetic Resonance Spectroscopy

By Gen TAKEYA, Mitsuomi ITOH, Akira SUZUKI and Susumu YOKOYAMA

(Received April 30, 1963)

Hitherto, various studies of hydrogen distribution in coals have been made by such methods as infrared[1] and broad-line NMR spectroscopy.[2] Of these analytical methods, although it would seem that the high resolution NMR method has some important advantages, only a few papers[3] have been published reporting on studies of the constitution of coal or coal-like materials made using it.

The present report deals with the constitution of the pyridine extracts of some Japanese coals, a study based upon their hydrogen distribution. The pyridine extracts of Yubari, Taiheiyo, Sumiyoshi and Sohya coal were separated from the solvent, dried and redissolved into deutero-pyridine, C_5D_5N. The C_5D_5N solutions (18~20%) of the coal extracts thus prepared were examined by NMR spectroscopy at 60 Mc. with a JNM-3H-60 NMR spectrometer.

The distribution of hydrogen was estimated from the intensities of the three different NMR bands. H_a represents the aromatic hydrogen atom which was situated ca. 7.5 p.p.m. from the tetramethyl silane peak in the NMR spectra; H_α, the hydrogen atom at α-positions to the aromatic rings (ca. 2.6 p.p.m.), and H_o, the hydrogen on the other saturated carbon atoms (ca. 1.5 p.p.m.). It has been confirmed by Ikenoue that the resonance peak for phenolic hydrogens in a pyridine solution appeared at a far lower position of the applied magnetic field than 8.5 p.p.m.[4]

From the contents of the different types of hydrogen atoms and the elementary analysis, the structural parameters: f_a (carbon aromaticity), σ (the measure of the substitution of the aromatc systems) and H_{au}/C_a (the aromatic hydrogen-to-carbon ratio of the hypothetical unsubstituted aromatic material) which were introduced by Brown et al.[3a] have been calculated for the pyridine extracts of coals. A new parameter of the length of the aliphatic carbon chain is proposed by the present authors

TABLE I. ANALYTICAL AND STRUCTURAL DATA OF THE PYRIDINE EXTRACTS

Coal sample		Yubari	Taiheiyo	Sumiyoshi	Sohya

on the basis of the following relation: $\mathbf{H}_o/\mathbf{H}_\alpha=(\mathbf{H}_o/\mathbf{H})/(\mathbf{H}_\alpha/\mathbf{H})$. In the derivation of the above four parameters, nitrogen and sulfur (less than 2% d. a. f.-basis) in coal constituents have been disregarded. Furthermore, two assumptions were made regarding the constitution of coal: (1) all oxygen elements are attached directly to the aromatic systems; i. e., practically all oxygen occurs as phenolic OH and quinone groups, and (2) the aromatic rings are not directly linked by a C–C bond.[3a]

Assumption 1 may be accepted on the basis of our experimental results,[5] which show that more than 60% of the oxygen involved in the four parent sample coals appears as phenolic OH and quinone groups; assumption 2 is reasonable since a high degree of C–C crosslinking between aromatic systems is unlikely because of the large steric interactions of the aromatic systems involved. A realistic value for x and y in Brown's relations appears to be close to 2, as Brown et al. have set forth.[3a]

The structural parameters, f_a, σ, $\mathbf{H}_{au}/\mathbf{C}_a$ and above $\mathbf{H}_o/\mathbf{H}_\alpha$, calculated on the above assumptions, together with the features for the mean structure which are inferred from these parameters, are given in Table I.

The NMR Spectrum of Acrylonitrile

By Kazunaga MURAYAMA and Kenkichi NUKADA

(Received June 25, 1963)

The NMR spectrum of acrylonitrile at the resonance frequency under 60 Mc. shows a very complicated ABC pattern, and the interpretation of the spectrum cannot be carried out without utilizing a high speed computer.

On the other hand, at the resonance frequency of 100 MC,* the spectrum showed a nearly AMX-type pattern (Fig. 1), and it was very easy to obtain the relative chemical shifts and spin coupling constants by using a simple rule of line splitting (case A).

A slightly more accurate treatment, in which the spin system was assumed to be ABX, was also carried out according to the method of Pople et al.[1] (caseB). In the latter case, the absolute values of each parameter were not

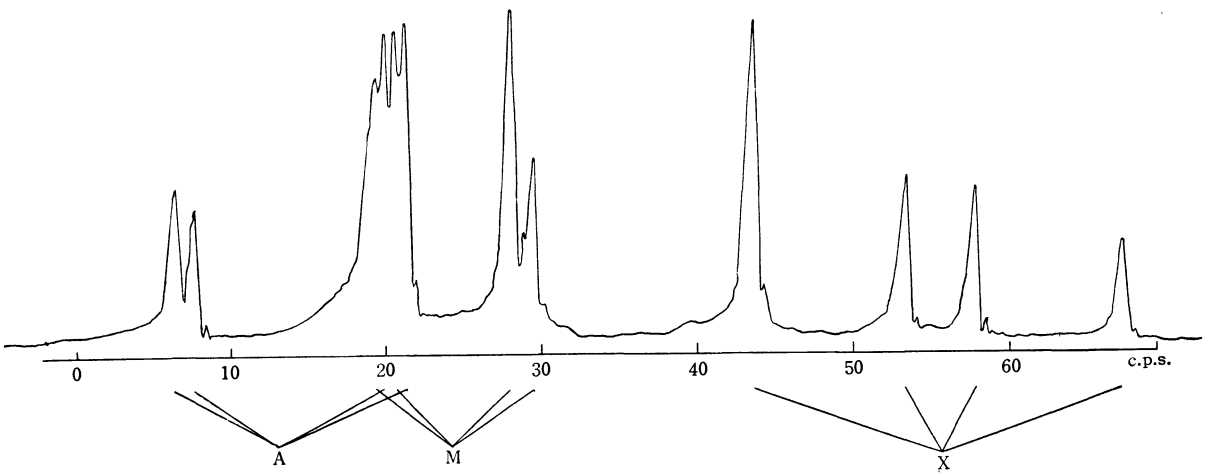

Fig. 1. NMR spectrum of acrylonitrile at 100 Mc.

* The NMR spectrum was recorded with a Varian HR-100 spectrometer.

The Production of High Specific Activities of Tin

By Shouzow FUKUSHIMA, Satori HAYASHI,[*1] Sanshiro KUME, Hideo OKAMURA, Kiyoteru OTOZAI, Koh SAKAMOTO,[*2] Ryuzo TSUJINO[*3] and Yasukazu YOSHIZAWA

(Received January 5, 1963)

Radioactive substances of a high specific activity are very useful in nuclear spectroscopy and in the tracer technique. In this work the production of the two long-lived radioactivities of tin, ^{113}Sn and ^{117m}Sn, was studied by means of cyclotron bombardment. These nuclides can be obtained separately from targets of a natural isotopic abundance by means of a cyclotron with a fixed frequency, provided the two reactions, ^{113}In(d, 2n)^{113}Sn and ^{115}In(α, pn)^{117m}Sn, are aimed at respectively. The purposes of the present investigation are to determine the thick target yield for these reactions and to establish the procedure for preparing the high specific activities of tin from the irradiated target.

Maxwell et al.[1] have reported procedures for the preparation of high specific activities of tin by means of alpha particle-induced reaction on cadmium of a natural abundance. In this case ^{113}Sn and ^{117m}Sn are produced concomitantly from the reactions ^{110}Cd(α, n)^{113}Sn, ^{111}Cd(α, 2n)^{113}Sn and ^{114}Cd(α, n)^{117m}Sn. In the present work, the thick target yields for these nuclides have also been determined.

Experimental

Thick Target Yield.—*Bombardment.*—Indium and cadmium plates of about 150 mg./cm^2 were bombarded with 11.2 MeV. deuterons or 22.1 MeV. alpha particles from the 110 cm. cyclotron of Osaka University. The target materials were 99.9% chemically pure. They were soldered on a water-cooled block of copper and irradiated at the "external target" position. The incident particle energies were degraded with aluminum absorbers and estimated from the range-energy relation.[2] The beam current was kept as low as about 2 μ amp. to prevent the target materials from melting. Total activations of about 2 μ amp.$\times$0.5 hr.=3600 microcoulombs were performed.

The total numbers of incident projectiles were determined by the use of monitor foils, by, that is, chromium and silver foils for deuterons and alpha particles respectively. The excitation function for the ^{52}Cr(d, 2n)^{52}Mn reaction[3] and the ^{107}Ag+$\alpha\rightarrow$ ^{109}Cd reaction[4] were used for the calibration.*

Source Preparation.—The procedures of chemical separations before the measurement of the tin activities were as follows. The irradiated cadmium target was dissolved in aqua regia. About 20 mg. of a iron(III) carrier was added, and the tin activity was coprecipitated with ferric hydroxide from a 2 N ammonia solution. The precipitate was then redissolved in 2 ml. of diluted hydrochloric acid.

The irradiated indium target was treated with hydrochloric acid, and a 20 mg. carrier of tin was added. The tin activity was separated from a 0.5 N hydrochloric acid solution as a sulfide. The sulfide was dissolved in 2 ml. of concentrated hydrochloric acid.

Activity Measurement.—The tin activities produced were measured with a gamma ray scintillation spectrometer. After the interfering activities had decayed off after several days, the activities of the 2 ml. liquid sample mentioned above were measured spectrometrically in a 1(3/4)$''\times$2$''$ well-type NaI scintillator. The photopeaks of the 390 keV. gamma ray from ^{113}Sn$-^{113m}$In and the 160 keV. gamma ray from ^{117m}Sn were measured. When both activities were contained, the contribution of the Compton part of the 390 keV. gamma ray to the 160 keV. photopeak was subtracted.

The counting efficiencies of the photopeaks (counting rates per disintegration rate) for both activities were calculated from several data as shown in Table I.

The Obtained Thick Target Yield.—The Thick target yields of the In+d, In+α and Cd+α reactions at some incident particle energies are summarized in Table II.

The Excitation Function for the ^{115}In(α, pn)^{117m}Sn Reaction.—The low values of thick target yields for the ^{115}In(α, pn)^{117m}Sn reaction suggest that the studied region of alpha particle energies is too low for the high-yield production of the activity. In order to study further the energy dependency of the yields in the higher region, the excitation function up to 40 MeV. for this reaction was obtained

by the use of the stacked foil method.

Indium was electrolytically deposited in a 10 mg./cm² thickness on a silver plate of 25 mg./cm², and the indium foil was stacked together with the backing. The excitation function was measured in the energy region of 40~22 MeV. with alpha particles of 40 MeV. from the 160 cm. cyclotron of the Institute for Nuclear Study, the University of Tokyo, and in the 22~12 MeV. region with alpha particles of 22 MeV. from the 110 cm. cyclotron of Osaka University. The incident energy for each foil was estimated from the range-energy relationship in silver.[2] After the appropriate chemical isolation of tin, the radioactivity of ^{117m}Sn was measured by the same method. The observed cross section was corrected for the straggling effect, the foil thickness and the initial beam energy spread.[4] The correction amounts, for example, to about 13% at 17 MeV.

The cross sections thus obtained for the $^{115}In(\alpha, pn)^{117m}Sn$ reaction are given in Table III and are expressed as the excitation function in Fig. 1. The thick target yield curve for this reaction calculated from the excitation function and the range-energy relation is shown in Fig. 2, together with the values of the thick target yields already given in Table II. Figure 2 shows that the yield at 40 MeV. is about twentyfold that at 20 MeV.

Flags: standard deviations in experimental values

from a 0.5 N hydrochloric acid solution. The sulfide was dissolved in a small amount of aqua regia, and the solution was evaporated almost to dryness. The residue was dissolved in 0.5 N hydrochloric acid. The tin activity was then again coprecipitated with copper sulfide from the solution containing 10 mg. each of indium and of cadmium carriers, After three coprecipitations, the copper sulfide with the tin activity was dissolved in a small amount of aqua regia, and then with water and hydrochloric acid; 10 ml. of a 2 N hydrochloric acid solution was obtained. The solution was passed through a column, 8 mm. in diameter, containing 3 ml. of Amberlite CG-400. After a complete elution of the copper by 30 ml. of 2 N hydrochloric acid, the carrier-free tin activity was eluted out with 25 ml. of 2 N nitric acid.

The irradiated cadmium target was dissolved in aqua regia. The solution was diluted with water, and 20 mg. of a iron(III) carrier was added. The tin activity was coprecipitated with ferric hydroxide from a 2 N ammonia solution. The reprecipitated ferric hydroxide was dissolved in hydrochloric acid, and 20 mg. each of indium and of copper carriers were added. Hydrogen sulfide was passed into the 0.5 N hydrochloric acid solution, and the tin activity was coprecipitated with copper sulfide. From this precipitate the carrier-free activity in a nitric acid solution was obtained by the same procedures as in the case of the indium target mentioned above.

Efficiencies of the carrier-free isolations of the tin activity are shown in Table IV. The nitric acid solution thus obtained has about 1 mg. of residue.

Table IV. Efficiencies of carrier-free isolations of the tin activity

Target	Chemical yield of Sn activity, %	Decontamination factor of In	Cd
In	87	>10^6	>10^3
Cd	94		

Electrolytic Deposition.—In order to obtain a sample for beta ray spectrometry, the activity was collected by means of an internal electrolysis from a 0.3 N hydrochloric acid solution. The apparatus for the internal electrolysis shown in Fig. 3. The anode is a zinc plate, while the cathode is a thin layer (10 μg./cm²) of gold deposited in vacuo on a thin "Mylar" tape (500 μg./cm², 2 mm.×15 mm.). About 80% of the activity was deposited in 20 hr. It must be noted that the tin activity is dissolved back into the hydrochloric acid solution in a moment if the external circuit is cut off.

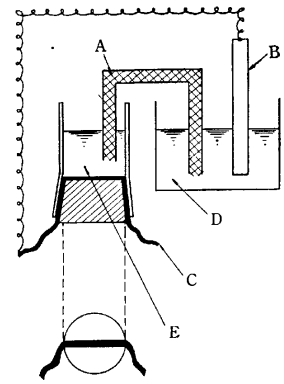

Fig. 3. Apparatus for the internal electrolysis.
A: Salt bridge (3% agar-agar, KCl satd.)
B: Zn-anode
C: Au-cathode (deposited in vacuo on "Mylar")
D: Anodic electrolyte (0.1 N $ZnCl_2$)
E: Cathodic electrolyte (0.3 N HCl, carrier-free tin activity, 0.2 ml.)

Discussion

If either ^{113}Sn or ^{117m}Sn is required separately, the In+d or In+α reactions respectively

may be used. However, if these nuclides can co-exist, the Cd+α reaction is preferable because of high thick target yield in the studied energy range and because of the higher melting point of cadmium than of indium.

The values of the thick target yield observed directly for the $^{115}In(\alpha, pn)^{117m}Sn$ reaction are in good agreement with the values from the excitation function at the energies lower than 21 MeV. If the values for the higher energies are necessary, the calculated values are available.

The separation procedure for the carrier-free activity by coprecipitation and ion exchange herein presented is efficient despite its simplicity in comparison with the distillation method.[1]

The tin activity was deposited internal-electrolytically on a gold film on "Mylar" foil (2 mm. × 15 mm.) and was used as a sample source for the beta ray spectrometer of Osaka University.[5] The L and M conversion electrons of the 159 keV. gamma ray were resolved separately.[6] Thus, the specific activity of the sample was sufficiently high so as to let the spectrometer exhibit its resolving power (0.2%) fully, even at the low energy region.

Summary

The production of high specific activities of tin, ^{113}Sn and ^{117m}Sn, with a cyclotron had been studied. Thick target yields for the reactions (A) $^{113}In(d, 2n)^{113}Sn$, (B) $^{115}In(\alpha, pn)^{117m}Sn$ and (C) $^{110}Cd(\alpha, n)^{113}Sn + ^{111}Cd(\alpha, 2n)^{113}Sn + ^{114}Cd(\alpha, n)^{117m}Sn$ were determined for several incident particle energies. The reactions A and B are available for the production of the single tin activity. Reaction C is preferable to the others in the total yields of tin activities for the energy range studied, i.e., up to the energy of about 5 MeV. per nucleon of the incident particle. A thick target yield for reaction B has also been obtained from the excitation function up to the alpha particle energy of 40 MeV. The procedures for the carrier-free isolation of the tin activity from indium and cadmium targets by coprecipitation and ion exchange have also been described.

The authors are indebted to Dr. Y. Koh of Osaka City University for his help throughout the work. They are also grateful to the members of the cyclotron group of Osaka University, and to both the cyclotron and radiochemical groups of the Institute for Nuclear Study, the University of Tokyo.

A Theoretical Assignment of the ESR Spectra of Cyclohexadienyl and Phenyl Radicals

By Keiji MOROKUMA, Shun-ichi OHNISHI, Takao MASUDA and Kenichi FUKUI

(Received January 23, 1963)

The assignment of observed unknown ESR spectra to a certain radical is often liable to involve some ambiguities; for example, the radicals from benzene and substituted benzenes cause trouble.

Fischer[1] irradiated benzene, toluene, ethylbenzene, cumene, fluorobenzene and chlorobenzene with an electron beam at 77°K and in all of the compounds studied observed the same spectrum, which consisted of a main triplet of the splitting of 50±2 gauss, each component of which separated into four triplets with the splittings 10.6±0.5 gauss (quartet) and 2.6± 0.2 gauss (triplet). He ascribed the spectrum to the cyclohexadienyl radical, $C_6H_7\cdot$, with the largest splitting (50 gauss) said to be that of the two methylene protons, with the splitting (10.6 gauss), that of the two ortho and the one para protons, and with the smallest splitting (2.6 gauss), that of the two meta protons.

Ohnishi et al.[2] studied ESR spectra of

1) H. Fischer, *Kolloid Z.*, **180**, 64 (1962).

2) S. Ohnishi, T. Tanei and I. Nitta, *J. Chem. Phys.*, **37**, 2402 (1962).

radicals produced by the electron beam irradiation at 77°K of benzene, toluene, chlorobenzene, phenylcyclohexane, benzoic acid and xylenes. For benzene at observation temperatures lower than −50°C, they obtained a triplet spectrum with a quartet structure, each component having a finer triplet structure with splittings of 47.5 gauss (triplet), 10.4 gauss (quartet) and 2.5 gauss (triplet). At the higher temperature this spectrum disappeared, while there remained another singlet spectrum with the width of 25 gauss. They attributed the former complex spectrum, which is very close to that observed by Fischer, to the cyclohexadienyl radical, as did Fischer, while the latter singlet spectrum was ascribed to the phenyl radical, $C_6H_5\cdot$. Kuwata[3] observed a broad spectrum from UV-irradiated halogenobenzenes which was considered to originate from the phenyl radical.

On the other hand, Chkheidze et al.[4] irradiated benzene with an electron beam and observed a triplet spectrum with the intensity ratio of 1 : 2 : 1 and with the splitting of 45.0±1.5 gauss; each component of this spectrum separated into a quartet with the splitting of 10.2±0.5 gauss. Though the spectrum seems to resemble very closely those found by Fischer and by Ohnishi et al., Chkheidze et al. assigned the spectrum to the phenyl radical, where the largest triplet was assigned to the two ortho protons and the quartet, to the two meta and one para protons.

As we have explained here, the assignment of the two kinds of observed spectra, the triplet with quartet structures and the broad singlet, is a matter still to be settled. Judging from the historical evidence that theoretical calculations and discussions have offered a great foundation for the interpretation of ESR spectra, it seems to be worthwhile to make a calculation on cyclohexadienyl and phenyl radicals and to compute the spin densities or the coupling constants of protons. Recently Fischer[5] presented a molecular orbital calculation on the spin density of the cyclohexadienyl radical to support his assignment. In the present paper the authors will make a valence bond calculation on both radicals, will compare the results with the two observed spectra, and will give the theoretical choice between the two assignments of the spectra.

The Valence Bond Calculation of Proton-coupling Constants in the Cyclohexadienyl Radical

The Model of the $C_6H_7\cdot$ Radical. — The cyclohexadienyl radical is treated as a system

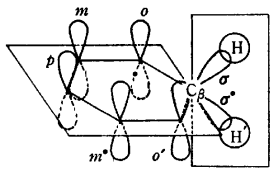

Fig. 1. Model of C_6H_7 radical.

consisting of 9 electrons on the following 9 atomic orbitals (Fig. 1):

- o: 2pπ orbital on one of the ortho carbons
- o': 2pπ orbital on the other ortho carbon
- m: 2pπ orbital on one of the meta carbons
- m': 2pπ orbital on the other meta carbon
- p: 2pπ orbital on the para carbon
- σ: Hybridized orbital on the carbon β directed to the AO H
- σ': Hybridized orbital on the carbon β directed to the AO H'
- H: Hydrogen 1s orbital on the hydrogen bonding with σ
- H': Hydrogen 1s orbital on the other hydrogen bonding with σ'

The plane on which the σ H and the σ' H' bonds are located is always assumed to be perpendicular to the molecular plane. As the hybridization of the methylene carbon, C_β in Fig. 1, and the bond length of the C_β–C_{ortho} bond do not seem to have been determined experimentally, we employed the following four different sets of configurational parameters in order to see the variation of the calculated results arising from these configurational differences.

a) The hybridization of the carbon β in the C_β–C_{ortho} bonds is assumed to be sp^2, which implies that the C–C bonds in benzene are not affected by a hydrogen addition; therefore, the hybridization of the σ and σ' orbitals is sp^5 (s nature 1/6 and p nature 5/6). The C_β–C_{ortho} bond length (r) is assumed to be 1.39Å, the C–C bond length in benzene.

b) The same hybridization as in a). The C_β–C_{ortho} bond length is 1.54Å, the bond length of a normal C–C single bond.

c) The carbon β is assumed to have the tetrahedral configuration: that is, all the valence orbitals of the carbon β are sp^3 hybridized. The C_β–C_{ortho} bond length is 1.39Å.

d) The same hybridization as in c). The bond length is 1.54Å.

In all of the four sets, the C_o–C_β–$C_{o'}$ angle is assumed to be 120°; this choice of angle affects the calculated value of the spin density scarcely at all.

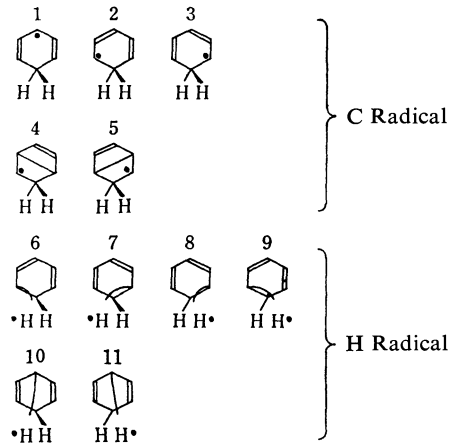

Fig. 2. Canonical structures taken into calculation of C_6H_7.

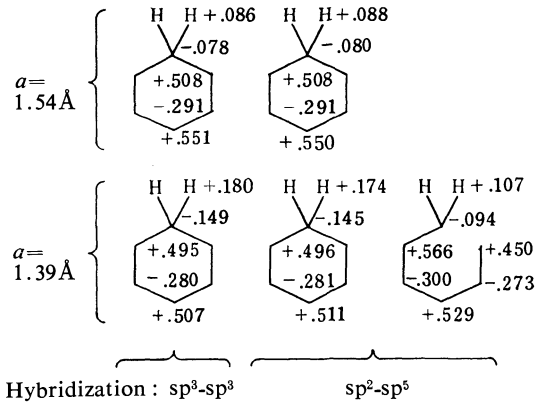

Fig. 3. Calculated spin density of C_6H_7 radical.

Canonical Structures. — Of all the possible canonical structures that have maximum bondings, 11 structures of lower energies corresponding to Kekulé and Dewar structures are taken into account on calculation. They are illustrated in Fig. 2.

Atomic Integrals.—The method of the evaluation of the necessary atomic integrals is the same as in the previous paper,[6] mainly the method of van Vleck[7] and of Karplus et al.[8], except for Altman's[9] exchange integrals between $p\pi$ orbitals. The values of the $p\pi$-$p\pi$ exchange integrals employed are $N_{\pi\pi\pi\pi}$ (1.39Å) $=-2.27$ eV. and $N_{\pi\pi\pi\pi}$ (1.54Å) $=-1.24$ eV. Exchange integrals between non-neighboring atomic orbitals are completely neglected.

Calculation Results.—The calculated coefficients of all the canonical structures in the ground state wave function are collected in Table I, from which the spin densities are derived in Fig. 3.

Figure 3 also gives the result of a comparative calculation on an imaginary compound in which the interaction of one of the ortho carbons with the methylene group is omitted. One can clearly see that the ring formation very markedly increases the spin density on the methylene proton; the calculated spin density on the methylene protons in a ring compound is almost twice as large as in an open-chain compound.

In Fig. 3 it is also obvious that the change of the hybridization of the carbon β have little effect on the spin distribution. Thus, the observed coupling constants seem to offer no information on the hybridization.

On the other hand, the change in the C_β-C_{ortho} distance, that is, the change in the exchange integral between C_β and C_{ortho}, exerts a great influence on the spin density in the methylene group. Elongation of the C_β-C_{ortho} bond length from 1.39Å to 1.54Å reduces the methylene proton spin density by half.

From these calculated values of spin density are derived the proton coupling constants in Table II, constants which are independent of the hybridization of C_β. The coupling constants of "σ" protons, that is, of ortho, meta and para protons, are calculated by the following popular relationship between the spin density on the adjacent carbon $p\pi$ orbital, ρ_C, and the proton isotropic constants, a_H:

$$a_H = Q_{HC}\rho_C \qquad (1)$$

where Q_{HC} is taken to be, as usual, -22.5

TABLE I. COEFFICIENTS OF CANONICAL STRUCTURES IN THE GROUND STATE WAVE FUNCTION OF C_6H_7

Hybridization of carbon C_1	C_1-C_{ortho} distance, Å	Coefficient				
		C_1	C_2, C_3	C_4, C_5	C_6, C_7, C_8, C_9	C_{10}, C_{11}

Meta	+ 6.5	+ 6.3	2.5∼ 2.6	—
Methylene	+36∼37	+73∼76	47.5∼50.0	45.2 (ortho)[a]
Spectrum (lines)	3×4×3	3×4×3	3×4×3	3×4 (Assigned to $C_6H_5\cdot$)

a) Assignment by Chkheidze.[4] Assigned to $C_6H_5\cdot$ radical.
b) No matter what the hybridization of C_β is.

gauss.[10] The isotropic coupling constants of methylene protons are related to spin densities on them by the equation:

$$a_H = Q_H \rho_H \qquad (2)$$

Though a_H is theoretically given as +507 gauss, a smaller value, +420 gauss, which has been previously used by the authors in a similar valence bond calculation on a deformed methylene group,[6] would be more appropriate. This is mainly due to our disregard of any contribution of ionic structures. The coupling constants in Table II are calculated with the latter Q_H value.

The Valence Bond Calculation of Proton-coupling Constants in the Phenyl Radical

The Model of the $C_6H_5\cdot$ Radical. — In the phenyl radical, the migration of the odd electron may be achieved in several ways. One example is such a mechanism as the σ-π interaction between the non-bonding σ orbital and the pπ orbital, both on the carbon, C_1 (see Fig. 4), followed by the π-π migration to the pπ orbital on the ortho carbon and then by σ-π interaction between the ortho pπ orbital and the ortho C–H bond. However, this mechanism seems less significant because of the double σ-π interaction, which would bring about a spin density on the ortho proton of the order of 1/500.

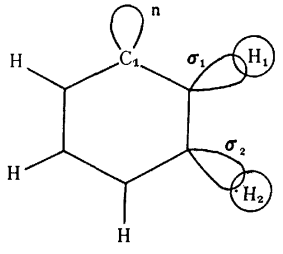

Fig. 4. Model of C_6H_5 radical.

A more probable mechanism would be direct interaction between the non-bonding σ orbital and the ortho C–H bond in the molecular plane. Therefore, in the present section we adopted the model in Fig. 4, consisting of 5 electrons on the following 5 atomic orbitals:

n: sp^2 hybridized non-bonding orbital on the carbon C_1
σ_1: sp^2 hybridized orbital on the ortho carbon, making a C–H bond with H_1
H_1: hydrogen 1s orbital on the hydrogen H_1
σ_2: sp^2 hybridized orbital on the meta carbon, making a C–H bond with H_2
H_2: hydrogen 1s orbital on the hydrogen H_2

For the sake of simplicity, the C–H bonds on only one side of the n orbital are considered. The inclusion of the other side would not affect the result seriously. Moreover, the para C–H bond is not taken into account, for the spin density of the para proton derived by the direct and in-plane interaction is relatively small and its order of magnitude can be estimated by the above calculation.

The change of the hybridization of the carbon, C_1, is not taken into consideration, for the change of the hybridization does not seem to affect the results. The C_1–C_{ortho} bond length is fixed as 1.39Å and the C_o–C_1–$C_{o'}$ angle, 120°. As the elongation of the C_1–C_{ortho} bond would reduce the coupling, as we saw in the previous section, the results of this calculation give the maximum value of the coupling constant.

Canonical Structures and Integrals. — All of the independent canonical structures that have the maximum bonding number, five structures in all, are taken as bases of the calculations, they are shown in Fig. 5. Ionic structures are not included in the present calculation at all. Integrals are evaluated by the same methods as in the preceding section.

Calculation Result.—The normalized ground state wave function is obtained as follows:

10) H. M. McConnell and D. B. Chesnut, *J. Chem. Phys.*, **28**, 107 (1958).

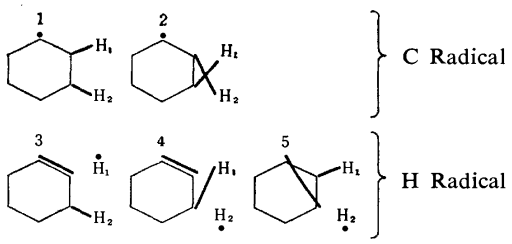

Fig. 5. Canonical structures taken into calculation of C_6H_5.

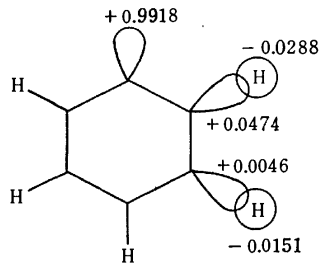

Fig. 6. Calculated spin density of C_6H_5 radical.

$$\Psi = 1.1338\phi_1 + 0.0968\phi_2 + 0.1144\phi_3 + 0.0673\phi_4 + 0.1779\phi_5 \quad (3)$$

where ϕ_i is the i-th canonical structure (for the numbering of them, see Fig. 5). From this function is derived the spin density shown in Fig. 6. The spin density is almost completely localized on the non-bonding hybridized orbital, n, on the carbon C_1; the phenyl radical may be said to be essentially a localized radical. From the spin densities in Fig. 6 the coupling constants of the ortho and meta protons are calculated by means of Eq. 2. The results are shown in Table III.

TABLE III. CALCULATED AND OBSERVED PROTON-COUPLING CONSTANTS OF $C_6H_5\cdot$ RADICAL

The Assignment of Observed Spectra and Discussion

After inspection of the calculated proton-coupling constants of the cyclohexadienyl radical $C_6H_7\cdot$, the complex spectrum, the triplet with finer structures of four triplets, observed by Ohnishi et al. and by Fischer, may safely be assigned to the cyclohexadienyl radical (see Table II). Agreement with the observed and the calculated spectra seems to be very good.* Though the coupling constant of methylene protons depends on the C_β–C_{ortho} bond length, the coincidence with the experimental value of 47.5∼50.0 gauss is accomplished at the bond length between 1.54 Å (C–C single bond) and 1.39 Å (C–C bond in benzene). This would be rational in the cyclohexadienyl radical, for it is produced from the regular hexagonal benzene molecule by hydrogen addition.

On the other hand, according to the theoretical results in Table III, the phenyl radical is considered to give a triplet with finer triplet structures. The singlet spectrum observed by Ohnishi has the width of 25 gauss between the maximum slopes and, depending on conditions, has slight nicks, showing that it might be a triplet. The large width just corresponds to the unresolved hyperfine structures of the theoretically-predicted splittings of 12 gauss. Thus, this broad singlet spectrum may safely be assigned to the phenyl radical. Chkheidze's assignment, in which the largest coupling constants, of 45 gauss, are attributed to ortho positions of the phenyl radical, does not correspond to the theoretical result at all. His spectrum, which is like those of Ohnishi and Fischer, would have to be ascribed to the cyclohexadienyl radical.

By the aid of this valence bond calculation, it seems that a theoretical basis can be given for the assignment of the two kinds of observed ESR spectra from irradiated benzene.

Summary

Two kinds of spectra—a triplet with a finer structure of four triplets, and a singlet--are known to be observed in ESR of irradiated benzene, and two different assignments of these spectra have been proposed—one assigning the triplet to the cyclohexadienyl radical and the singlet to the phenyl radical, and the other assigning the triplet to the phenyl radical. In the present paper, in order to give ground for a theoretical choice between the assignments, a valence bond calculation on the spin distribution of cyclohexadienyl and phenyl radicals has been carried out. On the cyclohexadienyl radical, though the numerical value of the spin density for methylenic protons is dependent on the C–$C_{methylene}$ bond length, the calculated spectrum is in good agreement with the observed triplet with four

* The coupling constant calculated for meta protons is a little too large. This seems to be either a general trend or a defect of the simple valence bond calculation of the conjugated system.

triplets. On the other hand, the phenyl radical has been shown theoretically to be an essentially localized radical and to give a singlet spectrum, which also agrees with that of the observed singlet.

Numerical calculations were carried out on the KDC-I digital computer of Kyoto University.

Chemical Reaction in a Shock Wave. I. The Ignition Delay of a Hydrogen-Oxygen Mixture in a Shock Tube

By Shiro FUJIMOTO

(Received February 22, 1963)

Many studies have been published about the reaction of hydrogen-oxygen mixtures.[1-4] In order to clarify the mechanism of this reaction, measurements of the induction period, during which the extent of reaction cannot be detected by the measuring instrument, are very useful.*,[5] Measurements of this induction period at low temperatures and low pressures have been already published[5] and those at high temperatures and low pressures have been conducted by Schott and Kinsey[3] and by Strehlow.[4]

In order to ignite the combustible mixture, there are various methods, such as ignition by electric spark,[6,7] by compression waves,[8] and by hot surfaces and by hot wires.[9] Howewer, the shock-tube technique is most useful for the measurement of the induction period or ignition delay, because the shock wave heats the mixture to a desired temperature almost instantaneously and homogeneously.

In the present experiment, the author tried to measure the induction period of a hydrogen-oxygen mixture in a shock tube at a moderate temperature and a rather high pressure ($825 \leq T_r \leq 1360°K$, $670 \leq P_r \leq 2670$ mmHg and $7.6\times10^{-4} \leq [O_2] \leq 3.0\times10^{-3}$ mol./l.); he tried also to examine the mechanisms proposed by other authors, whose measurements have been conducted under different conditions.

Experimental

The shock tube,[10] made from mild steel, has a square cross section with an inside lateral of 5 cm. and is divided into two sections, the reservoir chamber, A, 60 cm. in length and the test chamber, C, 180 cm. in length. Chambers A and C are separated by several sheets of cellophane film which can be punctured by the needle, N.

A brief scheme of the measuring system is shown in Fig. 1. As the shock wave passes down the tube, a signal on the piezo gauge, P_0, is thereby actuated; this signal is amplified through the amplifier circuit (AC) and triggers a raster-oscilloscope, Type SS 5101, made by the Iwasaki Communication Apparatus Co., which can respond to a time up to 1 μsec. The subsequent piezo gauges, P_1 and P_2, are actuated by the downward travelling shock wave, and the signals are fed through amplifier thyratron circuits (AT_1) and (AT_2), again on the raster-oscilloscope, thus providing a measurement of the incident shock speed. The measurement of the ignition was made in two ways. One method depends upon a raster-oscilloscope pattern actuated by a photo-multiplier (Fig. 1-(a)). A light signal initiated by the light emission of the gas mixture passes through a transparent plastic window, hits a photo-multiplier tube, and, appears in the sweep on the raster-oscilloscope, thus making possible an estimation of the exact time of ignition. A sample raster-oscilloscope pattern is shown in Fig. 2.

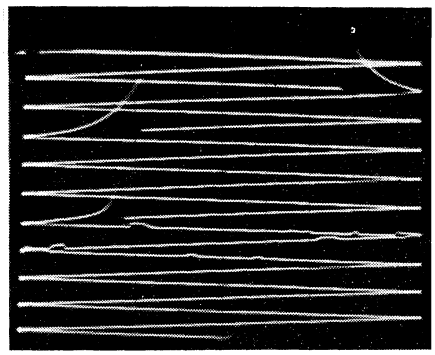

Fig. 2. Raster-oscilloscope diagram (an example).
N_2; 80%Ar+20%($2H_2+O_2$)
ω=740 m./sec., τ=298 μsec.
The 1st and 2nd signals are those from velocity gauges and 3rd signal is from photomultiplier gauge.

In the second method, measurements are carried out by using a piezo-gauge placed at the bottom of the shock tube. A pressure disturbance, accompanied by gas detonation, through a preamplification circuit (PA_2) (Fig. 1-(b)), gives a relevant pressure pattern on a synchroscope (Type 5302 of the Iwasaki Communication Apparatus Co.); this enables one to determine the exact time of the ignition. A sample pattern is given in Fig. 3. Both methods were applied for each run of measurements; the results obtained from the two ways were satisfactorily concordant. Piezogauges have been used by several investigators in shock studies.[11,12] A gauge of this type, made in this laboratory, has proven eminently successful as a detector of weak shock waves.

N_2; 70%Ar+30% ($2H_2+O_2$)
ω=733 m./sec., τ=530 μsec.

As a driver gas in the reservoir, A, nitrogen was used. In the test chamber, C, $0.067H_2+0.033O_2+0.900Ar$, $0.133H_2+0.067O_2+0.800Ar$ and $0.2H_2+0.1O_2+0.7Ar$ were used. In the present report, only ignitions caused by reflected shock waves will be described.

Results and Discussion

From Fig. 2, where a sample of a raster-oscilloscope diagram is shown, the incident shock velocity, ω, and ignition delay, τ, at various shock conditions can be obtained; they are tabulated in Tables I and II. For the evaluation of the τ values, it is assumed that the ignition occurs at the wall of the end plate of the shock tube; a Schlieren picture taken by Strehlow[4] seems to justify this assumption. Applying the usual process

of calculation,[13] the temperature, T_r, and the pressure, P_r, of the reflected shock wave and the concentration of oxygen behind the reflected shock wave are also tabulated in Tables I and II. In this procedure, a constant value of γ is assumed.*1

Steinberg and Kaskan[1] found a linear relationship between $\log_{10}\tau$ and $1/T_r$ for a $2H_2+O_2$ mixture without dilution. Schott and Kinsey[3] measured the formation of OH in the shock wave-induced combustion of H_2 and O_2 by using the ultraviolet absorption of OH and found a linear relationship between $\log_{10}\tau[O_2]$ and $1/T$ as follows:

$$\log_{10}\tau[O_2]\ (\text{mol.}\,l^{-1}\,\text{sec.}) = -10.647+(3966\pm625)/T \qquad (1)$$

Strehlow[4] obtained a similar result by using a conventional shock tube and the Schlieren system. In comparison with their results, our results are shown in Fig. 4. Although the position of our least square line is different from that of the other authors, the slope of the line is about the same. The least square line is expressed as follows;

$$\log_{10}\tau[O_2]\ (\text{mol.}\,l^{-1}\,\text{sec.}) = -9.581+3559/T_r \qquad (2)$$

The difference in the position of lines can not be explained as arising from experimental error, because the uncertainty of the τ value is less than 1 μsec. and that of T_r, less than 1%.*2

90%Ar+10%($2H_2+O_2$)	⊙	⊙
Strehlow's line	—·—·—	
Schott's line	----------	

In order to explain the induction time, τ, Semenov assumed the following reactions:

$$OH + H_2 \rightarrow H_2O + H \qquad (I)$$

$$O_2 + H \rightarrow OH + O \qquad (II)$$

$$O + H_2 \rightarrow OH + H \qquad (III)$$

Schott and Kinsey[3] also adopted Semenov's mechanism and derived the similar equation:

$$\tau[O_2] \propto \frac{1}{k_2} = \exp(E_2/RT)$$

In the derivations described above, Reaction IV is disregarded because of its low reactoin velocity compared with that of reaction II.

$$H + O_2 + M \rightarrow HO_2 + M \qquad (IV)$$

If reaction IV is taken into account, the following relation is derived:

$$\tau[O_2] \propto \frac{1}{k_2\{1-k_4[M]/2k_2\}}$$

13) I. I. Glass, W. Martin and G. N. Patterson, "A Theoretical and Experimental Study of the Shock Tube," UTIA Report No. 2, November, 1953.

*1 In the present experiment, the hydrogen-oxygen mixture is diluted with argon and the temperature is not very high. Therefore, the variation of γ with the temperature is not so large as to decrease the value of T_r beyond the range of experimental error.

*2 This uncertainty is guessed from the accuracy of the measuring instrument. However, according to the experimental results, the fluctuation of τ at a definite temperature is ±8% and the fluctuation of T_r at a definite τ value is ±5%.

Under the experimental conditions of Schott and Kinsey[3] $k_4[M]/2k_2$ is far less than 1 and the $\tau[O_2] \propto (1/k_2)$ relation may be applied. However, under the present experimental conditions, where pressure is comparatively high and temperature is low, $k_4[M]/2k_2$ can not be ignored in comparison with 1. According to Lewis and von Elbe,[14] $2k_2/k_4[M]$ is expressed as follows;

$$2k_2/k_4[M] = \frac{0.0556}{f_{H_2}+0.35f_{O_2}+0.20f_{Ar}} \times \frac{T}{P} \times \exp -\left[\frac{17000}{803R}\left(\frac{803}{T}-1\right)\right]$$

where is the mole fraction of the components of the mixture, P is the pressure in mmHg, and T is the absolute temperature. By using this equation, $k_4[M]/2k_2$ under the present experimental conditions can be calculated as follows.

T, °K	$k_4[M]/2k_2$
900	1.64
1000	0.69
1100	0.35
1200	0.20
1300	0.14

Obviously, $k_4[M]/2k_2$ is not ignored, and, therefore, reaction IV must be taken into consideration. However no quantitatively satisfactory explanation for the difference between our data and that of the others shown in Fig. 4 has yet been obtained. Also, it is difficult to explain why the value, 16.3 kcal., of the activation energy obtained by using the slope of the line in Fig. 4 is very close to those of Schott (18.1 kcal.) and Strehlow (16.5 kcal.). It is supposed that the simple scheme described above does not express the situation correctly.*3 In order to obtain a fully satisfactory explanation, it is necessary to conduct a more detailed study.

Summary

The values of the ignition delay of a hydrogen-oxygen mixture with a diluent in the reflected shock waves were measured by using a shock tube equipped with a piezo gauge for shock velocity measurements and a photomultiplier or another piezo gauge for the measurement of the time of ignition.

There was the following relationship between the ignition delay, τ, and the temperature, T_r, behind the reflected shock wave:

$$\log_{10}\tau\,[O_2]\ (\text{mol. } l^{-1}\ \text{sec.}) = -9.581 + 3559/T_r$$

where $825 \leq T_r \leq 1360$°K and $7.6\times10^{-4} \leq [O_2] \leq 3.0\times10^{-3}$ mol./l. The difference between this relationship and that set forth by other authors has been discussed.

The author wishes to express his gratitude to Professor Momotaro Suzuki of Defense Academy and Dr. Hajime Miyama of the Basic Resarch Laboratories of Toyo Rayon Co., Ltd., for their many helpful discussions during the course of this study, and to Mr. Tsuneo Kase for his help in performing the experiments.

*3 According to Dr. W. C. Gardiner's private communication to Dr. H. Miyama, it appears that there are three reactions in the induction time that have almost the same rate constants.

The Electronic Spectra of Aromatic Molecular Crystals. II. The Crystal Structure and Spectra of Perylene

By Jiro TANAKA

(Received March 27, 1963)

The electronic absorption spectra of aromatic molecular crystals have been investigated from several viewpoints in order to confirm the polarizations and the symmetry properties of excited states, and in order to discover the mechanism of electronic interactions in molecular crystals.[1] In spite of the many experiments which have been reported hitherto, few have been concerned with the same molecule in different crystalline forms. Perylene has two crystalline forms; the first was shown by Donaldson, Robertson and White[2] to have a dimeric structure, while a new form, herein reported, is monomeric and analogous to the structures of naphthalene and anthracene. The electronic spectra of the two crystalline forms has been studied, and it has been shown that the charge-transfer resonance interaction is very important, particularly in the dimeric crystal. The anomalous fluorescence of dimers of pyrene and naphthalene in a solution[3] and of pyrene and other substances in the crystalline state[4,5] have attracted attention; the present study provides an explanation of the mechanism of anomalous fluorescence.

Crystal Structure.—It is proposed to designate the previously-known form of perylene by α and the new one by β. Crystals of both the α and β forms have been obtained together from petroleum ether or benzene solutions, but they are easily distinguished from each other by their general appearance. The α form is usually obtained as a rectangular, tabular, yellow crystal (monoclinic), while the β form is obtained as hexagonal, greenish-yellow prisms (monoclinic). The β form is transformed into α at about 140°C. At and below room temperature, both forms are stable, and no transformation was found at lower temperatures.

X-Ray rotation and Weissenberg photographs show that the β form belongs to the $P2_1/a$ space group and give the following crystal data: $a=11.27\pm0.03$, $b=5.88\pm0.02$, $c=9.65\pm0.03$ Å, $\beta=92.1\pm0.3°$; absent spectra; ($h0l$) when h is odd and ($0k0$) when k is odd; space group, $P2_1/a$ (C^5_{2h}); two molecules per unit cell; the center of the molecule is at the origin; volume of the unit cell, 394.3 Å^3. It should be noted that the lattice constants are similar to those of the α form except for b, which is about half of the α form (α has $a=11.35$, $b=10.87$, $c=10.31$ Å and $\beta=100.8°$; space group $P2_1/a$ with four molecules in the unit cell.[2]

The crystal structure analysis has been carried out with the aid of a and b axes projection. The $h0l$ and $0kl$ reflections were recorded with a Weissenberg camera using Cu$K\alpha$ radiation. The multiple-film technique was used, and the intensity data were obtained by

visual comparison with crystal-reflected calibration spots of known relative exposures. In the *h0l* zone, 69 intensities out of 140 were measured, and 41 out of 78 for 0*kl*. The appropriate molecular orientation was deduced from the spectra of single crystals. A comparison with the spectrum showed that the directions of the long (L) and the short (M) axes of the molecules must be nearly the same in the two forms. Assuming that the tilts of the molecules on the axes are same in the two forms, the signs of the structure factors were determined; the first Fourier *h0l* projection showed the positions of all the carbon atoms. After a few cycles of refinement, the x and z parameters shown in Table I were obtained. The structure factors were calculated using the same temperature factor for all atoms, $B=4.2$, and at this stage of refinement, R (for the observed F_{h0l} reflection only) is 0.17. The calculated structure factors are compared in Table II with the observed values. The Fourier map for the b axis projection is shown in Fig. 1. The 0*kl* Fourier projection did not show resolved atoms because of serious overlapping in this projection. Assuming that the molecule is planar and has nearly the same structure as in the α form, the y parameters shown in Table I may be derived and the structure factors F_{0kl} shown in Table II may be calculated. For the observed 0*kl* reflections, the R factor is 0.27. Although, at this stage of refinement, the agreement between observed and calculated values is not sufficiently good to discuss the shape of the molecule, it seems reasonable to regard the β form as having a different structure from the α form and as resembling the structures of naphthalene and anthracene. For convenience in the following discussion, we will regard the α form as a

dimer structure and the β form as a monomer structure of perylene.

The Absorption Spectrum of the Perylene Crystals.—The electronic absorption spectrum of perylene in the *n*-heptane solution shown in Fig. 2 has been measured by using a Cary Model 14 spectrophotometer. Three strong absorption bands are clearly seen at 23050 cm^{-1} (f=0.33), at 39600 cm^{-1} (f=0.44) and at 48500 cm^{-1} (f=2.2), and another weaker bands, at 44200 cm^{-1}. Following the Hückel MO theory, the transition between the highest occupied and the lowest vacant orbital produces an excited state of symmetry $^1B_{2u}$, where the molecular symmetry is taken as D_{2h} and the two-fold axis is along the L-axis. This transition is allowed along the L-axis. The difference in orbital energy is 0.647β, and the second one, of the same symmetry, is at 1.347β, so that we can estimate roughly the energy of the first transition by the Pariser-Parr method[6] by taking only the interaction between the highest occupied MO i and the lowest vacant MO j and by disregarding the other orbitals. The excitation energy, ΔE, is then given by;

$$\Delta E = 0.674\beta + K_{ij} \quad (1)$$

where K_{ij} represents the exchange electron integral between MO i and j;

$$K_{ij} = \int \varphi_i^*(1)\varphi_j^*(2)\,1/r_{12}\varphi_i(2)\varphi_j(1)\mathrm{d}\tau_1\mathrm{d}\tau_2$$

The numerical calculation of ΔE, carried out with β taken as -2.371 eV.,[7] gives 2.84 eV., the observed value being 2.85 eV. Of course, this agreement occurs because of the cancellation of terms due to exchange integrals which

have been neglected and of the effect of configurational interaction with other higher excited states. However, it seems certain that the 23050 cm^{-1} band corresponds to the $^1B_{2u}$ excited state and is polarized along the L-axis. The 39600 cm^{-1} band is presumably polarized along the short axis (M-axis), since the next higher level is often orthogonal to the first level.

The crystalline absorption spectra of both the α and β forms presented in Figs. 3 and 4 have been obtained through the (001) plane by the method described in a previous paper.[8] The projection of molecules onto the (001) plane is also shown in Figs. 3 and 4. Hochstrasser[9] has discussed the spectrum of the α form in the 20000~30000 cm^{-1} region, but his labeling of the crystal axes seems to be misprinted; his a-axis should be read as b and his b-axis as a. In the present study, all crystalline axes were determined by X-ray rotation photograph. Based on the oriented gas model, the intensities of the crystalline absorption bands can be predicted as in Table III. Referring to the values of the direction cosine in Table III, it can be seen that the intensity of the absorption band polarized along the L-axis should be far less than the M-axis polarized band in the (001) spectrum if the oscillator strengths are the same. The f values of the 23050 cm^{-1} and 39600 cm^{-1} bands are of the same order of magnitude, so it can be shown from the spectra (Figs. 3 and 4) that the 23050 cm^{-1} band corresponds to the excited level of $^1B_{2u}$ symmetry, while the 39600 cm^{-1} band belongs to $^1B_{3u}$ symmetry. The observed dichroic ratios for the 39600 cm^{-1} band are in good agreement with the calculated values; hence the oriented gas model holds well for the 39600 cm^{-1} band in both the α and β forms.

Table IV lists all the observed band positions and assignments. The splitting of bands has been observed for 39600 cm^{-1} band; values of 500 cm^{-1} and 900 cm^{-1} are recorded for the $E_a - E_b$ splitting in the α and β forms.

The calculation of the Davydov splitting has been carried out by the standard method, taking into consideration the dipole-dipole interaction of molecules within a 20Å sphere.

8) J. Tanaka, This Bulletin, 36, 833 (1963).
9) R. Hochstrasser, *Can. J. Chem.*, 39, 451 (1961).

For the β form, the two excited state wave functions Ψ^{γ} and Ψ^{δ}, which are active along the a and b axes respectively, are written as:

$$\Psi^{\gamma}=\frac{1}{\sqrt{2N}}\left(\sum_{j=1}^{N}\varphi'_{1j}-\sum_{i=1}^{N}\varphi'_{2i}\right)$$
$$\Psi^{\delta}=\frac{1}{\sqrt{2N}}\left(\sum_{j=1}^{N}\varphi'_{1j}+\sum_{i=1}^{N}\varphi'_{2i}\right) \quad (2)$$

where φ'_{1j} represents a crystal wave function in which a molecule on the $1j$th site is excited and where φ'_{2i} denotes a crystal wave function in which the $2i$th site molecule is excited. The summation over N means that the excitation moves through the $2N$ molecules; $i=1, 2, \cdots, N$, $j=1, 2, \cdots, N$. The splitting between b and a axes (E_b-E_a) may then be given by

$$E_b-E_a=2V_{12}$$
$$=2\sum_{i=1}^{N}\int\varphi_1(1)\varphi'_1(1)H\varphi_2(2)\varphi'_{2i}(2)d\tau_1d\tau_2 \quad (3)$$

where $\varphi'_1(1)$ and $\varphi'_{2i}(2)$ are the excited state wave functions of the 1st and $2i$th molecules, and H is Hamiltonian of the system. The coordinates of transition dipoles chosen for the 1st and 2nd molecules are 1 (xyz) 2 $(1/2-x, 1/2+y, \bar{z})$; they are related to each other by the screw axis rotation about the b-axis.

For the α form, the excited states which belong to the B_u and A_u representation of the C^5_{2h} space group and which are active along the a- and b-axes respectively are written by:

$$\Psi^{\zeta}=\frac{1}{\sqrt{4N}}\left(\sum_{i=1}^{N}\varphi'_{1i}-\sum_{j=1}^{N}\varphi'_{2j}-\sum_{k=1}^{N}\varphi'_{3k}+\sum_{l=1}^{N}\varphi'_{4l}\right)$$
$$\Psi^{\varepsilon}=\frac{1}{\sqrt{4N}}\left(\sum_{i=1}^{N}\varphi'_{1i}-\sum_{j=1}^{N}\varphi'_{2j}+\sum_{k=1}^{N}\varphi'_{3k}-\sum_{l=1}^{N}\varphi'_{4l}\right) \quad (4)$$

where φ'_{1i}, φ'_{2j}, φ'_{3k}, and φ'_{4l} represent the crystal wave functions in which the $1i$, $2j$, $3k$, and $4l$ molecules are excited. They are related to each other by the symmetry operation of the crystal. The coordinates of transition dipoles chosen are 1 (x, y, z), 2 $(\bar{x}, \bar{y}, \bar{z})$, 3 $(1/2-x, 1/2+y, \bar{z})$ and 4 $(1/2+x, 1/2-y, z)$. The excitation transfer matrix elements for Ψ^{ζ} and Ψ^{ε} are given by:

$$V^{\zeta}=\frac{1}{4}\ (-V_{11}-V_{13}+V_{14}+V_{23}-V_{24}-V_{34})$$
$$V^{\varepsilon}=\frac{1}{4}\ (-V_{11}+V_{13}-V_{14}-V_{23}+V_{24}-V_{34}) \quad (5)$$

the notation for V_{12} is given in Eq. 3. The splitting between a and b axes is given by:

$$E_a-E_b=V_{14}-V_{13} \quad (6)$$

The calculated energies V_{12}, V_{13} and V_{14}, using the Hamiltonian for the dipole-dipole interaction only, are given in Table V.

The splittings calculated for the 39600 cm^{-1} band are -214 cm^{-1} and -2460 cm^{-1} for the α and β forms respectively, but the observed values are 500 cm^{-1} and 900 cm^{-1}. The calculated values do not agree even in sign for the two forms. Presumably the interaction with higher excited levels will be strong enough to change the energy level in the crystal.

In the region of the first absorption band near 20000~32000 cm^{-1}, we have found more important deviations from the oriented gas model based on the solution spectrum. First of all, we have noticed a broad band appearing in both the α and the β forms instead of the sharp vibrational band in solution, although, even at room temperature, some vibrational structure can be seen. The Davydov splitting has been calculated assuming both the L-axis polarization and the weak interaction model of Simpson and Peterson,[10] although the general pattern of the spectrum seems to be intermediate coupling. The results are listed in Table IV. It shows a general agreement between the observed and the calculated values, but the former is smaller than the latter. This discrepancy is attributed to the interaction with other excited states, particularly the charge transfer state, to the inadequacy of the dipole-dipole approximation, and to the overestimation of the transition moment in crystal because a large hypochromism was observed for this band.

All energies in $cm^{-1}/Å^2$. The explicit form for V_{12} is, for example, given by:

$$V_{12}=\frac{-e^2}{R^3}\mu^2\{2\cos\theta_z\cos\theta_{z'}-\cos\theta_x\cos\theta_{x'}-\cos\theta_y\cos\theta_{y'}\}$$

where R is the distance between the centers of two transition moments, μ is its magnitude (Å), and $\cos\theta_z$, $\cos\theta_{z'}$, $\cos\theta_x$, $\cos\theta_{x'}$, $\cos\theta_y$ and $\cos\theta_{y'}$ are the direction consines of the transition moments on each molecule referred to the axis drawn between the two centers as the Z axis, with the X and Y axes orthogonal to the Z axis.

10) W. T. Simpson and D. L. Peterson, *J. Chem. Phys.*, **26**, 588 (1957).

In the α form spectrum near 25000~28000 cm^{-1}, we have found another absorption band, one which we have assigned to the charge transfer between molecules for the following reasons. First of all, this band is particularly apparent in the dimer form, in which the charge transfer interaction should be larger than in the monomer form. However, the intensity of this type of band cannot be expected to be large since in the ground-state crystal configuration, the molecules are separated by about 3.5Å and since the electron overlap is relatively small. Therefore, this band will appear by borrowing intensity from the $^1B_{2u}$-allowed excited state by configurational mixing. Still, however, it has a different dichroic ratio ($D_b : D_a$) to the first two absorption bands near 21000~23000 cm^{-1}. The band is rather stronger along the a-axis than along the b-axis, which is another reason for assigning it to a different origin. The theoretical study of the electronic structure of the aromatic-excited dimer of perylene has recently been made by Murrell and Tanaka,[11] who show that the perylene dimer has four excited singlet states in this region and that the allowed charge transfer band should appear at about 26600 cm^{-1} (cf. Fig. 5 and the $^1G \rightarrow {}^1R_u$ transition at 3.5Å). The observed band is at 26500~27000 cm^{-1}; hence, its assignment to the charge transfer is supported by the theoretical treatment.

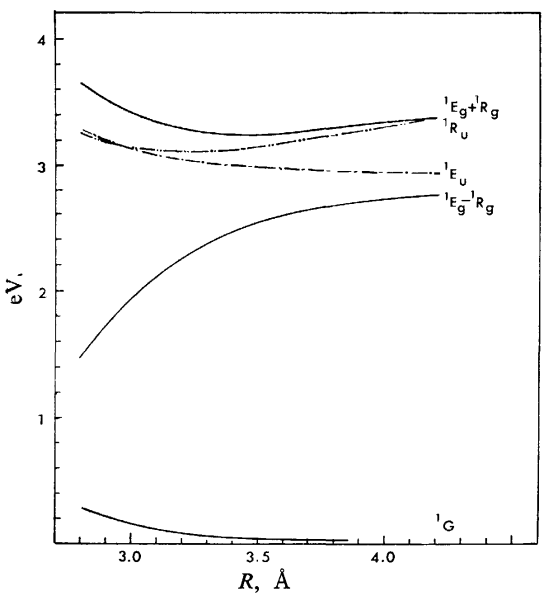

Fig. 5. Energy level diagram for the perylene dimer (only lower excited singlet levels having $^1B_{2u}$ symmetry are shown).
Ordinate; energy in eV.
Abscissa, distance between two molecules

The direction of the transition moment of this charge transfer band is of interest when compared with that in other molecular complexes, where the direction is vertical to the aromatic ring.[12] In the case of the aromatic dimer, the intensity is probably mainly due to the interaction with the allowed transition of the molecule, and the direction is along the molecular axis in the plane rather than vertical to it. The spectrum of the α form shows that the band is stronger along the a-axis, where the molecular L-axis lies.

The splitting of the charge transfer band along the a and b axes is, though less definite, nearly 550 cm^{-1}. This magnitude is so large that we must also consider the migration of the charge transfer state (the locally-ionized state) in the crystal. Although the charge transfer state will polarize the crystal and distort the lattice to some extent, its migration in the crystal introduces a new mechanism of photoconduction in aromatic crystals. By means of this mechanism, the locally-ionized state is considered to move rather easily, and its dissociation into electron and hole at an electrode surface will result in a transport of the electric charge. The band width of this state, or the excitation transfer matrix element between molecules, will be large than the usual band width of molecular orbitals in crystals; hence, the charge mobilities in molecular crystals will be increased.

The energy level of the charge transfer state for the monomer crystal (β form) can be estimated by the same method. Following the previous treatment,[11] it is given by $I-A-C$, where I is the ionization potential of the molecule, A, its electron affinity, and C the electrostatic coulomb force between electron and hole. Introducing the numerical values of $(I-A)=5.89$ eV. and $C=2.07$ eV. for $R=6.35$Å separation leads to a charge transfer state at 3.82 eV. (30800 cm^{-1}), a state which could not be observed in the longer wavelength region and one which is hidden under the strong transition to the $^1B_{3u}$ state.

Next we will discuss the hypochromism of the transition to the $^1B_{2u}$-excited state. It is seen from the projection in Figs. 3—4 that the L-axis is almost along the a-axis of the crystal. In this structure it is expected that absorption should appear only along the a-axis, not along the b-axis for the L-axis polarization band. However, the experimental results shows that the reverse is the case; it is rather stronger along the b-axis than along the a-axis. In

TABLE VI. INTENSITY RATIOS OF THE $^1B_{2u}$ BAND TO THE $^1B_{3u}$ BAND

	Calculated		Observed	
	a-Axis $^1B_{2u} : {}^1B_{3u}$	b-Axis $^1B_{2u} : {}^1B_{3u}$	a-Axis $^1B_{2u} : {}^1B_{3u}$	b-Axis $^1B_{2u} : {}^1B_{3u}$
α Form	0.027 : 1.00	0.0002 : 1.00	0.20 : 1.00	0.17 : 1.00
β Form	0.230 : 1.00	0.0025 : 1.00	0.11 : 1.00	0.21 : 1.00

Table VI the calculated and observed values of the intensity ratio of the $^1B_{2u}$ band to the $^1B_{3u}$ band are compared. It is seen that in the β form the observed a-axis absorption is greatly reduced while it is increased along the b-axis; in the α form it increases in both directions, but to a greater extent along the b-axis. The increase along the b-axis may be explained by mixing with the next higher excited levels, but the decrease in the intensity, particularly along the a-axis, cannot be explained simply by the interaction with the allowed transition at higher energies. As has been mentioned previously, the transition to the charge transfer state has very little transition moment, so the interaction with this state may result in the hypochromism of the $^1B_{2u}$ transition. This mechanism for hypochromism is reasonable if we consider the symmetry properties of these excited states. Both the $^1B_{2u}$ and the charge transfer states involve the excitation of an electron from the highest occupied to the lowest vacant orbital of the same molecule or of the nearest neighbor molecule. Therefore, the symmetries of the molecular orbitals concerned are the same and the mixing of these states is allowed. For the $^1B_{3u}$ excited state, however, no interaction with the lowest charge transfer state can be expected since the symmetry of the molecular orbital is different. Therefore, hypochromism, and other types of deviation from the oriented gas model, will be found only in the $^1B_{2u}$ excited state and is, in fact, observed in the crystalline spectrum.

In the α form the intensification of the charge transfer band and the decrease in the intensity of the $^1B_{2u}$ transition caused by this interaction is observed along the a-axis. For the β form, however, because the charge transfer absorption is at a higher energy region and cannot be discerned, we found only a decrease in the intensity of the $^1B_{2u}$ transition.* In the crystal the interaction will take place not only between a pair of molecules in the dimer but through neighboring molecules, and the energy level of the charge transfer state will form a band, the excitation transfer will occur more efficiently, and stronger hypochromism may be expected. The L-axis of the molecule, along which direction the interaction of molecular orbitals takes place, exactly coincides with the a-axis of both crystal forms, so that strong hypochromism is seen only along the a-axis. If the L-axis is not along the a-axis, but somewhere between the a- and b-axes, then hypochromism will be observed in both crystal directions.

Finally, it must be mentioned that at 29200 and 30500 cm^{-1} there are new absorption bands which are not observed in solution. These bands will be of a different origin rather than vibrational progressions of the $^1B_{2u}$ state because no splitting is observed in either the α or β forms. A very weak absorption band in the solution spectrum at about 34500 cm^{-1} is difficult to correlate without further information.

The Fluorescence Spectrum of Perylene Crystals.—The fluorescence spectra of both the α and the β forms have been measured by the recording spectrofluorometer of Professor Makishima's labotatory.* The machine consists of a mercury excitation lamp, a Kipp and Zonen double monochromator, and a

* The intensification of the charge transfer band along the a-axis, which will occur under the strong absorption band of the $^1B_{3u}$ transition, will influence the dichroic ratio of the $^1B_{3u}$ bands of the β form. In fact, the smaller observed value as compared with the calculated value or with the α form can be explained on this basis.

* The author wishes to express his thanks to Professors S. Makishima and S. Shionoya for the use of their spectrofluorometer.

photoelectric recording system. The spectra at room temperature and at the temperature of liquid nitrogen are shown in Fig. 6, together with the solution spectrum. It is most remarkable that the β form emits a green fluorescence at about 18950 cm^{-1}, while the α form glows yellow to red in the region of 16000 to 17000 cm^{-1} and shifts markedly with the temperature. The green emission of the β form is regarded as a monomer emission of the crystal, while the red emission of the α form is considered to be a dimer emission.

We will now discuss the origin of the dimer emission band from the theoretical point of view. First, a qualitative description of the charge transfer interaction, following Nagakura and Tanaka's one-electron approximation,[13] will be given. Let us consider the interaction between the two ground state molecules. The wave function and the resonance energy for the charge transfer are given by:

$$\Psi = a\varphi_1 + b\theta_2$$
$$\Delta E = \frac{2\beta^2}{I_P - E_A}, \quad \beta = \int \varphi_1 H \theta_2 d\tau \qquad (4)$$

where φ_1 is the highest occupied orbital of the donor molecule and θ_2 is the lowest vacant orbital of the acceptor molecule. Because of the symmetry of φ_1 and θ_2 (which are orthogonal if we take only the directly opposite interaction in the most symmetrical dimer), the resonance integral β will be very small; hence, no self-molecular complex can be formed between unexcited molecules, even if the relevant alternant hydrocarbon behaves as a good electron donor or acceptor in a mixed system. However, if one molecule is in the excited state, interaction takes place between φ_2 and θ_2, and the symmetry of the orbitals obviously favors a large interaction. Therefore, the molecule in the excited state (the $^1B_{2u}$ excited state in the case of perylene) will be stabilized to a greater extent by a charge transfer complex formation with another unexcited molecule of the same species. It is well established that the absorption and fluorescence spectra of a molecular complex appear in completely different positions from those of the individual molecules and are mainly determined by the values of I_p, E_A and β in Eq. 7. Hence, it is quite reasonable that the fluorescence of the excited dimer appears at longer wavelengths where there is no corresponding molecular transition. This is the qualitative explanation of the larger red shift of the excited dimer emission band.

Recently a more sophisticated quantitative treatment of this problem has been evolved by Murrell and Tanaka, and by Hoijtink and Konijnenberg.[11]

The calculation based on a non-overlap approximation which takes into account the exciton type interaction between the ^1E_u and ^1E_g states* shows that the splitting of this type is not enough to explain the observed shift and gives the wrong order when compared to the observed shifts for naphthalene, pyrene and perylene. When electron overlap and delocalization are considered, and when the Hamiltonian matrix elements are evaluated, it is shown that the interaction between ^1E_g and ^1R_g produces a large splitting, with only a very slight splitting for the $^1E_1$ and ^1R_u states. Figure 5 shows the results of the calculation for this configurational interaction. It is seen that the $^1E_g - {}^1R_g$ state is most stabilized by electron delocalization between the molecules. Although the transition between the ground state and the $^1E_g - {}^1R_g$ state is forbidden by symmetry, long wave emission band of the dimer certainly corresponds to this transition because this is the only state which is greatly stabilized by charge resonance interaction. If the dimer is not completely symmetric, as in the crystal, the selection rule will not strictly forbid emission from the lowest singlet level. The stabilization of this level is greater, the shorter the molecular separation, so it is conceivable that the molecules will approach each other following the excitation of one of them. This means that a self-molecular complex has been formed between two molecules, of which one is in the excited state. Figure 5 shows that the red shift is mainly due to the stabilization of the $^1E_g - {}^1R_g$ state, but it is also due, to some extent, to the repulsion of the ground state at the closer molecular approach. The estimation of this distance is very difficult and necessarily involves guesswork, but a comparison of the observed and calculated values suggests a separation of 3.1~3.2 Å. At this distance the stabilization of the $^1E_g - {}^1R_g$ state is about 0.6 eV., and the repulsion in the ground state is about 0.1 eV.

13) S. Nagakura and J. Tanaka, *J. Chem. Phys.*, **22**, 236 (1954).

* The notations for the electronic configuration of the dimer, in which only the $^1B_{2u}$ local excited state and the charge transfer state are considered, are as follows:

Configuration		
Ground	$^1A^1A$	G
Excited Resonance	$^1A^*{}^1A - {}^1A^1A^*$	^1E_u
	$^1A^*{}^1A + {}^1A^1A^*$	^1E_g
Charge Resonance	$^1(^2A^+{}^2A^- - {}^2A^-{}^2A^+)$	^1R_u
	$^1(^2A^+{}^2A^- + {}^2A^-{}^2A^+)$	^1R_g

$$^1A^1A = |\varphi_1\bar{\varphi}_1\theta_1\bar{\theta}_1|$$

$$^1A^*{}^1A = \sqrt{1/2}\{|\varphi_1\bar{\varphi}_2\theta_1\bar{\theta}_1| - |\bar{\varphi}_1\varphi_2\theta_1\bar{\theta}_1|\}$$

$$^1(^2A^+{}^2A^-) = \sqrt{1/2}\{|\varphi_1\bar{\theta}_2\theta_1\bar{\theta}_1| - |\bar{\varphi}_1\theta_2\theta_1\bar{\theta}_1|\}$$

where φ_1, θ_1 and φ_2, θ_2 are wave functions of the highest occupied and lowest vacant orbitals of each molecule and $^1A^*$ is the lowest singlet excited state of $^1B_{2u}$ symmetry.

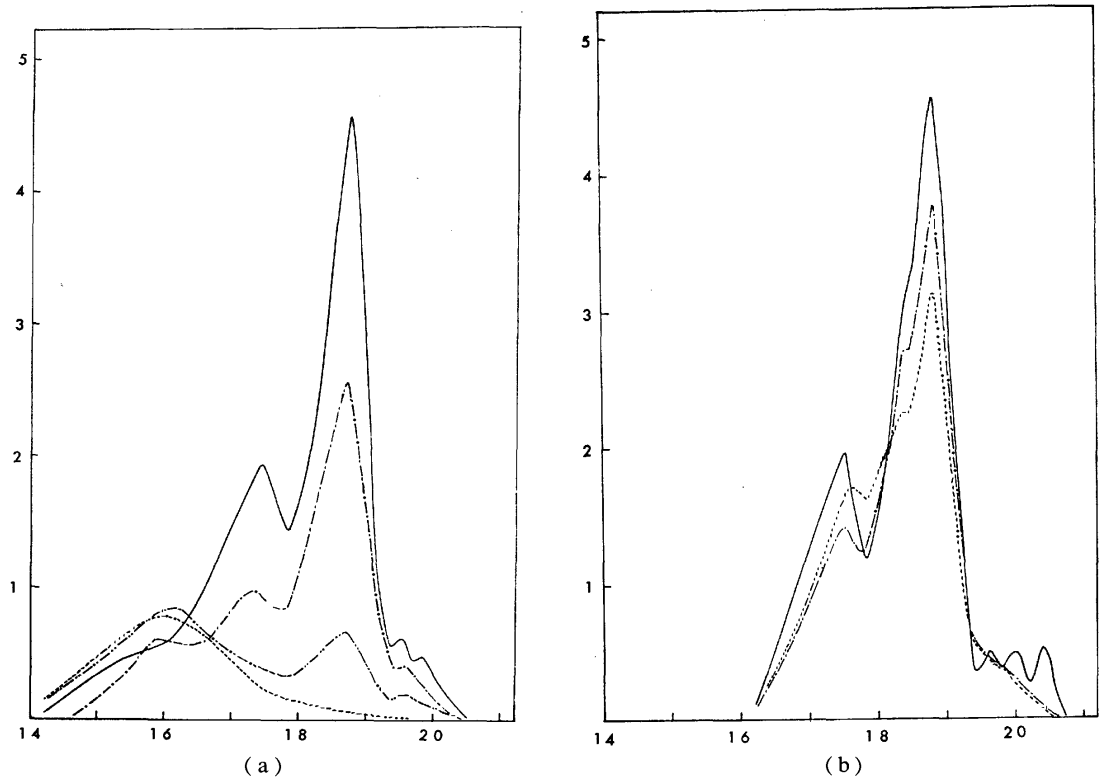

Fig. 7. Fluorescence spectrum of perylene crystals.

(b) β Form
—— at 4.2°K -·-·- at 28°K ---- at 80°K
Abscissa; frequency (in $10^3\,cm^{-1}$)
Ordinate; intensity of fluorescence (in arbitrary units, but with the same scale for different temperatures)

The dimer emission band shifts remarkably from 17300 cm^{-1} at room temperature to 16250 cm^{-1} at 77°K. This proves that the potential function of the excited state is rather shallow and that the population of the state is easily affected by the temperature.

The β form fluorescence shows a vibrational structure, but the α form is structureless. This is explained by the potential curves of Fig. 5. The emission of the dimer form takes place between the excited state stabilized by charge transfer interaction and the ground state destabilized by repulsive interaction. Since the potential in the ground state is repulsive, discrete vibrational levels do not exist for this state and its population is continuous. Therefore, the dimer emission band has no vibrational structure.

Further experimental support for the idea of the movement of the molecule in the excited state in the α-form crystal is given by the fluorescence measurement at the temperature of liquid helium. The fluorescence spectra of α and β forms between 4.2 to 77°K are shown in Figs. 7(a) and 7(b). The β form emission does not change in shape or position, but it does decrease in intensity with an increase in temperature; this is presumably due to the enhancement of the radiationless relaxation process at higher temperatures. In contrast to the small change of the β form emission, the yellow-red emission of the α form changes to green at 4.2°K with no accompanying crystalline phase transition.* By increasing the temperature to 77°K, the red emission appears again, and at intermediate temperatures both red and green emissions are observed.

* The phase transformation from β to α occurs at about 140°C. The β form is the metastable form at room temperature, and it is inconceivable that the $\alpha \rightarrow \beta$ transformation occurs at a lower temperature. In fact, we can recover the α crystal after its immersion in liquid helium without any of the damage to the original shape which would be expected if a phase transition had occurred.

Therefore, it is most probable that the dimer emission is prohibited at the temperature of liquid helium because the molecules are frozen out and cannot approach each other after excitation. In Fig. 5 we have considered only the energy of some molecular orbitals; however, the interaction between the other orbitals will give additional repulsion at a shorter molecular separation. The resultant potential function for the total system is as drawn in Fig. 8, in which the potential barrier appears at intermediate separation. Following the excitation of one molecule in the dimer with the nuclear separation fixed (the Franck-Condon principle) (process 1), it will relax into the lower of the singlet excited levels by radiationless process 2, cross the barrier (process 3) to the lowest of the singlet excited levels by changing the nuclear separation, and then emit at smaller energies (process 4). However, if the system is frozen out, the molecule has insufficient energy to surmount this potential barrier and hence remains at the larger molecular separation, with less stabilization of the excited energy level. In fact, the fluorescence spectrum of the α form between 4~25°K shows only a green emission which is nearly the same as that of the β form, indicating that no stabilization of the excited state occurs because of the prohibition of the molecular movement. In the range between 25~40°K, the green emission is slowly quenched and the red emission appears instead, while above 40°K the quenching of the green and the appearance of the red occur more rapidly.

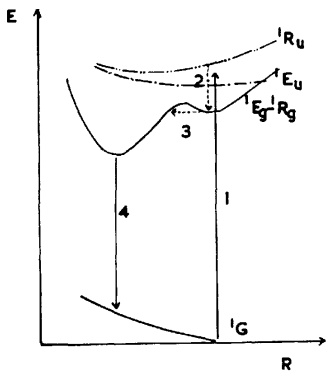

Fig. 8. Potential energy curve for the excited dimer including total repulsive energy.

The rate process of the movement of the molecule to the closest position has been analyzed by the measurement of the intensity of the emission bands. We assume that the number of molecules frozen at the lattice sites is proportional to the intensity of the green emission; the decrease in the green emission intensity is considered to be proportional to the number of molecules which cross the barrier. The temperature dependence of the ratio at the red emission to the green emission is shown in Fig. 9, where the abscissa is $1/T$ and the ordinate is the logarithm of the intensity ratio of the red to the green emission in an arbitrary unit. The kinetic scheme for the movement of the molecule after the excitation is given as follows:

$M + h\nu \rightarrow M^*$

(1) Molecules excited in the crystalline site

$M^* \rightarrow M + h\nu_G$

(2) Green emission, rate constant k_2

$M^* + M \rightarrow M_2^*$

(3) Excited dimer formation, rate constant k_3

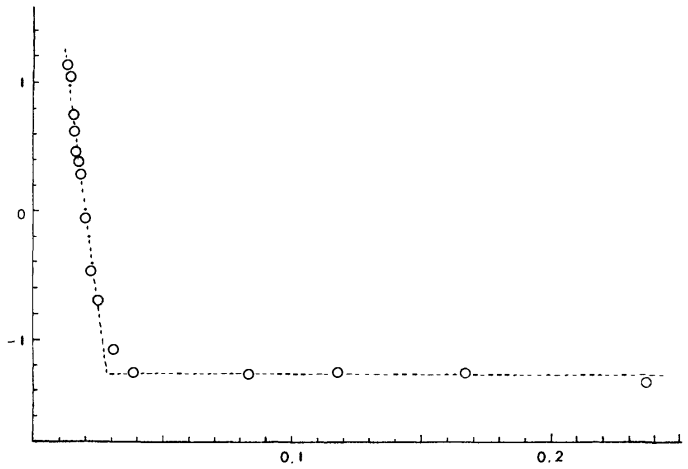

Fig. 9. Change in intensity ratio of red to green emission of the α form crystal with temperature.

TABLE VII

	Solution			β Form			α Form at 4.2°K		
	Abs.	Emis.	Shift	Abs.	Emis.	Shift	Abs.	Emis.	Shift
1st	23050	22800	250	21370	18880	2490	21400	18700	2700
2nd	24700	21500		22990	18400		22800		
3rd	26000	20000		25830	17550		25060	17420	

The band positions are expressed in wave numbers. The crystalline absorption is the mean value for the a- and b-axes.

$M_2^* \rightarrow 2M + h\nu_R$

(4) Red emission from an excited dimer, k_4

$M_2^* \rightarrow 2M$

(5) Radiationless deactivation of an excited dimer, k_5

$M^* \rightarrow M$

(6) Radiationless deactivation of an excited monomer, k_6

The molecule in the crystal is constantly illuminated; hence, the concentration of M* in 1 is assumed to be constant. At the lower temperature, between 4.2 to 25°K, no appreciable decrease in the green emission is observed, so process 2 predominates with the natural emission coefficient of k_2. The numerical value of k_2 is estimated from the absorption oscillator strength, f, by the use of the following relation:[14]

$$k_2 = \frac{1}{1.5}\frac{g_l}{g_u} f\nu^2 = 1.2\times10^8/\text{sec.} \qquad (10)$$

where g_l and g_u are the spin multiplicity of the lower and upper states and ν is the absorption frequency in wave numbers.

The intensities of the green and the red emission bands are given by

$$I_G = \frac{k_2[M^*]}{k_2+k_6}, \quad I_R = k_4[M_2^*] = \frac{k_4}{k_4+k_5}\cdot k_3[M^*] \qquad (11)$$

where [M*] and [M_2*] denote the concentration of the monomer and dimer molecules excited. The intensity ratio of the red to the green emission is given by

$$\frac{I_R}{I_G} = \frac{k_4[M_2^*]}{\frac{k_2[M^*]}{k_2+k_6}} = \frac{k_4 k_3(k_2+k_6)}{k_2(k_4+k_5)} = \frac{k_4(k_2+k_6)}{k_2(k_4+k_5)} A_3 e^{-h\nu/kT} \qquad (12)$$

where $k_3 = A_3 e^{-h\nu/kT}$.

It follows that if we take the logarithm of I_R/I_G in the ordinate and $1/T$ in the abscissa, we are able to estimate the activation energy of process 3. Figure 9 shows this relationship, the activation energy obtained from the slope between 40~80°K is $\nu = 285\ \text{cm}^{-1}$. This energy corresponds to the potential barrier in Fig. 8. At higher temperatures, most excited molecules go to the lowest state and emit a red fluorescence. The natural emission coefficient, k_4, estimated from comparison of the intensities of the red and green emission bands, gives $f = 0.089$. This fairly large value suggests a dipole-allowed transition, which is posible if the structure of the dimer is not completely symmetric and if the emission is not symmetry-forbidden.

The polarization of the dimer emission has been measured and the intensity was nearly the same in the a- and b-axes directions. However, the direction of the transition moment of the dimer emission band will not be discussed further, for we do not know the orientation of the excited molecule in the crystal.

Summarizing the above discussion, the mechanism of the red (dimer) emission is as follows:

After the excitation of one molecule of the dimer pair, the charge transfer resonance interaction taking place is larger at the shorter molecular separation, so the molecules approach each other and the excited dimer is formed. The emisson from this stabilized state to the repulsive ground state appears at longer wavelengths. At very low temperatures, the motion of the molecule is inhibited and no stabilization by the excited-dimer formation can occur.

The present phenomenon somewhat resembles the quenching of the impurity fluorescence at very low temperatures.[15] However, the mechanism of the emission is quite different, since the impurity fluorescence occurs by exciton migration to an impurity site, coupled with lattice vibrations, whereas the present phenomenon takes place by the movement of the molecule itself at each site in the crystal where a molecule is excited.

The emission of the β form appears at about

14) G. N. Lewis and M. Kasha, *J. Am. Chem. Soc.*, **66**, 2100 (1944).

15) Y. Kanda and H. Sponer, *J. Chem. Phys.*, **29**, 798 (1958); L. E. Lyons and J. W. White, ibid., **29**, 447 (1958); K. Gschwendtner and H. C. Wolf, *Naturwiss.*, **48**, 42 (1961).

18880 cm^{-1}; its vibrational progressions are tabulated in Table VII, together with those for the solution and α-form emissions. The β-form emission does not change position when the temperature is changed from 77 to 4.2°K. When the shifts of the first peak of the fluorescence from the first peak in the absorption is compared for the β form and for the solution, it is seen that a larger shift occurs in the β-form emission. The explanation for this stabilization of the excited state must be sought in such interaction as the charge transfer, but it is rather strange that the β-form and the α-form emissions at the temperature of liquid helium do not differ greatly. In fact, the first peak position differs by only about 180 cm^{-1}; the shift from the absorption peak is 2700 cm^{-1} for the α form and 2490 cm^{-1} for the β form, and the structure of the vibrational progression is certainly different. In view of the greater dependence of the charge-transfer resonance interaction on the nuclear separation, it is rather difficult to explain the almost identical emission bands from the different crystalline forms at low temperatures, but experiments show that the difference is rather small. The small peaks of the β-form emission near 20000 cm^{-1} are due to surface states.

As a result of the observation of a green emission from the β and α forms at the temperature of liquid helium, an alternative explanation for the observation by Hochstrasser[16] of perylene-pyrene charge transfer fluorescence can be given. Of couse, the possibility of charge-tranfer resonance interaction between perylene-pyrene cannot be ruled out, but it should certainly be smaller than in the cases of perylene-perylene or pyrene-pyrene because the molecular orbitals concerned are of different types. The emission at 5250 Å of perylene in pyrene is almost identical with the β-form emission; therefore, it should be interpreted as a monomer emission of perylene in pyrene crystal.

16) R. Hochstrasser, *J. Chem. Phys.*, 36, 1099 (1962).

Summary

A new crystalline form of perylene has been found and its crystal structure has been determined by the two-dimensional X-ray diffraction method. The new form is monomeric, while the previously known form has a dimeric structure. The electronic absorption and fluorescence spectra of both forms have been measured; on the basis of these data, an assignment is proposed for the observed transitions. Although the fluorescence spectrum of the monomer form shows a small shift, that of the dimer form shows a larger shift than would be expected from the absorption spectrum. This is explained as a stabilization of the lowest excited singlet state by a charge-transfer resonance interaction between the molecules in a pair. Because this stabilization increases as the distance between two molecules decreases, it is suggested that the molecules in a pair approach each other after excitation. At the liquid helium temperature the motion of molecules in the crystal will be frozen out, the larger stabilization of the excited level cannot occur, and the green emission which is characteristic of the monomer form is observed from the dimer form. The rate process of the molecular motion at lower temperatures has been analyzed.

The author would like to express his thanks to Professor Saburo Nagakura for his continued encouragement of this work and to Professor Yoshihiko Saito and Mr. Hazime Iwasaki for their kind advice on crystal structure analysis. The author would also like to thank to Dr. John N. Murrell for discussions and hospitality during his stay in Sheffield. He also wishes to thank Dr. Brian Stevens of Sheffield University and Dr. Stephen C. Wallwork of Nottingham University for their criticism of the manuscript.

The Application of the Archibald Ultracentrifugal Method to the Determination of the Micellar Molecular Weight of the Anionic Surface Active Agents

By Kinji KAKIUCHI, Ken'ichi HATTORI and Toshizo ISEMURA

(Received April 18, 1963)

Although the sedimentation equilibrium method of ultracentrifugation gives a reliable molecular weight, it requires a very long time to attain the equilibrium state. Archibald[1] has suggested procedures by which molecular weight can be determined without waiting for the equilibrium state. As he has shown, the sedimentation equilibrium equation always holds at the meniscus and at the bottom of a liquid column within the cell. The equations are given by:

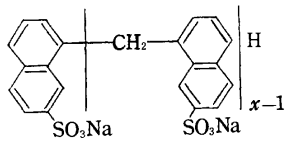
$$M_m = \frac{RT}{(1-\bar{v}\rho_0)\omega^2}\left(\frac{dc/dr}{rc}\right)_m \qquad (1)$$

for the meniscus, and

$$M_b = \frac{RT}{(1-\bar{v}\rho_0)\omega^2}\left(\frac{dc/dr}{rc}\right)_b \qquad (2)$$

for the bottom, where M is the molecular weight; R, the gas constant; T, the absolute temperature; $\bar{v}$, the partial specific volume of the solute; ρ_0 the density of the solvent; ω, the angular velocity; c, the solute concentration; r, the distance measured from the axis of the rotor to the meniscus or bottom of the liquid column within the cell, and the suffixes m and b, the meniscus and bottom of the liquid column respectively.

The Archibald ultracentrifugal method has been increasingly applied to the determination of the micellar weights of nonionic surface active agents[2,3] in an aqueous solution. It is worthwhile to investigate whether or not this method can also be applied to the determination of the miceller weight of anionic surface active agents. The purpose of the present investigation, therefore, is to confirm the applicability of the Archibald method to anionic surface active agents. The systems studied in the present investigation are the aqueous solution of sodium dodecyl sulfate (SDS) and the formalin condensates of sodium β-naphthalene sulfonate (β-NF). The latter compounds have the formula:[4]



where x is the number of naphthalene nuclei, 1, 2, 3, ·····, 8, 9.5 (average) and 13.5 (average).

Experimental

Apparatus.—The experiments were performed in a Hitachi Analytical Ultracentrifuger, UCA-1 type (maximum speed 60000 r.p.m.), equipped with a Schlieren cylindrical lens system. The temperature was measured with a radiation thermocouple provided a continuous indication of the temperature of the base of the rotor, with an accuracy of ± 0.1°C. To make the photographs more clear a piece of human hair was used for the inclined slit.

For each test a given sample of a definite concentration in water or in a sodium chloride solution was placed in a conventional cell. At a fixed speed of rotation, six photographs of the sedimentation pattern were taken at intervals of ten minutes. At the same time, the corresponding temperatures of the rotor were measured, and their average value was used for the calculations. The temperature was 20 ± 3°C.

The patterns are shown in Fig. 1. dc/dr corresponds to the vertical axis, since in our present experimental concentration we assume that dc/dr is proportional to dn/dr (n: refractive index). r corresponds to the horizontal axis. By measuring the area under the curve of the meniscus or bottom, it is possible to obtain a numerical value proportional to the decreased or increased concentration. Similarly, three patterns obtained from the boundary-forming cell give the average value proportional to the initial concentration by measuring the area under the curve. Thus, the apparent concentration at the meniscus and bottom at every interval of time is determined. The molecular weights at any one time are given by Eqs. 1 and 2, which represent the molecular weights at both the meniscus and bottom of the cell.[5,6] We denote these as

(b) Pictures from boundary-forming cell. By measuring the area it is possible to obtain the concn. of the initial solution, c_0.

$M_m(t)$ and $M_b(t)$ respectively. $M_m(t)$ or $M_b(t)$ tends to decrease or increase with time according as the solution is non-ideal or polydisperse. To obtain the appearent weight-average molecular weights of the solutes, M_0, $M_m(t)$ or $M_b(t)$ should be extrapolated to time zero.

$M_m(t)$ was exclusively used to obtain reliable data from the meniscus rather than the bottom. There is a possibility of an increase in micellar weight upon the addition of silicone oil[7] for the formation of the bottom surface.

The partial specific volume was calculated by the equation:

$$\bar{v}=\frac{1}{\rho_0}\left[1-\frac{\rho-\rho_0}{W}\right] \qquad (3)$$

Here ρ is the density of a solution containing W g. solute in 1 ml., and ρ_0 is the density of the solvent. The densities were determined by the picnometer of Lipkin et al.[8]

Materials. — *Sodium Dodecyl Sulfate (SDS).* — The dodecyl alcohol used for preparing sodium dodecyl sulfate was purified by fractional distillation under reduced pressure several times. It contained no homologues detectable by gas chromatographical analysis, and its hydroxyl value was found to be 301.0 (calcd. 301.1). Sodium dodecyl sulfate was prepared by the method of Dreger et al.,[9] followed by repeated recrystallization from ethanol and by extraction with petroleum ether. The aqueous solution of the purified propuct showed no minimum point in its surface tension-concentration curve.

The partial specific volume of SDS was found to be 0.825 in water and 0.855 in a 0.01～0.1 M sodium chloride solution.

The Condensates of Sodium β-Naphthalene Sulfonate (β-NF).—These compounds with x=1～8 were purified by a method previously reported.[4] The purity was confirmed by "one spot" on the paper chromatogram analysis. β-NF's with x=9.5 and 13.5 were synthesized by the usual methods and were not purified further except by dialysis to remove lower polymers. Their molecular weights were determined by infrared spectra.[10] Table I summarizes the partial specific volumes of β-NF in water and in a 0.1 M sodium chloride solution.

Table I. Partial specific volume of β-NF (at 25°C, concn. 1%)

x	Distilled water	0.1 M Sodium chloride
1	0.637	0.612
2		0.591
3		0.576
4		0.621
5		0.595
6		0.635
7		0.627
8		0.600
9.5		0.597
13.5	0.632	0.635
Average value	0.634	0.610

Results and Discussion

The determination of the micellar molecular weights of the ionic-surface active agent by the Archibald method has not previously been reported. The reason seems to have been that the micelle of ionizable molecules is disintegrated by the increasing repulsion between ionic groups because the micelles sediment faster, leaving the counter ions behind.

The Archibald method may be applicable to the determination of the micellar molecular weight if the disintegration of the micelle is prevented by adding a neutral electrolyte to the solution, although the micellar weight might be dependent on the concentration of the added electrolyte.

The Micellar Molecular Weight of Sodium Dodecyl Sulfate. — Table II summarizes the micellar molecular weights, M_0, of SDS at different concentrations in water or in a sodium chloride solution. In the absence of sodium chloride, SDS has a very low number of association, indicating the disintegration of the micelle mentioned above in the ultracentrifugal field.

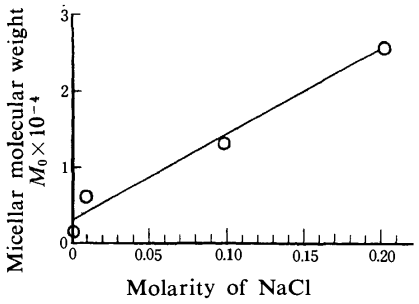

Fig. 2. Plots of micellar molecular weight of SDS as a function of molarity of sodium chloride. Concn. of SDS, 1.00%.

McBain and Hutchinson[11] are of the opinion that the micellar molecular weight of SDS is not changed by the addition of excess sodium chloride, that the effective volume of the micelle is enlarged, and that solubilizing power increases as the charge decreases. It is expected that the micellar molecular weight of SDS is obtainable in the presence of a neutral electrolyte. As Fig. 2 shows, however, the M_0 of a 1.00% SDS solution is proportional to the concentration of sodium chloride and, within the range of concentration of sodium chloride studied, the micellar molecular weight has no tendency to attain any limiting value.

The published values of the micellar molecular weight of SDS are very diverse, and the number of association, n, ranges over 40 to 80, as follows: 1.15×10^4 ($n=40$),[12] 1.14×10^4 ($n=40$),[13] 2.05×10^4 ($n=71$),[14] 2.3×10^4 ($n=79$)[15] and 1.80×10^4 ($n=62$)[16] are obtained by light scattering; $1.12\sim2.02\times10^4$ ($n=39\sim70$),[17] by diffussion and 1.70×10^4 ($n=57$),[18] by small angle X-ray scattering.

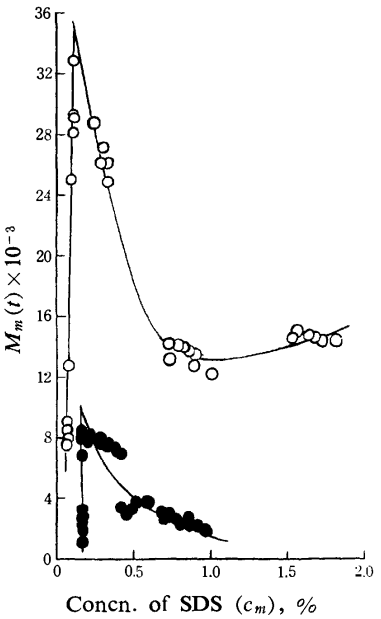

Fig. 3. Micellar molecular weight $M_m(t)$ as a function of the concn. of SDS. The concns. of SDS denote c_m at any time in the centrifugal run.

○: in 0.1 M sodium chloride solution
●: in water

Figure 3 shows the changes of $M_m(t)$ with the concentration of SDS at the meniscus, which varies with the time of the centrifugal run. It is clear that the numbers of association are varied from 40 to 80 at concentrations of more than 0.5% SDS in a sodium chloride solution. In the absence of sodium chloride, the numbers of association are much

smaller. Below the concentration of 0.5% SDS, the curves of the numbers of association vs. concentration abruptly show a sharp maximum point. The concentrations of SDS at a sharp maximum point are 0.16% and 0.13% in water and in 0.1 M sodium chloride respectively. These values agree with the reported values for critical micelle concentration (CMC).[19,20] Clearly the addition of sodium chloride lowers the CMC of SDS. Tartar[12] and Kolthoff[19] reported that the CMC of SDS decreased from 0.25% to 0.174~0.177% upon the addition of 0.1 M sodium chloride. Moreover, it is noted that above the CMC the slope of the linear relationship between $M_m(t)$ and time is positive, while below the CMC its slope is negative. Figure 4 illustrates that $M_m(t)$ increases with time above the CMC but decreases below the CMC.*

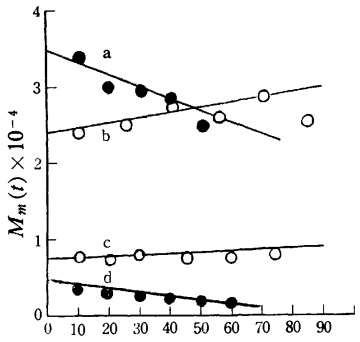

Fig. 4. Plots for $M_m(t)$ vs. time of centrifugation.

a : SDS 0.25%, NaCl 0.1 M
b : SDS 0.50%, NaCl 0.1 M
c : SDS 0.50%, NaCl (not contained)
d : SDS 0.20%, NaCl (not contained)

As Fujita et al.[21] have pointed out, $M_m(t)$ or $M_b(t)$ is a function of time. They also pointed out that the $M_m(t)$ of polystyrene in methyl ethyl ketone increased with time and that $M_b(t)$ decreased in an approximately linear fashion, but that they could be extrapolated to give the same intercept at $t=0$ in agreement with the theoretical requirement. Whether the slope of the $M_m(t)$-time curve is positive or negative depends on either the non-ideality or the polydispersity of the solution. It is supposed that non-ideality is predominant in the SDS solution above the CMC but the polydispersity is predominant below the CMC.

In the concentration of the critical micelle region, as Fig. 3 shows, it is necessary for us to handle with care a detailed treatment of the behavior by means of thermodynamic and hydrodynamic argument. However, it is very difficult to ascribe these deviations from the ideality to any non-ideality of the solute accompanied not only by the change of equilibrium between the micelle and the free ion but also by the disintegration of the micelle at the ultracentrifugal field. Goldberg[22] and Fujita et al.[21] have pointed out that in the application of the Archibald method the chemical potential is expressed in terms of both the concentration and the activity coefficient, γ, of the solute. For simplicity of theoretical development, they considered only two component systems, a homogeneous solute and a solvent. For such a solution the equation reduces to:

$$1/M_0 = 1/M_W + \boldsymbol{B}c + \text{higher terms in } c \quad (4)$$

where the coefficient $\boldsymbol{B}$ refers to the initial slope of $\ln\gamma$ at $c=0$ and, hence, is independent of the concentration, and M_W is the weight-average melecular weight. This equation indicates that a plot for $1/M_0$ vs. c allows an evaluation of M_W from its intercept at $c=0$ $\boldsymbol{B}$ from its initial slope. $\boldsymbol{B}$ corresponds to the second virial coefficient of light scattering. Fujita et al. have pointed out that for polystyrene in methyl ethyl ketone the plots for $1/M_0$ vs. concentration deviate from a straight line at relatively low concentrations and increase sharply with a further increase in c. This steep upward curvature suggests that the third and higher terms in the above equation would be quite different from those in the equation derived from the theory of light scattering.

In non-ideal solutions, the extended form of the Svedberg equation[23] reduces to:

$$M = \frac{\boldsymbol{R}T\mathrm{s}}{D(1-\bar{v}\rho)}\left[1-\frac{\mathrm{d}\ln\gamma}{\mathrm{d}\ln c}\right] \quad (5)$$

At an infinite dilution, the term in brackets becomes unity. Creeth[24] has shown that in a thallous sulfate-water system, $\mathrm{d}\ln\gamma/\mathrm{d}\ln c$ is positive within the range of his experimental concentration. This discrepancy between Eq.

* The concentrations described in Fig. 4 are those for the prepared samples. In the coures of the centrifugal run the solute sediments partially form the meniscus. Accordingly, the concentration of SDS at the meniscus, c_m, decreases gradually. Although the concentration of sample (a), 0.25%, is actually above the CMC, c_m decreases below the CMC soon after the beginning of ultracentrifugation with this solution.

5 and the experimental results is due to the incomplete dissociation of the electrolyte.

As has been described in the experimental part, it has been assumed that the difference between the refractive indices and the partial specific volumes does not depend on SDS concentration within the range of the experimental conditions. However, these values of free ions differ slightly from those of the micelle formed above the CMC.[25,26] Though it is difficult to explain the abnormally high association observed, it might be due to the incomplete dissociation of counter ions, accompanied by the change of the equilibrium between the micelle and the free ion of SDS at a given instant of centrifugation.

The Micellar Molecular Weight of Condensates of Sodium β-Naphthalene Sulfonate.—The association of purified β-NF in water has never been studied quantitatively. It is expected that the association would occur since their molecular structure is similar to that of direct dyes.[27] In fact, at concentrations above ca. 0.015%, the association of these compounds is shown in the light of their ultraviolet spectra[28]. The Archibald method in a cylindrical lens-Schlieren optical system is not easily applicable to such low concentration regions, and its use introduces appreciable errors. Table III summerizes the molecular weights, M_0, obtained for 0.25~1.0% β-NF solutions in 0.1 M sodium chloride.

In the absence of an elctrolyte the number of association of β-NF with $x=1$ and 13.5 nearly agrees with the value for non-association. The dependency of M_0 on the concentration of β-NF is not significant at concentrations below 1.00% when 0.10 M sodium chloride is present.

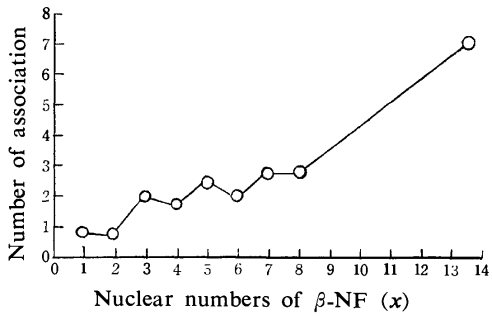

Fig. 5. Relation of number of association to x of 1.00% β-NF in 0.1 M NaCl.

Figure 5 shows that the number of association of β-NF in its 1.0% solution dissolved in 0.1 M sodium chloride increases with the number of nuclei, x, suggesting that the intermolecular van der Waals attraction[29,30] becomes stronger as x increases. The slopes of the curves of $M_m(t)$ against time for β-NF were found always to be negative. This indicates that polydispersity is more predominant than non-ideality in this case. This is reversed in the case of a SDS solution more concentrated than the CMC

Summary

(1) The values of the micellar molecular weight of SDS in water and in a sodium chloride solution could not be obtained by

25) H. B. Klevens, *J. Phys. and Colloid Chem.*, **52**, 130 (1948).
26) W. D. Harkins, R. W. Mattoon and M. L. Corrin, *J. Colloid Sci.*, **1**, 105 (1946).
27) I. Vickerstaff, "The Physical Chemistry of Dyeing," London and Edinburgh, Oliver and Boyd, 2. ed., (1954).
28) K. Hattori and Y. Tanino. *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **66**, 65 (1963).
29) R. H. Peters and H. H. Sumner, *J. Soc. Dye. Colourists*, **71**, 130 (1955).
30) C. H. Giles and A. S. A. Hassen, ibid., **74**, 846 (1958).

the Archibald method, whereas the observed M_0 may represent the relative values, each corresponding to a given instant of centrifugation. However, a CMC could be definitely determined which agreed with the values reported by other workers. As may be noted from the slope of the dependency of M_0 on time, the SDS solution is non-ideal above the CMC while it is polydisperse below the CMC. The abnormally high association in the critical micelle region might be caused by the incomplete dissociation of counter ions, accompanied by a change in the equilibrium between the micelle and the free ion of SDS at a given instant of centrifugation.

(2) When the electrolyte is absent, β-NF's presumably exist in a monomeric state, but in a 0.1 M sodium chloride solution they associate, the degree of association being proportional to the x. In the region of 0.25~1.0% concentration, micelles of β-NF were observed to be polydisperse.

Thermal and Radiation Oxidations of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. III.[1,2] *The Effect of Copper Ions*

By Hiroshi HOTTA, Nobutake SUZUKI and Akira TERAKAWA[3]

(Received April 18, 1963)

In this paper the results of the oxidation of benzene to phenol in cupric aqueous solutions will be discussed and will be compared with the results for iron salt solutions reported in Part II.[2] The most distinctive point is that cuprous ions are unstable because of the fast rate of oxidation by the oxygen dissolved in contrast to ferrous ions which are stable.

Experimental

Aqueous Solutions.—Cupric sulfate was dissolved initially by 0.01 M in 0, 0.01 and 0.1 N sulfuric acid; cupric chloride was similarly dissolved in hydrochloric acid. All reagents were of guaranteed grade.

Apparatus and Procedure. — The experimental procedure, described in detail previously,[1,2] may be outlined as follows: 1 cc. of benzene was put on 15 cc. of an aqueous solution in a hard-glass tube set in a 50 cc. stainless-steel reactor under an oxygen pressure of 30 atm., and then this system was heated by the programming heater and kept for 30 min. at a given temperature. When irradiated by cobalt-60 gamma rays, the dose was about 14000 r. for 25 min.

Analytical.—The yield of phenol was determined from the optical density of the ether extract at 273.5 mμ, as in Part II.[2]

The concentration of cupric species dissolved in the solution after reaction was determined from the optical density of the cupric-oxine complex in chloroform.[4] The concentration of ferrous species was measured in the form of the α, α'-dipyridyl complex.

Results and Discussion

The Irradiated Solutions of Cupric Sulfate.—The total amount of phenol produced in the irradiated 0.01 M cupric sulfate solutions of 0, 0.01 and 0.1 N sulfuric acid is plotted as the function of the reaction temperature by the solid marks and the solid lines in Fig. 1. A small amount of precipitates was found only at temperatures higher than 180°C, in contrast to the case of iron salts.[1]

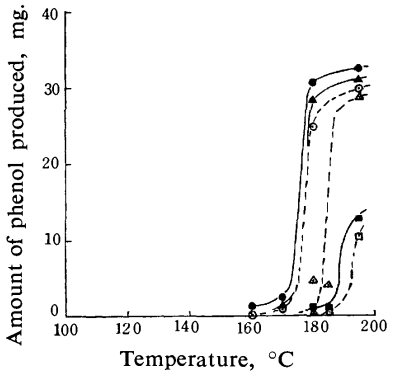

Fig. 1. Yields of phenol in 0.01 M cupric sulfate solutions with radiation (solid marks) and without radiation (open marks) in neutral (● and ⊙), in 0.01 N (▲ and △) and in 0.1 N (■ and ⊡) sulfuric acid.

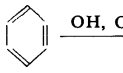
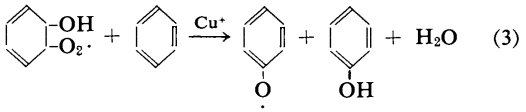
According to Part II,[2] the reaction scheme of the radiation oxidation of benzene in an aerated aqueous solution of copper salt at elevated temperatures is assumed to be as follows:

$$H_2O \xrightarrow{\sim\!\!\sim} H,\ OH,\ H_2,\ H_2O_2 \qquad (1)$$



(2)



(3)

$$PhO + PhH = PhOH + Ph \qquad (4)$$

$$Ph + O_2 = PhO_2 \qquad (5)$$

$$PhO_2 + PhH = PhO_2H + Ph \qquad (6)$$

$$PhO_2H + Cu^{2+} = PhO_2 + H^+ + Cu^+ \qquad (7)$$

$$PhO_2H + Cu^+ = PhO + OH^- + Cu^{2+} \qquad (8)$$

(Ph: phenyl radical)

In ferric sulfate solutions, it was assumed in Part II that the initiation of the chain oxidation of benzene (reaction 3) is to be attributed to a trace amount of ferrous ion present initially, as ferric ions are reduced successively through the propagation process (cf. reaction 7) once initiated. However, in cupric sulfate solutions, such a cuprous ion propagating the chain process (reactions 3 and 8) cannot be present, for cuprous ions, unlike ferrous ions, are readily oxidized by oxygen. Therefore, scarcely any phenol is produced up to 160°C, as Fig. 1 shows, unlike the case of ferric sulfate solutions.[2]

Phenol production is considerably suppressed in the 0.1 N sulfuric acid. This is mainly due to the acceleration of cuprous oxidation;

$$Cu^+ + O_2 + H^+ = Cu^{2+} + HO_2 \qquad (9)$$

On the other hand, as the open marks and dotted lines in Fig. 1 show, phenol is produced in the non-irradiated solutions at somewhat higher tempetatures than in the irradiated ones.

The Effect of Copper Metal in the Sulfate Solutions.—The amounts of phenol produced in the solutions with the composition given in Table I and containing 2 g. of copper metal pieces (99.99% purity), are shown in Fig. 2 by solid marks for the irradiated cases and by open marks for the non-irradiated cases. As Fig. 2 shows, when copper metal is present in the aqueous phase, the yield of phenol is large, even at lower temperatures, regardless of irradiation or non-irradiation, as in the ferrous solution.[2] This is especially clear in solution a.

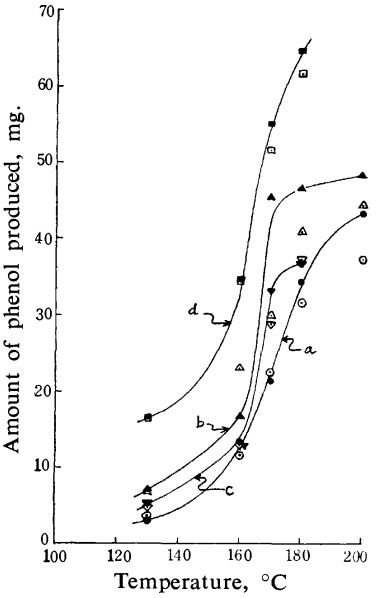


Fig. 2. Yields of phenol in (a) neutral 0.01 M cupric sulfate solution (● and ⊙), (b) 0.01 M cupric sulfate solution of 0.01 N sulfuric acid (▲ and △), (c) 0.01 N sulfuric acid (▼ and ▽) and (d) 0.1 N sulfuric acid (■ and ⊡) with radiation (solid marks) and without radiation (open marks). These systems contained 2 g. of copper metal pieces, respectively.

This fact supports the above assumption that scarcely any production of phenol in the cupric solution below 160°C is due to the lack of cuprous ions. Since cuprous ions are supplied continuously by the corrosion of the copper metal, the yield of phenol increases with an increase in the acidity. The concentration of cupric species in the solution after the reaction, given in Table I, is almost the same over the entire temperature range,

TABLE I. EFFICIENCIES OF COPPER METAL DISSOLVED FOR PHENOL PRODUCTION

System	Composition			Temp.	γ-Rays	Phenol produced to metal dissolved,	(Cu^{2+}) after reaction
	H_2SO_4 N	$CuSO_4$ M	Cu-metal g.	°C		mole ratio	M
a	0	0.01	2	160	Yes	>300	0.0101

					No	8.5	0.0434

independent of the increase in phenol yield. As the acidity increases, the number of metal ions dissolved increases, as does the yield of phenol. Therefore, the efficiency of the copper metal dissolved for phenol production, i. e., the mole ratio of the phenol produced to the copper metal dissolved, is the greatest for the neutral solution a, as Table I shows. This means that the majority of the cuprous ions produced from metal are oxidized by oxygen independent of the phenol production.

It should be noticed that phenol production is accelerated even for the case of solution a in Fig. 2, in which the concentration of cupric species increases only a little. This means that a trace amount of cuprous ions is sufficient to initiate the chain process. When a solution containing cupric ions is in contact with copper metal, the equilibrium constant of the disproportionation,

$$Cu^{2+} + Cu \rightleftharpoons 2Cu^{+} \qquad (10)$$

is

$$K_{10} = \frac{\sqrt{(Cu^{2+})}}{(Cu^{+})} = 10^{3}$$

at room temperature.[5] The production of cuprous ions in the neutral solution may be due to a slight corrosion of copper metal by the decomposed product of sulfate ions as well as to reaction 10.

It may be concluded from the mole ratios in Table I that the chain length of the oxidation reaction is at least 100 for 10 mg. of phenol produced. On the other hand, the *G*-value of phenol is 320 for 10 mg. of phenol produced at 160°C in the irradiated neutral ferric sulfate solution (from Figs. 2 and 4 in Part II.[2]) For this case, it is supposed that the apparent *G*-value of OH radical as the initiator of phenol production (reaction 2) is less than 3 in spite of the various paths for the OH radical production (cf. Part II), if one assumes that the efficiencies of ferrous and cuprous ions are equivalent for the whole chain process.

Cupric-Ferric Solutions. — In the aerated cupric-ferric solution at room temperature, ferrous ions are produced due to the reactions[6-8]

$$Cu^{2+} + HO_2 = Cu^{+} + H^{+} + O_2 \qquad (11)$$

and

$$Cu^{+} + Fe^{3+} = Cu^{2+} + Fe^{2+} \qquad (12)$$

However, in the cupric solution without ferric ions under high oxygen pressure at elevated temperatures, since cuprous ions are not scavenged by ferric ions if reduced, the equilibrium between reactions 9 and 11 depends on the oxygen pressure. Therefore, cupric ions are considered not to be reduced by reaction 11 in the solutions in Fig. 1.

Moreover, even in the irradiated and non-irradiated neutral and 0.1 N sulfuric acid solutions of 0.01 M cupric-0.01 M ferric[9] sulfate,

6) E. J. Hart, *Radiation Research*, 2, 33 (1955).

7) W. G. Barb, J. H. Baxendale, P. George and K. R. Hargrave, *Trans. Faraday Soc.*, 47, 462 (1951).

8) M. Cher and N. Davidson, *J. Am. Chem. Soc.*, 77, 793 (1955).

9) The concentration of 0.01M is not of ferric sulfate but of ferric ions.

in fact, ferrous ions were not produced, indicating that cupric ions are seemingly not reduced after all.

Next, benzene was oxidized in this neutral cupric-ferric solution. The amount of phenol produced (triangle marks) and the ferrous concentration (circle marks) are shown in Fig. 3 by solid marks for the irradiated case and by opon marks for the non-irradiated case. The ferrous concentration less than 1×10^{-5} M is unreliable.

In Fig. 3, the yield of phenol is much smaller than in the respective 0.01 M cupric and 0.01 M[9] ferric sulfate solutions, and scarcely any phenol is produced, even at 190°C, in the non-irradiated cupric-ferric solution. This means that, even if ferrous ions are produced by the oxidation process of benzene, they are reoxidized by the back path of reaction 12, and then the cuprous ions produced are consumed at once by the excess oxygen. Therefore, the oxidation process of benzene cannot be propagated successively. The mole ratios of the phenol produced to the ferrous concentration for the irradiated case are 22 and 54 at 170°C and 190°C respectively (cf. Fig. 3), suggesting such a consumption of ferrous ions.

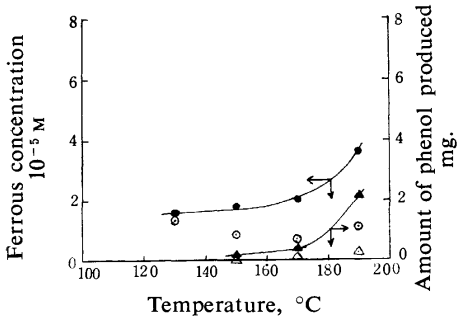

Fig. 3. Yields of phenol in the irradiated (▲) and non-irradiated (△) 0.01 M cupric-0.01 M ferric sulfate solution, and the corresponding ferrous concentrations (● and ⊙) after reaction.

These ratios are much larger than in the iron salt solutions discussed in Part II.[2] That is, the fast rate of cuprous oxidation kills not only the activity of cuprous ions but also that of ferrous ions.

Cupric Chloride Solutions.—The results of cupric chloride solutions in 0, 0.01 and 0.1 N hydrochloric acid are shown in Fig. 4 by marks similar to those in Fig. 1. Phenol production is suppressed in the presence of chloride ions, as has been seen in the iron chloride solution.[2]

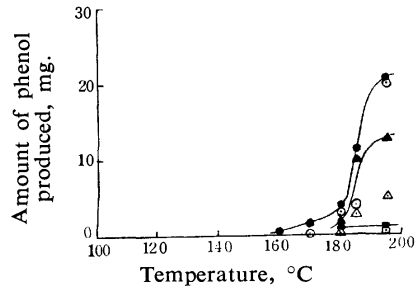

Fig. 4. Yields of phenol in 0.01 M cupric chloride solutions with radiation (solid marks) and without radiation (open marks) in neutral (● and ⊙), in 0.01 N (▲ and △) and in 0.1 N (■ and ⊡) hydrochloric acid.

Summary

The yield of phenol increases abruptly above 170°C in the cupric sulfate solutions. When the solutions contain copper metal pieces, phenol is produced, even below 160°C, regardless of irradiation or non-irradiation. On the other hand, scarcely any phenol is produced in the cupric-ferric sulfate solution, even at 180°C. These facts are to be attributed to the fast rate of cuprous oxidation by oxygen.

Experimental Sensitivity Data for Radioactivation Analysis with 14 MeV. Neutrons

By Yuzuru KUSAKA, Haruo TSUJI and Takayoshi ADACHI

(Received April 25, 1963)

The recent improvements, in such accelerators as the Cockcroft-Walton or Van de Graaff type in the shape, the operating methods, the available neutron fluxes and the cost of neutron generators, make them particularly useful as the neutron source in radioactivation analysis.[1-3]

In such machines 14 MeV. neutrons are produced by the $^{3}H(d, n)^{4}He$ nuclear reaction, using deuterons accelerated at 100 to 150 kV. The neutrons so produced can participate in (n, p), (n, α), (n, n) and (n, 2n) reactions for various nuclides. As the radioactivities produced by the reaction are generally of short half-lives, fast radioactivation is made possible for many elements.

Several concise summaries of theoretical sensitivity values for various elements activated by 14 MeV. neutrons have been published.[4,5] Although these data are very useful for a rough estimation of the sensitivities of each element, they are only approximate, mainly because of the inaccuracy of the present cross section value in the 14 MeV. neutron reaction.

This paper will describe experimental results concerned with the sensitivity, results which have been obtained by an experimental method with practical applications as an industrial routine analysis; it will also discuss radioactivity which has not been described in the sensitivity data so far published.

Experimental

Neutron Source.—A thick tritiated zirconium target (3 curies; The Radiochemical Centre, Amersham, Buckinghamshire, England) was bombarded with a deuteron beam of 100 to 170 KeV. and of 5 to 10 μamp. by the Cockcroft-Walton type accelerator of Konan University. The neutron strength during the irradiation was continuously measured by a proportional counter with a cesium iodide scintillator which had been set in the accelerator tube to count the associated alpha particles from the T-D reaction. The absolute neutron flux at the sample position was determined by the activation method of standard copper foil, the beta radioactivity of which was measured by a 4π gas-flow counter using Q gas.

Sample Transfer System and Neutron Irradiation.—A polyethylene "bunny" capsule (1.3 cm. i. d., 4.6 cm. long, 0.1 cm. thick) containing the sample was transferred, by means of a vacuum cleaner (500 watt), between the irradiation position, which was set to come to the sample center 3.5 cm. below the target, and the radioactivity detector through a flexible vinyl tubing (1.8 cm. i. d., 10 m. long). Irradiation was started by turning on the accelerator beam switch, and it was timed with a stop watch. At the end of 10.0 min. irradiation, the transfer system was turned on to bring the "bunny" capsule back to the well of the scintillation detector. The average travel time of the capsule from the irradiation position to the detector was 3.5 sec.

Radioactivity Measurement.—The radioactivity induced in the sample was measured by a shielded well-type sodium iodide-scintillation detector (Harshow, 4.45 cm. dia., 5.08 cm. height, well: 1.91 cm. dia., 3.81 cm. deep) optically contacted with a photomultiplier tube (RCA 6342-A). Pulses from the phototube were fed to a linear-amplifier and then to a single-channel pulse height analyzer, the output from which was fed to a scaler.

The gross gamma ray counting was done for 10.0 min. in the sensitivity determination. In another run using the same sample, the decay curve was traced for an appropriate length of time and, consequently, the produced radioactive nuclide was analyzed. In the runs the countings were started after only 5.0 sec. of irradiation. However, the oxide, carbonate, acetate and nitrate samples were started after 40 sec., it being necessary first to eliminate the influence of the ^{16}N produced by the (n, p) reaction on oxygen.

Using the mean value of neutron flux observed during the irradiation, all the net counts, which were obtained by subtracting the counts in the empty capsule from the counts with the sample, were normalized to the data in a standard neutron flux (1.0×10^{5} neutrons per cm^{2} per sec.) and were also corrected for the variations in the weight of each sample.

Irradiation Sample.—A definite amount of the sample was pressed into a pellet (1.2 cm. dia., less than 3.4 cm. long) and put in the bottom of the "bunny" capsule.

The chemical forms of the samples were as

follows: the elements of silver, aluminum, arsenic, bismuth, calcium, cerium, cobalt, chromium, copper, iron, indium, iridium, lithium, magnesium, manganese, molybdenum, nickel, phosphorus, platinum, rhodium, ruthenium, sulfur, antimony, selenium, silicon, tin, tantalum, tellurium, thallium, tungsten, zinc and zirconium; the oxides of dysprosium, gallium, germanium, mercury, lanthanum, niobium, lead, praseodymium, samarium, titanium, vanadium and yttrium; the carbonates of cesium, potassium, sodium and rubidium; the acetates of barium and strontium; fluorine as polytetrafluoroethylene; bromine as dibromobenzene; iodine as methyl iodide; nitrogen as ammonium nitrate and oxygen as oxalic acid.

Results

Radioactive Nuclide Produced by Fast Neutron Reaction. — The nuclides so produced were analyzed by the decay curves obtained in the radioactivity measurements. The quantity expressed with the counting rate of the nuclide at the end of irradiation has been plotted against the half-life of the radioactivity; it is shown in Fig. 1. In Fig. 1 the nuclide is marked with the parent isotope in the nuclear reaction, while the waved line shown under the reaction mark indicates the activation to the metastable state of an isomeric pair. The nuclear reactions shown with the black point, that is, in cerium, germanium, gold, rubidium and selenium, have not been described in previously-published sensitivity data[4,5] but, nevertheless, produce considerable amounts of radioactivity.

In Fig. 1 the ambiguous weak radioactivities of less than 100 counts per min. are not plotted.

In the other experiments, the sensitivity for the activation analysis has been estimated. In these cases the sensitivity was assumed to be the quantity of the element needed to give 500 counts in a 10-min. measurement. However, in oxygen and gold only 100 counts was adopted in the 1 min. measurement; this was because of their short-lived radioactivities. The results are shown in Table I.

A Consideration of Experimental Error.—The experimental error in the results described above was caused mainly by the fluctuations of the neutron flux on the sample during irradiation. A typical example of the fluctuation curve is shown in Fig. 2. In the adopted

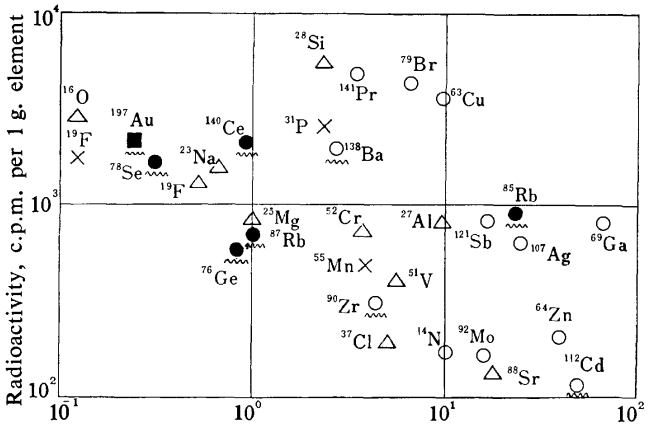

Fig. 1. Radioactive nuclide produced by 14 MeV. neutron reaction.
○: (n, 2n) reaction △: (n, p) reaction
×: (n, α) reaction □: (n, n′) reaction

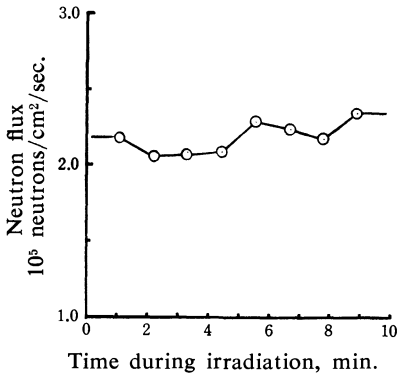

Fig. 2. Fluctuation of neutron flux during irradiation.

neutron flux itself, which was the mean value of the plots in Fig. 2, an uncertainty of 2.9% is estimated. In all the runs, an approximate 3.5% error could be assumed.

However, when relatively short-lived nuclides were to be measured, the neutron flux fluctuations near the end of irradiation become important and, therefore, the results tend to be less reliable. Although the theoretical error estimations in such nuclides are very difficult, roughly a 10% error was inferred from the experiments.

The neutron flux variation in the sample set at the irradiation position gave about a 5% error as a maximum. However, after the flux distribution had been determined by the activation method of copper monitor foils set at various positions in a polyethylene " bunny " capsule during irradiation, the corrections for sample position (sample thickness) were made in all the experimental results and, therefore, the error based on sample position became negligibly small.

Discussion

The short-lived radioactivities produced in germanium, selenium, rubidium and cerium are probably produced by (n, 2n) reactions; that is, they are due to Ge-75 m (48 sec.), Se-77 m (19 sec.), Rb-84 m (23 min.), Rb-86 m (1.02 m) and Ce-139 m (55 sec.). The radioactivity produced in gold might be due to the Au-197 m (7.2 sec.) produced by the (n, n') reaction.

It is possible improve the sensitivity by using a more sensitive gamma ray detector or higher neutron fluxes. Even in these cases, however, the relative sensitivity values are not expected to differ greatly from the data reported in the present paper. It is, therefore, believed that the present data will be useful in a general consideration of radioactivation analysis by 14 MeV. neutrons.

The authors wish to thank Dr. Kazunori Yuasa, Mr. Bunzaburo Saeki and Mr. Yoshinao Fujiwara of the Department of Physics of Konan University for their helpful discussions of the problem and their kind assistance in the use of the accelerator. The cost of this research was partly defrayed by a grant from the Scientific Research Expenditure Fund of the Ministry of Education, to which the authors' thanks are due.

The Composition of the Volatile Oil Obtained from the Leaves of Torreya nucifera and the Structure of Torreyol

By Tsutomu SAKAI, Kiichi NISHIMURA, Hiroaki CHIKAMATSU* and Yoshio HIROSE

(Received May 1, 1963)

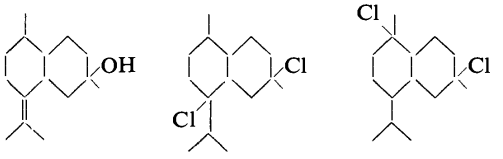
The volatile oil obtained from *Torreya nucifera Sieb. et Zucc.* was first examined by Shinozaki;[1] α-pinene, camphene, limonene (ca. 60%), cadinene, and a crystallin sesquiterpenic alcohol (m. p. 137~138°C), which was named torreyol, were found to be its components. The structure of torreyol was shown by Nishida and Uota[2] to be represented by formula I on the basis of the fact that torreyol gave cadinene dihydrochloride upon reaction with hydrogen chloride and yielded acetone

* Present address: Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka.

1) E. Shinozaki, *J. Soc. Chem. Ind.* (*Kōgyō-Kwagaku Zasshi*), **25**, 768 (1922).

2) K. Nishida and H. Uota, ibid., **43**, 150 (1940); **44**, 225 (1941).

by ozonolysis. The structure of cadinene dihydrochloride, at that time, was said by Ruzicka and Stoll[3] to be represented by structure II, and this formula was used in the study by Nishida and Uota. Later, this structure for cadinene dihydrochloride was found to be incorrect, and the revised structure, III, for it was suggested by Campbell and Soffer.[4] Therefore, the structure of torreyol also needed to be revised. Herout and his co-workers[5,6] reported that the physical properties of torreyol strikingly resemble those of δ-cadinol.



I II III

The purpose of this study is to elucidate the structure of torreyol and to obtain more precise data on the composition of the volatile oil.

Experimental

Two hundred and twenty-four grams of the volatile oil were obtained from 30.5 kg. of the leaves of *Torreya nucifera* by extraction with methanol, followed by steam distillation of the methanol extract. For the effectual recovery of torreyol and other sesquiterpene alcohols, the oil was treated by the following procedure. The oil was first separated by distillation under reduced pressure into a low-boiling fraction and a residual fraction containing mainly sesquiterpene alcohols. The latter was cooled, and the deposited crystals were collected. The same procedure was repeated on the filtrate until no crystalline material was deposited. The combined crystals were recrystallized from dilute ethanol. The oil recovered from the mother liquors of the recrystallization and the final filtrate were further separated by adsorption chromatogaphy on neutral alumina into three fractions, namely, a hydrocarbon fraction, a liquid sesquiterpene alcohol fraction, and a crystalline sesquiterpene alcohol fraction. By the above procedures, the original oil was separated into the following three fractions:

Fraction A: A low-boiling fraction separated by distillation, and a hydrocarbon fraction separated by adsorption chromatography on alumina. (209 g.)

Fraction B: A liquid sesquiterpene alcohol fraction separated by adsorption chromatography on alumina. (8.1 g.)

Fraction C: Crystalline sesquiterpene alcohol. (6.9 g.)

Fraction A.—Fraction A was further fractionated by distillation with Podbielniak's 13 mm.×2ft. Heli-Grid column under reduced pressure, followed by adsorption chromatography on silica gel. Each fraction was analyzed by gas chromatography, spectroscopy, and chemical methods. The course of the fractional distillation is presented in Fig. 1.

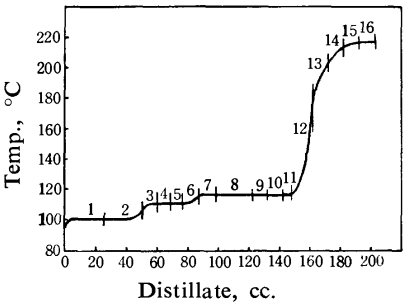


Fig. 1. The fractional distillation curve (50 mmHg).

The last fraction (fraction 17, 6 cc.) was recovered from the final residue by steam distillation.

Fractions 1 and 2 consisted only of α-pinene.

Fraction 3 was a mixture of hydrocarbons, which the infrared spectrum showed to contain myrcene. The myrcene was removed from the mixture as a maleic acid adduct. By adsorption chromatography of the unreacted portion, α-pinene, 3-carene, limonene, and γ-terpinene were isolated.

Fractions 4 to 6 contained limonene and myrcene.

Fractions 7 to 11 consisted only of limonene.

Fraction 12, the wide boiling range fraction, was a mixture of hydrocarbons and oxygen-containing compounds. The major constituents of this fraction were limonene and terpinolene. Minute amounts of linalool, terpinen-4-ol, citronellol, phenylethyl acetate and methyl salicylate were also found to be present by chromatographic separation.

Fractions 13 and 14 were complicated mixtures of hydrocarbons judged by gas chromatographic analysis to consist of at least nine hydrocarbons. However, it was so difficult to separate them by adsorption chromatography that only δ-cadinene, γ-cadinene, β-elemene, and two unknown sesquiterpene hydrocarbons could be isolated. Besides, fraction 13 contained small amounts of citronellol, geraniol and an unidentified carbonyl compound.

Fractions 15 to 17 consisted of relatively pure δ-cadinene.

Fraction B.—Fraction B, the liquid sesquiterpene alcohol fraction separated by adsorption chromatography on neutral alumina, was percolated again through a silica gel column. It contained nerolidol, two sesquiterpene alcohols, and an unidentified aromatic carbonyl compound.

One of the sesquiterpenic alcohols seemed to be identical with the so-called "cadinenol" isolated by Herout and his co-workers[5,7] from Juniper berry oil. The structure of cadinenol has not yet been

6) V. A. Pentegova, O. Motl and V. Herout, *Doklady Acad. Nauk SSSR*, 138, 850 (1961).
7) J. Pliva, M. Horak, V. Herout and F. Sorm, "Die Terpene. Der Spektrum und phys. Konstanten. Teil I. Sesquiterpene," Akademie-Verlag, Berilin (1960).

established. The infrared spectrum and the retention time on the gas chromatography of the alcohol isolated here were both identical with those of cadinenol, although the crystallization of the isolated alcohol was not effected by the seeding of an authentic sample of cadinenol. By referring to the values of the optical rotation of cadinenol ($[\alpha]_D$ −89°) and the isolated alcohol ($[\alpha]_D$ +69°), it was concluded that the isolated alcohol was an optical antipode of (−)-cadinenol obtained from Juniper berry oil.

The other sesquiterpene alcohol was difficult to separate from cadinenol, and its ultimated purity did not exceed 60%. The infrared spectrum of this compound was not identical with that of any known sesquiterpene alcohol, and further study was abandoned because there was an insufficient quantity of it.

Fraction C.—Fraction C was almost pure torreyol; m. p. 138~139°C. Sublimation and recrystallization from 50% ethanol afforded pure torreyol; m. p. 139.5~140.5°C, $[\alpha]_D^{18}$ 118.6° (*c* 2.075, ethanol).

The physical constants of the torreyols reported previously were m. p. 137~138°C[1] and 141~142°C[2], and $[\alpha]_D$ +99°19′[1] and +107°13′[2].

The findings on the composition of the volatile oil are summarized in Table I.

Table I. The composition of the volatile oil.

Compound	%
Iimonene	41.4
α-Pinene	23.0
Myrcene	6.8
Terpinolene	0.7
3-Carene	0.3
γ-Terpinene	0.1
Citronellol	0.7
Terpinen-4-ol	0.4
α-Terpineol	0.3
Linalool	+
Geraniol	+
Methyl salicylate	0.2
Phenylethyl acetate	0.1
Unidentified carbonyl compound	0.1
δ-Cadinene	13.6
γ-Cadinene	2.0
β-Clemene	0.8
Sesquiterpene hydrocarbon I	1.0
Sesquiterpene hydrocarbon II	0.8
Torreyol (now δ-cadinol)	3.1
Cadinenol	1.2
Nerolidol	0.6
Sesquiterpene alcohol	1.0
Sesquiterpene hydrocarbon mixture	2.5
Unidentified carbonyl compound I	0.3
Unidentified carbonyl compouod II	0.2

The Structure of Torreyol

Upon treatment with hydrogen chloride in dioxane-water, torreyol gave cadinene dihydrochloride; m. p. 119°C, $[\alpha]_D^{14}$ +40.8° (*c* 0.735, ethyl acetate). On the basis of the value of the optical rotation, the identity of the infrared spectrum, and the depression of the mixed melting point with (−)-cadinene dihydrochloride (m. p. 117~118°C, $[\alpha]_D^{14}$ −40.7°), it can be said that the dihydrochloride of torreyol is undoubtedly (+)-cadinene dihydrochloride.

The oxidation of torreyol with potassium permanganate yielded a dihydroxy-ketone (m. p. 143~144°C).[8] No acetone was detected by the ozonization of torreyol. These findings prove the previously suggested. Formula I for torreyol to be untenable; on the other hand, by a direct comparison of the mixed melting point and the infrared spectrum with an authentic sample,[9] torreyol was proved to be identical with (+)-δ-cadinol. It was an optical antipode of pilgerol[10] isolated from the oil of *Pilgerodendron uniferum* by Erdtman.[11]

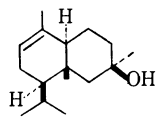
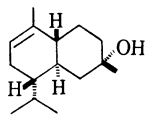
The structure of (−)-δ-cadinol has to be represented by formula IV, proposed by Dauben and his co-workers;[8] therefore the structure of (+)-δ-cadinol has to be shown by formula V.



IV



V

The physical constants of δ-cadinol obtained from various sources are shown in Table II.

Summary

It was found that the volatile oil from the leaves of *Torreya nucifera* contains limonene, 41.4%; α-pinene, 23.0%; myrcene, 6.8; terpinolene, 0.7%; 3-carene, 0.3%; γ-terpinene, 0.1%; citronellol, 0.7%; terpinen-4-ol, 0.4%; α-terpineol, 0.3%; methyl salicylate, 0.2%; phenylethyl acetate, 0.1%; δ-cadinene, 13.6%; γ-cadinene, 2.0%; β-elemene, 0.8%; torreyol (δ-cadinol), 3.1%; (+)-cadinenol, 1.2%; nerolidol, 0.6%; small amounts of linalool and geraniol; two unknown sesquiterpenic hydrocarbons, 1.8%; an unknown sesquiterpene alcohol, 1.0%, and three unidentified carbonyl compounds.

The authors wish to express their deep thanks to Professor V. Herout, Institute of Chemistry, Czechoslovak Academy of Science, for his valuable suggestions and kind supply of authentic samples of cadinenol and δ-cadinol. They are also indebted to Professor H. Erdtman, Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, for his kind help in identifying torreyol with pilgerol.

Synthesis of DL-Glutamic Acid from 1, 1, 1, 5-Tetrachloropentane

By Kazuo SAOTOME and Toshiaki YAMAZAKI

(Received May 22, 1963)

Various amino acids have been synthesized by Russian authors using ethylene-carbon tetrachloride telomers as the starting raw materials. In the previous papers,[1,2] the present authors have reported on the synthesis of DL-lysine from 1, 1, 1, 5-tetrachloropentane which had been prepared by the telomerization of ethylene and carbon tetrachloride. This paper presents a novel way for the synthesis of DL-glutamic acid from 1, 1, 1, 5-tetrachloropentane. The process involves the five steps shown below:

$$\underset{\text{(I)}}{Cl(CH_2)_4CCl_3} \rightarrow \underset{\text{(II)}}{HO(CH_2)_4CCl_3} \rightarrow \underset{\text{(III)}}{HOOC(CH_2)_3CCl_3} \rightarrow \underset{\text{(IV)}}{HOOC(CH_2)_2CH{=}CCl_2} \rightarrow \underset{\text{(V)}}{HOOC(CH_2)_2CHClCOOH} \rightarrow \underset{\text{(VI)}}{HOOC(CH_2)_2CHNH_2COOH}$$

Since the trichloromethyl group in I is inert towards a nucleophilic reagent, the chlorine atom at the other end can be substituted selectively by the hydroxy group in an aqueous alkaline solution. In a laboratory, however, the saponification of the acetoxy derivative of I prepared by treating I with potassium acetate in glacial acetic acid is a more convenient method.

According to Nesmeyanov et al.,[3] the oxidation of II by chromic anhydride in glacial acetic acid gave III, but in a poor yield. In our study, II was oxidized with potassium permanganate in an aqueous solution to afford III in a yield over 90%. The trichloroethyl group in aliphatic compounds is converted to dichlorovinyl group by heating in the presence of such a Lewis acid as ferric chloride.[4] The dehydrochlorination of III using such stronger Lewis acids as aluminum chloride and ferric chloride resulted only in a poor yield. However, when III was heated in the presence of a relatively weaker Lewis acid such

as zinc chloride or bismuth chloride, IV was found to be affoded in a good yield. Nesmeyanov et al.[3] synthesized IV through another process, in which dichloropropenylmalonic acid prepared from 3,3,3-trichloropropene-1 by malonic synthesis was decarboxylated.

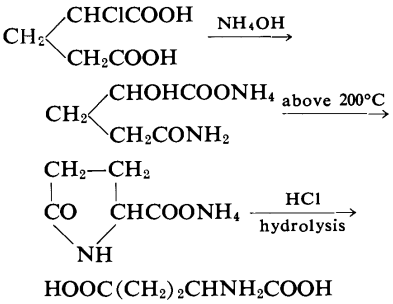
The synthesis of α-chlorocarboxylic acid by the chlorination of compounds containing a dichlorovinyl group in an acid medium has been reported recently.[5] The conjugated addition of chlorine to the dichlorovinyl group is considered to proceed according to the following scheme:

$$RCH{=}CCl_2 \xrightarrow[HA]{Cl_2} [RCHCl\text{-}CCl_2A] \xrightarrow{H_2O}$$
$$RCHClCOOH + 2HCl + HA$$

A chlorine atom and an acid residue (A) are added to the double bond of the dichlorovinyl group, and the resulting adduct is decomposed with water to give α-chlorocarboxylic acid.

Freidlina et al.[6] synthesized several amino acids by the ammonolysis of α-chlorocarboxylic acids which had been prepared by the above method. In their reports, DL-glutamic acid was also prepared from 5,5-dichloro-4-pentenoic acid (IV). Since the separation of α-chloroglutaric acid as crystals is somewhat difficult, they obtained the diethyl ester of α-chloroglutaric acid by treating the crude product with ethanol. The ammonolysis of diethyl α-chloroglutarate was carried out with ethanol-ammonia. They obtained DL-glutamic acid in a 70% yield after the hydrolysis of the amination product with hydrochloric acid. Another reason why Freidlina et al. converted the chlorination product to diethyl α-chloroglutarate may be the complicated behavior of α-chloroglutaric acid in ammonolysis.

According to Kawai,[7] the ammonolysis of α-chloroglutaric acid in aqueous ammonia at a temperature above 200°C proceeds according to the following scheme:



$HOOC(CH_2)_2CHNH_2COOH$

DL-glutamic acid

In our process, α-chloroglutaric acid was separated as crystals from the chlorination product. The ammonolysis of α-chloroglutaric acid was carried out in aqueous ammonia at 260°C, and the resulting product was hydrolyzed with hydrochloric acid to afford DL-glutamic acid in a 87% yield.

Experimental

1,1,1-Trichloro-5-hydroxypentane (II).—A mixture of 786 g. of I, 660 g. of potassium acetate and 900 ml. of glacial acetic acid was refluxed for 16 hr. in the presence of the catalyst iodine (1.5 g.). The reaction mixture was diluted with water after the acetic acid had been evaporated under reduced pressure. The oily layer and the benzene extract from the aqueous layer were then combined and washed with water. Distillation of the extract under reduced pressure afforded 1,1,1-trichloro-5-acetoxypentane; b. p. 79~80°C/1 mmHg, n_D^{20} 1.4683. Yield, 805 g. (92.0%).

The acetate prepared above was saponified with sodium hydroxide in aqueous methanol (1 : 1) at room temperature. The reaction mixture, after being allowed to stand overnight, was neutralized with hydrochloric acid and extracted with benzene. The distillation of the benzene extract under reduced pressure afforded a quantitative amount of II; b. p. 78~80°C/1 mmHg, n_D^{20} 1.4878 (lit.[3] b. p. 112~113°C/10 mmHg, n_D^{20} 1.4897).

5,5,5-Trichlorovaleric Acid (III).—Into an aqueous solution of potassium permanganate heated in a water bath, II was stirred in drop by drop. The reaction was continued for a few hours after the

addition of the reactant. The excess permanganate was decomposed by adding a small amount of methanol. The manganese dioxide which was precipitated was filtered from the reaction mixture and washed several times with hot water. The filtrate was then cooled and acidified with hydrochloric acid. The white crystals which precipitated were collected and dried over calcium chloride under reduced pressure. Recrystallization from petroleum ether afforded III; m. p. 64°C (lit. m. p. 65°C).

Found: C, 29.19; H, 3.41; Cl, 51.82. Calcd. for $C_5H_7O_2Cl_3$: C, 29.23; H, 3.43; Cl, 51.77%.

Details of the reaction are shown in Table I.

5,5-Dichloro-4-pentenoic Acid (IV). — The dehydrochlorination of III was investigated using several Lewis acids as catalysts. The reaction was carried out by heating and simultaneously stirring III in the presence of the catalyst. After the evolution of hydrogen chloride had ceased, the reaction mixture was washed with water, then distilled under reduced pressure to afford IV; b. p. 95～97°C/1 mmHg, n_D^{20} 1.4888 (lit.[3] b. p. 93～94°C/1 mmHg, n_D^{20} 1.4898).

Found: C, 35.32; H, 3.68; Cl, 41.83. Calcd. for $C_5H_6O_2Cl_2$: C, 35.53; H, 3.58; Cl, 41.96%.

The reaction conditions and the yields are shown in Table II.

As Table II shows, when a stronger Lewis acid ($AlCl_3$ or $FeCl_3$) was used as the catalyst, the resinous by-product increased and the yield of IV decreased. The best result was obtained when bismuth chloride was used as the catalyst. The effect of acetic acid as a solvent was not prominent.

α-Chloroglutaric Acid (V). — Into sulfuric acid cooled in ice-water, IV was dissolved slowly to make a clear solution. Chlorine gas was passed through this solution while it gas being stirred at a temperature below 10°C. The reaction was continued for a few hours until the evolution of hydrogen chloride had ceased. The reaction mixture was then poured into ice-water, and the product was extracted with ether. The ether extract was washed several times with water and dried with anhydrous sodium sulfate. After the evaporation of the ether, the residue was further dried under reduced pressure to obtain the crystals of V. Recrystallization from chloroform afforded white crystals; m. p. 95～97°C, (lit. m. p. 98°C).

Found: C, 36.19; H, 4.24; Cl, 21.43. Calcd. for $C_5H_7O_4Cl$: C, 36.05; H, 4.24; Cl, 21.29%.

In this reaction, formic and acetic acids were also applied in place of sulfuric acid. The reaction product was then treated as in the case of sulfuric acid. Details of the reaction are shown in Table III.

DL-Glutamic Acid (VI).—In an autoclave equipped with a magnetic stirrer, V (5.0 g.) and aqueous ammonia were placed. The reaction was carried out at the temperature of 260±5°C for 4 hr. The reaction mixture was concentrated almost to dryness on a water bath to remove any free ammonia. The residue was then dissolved in 40 ml. of hot water and filtered.

To this filtrate 40 ml. of concentrated hydrochloric acid was added, and the mixture was refluxed for 4 hr. to hydrolyze the reaction product. The solution was again concentrated to dryness under reduced pressure to remove hydrochloric acid. The solid product was dissolved in 100 ml. of water, and the solution was decolorized by boiling it with

active charcoal. The decolorized solution was then concentrated to about 30 ml. An aliquot of this solution was directed to the sample for the quantitative analysis of VI. The pH of the rest of the solution was adjusted at 3.2 (the isoelectric point of glutamic acid) and stored in a refrigerator. White crystals precipitated. Recrystallization from water gave VI; m. p. 185°C (lit. m. p. 185°C). This was identified by paper chromatography with an authentic sample and was shown to be one-spot.

Found: C, 40.67; H, 6.38; N, 9.39. Calcd. for $C_5H_9O_4N$; C, 40.82; H, 6.17; N, 9.52.

The Quantitative Analysis of DL-Glutamic Acid. —Five milliliters of the decolorized solution was diluted to 100 ml., of which 0.01 ml. was taken on a filter paper; the components other than DL-glutamic acid were removed by electrophoresis. The DL-glutamic acid was then extracted with ethanol from the paper, and the resulting solution was analyzed by electrophotometry. The DL-glutamic acid content was determined by comparison with the standard extinction curve. The relation between the concentration of aqueous ammonia and the yield is show in Table IV.

In Tabl IV, the yield may be seen to decrease as the concentration of ammonia increases.

TABLE IV. THE AMMONOLYSIS OF α-CHLOROGLUTARIC ACID

α-Chloroglutaric acid	Aqueous NH_3		DL-Glutamic acid	
g.	ml.	concn., %	g.	Yield, %
5.0	50	13.5	3.84	87
5.0	50	20.0	3.31	75
5.0	50	28.0	3.09	70

Summary

DL-Glutamic acid has been synthesized from 1, 1, 1, 5-tetrachloropentane. The process involves five steps through 1, 1, 1-trichloro-5-hydroxypentane (92%), 5, 5, 5-trichlorovaleric acid (94%), 5, 5-dichloro-4-pentenoic acid (85%), α-chloroglutaric acid (82%), and DL-glutamic acid (87%). The over-all field from 1, 1, 1, 5-tetrachloropentane to DL-glutamic acid was 52%.

In the dehydrochlorination of 5, 5, 5-trichlorovaleric acid to 5, 5-dichloro-4-pentenoic acid, rather weak Lewis acid catalysts, such as bismuth chloride and zinc chloride were found to give the best results.

The authors wish to expess their deep thans to Dr. Gentaro Noyori of the Noguchi Institute for his kind advice on the ammonolysis of α-chloroglutaric acid.

Oligomers and Polymers Containing Triple Bonds. II. Derivatives of Ethynylazobenzene

By Hisaya TANI, Sigeru TANAKA and Fumio TODA

(Received May 11, 1963)

Previous studies[1,2] have shown that various diethynyl compounds react with cupric or cuprous salts to produce linear and stable polymers containing triple bonds. In the present paper, the preparation of 4-ethynyl- and 4,4'-diethynylazobenzene and the polymerization of the latter will be described.

The treatment of 4-acetylazobenzene[3] (II), prepared from *p*-aminoacetophenone (I) and nitrosobenzene, with phosphorus pentachloride and then with a large excess of sodium amide in liquid ammonia, resulted in the formation of *trans*-4-ethynylazobenzene (IIIa), together with a small amount of cis-isomer (IIIb). When a nearly theoretical amount of sodium amide was employed, however, 4-(chloroethynyl)-*trans*-azobenzene (IVa) and IIIa were obtained in almost equal yields.

Confirmatory evidence for the configurations of IIIa and IIIb was found in the following experimental results: the relationship between the electronic absorption properties of IIIa and IIIb resembled that between those of *cis*- and *trans*-azobenzene (Fig. 1), and IIIa (m. p. 81~82°C) was eluted with carbon tetrachloride faster than was IIIb (m. p. 183.5°C) during the course of chromatography on alumina. It has previously been well known that cis-derivatives of azobenzene are more strongly adsorbed on

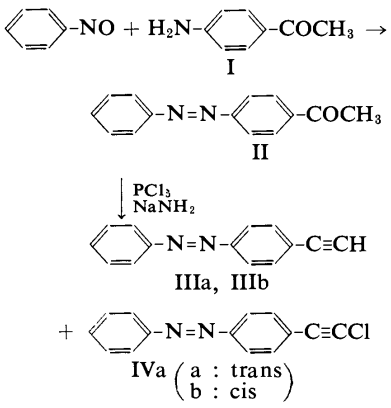
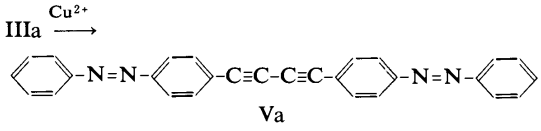
C 4-Ethynyl-*cis*-azobenzene (III_b)
all in dioxane.

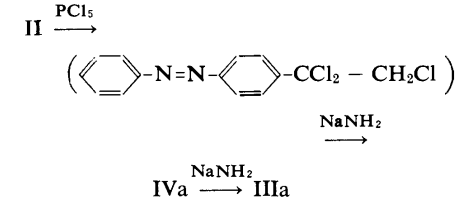




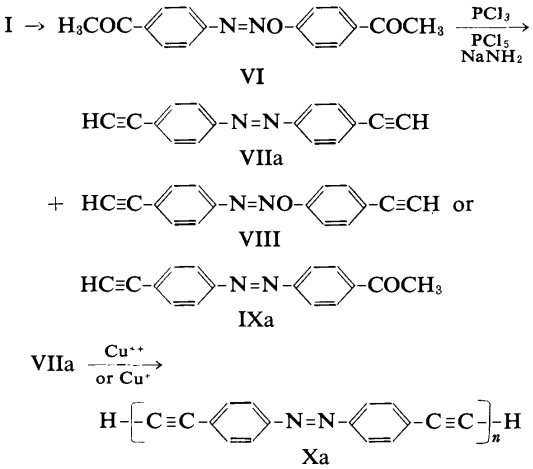
alumina and have higher melting points than do trans-derivatives. The configurations assigned to all the remaining compounds obtained in the present work were similarly confirmed.

IIIa gave, on oxidative coupling with cupric acetate in pyridine, the normal product Va in a good yield.

The formation of IVa in the course of the conversion of II to III may offer valuable evidence for the initial formation of 4-(1,2,2-trichloroethyl)azobenzene, from which IVa and further IIIa were produced by the action of sodium amide.



4,4'-Diethynyl-*trans*-azobenzene (VIIa) was prepared from 4,4'-diacetylazoxybenzene (VI), which had been obtained by the oxidation of I with neutralized Caro's acid[4] or with perboric acid,[5] by the reduction of azoxy group with phosphorus trichloride, followed by treatment with the same method as was employed for II. When phosphorus oxychloride and chloroform were used as solvents in the reduction process, 4,4'-diethynylazoxybenzene (VIII) and 4-ethynyl-4'-acetyl-*trans*-azobenzene (IXa) were formed as the respective by-products. The electronic spectra of VIIa, VIII and IXa, indicating valuable evidence for their configuration, are shown in Fig. 2.



The polymerizations of VIIa with copper salt catalysts in pyridine or in dimethylformamide, as summarized in Table I, resulted in the formation of insoluble and infusible reddish brown or dark brown solids. The infrared and electronic absorption spectra indicated that these products were conjugated linear polymers. When polymerizations were carried out in pyridine, the linear dimer of VIIa (Xa, $n=2$) was obtained. This is because of the low solubility of the initially-formed dimer in the solvent used for the polymerization. When the polymerization was carried out in dimethylformamide, linear hexamer (Xa, $n=6$) was obtained. It is not clear whether the

difference in the degree of polymerization is due to the basicity of the solvent or to the solubility of the oligomer in the solvent.

The degree of polymerization of all the polymers thus obtained was estimated by comparing the intensity at the ethynyl maximum (3300 cm^{-1}) in the infrared spectra of these polymers with that of VIIa, used as a reference standard (Fig. 3). This estimation was based on the assumption that the absorbancy of the ethynyl band is not affected by the length of the conjugation system. This assumption was justified by comparing the electronic spectra of Xa, $n=2$ with that of Va, as shown in Fig. 2; these spectra show that Xa, $n=2$ absorbs at wave lengths longer by ca. 11 mμ than does Va. It is most reasonable to consider that this bathochromic shift is attributable to the two additional ethynyl substituents. On the other hand, the shift exhibited when one more ethynyl group was introduced in to IIIa is 14 mμ (Figs. 1 and 2), which is comparable to the value (11 mμ) of the shift due to the conversion of Va to Xa, $n=2$.

TABLE I. POLYMERIZATION OF 4, 4'-DIETHYNYL-*trans*-AZOBENZENE (VIIa)

VIIa mg.	Catalyst mg.		Solvent* ml.	Reaction temp., °C	Reaction time, min.	Atmosphere	Color	Product mg.	Degree of polymerization

* P, Pyridine D, Dimethylformamide

The resistivities of Xa, $_{n=6}$ at 25° and at 0°C were found to be 3.8×10^{12} and 3.9×10^{-4} ohm. cm. respectively. The temperature dependence of the resistivity obeyed the following relation:

$\rho=\rho_0\exp. \Delta\varepsilon/2kT$ where $\Delta\varepsilon=1.85$eV. (Fig. 4)

From the above data, it is apparent that this polymer has the typical characteristics of an organo-semiconductor.

Experimental*

4-Ethynyl-*trans*-azobenzene (IIIa) and 4-Ethynyl-*cis*-azobenzene (IIIb).—A mixture of 4-acetylazobenzene (2.2 g., 0.01 mol.), phosphorus pentachloride (2.4 g., 0.011 mol.), and phosphorus oxychloride (20 ml.) was heated at 60°C for 1 hr. The crude chloride obtained by the evaporation of phosphorus oxychloride under reduced pressure was dissolved in dry ether, and the solution was then added to sodium amide in liquid ammonia (sodium 1.0 g., 0.044 g. atom, liquid ammonia 100 ml.). After the evaporation of the ammonia, the crude product was extracted with ether. The ethereal layer was washed with water and dried over sodium sulfate. The residue obtained by the evaporation of the ether was chromatographed on alumina.

The orange crystals obtained from the fraction eluted with carbon tetrachloride were recrystallized from *n*-hexane to give 4-ethynyl-*trans*-azobenzene (IIIa); 160 mg. as orange leaflets; m. p. 81～82°C. IR: KBr disk, 3270 (ethynyl), 1414 (azobenzene), 843 (*p*-disubstituted benzene) and 769, 675 cm^{-1} (monosubstituted benzene). UV: $\lambda_{max}^{Dioxane}$: 234 mμ (ε, 15500), 334 (28200), 442 (1400).

Found: C, 81.36; H, 4.88; N, 13.38. Calcd. for $C_{14}H_{10}N_2$: C, 81.53; H, 4.89; N, 13.58%.

Elution with benzene, followed by recrystallization from *n*-hexane, yielded a small amount of 4-ethynyl-*cis*-azobenzene (IIIb) as orange needles; m. p. 183.5°C. IR: KBr disk, 1400 (azobenzene), 845 (*p*-disubstituted benzene), and 773, 685 cm^{-1} (monosubstituted benzene). UV: $\lambda_{max}^{Dioxane}$: 234 mμ (ε, 11800), 344 (20000), 415 (1500), 432 (1500).

Found: N, 13.37. Calcd. for $C_{14}H_{10}N_2$: N, 13.58%.

* All melting points are uncorrected.

The mercury salt of IIIb (orange) did not melt, but turned black at ca. 245°C. IR: KBr disk, 2130 (acetylene), 1410 (azobenzene), 850 (*p*-disubstituted benzene) and 770, 685 cm^{-1} (monosubstituted benzene).

4-(Chloroethynyl)-*trans*-azobenzene (IVa).—4-Acetylazobenzene (5.1 g., 0.023 mol.) was treated with phosphorus pentachloride (5.0 g., 0.024 mol.) in phosphorus oxychloride (30 ml.) and then with sodium amide in liquid ammonia (sodium 1.5 g., 0.065 g. atom, liquid ammonia 150 ml.) in the manner described above. The ammonia was removed, and the residue was extracted with ether. The ether layer was washed with water and dried over magnesium sulfate. After evaporation of the solvent, the crude material remaining was chromatographed on alumina from carbon tetrachloride.

Recrystallization of the crystals obtained from the first fraction (eluted with carbon tetrachloride 700 ml.) from *n*-hexane afforded IVa (200 mg.), in the form of orange leaflets; m. p. 107.5°C. IR: KBr disk, 2210 (acetylene), 1410 (azobenzene), 838 (*p*-disubstituted benzene) and 763, 675 cm^{-1} (monosubstituted benzene). UV: $\lambda_{max}^{Dioxane}$: 221 mμ (ε, 10900) 236 (14600) 338 (26800), 445 (1100).

Found: C, 69.27; H, 3.67; N, 11.56; Cl, 14.70. Calcd. for $C_{14}H_9N_2Cl$: C, 69.86; H, 3.77; N, 11.64; Cl, 14.73%.

From the second fraction (eluted with carbon tetrachloride 800 ml.), there was obtained the crude solids, the recrystallization of which from *n*-hexane gave orange leaflets (200 mg.; m. p. 78～79°C), identified as 4-ethynyl-*trans*-azobenzene (IIIa) by comparing their infrared spectrum and melting point with those of an authentic sample.

4, 4'-Bis(phenyl-*trans*-azo)diphenyldiacetylene (Va).—To a solution of IIIa (100 mg.) in pyridine (20 ml)., cupric acetate monohydrate (2.0 g.) was added; the mixture was then stirred at 60°C for 30 min. The solid precipitates which formed were collected by filtration and washed with a small amount of pyridine. The solid was dried and then recrystallized from chloroform to yield Va (95 mg.) (quantitative yield) as orange leaflets; m. p. 243～234.5°C (decomp.). UV: $\lambda_{max}^{Dioxane}$: 238 mμ (ε, 13800), 374 (33100), 448 (2200).

Found: C, 80.73; H, 4.42; N, 13.70. Calcd. for $C_{28}H_{18}N_4$: C, 81.93; H, 4.42; N, 13.65%.

4, 4'-Diacetylazoxybenzene (VI).—*Procedure (A).*—A mixture of *p*-aminoacetophenone (1, 2.7 g., 0.02 mol.), acetic acid (80 ml.), and sodium perborate (3.3 g., corresponding to 0.02 g. atom of oxygen) was heated at 60°C for 2hr. The precipitates which had separated after the addition of water were collected, washed with water, dried, and then recrystallized from alcohol to give VI, 700 mg. (25%) as yellow leaflets; m. p. 187~190°C. IR: KBr disk, 1685 (ketone), 1462, 1360 (methyl), 1410 (azobenzene), 1260 (aromatic ketone) and 844 cm^{-1} (*p*-disubstituted benzene). UV: $\lambda_{max}^{Dioxane}$: 274 mμ (ε, 10900), 338 (21900).

When the reaction was carried out at 52°C and 30°C, VI was obtained in a yield of 15 and 11% respectively.

Found: C, 67.96; H, 5.05; H, 9.63. Calcd. for $C_{16}H_{14}N_2O_3$: C, 68,07; H, 5.00; N, 9.92%.

Procedure (B).—A solution of *p*-aminoacetophenone (1, 9.7 g., 0.072 mol.) in dioxane (10 ml.) was added to neutral Caro's acid (0.18 N, 900 ml.). After the solution had been shaken for 10 min. at room temperature, the precipitates which had formed were collected by filtration, washed with water, and dried. Recrystallization of the product from acetone afforded VI 3.2 g. (32%) as yellow needles (m. p. 195.5°C), which showed no depression of melting point upon being mixed with the sample prepared in procedure (A). When 0.07 N Caro's acid was used, the yield of VI was lowered to 14%.

4, 4'-Diethynyl-*trans*-azobenzene (VIIa) and 4, 4'-Diethynylazoxybenzene (VIII).—A mixture of 4, 4'-diacetylazoxybenzene (2.8 g., 0.01 mol.), phosphorus oxychloride (40 ml.), and phosphorus trichloride (1.5 g., 0.01 mol.) was treated at 50°C for 30 min. To this warm mixture, phosphorus pentachloride (4.5 g., 0.02 mol.) was added, and the mixture was heated at 50°C for 1 hr. After removal of the phosphorus oxychloride and phosphorus trichloride by distillation in vacuo, the crude chloride which remained was suspended in dry ether (200 ml.), and the resulting suspension was added drop by drop to sodium amide in liquid ammonia (sodium 2.3 g., 0.1 g. atom, liquid ammonia 100 ml.), Stirring was continued for a further 30 min. The residue which remained after the evaporation of the ammonia was decomposed with water and extracted with ether. The ether layer was washed with water and dried over sodium sulfate. After evaporation of the solvent, the crude material was chromatographed on alumina. The crude crystals which were obtained from the first fraction, eluted with carbon tetrachloride, were recrystallized from *n*-hexane, giving VIIa (10 mg.) as orangered needles. Although VIIa did not show a melting point and turned black in the usual m. p. measurement, it melted at 201~202°C with decomposition when immersed at 198°C. IR: Nujol mull, 3270 (ethynyl), 1925 (acetylene), 1419 (azobenzene) and 848 cm^{-1} (*p*-disubstituted benzene). UV $\lambda_{max}^{Dioxane}$: 239 mμ (ε, 14100), 264 (shoulder) (7600), 348 (30200), 450 (1100).

Found: C, 83.52; H. 4.41; N, 12.46. Calcd. for $C_{16}H_{10}N_2$: C, 83.45; N, 4.38; N, 12.17%.

On the other hand, from the second fraction, eluted with benzene, orange yellow crystals were obtained. The crystals were recrystallized from *n*-hexane to yield VIII (10 mg.) as orange yellow leaflets; m. p. 141.5~142.5°C. UV $\lambda_{max}^{Dioxane}$: 230 mμ (ε, 11700), 349 (21400), 480 (shoulder) (100).

Found: C, 77.40; H, 4.29; N, 11.53. Calcd. for $C_{16}H_{10}N_2O$: C, 78.03; H, 4.09; N, 11.38%.

4, 4'-Diethynyl-*trans*-azobenzene (VIIa) and 4-Acetyl-4'-ethynyl-*trans*-azobenzene (IXa).—A solution of 4, 4'-diacetylazoxybenzene (5.5 g., 0.02 mol.) in chloroform (80 ml.) with was treated phosphorus trichloride (2.7 g.) at 50°C for 1 hr. The resultant mixture was then heated with phosphors pentachloride (8.4 g., 0.04 mol.) at 50~60°C for 1 hr. The crude chloride which remained after the evaporation of the chloroform and phosphorus trichloride was treated with sodium amide in liquid ammonia (sodium 3.5 g., 0.15 g. atom; liquid ammonia 150 ml.). After removal of the ammonia, the residue was decomposed with water and extracted with ether. The ether layer was washed with water and then evaporated to leave the crude product, which was chromatographed on alumina from benzene. The first fraction gave the desired compound (VIIa) as orange-red leaflets (96 mg.; m. p. 201~202°C (decomp., immersed at 198°C) after recrystallization from *n*-hexane.

When the crystals which were obtained from the second fraction were recrystallized from aqueous ethanol, IXa (14 mg.) was obtained as orange leaflets; m. p. 163°C. IR: KBr disk, 3240 (ethynyl), 2090 (acetylene), 1660, 1264 (acetyl), 1414 (azo) and 850 cm^{-1} (*p*-disubstituted benzene). UV $\lambda_{max}^{Dioxane}$: 236 mμ (ε, 10000), 344 (22400), 455 (600).

Found: C, 76.27; H, 4.99; N, 10.76. Calcd. for $C_{16}H_{12}N_2O$: C, 77.40; H, 4.87; N, 11.28%.

Electric Constants.—Electric constants were measured for the tablet of Xa, $n=6$, on which indium had been sublimed in vacuo. The tablet was made by applying a pressure of 6000 kg./cm^2 on the powder of the polymer in a tube 13 mm. in diameter for a 30-min. period.

The authors wish to express their thanks to Mr. Yoshinobu Murakami of the Matsushita Electric Industrial Co., Ltd., for his measurements of the electric constants and also to Mr. Masakazu Okumiya of this faculty for his microanalyses.

Studies of Pyridotropolones. VII.[1,2] *Several Condensation Reactions of Isopropylpyrido[3, 2-d]tropolones*

By Kameji YAMANE, Tadashi MATSUMOTO and Akira YOKOO

(Received May 14, 1963)

Regarding the condensation reaction of pyridotropolones, one of the present authors, Yamane,[3] has previously reported that nitroso compound I of 8-isopropyl-2-methylpyrido-[3, 2-d] tropolone afforded a quinoxalo compound II by the condensation with *o*-phenylenediamine, and that 5-amino compound III, which was obtained by the catalytic reduction of I, gave an oxazolopyridotropone derivative IV upon being treated with acetic anhydride. Kikuchi and Muroi[4] reported that pyrido-[3, 2-d] tropolone and its 2-methyl derivative gave quinoxaline derivatives by condensation with *o*-phenylenediamine, and that 2-methylpyrido [3, 2-d] tropolone afforded a 2-styryl compound by condensation with benzaldehyde. The present authors carried out similar condensation reactions of isopropylpyrido [3, 2-d]-tropolones. Furthermore, some derivatives of pyridoindolotropones were obtained by reaction with phenylhydrazine.

As was reported by Kikuchi and Muroi,[4]

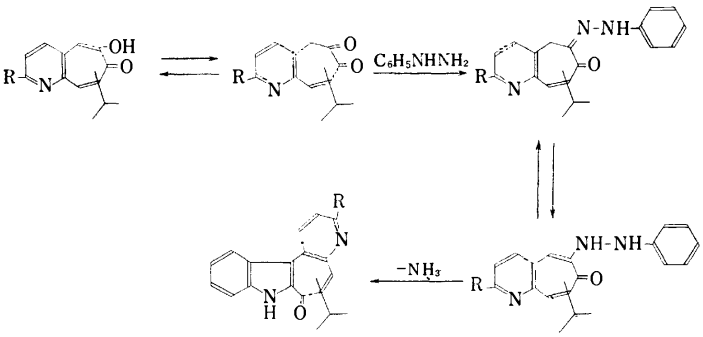
Scheme III



Scheme IV

8-isopropyl-2-styrylpyrido[3, 2-d]tropolone (VIa) and 9-isopropyl-2-styrilpyrido [3, 2-d] tropolone (VIb) were obtained from the reaction of benzaldehyde with 8-isopropyl-2-methylpyrido-[3, 2-d] tropolone (Vb) and with 9-isopropyl-2-methylpyrido[3, 2-d]tropolone (Vd) respectively.

Attempts to prepare quaternary salts of 8-isopropylpyrido [3, 2-d] tropolones by reaction with methyl iodide, ethyl iodide and ethyl *p*-toluenesulfonate were unsuccessful. This was probably due to the decrease in the electron density at the nitrogen atom through the contribution of the structure VII.

The heating of 8- and 9-isopropyl derivatives (Va, Vb and Vc) with *o*-phenylenediamine in acetic acid afforded quinoxaline derivatives in a good yield, as in the case[4] of pyrido [3, 2-d] - tropolone. Kikuchi and Muroi[4] proposed a structure (IX or X) for the condensation product. Treating VIIIb with amyl nitrite in an acidic medium gave II.[3] VIIIe was not acylated by acetyl chloride or benzoyl chloride in pyridine. The infrared spectrum of VIIIe has no absorption bands at the NH region and exhibits an absorption band at 1453 cm^{-1} due to the CH_2 deformation vibration. From these facts, it may be concluded that the condensation product VIII exists not as formula IX but as quinoxalo structure X (Schemes I and II).

The heating of 8-isopropyl-2-methylpyrido-[3, 2-d] tropolone (XIb) with phenylhydrazine in acetic acid unexpectedly gave yellow crystals (XIIb) of formula $C_{20}H_{18}ON_2$ in place of a phenylhydrazone. This suggests that one molecule of ammonia was lost during the reaction. The crystals did not react either with carbonyl reagents or with acylating agents, but *N*-methyl compound XIII was obtained by a method similar to that used in the case of

carbazole. The infrared spectrum of XIIb shows peaks at 1620 cm^{-1} and 3300 cm^{-1}. 8- and 9-isopropyl analogs (XIa and XIc) also gave similar compounds (XIIa and XIIc respectively). The ultraviolet absorption spectra of these compounds are shown in Fig. 2. From these facts it may be assumed that the condensation products have the pyrido[3, 2-d]-indolo[2, 3-b]tropone structure (Scheme III). It is interesting that the mother substance, pyrido[3, 2-d]tropolone and its 2-methyl derivative, gave no pyridoindolotropones. Further studies are now in progress. The mechanism of this condensation reaction seems to be analogous to Fischer's indole syntheses, as Scheme IV shows.

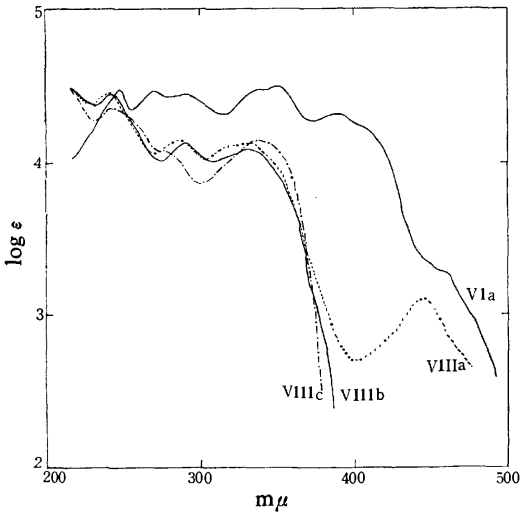


Fig. 1. Ultraviolet absorption spectra of VIa, VIIIa, VIIIb and VIIIc in methanol.

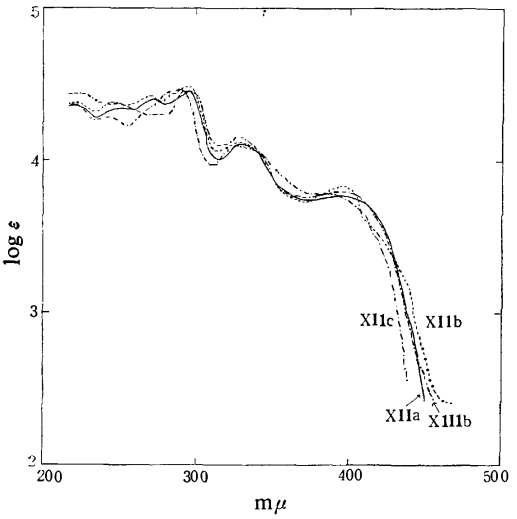

Fig. 2. Ultraviolet absorption spectra of XIIa, XIIb, XIIc and XIIIb in methanol.

Experimental[5]

8-Isopropyl-2-styrylpyrido[3,2-d]tropolone (VIa).—A mixture of Vb (0.4 g.), benzaldehyde (0.2 cc.) and a small amount of zinc chloride in a sealed tube was heated for 3 hr. at 150~160°C. The reaction mixture was diluted with water, and a reddish brown precipitate was then filtered out and sublimed under reduced pressure. The yellow sublimate was recrystallized from methanol to give yellow needles; m. p. 142~142.5°C.

Found: C, 79.45; H, 6.10; N, 4.21. Calcd. for $C_{21}H_{19}O_2N$: C, 79.47; H, 6.03; N, 4.11%.

9-Isopropyl-2-styrylpyrido[3, 2-d]tropolone (VIb).—This was prepared from Vd by a method similar to that described above. Yellow needles; m. p. 182~183°C.

Found: C, 79.36; H, 6.21; N, 4.23. Calcd. for $C_{21}H_{19}O_2N$: C, 79.47; H, 6.03; N, 4.11%.

The Quinoxalo Derivative of 8-Isopropylpyrido-[3,2-d]tropolone (VIIIa).—A mixture of Va (0.4 g.) and *o*-phenylenediamine (0.22 g.) in acetic acid (1.5 cc.) was refluxed for 4 hr. After being cooled, the reaction mixture was diluted with water and made alkaline with aqueous ammonia. The syrupy matter which separated was washed with water and dried in a vacuum dessicator. Recrystallization from ethanol gave pale brownish yellow needles; m. p. 133~134°C (0.43 g., yield 81%).

Found: C, 79.04; H, 5.99; N, 14.54. Calcd. for $C_{19}H_{17}N_3$: C, 79.41; H, 5.96; N, 14.62%.

The Quinoxalo Derivative of 8-Isopropyl-2-methylpyrido[3, 2-d]tropolone (VIIIb).—A mixture of Vb (0.4 g.) and *o*-phenylenediamine (0.2 g.) was treated by a method similar to that described above. Colorless cubic crystals; m. p. 149.5~150.5°C (0.45 g., yield 86%).

Found: C, 79.59; H, 6.18; N, 13.70. Calcd. for $C_{20}H_{19}N_3$: C, 79.70; H, 6.35; N, 13.94%.

The Reaction of VIIIb with Amyl Nitrite.—To a solution of VIIIb (0.5 g.) in concentrated hydrochloric acid (2 cc.), amyl nitrite (3 cc.) was added at room temperature; the mixture was then warmed at 50°C in a water bath to deposit the hydrochloride of II. After the mixture had been allowed to stand overnight, the hydrochloride was filtered and washed with ethanol. Yield, 0.56 g. Recrystallization from ethanol gave colorless plates melting at 259~260°C (decomp.). The hydrochloride (0.12 g.) was dissolved in a large amount of 1 N sodium hydroxide solution by heating on a water bath. After insoluble matter had been removed by hot filtration, the filtrate was acidified with acetic acid and allowed to stand at room temperature to cause crystallization. Recrystallization from alcohol gave a free base, II, as pale yellow plates melting at 238~238.5°C (0.1 g.); the plates were found to be identical with the authentic sample[3] by the mixed melting point and the infrared spectrum.

The Quinoxalo Derivative of 9-Isopropylpyrido-[3,2-d]-tropolone (VIIIc).—A mixture of Vc (0.1 g.) and *o*-phenylenediamine (0.05 g.) was

5) The microanalyses were carried out by Mrs. K. Kodaira and Miss A. Iwanaga (Nozoe Laboratory), to whom deep gratitude is here expressed.

treated as in VIIIa. Colorless plates, m. p. 158.5～159°C (0.11 g., yield, 81%).

Found: C, 79.56; H, 5.61; N, 14.77. Calcd. for $C_{19}H_{17}N_3$: C, 79.41; H, 5.96; N, 14.62%.

6-Isopropylpyrido[3, 2-d]indolo[2, 3-b]tropone (XIIa).—A mixture of XIa (0.3 g.) and phenylhydrazine (0.19 g.) in acetic acid (1.5 cc.) was refluxed for 10 hr. After it had cooled, the crystals were collected by filtration and washed with water. Recrystallization from ethanol gave yellow needles; m. p. 185.5～186.5°C (0.17 g., yield 42%).

Found: C, 79.34; H, 6.22; N, 9.38. Calcd. for $C_{19}H_{16}ON_2$: C, 79.14; H, 5.59; N, 9.72%.

6-Isopropyl-3-methylpyrido[3, 2-d]indolo[2, 3-b]-tropone (XIIb).—A mixture of XIb (0.3 g.) and phenylhydrazine (0.15 g.) was treated as in XIIa. Yellow needles; m. p. 220～221°C (0.21 g., yield 53%).

Found: C, 79.50; H, 5.85; N, 9.45. Calcd. for $C_{20}H_{18}ON_2$: C, 79.44; H, 6.00; N, 9.27%.

Picrate.—Orange yellow prisms; m. p. 223～224°C (from ethanol).

Found: N, 12.94. Calcd. for $C_{26}H_{21}O_8N_5$: N, 13.18%.

N-Methyl Compound (XIIIb).—A mixture of XIIb (0.1 g.) and potassium hydroxide (0.05 g.) was heated in a test tube at 230～240°C. After the mixture had cooled, red potassium salt was refluxed with methyl iodide (1 g.) for 3 hr. The excess methyl iodide was then evaporated, and the residue was extracted with benzene. The benzene extracts were treated with charcoal, and the solvent was distilled out. The residue was recrystallized from ethanol to give yellow needles; m. p. 147～148°C, (0.08 g., yield 76%).

Found: C, 80.09; H, 6.13; N, 8.34. Calcd. for $C_{21}H_{20}ON_2$: C, 79.71; H, 6.37; N, 8.85%.

5-Isopropylpyrido[3, 2-d]indolo[2, 3-b]tropone (XIIc).—A mixture of XIc (0.13 g.) and phenylhydrazine (0.13 g.) in acetic acid (1.5 cc.) was refluxed for 8 hr. After the reaction mixture had cooled, water was added, and the product was recrystallized from ethanol to give yellow needles melting at 255°C (by Kofler block). (A very poor yield).

Found: C, 79.24; H, 5.79; N, 9.14. Calcd. for $C_{19}H_{16}ON_2$: C, 79.14; H, 5.59; N, 9.72%.

The present research was financed by a grant-in-aid for Scientific Research granted by the Ministry of Education. The authors wish to express their hearty thanks to Professor Tetsuo Nozoe, and Assistant Professor Toshio Mukai of Tohoku University and Assistant Professor Katsuo Kikuchi of Yamagata University for their helpful advice.

*Studies on Amino-hexoses. VI. The Synthesis of Phenyl 2-Acetamido-3-O-(D-1'-carboxyethyl)-2-deoxy-α- and β-D-Glucopyranoside and Their Methyl Esters**

By Kazuhiko YAMAMOTO, Mamoru FUJINAGA and Yoshio MATSUSHIMA

(Received June 5, 1963)

A new aminosugar named muramic acid has been discovered in uridine pyrophosphate peptide complexes in *Staphylococcus aureus*[1] and was determined to be 2-amino-3-*O*-(D-1'-carboxyethyl)-2-deoxy-D-glucose.[2] It has been found to be distributed among the cell walls of a number of bacteria. Lysozyme, the enzyme which exerts a bacteriolytic action, has been found to split the cell-wall polysaccharide-peptide complex called muco-peptide at the site of the glycosidic bond of the *N*-acetyl-muramic acid component.[3] However, the substrate specificity of lysozyme is not very clear because of the complexity of the chemical structure of the mucopeptide.

One of the present authors has reported on a convenient method for synthesizing *N*-acetyl-muramic acid glycosides.[4] The present paper will describe the synthesis of phenyl *N*-acetyl-α- and β-muramide and their methyl esters by this method and will also describe the action of lysozyme on these model substrates.

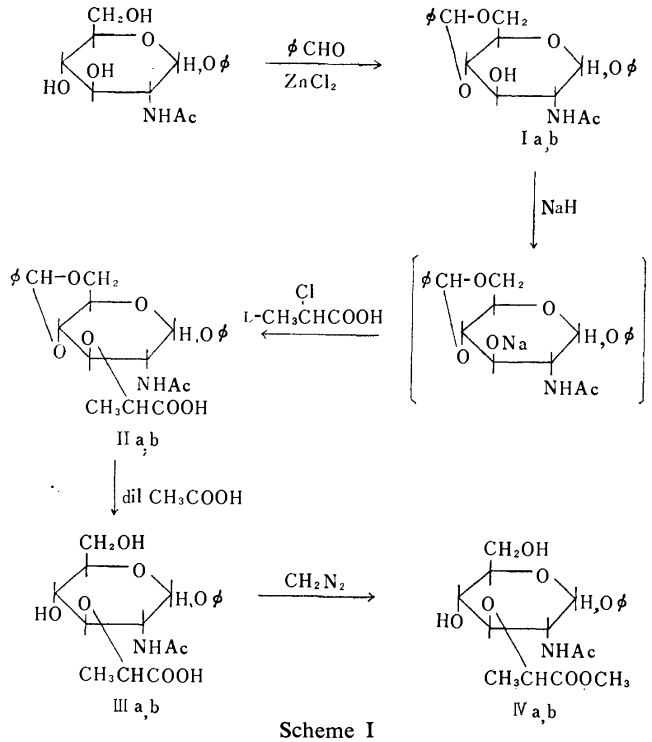

Scheme I

Phenyl α- and β-D-glucosaminide were prepared according to the methods cited.[5,6] These phenyl glycosides were converted by the usual method into 4,6-*O*-benzylidene derivatives, and the latter were condensed with L-α-chloropropionic acid, as has been reported.[4] The debenzylation with dilute acetic acid of these condensation products yielded phenyl *N*-acetyl-α- and β-muramide repectively. Methylation with diazomethane gave the respective methyl esters. The procedure of the synthesis is shown in Scheme I.

Lysozyme action[7] was tested on these acids as well as on methyl esters over a range of pH values. It was found that no appreciable cleavage of the phenyl group occurred in either α- or β-anomer.

Experimental

Phenyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (Ia).—Four grams of phenyl 2-acetamido-2-deoxy-α-D-glucopyranoside,[5] 40 g. of freshly distilled benzaldehyde, and 4.0 g. of anhydrous zinc chloride were kept in a tightly closed polyethylene bottle while being mechanically shaken at room temperature for 24 hr. The reaction mixture was then poured into 1000 ml. of cold water, and the water layer was separated by decantation from the oily product. This product was washed three times with petroleum ether, at which the product turned into a fine powder which was recrystallized from methanol. The crystals melted at 282~284°C. $[\alpha]_D^{18}$ +182.7 (*c* 0.684, pyridine). The yield was 4.3 g. (82.9%).

Found: C, 62.39; H, 6.24; N, 3.61. Calcd. for $C_{21}H_{23}O_6N \cdot H_2O$: C, 62.52; H, 6.25; N, 3.47%.

Phenyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (Ib). — Two grams of phenyl 2-acetamido-2-deoxy-β-D-glucopyranoside[6] were treated as in the case of the α-anomer (Ia). After recrystallization from methanol, the product melted at 254°C with decomposition. $[\alpha]_D^{24}$ −27.1 (*c* 5.10, pyridine). The yield was 2.3 g. (90%).

Found: C, 62.27; H, 6.31; N, 3.47. Calcd. for $C_{21}H_{23}O_6N \cdot H_2O$: C, 62.52; H, 6.25; N, 3.47%.

Phenyl 2-Acetamido-4,6-*O*-benzylidene-3-*O*-(D-1'carboxyethyl)-2-deoxy-α-D-glucopyranoside (IIa). —Five grams of Ia were dissolved in dry hot dioxane (450 ml.) under mechanical stirring; after the addition of 2.5 g. of sodium hydride (a fine powder dispersed in mineral oil at a ca. 50% concentration), the mixture was kept at 90°C for 150 min. Eight grams of L-α-chloropropionic acid[8] were added when the temperature had gone down to 60°C. The mixture became a heavy paste and was vigorously stirred for 50 min. 5.5 g. of sodium hydride were again added, where-upon the mixture became thin. The temperature was again raised

to 90°C for a short time, and then the mixture was allowed to stand overnight at room temperature. After the cautious addition of 100 ml. of water to decompose the excess sodium hydride, concentration in vacuo gave a thick yellow brown syrup, which was then washed with petroleum ether and dried in vacuo. The aqueous solution (1000 ml.) of the product, after it had once been filtered from a trace of insoluble matter, was made acidic (pH=2.0~2.2) by adding, drop by drop, 6 N hydrochloric acid while the solution was cooled by ice water. The slightly yellow crystals which precipitated were filtered, washed with water, and recrystallized from ethanol. The colorless crystals melted at 243~244°C. $[\alpha]_D^{20}$ +185.6 (*c* 0.388, pyridine). The yield was 4.5 g. (75.9%).

Found: C, 62.48; H, 5.91; N, 3.27. Calcd. for $C_{24}H_{27}O_8N$: C, 63.01; H, 5.95; N, 3.06%.

Phenyl 2-Acetamido-4, 6-*O*-benzylidene-3-*O*-(D-1'-carboxyethyl)-2-deoxy-β-D-glucopyranoside (IIb).—2.4 g. of Ib were treated as in the case of IIa. The crystals from ethanol melted at 248~249°C with decomposition. $[\alpha]_D^{28}$ −15.0 (*c* 2.93, pyridine). The yield was 2.3 g. (81%).

Found: C, 60.72; H, 6.15; N, 2.97. Calcd. for $C_{24}H_{27}O_8N \cdot H_2O$: C, 60.62; H, 6.15; N, 2.95%.

Phenyl-2-Acetamido-3-*O*-(D-1'-carboxyethyl)-2-deoxy-α-D-glucopyranoside (IIIa).—Four grams of IIa were boiled for exactly 10 min. in 820 ml. of 67% acetic acid. After evaporation of the mixture in vacuo, the repeated addition of a small amount of water, and evaporation in vacuo until no odor of acetic acid remained, there remained an amorphous residue which failed to crystallize. $[\alpha]_D^{20}$ +164.5 (*c* 0.106, pyridine).

Phenyl 2-Acetamido-3-*O*-(D-1'-carboxyethyl)-2-deoxy-β-D-glucopyranoside (IIIb).—One gram of IIb was treated as in the case of IIIa. The product was recrystallized from water. The crystals melted at 192~193°C with decomposition. $[\alpha]_D^{19}$ −4.1 (*c* 3.83, pyridine).

Found: C, 55.77; H, 6.02; N, 3.84. Calcd. for $C_{17}H_{23}O_8N$: C, 55.28; H, 6.28; N, 3.79%.

Phenyl 2-Acetamido-3-*O*-(methyl D-1'-ethylcarboxylate)-2-deoxy-α-D-glucopyranoside (IVa).—An ethereal solution of diazomethane was dropped into a solution of IIIa in 50 ml. of methanol which had been cooled with ice water. The reagent was added until a consistent yellow color remained. The residue which was obtained by evaporating the solution in vacuo was recrystallized from a mixture of ethyl acetate and petroleum ether. The colorless crystals melted at 170~175°C with decomposition. $[\alpha]_D^{20}$ +169.6 (*c* 1.256, ethyl acetate). The yield was 2.2 g. (65.7%).

Found: C, 56.73; H, 6.76; N, 3.75. Calcd. for $C_{18}H_{25}O_8N$: C, 56.39; H, 6.57; N, 3.65%.

Phenyl 2-Acetamido-3-*O*-(methyl D-1'-ethylcarboxylate)-2-deoxy-β-D-glucopyranoside (IVb).—One gram of a crude specimen of IIIb was treated with diazomethane as in the case of IVa. The crystalline product obtained melted at 216~217°C with decomposition. $[\alpha]_D^{14}$ +5.3 (*c* 3.90, pyridine). The yield was 0.7 g. (83%).

Found: C, 56.47; H, 6.57; N, 3.65. Calcd. for $C_{18}H_{25}O_8N$: C, 56.39; H, 6.56; N, 3.65%.

The Hydrolysis of IIa and IIb to 2-Amino-3-*O*-(D-1'-carboxyethyl)-2-deoxy-D-glucose (Muramic Acid).—IIa and IIb both gave a single spot of muramic acid on a papergram after hydrolysis with 2 N hydrochloric acid at 100°C for 4~5 hr. Runs were made along with an authentic muramic acid specimen in a solvent system of phenol-water (75 : 25); the R_f value of the spot developed with ninhydrin was about 0.51. These findings confirm the previously-assigned structures II—V.

Summary

A convenient method for the synthesis of anomeric phenyl glycosides of *N*-acetyl muramic acid and their methyl esters has been described. The test of lysozyme action on these model substrates was negative.

The expenses of this research were covered by U. S. Public Health Service Grant No. AI-04586-02.

The authors are indebted to Dr. James T. Park of the Department of Microbiology, Tufts University School of Medicine, for his gift of *N*-acetyl-glucosamine.

The Determination of Water Contents in Low Polymers of Formaldehyde by the Karl Fischer Method. II. The Determination of the Total Amounts of Adsorbed Water and Bound Water by the Methanol Absorption Method

By Kaname MUROI and Kunihiko OGAWA

(Received June 7, 1963)

In the previous paper,[1] the present authors reported a method for the determination of adsorbed water and bound water separately in low polymers of formaldehyde by using the Karl Fischer method. Recently, on the basis of the already-established method of determining the trace content of water in gases by Karl Fischer titration,[2] the same authors have developed a simple methanol absorption method for determining the sum of the amounts of adsorbed water and bound water in low polymers of formaldehyde. In the present method, the sample was pyrolyzed in a steam of dry nitrogen; the water vapor thus formed was absorbed in methanol, which was then titrated with a Karl Fischer reagent.

Experimental

Materials.—Both commercial-grade and special-class reagents of paraformaldehyde were used without further purification. The α-polyoxymethylene was supplied by our laboratory. The methanol was dried by magnesium metal. The propylene glycol was dried by boiling. The Karl Fischer reagent SS "Mitsubishi," free of methanol and supplied by the Mitsubishi Chemical Industries, was used (titer: 3.0 mg. H_2O/ml.).

Apparatus and Procedure. — The apparatus is illustrated in Fig. 1. Titration flask, F, was kept at about 10°C by running water through the jacket, G. One hundred milliliters of dry methanol was added to F through a side arm, H. Dry nitrogen, adjusted to a constant velocity of about 0.2 l./min., was passed to A, D and F. The methanol in F was titrated to the dead stop-end point with the Karl Fischer reagent. One to three grams of the sample were added to A through the side arm B. The tubing, D, was heated to about 100°C with a tape heater, E, and then A was heated at 200~250°C with a mantle heater, C. The water formed by pyrolyzing the sample was absorbed in cool methanol in F, and the water content in methanol was titrated every 5~10 min. with the Karl Fischer reagent. The dead stop-end point was attained after 30 min.; then the heating of A was stopped. The percentage of water was calculated from the titration value of the Karl Fischer reagent.

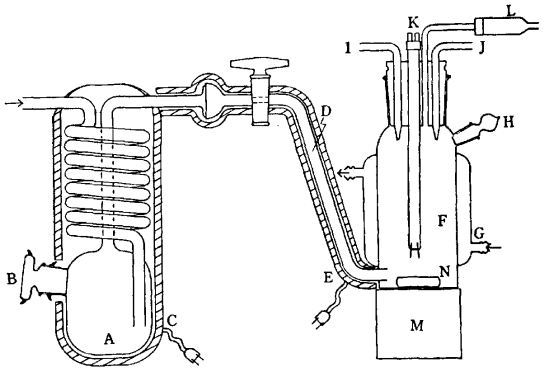

Fig. 1. Apparatus for the methanol absorption method.

A: Pyrolysis flask, 75 ml.
B: Side arm for sampling
C: Mantle heater, 200 W.
D: Conduit tube for gaseous formaldehyde
E: Tape heater, 100 W.
F: Titration flask, 200 ml.
G: Condenser
H: Side arm for methanol
I: Buret for standard water-in-methanol solution
J: Buret for Karl Fischer reagent
K: Platinum electrode
L: Outlet (with drying tube)
M: Magnetic stirrer
N: Stirrer bar

After A had been cooled to room temperature, the sample was added to A again through the side arm B, and the water contents was determined continuously by the same procedures. The bound water content was given by the difference in values between this method and the previously-reported methanol extraction method.[1]

Results and Discussion

In this method, the authors mainly attempted to find an adequate solvent to absorb the gas formed by the pyrolysis of the polymer. Since formaldehyde is known to be readily soluble in alcohols with evolution of heat and is known not to yield formaldehyde gas, the glycol reported in previous paper,[1] which

1) K. Muroi and K. Ogawa, This Bulletin, **36**, 965 (1963).
2) K. Muroi, *Japan Analyst (Bunseki Kagaku)*, **10**, 847 (1961).

Table I. Effects of interferences on the determination of water in formaldehyde at various temperature

Titration temp. °C	Nature of end point (visual titration)		Amount of water formed at 10 min's by interfering reaction in end point mg.
	Color change	Stability	
10	Good	Fairly stable	0
20	Good	Fairly stable	0
30	Good	Stable	0
40	Poor	Fades stowly	0.12
50	Very poor	Fades	0.35

do not react with formaldehyde below about 100°C, were first used as absorbing solvents of the gas; it was found, however, that the glycols did not absorb the gas completely. Then methanol, which has the strongest affinity for formaldehyde among primally alcohols, was used. The interference of formaldehyde with the Karl Fischer titration was studied. Mitchell et al.[3] have reported that formaldehyde does not interfere with the direct titration of an ordinary Karl Fischer reagent. On the contary, Iliceto et al.[4] have reported that formaldehyde interfered with the results of the Karl Fischer titration. To study the interference of the formaldehyde which was adsorbed in methanol, 3 g. of paraformaldehyde was pyrolyzed and absorbed in 50 ml. of methanol. Then the methanol solution was titrated with a Karl Fischer reagent at various temperatures. The water content thus measured and the nature of the titration end point visually observed are listed in Table I. It was found that the formaldehyde reacted with methanol very slowly above 30°C, and that it did not react at all below 30°C. From these results, as well as from the fact that the rate of the vaporization of methanol on the bubbling of a dry nitrogen carrier decrease with a decrease in the temperature, the methanol solution in flask F was kept at 10°C. Though the time necessary for analysis procedure not depended on the flow rate of the dry nitrogen carrier gas but, rather, mainly on the heating temperature of flask A, the optimum flow rate for reducing the vaporization loss of methanol was found to be 0.2 l./min. Table II lists the water content values in the various types of low polymers of formaldehyde determined by this method. An excellent reproducibility was obtained. Table III lists the water content values in the same samples as determined by this method and by the propylene glycol dissolution method reported in the previous paper.[1] The agreement between the two methods was remarkably good. When this method was compared with the propylene glycol dissolution method, it was found that this method had these advantages:

1) The operation of this method is simple, it is not affected by the moisture in the air, and the reproducibility is good.

2) The propylene glycol dissolution method can not be applied to samples pyrolized above about 170°C, but this method is applicable to such samples.

3) It has been found that the propylene glycol dissolution method is interfered with the small amount of an alkali component contained in commercially-available paraformaldehyde, but in this method, this small

TABLE V. RESULTS ON THE VARIATION OF WATER CONTENTS IN PARAFORMALDEHYDE IN AIR

	Days on shelf					
	0	1	3	5	7	10
Adsorbed water, %	8.1	7.8	7.6	6.6	4.2	2.7
Bound water, %	6.1	7.7	4.3	3.1	3.0	2.9

amount of an alkali component remains in the pyrolysis flask A and does not enter into the titration flask F; therefore, titration is not interfered with alkali. Table IV lists the adsorbed water content value and the summed content of adsorbed water and bound water in various types of low polymers of formaldehyde as determined by the methanol extraction method and by this method. The difference in the values corresponds to the content of bound water in the polymers from which the average degree of polymerization was calculated. Table V lists the results of the variation of adsorbed water and bound water in paraformaldehyde in air with time. At first, both adsorbed and bound water decreased rapidly. After 5 days, while bound water was stabilized at the value of about 3% (n=about 20), adsorbed water was still decreasing slowly. The authors are now studying the processes of the depolymerization of paraformaldehyde from the variation of adsorbed and bound water.

Summary

The summed content of adsorbed water and bound water in low polymers of formaldehyde has been determined by the following method: (1) The sample is pyrolized in a steam of dry nitrogen. (2) The water thus formed is absorbed in methanol. (3) The water content of the methanol solution is determined by titrating with a Karl Fischer reagent. A comparison between the present method and the propylene glycol dissolution method reported in the previous paper has made it evident that the present method is easy in its operations and is applicable to polymers having a wide range of polymerization. It has also been found that formaldehyde does not react with methanol below 30°C.

The Absorption Spectra of Cobalt(III) Complexes. III.[1] *The Spin-forbidden Bands*

By Junnosuke FUJITA and Yoichi SHIMURA

(Received May 11, 1963)

In marked contrast to the extensive work on the first and the second absorption bands of cobalt(III) complexes, relatively few investigations have been made of the weak absorption bands observed on the longer wavelength side adjacent to the first band. According to the ligand field theory,[2] the former two can be assigned to the spin-allowed transitions and the weak latter to the spin-forbidden transitions, although all these bands between the d levels of the cobalt(III) ion split because of the field perturbations of ligands.

Previously, Yoneda et al.[3] have reported on the existence of some weak absorption bands in the near infrared spectra (0.8~1.3 μ) of $[Co(CO_3)(NH_3)_4]NO_3$ and $K_3[Co\ ox_3]$. Inamura and Kondo[4] have also found weak bands in this region for some polynuclear cobalt(III) complexes. Later, Jørgensen[5] studied the nature of these weak bands and assigned them to the spin-forbidden transitions. More recently, Linhard and Weigel[6] have carefully measured the near infrared spectra of $[Co\ en_3]^{3+}$, $[Co(NH_3)_6]^{3+}$ and $[Co(X)(NH_3)_5]^{2+}$ ($X=F^-$, Cl^-, Br^-, I^-) and shown that each complex has two absorption bands due to the spin-forbidden transitions which correspond well with the theoretical assignment.[2] These two bands were named the A and the B bands, beginning from the longer wavelength side.

In order to investigate the nature of these A and B bands in more detail, as has been done for the first and the second bands,[1] we have measured the absorption spectra of about fifty complexes of cobalt(III). By combining these findings with those on the first and the second bands, it will be possible to discuss the experimental relationships among them in this paper.

Experimental

A Beckman DU spectrophotometer was used to obtain the absorption spectra in the range between 25 and 120 ($\times 10^{13}$/sec.). Aqueous solutions almost saturated were used to measure the near infrared spectra. All measurements were made at room temperature.

The complexes used in this work were prepared according to the methods described in the available literature, except for several new compounds which will be described below. All the compounds were recrystallized carefully before measuring the weak absorption bands.

***trans*-Chloro-nitro-bis(ethylenediamine)-cobalt(III) Perchlorate, *trans*-$[Co(Cl)NO_2\ en_2]ClO_4$.**—A finely powdered *trans*-$[Co(NO_2)_2\ en_2]NO_3$ was dissolved in hydrochloric acid (1 : 1). The crude product was precipitated from this clear solution by the addition of solid sodium perchlorate. The red precipitate which was filtered off was dissolved again in hydrochloric acid (1 : 1). The addition of perchloric acid (60%) to this solution resulted in the formation of orange red crystals, which were then filtered, washed with alcohol and dried in air. This complex was anhydrous.

Found: ClO_4^-, 27.1. Calcd. for $[Co(Cl)NO_2\text{-}en_2]ClO_4$: 27.6%.*

***trans*-Bromo-nitro-bis(ethylenediamine)-cobalt(III) Perchlolate, *trans*-$[Co(Br)NO_2\ en_2]ClO_4$.**—The mixture of 4 g. *trans*-$[Co(NO_2)_2\ en_2]Br\cdot 2H_2O$ and 6 ml. concentrated hydrobromic acid ($d=1.48$) was warmed on a water bath while being stirred. After the evolution of gas ceased, the resulting materials were kept in a cool place for a while. Then the precipitate was separated; it was the crude product of *trans*-$[Co(Br)NO_2\ en_2]Br$ and could be recrystallized from concentrated hydrobromic acid by the addition of acetone. The pure perchlorate was prepared by the addition of perchloric acid (60%) to the solution of this precipitate in concentrated hydrobromic acid. The complex was separated as anhydrous, brownish red crystals.

Found: ClO_4^-, 23.8. Calcd. for $[Co(Br)NO_2\text{-}en_2]ClO_4$: 24.6%

Tetrammine-mono(ethylenediamine)-cobalt(III) Bromide Monohydrate, $[Co(NH_3)_4\ en]Br_3\cdot H_2O$.—This complex was prepared by the method described previously.[8]

Potassium Pentacyano-nitro-cobaltate(III), $K_3[Co(CN)_5NO_2]$.—The mixture containing 8 g. of $[Co(NO_2)(NH_3)_5]Cl_2$ and 10 g. of potassium cyanide

dissolved in 100 ml. of water was warmed on a water-bath while being stirred. After the evolution of gaseous ammonia, the orange yellow solution obtained was filtered and kept at room temperature for a while. The addition of methanol to the solution gave a pale yellow precipitate, which was then filtered off, washed with alcohol and ether, and dried in air. Recrystallization from the aqueous solution to obtain well-formed pale yellow crystals was effected by the slow addition of methanol and by leaving it to stand in a refrigerator.

Found: Co, 16.5; C, 16.40; N, 23.51. Calcd. for $K_3[Co(CN)_5NO_2]$: Co, 16.73; C, 17.05; N, 23.85%.

Potassium Pentacyano-azido-cobaltate(III) Dihydrate, $K_3[Co(CN)_5N_3]\cdot 2H_2O$.—The recrystallized yellow crystals of this complex were obtained by almost the same method as the nitro-complex, described above, using 8.4 g. of $[Co(N_3)(NH_3)_5]Cl_2$ and 10 g. of potassium cyanide. The only difference was that the reaction took place at room temperature, without the complex being warmed on a water-bath.

Found: Co, 15.8; C, 15.77; N, 30.15; H_2O, 9.53. Calcd. for $K_3[Co(CN)_5N_3]\cdot 2H_2O$: Co, 15.33; C, 15.75; N, 29.15; H_2O, 9.37%.

Potassium Pentacyano-sulfono-cobaltate(III) Trihydrate, $K_4[Co(CN)_5SO_3]\cdot 3H_2O$.—To 50 ml. of an aqueous solution containing 10 g. of $K_3[Co(CN)_5Br]$, 5 g. of $K_2SO_3\cdot 2H_2O$ dissolved in 50 ml. of water was added. The resulting solution was heated on a water-bath until the initial reddish color turned pale yellow. After the solution had cooled, the addition of methanol to the filtered solution gave pale-yellow crystals, which were then filtered off, washed with alcohol and ether, and dried in air. These were recrystallized from the aqueous solution by the addition of methanol.

Found: Co, 12.5; C, 12.26; N, 15.08; H_2O, 11.52. Calcd. for $K_4[Co(CN)_5SO_3]\cdot 3H_2O$: Co, 12.29; C, 12.52; N, 14.60; H_2O, 11.27%.

Results and Discussion

In Table I are listed the numerical data for the A, the B, the first, and the second absorption bands. Some typical absorption curves of all the spectra measured are shown in Figs. 1—6.

From these data, the following conclusions may be obtained.

1) The spectrochemical series[1,12] determined experimentally for the first and the second bands is also valid for the A and the B bands. This indicates that the lower the frequencies of the first and the second bands, the lower the corresponding A and B bands. In Fig. 1, the spectra of the cobalt(III) complexes of the ammine-oxalato series are shown to illustrate how the successive substitutions of ammonia by oxalate ions cause shifts in all these bands and how the magnitude of the shifts is proportional to the degree of substitution.[1]

2) As may be seen in Fig. 7, there is a linear relationship between the frequencies of the A band and those of the first band. A similar relation is seen between the first and the second bands[13] (Fig. 8), and also between the A and the B bands (Fig. 9). This indicates that these bands are closely related to

each other in origin, in agreement with the theoretical assignment.

3) The slope of the straight line for the relation between the A band and the first band (Fig. 7) indicates that the frequency separation between these bands becomes smaller as the first band shifts to a shorter wavelength. For this reason, the spin-forbidden bands, especially the B band, of a complex, the first band of which appears in the shorter wavelength region, are often hidden by the strong first band. For the ion $[Co(CN)_6]^{3-}$, for example, only the band is observed as a shoulder on the foot of the first band, as may be seen in Fig. 2.

4) The absorption intensities of the A and the B bands are usually about 1/100 as weak as those of the first and the second bands. For most complexes, as the intensity of the first band increases, the intensity of the A band increases also. A parallel relationship exists, therefore, between the first and the A bands in both the frequencies of absorption maxima and the intensities. Figures 1 and 3 show such relationships clearly.

5) The absorption curves shown in Figs. 4 and 5 indicate that the absorption intensity of the A band in a cis-complex is higher than that in the corresponding trans-complex. This may be due to the lower molecular symmetry in a cis-complex as compared with that in a trans-complex.

6) The absorption intensities of the A bands

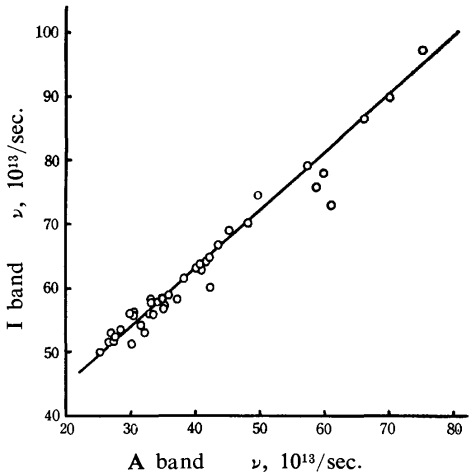

Fig. 7. The linear relation between the A and the I bands.

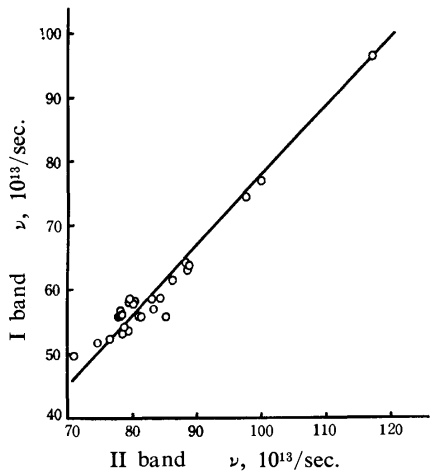

Fig. 8. The linear relation between the I and the II bands.

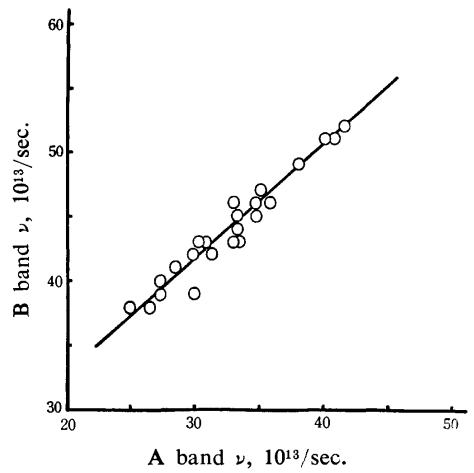

Fig. 9. The linear relation between the A and the B bands.

in bromo-complexes are quite high compared with those of the other complexes (Figs. 5 and 6). The same observation has been made on the spectrum of $[Co(Br)(NH_3)_5]^{2+}$ by Linhard and Weigel.[6] Furthermore, the linear relationship mentioned above between the maximum positions of the first band and those of the A band does not hold for these bromo-complexes. If the data for the bromo-complexes are plotted, as in Fig. 7, these points deviate considerably from a straight line. In other halogeno-complexes such as $[Co(I)(NH_3)_5]^{2+}$,[6] *cis*- and *trans*-$[Co(X)NH_3\,en_2]^{2+}$ ($X=Br^-$, I^-)[14] or a series of halogeno-pentacyanocobalt(III) complexes, $[Co(CN)_5X]^{3-}$ ($X=Cl^-$, Br^-, I^-),[11] the same anomalies have been observed.

7) As may be seen in Figs. 3 and 6, in a complex the first band of which splits, the A band is broad. This indicates that the band splittings may also occur in the A bands. In the case of $[Co(NO_2)edta]^{2-}$, a linear relationship for the A and the first bands shown in Fig. 7 exists, if the observed A band is plotted against the low frequency component (Ia) of the first band. If the mean frequency of the two components of the first band is taken, however, the linear relationship breaks down. This suggests that the other component of the A band which corresponds to the high frequency component of the first band (Ib) may be hidden under or may be overlapped by the B band.

All the conclusions 1)—7) mentioned above coincide well with the theoretical assignments of the weak bands A and B to the spin-forbidden transitions, $^1A_{1g}\rightarrow{}^3T_{1g}$ and $^1A_{1g}\rightarrow{}^3T_{2g}$ respectively, in the expression of an O_h-symmetry approximation. The numerical data listed in Table I may be useful in determining the "nephelauxetic series"[15] of these low-spin d^6 complexes.

Summary

The near infrared, visible and near ultraviolet absorption spectra of about fifty complexes of cobalt(III) have been measured and the data discussed mainly in order to find the relationships existing among the two weak spin-forbidden bands and the two well-known spin-allowed bands.

The Absorption Spectra of Cobalt(III) Complexes. IV.[1] *The Preparation and the Absorption Spectra of Monohalogenomonoamine-bis(ethylenediamine)-cobalt(III) Complexes*

By Takaji YASUI and Yoichi SHIMURA

(Received May 11, 1963)

It is well known that $[Co\,Cl(amine)en_2]^{2+}$ and $[Co\,Br(amine)en_2]^{2+}$ ions are formed in the reactions of chloro- and bromo-praseo salts, respectively, with aliphatic or aromatic primary amines,[2-4] but not with secondary and tertiary amines. In the cases of $[Co\,Cl(NH_3)en_2]^{2+}$ and $[Co\,Br(NH_3)en_2]^{2+}$ ions, both the cis and the trans isomers have been prepared by Werner,[5] and the cis salts have been resolved into the optically active isomers. The geometrical structures of the complexes containing organic amines, however, have not been precisely determined. A few studies[2,4] have been made trying to resolve the complexes by the use of α-bromo-*d*-camphorsulfonate, but none of these efforts have succeeded. Bailar and Clapp[4] investigated the reactions of an optically-active violeo salt with the organic amines, but they could not isolate the reaction products with optical activities, except for an optically-active complex of *p*-toluidine, *cis*-$[Co\,Cl(p\text{-toluidine})en_2]\,Cl_2$.

In the present paper, a few complexes which belong to the corresponding iodo series, i. e., *trans*- and *cis*-$[Co\,I(NH_3)en_2]\,I_2$ and *cis*-$[Co\,I(amine)en_2]\,I_2$ (amine = methylamine and pyridine), have been newly synthesized. Furthermore, some missing members of the chloro and the bromo series have also been prepared. The absorption spectra of the complexes have been measured in the region of 210~1200 mμ, with especially great care in the near-infrared region, and the results will be discussed mainly in relation to the geometrical structures of the complex ions.

Experimental

Measurements.—A Beckman DU quartz spectrophotometer was used for the measurements of the absorption spectra in the 210~1200 mμ region. All the aqueous solutions of the complexes obeyed Beer's law at concentrations of $1\sim10^{-5}$ mol./l. The measurements for the dilute solutions were made rapidly in the cold to avoid the aquotization of the complex ions.

The absorption spectrum of *cis*-$[Co\,I(NH_3)en_2]I_2$ coincided well with that of the corresponding chloride, *cis*-$[Co\,I(NH_3)en_2]Cl_2$. Therefore, the effects of the outer-sphere anions have not been considered as long as no extra hydrogen halide or halide salt was added to the sample solutions.

Materials.—*trans-[Co Cl(NH$_3$)en$_2$]Cl$_2$·H$_2$O.*— This compound was prepared from *trans*-$[Co\,Cl(NCS)\text{-}en_2]NCS$ by the procedure of Werner.[6] The color of the crystals isolated was ruby red.

cis-[Co Cl(amine)en$_2$]Cl$_2$.—The complex containing NH_3 instead of amine was prepared by the method of Werner[7] and was recrystallized from concentrated hydrochloric acid. The crystals were reddish in color and needle-shaped. The compounds containing methyl-, ethyl- or *n*-propyl-amine, or pyridine, instead of ammonia, were prepared by similar procedures. The *n*-propylamine complex is a new compound.

Found: C, 23.18; H, 7.50; N, 19.31; H_2O, 4.82. Calcd. for $C_7H_{25}N_5Cl_3Co\cdot H_2O = [Co\,Cl(C_3H_9N)(C_2H_8N_2)_2]Cl_2\cdot H_2O$: C, 23.43; H, 7.50; N, 19.16; H_2O, 4.96%.

cis-[Co Cl(aniline)en$_2$]Cl$_2$.— This complex was prepared by the method of Bailar and Clapp.[4] The toluidine complex, *cis*-$[Co\,Cl(p\text{-toluidine})en_2]Cl_2\cdot H_2O$, was obtained by a similar method. These complexes of aromatic amines are less soluble in water than those of aliphatic amines.

trans-[Co Br(NH$_3$)en$_2$]Br$_2$·H$_2$O. — The compound was obtained by the method of Werner,[8] but this was somewhat modified as follows. A pure complex, *trans*-$[Co(OH_2)(NH_3)en_2]Br_3$, was suspended in an appropriate amount of concentrated hydrobromic acid and was gently heated to 70°C. After being kept for a few minutes at this temperature, the color of the solution changed from orange to violet. This solution was then cooled to room temperature and alcohol was added. By letting the solution stand in an ice-bath, the compound was obtained as reddish violet crystals.

cis-[Co Br(NH$_3$)en$_2$]Br$_2$·H$_2$O. — This salt was obtained by the reactions of the bromo-praseo salt, *trans*-$[Co\,Br_2en_2]Br$, with aqueous ammonia upon

cooling in a freezing mixture.[9] The same compound was also obtained by dehydrating *cis*-[Co(OH$_2$)(NH$_3$)en$_2$]Br$_3$ in a drying apparatus.

cis-[Co Br(methylamine)en$_2$]Br$_2$. — This compound was prepared by the same procedure as was the ammine complex, *cis*-[Co Br(NH$_3$)en$_2$]Br$_2$.

cis-[Co Br(amine)en$_2$]Br$_2$.—The ethylamine, *n*-propylamine and pyridine complexes were easily synthesized from bromo-praseo salt and the respective amines. The latter two complexes are new.

Found: C, 17.86; H, 5.23; N, 14.70. Calcd. for $C_7H_{25}N_5Br_3Co$=[Co Br(C_3H_9N)($C_2H_8N_2$)$_2$]Br$_2$: C, 17.59; H, 5.27; N, 14.65%.

Found: C, 21.70; H, 4.28; N, 14.25. Calcd. for $C_9H_{21}N_5Br_3Co$=[Co Br(C_5H_5N)($C_2H_8N_2$)$_2$]Br$_2$: C, 21.71; H, 4.25; N, 14.06%.

trans-[Co I(NH$_3$)en$_2$]I$_2$. — A finely powdered, pure complex, *trans*-[Co(OH$_2$)(NH$_3$)en$_2$]I$_3$,[10] was spread on a watch-glass and was dehydrated in vacuo at room temperature for two or three days. The color of the powder changed from brown to brownish-black. The crude product obtained was purified as follows. A more soluble by-product was extracted by a small amount of water; the greenish residue remaining was then dissolved in a large quantity of water, and the solution was filtered. In an ice-bath, the greenish crystals were deposited from the filtrate. The crystals collected by filtration were recrystallized repeatedly from water by the addition of potassium iodide. The greenish-brown crystals obtained were washed with cold water, with alcohol, and then with acetone. The trans-salt was less soluble in water than the corresponding cis salt.

Found: C, 8.31; H, 3.57; N, 12.00. Calcd. for $C_4H_{19}N_5I_3Co$=[Co I(NH$_3$)($C_2H_8N_2$)$_2$]I$_2$: C, 8.33; H, 3.32; N, 12.14%.

cis-[Co I(NH$_3$)en$_2$]I$_2$.—Purified *cis*-[Co(OH$_2$)(NH$_3$)en$_2$]I$_3$ was spread on a watch-glass and dehydrated in a drying apparatus at 70~75°C for about three hours. The color of the compound gradually changed from brown to brownish-black. The crude product was dissolved in a little amount of water, and then the solution was filtered. To the filtrate, powdered potassium iodide was added. After this solution had cooled in an ice-bath, a large number of dark brown, hexagonal crystals were deposited. The product separated by filtration was recrystallized from water by the addition of potassium iodide, and it was washed with cold water, with alcohol and then with acetone.

Found: C, 8.15; H, 3.50; N, 12.15. Calcd. for $C_4H_{19}N_5I_3Co$=[Co I(NH$_3$)($C_2H_8N_2$)$_2$]I$_2$: C, 8.33; H, 3.32; N, 12.14%.

cis-[Co I(methylamine)en$_2$]I$_2$. — Twenty grams of *cis*-[Co Cl(methylamine)en$_2$]Cl$_2$·H$_2$O was dissolved in 30 ml. of an aqueous solution of potassium hydroxide (1:5). After it had stood for a while, the solution was filtered with a glass filter. When an excess of concentrated hydrobromic acid was added to the filtrate drop by drop and cooled in an ice-bath, crystals began to deposit. After the solution had cooled in an ice-bath for a few hours, a large amount of the mono-aquo bromide, [Co(OH$_2$)(methylamine)en$_2$]Br$_3$ was obtained. This complex was transformed to the iodide by double decomposition with potassium iodide.

By the dehydration of the mono-aquo iodide, [Co(OH$_2$)(methylamine)en$_2$]I$_3$, at 80~85°C for two to three hours, a crude, brownish-black product was obtained. The recrystallization was made by a procedure to that used with *trans*-[Co I(NH$_3$)en$_2$]I$_2$. After repeated recrystallizations, the crystal was a dark greenish-brown, hexagonal plate. This is sparingly soluble in water.

Found: C, 10.40; H, 3.69; N, 11.68. Calcd. for $C_5H_{21}N_5I_3Co$=[Co I(CH_5N)($C_2H_8N_2$)$_2$]I$_2$: C, 10.16; H, 3.58; N, 11.85%.

cis-[Co I(pyridine)en$_2$]I$_2$. — The aquo complex, [Co(OH$_2$)(pyridine)en$_2$]I$_3$, was obtained by a method similar to that used for the methylamine complex, and this was dehydrated at 70~80°C for a day. From the crude product, a more soluble substance was extracted with a little water. A large amount of water was saturated with the greenish residue, and the solution was filtered. A few drops of saturated potassium iodide solution were then added to the filtrate. The solution was cooled in an ice-bath until dark green, octahedral crystals were deposited. A pure sample was sparingly soluble in water.

Found: C, 17.22; H, 3.35; N, 10.54. Calcd. for $C_9H_{21}N_5I_3Co$=[Co I(C_5H_5N)($C_2H_8N_2$)$_2$]I$_2$: C, 16.92: H, 3.31; N, 10.96%.

The aquo complexes, [Co(OH$_2$)(aniline)en$_2$]I$_3$ and [Co(OH$_2$)(*p*-toluidine)en$_2$]I$_3$, which were obtained by procedures similar to those used for the pyridine complex, were unstable. Therefore, the corresponding iodo-amine complexes could not be isolated.

Results and Discussion

The Near-infrared Absorption Spectra. — It has been known that the cobalt(III) complexes generally have two weak absorption bands in the near-infrared region,[1,11-13] of which the band appearing at the longer wavelength is named the A band and the band at the shorter wavelength, the B band. In most cases the B band is overlapped by the so-called first band, which is located just adjacent to the B band in a shorter wavelength and which has a moderate intensity.

The absorption maxima of the complexes of the [Co X(NH$_2$-R)en$_2$]X$_2$ type, which were measured in aqueous solutions, are summarized in Table I. In Figs. 1 and 3—5, the representative absorption curves are shown. As may be understood from the table and the figures, the molar extinction coefficients of the A bands increase by a factor of about ten in each substitution of the ligand X in the

order of $Cl^- \rightarrow Br^- \rightarrow I^-$. This factor is larger than that of the first band. This finding agrees well with Linhard's finding for the halogenopentammine cobalt(III) complexes.[12] The first and the second bands of the cobalt(III) complexes arise from the forbidden transitions between the splitted d-energy levels which have the same spin-multiplicity, while the A and B bands arise from those between the levels of the different spin-multiplicity values (from singlet to triplet). More particulary, the A and B bands are spin-forbidden and their intensities are very weak, in accordance with the theoretical considerations.[13]

If the A band arises from the splitted d-levels, it is expected that the bands will split because of the lower symmetries of the halogeno-amine complexes, just as the first bands split to Ia and Ib. As may be seen in Fig. 4, a weak splitting of the A bands was observed in some of the bromo complexes. In Fig. 1, the absorption spectra of the trans- and the cis-forms of $[Co\,X(NH_3)en_2]X_2$ are shown. The A band of the trans-form is at a longer wavelength and has a weaker intensity than that of the corresponding cis-form.

For the measurements of the A bands, rather concentrated solutions were necessary in most cases because of the lower absorption intensities of the complexes in this region. For some cases, two or three irregular fine structures were observed on the longer wavelength side of the A bands. It could be ascertained that such a phenomenon arose from the difference in the concentrations of the solvent water between the sample and the reference cells. For example, the near-infrared absorption spectra of water and of *trans*-$[Co\,Cl(NH_3)en_2]Cl_2\cdot H_2O$ are shown in Fig. 2. The A

band of the complex shows minima in a region corresponding to that of the absorption maxima of the solvent water (30.7 and 29.1×10^{13} sec^{-1}).

The Visible and Ultraviolet Spectra. — The so-called first and second absorption bands which appear in the visible and ultraviolet region also belong to the d-d transitions. The first bands of the complexes concerned split into two components, Ia and Ib, because of the lower symmetries of the complex ions (Figs. 1 and 3). In the iodo complexes, only the Ia components are observed, while the Ib components are hidden under the strong charge-transfer bands, as Fig. 5 shows. The molar extinction coefficient of the first band increases with an increase in the atomic weight of the coordinated halogen, but this is not so remarkable as that of the A band.

The absorption spectra of the trans- and the cis-forms of $[Co\,X(NH_3)en_2]X_2$, ($X=Cl^-$, Br^-) showed some differences in the Ia bands. The difference in the intensities was about 0.2 by log ε. The iodo-ammine complexes also showed the same trend. It was concluded, therefore, that the complex which showed a higher intensity in the Ia band was the cis-form, while that which showed a lower intensity was the trans-form (Fig. 1). If this conclusion is applicable to the complexes containing organic amines, it may be possible to determine the geometrical structures of theses complexes. As is shown in Table I and Figs. 3—5, the intensities of the Ia bands of the complexes which have aliphatic amines are almost identical with those of the cis-forms of $[Co\,X(NH_3)en_2]X_2$. Therefore, all these complexes, except for those containing aromatic amines, probably have the cis configuration. This conclusion agrees with the inference by Meisenheimer and Kiderlen[2] and that by Bailar et al.[4] The first absorption bands of the complexes of aromatic amines do not necessarily coincide with those of *cis*-$[Co\,X(NH_3)\,en_2]X_2$, because of the overlapped specific absorption bands of the aromatic amines (Fig. 3). The spectrum of the bromo-aniline complex, however, coincides very well with that of *cis*-$[Co\,Br(NH_3)en_2]Br_2$, as Fig. 4 shows.

In their spectral features the pyridine complexes resemble the aliphatic amine complexes.

As for the ultraviolet spectra of the chloro- and bromo-amine complexes, some studies

have been reported by Ablov and Filippov.[14,15] We investigated all the chloro-, bromo-, and iodo-amine complexes in this region. As Table I and Fig. 1 show, the charge transfer bands shift to longer wavelength in the following order of ligand halogens: $Cl^- \rightarrow Br^- \rightarrow I^-$. Some differences between the spectra of the trans- and the cis-forms were also noted in this region.

Summary

The four iodo-amine complexes and some chloro- and bromo-amine complexes belonging to [Co X(NH_2-R)en_2]X_2 type have been newly synthesized to complete the series.

From the measurements of the near-infrared, visible and ultraviolet absorption spectra, the geometrical structures of the complexes have been determined. The ammine complexes, [Co X(NH_3)en_2]X_2, exist in both the cis- and the trans-forms, but the organic amine complexes, [Co X(NH_2-R)en_2]X_2, exist only in the cis-form.

The weak splitting of the A band has been observed for the first time in the bromo-amine complexes.

High-kinetic Energy Fragment Ions from Aliphatic Hydrocarbons under Electron Impact. III. Nine Hydrocarbons Ranging from C_2 to C_4

By Toshikazu TSUCHIYA

(Received May 30, 1963)

In previous papers, we have described a method for measuring the kinetic energy of the fragement ions observed in the mass spectra of hydrocarbons[1] and have reported some findings.[2] In the present work, we will measure the kinetic energies of the fragment ions of nine hydrocarbons by the method and will discuss the findings in an attempt to clarify the mechanism of the decomposition of molecules into various high-kinetic energy fragment ions.

The samples were standard one obtained from the Takachiho Chemicals Co.; their nominal purities were 99% or higher and we found them to be pure by a mass spectrometer. The procedure of measurement has been described previously.[1] The approximate values of the appearance potential of a few high-kinetic energy fragment ions were measured by the vanishing current method, using neon as the calibrating gas.

Results

The results of these measurements are given in Tables I—III. The previously-reported data, for ethylene, propane and methyl high-kinetic energy ions from 1, 3-butadiene,[1] are also included for the purpose of comparison. Table I summarizes the measurements of the kinetic energies of fragment ions. The measured peak height values are given in Table

Discussion

Hustrulid[3] and Mohler[4] have discussed the mechanism of the formation of KE ions and have proposed that KE ions result from the dissociation of doubly-charged ions formed by electron impact. For convenience, this mecha-

* For convenience, ions having excess kinetic energies will hereafter be called KE ions, while those having thermal energies corresponding to the temperature of the ion-source will be called TE ions.

nism will hereafter, as in the previous report, be referred to as the H-M mechanism.

***m/e* 16.**—In some cases weak doublets are observed at *m/e* 16, as Table II shows. One or more of the following ions can contribute to the peak at *m/e* 16: (a) rearrangement ions of the sample material, (b) isotope ions of the *m/e* 15 ion, (c) ions from impurities contained in samples such as the parent ion of methane and oxygen ions from oxygen or from water, and (d) the background peaks of oxygen ions from oxygen or from water. The contributions from (c) and (d) could be eliminated by scrutinizing the kinetic energy value of the satellites[5] and the sensitivity of the instrument and by referring to the *m/e* 32 and to the *m/e* 18 peaks. After the isotope contribution was subtracted, it was found that some of the *m/e* 16 satellites of ethane, propane, *n*-butane, isobutane, and isobutene are due to inherent high-kinetic energy ions. Presumably, these ions are methane ions, produced by rearrangement. Though the intensities of the satellites are small, the following trends, concerning the intensity of *m/e* 16 KE ions, can be seen from Table I. The longer the carbon chain of a molecule, the smaller the intensity of the KE ion. Whereas the isostructure has a favorable effect on KE ion production, double bond has a negative influence.

Ethane.—In the following discussions, the numbers shown after each reaction equation indicate the energy of the formation of the KE ions, as computed from the values in Table IV and the measured KE values of the concerned ions in eV. These computed energies represent the lower limits of the true energies of formation, since the produced fragments may possibly be in the excited state.

The following reactions were investigated as reactions giving CH_3^+ KE ions according to the H-M mechanism:

$$C_2H_6 \rightarrow C_2H_6^{2+} \rightarrow \begin{cases} 2CH_3^+ & 28.7 \quad (1) \\ CH_3^+ + CH_2^+ + H & 33.6 \quad (2) \\ CH_3^+ + CH^+ + 2H & 37.2 \quad (3) \end{cases}$$

For example, the energy of the formation of CH_3^+ KE ions, $F(CH_3^+)$, in reaction 2 was computed by the following cycle:

$$F(CH_3^+) = D(CH_3\text{–}CH_3) + 2I(CH_3) + D(CH_2^+\text{–}H) + E(CH_3^+) + E(CH_2^+) + E(H)$$

Where

D(X–Y): the dissociation energy of the X–Y bond,
I(X): the ionization potential of the radical X,
E(Y); the kinetic energy of the radical or ion Y.

From the experimental values in Table I and from the data in Table IV, $F(CH_3^+)$ is found to be:

$$F(CH_3^+) = 33.6 + E(H)$$

Other F values were computed in a similar way.

The appearance potential of the CH_3^+ ion, $A(CH_3^+)$, is 30±3 eV. (Table III). The F value for reaction 1 is compatible with the experimental value, $A(CH_3^+)$. The experimental value for the total kinetic energy, which is the summation of the kinetic energies of the ions, 5.0 eV., differs from the value, 5.6 eV., calculated by Mohler et al.[4] Taking into consideration, however, the fact that the computation of Mohler et al. contains an assumption about the distance between charges, reaction 1 may also be valid.

Reactions 2 and 3 are both accompanied with neutral fragments. Comparing the F values with $A(CH_3^+)$, these reactions are considered to be improbable. If hydrogen is produced as a molecule instead of atoms, however, reaction 3 is not impossible.

Apart from the H-M mechanism, the following reactions were investigated:

5) J. D. Morrison and H. E. Stanton, *J. Chem. Phys.*, **28**, 9 (1958).

$$C_2H_6 \rightarrow C_2H_6^+ \rightarrow \begin{cases} CH_3^+ + CH_3 & 18.7 \quad (4) \\ CH_3^+ + CH_2 + H & 22.2 \quad (5) \\ CH_3^+ + CH + 2H & 26.5 \quad (6) \\ CH_3^+ + C + 3H & 28.9 \quad (7) \end{cases}$$

In computing the F values, the kinetic energies of the neutral fragments as a whole were assumed to be equal to that of the CH_3^+ ion, i. e., 2.5 eV. The energy of formation for reaction n, F_n, was computed as before. D(CH-H) = 4.3 eV., necessary to determine F_6, was calculated from the equation:

$$D(\text{CH-H}) = I(CH_2) + D(CH^+\text{-H}) - I(CH)$$

From a similar cycle, D(H-C-H) was found to be 6.7 eV. and was used to obtain F_7.

Comparing the $A(CH_3^+)$ values with the F values, reactions 4 and 5 can be eliminated, provided the products are not in the excited state. Since we know very little about the energies of the neutral fragements in reactions 4 and 5, nothing can be inferred from their F values about these reactions. The summation of the intensities of ions other than the m/e 15 ion is about one-half of the intensity of the m/e 15 ion (Table II). Accordingly, only some m/e 15 ions are produced in pairs with other KE ions, since equal numbers of the two species of an ion pair are necessarily produced by a particular reaction and the sensitivities of those ion pairs in Eqs. 1—7 are reasonably assumed to be approximately equal.[2] Thus, the CH_3^+ KE ion seems to be produced from ethane by reaction 1 according to the M-H mechanism and by some of the reactions 4—7 with neutral fragments, if the produced fragments are excited appropriately.

C_3H_6.—When a doubly-charged molecular ion dissociates, the two resulting fragments have equal momentum. As has been discussed previously,[2] pairs of ions were selected in this respect and the following reactions were investigated:

$$C_3H_6 \rightarrow C_3H_6^{2+} \rightarrow \begin{cases} CH_3^+ + C_2H_3^+ & 28.1 \quad (8) \\ C_2H_3^+ + CH_2^+ + H & 33.4 \quad (9) \\ C_2H_3^+ + CH^+ + 2H & 36.8 \quad (10) \\ C_2H_2^+ + CH^+ + 3H & 40.5 \quad (11) \end{cases}$$

Mohler et al.[4] gave 3.7 eV. as their "Coulomb energy" for propane. Using an appropriate value[6] for the distance between end carbon atoms in propylene, instead of that in propane,[7] computation similar to Mohler gives 3.9 eV. as the "Coulomb energy" of propylene. The summation of the kinetic energies of the ion pair in reaction 8 is 3.9 eV. (Table I), which agrees with the computed value. $A(C_2H_3^+)$ in Table III is also compatible with the energy of the formation of 8.

6) D. R. Lide, Jr., and E. E. Mann, *J. Chem. Phys.*, **27**, 868 (1957).

7) L. Pauling and L. O. Brockway, *J. Am. Chem. Soc.*, **59**, 1223 (1937).

While the energies of the formation of reactions 9 and 10 are incompatible with the appearance potentials (Table III), that of reaction 11 is compatible with $A(C_2H_2^+)$ in Table III, provided we assume that the hydrogen atoms produced have no kinetic energy. Thus 8 and 11 seem to be important reactions from the standpoint of the H-M mechanism.

Apart from the H-M assumption, the following reactions were investigated because their energies of formation are reasonable when compared with the measured appearance potentials of the corresponding ions. In deriving the energy of formation, the momentum of the KE ions and of the neutral fragments as a whole were assumed to be conserved.

Among the reactions producing the CH_3^+ KE ion only, reaction 12 requires an energy of formation less than $A(CH_3^+)$:

$$C_3H_6 \rightarrow C_3H_6^+ \rightarrow CH_3^+ + CH_2 + CH \qquad 25.9 \quad (12)$$

Similarly, for CH_2^+, we have reaction 13:

$$C_3H_6 \rightarrow C_3H_6^+ \rightarrow CH_2^+ + CH_2 + CH + H \qquad 31.2 \quad (13)$$

For $C_2H_3^+$ and $C_2H_2^+$, we have:

$$C_3H_6 \rightarrow C_3H_6^+ \rightarrow \begin{cases} C_2H_3^+ + C + 3H & 28.0 \quad (14) \\ C_2H_2^+ + C + 4H & 31.4 \quad (15) \end{cases}$$

As the neutral fragments produced may be excited, 12—15 are feasible reactions from the standpoint of the energy of formation.

The sum of the peak heights of high-energy ions in the C_1 group is about 11.6, while that of those in the C_2 group is 11.5 (Table II). As has already been reported for propane,[2] this suggests that the two groups of ions are produced simultaneously in pairs and that the contributions of 12—15 may be of little importance.

C_4 Compounds.—The KE values and the intensities of KE ions of a mass number higher than m/e 30 could not be measured because the resolving power of the present instrument was insufficient, although the presence of KE ions could be recognized clearly because of partly-overlapped satellites. The KE values in this m/e range were roughly estimated to be about 0.8 eV. The number of + marks in Table II indicates the approximate intensity of the KE ions.

Although the results of the present experiment on C_4 compounds are insufficient to describe the phenomena accurately, the following points are conceivable. The KE of each m/e 12~15 ion is larger than that of each m/e 25~29 ion, but the magnitude of momentum is in the reverse order. By the H-M mechanism, when a doubly-charged molecular ion dissociates, the two resulting fragments have equal momentum. Since the kinetic energies of the m/e 40 group ions are, roughly,

0.8 eV., their momentum is in the same range as that of *m/e* 12~15 group ions. The summation of the KE of the two groups is about 3 eV., a value which is nearly the same as the total KE value computed by Mohler et al.[4]* Thus, the reaction giving the two groups of ions *m/e* 12~15 and *m/e* 40 simultaneously is possible from this point of view.

The intensities of the *m/e* 15 KE ions of isobutane and isobutene are very large, and they might be produced in pairs with neutral fragments. As in the case of the H–M mechanism, the process can be considered as follows: From Table I, it is seen that the KE of isobutene is 2.7 eV. and that that of isobutane is 2.5 eV. Although the precision of the present experiment is ±0.2 eV., the order of magnitude of the KE values is reliable, i. e., the *m/e* 15 KE value of isobutene is larger than that of isobutane. The C–C distance of isobutane is 1.54±0.02 Å,[8] while that of isobutene between the tertiary carbon atom and the CH_3 radical is 1.50 Å.[9] We assume that, in a section along the C–C bond of the potential energy diagram of the two substances, the potential energy curve for the ground states and for the upper repulsive state, along which a molecule dissociates into a CH_3^+ ion and another fragment, are nearly the same. Since the C–C distance of isobutene is smaller than that of isobutane, the Franck-Condon region corresponding to isobutene crosses the potential energy curve for the upper state at a region higher than in isobutane; consequently, the KE of *m/e* 15 ion from isobutene is larger than that from isobutane.

* *n*-Butane, 2.9; Isobutene, 3.7; 1-Butene, 3.0 eV.

Summary

Fragment ions produced by electron impact with excess kinetic energies from into nine hydrocarbons ranging from C_2 to C_4 have been investigated. Fragment ions of a higher mass number could not be measured. The decomposition mechanism of propylene has been explained by the mechanisms proposed by Hustrulid and by Mohler et al. To explain the decomposition of other molecules, reactions producing ions with excess kinetic energy as well as neutral fragments must also be taken into consideration.

The author would like to express his thanks to Dr. Akira Kuboyama for his advice and to Mr. Ryuzo Shiota for his valuable discussions and survey of the manuscript.

The Viscometric Properties of Polyesters. I. A Comparison between Crystalline and Amorphous Polyesters

By Ryuzo NAKATSUKA

(Received May 23, 1963)

The need for knowledge of the factors influencing the viscometric property of linear polyesters and for an interpretation based on the molecular theories of these relationships has increased with the technological advances of recent years. In order to gain a satisfactory understanding of flow, detailed data are required on well-defined polymers, linear polyesters for example, over a wide range of temperature.

Fox et al.[1] have reviewed recent research on the viscosity of polymers and their concentrated solutions. In their review the experimental problems, the data actually measured and the empirical laws of flow are discussed, and besides, the results are interpreted in terms of qualitative quantitative molecular theories of flow.

The purposes of this experiment are, (1) to deduce the relationship between the chemical structure and the viscometric property of long chain polyesters, (2) to gain detailed information about viscosity over a wide range of temperature, and (3) to point out several interesting problems incident to these results.

1) T. G. Fox, S. Gratch and S. Loshaek, "Rheology," Vol. I, Academic Press, New York (1956), Chap. 12.

For polyester, Flory[2] has already measured their viscosity extensively and has quantitatively examined the influence of molecular weight and temperature on viscosity.

Takayanagi et al.[3] have also studied the temperature dependence of viscosity over a wide range of temperature and applied Bueche's[4] theory to their results. The present author has suggested in a previous report[5] that, for the study of the viscometric property of polyeters, it might be necessary to compare the crystalline with the amorphous polyesters in connection with the viscometric property in the super-cooled liquid state of low molecular substance.[7] Moreover, for the purpose of confirming this opinion, the viscosity of aliphatic polyesters with similar simple chemical structures has been studied in detail. However, discussions of the viscosity of polyesters should be based on exact and detailed experimental results for many kinds of polyesters over a wide range of viscometric conditions; therefore, the present experiment may be considered only an attempt in this direction.

Experimental

The Measurement of Viscosity.—Generally it is important to select a suitable instrument for rheological studies. The rotational viscometer is more useful than the capillary one to obtain the temperature dependence of a steady flow viscosity over a wide range of temperature. The former can easily measure viscosity in several seconds at any desired temperature; therefore, there is little need of a fine temperature regulator if the temperature of the apparatus is observed closely.

Under normal conditions of measurement, for the purposes of this experiment, we may regard the linear long chain polyesters with relatively low molecular weights (about 2000) as almost Newtonian fluids.[5]

The viscometer used in this experiment was as follows:

Rotational viscometer (Brookfield type)
Measuring range: $10^{-1}\sim10^{3}$ poises
Shear rate: 6~60 r.p.m. (4-stage change)

The Preparation of the Polyesters.—Aliphatic long chain polyesters with a low viscosity were prepared by the ordinary method. The combinations of acid and glycol are shown in Table I.

The polyesters were prepared in a 2-liter, 4-necked flask equipped with a thermometer, an inlet tube for inert gas, a device for the azeotropic removal of water, and a mechanically-sealed agitator. In most cases 3 mol. of acid and 3.3 mol. of glycol were reacted under a xylene reflux until the acid number was reduced to approximately 50; this was accomplished by the continuous agitation arising from the introduction of a stream of inert gas. Next, such residual volatile matters as water, glycol and acid were removed by vacuum distillation until the acid number was reduced to approximately 30.

Measurement of the Melting Point of the Crystalline Polyester.—In the polyesters used in this experiment, we can easily distinguish the crystalline from the amorphous one. A certain group of polyesters changes abruptly from the transparent liquid state to the opaque solid state at a certain temperature if they are cooled slowly in the melted state. As a result of the solidification, no viscosity under this temperature can be obtained. On the contrary, there is an other group of polyesters which cannot solidify or for whom it is extremely difficult to solidify from the melted state, even when kept at a low temperature near the glass transition point for several days.

In this report the former and the latter groups of polyesters are termed the crystalline and the amorphous respectively. If the temperature dependence of the infrared spectrum of polyester is studied, the crystalline band is observed for the crystalline, but not for the amorphous.[8]

The melting point of the crystalline was measured with a polarizing microscope. Usually the value of the melting point of any crystalline polymer is somewhat different from its solidifying point which can be pointed out in measuring its viscosity.

Results and Discussion

As the full curve of viscosity can be obtained easily over a wide range of viscosity (about $10^{-1}\sim10^{6}$ poises) in the case of amorphous long chain polyesters of a low viscosity, it seems that these kinds of polyesters may serve as typical models for rheological studies.

The aliphatic saturated polyesters used in this experiment are listed in Table I.

The temperature dependence of the steady flow viscosity in the range of $10^{-1}\sim10^{3}$ poises is shown in Figs. 1—2 for amorphous polyesters and in Fig. 3 for crystalline polyesters.

Within the limits of these aliphatic long chain polyesters, the viscosity-versus-temperature curves are very similar to one another; the very small difference in viscosity may depend on the change in chemical structure.

Since all samples were prepared to have similar molecular weights (1600~2000), the results of this experiment are not considered to have been remarkably affected by the differences in molecular weights of the samples.

A Comparison between the Crystalline and the Amorphous Polyesters.—Aliphatic linear polyesters without side chains are generally crystalline, with the exception of diethylene adipate and several polymers similar to it.[6] As Table I shows, what are called "ether-type polyesters" with ether bonds in the main chain, prepared from such polyglycols as diethylene or triethylene glycol, show a peculiar behavior in their crystallizing tendency.

Though such "ether-type polyesters" without side chains[6] as diethylene adipate are generally recognized to be amorphous, several crystalline "ether-type polyesters" were found among the samples prepared and used in this experiment. Accordingly, we can easily select several sets of polymers very similar in chemical structure, while differing in crystallinity, and compare their viscosities. For example, triethylene azelate is amorphous and triethylene sebacate is crystalline, while both are very similar in chemical structure and viscometric

property over the range of temperature higher than their melting points.

In other words, as is apparent from Figs. 1 and 2, the difference in viscosities between sebacate and azelate in combination with various glycols is so little as to be almost negligible, independently of whether they are crystalline or amorphous.

The relation between chemical structure and crystallizing tendency is shown in Table I.

It seems well established by Table I (1) that every polyester with side chains which was prepared from 1,3-butanediol or dipropyleneglycol is amorphous; (2) that all the ordinary aliphatic-saturated polyesters without side chains or ether bonds in the main chains are crystalline, and (3) that "ether-type polyesters" without side chains are not always crystalline. For example, triethylene azelate and triethylene sebacate are similar in chemical structure, but the former is amorphous and the latter crystalline. Yet both show a very similar viscosity vs. temperature behavior within a comparatively wide temperature range, including the melting point of the latter.

The difference in the crystallizing tendencies of polyesters is probably caused by the intramolecular rotation of the ether bond being easier than that of the methylene bond. From Table I, it may be found that the crystallizing tendencies are relative to the ratio, (m/n), of the number of methylene members of the acid

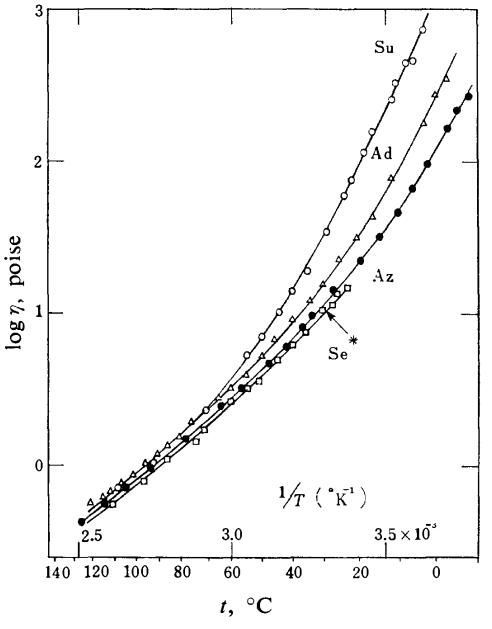

Fig. 1. Relationship between viscosity and temperature (triethylene glycol series).

* Crystalline polyester
↓ Melting point

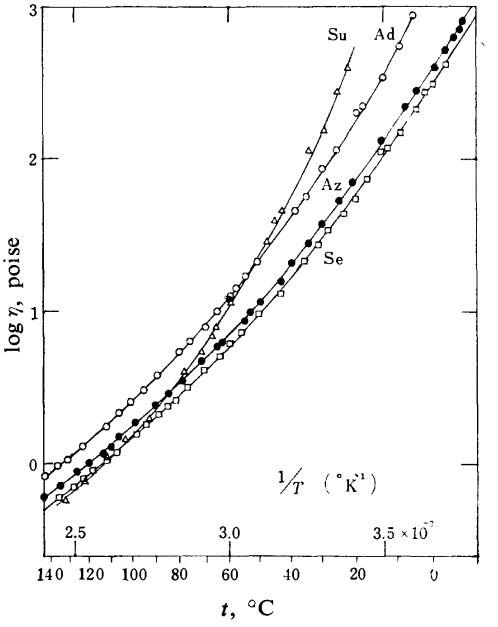

Fig. 2. Relationship between viscosity and temperature (1,3 butanediol series).

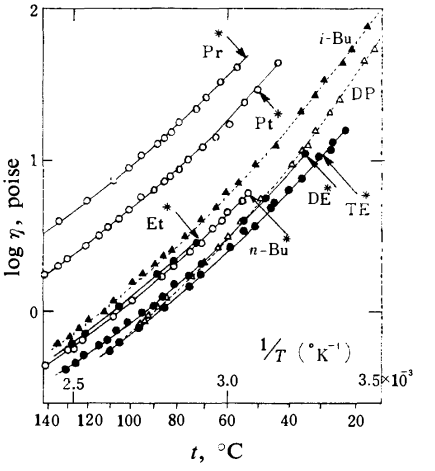

Fig. 3. Relationship between viscosity and temperature (sebacic acid series).

* Crystalline polyester
↑ Melting point

component, (m), to the number of oxygen plus methylene members of the glycol component, (n), in the "ether-type polyesters." That is, "ether-type polyesters" may be shown as follows:

$$-\overset{\overset{O}{\|}}{C}-(CH_2)_m-\overset{\overset{O}{\|}}{C}-O-(-CH_2-CH_2-O-)_{(n-1)/3}-\overset{\overset{O}{\|}}{C}-$$

Acid component — Glycol component

The corresponding numbers for various acid or glycol components are shown in Table I.

For example, in crystalline diethylene sebacate, the numbers of chain members of the acid and the glycol components are 8 and 7 respectively. On the contrary, in amorphous diethylene adipate, the numbers are 4 and 7 respectively. It can be said that "ether-type polyesters" in which m/n is approximately equal to 1 are crystalline.

In order to study their crystallizing tendency further, some polyesters were prepared from such a higher aliphatic dibasic acid as brassylic acid. Both diethylene brassylate (11—7 polyester) and triethylene brassylate (11—10 polyester) were crystalline, as was to be expected.

However, the author believes that further investigation into this matter is required in order to conclude that the ratio of the numbers of members between the methylene of the acid and the ether chain of the glycol is very significant in the crystallizing tendency of "ether-type polyesters."

The $\log \eta$ vs. $1/T$ curves are shown in Figs. 1 and 2 for the amorphous and in Fig. 3 for the crystalline. The slopes of these curves are proportional to the apparent activation energy (E^*) for viscous flow in the Andrade equation:

$$\ln \eta = \ln A + E^*/RT$$

where A and E^* are constants, and R is the gas constant.

Generally, over a wide range of temperature, no apparent activation energy (E^*) of any polyester is constant, no can the curve of $\log \eta$ against $1/T$ be regarded as a straight line.

The findings on the connection between the viscometric property and the crystallizing tendency are as follows:

As Figs. 1—3 show, in the range of temperature higher than the point corresponding to their melting points, all $\log \eta - 1/T$ curves of polyesters used in this experiment are nearly parallel to one other, in spite of their differences in crystallinity and their differences in chemical structure.

Therefore, in a perfectly molten state, or in a state wherein molecules can flow practically free of molecular interaction, the E^* values of the polyesters practically coincide and tend to approach a fixed value when the temperature is raised.

Moreover, when polyesters with similar chemical structures, such as several pairs of sebacate and azelate combined with the same glycol, are compared, it may be seen that almost all the $\log \eta - 1/T$ curves overlap over a wide range of temperature when they are shifted along the η-axis.

On the contrary, in the range of temperature lower than the point corresponding to the melting point of the crystalline counterpart, the discrepancy in the temperature dependence of the viscosity of amorphous polyesters may be ascribed to the differences in their chemical structures.

By comparing the temperature dependence of the viscosity of the crystalline polyesters with that of the amorphous ones, it may be seen that the mechanism of the viscous flow of the latter changes discontinuously in a certain temperature region near the melting point of the corresponding crystalline polyesters. In other words, it seems that in the range of temperature lower than the melting point of crystalline polyesters, a certain sort of force acting on molecules of the crystalline polyesters also exists in the case of the corresponding amorphous polyesters and that this is a cause of the change in their viscous flow state.

"Transition Area" near the Melting Point.— As has been stated above, it has been inferred that there exists a "transition area" for viscous flow in amorphous polyesters in the region of temperature near the melting point of crystalline polyesters with similar chemical structures.

When the temperature is raised beyond the "transition area," the viscous flow of every polyester aproaches an "Andrade liquid state." Though the absolute values of the viscosity of all polyesters are not always equal, their apparent activation energies at a fixed temperature become almost equal. That is, if the difference in molecular weight between polyesters is negligible, the A constant in the Andrade equation depends upon the chemical structure, but the E^* constant does not. With temperature change within the "transition area," the viscous flow state of each polyester begins to change remarkably according to its chemical structure. When the temperature is lowered near the glass transition temperature of each polyester, the $\log \eta - T$ curves, independently of the chemical structure of each, become parallel with one another.

It is clear that the effect of chemical structure on viscosity becomes most remarkable near the "transition area." For example, as Fig. 1 shows, in the case of the triethylene glycol series, the longer the chain of the acid component, the smaller the value of the apparent activation energy.

This relation can be more directly represented by plotting the curves of $\log \eta - 1/T^2$ in Figs. 4 and 5. The curve for each polyester is virtually represented by two intersecting straight lines.

This point of intersection may be regarded as a center of the "transition area" of each amorphous polyester; in the case of crystalline polyesters, with the exception of diethylene

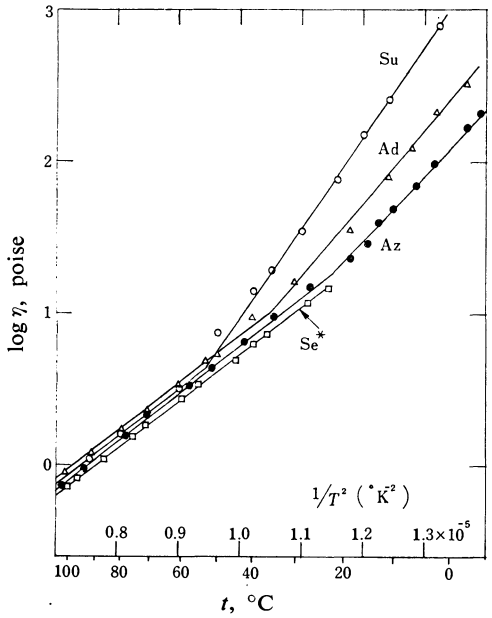

Fig. 4. Relationship between viscosity and temperature (triethylene glycol series).

* Crystalline polyester
↓ Melting point

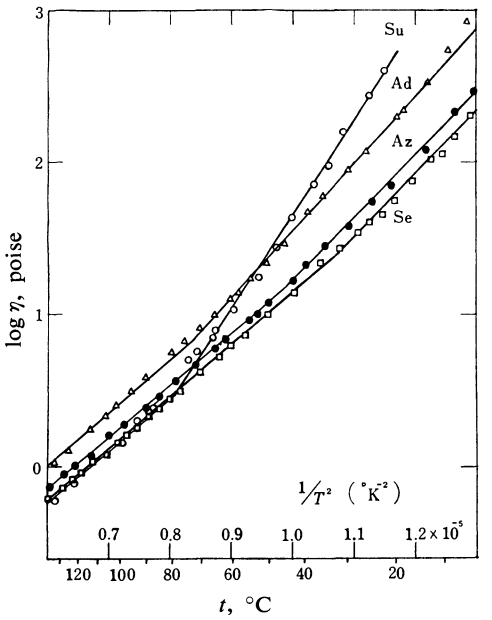

Fig. 5. Relationship between viscosity and temperature (1,3 butandicl series).

azelate whose rate of crystallization is very slow, this point is near the melting point. Therefore, it can be considered that practically no viscosity curve exists beyond this point. As to the relation between $\log\eta$ and $1/T$, all straight lines under this point are almost parallel with one another, irrespective of chemical structure. The values of the "center of transition area" determined by this method are shown in Table II.

By comparing Table I with Table II, it may clearly be seen that the center of the "transition area" of an amorphous polyester almost corresponds to the melting point of a crystalline polyester. This experimental fact shows the close connection between the "transition area" and the melting point.

The Temperature Dependence of the Activation Energy for the Viscous Flow near the "Transition Area".—The relationship between E^* and $1/T$ over the range of viscosity 10^{-1} $\sim 10^3$ poises is shown in Figs. 6 and 7. For example, as Fig. 6 shows, these relations are represented as nearly S-type curves, and the center of the "transition area" is regarded as being practically the point at which the slope of the E^*-1/T curve is steepest. The values of the viscosity and apparent activation energy at this point reach about 10 poises and about 11 kcal./mol. respectively.

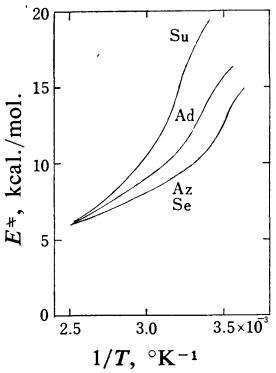

Fig. 6. Apparent activation energy for viscous flow (triethylene glycol series).

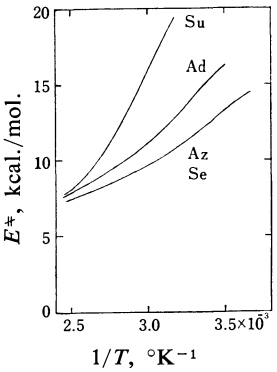

Fig. 7. Apparent activation energy for viscous flow (1,3 butanediol series).

The E^*-1/T curve in the range of high viscosity (10^3~10^6 poises) will be shown in a the next report of the present series.

As has been stated above, by studying the relations between $\log\eta$ and $1/T$, $\log\eta$ and $1/T^2$, and E^* and $1/T$, it may be easily deduced that there is a "transition area" for the viscous flow in the case of aliphatic long-chain polyesters. However, this concept is quite different from that regarding the glass transition point discussed previously, because the abrupt changes of temperature dependence in the infrared absorption[8] and in the refractive index are not observed in the transition area." In the "transition area" for the viscous flow, the viscous flow mechanism changes suddenly and, accordingly, it should be possible to distinguish viscometric properties between the higher and the lower temperature.

However, at present, it can be said with certainty only that no abrupt change in the arrangement of long chain molecules as shown at the crystallizing point has yet occurred at this stage.

In this manner, the existence of the "transition area" is more clearly shown in the relationship between E^* and $1/T$ than in the $\log\eta - 1/T$ curves.

Every apparent activation energy (E^*) at a certain temperature within the "transition area" differs from the others according to the chemical structure of each polyester, and the abrupt rise of E^* in the same area shows the change of interaction among linear polyester molecules with many dipoles.

The effects of chemical structure on E^* may be compared approximately as follows:

Glycol series

dipropylene glycol $>$ diethylene glycol $>$ triethylene glycol $\fallingdotseq$ 1,3-butanediol

Acid series

succinic acid $\gg$ adipic acid $>$ azelaic acid $\gg$ sebacic acid

It seems usual that the larger the chain between two adjacent carbonyl groups in a homologous series of polyesters, the lower the apparent activation energy near the "transition area." This phenomenon may be caused by the diluting effect of larger chains for dipole interaction.

However, it seems unusual that both triethylene glycol and 1,3-butanediol have the effect of reducing E^*, in spite of the fact that the side chains of 1,3-butanediol generally increase the E^* value because of their effect of reducing the fluxibility of long-chain molecules.

From these experimental results, it may be presumed that the methylene chain is more flexible than the ether chain in the "transition area" for viscous flow, and that the ether bond has a smaller dependence of intramolecular rotation on the temperature than does the methylene bond.

Summary

From the study of the viscosity of aliphatic long-chain polyesters over a wide range of temperatures, the following results have been obtained:

(1) Among aliphatic long-chain polyesters with ether bonds in the main chains, several crystalline polyesters have been obtained.

(2) Accordingly, it has been possible to compare the temperature dependence of the viscosity of the amorphous and the crystalline polyesters with similar chemical structures.

(3) When the temperature is raised, every apparent activation energy for viscous flow (E^*) approaches a fixed value, independently of the chemical structure of the polyester.

(4) However, the viscous flow state of the amorphous polyester changes discontinuously in connection with the chemical structure near the melting point of the corresponding crystalline polyester.

(5) In the "transition area" for viscous flow, the viscosity and the apparent activation energy (E^*) are, respectively, about 10 poises and 11 kcal./mol.

The author is indebted to Professor Hiromu Murata of the Faculty of Science, Hiroshima University for his helpful discussions and encouragement throughout the work, and to Dr. Keiji Oshima, Director of the Osaka Municipal Technical Institute for his advice and encouragement. The Normal Vibrations of Polyglycine I

By Kunio FUKUSHIMA, Yoshiko IDEGUCHI and Tatsuo MIYAZAWA

(Received June 12, 1963)

The molecular structure and vibrational spectra of polyglycine I, $(-CH_2CONH-)_n$, are closely related to those of polypeptides and proteins. According to X-ray analyses,[1] it has been concluded that the chain conformation of polyglycine I is in the β-conformation. On the basis of this conformation, measurements and partial assignments of the infrared absorption bands of polyglycine I in the spectral region between 2 and 30 μ have been made by Shimanouchi et al. using a sample prepared by them.[2]

We are interested in the relationship between the chain conformation of polypeptides and their normal frequencies, especially the characteristic amide frequencies and skeletal frequencies. We have calculated the normal vibrations of polyglycine I and its *N*-deuterated species in order to elucidate the nature of the normal vibrations characteristic of β-chain polypeptides, in which the molecular chain is in the all-trans zig-zag conformation.

Internal Co-ordinates

According to X-ray investigations,[1] the molecule of polyglycine I belongs to the factor group C_{2v}. Therefore, the twenty-six normal vibrations (characteristic amide vibrations and skeletal vibrations) of the polyglycine I molecule are grouped into nine A_1, nine B_1, four A_2 and four B_2 vibrations. Of these, only the infrared active in-plane vibrations, A_1 and B_1 will be treated in the present study.

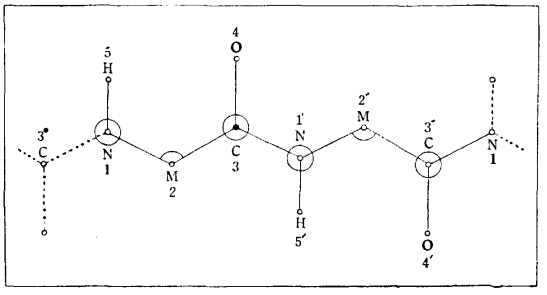

Fig. 1. Numbering of the atoms of the polyglycine I molecule.

The calculations were carried out according to Wilson's ***GF*** matrix method[3]; the methylene groups were treated as mass points, as the aim of these calculations was the analysis of only skeletal vibrations and characteristic amide vibrations. The molecular model is presented in Fig. 1; the internal co-ordinate vectors belonging to the m-th unit of the infinite molecular chain of the polyglycine I molecule will be denoted as $R^{(m)}$ and $R'^{(m)}$. The internal co-ordinates used are;

$$R_1^{(m)} \quad \Delta r_{NH} = \Delta r_{15}$$
$$R_2^{(m)} \quad \Delta\gamma_{NH} = (1/\sqrt{2})\Delta(\alpha_{513'} - \alpha_{215})$$
$$R_3^{(m)} \quad \Delta\beta_{NH} = (1/\sqrt{6})\Delta(2\alpha_{3'12} - \alpha_{513'} - \alpha_{215})$$
$$R_4^{(m)} \quad \Delta r_{NM} = \Delta r_{12}$$
$$R_5^{(m)} \quad \Delta\alpha_{NMC} = \Delta\alpha_{321}$$
$$R_6^{(m)} \quad \Delta r_{MC} = \Delta r_{23}$$
$$R_7^{(m)} \quad \Delta r_{CO} = \Delta r_{34}$$
$$R_8^{(m)} \quad \Delta\gamma_{CO} = (1/\sqrt{2})\Delta(\alpha_{432} - \alpha_{1'34})$$
$$R_9^{(m)} \quad \Delta\beta_{CO} = (1/\sqrt{6})\Delta(2\alpha_{231'} - \alpha_{1'34} - \alpha_{432})$$
$$R_{10}^{(m)} \quad \Delta r_{CN} = \Delta r_{31'}$$
$$R'^{(m)}_1 \quad \Delta r'_{NH} = \Delta r_{1'5'}$$
$$R'^{(m)}_2 \quad \Delta\gamma'_{NH} = (1/\sqrt{2})\Delta(\alpha_{31'5'} - \alpha_{5'1'2'})$$
$$R'^{(m)}_3 \quad \Delta\beta'_{NH} = (1/\sqrt{6})\Delta(2\alpha_{2'1'3} - \alpha_{31'5'} - \alpha_{5'1'2'})$$
$$R'^{(m)}_4 \quad \Delta r'_{NM} = \Delta r_{1'2'}$$
$$R'^{(m)}_5 \quad \Delta\alpha'_{NMC} = \Delta\alpha_{1'2'3'}$$
$$R'^{(m)}_6 \quad \Delta r'_{MC} = \Delta r_{2'3'}$$
$$R'^{(m)}_7 \quad \Delta r'_{CO} = \Delta r_{3'4'}$$
$$R'^{(m)}_8 \quad \Delta\gamma'_{CO} = (1/\sqrt{2})\Delta(\alpha_{2'3'4'} - \alpha_{4'3'1})$$
$$R'^{(m)}_9 \quad \Delta\beta'_{CO} = (1/\sqrt{6})\Delta(2\alpha_{13'2'} - \alpha_{2'3'4'} - \alpha_{4'3'1})$$
$$R'^{(m)}_{10} \quad \Delta r'_{CN} = \Delta r_{3'1}$$

where r_{ij} and α_{ijk} represent the bond length between atoms, i and j, and the bond angle formed by atoms, i, j and k respectively.

TABLE I. FORCE CONSTANTS (mdyn./Å) AND MOLECULAR PARAMETERS

K(N-H)	5.6	H(H-N-C)	0.35	F(H. N. C)	0.50
K(N-C)	5.5	H(C-N-M)	0.30	F(C. N. M)	0.30
K(N-M)	3.4	H(H-N-M)	0.15	F(H. N. M)	0.50
K(M-C)	3.1	H(N-M-C)	0.20	F(N. M. C)	0.30
K(C=O)	8.5	H(O=C-M)	0.30	F(O. C. M)	0.50
		H(M-C-N)	0.30	F(M. C. N)	0.50
		H(O=C-N)	0.35	F(O. C. N)	1.50
		r_{NH}	1.00Å	α_{HNC}, α_{CNM}, α_{MNH},	
		r_{NM}	1.47Å	α_{NMC}, α_{OCM}, α_{MCN},	
		r_{MC}	1.54Å	α_{NCO}.....120°	
		r_{CO}	1.21Å		
		r_{CN}	1.32Å		

By the use of these internal co-ordinate vectors, the $\boldsymbol{G}$ matrix of the polyglycine I molecule was constructed; it is expressed in the form shown in Fig. 2.

Potential Energy

The Urey-Bradley potential energy[4] of the polyglycine I molecule is expressed as:

$$V=\sum_{m,i,j}K'_{ij}r_{ij}^{(m)}[\Delta r_{ij}^{(m)}]+(1/2)K_{ij}[\Delta r_{ij}^{(m)}]^2+\sum_{m,i,j,k}H'_{ijk}r_{ij}^{(m)}r_{jk}^{(m)}[\Delta\alpha_{ijk}^{(m)}]+(1/2)H_{ijk}r_{ij}^{(m)}r_{jk}^{(m)}[\Delta\alpha_{ijk}^{(m)}]^2+\sum_{m,i,j,k}F'_{ik}q_{ik}^{(m)}[\Delta q_{ik}^{(m)}]+(1/2)F_{ik}[\Delta q_{ik}^{(m)}]^2$$

For the term containing F'_{ik} and F_{ik}, the summation is taken for all i and k combinations which correspond to the index i and k in α_{ijk}. In the above formula, m is the index for chain units, while $r_{ij}^{(m)}$, $r_{jk}^{(m)}$ and $q_{ik}^{(m)}$ represent the equilibrium value of the interatomic distance.

The Reduction of the Secular Equation

For a long chain molecule such as polyglycine I, only the vibrations in which all units in the molecular chain vibrate in phase are optically active.[5] Since the polyglycine I molecule has a plane of symmetry as well as a two-fold screw axis (fiber axis), the optically-active vibrations are classified into four species, A_1, B_1, A_2 and B_2. The A_1 and B_1 vibrations are symmetric with respect to the molecular plane, whereas the A_2 and B_2 vibrations are antisymmetric with respect to this plane. From the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices of infinite order shown in Fig. 2, the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices for the optically-active A_1 and B_1 vibrations were constructed by the symmetry co-ordinates shown below:

$$S_i=(1/\sqrt{N})\sum_m(R_i^{(m)}+R'^{(m)}_i) \quad \text{for } A_1 \text{ species} \tag{2}$$

$$S'_i=(1/\sqrt{N})\sum_m(R_i^{(m)}-R'^{(m)}_i) \quad \text{for } B_1 \text{ species} \tag{3}$$

In these equations, N is the total number of chain units in the polyglycine I molecular chain.

The secular equations (10th order) for the A_1 and B_1 vibrations

$$|\boldsymbol{G}_A\boldsymbol{F}_{A_1}-\lambda E|=0 \tag{4}$$

$$|\boldsymbol{G}_{B_1}\boldsymbol{F}_{B_1}-\lambda E|=0 \tag{5}$$

were solved by an NEAC model 2101 electronic computer. The force constants and the molecular parameters used in this calculation are listed in Table I. The calculated normal frequencies and the diagonal terms of potential

energy distributions are shown in Tables II and III respectively. The L^x matrix, which is used for the transformation from the normal co-ordinate vector, Q, into the cartesian co-ordinate vector fixed to the molecule, X, was calculated by the following formulae;[6]

$$X = L^x Q \tag{6}$$

$$L^x = M^{-1}\tilde{B}FL\Lambda^{-1} \tag{7}$$

The schematic representations of the atomic displacements thus calculated are shown in Figs. 3 and 4. The ^{15}N isotope shifts of the normal frequencies of the polyglycine I molecule were calculated by the following equation:[7]

$$\lambda_a = (1/m'_n - 1/m_n)(m_n)^2 \times [(L^x_{na})^2 + (L^y_{na})^2 + (L^z_{na})^2] \tag{8}$$

λ_a : The isotope shift of the a-th frequency parameter
m_n : The mass of the n-th atom
m'_n : The mass of the isotope atom
$(L^x)_{na}$: The vector associated with the n-th atom in the a-th normal vibration

$$(L^x)_{na} = \begin{pmatrix} L^x_{na} \\ L^y_{na} \\ L^z_{na} \end{pmatrix}$$

The calculated isotope shifts of the normal frequencies are shown in Table II.

Discussion

Polyglycine I is in the antiparallel chain-pleated sheet structure in the crystalline state.[1] Therefore, the assignment of the infrared absorption bands has to be made according to this structure, which contains interchain hydrogen bonds. Each of the internal vibrations of the polyglycine I molecule splits into two normal vibrations in the case of the polyglycine I crystal as follows:[8]

Molecule	Crystal	Selection rule
A_1	(0, 0)	IR inactive
	(0, π)	IR active
B_1	(π, 0)	IR active
	(π, π)	IR active
A_2	(0, 0)	IR inactive
	(0, π)	IR inactive
B_1	(π, 0)	IR active
	(π, π)	IR active

In principle, all the infrared active vibrations of the polyglycine I crystal are expected to appear in the infrared absorption. However, except for the amide I, II and III vibrations the frequency difference of each pair of splitted

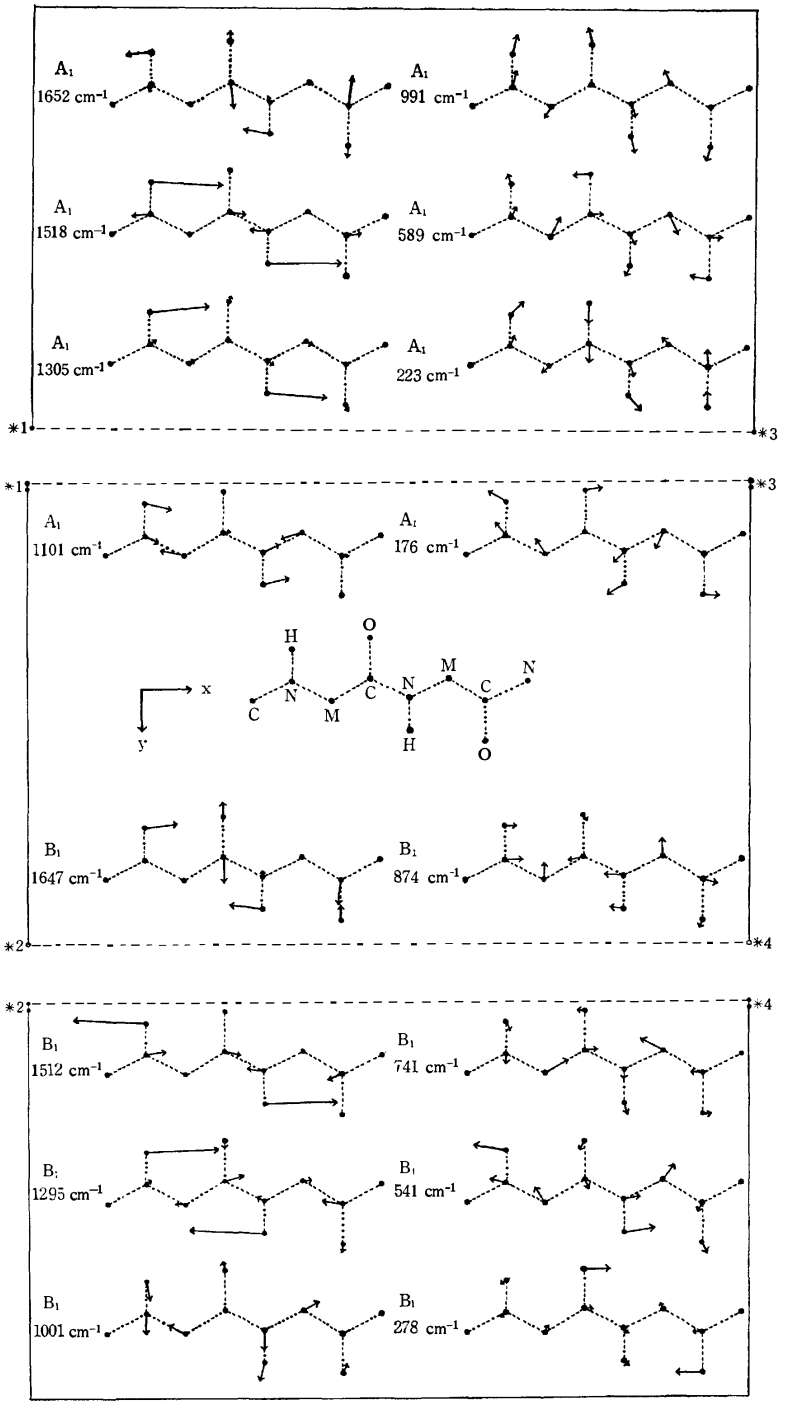

Fig. 3. Calculated normal modes of the A_1 and B_1 vibrations of polyglycine I.

bands may be very small in the case of in-plane vibrations. Therefore, detailed assignments on the basis of the selection rule for the crystal were made only for the amide I, II and III vibrations; the assignments of the other vibrations were made according to the selection rule based on the molecular symmetry. Accordingly, the bands assigned to the B_1 vibrations are considered to be due to the $\nu(\pi, 0)$ and $\nu(\pi, \pi)$ vibrations.

Characteristic Amide Vibrations.—Among the vibrations characteristic of polypeptides, six

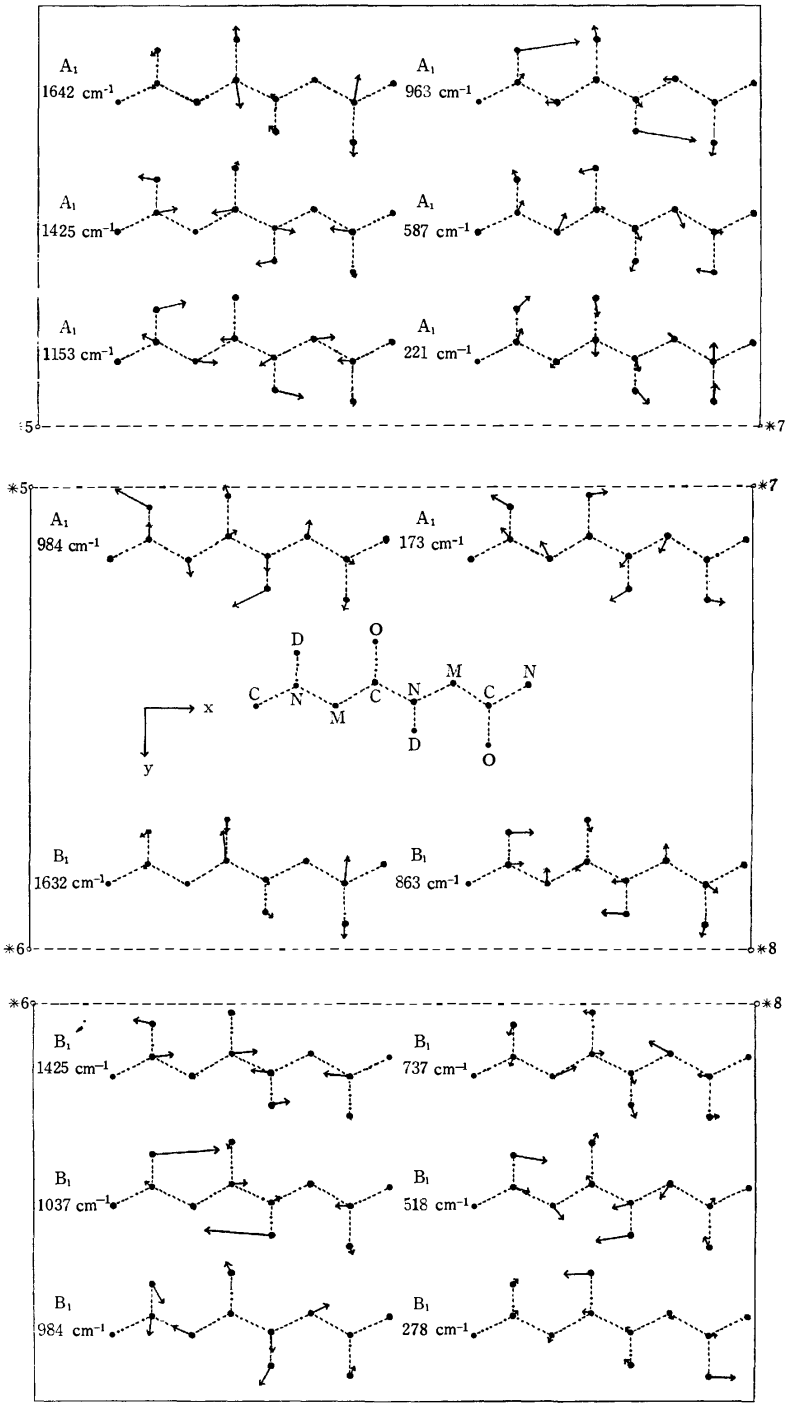

Fig. 4. Calculated normal modes of the A_1 and B_1 vibrations of *N*-deuterated polyglycine I.

vibrations (amide I, amide II, amide III, amide IV, amide II′ and amide III′) are treated as the in-plane vibrations of polyglycine I and its *N*-deuterated compound. The nature of these vibrations will now be discussed.

Amide I Vibration.—As Table III shows, this vibration is the antisymmetric stretching vibration of the O=C–N skeleton, in which the ratios of the energy associated to the C=O and C–N bonds are 0.78 : 0.14 for the A_1 vibration and 0.78 : 0.10 for the B_1 vibration. There are three types of amide I vibrations, $\nu(0, \pi)$,

$\nu(\pi, 0)$ and $\nu(\pi, \pi)$. The frequency of the $\nu(0, \pi)$ vibration is higher than those of $\nu(\pi, 0)$ and $\nu(\pi, \pi)$. These vibrations have been observed at 1688 cm^{-1} ($\nu(0, \pi)$) and 1630 cm^{-1} ($\nu(\pi,0)$). The direction of the transition moment associated with the $\nu(0, \pi)$ vibration is parallel to the fiber axis. Since the C=O bonds are nearly perpendicular to the chain axis, the C=O bond transition moments are largely canceled in the $\nu(0, \pi)$ vibration. Therefore, this vibration is expected to be weak in intensity. For the $\nu(\pi, 0)$ vibration, in which the direction of the transition moment is perpendicular to the fiber axis, the contribution of the C=O bond moment change is great. Therefore, the intensity of this vibration is expected to be strong. The assignments of the 1685 cm^{-1} band to $\nu(0, \pi)$ and the 1630 cm^{-1} band to $\nu(\pi, 0)$ reasonably follow from a consideration of their intensities.

Amide II Vibration. — This is the coupled vibration of the N-H in-plane bending and the amide C-N stretching vibrations. The degree of the coupling of these two vibrations is nearly the same for the A_1 and B_1 vibrations. These vibrations are observed at 1524 cm^{-1}.

Amide II' Vibration. — This is the coupled vibration of the C-N stretching, the N-D in-plane bending and the C-M stretching vibrations.

Amide III Vibration.—To this vibration, the contributions of the N-H in-plane bending, the C-M stretching and the N-C stretching modes are important. The couplings of these modes are different for the A_1 and B_1 vibrations, as Table IV shows. The frequency of the A_1 vibration is higher than that of the B_1 vibration. The $\nu(0, \pi)$ (A_1) vibration appears at 1236 cm^{-1} and the $\nu(\pi, 0)$ and $\nu(\pi, \pi)$ (B_1) vibrations at 1214 cm^{-1}.

Amide III' Vibration.—To this vibration, the N-D in-plane bending mode contributes mainly; however, the contributions of skeletal stretching modes are also important.

Amide IV Vibration. — In this vibration, the frequency difference between the A_1 and B_1 vibrations is large. The calculated A_1 frequency is 589 cm^{-1} while the calculated B_1 frequency is 741 cm^{-1}. The A_1 vibration is an almost pure C=O in-plane bending vibration with a small contribution by the C-M stretching mode, whereas the B_1 vibration is a coupled vibration of the C=O in-plane bending, C-N-M skeletal deformation and C-M stretching modes. In the A_1 vibration, all the C=O bonds displace in phase, with a resultant strong transition moment along the molecular chain, so the intensity of this vibration may be expected to be very strong. Therefore, the strong band at 628 cm^{-1} is assigned to this vibration. In the B_1 vibration the bond moment change associated with the C=O in-plane bending mode will not contribute much to the total dipole moment change, and the transition moment of this B_1 vibration is possibly due to the dipole moment change of the C-N-M skeletal mode. Since the intensity of this B_1 vibration is considered to be weak, the weak band at 773 cm^{-1} is assigned to this vibration.

Nature of the Skeletal Vibrations. — The skeletal vibrations of polyglycine I are important in studying the changes in the polypeptide chain conformation. From the results of the calculations, the nature of the skeletal vibrations of the β-type polypeptide chain with no side chains has been made clear.

Skeletal Stretching Vibrations.—There are four skeletal stretching vibrations in the polyglycine I molecule, two belonging to the A_1 species and the other two belonging to the B_1 species. As Table II shows, the A_1 vibration calculated at 1101 cm^{-1} is the antisymmetric stretching vibration of the N-M-C skeleton. The band at 1112 cm^{-1} is assigned to this vibration. The other A_1 vibration, calculated at 991 cm^{-1}, is the C-M stretching vibration coupled with the M-C-N and C-N-M skeletal deformation modes. The band at 987 cm^{-1} is assigned to the A_1 vibration. For the B_1 species, the vibration calculated at 1001 cm^{-1} is the antisymmetric stretching vibration of the C-N-M skeleton coupled with the C-N-M skeletal deformation mode. The band at 1015 cm^{-1} is assigned to this vibration. The other B_1 vibration calculated at 874 cm^{-1} is the symmetric stretching vibration of the N-M-C skeleton. The band due to this vibration has not yet been identified.

Skeletal Deformation Vibrations. — There are four skeletal deformation vibrations, two belonging to the A_1 species and two belonging to the B_1 species. The A_1 vibrations include the antisymmetric skeletal deformation vibration of the M-C-N-M skeleton calculated at 223 cm^{-1} and the antisymmetric skeletal deformation vibration of the C-N-M-C skeleton calculated at 176 cm^{-1}. The two skeletal deformation frequencies of the B_1 species are very different from those of the A_1 species. The B_1 vibrations include the symmetric deformation vibration of the C-N-M-C skeleton, coupled with the amide IV vibration calculated at 278 cm^{-1}, and the symmetric deformation vibration of the N-M-C-N skeleton (calculated frequency at 541 cm^{-1}).

An Unsaturated Cyclic Alcohol in the Nonsaponifiable Matter of the Liver Oil of the Crab, Paralithodes Camtschatica

(Received June 21, 1963)

By Suketaka ITO[*1] and Yoshiyuki TOYAMA[*2]

The presence of an unsaturated alcohol with the formula $C_{10}H_{18}O_2$ in the nonsaponifiable matter of the liver oil of the crab, *Palalithodes Camtschatica*, was reported forty years ago by Tsujimoto.[1] This alcohol, named kanyl alcohol by him, was shown to be an unsaturated monohydric alcohol, whereas the nature of the other oxygen atom was not decided. It was postulated as having a branched chain of carbon atoms or a cyclic structure from the fact that both this alcohol and its hydrogenation product had low freezing points. The hydroxyl group of this alcohol was inferred to be located in a position which is unfavorable for urethan formation, since neither phenyl urethan nor α-naphthyl urethan of a crystalline form could be obtained from this alcohol. Later, Nakamiya[2] reinvestigated a fraction corresponding to the kanyl alcohol of Tsujimoto and concluded that kanyl alcohol was not a uniform substance but a mixture of different components.

In this study, the liquid fraction was separated from the nonsaponifiable matter of the liver oil of the crab, *Paralithodes Camtschatica*. The acetate of this fraction was fractionally distilled to give an acetate fraction which accords with Tsujimoto's kanyl alcohol in its refractive index, saponification value and iodine value. However, when this fraction was subjected to chromatography on silica gel, a main fraction and a by-fraction were collected in the ratio of approximately 2 : 1. The gas-liquid chromatography of these two fractions indicated that while the by-fraction contained at least several components, the main fraction consisted almost exclusively of a uniform substance. When the main fraction was studied further, the conclusion was reached that the free alcohol, $C_{12}H_{20}O_2$, corresponding to this acetate fraction is α-octa-2, 5-dienyl-β-hydroxytetrahydrofuran.

Experimental

The Properties of Liver Oil.—A 37.35 kg. batch of livers separated from crabs, *Paralithodes Camtschatica*, caught in northern waters was supplied by the Nihon Suisan K. K. It was heated on a water bath to remove the bulk of the water; the concentrated material, 11 kg., was extracted with ether, yielding 2.033 g. of oil. The oil was completely soluble in acetone. It was a dark brown liquid with a peculiar odor and had the following characteristics: d_4^{20} 0.9280, n_D^{20} 1.4796, A. V. 89.4, S. V. 160.4, I. V. (Wijs) 174.1[*3] and nonsaponifiable matter 11.0 %.

The Separation of the Liquid Fraction of Nonsaponifiable Matter and the Fractional Distillation of Its Acetate.—A crude nonsaponifiable matter was separated from the oil by saponification with potassium hydroxide in ethanol, followed by the extraction of the soap solution with ether in the usual way. A 202 g. portion of the crude nonsaponifiable matter was dissolved in 600 ml. of hot methanol, and the solution was cooled with ice to separate 53 g. of a crystalline solid which consisted chiefly of cholesterol. The solid was filtered, and the material recovered from the filtrate was dissolved in 440 ml. of hot acetone. When the acetone solution was cooled, 14.5 g. of a crystalline solid was separated and filtered. This solid consisted chiefly of batyl alcohol, together

*3 The abbreviations A. V., S. V. and I. V. are used for acid value, saponification value and iodine value respectively.

with a small amount of cholesterol. From the acetone filtrate a liquid fraction of nonsaponifiable matter was recovered (n_D^{22} 1.4898, A. V. 8.4 and I. V. 142.8). It was acetylated by refluxing it with acetic anhydride to give an acetate of S. V. 206.9 and I. V. 100.7. A 145 g. portion of this acetate was distilled to give a distillate of b. p. 110~223°C/2 mmHg, S. V. 231.2 and I. V. 84.3. The fractional distillation of this distillate (94.5 g.) gave the results shown in Table I.

Fraction 1 and fractions 3—6 in Table I were refractionated. A fraction approximating fraction 2 was separately collected and united to fraction 2. This united fraction was fractionated further to give, eventually, 8.7 g. of a fraction with b. p. 130~135°C/2 mmHg, n_D^{22} 1.4624, S. V. 265.0 and I. V. 143.9. These values approximate those for kanyl acetate reported by Tsujimoto:[1] n_D^{20} 1.4623, S. V. 251 and I. V. 145.

The Chromatography of the Acetate Fraction (B. p. 130~135°C/2 mmHg).—This fraction (8.5 g.) was chromatographed on silica gel and eluted with hexane and then with hexane-ether (100 : 0.5, 100 : 1 and 100 : 2). Each 100 ml. of the eluate was separately collected, giving a total of 60 fractions. The chromatogram is shown in Fig. 1. The eluate

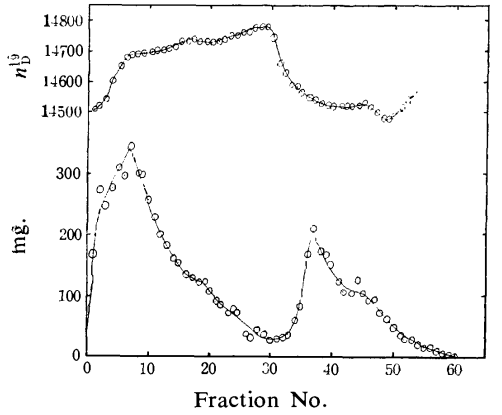

Fig. 1. Elution chromatogram of the acetate fraction, b. p. 130~135°C/2 mmHg.

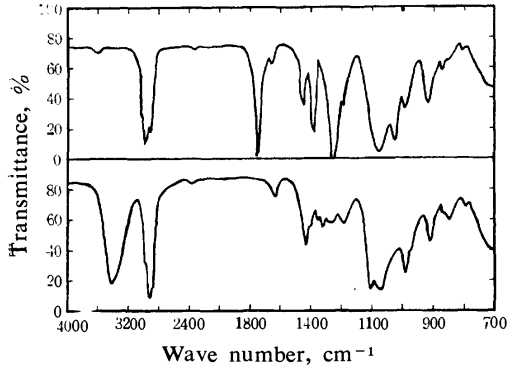

Fig. 2. Infrared spectra of the fraction A (upper) and the free alcohol (lower). Film on NaCl flats.

fractions 5—14 were united, and 2.6 g. of united material were rechromatographed on silica gel. After the earlier and later eluate fractions had been removed, the intermediate fractions, 2.05 g. in total (n_D^{20} 1.4703~1.4712) were combined into a fraction A of S. V. 235.5 and I. V. 196.5 (calculated for $C_{12}H_{19}O \cdot OCOCH_3$: S. V. 235.4 and I. V. 213.0). Fraction A was analyzed by gas-liquid chromatography at 210°C, using a 225 cm×6 mm. column of diethylene glycol succinate polyester on Celite 545. The chromatogram indicated that this fraction contained a uniform substance almost exclusively. The infrared spectra of this fraction and the free alcohol obtained by saponification are shown in Fig. 2.

The eluate fractions 36—46 in Fig. 1 were united, and the united material, 1.55 g., was chromatographed on silica gel to give 0.96 g. of a fraction B having S. V. 322.7 and I. V. 107.6, but this fraction was found by gas-liquid chromatography to be a complicated mixture of different components.

Alkali-Isomerization and Ozonolysis of Fraction A. — Fraction A, after isomerization with a 6.6% solution of potassium hydroxide in ethylene glycol at 180°C for 25 min., exhibited the characteristic absorption of conjugated dienes, $k_{233}=37.6$.

A 100 mg. portion of fraction A in 10 ml. of chloroform was ozonized at −15°C. Then 10 ml. of water was added to the solution, and the mixture was gradually heated from 20°C to 90°C while a current of hydrogen was being passed through the mixture. The volatile substances formed were carried off by the hydrogen current and passed successively through a trap containing a solution of 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid and a trap containing a solution of barium hydroxide. A considerable amount of precipitates of barium carbonate was formed in the second trap. The precipitates of 2,4-dinitrophenylhydrazone (DNPH) formed in the first trap were filtered. The DNPHs in the filtrate were recovered by extraction with benzene, followed by washing of the benzene solution with 2 N hydrochloric acid and water, and finally by the distilling off of the benzene. The total yield of crude DNPHs was 294 mg. Crude DNPHs were chromatographed on silica gel. Two eluate fractions were collected using hexane and hexane-ether as the eluants. The first eluate fraction gave 90 mg. of a DNPH which was then purified by rechromatography on silica gel, followed by recrystallization from hexane. The purified substance was in the form of orange yellow needles of m. p. 155.5~156.5°C (lit.[3] 155°C for propionaldehyde DNPH).

Found: N, 23.40. Calcd. for $C_9H_{10}N_4O_4$: N, 23.50%.

The second eluate fraction gave 78 mg. of a DNPH which was purified by rechromatography on silica gel and recrystallization from hexane to give, eventually, yellow needles of m. p. 165~165.5°C (lit.[4] 168.5°C for acetaldehyde DNPH). No depression of the melting point was observed on admixture with an authentic specimen of acetaldehyde DNPH.

4) W. M. D. Bryant, ibid., **60**, 2814 (1938).

A Saturated Alcohol from the Hydrogenation Product of Fraction A.—Fraction A was hydrogenated in ethanol using platinum black as the catalyst. The hydrogenation product was saponified to give a crude saturated alcohol which had n_D^{17} 1.4581 and I. V. 6.2. It was a pale yellow liquid with a solidifying point below −15°C, which was negative to the iodoform reaction. This material was used as a saturated alcohol in the experiments described below.

Phenyl Urethan. — A solution of 50 mg. of the saturated alcohol in 3 ml. of benzene, which had been dried over metallic sodium, was refluxed with 50 mg. of phenyl isocyanate for 30 min. When the solvent and the excess of the reagent were distilled off, the reaction product, phenyl urethan, was obtained in a yield of 80 mg. It did not solidify on standing at room temperature. Only after repeated heating and cooling did it begin to solidify. After repeated recrystallizations from hexane, fibrous crystals of m. p. 57.5~58.5°C were obtained.

Found: C, 71.22; H, 9.08; N, 4.84. Calcd. for $C_{19}H_{29}O_3N$: C, 71.44; H, 9.15; N, 4.39%.

The Oxidation of the Saturated Alcohol with Chromic Acid. — A solution of 100 mg. of chromic anhydride in 5 ml. of 90% acetic acid was gradually added to a solution of 180 mg. of the saturated alcohol in 10 ml. of glacial acetic acid; the resulting solution was allowed to stand overnight at room temperature. Then the solution was heated at 60°C for 15 min., and the reaction product was extracted with ether. The ether solution was washed succesively with a solution of sodium bisulfite, water, a solution of sodium carbonate and water. When the ether was distilled off, 162 mg. of the reaction product remained. To a solution of this material in 5 ml. of ethanol was added the reagent prepared from 0.2 g. of 2,4-dinitrophenylhydrazine, 1 ml. of sulfuric acid, 1.5 ml. of water and 5 ml. of ethanol. The mixture was heated at 60°C for 10 min. and then allowed to stand for 24 hr. The precipitates of crude DNPH formed were filtered. Yield, 152 mg. These were purified by chromatography on silica gel and elution with hexane and hexane-ether. The material obtained from the main eluate fraction was purified further by repeated recrystallizations from hexane to give, eventually, 35 mg. of yellow needles of m. p. 84.5~85.5°C.

Found: C, 57.13; H, 6.91; N, 14.83. Calcd. for $C_{18}H_{26}N_4O_5$: C, 57.13; H, 6.93; N, 14.81%.

The Oxidative Cleavage of the Saturated Alcohol with Potassium Permanganate. — To a solution of 90 mg. of the saturated alcohol in 30 ml. of acetone an excess of potassium permanganate in small portions was added, and the mixture was refluxed for 7 hr. The reaction product was treated in the usual way, and 46 mg. of an acidic substance was separated. This was converted to the methyl ester, and the latter was analyzed by gas-liquid chromatography (temperature: 160°C). Methyl pelargonate, together with a small amount of methyl caprylate and oenanthate, was identified.

The Preparation of *n*-Dodecane by the Reduction of the Reaction Product of the Saturated Alcohol and Hydrogen Iodide. — Six grams of hydrogen iodide (d=1.7) were added to a solution of 205 mg. of the saturated alcohol in 2 ml. of glacial acetic acid, and the mixture was refluxed for 1 hr. The reaction product was extracted with ether, and the ether solution was washed successively with a solution of sulfurous acid, a solution of sodium bicarbonate, and water. When the ether was distilled off, there remained 380 mg. of the reaction product, which was regarded as alkyl iodide by its infrared spectrum.*4 To a solution of 160 mg. of this iodide in 35 ml. of ether, which had been dried over metallic sodium, 200 mg. of lithium aluminum hydride were added and the solution was refluxed for 2 hr. The reaction product was separated in the usual way. Yield, 63 mg. *n*-Dodecane was identified by gas-liquid chromatography (temperature: 100°C).

The Ozonolysis of the Debromination Product of the Alkyl Bromide Derived from the Saturated Alcohol.—To a solution of 190 mg. of the saturated alcohol in 2 ml. of glacial acetic acid 10 g. of hydrogen bromide (d=1.49) were added, and the mixture was refluxed for 5 hr. The reaction product was separated in the usual way. Yield, 267 mg. This was considered to be alkyl bromide from its infrared spectrum.*4 The bromide was dissolved in 15 ml. of glacial acetic acid, and 750 mg. of zinc powder were added to the solution. After this solution had been refluxed for 2 hr., the debromination product was obtained by extraction with ether. The debromination product (130 mg.) in 10 ml. of methylene chloride was ozonized at −15°C. The ozonide was decomposed by adding 5 ml. of a 10% solution of potassium hydroxide and 1 ml. of 30% hydrogen peroxide, after which the mixture was gradually heated to 85°C while passing a current of nitrogen through it. The alkaline solution was then acidified with diluted sulfuric acid and distilled. The distillate, after neutralization with a N/10 solution of potassium hydroxide, was evaporated, and the residue was taken up with ethanol. The ethanol solution was concentrated to a volume of 2~3 ml. Benzyl bromide in an amount equivalent to the alkali required for the neutralization of the distillate was added to the concentrated ethanol solution, and the mixture was refluxed for 25 min. The benzyl esters thus obtained were extracted with ether. Yield, 63 mg. These were analyzed by gas-liquid chromatography (temperature: 200°C); benzyl propionate and pelargonate were identified as the main components.

Discussion

Since cholesterol and batyl alcohol are the main components of the crystalline solid which was obtained by recrystallizations of the total nonsaponifiable matter from methanol and acetone, and since batyl and selachyl acetates are found as main components of the higher-boiling acetate fractions (Table I) of the liquid nonsaponifiable matter, cholesterol, batyl

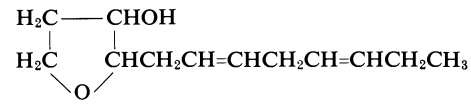
*4 The absorption bands associated with the hydroxyl and ether groups in the original unsaturated alcohol were absent in the spectrum of this substance.

alcohol and selachyl alcohol are considered to be major components of the total nonsaponifiable matter.

An acetate fraction (b. p. 130~135°C/2 mmHg) obtained by the fractional distillation of the acetate of liquid nonsaponifiable matter accorded with Tsujimoto's kanyl acetate in its properties, but this fraction was found to be a heterogeneous mixture by gas-liquid chromatography. Of the two eluate fractions (A and B) obtained by column chromatography of this fraction on silica gel, fraction A consisted of a uniform substance, while fraction B was found to be a mixture of different components. Hence, kanyl alcohol is not a uniform substance but a mixture which contains a peculiar alcohol as a main component, namely, the alcohol of fraction A. Since fraction A was readily separated by column chromatography, it appears to be of a series quite different from the other component acetates.

It may be seen from Fig. 2 that the infrared spectra of fraction A and the free alcohol obtained therefrom show an absorption band at 1075 cm^{-1} which may be assigned to the C–O stretching vibration of aliphatic ethers or five- or six-membered cyclic ethers,[5] while the infrared spectrum of the free alcohol shows an absorption band at 1105 cm^{-1} which may be assigned to the C–O stretching vibration of secondary alcohols. Since the formula of the saturated alcohol obtained by the hydrogenation of fraction A is demonstrated as $C_{12}H_{24}O_2$ by analyses of its phenyl urethan and of the DNPH obtained from its oxidation product (ketone), the formula of the unsaturated alcohol should be $C_{12}H_{20}O_2$, since it has two double bonds, as is seen from its iodine value of 241.4. The proportion of carbon and hydrogen atoms indicated that there should be a cyclic group in its molecule.

Fraction A has an alkali-conjugatable diene $=CHCH_2CH=$, and the ozonolysis of fraction A gives propionaldehyde as a cleavage product. Accordingly, fraction A should have the group $CH_3CH_2CH=CHCH_2CH=CH-$. Further, the oxidative scission of the saturated alcohol with potassium permanganate yields pelargonic acid as a main cleavage product. Hence, the saturated alcohol should have a straight chain of 9 carbon atoms; $CH_3(CH_2)_7CH<$. This fact, together with the fact that the reduction of the alkyl iodide derived from the saturated alcohol with lithium aluminum hydride yields *n*-dodecane, leads to the conclusion that the unsaturated alcohol is α-octa-2, 5-dienyl-β-hydroxytetrahydrofuran:



This structure is also consistent with the fact that the ozonolysis of the debromination product of the alkyl bromide derived from the saturated alcohol yields pelargonic and propionic acids.

The Rearrangement Reaction of Levulinic Acid in a Selenium Dioxide-catalyzed Hydrogen Peroxide Oxidation

By Noboru SONODA and Shigeru TSUTSUMI

(Received May 10, 1963)

In previous reports[1-4] we described the synthesis of carboxylic acids from dialkyl ketones and aryl alkyl ketones by oxidation with hydrogen peroxide using a selenium dioxide catalyst. Our findings have shown that the process of the formation of carboxylic acids from an unsymmetrical dialkyl ketone involved the migration of one of the alkyl groups to the α-carbon atom of the other

1) N. Sonoda and S. Tsutsumi, This Bulletin, **32**, 505 (1959).
2) N. Sonoda, T. Yamaguchi and S. Tsutsumi, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **63**, 737 (1960).
3) N. Sonoda and S. Tsutsumi, This Bulletin, **33**, 1440 (1960).
4) N. Sonoda and S. Tsutsumi, ibid., **34**, 1007 (1961).

alkyl group and the oxidation of the carbonyl group to a carboxyl group. This observation led us to guess that keto-acid might be oxidized to dibasic acid with the same number of carbon atoms as the original keto-acid; therefore, levulinic acid was used as the starting material.

The oxidation of levulinic acid with hydrogen peroxide was carried out in a tertiary butyl alcohol solution in the presence of a catalytic amount of selenium dioxide at 82°C. Distillation of the reaction mixture under reduced pressure afforded glutaric acid as the main acid product; a small amount of methylsuccinic acid was also isolated as the isomer of glutaric acid.

Several studies[5-11] have been made of the syntheses of glutaric acid derivatives from levulinic acid. Hara and Fujise[5] have reported the one-step synthesis of glutaramide from levulinic acid by a Willgerodt reaction, and recently Motoki and Odaka[9-11] have studied a method for the syntheses of various derivatives of glutaric acid. In these cases, however, no rearrangement of the carbon skelton was observed, because these reactions proceeded via a process involving the reduction of the carbonyl group and the oxidation of the active methyl group. In the present case, glutaric acid may be formed by the intramolecular migration of the β-carboxyethyl group to the methyl carbon atom and by the oxidation of the original carbonyl group to the carboxyl group; these possibilities are based on the rearrangement behavior[1,12] of unsymmetrical dialkyl ketones. Furthermore, the evidence of the rearrangement was supported by the fact that the methylsuccinic acid isolated was produced by the migration of the methyl group to the methylene carbon atom adjacent to the carbonyl group:

$$CH_3-\overset{\overset{O}{\|}}{C}-CH_2-CH_2-COOH \xrightarrow{H_2O_2\text{-}SeO_2}$$

$$HOOC-CH_2-CH_2-CH_2-COOH$$
$$+\ HOOC-\underset{\underset{CH_3}{|}}{CH}-CH_2-COOH$$

It has been shown that the active species of this rearrangement reaction may be peroxyselenous acid $\left(HOO-Se\begin{matrix}\nearrow O\\ \searrow OH\end{matrix}\right)$ generated by the oxidation of selenium dioxide with hydrogen peroxide in the reaction system,[12] so that the rearrangement may be caused by the attack of peroxyselenous acid on levulinic acid in a process similar to that described in the previous reports.[4,12]

The reactivity of levulinic acid was considerably lower than that of dialkyl ketone with a low molecular weight, so that the yield of C_5-dibasic acids amounted to about 10% of the levulinic acid used, and a fairly good recovery of the starting levulinic acid was observed in spite of an excess amount of hydrogen peroxide having been used.

Small amounts of β-acetylacrylic acid and of fumaric acid were also isolated as by-products. Raymond[13] has reported that the oxidation of various esters of levulinic acid yielded the corresponding esters of β-acetylacrylic acid by dehydrogenation. Accordingly, it was assumed that β-acetylacrylic acid might be produced by the action of the selenium dioxide used as the catalyst in the present case:

$$CH_3-\overset{\overset{O}{\|}}{C}-CH_2-CH_2-COOH \xrightarrow{SeO_2}$$

$$CH_3-\overset{\overset{O}{\|}}{C}-CH=CH-COOH$$

Fumaric acid may be generated by the oxidative cleavage of β-acetylacrylic acid or by the dehydrogenation of succinic acid[14] with selenium dioxide. Succinic acid can be formed by the oxidative cleavage of levulinic acid, but the formation of succinic acid was not detected in the present experiment.

Experimental

Material.—Levulinic acid used in this experiment was purified by the distillation of the commercial product; b. p. 152°C/21 mmHg (reported[15] b. p. 138~140°C/10 mmHg).

Oxidation of Levulinic Acid. — To 150 ml. of a tertiary butyl alcohol solution[16] containing 1.0 g. of selenium dioxide and 0.3 mol. of hydrogen peroxide, 17.4 g. (0.15 mol.) of levulinic acid was added. The hydrogen peroxide was completely consumed by the refluxing of the solution for

12 hr., and at this stage a small amount of metallic selenium was deposited. After the removal of the solvent by distillation from the reaction mixture, the residual high-boiling liquid was distilled under reduced pressure and was divided into two fractions: fraction A, 11.5 g., b. p. <150°C/3.5 mmHg; fraction B, 2.8 g., b. p. 150~160°C/3.5 mmHg; residue, ca. 2.5 g., resinous substance containing metallic selenium.

Fraction A was kept for two days at room temperature, and the deposited crystalline material was then fitered (0.5 g.) and recrystallized from benzene to yield 0.3 g. of β-acetylacrylic acid; m. p. 125°C (reported[17] m. p. 125~126°C). Upon admixture with an authentic sample of β-acetylacrylic acid, the melting point was not depressed, and the infrared spectrum of the product was identical with that of an authentic sample.

Found: C, 52.61; H, 5.48. Calcd. for $C_5H_6O_3$: C, 52.63; H, 5.30%.

After the removal of β-acetylacrylic acid by filtration, the residual liquid was redistilled under reduced pressure, giving a trace amount of β-acetylacrylic acid and 8.7 g. of unchanged levulinic acid; the infrared spectra of these samples closely resembled those of authentic materials.

Fraction B, which partly contained crystalline materials, was cooled at 0°C overnight, and the solid which was then deposited was filtered and dissolved into hot benzene. After the removal of a small amount of insoluble substance, the hot benzene solution was cooled and the crystalline material deposited was filtered and recrystallized from benzene to yield 1.2 g. of glutaric acid; m. p. 96~97°C (lit.[18] m. p. 97°C)). Upon admixture with an authentic sample of glutaric acid, the melting point was not depressed, and the infrared spectrum of the product was identical with that of an authentic sample.

Found: C, 45.67; H, 6.22. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10%.

The substance insoluble in hot benzene was purified three times by sublimation at 200°C/25 mmHg, yielding 0.03 g. of fumaric acid, which melted at 286~288 °C (sealed tube) (lit.[19] m. p. 286~287°C); the mixed melting point with an authentic sample showed no depression, and the infrared spectrum of the product was identical with that of an authentic sample.

Found: C, 41.67; H, 3.62. Calcd. for $C_4H_4O_4$: C, 41.39; H, 3.47%.

The residual liquid obtained from fraction B by the filtration of the solid materials was cooled at 0°C for a few days, and 0.6 g. of the solid deposited was filtered. After recrystallization was repeated from benzene containing a small amount of ether, there was obtained 0.2 g. of methylsuccinic acid, which melted at 108~109°C (reported[20] m. p. 110°C); the mixed melting point with an authentic sample (m. p. 109~109.5°C), synthesized by the hydrolysis of ethyl β-cyanobutyrate showed no depression, and the infrared spectrum of the product was identical with that of an authentic sample; neutral equivalent, 65.9 (theoretical value, 66.1).

Found: C, 45.13; H, 5.90. Calcd. for $C_5H_8O_4$: C, 45.45; H, 6.10%.

Summary

The selenium dioxide-catalyzed oxidation of levulinic acid with hydrogen peroxide in *t*-butyl alcohol gave glutaric acid and methylsuccinic acid as the rearrangement products. The glutaric acid may be formed by the migration of the β-carboxyethyl group to the methyl carbon atom and by the oxidation of the carbonyl group to the carboxyl group, and the formation of methylsuccinic acid may be due to the migration of the methyl group to the methylene carbon atom adjacent to the carbonyl group.

Studies of Isocyanides. I. The Formation of Urethanes and Ureas from Isocyanides

By Masaya OKANO, Yoshihiko ITŌ, Tatsuya SHŌNO and Ryohei ODA

(Received May 13, 1963)

In recent years new addition reactions of isocyanides have been widely developed by Ugi and his co-workers. Their studies mainly covered the reactions with several carbonyl and similar compounds, such as ketenes, carboxylic acids, acyl chlorides and Schiff bases.[1] It seems that these new reactions, as well as the well-known Passerini reaction,[2] essentially involve an electrophilic attack by the positive carbon of these reagents on the negatively-charged carbon of isocyanides. Since the electrophilic nature of *t*-butyl hypochlorite[3] and *N*-bromosuccinimide (NBS)[4] in aromatic halogenations and that of hydroxylamine[5] (with a Lewis acid catalyst) in aromatic amination have previously been established, we have now examined the reactions of these electrophiles with isocyanides, which may be expected to yield urethanes and ureas, after successive hydrolysis if necessary.

When cyclohexyl isocyanide was treated with *t*-butyl hypochlorite in the presence of zinc chloride catalyst, an instantaneous reaction took place, and a 20% yield of *t*-butyl *N*-cyclohexylcarbamate, in addition to cyclohexyl isocyanate (16%), was obtained by successive treatment with water. In the absence of the catalyst, however, the isocyanate (40%) was the sole product. Similarly, the addition of phenyl isocyanide to *t*-butyl hypochlorite, followed by hydrolysis, afforded *t*-butyl *N*-phenylcarbamate in a 69% yield. The use of other Lewis acid catalysts (e.g., aluminum trichloride, boron trifluoride and ferric chloride) is not suitable, since isocyanide itself rapidly converts to a tarry matter when the catalysts are added. A reasonable path for this reaction would involve the formation of an imidoyl-chloride intermediate,[6] as in the case of the reaction between isocyanide and acyl chloride:[7]

$$R\text{-}N\rightleftarrows C + t\text{-}BuOCl \xrightarrow{ZnCl_2\ cat.} \left[R\text{-}N{=}C\begin{matrix}Cl\\OBu\text{-}t\end{matrix}\right] \xrightarrow{H_2O} RNHCOOBu\text{-}t$$

$$R = C_6H_{11},\ C_6H_5$$

The reaction of cyclohexyl isocyanide with wet NBS (containing ca. 5~10% of water) proceeded smoothly at room temperature and gave a 21% yield of *N*-(cyclohexylcarbamoyl) succinamic acid after hydrolysis. When the reaction was conducted under completely anhydrous conditions, the formation of a tarry matter was observed after a short induction period and the above acid could not be isolated by successive treatment with water. A preliminary test indicated that the addition of zinc bromide caused the decomposition of NBS; therefore, no effort was made to examine the zinc salt-catalyzed reaction. An analogous reaction of phenyl isocyanide with *N*-bromoacetamide (NBA) yielded the expected adduct, *N*-acetyl-*N'*-phenylurea, in a 38% yield. Since this type of reaction proceeds smoothly even in the dark, an ionic process appears to be favorable; on this point, however, more conclusive evidence would be desirable.

$$C_6H_{11}\text{-}N\rightleftarrows C + \begin{matrix}CH_2\text{-}CO\\|\\CH_2\text{-}CO\end{matrix}NBr \rightarrow \left[C_6H_{11}\text{-}N{=}C\begin{matrix}Br\\N\end{matrix}\begin{matrix}CO\text{-}CH_2\\|\\CO\text{-}CH_2\end{matrix}\right] \xrightarrow{H_2O} C_6H_{11}NHCONHCOCH_2CH_2COOH$$

$$C_6H_5\text{-}N\rightleftarrows C + CH_3CONHBr \rightarrow \left[C_6H_5\text{-}N{=}C\begin{matrix}Br\\NHCOCH_3\end{matrix}\right] \xrightarrow{H_2O} C_6H_4NHCONHCOCH_3$$

Lastly, the treatment of a mixture of cyclohexyl isocyanide and hydroxylamine hydrochloride with zinc chloride afforded a 42% yield of *N*-cyclohexylurea, as shown in the following equation:

1) I. Ugi et al., *Chem. Ber.*, **94**, 734, 1116, 2233, 2797, 2802 (1961); *Angew, Chem.*, **74**, 10 (1962).
2) M. Passerini, *Gazz. chim. ital.*, **51**, 181 (1921) [*Chem. Abst.*, **16**, 556 (1922)].
3) D. Ginsberg, *J. Am. Chem. Soc.*, **73**, 2723 (1951).
4) S. D. Ross, M. Finkelstein and R. C. Petersen, ibid., **80**, 4327 (1958). NBS is generally considered to be a homolytic brominating agent, especially for an allylic system; however, Ross et al. recently cited the possibility of the heterolytic bromination of reactive aromatics with NBS.
5) C. Graebe, *Ber.*, **34**, 1778 (1901); G. F. Jaubert, *Compt. rend.*, **132**, 841 (1901).
6) Unfortunately, an attempt to isolate the intermediate oil was not successful because of its thermal instability.
7) I. Ugi and U. Fetzer, *Chem. Ber.*, **94**, 1116 (1961).

$$C_6H_{11}\text{-}N\rightleftharpoons C + \underset{(HCl\ salt)}{NH_2OH} \xrightarrow{ZnCl_2\ cat.}$$

$$\left[C_6H_{11}\text{-}N{=}C\begin{matrix}NH_2\\OH\end{matrix}\right] \rightarrow C_6H_{11}NHCONH_2$$

Unfortunately, in a similar reaction with phenyl isocyanide, no adduct could be isolated from the tarry reaction product. Phenylhydroxylamine also did not give the expected *N*-cyclohexyl-*N'*-phenylurea under similar conditions; rather, somewhat unexpectedly, *N*,*N'*-dicyclohexylurea (53%) was obtained. Controlled experiments in which the isocyanide was treated with phenylhydroxylamine alone or with zinc chloride alone did not afford any product. Thus, it is highly probable that phenylhydroxylamine acts as an oxygen donor, though the reaction mechanism is not quite clear.

Experimental[8]

The Reaction of Cyclohexyl Isocyanide with *t*-Butyl Hypochlorite.—Into a mixture of 5.4 g. (0.05 mol.) of *t*-butyl hypochlorite (prepared by the procedure of Teeter and Bell[9]) and 1.3 g. (0.01 mol.) of zinc chloride in 20 ml. of dry ethylene dichloride, 5.5 g. (0.05 mol.) of cyclohexyl isocyanide was added dropwise with stirring, at such a rate that the reaction temperature was kept below 10°C. The stirring was continued at that temperature for an additional hour, and then the reaction mixture was allowed to stand overnight at room temperature. After removal of the unchanged hypochlorite and the solvent, the residue was poured into water. After this mixture had stood for 2 hr., the organic layer that separated was extracted with ether. The ethereal solution was washed twice with water, dried, and evaporated. The resulting oil was distilled in vacuo to yield 1.0 g. (16%) of cyclohexyl isocyanate (b. p. 60~65°C/18 mmHg), identified as dicyclohexylurea (m. p. 228°C), and a dark residue. Recrystallization of the residue from methanol afforded 2.0 g. (20%) of *t*-butyl *N*-cyclohexylcarbamate (m. p. 68~69°C). The melting point was undepressed on admixture with a sample prepared from cyclohexyl isocyanate and *t*-butyl alcohol.

Found: C, 66.13; H, 10.64; N, 7.42. Calcd. for $C_{11}H_{21}NO_2$: C, 66.29; H, 10.62; N, 7.03%.

When this reaction was carried out in the absence of the catalyst, only cyclohexyl isocyanate (40%) was isolated.

The Reaction of Phenyl Isocyanide with *t*-Butyl Hypochlorite.—The procedure employed was similar to that used for the above reaction except that dry dioxane was used as the solvent. The working up of the reaction mixture, as described above, gave *t*-butyl *N*-phenylcarbamate (69%), which after recrystallization from ethanol melted at m. p. 134~135°C. No mixed melting point depression was observed with an authentic material prepared by the usual method. In the non-catalyzed reaction, phenyl isocyanate (13%) was the sole isolable product.

The Reaction of Cyclohexyl Isocyanide with NBS.—After 8.9 g. (0.05 mol.) of NBS had been moistened with 0.9 g. of water, the mixture was gradually stirred into a solution of 5.5 g. (0.05 mol.) of cyclohexyl isocyanide and 50 ml. of dry carbon tetrachloride. The reaction temperature was maintained at ca. 10~15°C by means of a water bath. At the end of the addition, a color change from dark red to yellow was observed. Then the reaction mixture was allowed to stand overnight at room temperature. The solid that separated was collected and treated with water. There were obtained 1.3 g. (11%) of *N*-(cyclohexylcarbamoyl), succinamic acid, which after recrystallization from acetone had an m. p. of 162~164°C. Some additional product was also obtained from the solvent layer; it weighed 1.2 g. (10%). The acid showed no depression in melting point when mixed with an authentic material which had been prepared from *N*-cyclohexylurea and succinic anhydride in acetic acid.

Found: C, 54.68; H, 7.52; N, 11.44. Calcd. for $C_{11}H_{18}N_2O_4$: C, 54.53; H, 7.48; N, 11.56%.

The Reaction of Phenyl Isocyanide with NBA. In a smimilar way, 7.2 g. (0.07 mol.) of phenyl isocyanide was added dropwise to a mixture of 9.5 g. (0.07 mol.) of wet NBA (prepared by the procedure of Oliveto and Gerold[10]) and 50 ml. of dry chloroform. The reaction mixture was worked up as in the preceeding experiment to give 4.7 g. (38%) of *N*-acetyl-*N'*-phenylurea. Recrystallization from ethanol gave the pure product (m. p. 183°C). No depression in melting point was observed upon admixture with an authentic material which had been prepared by the addition reaction of acetamide to phenyl isocyanate.[11]

The Reaction of Cyclohexyl Isocyanide with Hydroxylamine Hydrochloride.—A mixture of 3.5 g. (0.05 mol.) of hydroxylamine hydrochloride, 5.5 g. (0.05 mol.) of cyclohexyl isocyanide, 1.3 g. (0.01 mol.) of zinc chloride and 30 ml. of dioxane was heated at 50°C for 3 hr. with stirring. The reaction mixture was evaporated in vacuo to remove dioxane, and the residue was poured into 30 ml. of water; then the solution was made slightly basic with aqueous sodium hydroxide. The crude product which separated from the solution was redissolved in ethanol to remove zinc hydroxide, and the alcohol was evaporated to dryness. Recrystallization of the resulting solid from water afforded 3.0 g. (42%) of *N*-cyclohexylurea (m. p. 189°C). A mixed melting point with an authentic sample, prepared from cyclohexyl isocyanate and aqueous ammonium hydroxide, showed no depression.

The Reaction of Cyclohexyl Isocyanide with Phenylhydroxylamine.—A mixture of 6.5 g. (0.06 mol.) of phenylhydroxylamine, 5.5 g. (0.05 mol.) of cyclohexyl isocyanide, 1.3 g. (0.01 mol.) of zinc chloride and 30 ml. of dioxane was stirred at 50°C for 25 hr. After removal of the solvent in vacuo,

11) P. F. Wiley, *J. Am. Chem. Soc.*, 71, 1310 (1949).

the reaction mixture was poured into water, and the organic layer was extracted with ether. The evaporation of the ether and the unreacted isocyanide in vacuo afforded 3.0 g. (53%) of *N,N'*-dicyclohexylurea. Two recrystallizations from acetone or ethanol gave a pure sample (m. p. 228°C), which was identified with an authentic sample by a mixed melting point determination.

Summary

The reactions of isocyanides with alkyl hypochlorite, *N*-bromoamides, and hydroxylamine have been investigated. Cyclohexyl and phenyl isocyanides give *t*-butyl carbamates (urethanes) by the zinc chloride-catalyzed reaction with *t*-butyl hypochlorite, followed by treatment with water. An analogous reaction with *N*-bromosuccinimide or *N*-bromoacetamide in the presence of a small amount of water gives the corresponding acylureas. On treatment with hydroxylamine hydrochloride and zinc chloride, cyclohexyl isocyanide affords *N*-cyclohexylurea.

Studies of the Synthetic Inorganic Ion Exchanger. II.[1] *The Properties of Stannic Phosphate*

By Yasushi INOUE

(Received May 25, 1963)

The stannic phosphates, a group of synthetic inorganic ion exchangers which would be expected to have radiation and thermal stability, have been prepared by various methods and their compositions, ion exchange capacities and chemical stabilities have been investigated, as the preceding report describes.[1]

The exchanger, precipitated from a slightly acidic solution by mixing phosphate with stannic in the ratio of over two to one, has the stoichiometric composition of $PO_4^{3-}/Sn^{4+}=5/4$. It is in the form of white, hard and semitransparant granules and can be used for column operation. The neutral salt decomposition capacity is about 1.3~1.4 meq./g., considerably higher than that of natural inorganic ion exchangers. As to chemical stability, stannic phosphate is comparatively stable in mineral acid, except in concentrated hydrochloric acid, but in alkaline solutions it is unstable, even in a 0.1 N sodium hydroxide solution.

For the purpose of evaluating the availability for a typical ion exchanger like an ion exchange resin, the mutual separation of the alkali metal has been conducted. By using various concentrations of ammonium chloride as eluants, the complete separation of sodium, potassium and cesium from one other has been achieved with a relatively small column. The object of this report is to contribute to the knowledge concerning such fundamental properties of this exchanger as its ion exchange characteristics, its thermal stability and its radiation stability. Moreover, the recommended preparation method and the structure of the exchanger are suggested.

Experimental

Preparation. — The synthetic method has been outlined in the previous report, but the procedure was not detailed.[1] From the evidence which is to be presented later, the following procedure is most recommended. This method corresponds to that used for No. 7 in the first report of this series.

Two hundred and ten grams of stannic chloride pentahydrate were dissolved in 600 ml. of distilled water while it was being heated, and it was then filtered to remove the suspended materials. Into this solution 1.2 l. of a 1.2 N sodium hydroxide solution containing 187 g. of sodium dihydrogen phosphate dihydrate was added rapidly, stirring vigorously at room temperature. At first, the flocculent precipitate was formed, then the gel structure grew from one minute to the next, and finally the solution completely coagulated as a gelatinous mass. After the solution had thus stood for several hours, distilled water was added, and it was stirred to obtain a homogeneous suspension. After the gelatinous suspension had settled down, the supernatant liquid was decanted. This procedure was repeated

1) Y. Inoue, *J. Inorg. Nucl. Chem.*, in press.

several times till the pH of the washings (nearly 3) remained constant. At the last stage of washing, the precipitate was filtered through fine filter paper under suction, washed twice or three times by distilled water, removed from the funnel, and dried at room temperature till it shrank. The gel thus obtained broke down easily to small particles with cracking and with slight evolution of heat when it was immersed in water. If the gel did not break down to the desired particle size, it was ground in a porcelain mortar and sized by sieving. To convert it thoroughly to the hydrogen form, it was then immersed in 1 N nitric acid or 1 N hydrochloric acid for two or three days (the solution was sometimes renewed in the course of immersion), washed several times by distilled water, filtered, and dried in air. In the present work, an exchanger of a 100~200 mesh size was used unless otherwise stated, except in the K_d determination, in which a 200~350 mesh was used.

Titration Curves.—These were determined by the standard technique.[2] A half gram of stannic phosphate was equilibrated with 75 ml. of a solution containing sodium chloride and sodium hydroxide, the total sodium concentration being 0.1 M. After the mixture had stood for three days with intermittent shaking, the pH of the supernatant liquid was measured on a Toa Dempa pH meter. As will be described later, the titration curves were different from batch to batch, therefore, the samples of the same batch were used throughout one set of experiments.

Distribution Coefficients. — Batch distribution coefficients were determined by equilibrating weighed amounts (usually 500 mg.) of the ion exchanger with 50 ml. of suitable solutions for two or three days in a thermostat at 25°C. The acidities of solutions containing 10^{-3} M of the cation in question were adjusted by dilute nitric acid. This was followed by filtration of the mixture, and analysis and pH measurement of the filtrate were then made. The metallic ion content of the exchanger after equilibrium was estimated from the difference between the total initial and final concentrations of metal present in the solutions.

Distribution coefficients were calculated by means of the usual relationship.

$$K_d = \frac{\text{meq. of cation in exchanger/g. of exchanger}}{\text{meq. of cation in solution/ml. of solution}}$$

The analyses of sodium, potassium, rubidium, cesium, copper, gallium, zinc, strontium, calcium, iron and cobalt were carried out radiometrically using ^{24}Na, ^{42}K, ^{86}Rb, ^{137}Cs, ^{64}Cu, ^{72}Ga, ^{65}Zn, ^{89}Sr, ^{45}Ca, ^{59}Fe and ^{60}Co respectively as tracers. The analysis of lithium was made by flame photometry; manganese, by the persulfate oxidation-permanganate photometric method; chromium, by the diphenyl carbazide photometric method; and ammonium, by the extraction-photometric method.

Rate of Exchange.—This was measured by almost the same method as K_d determination. The temperature employed was 25°C or 80°C, and exchangers of a 100~200 mesh or a 200~350 mesh were used. From the analytical results of an aliquot of the supernatant liquid taken every suitable time interval, the rate of exchange was determined. In this case, 500 mg. of the exchanger was used with 100 ml. of the solution.

Gamma-ray Irradiation.—The samples, sealed in a hard glass tube, were irradiated by a 10000 curies cobalt-60 gamma-ray irradiation facility of The Japan Atomic Energy Research Institute at the dose rate of 1.11×10^6 r./hr. for a definite period. After this irradiation, the samples were conditioned as described before; then the titration curves, exchange capacities, selectivity and so on were measured. When irradiation was done in an aqueous solution, 8 g. of the exchangers were immersed in 8 ml. of the solutions.

Treatment of the Exchanger with High Temperature Water. — Ten grams of exchanger were immersed in 50 ml. of distilled water; this was treated for eight days in static autoclaves up to 300°C. The samples were then taken out of the autoclaves and conditioned as described above; then the titration curves, exchange capacities, selectivities and so on were measured.

Another Experimental Method. — The densities of the exchangers were measured by the usual manner, using a 5 ml. pycnometer. The column operation and the measurement of the exchange capacity were carried out as described in the first report. The exchange capacity is the "hydrogen liberation capacity" as defined in the previous report.

Thermogravimetry was performed with Shimadzu Model T-1A thermal analysis equipment, employing an TB-1 thermal balance as additional equipment. Measurement was carried out in air at a heating rate of 10°C/min. over the temperature range from 20°C to 800°C.

In the X-ray diffraction experiments, copper K_α radiation was employed.

Results

The Recommended Method for the Synthesis of Stannic Phosphate.—The yields and densities of the stannic phosphates obtained by six typical preparation methods are presented in Table I. Densities are about 2.0~2.4 g./cm^3, and no differences among the methods of preparation were observed. From the exchange capacities and physical properties described in the first report, the mixing ratio of stannic to phosphate of 2 to 1 is the most appropriate. As to yield, from the economical point of view, that for stannic chloride would be most important. The No. 7 sample shows the highest yield per unit amount of stannic chloride. Putting the above results together, the synthetic method of No. 7 is most recommended.

Titration Curves.—The titration curves of stannic phosphates prepared by various methods are represented in Fig. 1. The curves show that the stannic phosphates are weakly acidic

cation exchangers and possess several dissociable hydrogen atoms over a range of pK_a values. The lack of sharpness of the inflection points suggests that there may be somewhat overlapping values of pK_a. However, it seems that the most acidic exchange group has a pK_a value of approximately three. This value probably corresponds to the pK_a value of the second hydrogen ion of the activated phosphoric acid group. In an acidic solution this dissociable hydrogen is most important, and it is considered that the neutral salt decomposition capacities result from one hydrogen ion of the $H_2PO_4^-$. From the practical point of view, it is sufficient to pay special attention to this exchanging group.

The reproducibility of the preparation was fairly good from the point of view of exchange capacity, as has been discussed in the preceding report, but variations in the titration curves have been observed between different batches; these variations are usually most marked in the high pH region (above 8) of the curve. This is perhaps attributable to the unstability in the face of an alkaline medium. The general pattern is, however, fairly constant in the pH range of less than 8, as Fig. 2 shows. The influence on the shape of the titration curves

of the different acids by which the exchangers are converted to the hydrogen form, has been investigated, hydrochloric acid gives titration curves more acidic than nitric acid, but this effect is not very great. No effect of particle size on the titration curves was recognized.

Rate of Exchange.—To evaluate the time of standing indispensable for batch experiments, the rate of exchange was investigated using a 100~200 mesh or a 200~350 mesh exchanger at 25°C and 80°C (cf. Fig. 3). Carrier-free ^{137}Cs, 10^{-3} M cesium, 10^{-2} M sodium and 10^{-3} M sodium ion were used as the exchanging cations.

When the concentration of the exchanging cation was 10^{-3} M, the maximum adsorption was attained immediately after the exchangers were immersed in a solution; thereafter the amount of exchange gradually decreased with the lapse of time. After ten or twenty four hours, equilibrium was reached. On the contrary, when the concentration was 10^{-2} M or a tracer concentration, the amount of adsorbed cation gradually increased and then reached constant. In the case of 80°C, equilibrium was attained within two hours, and it was apparent that the exchange rate was accerelated by a high temperature. As a result of the above investigation, to be on the safe side, a standing period for two or three days is recommended for batch equilibrium experiments.

Distribution Coefficients. — The distribution coefficients of various cations are tabulated in Table II. They were measured using nearly neutral solutions of the cations in question. The pH of the solution in equilibrium with the exchanger was also measured, as the table shows.

The affinity series for alkali metal follows the pattern shown by many organic exchangers, viz.

$$Li < Na < NH_4 < K < Rb < Cs$$

Table II. Distribution coefficients of cations

Cr^{3+}	Sulfate	2.48	3595±318

There are, however, differences between the behavior of ion exchange resins and stannic phosphates. For example, it is interesting to note that calcium is adsorbed more selectively than strontium and that ferric ions show an exceptionally high distribution coefficient. The reason for this is not clear, although it might be due to a specific chemical interaction other than a simple ionic reaction.

Thermal Stability.—*Heat Treatment in Air.*— In order to obtain a rough idea of the thermal stability of the stannic phosphate, a thermogravimetric analysis was conducted on material which had been dried at room temperature (cf. Fig. 4). Also, the weight losses and exchange capacities of the exchangers dried to a constant weight at temperatures ranging from 110 to 410°C are shown in Table III.

Figure 4 shows a step-by-step decomposition

curve. It is assumed that the weight loss observed from room temperature to 200°C mainly corresponds to the desorption of water retained in the gel structure and that structural water is lost at the inflection point near 350°C. The weight loss obtained from the thermal analysis curve is generally identical with that obtained by heating to a constant weight, but at 110°C these values differ from one other. This difference is perhaps due to the non-equilibrium condition of the thermal analysis. This is clear from the fact that the thermal analysis curve shows a steep slope near 110°C.

The exchange capacity does not change upon heat treatment at 110°C, provided the correction due to the weight loss is performed. However, it is reduced to half when it is heated to 210°C. If stannic phosphate is treated at 410°C to a constant weight, the cation exchange capacity completely diminishes. The

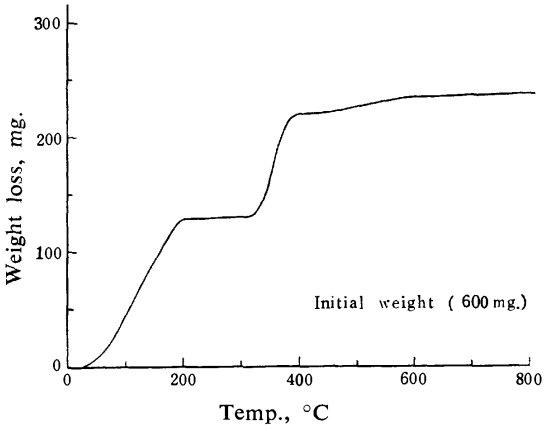

Fig. 4. Thermogram for stannic phosphate.

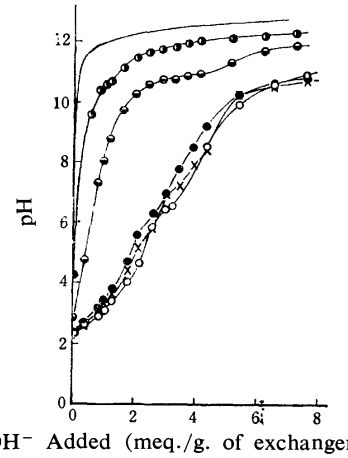

Fig. 5. Titration curves of stannic phosphate as a function of drying temperature.

TABLE III. EFFECT OF HEAT TREATMENT IN AIR

Temp.	Exchange capacity, meq./g.		Weight, mg.	
°C	Calculated value	Experimental value	Calculated value	Experimental value
Room temp.	1.28	1.35	600	600
110	1.62	1.62	475	475
210	0.81	0.82	468	469
320	—	0.23	461	460
410	—	0.02	392	392

titration curves obtained by the samples dried at various temperatures give support to this observation ; that is to say, the titration curve of stannic phosphate dried at 320°C shows a considerable decrease in the most acidic exchange group. At 410°C, the inflection point originating from the most acidic hydrogen ions completely disappears (Fig. 5).

To evaluate the separation abilities of the stannic phosphates dried at temperatures higher than room temperature, the separation of sodium and cesium was conducted by the same method as in the preceding paper. Even in the sample dried at 110°C one can not separate these ions, presumably because of the tailing of the elution curve. Thus, the stannic phosphates dried at temperatures 110°C or higher cannot be used as cation exchangers.

Heat Treatment in an Aqueous Solution.—As has been mentioned above, the stannic phosphate is not stable against heat treatment in air. To know whether or not this is also true in an aqueous solution, an examination was conducted of the ion exchange properties of a stannic phosphate refluxed with distilled water or 7 N nitric acid for five hours and then treated with distilled water in a static autoclave up to 300°C for eight days. The results are summarized in Table IV and Fig. 6. When stannic phosphate is treated both in water and 7 N nitric acid at their boiling points, its external appearance does not change, but at 200°C it slightly loses its transparency. At 250°C the particles break down to some extent. If the temperature of water rises to 300°C, the particles completely break down and disperse into

TABLE IV. EFFECT OF HEAT TREATMENT IN AQUEOUS SOLUTIONS

Solution	Temp. °C	Time	Exchange capacity meq./g.
—	—	—	1.23
7 N HNO_3	100	5 hr.	1.17
H_2O	100	5 hr.	1.22
H_2O	100	8 days	1.22
H_2O	200	8 days	1.27
H_2O	250	8 days	1.10

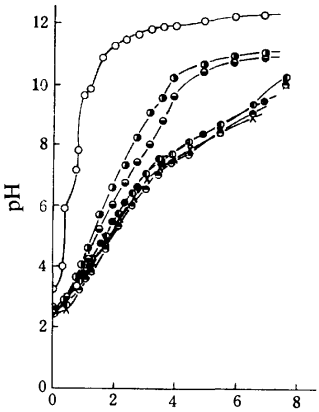

Fig. 6. Effect of heat treatment in aqueous solution on the titration curves of stannic phosphate.
Legend: -◐- In 7 N HNO_3, at boiling point, 5 hr.; -◓- In H_2O, at boiling point, 5 hr.; -●- In H_2O, 100°C, 8 days; -◒- In H_2O, 200°C 8 days; -◑- In H_2O, 250°C, 8 days; -○- In H_2O, 300°C, 8 days

the water as a suspension and, therefore, the exchanger cannot be used.

The exchange capacity does not change up to 200°C, but it slightly decreases upon treatment at 250°C; the titration curves show a similar trend. Samples treated at 300°C do not only break down physically, but they also completely lose their cation exchange capacity, as Fig. 6 shows. Moreover, in the same way as in the preceding section, the separation of sodium and cesium was carried out. These separations go well using stannic phosphate treated in water at temperatures up to 250°C.

It is apparent from the above results that stannic phosphate can be used in pressurized, high-temperature water or in boiling concentrated nitric acid.

Radiation Stability.—The exchange capacities and titration curves of the irradiated samples are shown in Table V and Fig. 7 respectively. These coincide with those of reference runs within the range of experimental error. The separation of sodium and cesium gose as well as before, and it is concluded that stannic phosphate is stable against irradiation of about 10^9 r.

X-Ray Diffraction.—The results are shown in Fig. 8. Stannic phosphate dried at room temperature shows a weak line at d=4.14 Å, and one more line appears at d=3.73 Å when the sample dried at 110°C is used. When the drying temperature is 410°C, it shows 7 lines; however, the spacings of these lines do not coincide at all with that of the lines which appear in the diffraction patterns of exchangers

TABLE V. EFFECT OF RADIATION

Environment	Dose, r	Exchange capacity meq./g.
Reference	—	1.44
Air	1.10×10^8	1.40
Air	1.13×10^9	1.40
H_2O	1.02×10^9	1.45
7 N HNO_3	1.02×10^9	1.45

dried at 210°C or a lower temperature. This suggests that some remarkable changes in structure may occur between 210°C and 410°C. There are only a small number of diffraction lines, and the intensities of these lines are so weak that the relative intensity can not be determined. Consequently, the stannic phosphate has a nearly amorphous structure, and, therefore, a detailed analysis of the results is impossible.

Discussion

Structure.—On the basis of the results concerning the properties of the exchanger hitherto obtained, one can put forward the following assumptions.

a) When the air-dried exchanger is heated at 110°C to a constant weight, the weight loss measured is due to water retained in the gel structure; this water completely volatilizes off at this temperature. (About 20.8% of this water is contained in an air-dried exchanger.)

b) The neutral salt decomposition capacity results from one hydrogen ion of the H_2PO_4– group. The strongly dissociable hydrogen ions due to one-half of the H_2PO_4–groups disappear at 210°C, and the other half, at 320°C with the condensation of the H_2PO_4– groups. The titration curves support this assumption.

c) The weight loss near 350°C is due to the loss of structual water. This assumption is supported by the evidence of X-ray diffraction study and by the marked change in appearance.

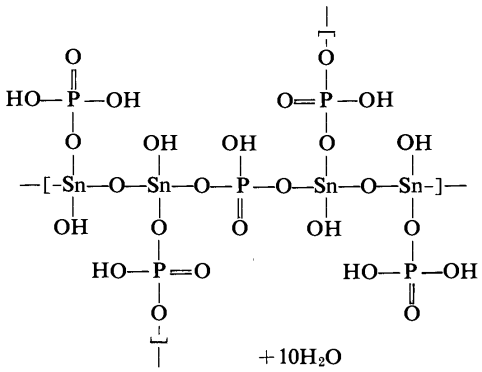

Fig. 9. Structure of stannic phosphate.

Taking the composition of stannic phosphate (P/Sn=5/4) and the above assumptions into consideration, the structure represented in Fig. 9 may be inferred.

The neutral salt decomposition capacities and weight losses calculated on the basis of the above assumptions are presented in Table III. These values and experimental results agree fairly well.

It seems that the arrangement of such a unit structure is not very regular because the X-ray diffraction patterns display a nearly amorphous structure.

Rate of Exchange.—The separation of sodium and cesium did not go well when stannic phosphate dried at 110°C was used, even though the exchange capacity was unchanged. This is mainly due to prolonged tailing, and it is perhaps also attributable to the slow rate of exchange. On the other hand, this phenomenon does not occur when stannic phosphate treated in water even at so high a temperature as 250°C is used. If one thinks of the rate-determining step as particle diffusion, as has been made clear in the case of zirconium phosphate,[3] and if one considers that ions migrate through adsorbed water, the above phenomenon may be explained well.

The findings of Fig. 3 can be illustrated as follows. When the concentration of exchanging cations is 10^{-3} M, which corresponds to about one-seventh of the exchange capacity, the cations are adsorbed in a high distribution coefficient immediately after the exchanger comes in contact with the solution. Part of the cations, once adsorbed on the exchanger, are liberated into the solution at a finite rate in consequence of the decrease in the distribution coefficient, which is accompanied by the drop of the pH of the solution; then equilibrium is attained. The adsorption curve when a 10^{-2} M solution is used, differs from that obtained when the concentration is 10^{-3} M. In this case the exchanging cations added are not adsorbed rapidly in so high a distribution coefficient as when the pH of the solution is high. As a result of this fact and of the pH change of the solution during the exchange step, such a curve as represented in Fig. 3 is obtained. On the other hand, in the case of infinite dilution, no pH change of the solution occurs during the adsorption process and the exchange occurs in a simple adsorption process.

Ion Exchange Equilibria.—Assuming that the exchanging ion is a simple cation, which does not undergo complexing, polymerization or hydrolytic reaction in the media of interest, and assuming that only one type of exchanging group contributes to the ion exchange reaction, the ion exchange equilibria may be written in the form:

$$M^{n+} + nHR = MR_n + nH^+ \quad (1)$$

with the equilibrium constant:

$$K = \frac{(MR_n)\,[H^+]^n \gamma_{MR_n} \gamma_{H^+}^n}{[M^{n+}]\,(HR)^n \gamma_{M^{n+}} \gamma_{HR}^n} \quad (2)$$

where brackets is the concentration of the ion in the aqueous phase, parentheses is the concentration in the exchanger phase, and γ is the activity coefficient. K is the equilibrium constant. Equation 2 is useful as an ion exchange equation, at least under some limiting conditions, if the activity coefficients in the exchanger phase do not vary rapidly.

With organic exchangers, the activity coefficient ratio, $\gamma_{MR_n}/\gamma_{HR}^n$, for the exchanger phase is essentially constant if exchange reactions are carried out in moderately dilute electrolyte solutions, if one of the adsorbed ions occurs at dilute concentrations, and if no complexing or hydrolytic reactions occur. The composition of the exchanger is, therefore,

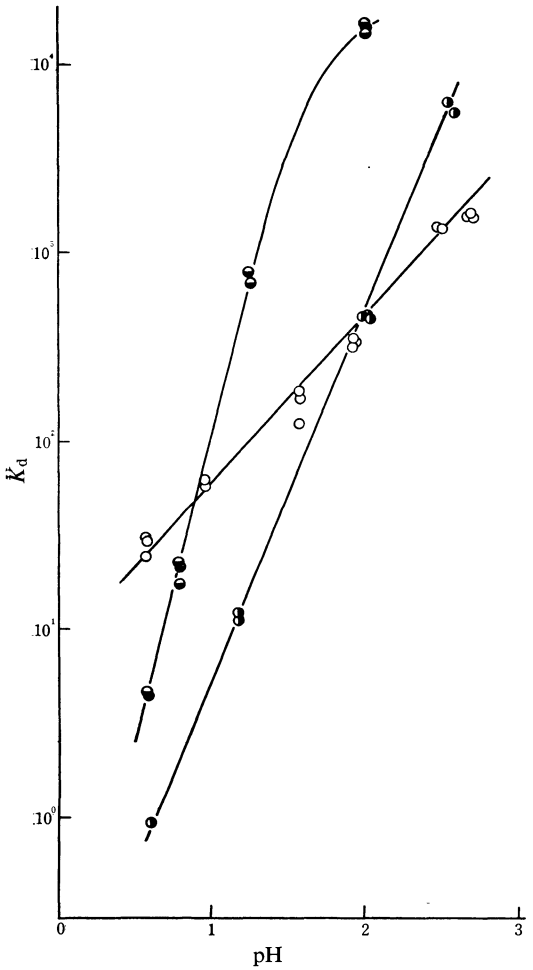

Fig. 10. Distribution coefficients for Cs(I), Cu(II) and Ga(III) on stannic phosphate at different pH.
Legend: -○- Cs(I); -◑- Cu(II); -◒- Ga(III)

essentially independent of the concentration of the adsorbed ions and Eq. 2 simplifies to:

$$K_d [H^+]^n \frac{\gamma_{H^+}^n}{\gamma_{M^{n+}}} = \text{const.} \quad (3)$$

where the distribution coefficient, K_d, is defined by:

$$K_d = \frac{(MR_n)}{[M^{n+}]} \quad (4)$$

If the ionic strength of the solution is low, the activity coefficient, $\gamma_{M^{n+}}$, will be unity. Equation 3 can, therefore, be rewritten to:

$$\log K_d = \text{const.} + n \times \text{pH} \quad (5)$$

According to Eq. 5, a plot of log K_d vs. pH should be a straight line with a slope of n.

This relationship has been verified for cesium(I), copper(II) and gallium(III) ions, as illustrated in Fig. 10. This relationship shows that only one type of exchange reaction contributes to the reaction in such a low pH as less than 3.

Summary

A recommended procedure for the preparation of stannic phosphate and a discussion of its ion exchange properties have been presented.

Some of the results obtained are as follows.

1) The density of the stannic phosphate is 2.17 g./cm^3.

2) Stannic phosphate is a weakly acidic cation exchanger and possesses several dissociable hydrogen atoms in the range of pK_a values. In a weakly acidic solution, in which the exchanger is useful, the exchange group having the pK_a value of approximately three is most important.

3) The ion exchange equilibrium can be elucidated by the mass action law.

4) The affinity series for alkali metal coincides with the usual relationship observed in the ion exchange resin.

5) The rate-determining step is assumed to be the migration of ions through the water retained in the gel structure.

6) Stannic phosphate is unstable against heat treatment in air; that is, the separation of alkali metal does not go well with the exchanger dried at 110°C due to the slow rate of exchange.

7) It is fairly stable against heat treatment in water; that is, it undergoes only a slight decrease in ion exchange capacity even when it is treated in water at 250°C for 8 days.

8) It is stable against irradiation of about 10^9 r.

9) The structure of stannic phosphate has been suggested on the basis of its thermal decomposition curve, its exchange capacity, its titration curves, and its X-ray diffraction patterns.

Studies of the Synthetic Inorganic Ion Exchanger. III. The Separation of the Fission Product by Means of a Stannic Phosphate Cation Exchanger

By Yasushi INOUE

(Received June 8, 1963)

Previously, stannic phosphate, one of the synthetic inorganic ion exchangers which would be expected to have radiation and thermal stability, has been prepared and its fundamental properties investigated, as has been described in preceding reports.[1,2]

Stannic phosphate is one of the polybasic acids which have several dissociable hydrogen atoms. However, the functional group, with the pK_a value of approximately three, is most important in a weakly acidic solution, and in such a solution this exchanger is useful; therefore, it may be assumed that, from the practical point of view, stannic phosphate is a weakly acidic cation exchanger with only one functional group. The ion exchange equilibrium can be elucidated from the mass action law; the ion exchange properties of stannic phosphate are also affected by heat treatment in air. For instance, the separation of alkali metals does not proceed well when the exchanger is dried at 110°C because of the slow rate of exchange. On the other hand, stannic phosphate is fairly stable against heat treatment in water; that is, it changes for the worse only in a slight decrease in exchange capacity even when it is treated in water at 250°C. It is so stable against radiation that is not affected at all by gamma ray irradiation up to 10^9 r. Thus, the stannic phosphate has been shown to be, for the most part, a good cation exchanger except for a few shortcomings such as unstability against alkaline solutions and against heat treatment in air; as an example of practical applications, the mutual separation of various nuclides in a fission product cooled for one or two years has been carried out using ammonium chloride and nitric acid as eluants. The results will be described below.

Experimental

Reagents and Apparatus. — *Reagents.* — *Ion Exchanger:* Stannic phosphate prepared by the method described previously was used.[2]

Radioactive Isotopes: The kinds of radioactive isotopes, their suppliers, commercial forms and the methods of pretreatment are shown in Table I. Their radiochemical purity was certified by gamma ray spectrometry or by analyses of their beta ray absorption curves before use.

Other chemicals, such as nitric acid and ammonium chloride, were of the highest purity grade.

Apparatus.—All pH measurements were performed with a Toa Dempa pH meter, model HM-5, calibrated with the appropriate buffer solutions prior to the experiments. Measurements of beta rays and gamma rays were made by a Hitachi Model RT-1 G. M. counter and a Hitachi well-type scintillation counter respectively. A Hitachi Model RDA-2 single-channel gamma-ray spectrometer or TMC-400 channel pulse-height-analyzer Model 406-6 were used for the measurement of the gamma-ray spectra.

Procedures.—The column was prepared as follows. To 2 g. of a dried exchanger in hydrogen form (100~200 mesh) sufficient distilled water was added to allow thorough enough mixing to expell any adhering air bubbles. After mixing, the slurry was poured into a glass column, 7 mm. in internal diameter, using glass wool as a column support. The column thus prepared had the height of 40 mm.. When the ammonium form exchanger was used, the column was conditioned by the passage of 50 ml. of a 3 M ammonium chloride solution, followed by that of 50 ml. of distilled water, at the flow rate of 0.5~0.6 ml./min.

The flow rate of the influent was kept nearly constant, 10~12 drops per min. corresponding to 0.5~0.6 ml./min., throughout this experiment.

For making elution curves, effluents were received in polyethylene test tubes every 2 g. by means of a Toyo Kagaku Sangyo Model SF-200A fraction collector unless otherwise noted; their radioactivity was measured with the well-type scintillation counter. When beta rays were used for the measurement of radioactivity, one drop of effluent was received on aluminum dishes every 2 g. and their radioactivity was measured with the G. M. counter in the usual manner. The identification of the nuclides present in the effluent and the determination of their radiochemicl purity were made by gamma ray spectrometry and by analyses of beta-ray absorption curves at several important points on the elution curves.

The content of rare earth in the cesium fraction was determined in the following way: To the sample solution, 5 mg. of cesium and 20 mg. of lanthanum

were added as carriers, and a slight excess of ammonium hydroxide solution was also added to precipitate lanthanum hydroxide. The precipitate thus formed was filtered, washed, and dissolved into a possibly small amount of hydrochloric acid. Precipitation was repeated until the activity of the lanthanum hydroxide became free from that of the cesium. Then the precipitate was put into a polyethylene sample tube and its activity was measured by the well type scintillation counter.

Results

Distribution Coefficients.—To contribute to the establishment of the method of separation, the distribution coefficients of various nuclides contained in the fission product were determined in a nitric acid medium, as shown in Table II.

^{95}Zr and ^{95}Nb show high distribution coefficients of about 3×10^3 ml./g. extending over a wide range of acidity. This is perhaps attributable to the formation of insoluble phosphates. On the contrary, although there is a slight tendency for ruthenium to adsorb from concentrated nitric acid on the exchanger bed, the distribution coefficients for ruthenium are nearly zero throughout the wide range of acidity. For ^{137}Cs, ^{89}Sr, ^{90}Y, ^{144}Ce(III) and ^{144}Ce(IV), the distribution coefficients decrease with increasing acidity in accordance with the usual relationship observed in ion exchange resins. It is noticeable that cesium has exceedingly high distribution coefficients. It is assumed that a zirconium-niobium equilibrium mixture and ruthenium may be easily separated from the remaining nuclides because of their peculiar behavior toward the exchanger. Therefore, at first the conditions for the mutual separation of ^{137}Cs, ^{89}Sr and ^{144}Ce, and of ^{90}Sr and ^{90}Y were determined; then the behavior of zirconium-niobium and ruthenium towards the column operation was investigated.

The Separation of ^{137}Cs and ^{89}Sr.—As Table II indicates, the separation of ^{137}Cs and ^{89}Sr by the hydrogen-form exchanger was intended using nitric acid as the eluant. In this case, strontium shows a gently sloping elution curve when acidity is low; the peak of the elution curve cannot become sharp until the acidity of the eluant is increased to more than 5 N. Cesium is in part eluted with nitric acid of a high concentration such as 5 N, but the major part of it remains on the top of the column.

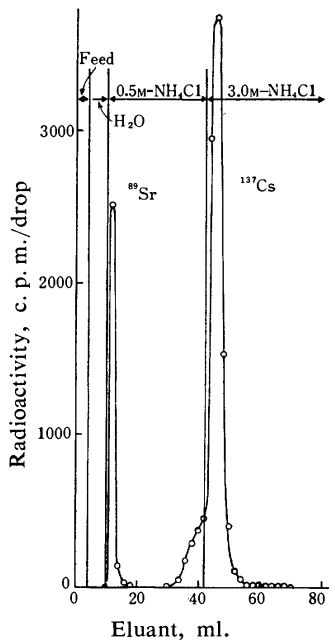

Fig. 1. Separation of ^{137}Cs and ^{89}Sr by hydrogen-form exchanger.

TABLE II. DISTRIBUTION COEFFICIENTS IN NITRIC ACID SOLUTION (ml./g.)

* The species of ^{106}Ru is not identified.

Therefore, cesium and strontium cannot be separated with the hydrogen-form exchanger using nitric acid as the eluant. When ammonium chloride is used, the sharp peaks of ^{89}Sr and ^{137}Cs appeared in the 0.5 M and 3.0 M fractions respectively, as Fig. 1 shows. The amount of cesium remaining on the column after the elution is only 0.1% or less of the total cesium present; therefore, it is concluded that the separation is complete. When the ammonium-form exchanger is used instead of the hydrogen-form, the elution of strontium by 0.5 M ammonium chloride solution is not sharp, as Fig. 4 shows. To get a sharp elution curve, it is necessary to add a little hydrogen ion to the eluant, as shown in Fig. 5. According to this principle, strontium and cesium can be separated on the ammonium-form exchanger by a step elution technique using 0.1 N nitric acid-0.2 M ammonium chloride and 3 M ammonium chloride as the eluants respectively.

The Separation of ^{89}Sr and ^{144}Ce and of ^{90}Sr and ^{90}Y.—The separation of ^{89}Sr and ^{144}Ce was carried out using a hydrogen-form exchanger,

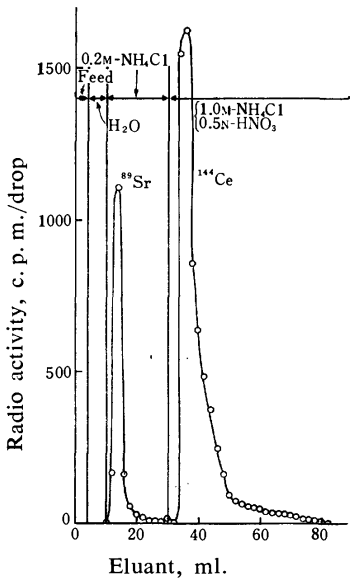

Fig. 2. Separation of ^{89}Sr and ^{144}Ce by hydrogen-form exchanger.

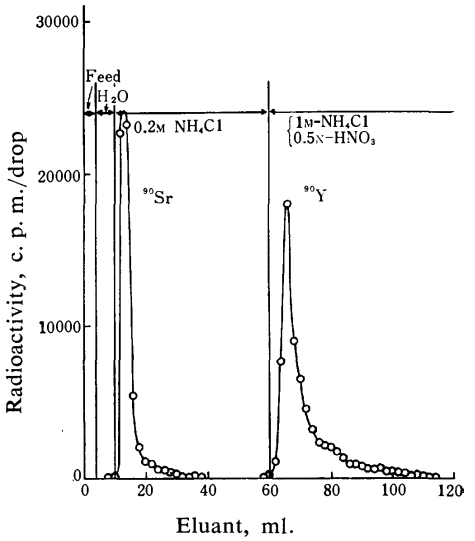

Fig. 3. Separation of ^{90}Sr and ^{90}Y by hydrogen-form exchanger.

as Fig. 2 shows. As to strontium, the elution was performed in a manner similar to that in Fig. 1. Because cerium is eluted only in a small part when ammonium chloride is used alone, whatever concentrated solution may be used, it is necessary to add hydrogen ions to some extent for the complete elution of cerium. In this case, however, the addition of ammonium chloride is not always necessary and cerium can be completely eluted by nitric acid above 1 N alone, as Fig. 10 shows.

In the case of the ammonium-form exchanger, in contrast to the hydrogen-form, strontium is completely eluted with dilute ammonium chloride as 0.5 M only with the aid of nitric acid, as shown in Figs. 4 and 5. Figure 6 shows that cerium is not eluted at all with a 0.1 N nitric acid-0.2 M ammonium chloride solution. Therefore, these nuclides can be separated according to this principle (Fig. 7). The separation of a ^{90}Sr–^{90}Y equilibrium mixture is possible in an analogous manner, as Figs. 3 and 8 show.

The Separation of ^{137}Cs and ^{144}Ce.—Applying the fact that cerium can not be eluted by

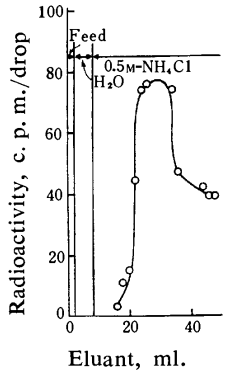

Fig. 4. Elution of strontium by 0.5 M ammonium chloride (ammonium-form exchanger).

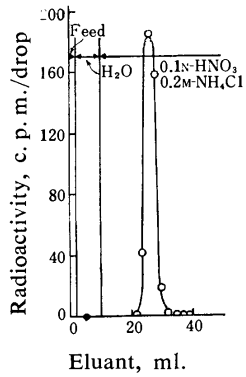

Fig. 5. Elution of strontium by 0.1 N nitric acid−0.2 M ammonium chloride (ammonium-form exchanger).

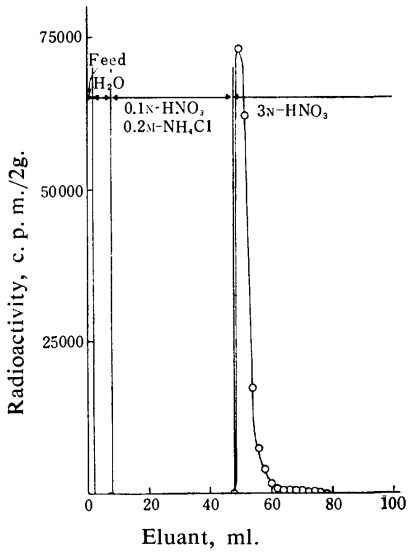

Fig. 6. Elution of cerium by hydrogen-form exchanger.

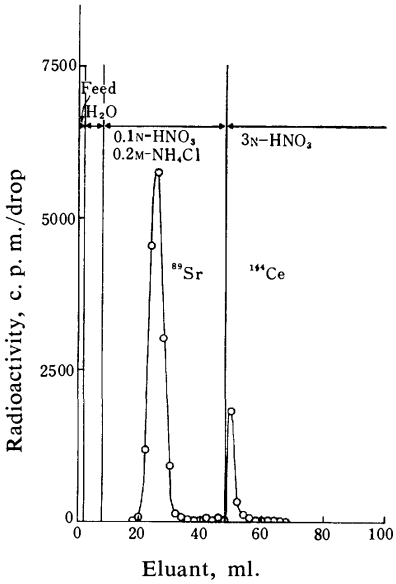

Fig. 7. Separation of ^{89}Sr and ^{144}Ce by ammonium-form exchanger.

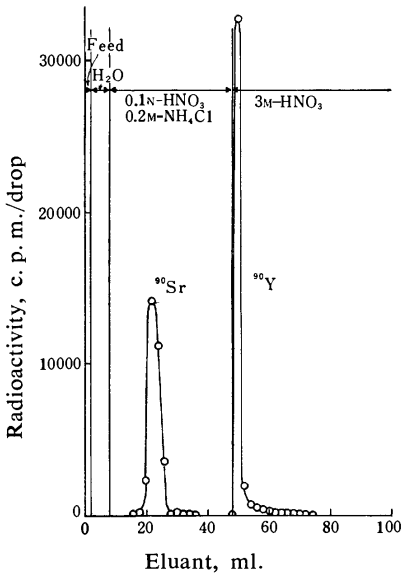

Fig. 8. Separation of ^{90}Sr and ^{90}Y by ammonium-form exchanger.

ammonium chloride alone, the separation of cesium and cerium has been carried out with the hydrogen-form exchanger, as shown in Fig. 9. It is necessary to note that the small peak appears in the beginnig of the 3 M ammonium chloride fraction. The analytical results show that this is mainly due to cerium. This is attributable to the elution of cerium with the hydrogen ions which are liberated from the hydrogen-form exchanger when the concentrated ammonium chloride solution is

passed through it. Therefore, the complete separation of cesium and cerium on the hydrogen-form exchanger is impossible. However, as represented in Fig. 10, cerium is seldom eluted by 3 M ammonium chloride from the ammonium-form exchanger. On the basis of the above results, it is assumed that cesium and cerium can be separated by the step elution technique using 3 M ammonium chloride and 3 N nitric acid as the respective eluants. It is apparent from Fig. 11 that well-defined curves are obtained and that the separation is complete.

The Adsorption of Zirconium and Niobium. —The behavior of the zirconium-niobium equilibrium mixture was investigated in detail with the column operation in order to determine whether or not the results of the batch experiments could be applied to the column separation experiment. Ten milliliters of a 0.1 N nitric acid solution containing a zirconium-niobium equilibrium mixture were applied to the top of the column, and the column was then washed with 50 ml. of 5 N nitric acid. The leakage of ^{95}Zr–^{95}Nb from the column bed amounts to about 4.5 per cent, and the uptake is not complete. However, from the shape of

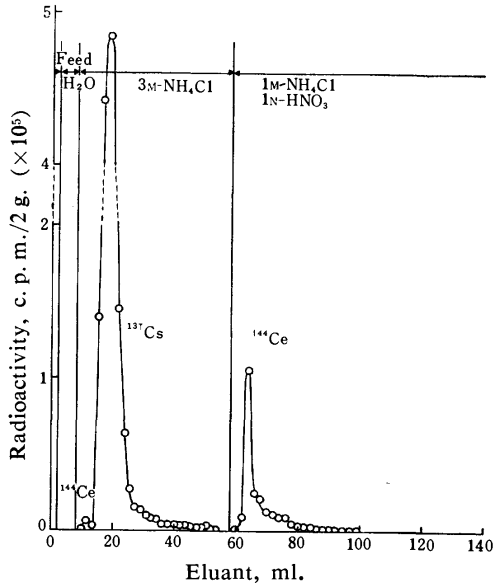

Fig. 9. Separation of ^{137}Cs and ^{144}Ce by hydrogen-form exchanger.

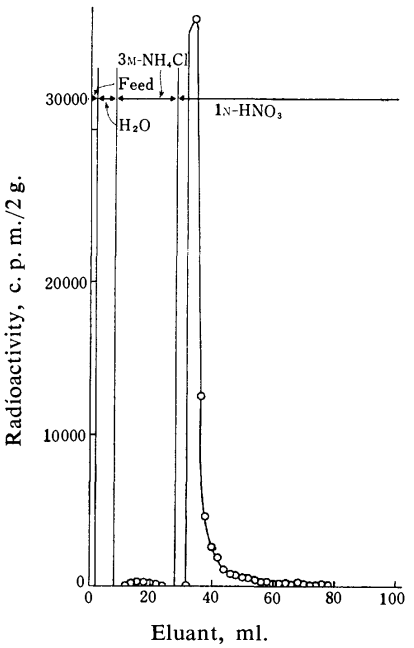

Fig. 10. Elution curve of cerium by ammonium-form exchanger.

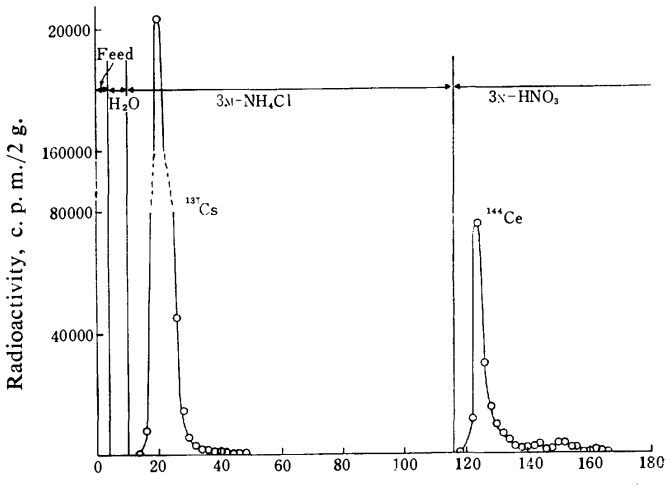

Fig. 11. Separation of ^{137}Cs and ^{144}Ce by ammonium-form exchanger.

the breakthrough curve it seems that the leakage from the exchanger bed does not occur by the elution of ions once retained on exchanger, but takes place during the adsorption step (Fig. 12a). Such peculiar behavior can probably be attributed to the presence of a radiocolloidal form of zirconium. This seems quite possible, since the stock solution was only 0.1 N in free acid. On the basis of the above considerations, a zirconium solution which had been treated with hot concentrated nitric acid for a few hours was used immediately after being diluted to the desired acidity, but no decrease in the leaked activity was observed. When the effluent is passed through the exchanger bed three times, zirconium can be adsorbed almost completely, but this method cannot be used in the practical separation of the fission product because the separation of cesium and strontium is interfered with by this operation. The unadsorbed zirconium is almost completely washed out with 10 ml. of distilled water, as Fig. 12(b) shows. In order

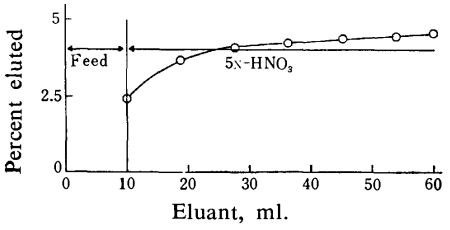

Fig. 12 (a). Breakthrough curve of zirconium by 5 N nitric acid.

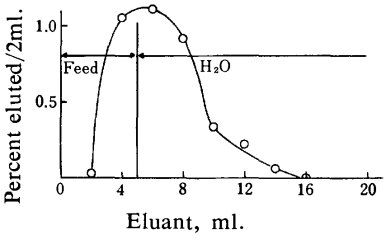

Fig. 12 (b). Breakthrough curve of zirconium by water.

to make sure, the distribution coefficients of zirconium and niobium in a 1 N nitric acid solution were determined as a function of the ammonium nitrate concentration; it was found that these elements can be completely retained on the column, even in the concentrated salt solution. Putting these findings together, it is apparent that the total zirconium and niobium activity can be precisely estimated from the sum of the activity remaining on the column after the elution is finished and the sum of the leaked activity during the adsorption step.

The Adsorption of Ruthenium.—The behavior of ruthenium was investigated in detail with the column operation in order to determine whether or not the results of batch experiments could be applied to the column operation.

Ten milliliters of a 0.1 N or 0.2 N nitric acid solution containing ruthenium activity was passed through the exchanger bed. When the level of the solution reached the top of the exchanger bed, nitric acid of the same concentration was percolated through and the effluent was collected every 10 ml. The results are presented in Fig. 13. The curves represent the accumulated percentage value of the eluted activity as a function of the effluent volume. When the ruthenium solution which has been treated with concentrated nitric acid is used, only about 40% of ruthenium activity is eluted. When the ruthenium treated enough with fuming nitric acid is used, more ruthenium is eluted, but the percentage still does not reach 80%. When the concentration of the eluant is 0.2 N nitric acid, the 90% mark of the ruthenium is broken through. However, strontium is also completely eluted under these conditions, so this concentration is unfavorable for the elution of ruthenium in the separation of the fission product. The reason for the discrepancy between this and the batch experiment is not clear; at any rate, it is impossible to separate ruthenium from the other nuclides with the column operation. Consequently, the complete separation of fission product cannot be effected without the separation of ruthenium in advance by a method other than the ion exchange.

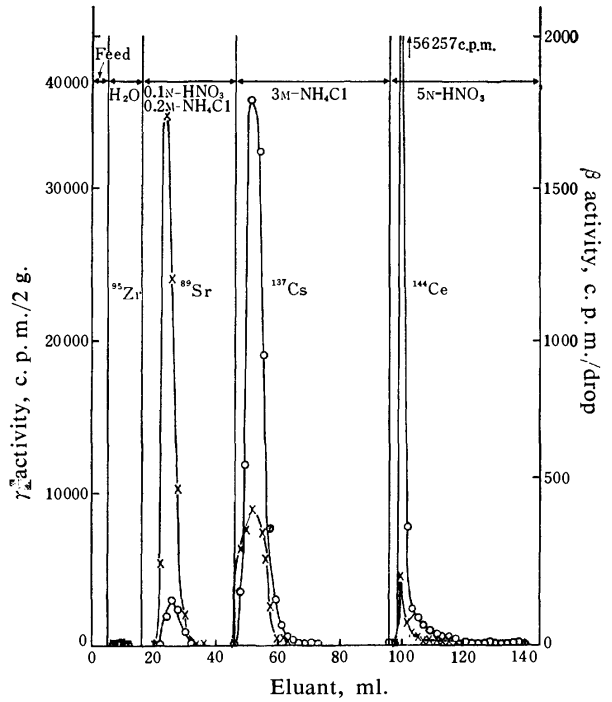

Fig. 14. Separation of synthetic sample.

examinations that the best method for removing ruthenium was the volatilization from boiling concentrated perchloric acid. Not less than 99% of ruthenium is removed by the boiling of concentrated perchloric acid solution, and this procedure does not affect the following ion exchange separation. It is necessary, however, to boil off ruthenium violently instead of fuming it gently.

The Separation of a Fission Product Solution. —Putting the above results together, the mutual separation of various nuclides contained in a fission product is carried out in the following way: To the sample solution, 5 ml. of concentrated perchloric acid is added, and this is boiled until a yellow color has once appeared and then diminished. (It is advisable to lead the distillate into water in order to prevent any health hazard.) Then the residual solution is evaporated almost to dryness on the hot plate. After cooling, 1 ml. of 1 N nitric acid is added, heated to dissolve the residue, and diluted to 10 ml. with water. This is poured into an ammonium-form exchanger bed;

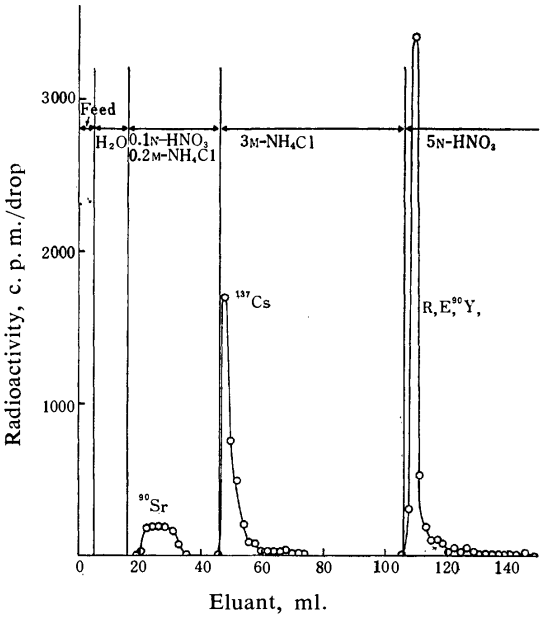

Fig. 15. Separation of fission product.

when the level of the solution reaches the top of the exchanger bed, 10 ml. of water, 30 ml. of 0.1 N nitric acid-0.2 M ammonium chloride, 60 ml. of 3 M ammonium chloride, and 60 ml. of a 5 N nitric acid solution are passed through the column successively.

The separation of a synthetic sample containing nearly equal activities of ^{89}Sr, ^{137}Cs, ^{95}Zr–^{95}Nb, ^{106}Ru and ^{144}Ce is shown in Fig. 14. Although the shape of the elution curve shows that satisfactory separation is achieved, it is observed from the analytical results that there is a contamination by cerium of the cesium fraction. The material balance represented in Table III convinces one of this observation. The corrected values obtained by the analysis of the cesium fraction are also shown in Table III; these values agree quite well within the experimental error.

The results of the separation of the fission product are shown in Fig. 15 and Table IV. The reason for the contamination of the cesium fraction is not clear, although it is assumed that the elution step of strontium may affect the separation.

Summary

The mutual separation of various nuclides contained in fission product has been carried out with a stannic phosphate cation exchanger. Various concentrations of nitric acid and ammonium chloride solutions have been used as eluants, and the separation has been performed on hydrogen- and ammonium-form exchangers.

The separations of ^{89}Sr–^{137}Cs, ^{89}Sr–^{144}Ce, ^{137}Cs–^{144}Ce and ^{90}Sr–^{90}Y were easy and complete except for that of ^{137}Cs–^{144}Ce on a hydrogen-form exchanger. ^{95}Zr and ^{95}Nb were almost completely adsorbed on the exchanger over a wide range of acidity and salt concentration; therefore, they were not eluted at all. As the behavior of ^{106}Ru is complex and its separation from other nuclides is impossible, it is necessary to separate the ruthenium from the fission product in advance by a method other than that of ion exchange.

With reference to the above results, the total analysis of the fission product on an ammonium-form exchanger has been carried out. It is almost complete except for the contamination of rare earth in the cesium fraction.

The author wishes to thank Dr. Hidehiro Goto and Dr. Shin Suzuki of Tohoku University for their guidance, discussion and continuous encouragement.

Part of the expenses for this investigation have been defrayed by a grant-in-aid by the Ministry of Education.

Syntheses of 23-Ketositosterol and Its Derivatives

By Ken-ichi MORITA,* Takeshi IWAMA and Yoshiaki KAMANO**

(Received March 27, 1963)

In connection with other studies, it was necessay to prepare sitosterol derivatives with oxygen functions at the C_{22} and C_{23} carbon atom, respectively. This article describes a method for the introduction of oxygen functions into the C_{23} carbon atom of sitosterol.

The peroxybenzoic acid oxidation of 3β-acetoxy-5α-chlorostigmast-22-ene (II)[1] proceeded stereospecifically and gave a single isomer of 5α-chloro-3β-acetoxy-22ξ, 23ξ-epoxystigmastane (III). Bladon et al.[2] have reported that the peroxybenzoic acid oxidation of 3β-acetoxy-5α, 8α-epidioxyergosta-6, 9 (11), 22-triene gives two isomers of 3β-acetoxy-22ξ, 23ξ-epoxy-5α-hydroxyergosta-7, 9(11)-diene. The difference is probably due to the alkyl side chains at C_{24}. The side chain at C_{24} is an ethyl group with an α-configuration[3] in the stigmastane series, whereas it is a methyl group with a β-configuration[4] in the ergostane series. The oxide ring of compound III probably has the α-configuration, since an examination of the

Dreiding model[5] seems to indicate that the α-side of the Δ^{22}-double bond of compound II is less hindered.

The treatment of compound III with hydrogen chloride in acetic acid gave a chlorohydrin mixture. The chromic acid oxidation of the chlorohydrin gave two isomeric chloroketones: isomer A [(m. p. 161~162°C, $[\alpha]_D$+43°, λ_{max} 305 mμ (ε, 57), and isomer B (m. p. 178~179°C $[\alpha]_D$+17°, λ_{max} 298 mμ (ε, 60)]. It is possible that one, after formed, was in part epimerized to the other. Both the isomers possess the 22-chloro-23-keto structure (V), as the following evidence shows. Both gave the same keto acetate on reduction with zinc dust and acetic acid. The hydrogenation of the keto acetate on an Adam platinum catalyst in an acidic medium, followed by an alkaline hydrolysis, gave a saturated keto alcohol. The chromic acid oxidation of the saturated keto alcohol gave a diketone (m. p. 159~160°C, $[\alpha]_D$+54.4°) which was different from the stigmastane-3, 22-dione (m. p. 176~177°C, $[\alpha]_D$+21.8°) obtained by Fischer and Mägerlein.[6] Therefore, the only possible structure for the diketone is VIII (stigmastane-3, 23-dione). When the crude oxidation product of the chlorohydrin (IV) was treated with zinc dust and acetic acid the only isolable ketone was 3β-acetoxystigmast-5-en-23-one (VIb). The attack of the chloride ion upon the oxide III occurred exclusively at the C_{22} carbon atom.

It is noteworthy that the prolonged hydrogenation of 3β-acetoxystigmast-5-en-23-one (VIb) on a platinum oxide catalyst in an acidic medium furnished saturated ketone VIIb in a good yield. No hydroxy compound was formed.[7] The treatment of 3β-acetoxystigmast-5-en-23-one (VIb) with hydroxylamine hydrochloride in pyridine[8] uner reflux for 30 hr., under the condition which give oximes from hindered ketones, gave the unchanged starting material. The attempted esterification of 3β-acetoxy-5α, 22ξ-dichlorostigmastan-23-one (V) by Baeyer-Villiger reaction (peroxybenzoic acid in chloroform for one month) also failed. These facts indicate that the C_{23}-keto group in a stigmastane series is sterically highly hindered.

The reduction of compound VIb with lithium aluminum hydride gave epimeric diols. Two isomers were separated as benzoates (IX) (major one: m. p. 130~130.5°C, $[\alpha]_D$ −9°; minor one: m. p. 160~162°C, $[\alpha]_D$ −31°). According to Cram's rule[9] for the steric control of asymmetric induction, the major isomer may have the α-configuration.

The treatment with an alkali and the reacetylation of compound III gave 3β-acetoxy-22ξ,

23ξ-epoxystigmast-5-ene (X). The peracid oxidation of stigmasta-4, 22-dien-3-one[10] and 3α-acetoxy-5β-stigmast-22-ene[11] gave the corresponding oxides, XI and XII respectively. The oxidation of stigmasta-4, 22-dien-3-one with alkaline hydrogen peroxide gave 4, 5-oxide XIII. The treatment of XI with hydrogen chloride gave a corresponding chlorohydrin XIV. The 22ξ-chloro-23ξ-hydroxy structure was assigned by analogy with a previous reaction.

The dehydrohalogenation of V was attempted as the means of obtaining $\Delta^{20(22)}$-23-ketone by treatment with *s*-collidine or lithium carbonate in dimethylformamide, but no such compound could be isolated, although the crude product showed a slight ultraviolet absorption around 230~240 mμ. The only isolable compound was epimeric 3β-acetoxy-22ξ-chlorostigmast-5-en-23-one (XV.)

The purity of the compounds described in this article was examined by thin-layer chromatography; the R_f values of some of the compounds are recorded in Table I.

TABLE I. THIN-LAYER CHROMATOGRAPHY OF STIGMASTANE DERIVATIVES (BENZENE, SILICA GEL G)

No	Compound	R_f
1	Stigmast-5-ene-3β, 23ξ-diol	0.02

V XVa, b

Experimental[12]

3β-Acetoxy-5α-chlorostigmast-22-ene (II).—This material was prepared essentially by the procedure previously described.[1] The presence of acetic acid (100 ml. for 100 g. of stigmasteryl acetate) increased the yield. The product was obtained as needles; m. p. 183~184°C, $[\alpha]_D^{19}$ −7° (*c* 0.997) (reported m. p. 183~185°C, $[\alpha]_D^{24}$ −8.1°)

3β-Acetoxy-5α-chloro-22ξ, 23ξ-epoxystigmastane (III).—To a cold solution of 18.4 g. of II in 184 ml. of chloroform was added 45 ml. of a chloroform solution of peroxybenzoic acid containing 1.3 molar equivalents of the peracid. The mixture was then allowed to react at 0~3°C for fifteen days. The excessive peracid was decomposed with 10% aqueous potassium iodide, and the liberated iodine was titrated with 0.1N sodium thiosulfate (1.05 mol. of peracid were consumed). The chloroform solution was washed with 10% aqueous potassium carbonate and water and dried over anhydrous sodium sulfate. The chloroform was expelled under reduced pressure (the inner temperature was kept below 50°C). Recrystallization from ethyl acetate gave 12.5 g. of needles; m. p. 137~138°C, $[\alpha]_D^{22}$ −15° (*c* 0.46).

Found: C, 73.49; H, 10.34; Cl, 7.34. Calcd. for $C_{31}H_{51}O_3Cl$: C, 73.41; H, 10.14; Cl, 6.99%.

3β-Acetoxy-22ξ, 23ξ-epoxystigmast-5-ene (X).—To a solution of 3.2 g. of III in 150 ml. of ethyl alcohol was added a solution of sodium carbonate (3.2 g.) in water (18 ml.); the mixture was then heated under reflux for 5 hr. the usual manipulation gave 2.9 g. of an oil which was acetylated by treating it with acetic anhydride (5 ml.) and pyridine (11 ml.) overnight at room temperature; 3 g. of an sticky oil was thus obtained. Chromatography and recrystallization form methanol gave crystals (m. p. 114.5~115°C, $[\alpha]_D^{17}$ −71° (*c* 0.47)).

Found: C, 79.09; H, 10.71. Calcd. for $C_{31}H_{50}O_3$: C, 79.10; H, 10.71%.

22ξ, 23ξ-Epoxystigmast-4-en-3-one (XI).—Stigmasta-4, 22-dien-3-one (500 mg., m. p. 125~126°C) was dissolved in 2 ml. of chloroform containing 170 mg. of perbenzoic acid. The mixture was allowed to react at room temperature for three days in the

11) D. H. R. Barton and C. J. W. Brooks, ibid., 72, 1633 (1950).

12) All melting points were uncorrected. Rotations were measured in chloroform solution. Infrared spectra were determined with a Perkin-Elmer Model 21. Ultraviolet spectra were determined with a Hitachi Type EPU-2. We are indebted to Miss Sachiko Yoshikawa for measurements of rotations and some technical assistance and to Sankyo Co. for analyses.

dark. The usual manipulation gave 600 mg. of a cake which was chromatographed on 16 g. of alumina. Elution with a mixture of petroleum-ether and benzene (2 : 8) gave 200 mg. of the starting material. Further elution with chloroform gave 250 mg. of crystals (m. p. 117.5~118.5°C) after recrystallization from methanol. The infrared spectrum showed the absence of a Δ^{22}-double bond (970 cm^{-1}).

Found: C, 81.73; H, 10.83. Calcd. for $C_{29}H_{46}O_2$: C, 81.63; H, 10. 86%.

4β, 5β-Epoxystigmast-22-en-3-one (XIII).—To a stirred solution of 500 mg. of stigmasta-4, 22-dien-3-one in 20 ml. of methanol, 1.2 ml. of 4 N sodium hydroxide and 3 ml. of 30% hydrogen peroxide were added at 0~3°C. The mixture was then left to stand for 48 hr., poured into water and extracted with ether. The evaporation of ether and the crystallization of the residue from methanol gave 350 mg. of crystals (m. p. 120~122°C). The infrared spectrum showed the presence of a Δ^{22}-double bond (970cm^{-1}). The β-configuration of the oxide was assumed, since cholest-4-en-3-one gave 4β, 5β-epoxycholestan-3-one when similarly treated.[13]

Found: C, 81.25; H, 11.32. Calcd. for $C_{29}H_{46}O_2$: C, 81.63; H, 10.86%.

3α-Acetoxy-22ξ, 23ξ-epoxy-5β-stigmastane (XII). —This material was prepared by a procedure similar to that described for compound III. Recrystallization from methanol gave crystals (m. p. 105~107°C).

Found: C, 78.32; H, 11.34. Calcd. for $C_{31}H_{52}O_3$: C, 78.76; H, 11.08%.

5α-Chlorostigmast-22-en-3-one. — Two hundred milligrams of 5α-chlorostigmast-22-en-3β-ol [m. p. 153.5~155°C (from benzene-methanol)], prepared from stigmasterol and hydrochloric acid by a procedure similar to that employed in the preparation of 3β-acetoxy-5α-chlorostigmast-22-ene (II), was dissolved in 5 ml. of chloroform and treated with 100 mg. of chromic acid in a mixture of 0.5 ml. of water and 10 ml. of acetic acid at room temperature overnight. Crystallization of the product from benzene-methanol gave 100 mg. of crystals (m. p. 136~136.5°C, $[\alpha]_D^{18}$ −5° (*c* 0.41)).

Found: C, 77.78; H, 10.62; Cl, 7.75. Calcd. for $C_{29}H_{47}OCl$: C, 77.90; H, 10.60; Cl, 7.93%.

Semicarbazone; m. p. 216~218°C.

Found: C, 71.73; H, 9.54; Cl, 7.02; N, 8.35. Calcd. for $C_{30}H_{50}OClN_3$: C, 71.46; H, 9.99; Cl, 7.03; N, 8.33%.

3β-Acetoxy-5α, 22ξ-dichlorostigmastan-23ξ-ol (IV).—To a solution of 21.3 g. of 3β-acetoxy-5α-chloro-22ξ, 23ξ-epoxystigmastane (III) in 200 ml. of chloroform, 270 ml. of a 4% solution of hydrogen chloride in glacial acetic acid was added, and the mixture was allowed to stand for 24 hr. at room temperature. The reaction mixture was then poured into water and extracted with chloroform three times. The combined chloroform extract was washed with 5% aqueous potassium carbonate and water, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure to give 23 g. of a yellow foam.

Crystallization from a 1 : 1 mixture of ethyl acetate and ethyl alcohol gave 10.0 g. of the first crop (m. p. 157~160°C) and 6.5 g. of the second crop (m. p. 152~156°C). The analytical sample was recrystallized from acetone; m. p. 162~164°C, $[\alpha]_D^{20}$ 0° (*c* 0.69).

Found: C, 68.71; H, 9.70; Cl, 12.73. Calcd. for $C_{31}H_{52}O_3Cl_2$: C, 68.48; H, 9.64; Cl, 13.04%.

22ξ-Chloro-23ξ-hydroxystigmast-4-en-3-one (XIV).—One gram of 22ξ, 23ξ-epoxystigmast-4-en-3-one (XI) was dissolved in 15 ml. of a 5% solution of hydrogen chloride in glacial acetic acid, and the mixture was allowed to react for 24 hr. at 0~5°C. The product was crystallized from methanol to 0.65 g. of crystals (m. p. 216~218°C).

Found: C, 75.51; H, 10.27; Cl, 7.86. Calcd. for $C_{29}H_{47}O_2Cl$: C, 75.20; H, 10.23; Cl, 7.65%.

3β-Acetoxy-22ξ-chlorostigmastan-23-one (V). — To a stirred solution of 11.5 g. of 3β-acetoxy-22ξ-chlorostigmastan-23ξ-ol (IV) in a mixture of 80 ml. of chloroform and 80 ml. of glacial acetic acid, a solution containing 6 g. of chromic acid in a mixture of 6 ml. of water and 90 ml. of acetic acid was added at 20~30°C over a 3-hr. period. The mixture was continuously stirred for a further twenty hours at room temperature. Excessive chromic acid was decomposed with 30 ml. of ethanol (stirred for 1 hr.), and the mixture was poured into water. The chloroform extracts were combined, washed with 5% aqueous sulfuric acid (three times) and water (three times), dried over anhydrous sodium sulfate, and concentrated. The residue was crystallized from acetone to 8.5 g. of crystals (m. p. 145~150°C). The crude material was used for the next reaction.

The fractional recrystallization of the crude crystals gave two compounds that were found to be epimeric isomers.

Isomer A: m. p. 161~162°C; $[\alpha]_D^{14}$ +43° (*c* 1.0).

Found: C, 69.13; H, 9.52; Cl, 12.85. Calcd. for $C_{31}H_{50}O_3Cl_2$: C, 68.74; H, 9.36; Cl, 13.09%.

UV $\lambda_{max}^{CHCl_3}$ 305 mμ (ε, 57); IR (KBr) 1732, 1714, 1247 cm^{-1}.

Isomer B: m. p. 178~179°C; $[\alpha]_D^{13}$ +17° (*c* 1.0).

Found: C, 68.77; H, 9.24; Cl, 13.16. Calcd. for $C_{31}H_{50}O_3Cl_2$: C, 68.74; H, 9.36; Cl 13.09%.

UV $\lambda_{max}^{CHCl_3}$ 298 mμ (ε, 60); IR (KBr) 1733, 1707, 1241 cm^{-1}.

3β-Acetoxy-22ξ-chlorostigmast-5-en-23-one (XV). —Five grams of crude V (m. p. 145~150°C) were dissolved in 60 ml. of *s*-collidine, and the mixture was heated under reflux for 24 hr. The precipitated collidine hydrochloride was then removed by filtration and washed with ether. The mother liquor was diluted with more ether and washed with 10% sulfuric acid and water. The evaporation of the ether gave 4.5 g. of a brown oil. Crystallization from ethyl alcohol gave 1.5 g. of needles (m. p. 160~163°C). Further recrystallization from methylenechloride-acetone gave isomer A, 166.5~168°C, $[\alpha]_D^{19}$ −31° (*c* 0.67).

Found: C, 73.33; H, 9.80; Cl, 7.49. Calcd. for $C_{31}H_{49}O_3Cl$: C, 73.70; H, 9.78; Cl, 7.02%.

UV $\lambda_{max}^{CHCl_3}$ 296 mμ (ε, 93), IR (Nujol) 1736, 1256, 802 cm^{-1}.

13) P. A. Plattner, H. Heusser and A. B. Kulkarni, *Helv. Chim. Acta*, 31, 1822 (1948).

The mother liquor of the first crystallization of the above experiment was concentrated to a brown oil, which was then chromatographed on 60 g. of florisil packed in petroleum ether. Elution with 1% acetone in petroleum ether and recrystallization from acetone gave 230 mg. of isomer B; m. p. 177.5~180.5°C; $[\alpha]_D^{19}$ −63° (*c* 0.67).

Found: C, 73.78; H, 9.78; Cl, 7.47. Calcd. for $C_{31}H_{49}O_3Cl$: C, 73.70; H, 9.78; Cl, 7.02%.

UV $\lambda_{max}^{CHCl_3}$ 297 mμ (ε, 65); IR(Nujol) 1729, 1251, 800 cm^{-1}.

Further elution gave no crystalline material.

3β-Acetoxystigmast-5-en-23-one (VIb). — Seven grams of crude V (m. p. 145~150°C) were dissolved in 140 ml. of glacial acetic acid, and 7 g. of zinc dust was added with swirling. The mixture was then heated under reflux for 3 hr. After cooling, excessive zinc dust was removed and washed with benzene. The mother liquor was diluted with water and extracted with benzene. The combined benzene extract was washed with a saturated solution of sodium bicarbonate in water, dried over anhydrous sodium sulfate, and concentrated. The residue (6.9 g.) was dissolved in a small amount of methylene chloride and the solution was put on 200 g. of a florisil column packed in petroleum ether (b. p. 35~70°C). Elution with petroleum ether (fractions Nos. 1 and 2) and recrystallization from benzene-methanol gave 189 mg. of aliphatic saturated hydrocarbon (paraffin), which was present in the stigmasterol extracted from soybean oil[14] as an impurity; m. p. 67~69°C; IR (KBr) 2590, 2870, 1475, 1470, 734, 723 cm^{-1}. (Found: C, 84.78; H, 14.67%.) The Liebermann-Burchard and Beilstein reactions were both negative. Futher elution with 1% ethyl acetate in petroleum ether (Nos. 19—24) and recrystallization from ethyl acetate gave 1.53 g. of an unidentified material; m. p. 136~138.5°C (sintering at 127°C). The infrared spectrum showed the presence of an acetate and the absence of a hydroxyl group and of a Δ^{22}-double bond and no ketone band other than that of an acetate (Found: C, 77.01; H, 10.33). Further elution with 1% and 2% ethyl acetate in petroleum ether (Nos. 44—107) and recrystallization from acetone gave 2.4 g. of 3β-acetoxystigmast-5-en-23-one (VIa); m. p. 153~154°C, $[\alpha]_D^{18}$ −16° (*c* 0.69).

Found: C, 79.22; H, 10.39. Calcd. for $C_{31}H_{50}O_3$: C, 79.10; H, 10.71%.

UV $\lambda_{max}^{CHCl_3}$ 291 mμ (ε, 46); IR (KBr) 1733, 1709, 1249, 1037, 800 cm^{-1}.

3β-Hydroxystigmast-5-en-20-one (VIa). — The alkakine hydrolysis of VIb gave a free corresponding alcohol of VIb. Recrystallization from acetone gave crystals; m. p. 157~157.5°C, $[\alpha]_D^{18}$ −11° (*c* 0.62).

Found: C, 80.85; H, 11.39. Calcd. for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

UV $\lambda_{max}^{CHCl_3}$ 291 mμ, (ε, 67); IR(KBr) 3465, 1716, 1700 (shoulder), 794 cm^{-1}.

Stigmast-4-ene-3, 23-dione.—The Oppenauer oxidation of VIa gave stigmast-4-ene-3, 23-dione; m. p. 122~123°C, $[\alpha]_D^{19}$ +93° (*c* 0.68).

Found: C, 81.08; H, 10.61. Calcd. for $C_{29}H_{46}O_2$: C, 81.63; H, 10.87%.

UV λ_{max}^{MeOH} 241 mμ (ε, 16300); IR(Nujol) 1712, 1678, 1623 cm^{-1}.

3β, 23α(and β)-Dibenzoxystigmast-5-ene (IX).— To a solution of 500 mg. of 3β-acetoxystigmast-5-en-23-one (VIb) in dry tetrahydrofuran, 0.4 g. of lithium aluminum hydride was added; the mixture was then heated under reflux for 5 hr. After the mixture had been allowed to stand overnight, the product was isolated in a conventional way to give 490 mg. of a solid. A portion of the solid was recrystallized from methylene chloride-ethyl alcohol to form crystals; m. p. 178~180°C, $[\alpha]_D^{19}$ −34° (*c* 0.69).

Found: C, 80.52; H, 11.56. Calcd. for $C_{29}H_{50}O_2$: C, 80.87; H. 11.70%.

The remaining solid (445 mg.) was converted into a benzoate by treating it with benzoyl chloride-pyridine at 50°C for 6 hr.; it was then allowed to stand at room temperature overnight after which the benzoate was chromatographed on 100 g. of alumina (Sumitomo Kagaku Co., 100 mesh). Elution with 1% ethyl acetate in petroleum ether and recrystallization from ethyl acetate-methanol gave 282 mg. of needles; m. p. 130~130.5°C, $[\alpha]_D^{18}$ −9° (*c* 0.67).

Found: C, 80.45; H, 9.10. Calcd. for $C_{43}H_{58}O_4$: C, 80.83; H, 9.15%.

Further elution with the same solvent and recrystallization from ethyl acetate-methanol gave 54 mg. of needles; m. p. 159~162°C, $[\alpha]_D^{19}$ −31° (*c* 0.86).

Found: C, 80.21; H, 8.95. Calcd. for $C_{43}H_{58}O_4$: C, 80.83; H, 9.15%.

The two isomers gave similar infrared spectra.

3β-Acetoxystigmastan-23-one (VIIb). — 3β-Acetoxystigmast-5-en-23-one (VIb) (942 mg.) was dissolved in a mixture of 40 ml. of dry ether and 20 ml. of acetic acid (distilled over potassium permanganate), and then 44 mg. of platiunm oxide was added. The mixture was agitated with hydrogen. After 58 ml. of hydrogen had been absorbed during a 30-min. period, the absorption of hydrogen ceased. The product was isolated in the usual way and was recrystallized from ethanol to give 747 mg. of crystals; m. p. 151~152°C, $[\alpha]_D^{17}$ +27° (*c* 0.68).

Found: C, 78.47; H, 10.97. Calcd. for $C_{31}H_{52}O_3$: C, 78.76; H, 11.09%.

UV $\lambda_{max}^{CHCl_3}$ 291 mμ (ε, 54); IR(Nujol) 1733, 1704, 1250 cm^{-1} (no absorption at 800 cm^{-1}). The tetranitromethane test was negative.

3β-Hydroxystigmastan-23-one (VIIa).—To a solution of 540 mg. of 3β-acetoxystigmastan-23-one (VIIb) in a mixture of 10 ml. of methylene chloride and 10 ml. of methanol, a solution of 0.1 g. of potassium hydroxide in 1 ml. of water was added; the mixture was allowed to stand overnight. The usual manipulation gave 525 mg. of crystals; m. p. 175~175.5°C; $[\alpha]_D^{17}$ +40° (*c* 0.65).

Found: C, 80.53; H, 11.49. Calcd. for $C_{29}H_{50}O_2$: C, 80.87; H, 11.70%.

UV $\lambda_{max}^{CHCl_3}$ 290 mμ (ε, 49); IR(Nujol) 3460, 3333, 1714, 1695 cm^{-1}.

Stigmastane-3, 23-dione (VIII).—To a solution of 200 mg. of 3β-hydroxystigmastan-23-one (VIIa)

14) For the isolation of stigmasterol from phytosterol, see, T. Yamada and K. Morita, *J. Japan Oil Chemist's Association*, 11, 290 (1962).

in a mixture of 1 ml. of methylene chloride and 10 ml. of acetic acid, 0.1 g. of chromic acid in 0.5 ml. of water was added; the mixture was allowed to stand overnight. After the decomposition of the excessive chromic acid with ethyl alcohol, the product was extracted with methylene chloride. The extract was washed with aqueous sodium carbonate and water, dried over anhydrous sodium sulfate, and concentrated. The residue was crystallized from ethanol to give 118 mg. of crystals; m. p. 159~160°C; $[\alpha]_D^{17}$ +54° (*c* 0.68).

Found: C, 80.97; H, 11.17. Calcd. for $C_{29}H_{48}O_2$: C, 81.25; H, 11.29%.

UV $\lambda_{max}^{CHCl_3}$ 290 mμ (ε, 71); IR (Nujol) 1724, 1709 cm^{-1}.

3β-Acetoxy-22ξ-chlorostigmast-5-en-23ξ-ol.—*From 3β-Acetoxy-5α, 22ξ-dichlorostigmastan-22ξ-ol.*—A solution of 800 mg. of 3β-acetoxy-5α, 22ξ-dichlorostigmastan-23ξ-ol (IV) in 16 ml. of *s*-collidine was heated under reflulx for 17 hr. The mixture was poured into water and extracted with chloroform. The chloroform extract was washed with diluted sulfuric acid and water, dried with anhydrous sodium sulfate, and concentrated to dryness. The residual crude material (780 mg.) was chromatographed on 24 g. of florisil. Elution with benzene and recrystallization from acetone gave crystals (m. p. 168.5~169.5°C). The Beilstein test was positive.

Found: C, 73.48; H, 9.86; Cl, 7.04. Calcd. for $C_{31}H_{51}O_3Cl$: C, 73.41; H, 10.13; Cl, 6.99%.

From 3β-Acetoxy-22ξ, 23ξ-epoxystigmast-5-ene (X).—To a solution of 300 mg. of oxide X in 20 ml. of glacial acetic acid, 6 ml. of a 5% solution of hydrogen chloride in acetic acid was added; the mixture was then heated at 65~70°C for 2 hr. The reaction mixture was poured into water, and the precipitated solid was collected by filtration. Recrystallization of the dried sample from acetone gave crystals with a m. p. 166~168°C. Mixed melting point determination with the 3β-acetoxy-22ξ-chlorostigmast-5-en-23ξ-ol obtained above showed no depression, and the infrared spectra were identical.

Thin-layer Chromatography.—Silica gel G was used as the adsorbent (0.25 mm. thick) and benzene was used as the eluant. A spray reagent was prepared by dissolving potassium permanganate (0.1%) in 5% aqueous sodium carbonate.[15] Slightly different R_f values were obtained for each run. The values in Table I are averages of several runs. A mixture of stigmasterol, 3β-acetoxystigmast-5-en-23-one and stigmasteryl acetate was chosen as the reference mixture; it was run each time with the other compounds.

The authors are indebted to Professor Susumu Mori, Tokyo Metropolitan University, and to Dr. Mitsuo Nakamura and Mr. Ryoji Mamine, Directors of the institute, for their encouragement.

An Abnormal Reaction of Hypohalous Acids with Hindered Double Bonds

By Ken-ichi MORITA,* Yoshiaki KAMANO** and Takeshi IWAMA

(Received March 27, 1963)

The isolation of stigmast-5-ene-3α, 7α, 22α-triol from the leaves of the horse chestnut[1] and of Tochinoki *(Aesculum turbinata)*[2] prompted us to investigate methods for the introduction of the oxygen atom into the side chains of stigmastane derivatives.[3] During the course of our investigation, we observed that the double bond of stigmast-22-ene derivatives gave dihalides instead of halohydrins upon conventional treatment with positive halogen compounds such as *N*-bromoacetamide, *N*-bromosuccinimide, isocyanuric bromide or isocyanuric chloride in aqueous dioxane in the presence of perchloric acid. This paper deals with the mechanism of this abnormal reaction.

The treatment of 3β-acetoxy-5α-chlorostigmast-22-ene (II) with *N*-bromoacetamide (NBA), *N*-bromosuccinimide (NBS) or isocyanuric bromide (ICB)[4] in aqueous dioxane in

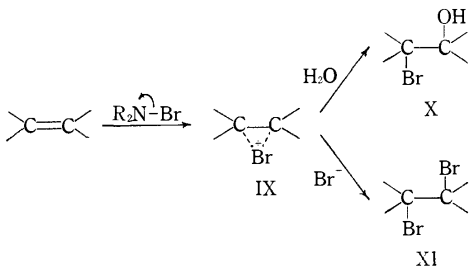
the presence of perchloric acid gave 3β-acetoxy-5α-chloro-22ξ, 23ξ-dibromostigmastane (III), while treatment with isocyanuric chloride (ICC) gave 3β-acetoxy-5α, 22ξ, 23ξ-trichlorostigmastane.[5,9]

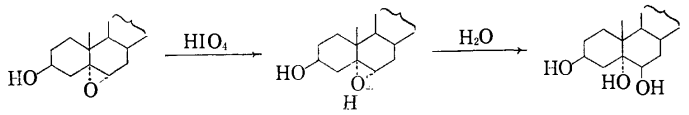
The treatment of stigmasteryl acetate (IV) with 1.4 molar equivalents of *N*-bromoacetamide in aqueous dioxane in the presence of perchloric acid, followed by acetylation and careful chromatography, gave the starting material (IV), 5α-bromo-3β, 6β-diacetoxystigmast-22-ene (V) and 3β, 6β-diacetoxy-5α, 22ξ, 23ξ-tribromostigmastane (VI). The treatment of stigmasteryl acetate (IV) with 1.4 molar equivalents of isocyanuric chloride, followed by acetylation and chromatography, gave the starting material IV 5α-chloro-3β, 6β-diacetoxystigmast-22-ene (VII) and 3β, 6β-diacetoxy-5α, 22ξ, 23ξ-trichlorostigmastane (VIII). These results clearly show that the Δ^{22}-double bond gives dihalides under reaction conditions where the Δ^{5}-double bond gives halohydrins.

The mechanism[6] of the addition of hypohalous acids to olefins is probably the formation of halogenium ring intermediates, IX, followed by an attack of the water molecule on halogenium ions, IX, to furnish halohydrins, X.



IX X XI

Fieser and Rajagopalan[7] reported that the brief refluxing of 5α, 6α-epoxycholestan-3β-ol (XII) with periodic acid in aqueous acetone afforded pure triol, XIV, in a 94% yield. It may most probably be assumed that the reaction proceeds through an oxonium ion intermediate, XIII, that is then attacked by water



XII XIII XIV

5) When stigmasta-4, 22-dien-3-one was treated with *N*-bromoacetamide or isocyanuric chloride, a small amount of a bromohydrin or a chlorohydrin was obtained, respectively (see experimental part). Therefore, some halohydrins may be present in the mother liquor of the crystallization.

XV XVI

molecule to afford triol, XIV, since the treatment of XII with most acids other than periodic acid either produces esters (CH_3COOH, H_2SO_4) or effects a displacement (HCl).[8]

Similar hydrolytic fission was attempted with 3β - acetoxy - 5α - chloro - 22ξ, 23ξ - epoxystigmastane[13] (XV) under more drastic conditions without observing any fission of the oxide ring. This fact supports the assumption that the rear side of the 22ξ, 23ξ-oxonium ring XVI is so sterically hindered[14] as to prevent the attack of the water molecule.

We now come to the assumption that the 22ξ, 23ξ-halogenium ions are also inert against the attack of the water molecule, since the configuration of the epoxide ring[16] in XV and that of the halogenium ion ring in the intermediate should be the same. Accordingly, the Br^- or Cl^- that may be present in a small concentration determines whether the reaction will give dibromide X, or dichloride. The reactivity of the Br^- or Cl^- against the halogenium ion, IX, should be greater than that of the water molecule because of their greater polarizability, although the bulkiness of the Br^- and Cl^- are comparable to it.

The evidence presented in this article supports the theory that the water molecule and not the OH^- species attack the halogenium ion intermediate to form halohydrins.

Experimental[17]

3β-Acetoxy-5α, 22ξ, 23ξ-trichlorostigmastane (I).—To a solution of 1.0 g. of 3β-acetoxy-5α-chlorostigmast-22-ene (II)[13] (m. p. 183~185°C) in 60 ml. of dioxane containing 0.3 ml. of 60% perchloric acid and 6 ml. of distilled water, 0.7 g. of isocyanuric chloride (purity 82%) was added; the mixture was then allowed to stand for 50 hr. at room temperature. The mixture was poured into water and extracted with ether. The ethereal extract was washed with 10% aqueous sodium bisulfite, 10% aqueous sodium carbonate and water, dried over anhydrous sodium sulfate, and concentrated. The recrystallization of the residue from ethyl acetate gave 0.3 g. of crystals; m. p. 208~209°C, $[\alpha]_D^{15}$ +20° (*c* 0.67).

IR (KBr) 1736, 1241 cm^{-1}; (no hydroxyl and no Δ^{22}-double bond absorption).

Found: Cl, 18.31. Calcd. for $C_{31}H_{50}O_2Cl_3$: Cl, 18.9%.

3β - Acetoxy - 5α - chloro - 22ξ, 23ξ - dibromostigmastane (III).—*With N-Bromoacetamide.*—Into a suspension of 5 g. of 3β-acetoxy-5α-chlorostigmast-22-ene (II) in 200 ml. of dioxane, 15 ml. of water, 1.5 ml. of 60% perchloric acid and 1.3 g. of *N*-bromoacetamide was added. The mixture was then warmed at 50°C for 30 min. and allowed to stand at room temperature overnight. Recrystallization of the product from benzene-methanol gave 0.9 g. of crystals; m. p. 205~206°C, $[\alpha]_D^{17}$ +9° (*c* 1.01).

IR (KBr) 1730, 1239 cm^{-1}; (no hydroxyl and no Δ^{22}-double bond).

Found: BrCl, 29.91. Calcd. for $C_{31}H_{51}O_2ClBr_2$: BrCl, 29.94%.

With N-Bromosuccinimide or Isocyanuric Bromide.[4]—When a similar reaction was carried out using *N*-bromosuccinimide or isocyanuric bromide instead of *N*-bromoacetamide, compound III was obtained in 35 and 60% yields respectively. The identity was established by the mixed melting point and infrared spectra. The better yield observed with isocyanuric bromide is probably due to the ease in liberating bromine.

With Bromine.—To a stirred solution of 1 g. of 3β-acetoxy-5α-chlorostigmast-22-ene (II) in 20 ml. of carbon tetrachloride, a solution of 0.33 g. of

8) L. F. Fieser, "Steroids," Reinhold Publishing Co., New York (1959), p. 196.

9) Mori reported that cholest-5-ene gave 5α, 6α-dichlorocholestane[10] instead of a chlorohydrin when treated with bleaching powder in ether in the presence of acetic acid, whereas cholestery esters,[11] cholesteryl halides[12] and cholest-5-en-3-one[13] gave the corresponding chlorohydrins under the same condition. The reason for this is not clear, but it is conceivable that C_3-substituents may have something to do with it and also the concentration of Cl^- may be greater in the system of bleaching-powder-acetic acid. Dihalides are usually formed as by-products when one uses dilute solutions of halogens in water to generate hypohalous acids, since halogens are present in the system as a result of equilibration. We know no examples of positive halogen compounds to attack olefins with the formation of dihalides.

14) In this connection, it may be noted that C_{22}-keto[16] and C_{23}-kete group in stigmastane series are sterically highly hindered.[13] Attempted fission of the epoxide ring of XV with $LiAlH_4$ in refluxing ether (24 hr.) failed.

15) Fischer and Mägerlein (Ref. 1) reported that C_{22}-carbonyl group in stigmastane derivatives did not form semicarbazones.

16) The configuration of the ring is probably α, since an examination of the Dreiding model seems to indicate that the α-side of Δ^{22}-double bonds of stigmastene derivatives are less hindered (cf. Ref. 13).

17) All melting points were uncorrected. Rotations were measured in chloroform solution. Infrared spectra were determined with a Perkin-Elmer Model 21. We are indebted to miss Sachiko Yoshikawa for some technical assistance and to Sankyo Pharmaceutical Co. for analyses.

bromine in 50 ml. of the same solvent was added over a period of 30 min. at 0°C; the mixture was then allowed to stand at the same temperature overnight. The product was isolated in the way described above. There was obtained 0.6 g. of needles (m. p. 205~206°C) (Found: BrCl, 29.71%). The identity was established by the mixed melting point and by the infrared spectra.

The Reaction of 3β-Acetoxy-5α-chloro-22ξ, 23ξ-dibromostigmastane (III) with Polling Pyridine. —A solution of 0.7 g. of III in 6 ml. of pyridine was heated under reflux for 11 hr. After it had cooled, the mixture was poured into water and the precipitated solid was collected by filtration. The solid was chromatographed on 30 g. of alumina (300 mesh, Wako Junyaku Co.). Elution with benzene-ether (9:1) and recrystallization from ethanol gave 250 mg. of crystals (m. p. 130~135°C). Although the material showed a weak ultraviolet absorption around 236 mμ, its infrared spectrum was identical with that of stigmasteryl acetate. Three more recrystallizations from ethanol gave pure stigmasteryl acetate (m. p. 138~139°C) (Found: C, 82.35; H, 10.75%).

The Reaction of *N*-Bromoacetamide with Stigmasteryl Acetate (IV). — To a mechanically-stirred solution of 13.6 g. (3 mmol.) of stigmasteryl acetate (IV) in 300 ml. of dioxane containing 3 ml. of 60% perchloric acid and 3 ml. of water, was added 5.8 g. (1.4 mol. eq.) of *N*-bromoacetamide over a period of 5 hr. at room temperature. The reaction mixture was allowed to stand overnight. Then 3% aqueous sodium bisulfite, and a large amount of water were successively added to the stirred solution. The product was extracted with ether four times. The combined ethereal solution was washed with water, dried over anhydrous magnesium sulfate, and evaporated to give 18.6 g. of an oil. The oil was acetylated by treatment with 50 ml. of acetic anhydride and 100 ml. of pyridine overnight at room temperature. The usual manipulation gave 18.6 g. of an oil containing crystals and an oil which was chromatographed on 410 g. of alumina (100 mesh, Sumitomo Kagaku Co.). Elution with 2% ethyl acetate in petroleum ether (b. p. 35~70°C) (fraction, Nos. 7—9) gave 2.58 g. of stigmasteryl acetate (IV). Further elution with the same solvent (Nos. 11—15) gave 4.8 g. of crude 5α-bromo-3β,6β-diacetoxystigmast-22-ene (V) which, on recrystallization from methylene chloride-ethanol, gave 3.5 g. of crystals with a m. p. of 152~155.5°C. The analytical sample was prepared by further recrystallization from ethyl acetate to needles; m. p. 156~158°C; $[\alpha]_D^{18}$ −68° (*c* 0.67, $CHCl_3$).

IR (KBr) 1736, 1244, 1236 (acetate); 973 cm^{-1} (Δ^{22}-double bond).

Found: C, 67.05; H, 9.06; Br, 12.78. Calcd. for $C_{33}H_{53}O_4Br$: C, 66.76; H, 9.00; Br, 13.46%.

Elution with 3 and 4 per cent of ethyl acetate in petroleum ether (Nos. 22—26) gave 462 mg. of crude 5α,22ξ,23ξ-tribromo-3β,6β-diacetoxystigmastane (VI). Recrystallization from methanol gave crystals; m. p. 211.5~212°C, $[\alpha]_D^{18}$ −73° (*c* 0.67, $CHCl_3$).

IR (Nujol) 1745 (shoulder), 1733, 1250, 1230 cm^{-1} (acetate).

Found: C, 52.99; H, 7.09; Br, 32.43. Calcd. for $C_{33}H_{52}O_4Br_3$: C, 52.60; H, 7.09; Br, 31.82%.

Elution with 10% ethyl acetate in petroleum ether (Nos. 32—39) gave 777 mg. of unidentified crystals, IR (Nujol) 3236, 1067, 970, 880, 800 and 765 cm^{-1} (Found: C, 81.80; H, 11.35; Br, 0%), while elution with 20% and 50% ethyl acetate in petroleum ether (Nos. 40—43) (2.276 g.) and recrystallization from ethyl acetate gave other unidentified crystals (m. p. 217.5~218°C). IR (Nujol) 3521, 1712, 1282, 1256, 1038, 970, 878 and 866 cm^{-1}. (Found: C, 74.15; H, 10.67; Br, 3.08%.)

All fractions not described here were uncrystallizable oils.

3β, 6β-Diacetoxy-5α, 22ξ, 23ξ-tribromostigmastane (VI) from V. — To a solution of 2.0 g. of 5α-bromo-3β,6β-diacetoxystigmast-22-ene (V) in 50 ml. of dioxane containing 0.5 ml. of 60% perchloric acid and 0.5 ml. of water, 0.7 g. of *N*-bromoacetamide was added; the mixture allowed to stand overnight at room temperature. The mixture was then poured into water containing some sodium bisulfite, and the product was well extracted with ether. The ethereal solution was washed with aqueous sodium carbonate and with water, dried over anhydrous sodium sulfate, and evaporated. The product was crystallized from methylene chloride-ethanol to give 1.6 g. of VI (m. p. 209~211°C). Its identity was established by the mixed melting point and the infrared spectra.

The Reaction of Isocyanuric Chloride with Stigmasteryl Acetate (IV).—Into a solution of 8 g. (1.7 mmol.) of stigmasteryl acetate (IV) in 150 ml. of dioxane containing 2 ml. of 60% perchloric acid and 2 ml. of water, 2.3 g. of isocyanuric chloride (83% purity) was added with swirling and the mixture was stored in the dark at room temperature (26°C) overnight. When the product was isolated as above, 9.666 g. of the yellow oil were acetylated by treatment with 5 ml. of acetic anhydride and 15 ml. of pyridine overnight at room temperature to give 9.8 g. of an oil, which was chromatographed on 300 g. of alumina (100 mesh, Sumitomo Kagaku Co.). Elution with 2% ethyl acetate in petroleum ether (b. p. 35~70°C) (fraction Nos. 8 and 9) gave 1.586 g. of stigmasteryl acetate (IV) (m. p. 138~138.5°C). Further elution with the same solvent (Nos. 15—21) gave 1.68 g. of 5α-chloro-3β,6β-diacetoxystigmast-22-ene (VII) with a m. p. of 147~151°C. The analytical sample was recrystallized from acetone; m. p. 153~153.5°C, $[\alpha]_D^{18}$ −51° (*c* 0.68).

Found: C, 72.35; H, 9.68; Cl, 6.25. Calcd. for $C_{33}H_{53}O_4Cl$: C, 72.16; H, 9.73; Cl, 6.46%.

Further elution with 2% ethyl acetate in petroleum ether (Nos. 22—24) and recrystallization from methanol gave 361 mg. of 3β,6β-diacetoxy-5α,22ξ,23ξ-trichlorostigmastane (VIII), m. p. 215~217°C, $[\alpha]_D^{18}$ −37° (*c* 0.60).

Found: C, 63.65; H, 8.48; Cl, 17.30. Calcd. for $C_{33}H_{53}O_4Cl_3$: C, 63.91; H, 8.61; Cl, 17.15%.

Bromohydrin of Stigmasta-4,22-dien-3-one.—To a stirred solution of 5 g. of stigmasta-4,22-dien-3-one (m. p. 121~123°C) in a mixture of 100 ml. of ether, 300 ml. of acetone and 30 ml. of water, 1.5 ml. of 60% perchloric acid and 2.0 g. (1.2 mol.) of *N*-bromoacetamide were added; the mixture was

then allowed to stand at room temperature for 24 hr. The product was extracted with ether, washed with 10% aqueous sodium bisulfite and 10% aqueous sodium carbonate and water, dried, and concentrated. The residue was repeatedly recrystallized from acetone to give a small amount of crystals; m. p. 210~212°C $[\alpha]_D^{18}$ +51° (*c* 0.69).

IR (KBr) 3466, 1661 and 1618 cm^{-1} (no Δ^{22}-double bond absorption).

Found: Br, 16.17. Calcd. for $C_{29}H_{47}O_2Br$: Br, 15.85%.

A similar result was obtained when dioxane was used as the solvent instead of a mixture of ether and acetone.

No attempt was made to isolate the dibromide that should be present in the reaction mixture.

The structure of the bromohydrin is pobably 23ξ-bromo-22ξ-hydroxystigmast-4-en-3-one, since the opening of the oxide of the Δ^{22}-double bond of 3β-acetoxy-5α-chlorostigmast-22-ene with hydrogen chloride gave a 22ξ-chloro-23ξ-hydroxy compound.[13] The course of the entering groups to the oxide ring (for Cl^-) and the course to the bromonium ring (for H_2O) are probably the same.

Chlorohydrin of Stigmasta-4, 22-dien-3-one.—To a stirred solution of 0.9 g. of stigmasta-4, 22-dien-3-one in a mixture of 60 ml. of dioxane and 6 ml. of water, 0.3 ml. of 60% perchloric acid and 0.7 g. of isocyanuric chloride (purity 63.3%) were added; the mixture was then allowed to stand for 48 hr. The product was extracted as described above, and the residue was repeatedly recrystallized from benzene-methanol to give a small amount of crystals (m. p. 216~218°C). The mixed melting point with the bromohydrin of stigmasta-4,22-dien-3-one described above showed no depression, and the infrared spectrum showed the presence of hydroxyl and α, β-unsaturated ketone groups.

Found: C, 75.51; H, 10.27; Cl, 7.86. Calcd. for $C_{29}H_{47}O_2Cl$: C, 75.20; H, 10.23; Cl, 7.65%.

A similar result was obtained when we used a mixture of ether and acetone instead of dioxane as the solvent.

The Reaction of 3β-Acetoxy-5α-chloro-22ξ, 23ξ-epoxystigmastane (XV) with Hydroiodic Acid.—To a solution of 200 mg. of 3β-acetoxy-5α-chloro-22ξ, 23ξ-epoxystigmastane (XV) in 8 ml. of glacial acetic acid, 5 ml. of hydroiodic acid in 10 ml. of acetic acid were added; the mixture was then allowed to stand at room temperature for 20 hr. in the dark. The mixture was poured into water and extracted with ether. The usual manipulation gave 145 mg. of 3β-acetoxy-5α-chlorostigmast-22-ene (II) (m. p. 183~184°C).

Its identity was established by the mixed melting point determination and by a comparison of the infrared spectra.

An Attempted Reaction of 3β-Acetoxy-5α-chloro-22ξ, 23ξ-epoxystigmastane (XV) with Periodic Acid.—To a solution of 0.5 g. of XV[13] (m. p. 137~138°C) in 20 ml. of acetone, 0.4 g. of periodic acid in 6.5 ml. of distilled water was added; the mixture was then heated under reflux for 2 hr. and allowed to stand overnight. The reaction mixture was extracted with ether, and the ethereal extract was washed with water, dried and concentrated. Recrystallization of the residue gave 0.4 g. of the starting material; m. p. and mixed m. p. 137~138°C.

The Spectrophotometric Determination of Titanium with Hydrogen Peroxide and Xylenol Orange[1)]

By Makoto Otomo

(Received June 18, 1963)

The yellow complex of titanium-hydrogen peroxide has been widely used for the spectrophotometric determination of titanium.[2-4)] By treatment of the complex with EDTA, Sweeter and Bricker[5)] found a new complex, the absorption spectrum of which differed from that of titanium-hydrogen peroxide. Recently Musya and Ogawa[6)] applied the above reaction to the spectrophotometric determination of titanium and clarified the composition of the

new complex. No workers, however, have yet applied such a reaction to the spectrophotometric determination of metals with xylenol orange in the presence of a "third reactant."

The present author has dealt with a number of metal chelates of xylenol orange and has found that, upon the addition of the third reactants, most of these chelates do not produce any new complex which is useful for the spectrophotometric determination of the corresponding metals. When, however, titanium(IV) salt is treated with xylenol orange in the presence of hydrogen peroxide, a new, red complex with an absorption maximum at about 535 mμ is formed. This study was undertaken to determine the conditions under which up to 70 μg. of titanium could be determined spectrophotometrically and to ascertain the composition of the new chelate by means of appropriate spectrophotometric techniques.

Experimental

Reagents and Apparatus.—The solutions of titanium and xylenol orange and the spectrophotometer used were the same as those reported on previously.[7]

A solution of hydrogen peroxide was used after standardizing it as usual against a standard solution of potassium permanganate. Perchloric acid was used for all acidity adjustments because of its low complexing action.

All experiments were carried out at 25±0.5°C.

Standard Procedure for the Determination of Titanium.—To a 25 ml. volumetric flask containing up to 70 μg. of titanium, 0.2 to 5 ml. of a 0.3% solution of hydrogen peroxide, 3.5 to 6 ml. of a 1×10^{-3} M solution of xylenol orange, and 2 to 3 ml. of a 0.5 N solution of perchloric acid were added. The solution was diluted to the mark with water, mixed, and allowed to stand for about 15 min. The absorbance of the solution was then measured at 532 mμ against a solution containing the same amounts of hydrogen peroxide, xylenol orange and perchloric acid.

Results and Discussion

Absorption Spectra.—The absorption spectrum of the titanium-hydrogen peroxide-xylenol orange complex is greatly affected in its shape by the concentration of perchloric acid and also by the amount of hydrogen peroxide and xylenol orange. Under the conditions described above, however, a reproducible spectrum with an absorption maximum at about 532 mμ* was obtained. The spectra thus obtained are shown in Fig. 1.

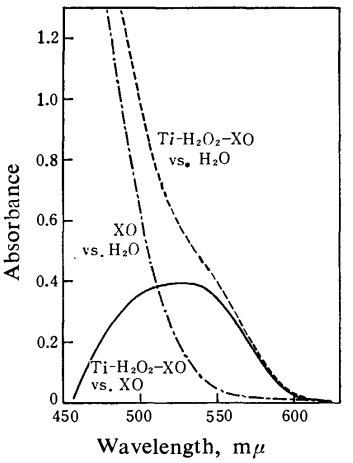

Fig. 1. Absorption spectra.
Ti: 32.4 μg., H_2O_2: 0.3% soln. 1ml., XO: 1.65×10^{-4} M, $HClO_4$: 0.05 M

The Effect of Acidity.—A choice of perchloric acid concentration is quite significant, for the absorption maximum and also the stability of the color are greatly affected by the concentration of perchloric acid. A series of solutions containing 23.2 μg. of titanium, 3.3 ml. of a 1×10^{-3} M solution of xylenol orange, and varying amounts of perchloric acid were prepared. The results obtained will be summarized in the following three sections.

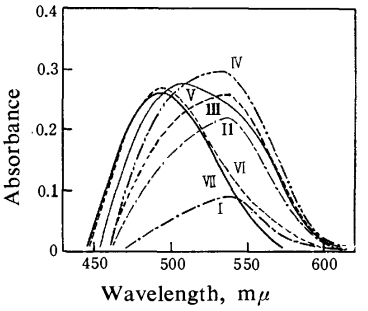

Fig. 2. Effect of acidity on the spectra of the Ti-H_2O_2-XO complex.
Ti: 23.2 μg., H_2O_2: 0.3% soln. 5ml., XO: 1.32×10^{-4} M, $HClO_4$ concn.: I; 0.174 M, II; 0.116 M, III; 0.078 M. IV; 0.06~0.04 M, V; 0.029 M, pH: VI; 4.0, VII; 4.5~5.0

The Relationship between Acid Concentration and Absorption Spectra.—Figure 2 shows the effect on the absortion spectra of the concentration of perchloric acid added to the solution containing titanium, hydrogen peroxide and xylenol orange. From the inspection of the curves, it is found that, depending on the concentration of perchloric acid two different absorbing species can subsequently be formed; one of them, which is formed in the considerably high acidic region, has an absorption

7) M. Otomo, This Bulletin, to be published.

* The absorption maximum shifts subsequently to 535 mμ with the increasing amount of titanium.

maximum at 535 mμ, while the other, which is formed in the slightly acidic region, has an absorption maximum at 495 mμ. In the practical spectrophotometric determination of titanium, the former complex was used; thereby not only could the hydrolysis of titanium be prevented, but also the interference of other cations could be conveniently reduced.

Maximum Color Development.—The reaction is not as rapid as the speed (about 15 min.) required for maximum color development. Figure 3 shows that the maximum absorbance is obtained over the perchloric acid concentration range 0.04 to 0.06 N.

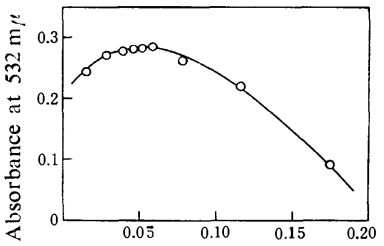

Fig. 3. Effect of acidity.
Ti: 23.2 μg, H_2O_2: 0.3% soln. 5ml.,
XO: 1.32×10^{-4} M

The Relationship between Acid Concentration and Color Stabiliy.—The stability of the color increases with the perchloric acid concentration. In solutions at low concentrations of perchloric acid, the absorbance of the colored solution decreases slowly with time, probably because of the hydrolysis of titanium. In solutions at high acidities, the color is stable for a long period, but the color development is not complete. When, however, the perchloric acid concentration was kept at 0.04 to 0.06 N, the absorbance of the solution remained constant for several ten minutes.

The Effect of the Amount of Hydrogen Peroxide.—It was found that the amount of hydrogen peroxide considerably affects the position of the absorption maximum and the stability of the color. These relations are summarized in Table I. The maximum and constant absorbance is obtained when 0.2 to 5 ml. of a 0.3% solution of hydrogen peroxide is added. Under these conditions, an absorption maximum is found at 532 mμ and the absorbance of the solution remains constant for about 30 min. When a too small amount of hydrogen peroxide is added, the color is indeed stable for a long period, but too low an absorbance is obtained. With a large amount of hydrogen peroxide, on the other hand, a relatively higher absorbance is obtained, but the color becomes somewhat unstable.

	5	535	0.263	20～50
	8	535	0.265	10～30

* In which the absorbance of the colored solutions being kept constant.

The Effect of the Addition of Xylenol Orange.—The maximum color development was obtained when 3.5 to 6 ml. of a 1×10^{-3} M solution of xylenol orange was used. Under these conditions, no visual shift in the position of the absorption maximum was observed.

The Order of the Addition of Reagents.—Varying the order in which the reagents were added had no significant effect on the results. In all cases, the color was completely developed within 15 min.

Beer's Law.—As is shown in Fig. 4, the calibration plot obeys Beer's law over the concentration range investigated, 7 to 70 μg. of titanium. The molar extinction coefficient is found to be 15000 at 532 mμ and the sensitivity, 0.003 μg. per cm^2. This sensitivity is comparable with that of the thymol method[8]

or that of the chromotropic acid method,[9] and it is much higher than that of the tiron method[10] or that of the resoflavine method.[11]

The Effect of Diverse Ions.—Separate tests were made to elucidate the interference of various cations as well as that of anions on the determination of titanium. The results are shown in Tables II and III.

Complex Formation.—Some attempts were made to establish the nature of the complex in solution and to determine the composition of the complex.

(1) The Mole Ratio Method.—The mole ratio method was employed to determine the molar ratio of xylenol orange to the titanium-hydrogen peroxide complex. A known aliquot of a titanium solution was treated preliminarily with an excess of hydrogen peroxide to form the yellow titanium-hydrogen peroxide complex. Varying amounts of a xylenol orange solution were then added, and the absorbance of the mixture was measured at 15 wavelengths between 420 and 600 mμ. The concentration of perchloric acid was held constant at 0.048 N. Some typical plots are shown in Fig. 5. It is seen that changes in the slope occur at a mole ratio of 1, indicating the presence of a 1 : 1 complex between xylenol orange and the titanium-hydrogen peroxide complex.

11) G. Charlot, *Anal. Chim. Acta*, **1**, 244 (1947).

(2) The Application of the Method of Lewis and Skoog.—In order to determine the combining ratio of titanium, a spectrophotometric method described by Lewis and Skoog[12] was applied in which the perchloric acid concentration was high enough for the complex formation to be quite incomplete. The concentration of perchloric acid was held constant at 0.4 N. Under these conditions, it is possible to assume that the equilibrium concentrations of the reactants are not appreciably different from their initial concentrations. The reaction producing the absorbing species is assumed to be

$$m\,\mathrm{Ti} + n\,\mathrm{H_2O_2} + p\,\mathrm{XO} \rightleftharpoons (\mathrm{Ti})_m(\mathrm{H_2O_2})_n(\mathrm{XO})_p$$

The equilibrium constant for this reaction can be expressed in terms of the apparent molar extinction coefficient, ε_c, of the complex and the absorbance, D, of the color-developing solution, which is measured against the reference solution containing the same amounts of perchloric acid and the reactants.

$$K'_{\mathrm{Ti}} = (D/\varepsilon_c)/[\mathrm{Ti}]^m[\mathrm{H_2O_2}]^n[\mathrm{XO}]^p \quad (1)$$

If the conditions are now chosen so that the reaction does not proceed very far to the right, the initial concentration of the reactants, $[\mathrm{Ti}]_i$, $[\mathrm{H_2O_2}]_i$ and $[\mathrm{XO}]_i$, can be substituted for the equilibrium concentration.

Thus,

$$K'_{\mathrm{Ti}} = (D/\varepsilon_c)/[\mathrm{Ti}]_i^m[\mathrm{H_2O_2}]_i^n[\mathrm{XO}]_i^p \quad (2)$$

which may be written as

$$\log D = m\log[\mathrm{Ti}]_i + n\log[\mathrm{H_2O_2}]_i + p\log[\mathrm{XO}]_i + \log K'_{\mathrm{Ti}}\varepsilon_c \quad (3)$$

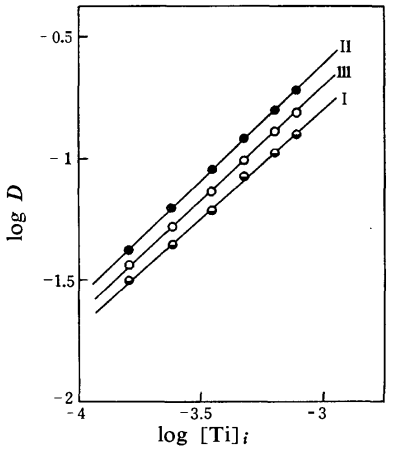

Fig. 6. Plots of log D vs. log$[\mathrm{Ti}]_i$.
$[\mathrm{H_2O_2}]_i$: 1.64×10^{-3} M, $[\mathrm{XO}]_i$: 1.55×10^{-4} M, $HClO_4$: 0.40 M, I: 510 mμ, II: 530 mμ, III: 550 mμ

12) C. Lewis and D. A. Skoog, *J. Am. Chem. Soc.*, **84**, 1101 (1962).

If $[\mathrm{H_2O_2}]_i$ and $[\mathrm{XO}]_i$ are held constant, a plot of log D vs. log $[\mathrm{Ti}]_i$ should yield a straight line with slope m. When the experimental data were treated in this way, a good straight line with a slope of 0.95 (as an average at six wavelengths between 510 and 560 mμ) was obtained. Some of these data are plotted in Fig. 6.

(3) The Combining Ratio of Hydrogen Peroxide.—It now becomes necessary to determine the combining ratio of hydrogen peroxide. An interesting spectrophotometric method, which makes possible the interpretation of the experimental data for systems involving three components, was recently described by Newman and Hume.[13] This method, however, is not directly applicable to the present system, involving titanium, hydrogen peroxide and xylenol orange. Therefore, a modified method was developed. Assuming the following equilibrium:

$$\mathrm{Ti} + \mathrm{XO} + n\,\mathrm{H_2O_2} \rightleftharpoons \mathrm{Ti\cdot XO\cdot(H_2O_2)}_n$$

the equilibrium constant, $K'_{\mathrm{H_2O_2}}$, may be defined as;

$$K'_{\mathrm{H_2O_2}} = [\mathrm{Ti\cdot XO\cdot(H_2O_2)}_n]/[\mathrm{Ti}][\mathrm{XO}][\mathrm{H_2O_2}]^n \quad (4)$$

If two species, xylenol orange and the complex, are absorbing and if the absorbance is measured against the solution containing the same amounts of the reactants except for hydrogen peroxide, the following relationship may hold:

$$D = \varepsilon_c[\mathrm{Ti\cdot XO\cdot(H_2O_2)}_n] \quad (5)$$

where D is the observed absorbance and ε_c is the apparent molar extinction coefficient of the complex. The initial concentrations of titanium, xylenol orange and hydrogen peroxide in any given experiment are, respectively:

$$[\mathrm{Ti}]_i = [\mathrm{Ti}] + [\mathrm{Ti\cdot XO\cdot(H_2O_2)}_n]$$
$$[\mathrm{XO}]_i = [\mathrm{XO}] + [\mathrm{Ti\cdot XO\cdot(H_2O_2)}_n] \quad (6)$$

and

$$[\mathrm{H_2O_2}]_i = [\mathrm{H_2O_2}] + n\,[\mathrm{Ti\cdot XO\cdot(H_2O_2)}_n]$$

If the initial concentration of xylenol orange is considerably higher than that of titanium, the equilibrium concentration of xylenol orange may be assumed to equal its initial concentration. Substituting Eqs. 5 and 6 into Eq. 4, rearranging it, and then taking logarithms,

$$\log\{D/([\mathrm{Ti}]_i\,\varepsilon_c - D)\} = \log K'_{\mathrm{H_2O_2}} + \log[\mathrm{XO}]_i + \log\{([\mathrm{H_2O_2}]_i - nD)/\varepsilon_c\}^n \quad (7)$$

If the proper value of n is assumed, a plot of

13) L. Newman and D. N. Hume. ibid., **79**, 4571 (1957).

$$\log\{D/([\mathrm{Ti}]_i\,\varepsilon_c - D)\} \text{ vs. } \log\{([\mathrm{H_2O_2}]_i - nD)/\varepsilon_c\}^n$$

should yield a straight line with a unit slope. When the experimental data were treated in this way and the value of n was assumed to be one, a good straight line with a slope of 0.9 ± 0.03 was obtained. Values of n equal to one-half and two were tried unsuccessfully. These findings hold for solutions containing a fixed amount of titanium (2.709×10^{-5} M) and xylenol orange (1.653×10^{-4} M) and varying amounts of hydrogen peroxide (0.286 to 4.090 $\times10^{-4}$ M). In all the experiments, the concentration of perchloric acid was held constant at 0.048 N.

(4) Conclusion.—From the foregoing results, it is possible to conclude that a 1 : 1 : 1 complex is formed as a result of the reaction of titanium with hydrogen peroxide and xylenol orange.

The formation constant, K_c, of the complex can be calculated from Eq. 3, using the data obtained in section 2 and the step-by-step acid dissociation constants of xylenol orange[14] (see also Ref. 7). The results, along with the apparent molar extinction coefficients at six wavelengths, are summarized in Table IV. The value of the formation constant agrees approximately with that (1.8×10^{37}) calculated from Eq. 7.

Table IV. Formation constant, K_c, and apparent molar extinction coefficient, ε_c, of the complex

Wavelength, mμ	ε_c	K_c*
510	14000	4.0×10^{37}

Summary

Although almost no color reaction occurs when titanium is treated with a solution of xylenol orange at pH below 2, the addition of hydrogen peroxide as a third reactant yields a new, red complex with an absorption maximum at about 535 mμ. On the basis of the above reaction, a new method for the spectrophotometric determination of titanium has been described. The color stability is affected by the amount of hydrogen peroxide and xylenol orange. When, however, 0.2 to 5 ml. of a 0.3% solution of hydrogen peroxide and 3.5 to 6 ml. of a 1×10^{-3} M solution of xylenol orange are used for less than 70 μg. of titanium and a total volume of 25 ml., the color obtained is stable for at least 30 min. Beer's law is obeyed over the 7 to 70 μg. range of titanium. The mole ratio method and the two spectrophotometric methods have been employed to determine the composition of the complex. It has been concluded that a 1 : 1 : 1 complex is formed under the conditions investigated.

The author wishes to acknowledge the kind guidance and the many helpful suggestions of Professor Kôichi Tonosaki.

Cadmium Sulfodichlorohydroxydimethylfuchsondicarboxylate Chelate—A Spectrophotometric Study

By Satendra P. SANGAL and Arun K. DEY

(Received May 28, 1963)

Sulfodichlorohydroxydimethylfuchsondicarboxylic acid (trisodium salt; trivial name Chrome Azurol S; Color Index 43825) has extensively been used in these laboratories as a colorimetric reagent[1] and as a chelating agent for metal chelate formation in aqueous solution.[2-6] The use of Chrome Azurol S as a chelatochromic indicator in the complexometric determination of thorium has also been reported.[7] The present communication reports our work on the composition and stability of the cadmium(II)-Chrome Azurol S chelate.

Experimental

Materials.—Solutions of cadmium sulfate and Chrome Azurol S (B. D. H.) were prepared in double distilled carbon dioxide free water.

Instruments.—For the absorbance measurements a Unicam SP 500 spectrophotometer was used.

pH measurements were done with a Leeds and Northrup direct reading pH indicator.

Results and Discussion

Behavior of the Reagent as a Colloidal Electrolyte.—Dey et al. reported earlier[8] that

$$\frac{\tan\theta}{\tan\theta'} = 1.9 \qquad \frac{\tan\theta_1}{\tan\theta_1'} = 2.0$$

Chrome Azurol S behaves as a colloidal electrolyte in concentrated solutions. Therefore, during these investigations solutions were used of the order of 10^{-4} M so that the solutions may behave as true solution.

Effect of Time on the Chelate.—The chelate formation was found to be immediate and the absorbance values remained constant upto 48 hr. However, the solutions were kept for half an hour to attain equilibrium.

Nature of the Chelate Formed.—The method of Vosburgh and Cooper[9] was employed. Mixtures containing cadmium sulfate and Chrome Azurol S in the ratio of 0 : 1, 1 : 1, 1 : 2, 1 : 4 and 1 : 5 (pH 11.0) were prepared and their absorbances measured at various wavelengths. The results show that the region of maximum absorbance of Chrome Azurol S lies at 430 mμ, whereas, that of the mixtures at 540 mμ. This shows clearly that only one chelate having λ_{max} 540 mμ is formed under the conditions of study.

Stoichiometry of the Components.—The composition was studied using three different methods viz. (i) the method of continuous variations,[10] (ii) mole ratio method[11] and the (iii) slope ratio method.[12] Measurements were made at pH 11.0, adjusted by ammonia added to the mixtures. The results obtained by the continuous variations method are summarized in Table I.

From Table I and Fig. 1 it is clear that the composition of the chelate is $Cd(CAS)_2$. This is further corroborated by the mole ratio method (Fig. 2) and slope ratio method (Fig. 3).

TABLE II. STABILITY CONSTANTS K

Method employed	pH	log K at 25°C	ΔG (kcal.) at 25°C
Method of Dey et al.	11.0	9.1±0.2	−12.7±0.2
Mole ratio method	11.0	9.0±0.2	−12.5±0.2

12) A. E. Harvey and D. L. Manning, *J. Am. Chem. Soc.*, **12**, 4488 (1950).

Effect of pH on the Stability of the Chelate.—Mixtures containing cadmium sulfate and Chrome Azurol S in the ratio of 1:2 were prepared, and their absorbances were measured at various wavelengths after adjusting their pH to different values. It was observed that the λ_{max} of the chelate which is 540 mμ holds good between pH 9.5 to 11.5. This shows that the chelate is stable within this range of pH.

Calculations of the Stability Constant *K*.—The stability constants were calculated using the method of Dey et al.[13,14] and the mole ratio method.[11] The results are given in Table II.

Summary

Sulfodichlorohydroxydimethylfuchsondicarboxylate forms a 1:2 violet colored chelate (λ_{max} 540 mμ) with cadmium(II). The chelate is stable between pH 9.5 and 11.5. The values of stability constant as determined by two different methods are 9.1 and 9.0, at 25°C.

Behavior of Chromotropic Acid as a Colloidal Electrolyte in Aqueous Solution

By Satendra P. SANGAL

(Received June 6, 1963)

A number of organic reagents have been used in these laboratories as complexants, and during the study of composition and stability of their metal chelates spectrophotometrically, it was observed that they deviated from stoichiometry when the solutions employed were not dilute. This was found to be due to the behavior of the reagents as colloidal electrolytes. In concentrated solutions, such reagents display colloidal behavior, but when extremely dilute they show the characteristics of true solutions. The reagents so far investigated from this point of view in these laboratories are ammonium aurintricarboxylate,[1] sodium alizarin-3-sulfonate,[2] *p*-nitrobenzene azochromotropic acid,[3] 7-iodo-8-hydroxy-quinoline-5-sulfonic acid,[4] sulfodichlorohydroxydimethylfuchsondicarboxylic acid,[5] sodium 2-naphthol-3, 6-disulfonic acid,[6] and 1-(*o*-arsonophenylazo)-2-naphthol-3, 6-disulfonic acid.[7]

Chromotropic acid has widely been studied and it is observed that it forms colored chelates with many metals. As a part of a detailed study on the composition and stability of the metal chelates of chromotropic acid, its behavior as a colloidal electrolyte has been investigated and the results are communicated in this paper.

Experimental

Instruments. — Electrical conductance of the reagent in solution was measured with a Leeds and Northrup Kohlrausch Slidewire with an audiofrequency oscillator in the circuit, operated by 220/50 cycles a. c. mains, and using a dip type measuring cell having a cell constant 0.5875.

Materials.—Solutions of the reagent was prepared by dissolving chromotropic salt (B. D. H.) in conductivity water.

Results and Discussion

The electrical conductance of solutions of chromotropic salt was determined at different dilutions at 25°C, and the curve obtained by plotting the square root of the concentration of reagent solution against molar conductance (Fig. 1, Table I) is not linear and resembles that of colloidal electrolytes as recorded by

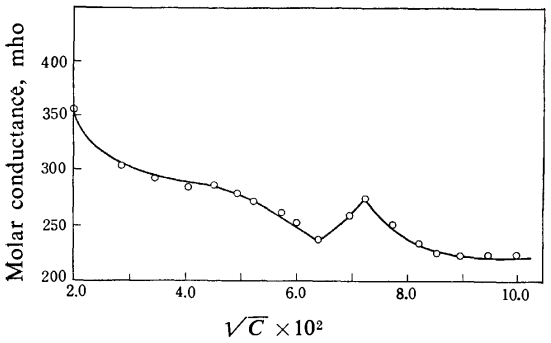

Fig. 1. Variation of molar conductance with concentration.

TABLE I. VARIATION OF MOLAR CONDUCTANCE WITH CONCENTRATION

Concentration of chromotropic acid, M	$\sqrt{C} \times 10^2$	Molar conductance mho
0.0004	2.00	357
0.0008	2.83	304
0.0012	3.46	292

0.0100	10.00	250

McBain.[8] It would have been a straight line if the system behaved as a true electrolyte and the Debye-Hückel equation would have been applicable.

The specific conductance of the aqueous solution of chromotropic acid was also determined at different temperatures (Table II).

8) J. W. McBain, "Colloid Science," D. C. Heath and Co., Boston (1950).

TABLE II. VARIATION OF SPECIFIC CONDUCTANCE WITH TEMPERATURE

Concentration of chromotropic acid, M	Specific conductance mho $\times 10^4$						
	0°	10°	20°	30°	40°	50°	60°C
0.003	2.9	3.5	4.7	5.8	7.0	8.2	9.4
0.005	4.7	5.2	6.4	8.8	9.9	11.7	14.1
0.010	8.1	10.5	12.7	17.6	20.5	24.0	26.0

The curve obtained by plotting specific conductance against temperature (Fig. 2) was extrapolated to give the temperature of zero conductance which was found to be −20.0°C. The temperature coefficient per degree centigrade per hundred units of conductance at 35°C calculated from Fig. 2 is shown in Table III.

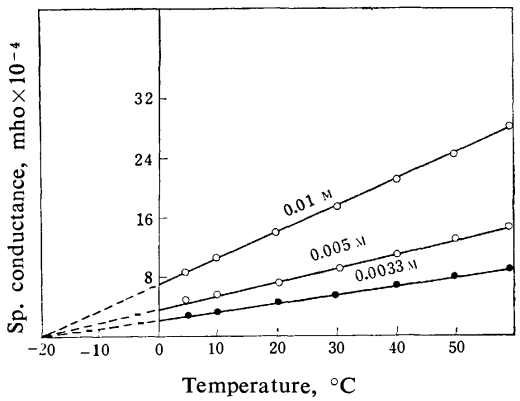

Fig. 2. Variation of specific conductance of chromotropic acid solution with temperature.

TABLE III. TEMPERATURE COEFFICIENT OF CONDUCTANCE

Concn. of chromotropic acid, M	Sp. cond. at 35°C (from graph) mho $\times 10^4$	Temp. coefficient per degree centigrade	Temp. coefficient per hundred of the conductance
0.003	6.5	0.10	1.5
0.005	10.0	0.16	1.6
0.010	19.5	0.33	1.7

The results conclusively establish the colloidal nature of the reagent. Mushran and Prakash[9] as a result of their investigations with a number of colloidal systems found that in general the temperature of zero conductance of true electrolytes lies near about −40°C, whereas, in the case of colloidal electrolytes this temperature ranges between −15 and −35°C. Shivapuri and Prakash[10] also corroborated these results from their study on the

9) S. P. Mushran and S. Prakash, *J. Phys. Chem.*, **50**, (1946).

colloidal behavior of a number of dyes in aqueous solution. Also the temperature coefficient per degree centigrade per hundred units of conductance at 35°C in colloidal systems and colloidal electrolytes is mostly below 2.0.

Hence on the basis of the above results it is concluded that chromotropic acid behaves as a colloidal electrolyte. In the determination of the composition and stability of the chelates the colloidal characteristics of the chelating agent plays a significant part due to what non-stoichiometric ratios are often arrived at. Therefore, for physico-chemical studies it is advisable to work with extremely dilute solutions when the chelating agent behaves as a true solution.[11]

Summary

The nature of chromotropic acid as a colloidal electrolyte has been established from electrical conductance studies. The curve obtained by plotting the square root of concentration and molar conductance of the reagent solution is not linear and resembles that of a colloidal electrolyte. The temperature coefficient per degree centigrade per hundred units of conductance at 35°C is between 1.5 and 1.7. The temperature of zero conductance, determined by extrapolation, is −20.0°C.

The author is thankful to Dr. Arun K. Dey for his valuable guidance throughout the progress of this work. Thanks are also due to the Council and Scientific and Industrial Research, New Delhi for an award of a fellowship.

The Preparation of Dimer Aldehydes and Dimer Alcohols in an Oxo Reactor. I. Modifiers Effective in Producing Dimer Aldehydes and the Hydrogenation of the Aldehydes with Synthesis Gas

By Hiroshi UCHIDA and Akio MATSUDA

(Received July 2, 1963)

The oxo process has here been modified to produce aldehydes with $2n+2$ carbon atoms in an oxo reactor, starting with an olefin of n carbon atoms. The modified oxo process was previously reported to use zinc metal and such zinc compounds as naphthenate and acetylacetonate as the modifiers,[1-3] together with a cobalt carbonyl catalyst. However, previous work[4] in our own laboratory has established that the hydroformylation rate is considerably decreased in the presence of zinc, presumably owing to the formation of an oil-soluble mixed carbonyl of $[Co(CO)_4]_2Zn$. The mixed carbonyl had already been discovered by Hieber and Schulten.[5] The present paper deals first with search for more efficient modifiers and then with another attempt to obtain alcohols from the corresponding aldehydes by hydrogenation with the synthesis gas at the pressure prevalent in the oxo reaction conditions without removal of the cobalt carbonyl. Although the hydrogenation process using synthesis gas has been known for a long time,[6] hydrogenation at a reasonable rate could be achieved only with difficulty under the pressure of the oxo reaction.[7]

Experimental

The synthesis run was conducted in a 300 cc. stainless-steel autoclave. The autoclave was connected by a copper tube and a needle valve to a pressure vessel (0.5 l. in volume) into which an equimolecular mixture of hydrogen and carbon monoxide had been compressed at the pressure of a little above 200 kg./cm^2. It was equipped with a stirrer with a vertical movement. A solution containing dicobalt octacarbonyl crystals, a solvent, and a modifier were placed in the autoclave. After

flushing the air out with the synthesis gas, the autoclave was loaded with some propylene and pressured with the synthesis gas from the pressure vessel to about 140 kg./cm^2 at room temperature; then the autoclave was heated. It took about 20 min. to heat the autoclave to 150°C. Thereafter, the stirring mechanism was started. During the reaction period, the temperature was controlled at 150±1°C, and the pressure in the autoclave was maintained at 200 kg./cm^2 by the continuous introduction of the synthesis gas from the pressure vessel through the needle valve. Pressure falls in the pressure vessel with time were recorded. The amounts of synthesis gas calculable from the pressure falls stood for the gas consumption in the hydroformylation. After the reaction period of an hour or two hours, the autoclave was cooled in running water and the gas was purged and metered while the liquid product was weighed. In several cases, the gas was analyzed for unreacted propylene. The composition of the liquid product was determined gas chromatographically by means of a 3 m. column of cellite plus P. E. G. 1500, while the unreacted propylene was measured by means of a 2 m. column of alumina plus silicon oil.

The propylene was 93 mol.% pure and contained 6.5 mol.% propane and 0.5 mol.% ethane according to the gas chromatographic analysis. Solvents such as cyclohexane and *n*-butyraldehyde, which were free from any impurities detectable from gas chromatographic analyses, were obtained by the fractional distillation of the commercial products. Dicobalt octacarbonyl was manufactured by the reaction between cobalt carbonate in benzene and the synthesis gas at high pressure. The liquid content after the reaction was cooled to deposit crystals of the carbonyl, which were then stored for use in a pressure vessel under carbon monoxide.

A variety of the modifiers were examined for their effects on both the dimerization of aldehydes and the rate of hydroformylation. Among these, magnesium methylate, isopropylates of aluminum and titanium, and zinc naphthenate were from commercial sources; all of them except the last were supplied by the Kawakami Institute, Inc. The zinc isopropylate was prepared from zinc chloride and sodium isopropylate, while the zinc acetylacetonate was prepared from zinc carbonate and acetylacetone. The acetylacetonates of vanadium ($VO(C_5H_7O_2)_2$), chromium ($Cr(C_5H_7O_2)_3$), molybdenum ($MoO_3(C_5H_7O_2)_2$), and zirconium ($Zr(C_5H_7O_2)_4\cdot 10H_2O$) were prepared, according to the method described in the literature,[8] by reacting acetylacetone with vanadium pentoxide, with chromium trichloride in the presence of urea, with molybdenum trioxide, and with zirconium oxychloride ($ZrOCl_2\cdot 8H_2O$) in the presence of sodium carbonate respectively. The acetylacetonate of magnesium was the product obtained by the reaction between magnesium foil and acetylacetone, while that of titanium was prepared from titanium isopropylate and acetylacetone. Stannous oleate was prepared by the extraction with ether of a mixture of aqueous sodium oleate and aqueous stannous chloride, followed by the evaporation of the ether. In the experimental runs to study the hydrogenation of dimer aldehydes with the synthesis gas, the carbonyl of iron, besides that of cobalt, was used. It was prepared in a way which has been described elsewhere.[9]

Results and Discussion

The Effects of Modifiers on the Hydroformylation Rate and on the Yield of Dimer Aldehydes. — On the reasonable assumption[10] that the initial rate of hydroformylation is of the first order with respect to propylene concentration, the magnitude of an initial rate constant, k, evaluated by the aid of the formula $k=(1/t)\ln[c_0/(c_0-V/2)]$, where t is the reaction time (min.), c_0 is the initial amount of propylene (mole), and V is the amount of the consumed synthesis gas (mole) as estimated as mentioned afore,[11] gives an appoximate measure of the initial rate. In the present study, k is conventionally calculated by putting the value of t as the point at which $c_0-V/2$ is equal to $0.9\,c_0$.

Tables I and II summarize the results of experimental runs made to examine the effects of modifiers. The reaction conditions differ in some respects between series I of Table I and series II of Table II. The main difference is that in the former series cyclohexane was used as the reaction medium, while *n*-butyraldehyde was used in the latter series. Accordingly, the effects of modifiers can not be compared directly throughout the runs of the two series. However, an approximate and reasonable comparison is possible if the data with no modifiers in each of the series and the data with the modifiers (magnesium methylate and aluminum isopropylate) that are common to both the series are taken into consideration.

The choice of *n*-butyraldehyde as the reaction medium in series II was made after a few preliminary experiments, according to which a larger content of the dimer aldehydes in the product, as well as a higher rate of hydroformylation, was obtained by its use.[12] Moreover, the choice is preferable in view of the fact that in the industrial oxo reactor for aldehyde production from propylene, the

9) H. Uchida, *Rpt. Gn't. Chem. Ind. Research Inst. Tokyo*, **44**, 43 (1949).

10) A. R. Martin, *Chem. & Ind.*, **1954**, 1536.

11) For a more rigorous estimation of V, the change of the partial pressure of propylene in the gas phase of the autoclave should be taken into account, since the partial pressure decreases with the progress of the hydroformylation.

12) The experimental data will be reported elsewhere in detail.

hydroformylation proceeds in the medium of butyraldehydes.

In the tables, the conversion is calculated on the basis of the amount of synthesis gas consumed, or more accurately, of the amount of propylene unconverted. Data of the former calculation are shown in brackets. The product composition in Table I shows the composition of liquid product exclusive of cyclohexane, while that in Table II shows the composition of the total liquid product. The residue stands for matter not yet identified.

Although a comparatively small amount of zinc compound causes an increase in the yield of dimer aldehydes without much reduction of the rate of hydroformylation, a greater amount completely inhibits the progress of the reaction. The inhibition is similarly observed with zirconium acetylacetonate and stannous oleate. The acetylacetonates of titanium and vanadium considerably increased the yield of dimer aldehydes, with some decrease in the rate. Aluminum isopropylate and the acetylacetonates of chromium and molybdenum have scarcely any effect upon either the dimerization or the rate. In contrast to the above modifiers, magnesium compounds such as methylate and acetylacetonate appear to be significant in effectively increasing the yield of dimer aldehydes without any reduction of the hydroformylation rate. The investigation will hereafter be conducted by emphasizing the magnesium compounds.

The Dimerization Rate of *n*-Butyraldehyde in the Presence of Magnesium Methylate. — In order to obtain more comprehensive knowledge on the effect of magnesium methylate, the rates of the dimerization of *n*-butyraldehyde at the pressure and the temperature of the oxo reaction were measured in the presence of either dicobalt octacarbonyl or magnesium methylate, and then in the presence of both of them. The measurement was conducted by means of the determination of the contents of C-4 and C-8 aldehydes in several liquid samples (1 cc.) withdrawn from the initial charge of *n*-butyraldehyde (20 cc.) by means of a dip tube at time intervals over the dimerization period. The results are shown in Fig. 1 as plots of the respective aldehyde contents vs. the reaction time. The figure also includes the plots of the residue. The dimerization takes place in the presence of dicobalt octacarbonyl alone (curve I); the extent of this dimerization is rather high compared with that due to the presence of magnesium methylate alone (curve II). In their simultaneous presence (curve III), the extent is considerably increased, and the C-8 aldehydes are produced in an amount greater

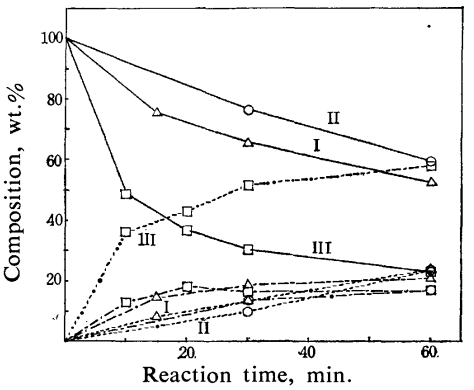

Fig. 1. Dimerization of *n*-butyraldehyde under high pressure of the 1 : 1 synthesis gas. Reaction temperature, 150°C; the synthesis gas pressure, 200 kg./cm². Full line, *n*-butyraldehyde: dotted line, C-8 aldehydes; dotted and dashed line, residue.
-△- In the presence of 0.8 mmol. $Co_2(CO)_8$

-□- In the presence of 0.8 mmol. $Co_2(CO)_8$ plus 0.8 mmol. $Mg(OCH_3)_2$

than the sum of the respective amounts of curves I and II.[13]

The Effects of Organic Bases on the Hydroformylation Rate and on the Yield of Dimer Aldehydes. — It had already been established that the rate of hydroformylation is increased by the addition of small amounts of organic bases.[14] With the intention of increasing the rate, the reaction was now carried out in the presence of one of the two organic bases, either pyridine or *N*, *N*-dimethylaniline, in addition to dicobalt octacarbonyl and magnesium methylate. The results are listed in Table III, which also includes the product composition after hydrogenation in the usual way, using a cobalt catalyst. Pyridine unexpectedly caused an increase in the yield of dimer aldehydes with an approximately equal rate, while *N*, *N*-dimethylaniline caused an increase in the rate with an invariable yield. The remarkable effect of pyridine can be seen more readily with the composition of the product after hydrogenation (cf. numerals in brackets).

The Direct Synthesis of C-8 Alcohols from Propylene in the Oxo Reactor. — As is recognizable in the foregoing tables, the products of hydroformylation at 150°C always contain

13) As for the C-8 aldehydes in the products along curve II, only unsaturated ones are present, whereas in the products along curves I and III, the saturated ones are increasingly present with the passage of reaction time. The product of curve III after the reaction period of an hour contains a greater amount of the saturated C-8 aldehydes than of the unsaturated ones. Detailed data on the produt composition will be reported elsewhere.

The initial charge consisted of 0.44±0.01 mol. C_3H_6, 0.5 mol. *n*-C_3H_7CHO, and 0.8 mmol. $Co_2(CO)_8$, without or with 1.6 mmol. $Fe(CO)_5$.

minor amounts of butanols. Wender et al.[15] pointed out that the hydrogenation of butyraldehyde to butanol proceeded smoothly at 185°C under 200 atm. of the synthesis gas, but they presented no experimental data on the rate. According to our preliminary experiments, the hydrogenation, even at this high temperature, proceeded at a rate lower than that as did propylene hydroformylation at 150°C, when a considerable amount of aldehydes, particularly of dimer aldehydes, used to remain after hydrogenation of an hour. A higher temperature, for instance, one of 200°C might naturally be expected to increase the hydrogenation rate. Nevertheless, the hydrogenation stopped soon after the temperature rose to 200°C, because of the decomposition of the dicobalt octacarbonyl to cobalt metal (cf. Exp. No. 23 in Table IV). In this connection, Berty et al.[7] had already stated that not only the simple elevation of temperature to 200°C, but also the higher pressure of 300 atm., could barely bring about the hydrogenation of octylaldehyde. The higher pressure, however, was not economical from a practical point of view.

Previous data available for the equilibrium concentration of metal carbonyls under carbon monoxide, of dicobalt octacarbonyl by Berty et al.,[7] and of iron pentacarbonyl by Pichler et al.[16] indicated that the latter metal carbonyl was more stable at a high temperature at a fixed carbon monoxide pressure. Moreover, our previous paper[17] reported that iron pentacarbonyl was a catalyst capable of hydrogenating methylacrylate to methylpropionate with a gas mixture including hydrogen and carbon monoxide. On the basis of these findings, an attempt has been made to carry out the hydroformylation in the presence of iron pentacarbonyl, besides that of dicobalt octacarbonyl and magnesium methylate, and then to effect, without any treatment of the oxo product, the hydrogenation of the resulting aldehydes to the corresponding alcohols by the simple elevation of the temperature to 200°C.

In the experimental runs, $2H_2$: 1CO synthesis gas at 200 kg./cm^2 was used in place of the 1 : 1 synthesis gas used in the preceding runs, since hydrogen and carbon monoxide were to be consumed in the ratio of 2 : 1. The hydroformylation was conducted at 150°C for an hour, followed by a rapid temperature rise to 200°C, which was accompanied by a temporary pressure rise to 210~217 kg./cm^2. Thereafter, the pressure was fixed at 200 kg./cm^2, which level was maintained during the hydrogenation period of an hour by the continuous introduction of the 2 : 1 synthesis gas from the pressure vessel.

The results are listed in Table IV. It has now been proved that in the presence of iron pentacarbonyl almost all C-8 as well as C-4 aldehydes are hydrogenated to the corresponding alcohols, whereas in its absence the aldehydes are left unhydrogenated. Pyridine again effects the dimerization favorably, resulting in a greater yield of C-8 alcohols, but it, in this series of runs, decreases the rate of hydroformylation to some extent (cf. Exp. Nos. 28, 29, 30, and 31). The yield of C-8 alcohols is increased by increasing the amount of magnesium methylate (cf. Exp. Nos. 31, 32, and 33).[18]

It has, however, remained unclarified whether cobalt carbonyl or iron carbonyl is the catalyst for the hydrogenation. It may be plausible that part of the cobalt carbonyl, at least, should be left as such in the product after the hydrogenation if the carbonyl does catalyze the hydrogenation. To confirm this, the carbonyl content in the product was determined. The hydroformylation and hydrogenation procedures were similar to those described just above, but they differed in some details; the runs were made with no modifiers for aldehyde dimerization, and in the hydrogenation stage hydrogen was supplied from another pressure vessel. Moreover, caution was exercised to avoid contamination of the product because of the corrosion of the autoclave material with carbon monoxide; this was avoided by using another shaking 400 cc. autoclave, the whole inner surface of which was lined with titanium. After the hydrogenation, the carbonyls of cobalt and, at the same time, of iron remaining dissolved in the liquid products were determined in the following way; the carbonyls in the filtrate free from finely divided metal precipitates were quantitatively decomposed into sulfates with sulfuric acid, and the resulting metal ions were determined by means of a chelate titration method using EDTA.

16) H. Pichler and H. Wallenda, *Brennstoff-chem.*, 21, 133 (1956).
17) H. Uchida and K. Bando, This Bulletin, 29, 953 (1956).
18) Most of the residue in Table IV is probably a mixture of compounds whose individual boiling points are higher than that of octylalcohol. The porducts from runs Nos. 24-26 and 29-33 were collected and removed from octylalcohol, together with the lower boiling constituents, by distillation. The composition of the material at the bottom, amounting to 14% of the total product, was then determined by means of a gas chromatographic procedure (for details of the procedure, cf. our previous paper[19]): it proved to include 4.5 2-ethylhexyl-isobutyrate, 12.3 2-ethylhexyl-*n*-butyrate, and 19.0 2-ethyl-1, 3-hexanediol in wt. %.
19) A. Matsuda and H. Uchida, *Rpt. Gn't. Chem. Ind. Research Inst. Tokyo*, 57, 50 (1962).

The product obtained from a raw material consisting of 0.5 mol. *n*-butyraldehyde, 0.44± 0.01 mol. propylene, 0.8 mmol. dicobalt octacarbonyl, and 1.6 mmol. iron pentacarbonyl should contain respective carbonyls equivalent to about 20 mg. atom cobalt and 20 mg. atom iron per liter.

The results, as summarized in Table V, indicate that only minute amounts of dibutyracetals and of butyraldehydes remain unhydrogenated in the product from the raw material including iron pentacarbonyl, while a greater amount remains in the product from the raw material including no iron pentacarbonyl, and that under relatively high pressures of carbon monoxide, the oil-soluble cobalt in the former product is about three times the amount of that in the latter product. The hydrogen absorption, in the absence of iron pentacarbonyl, stopped in a short time after the temperature was raised to 200°C, but in the presence of iron pentacarbonyl, it took place continuously until the hydrogenation was nearly completed. An additional fact sheds light on the role played by iron pentacarbonyl; a hydrogenation run of *n*-butyraldehyde (3 mol.) carried out in the presence of iron pentacarbonyl (3 mmol.) alone at 200 kg./cm^2 of the 1 : 1 synthesis gas showed scarcely any absorption of hydrogen, even after a prolonged reaction of 10 hr.[20] These facts lead to the conclusion that iron pentacarbonyl is not the real catalyst for the hydrogenation of the aldehyde but that it contributes to the hydrogenation by suppressing, at high temperatures, the decomposition of the dicobalt octacarbonyl that does catalyze the hydrogenation.

20) The product consisted of 12.1 *n*-butyraldehyde, 2.3 *n*-butanol, 1.1 C-8 saturated aldehydes, 3.4 *n*-butyr-*n*-butyrate, 67.5 C-8 unsaturated aldehydes, and 13.5 residue in wt. %.

Summary

Among the modifiers which have been tested, magnesium compounds are the most effective in producing a great amount of dimer aldehydes in the course of the propylene hydroformylation. The addition does not result in any reduction of the hydroformylation rate at 150°C. A certain amount of C-4 aldehydes had already been dimerized in the presence of dicobalt octacarbonyl alone, but the amount of dimerized aldehydes is greatly increased by the further addition of magnesium compounds, the total amount exceeding the sum of the amounts obtainable in the presence of either one of them. Moreover, the addition of an organic base further increases the yield of dimer aldehydes to some extent.

When starting with the raw material also containing iron pentacarbonyl, the hydrogenation of the aldehydes with the synthesis gas can be accomplished by the simple elevation of the temperature to 200°C. In the hydrogenation stage, iron pentacarbonyl does not behave as the catalyst for itself, but it contributes to the hydrogenation by suppressing, at that high temperature, the decomposition of the dicobalt octacarbonyl that is the real catalyst.

The Electronic Spectra and Electronic Structures of the Nitrobenzene and Nitrotoluene Anions

By Akira ISHITANI, Keiji KUWATA, Hiroshi TSUBOMURA* and Saburo NAGAKURA

(Received June 28, 1963)

Recently the study of the electronic and ESR spectra of anion radicals of organic compounds has made remarkable progress. The ESR spectra of the nitrobenzene and nitrotoluene anions have been observed by several research workers, and the hyperfine structures of these spectra have been analyzed.[1-7] The electronic spectra of these anions, however,

have never been observed. In view of this, we undertook to measure their electronic absorption spectra in parallel with their ESR spectra for the purpose of deepening our knowledge about the electronic structures of substituted benzene ion radicals. Furthermore, in order to clarify the nature of the observed electronic absorption bands, a theoretical study of the π-electron system of the nitrobenzene anion has been carried out by considering the configurational interaction among several electron configurations, such as ground, locally excited and charge-transfer configurations.

Experimental

Commercial nitrobenzene of E. P. grade was purified by vacuum distillation. Commercial *p*-nitrotoluene of E. P. grade was purified by repeating recrystallization from ethanol. Tetrahydrofuran (abbreviated hereafter to THF) and dimethoxyethane (abbreviated hereafter to DME) used as solvents were dried over calcium chloride, refluxed with sodium metal for two days, and fractionally distilled. Since the anion radicals are very sensitive to oxygen and moisture, their preparations and the measurements of their ESR and electronic spectra must be done in vacuo (10^{-4}~10^{-5} mmHg). Therefore, a vacuum line system with a tube attached for the ESR measurement and a quartz cell of 1 cm. path length for the electronic absorption measurement was used for the preparation of the anion radicals (see Fig. 1). They were prepared by keeping the 10^{-2}~10^{-3} M solutions of nitrobenzene or nitrotoluene in contact with a pure alkali metal film made by distillation in vacuo.

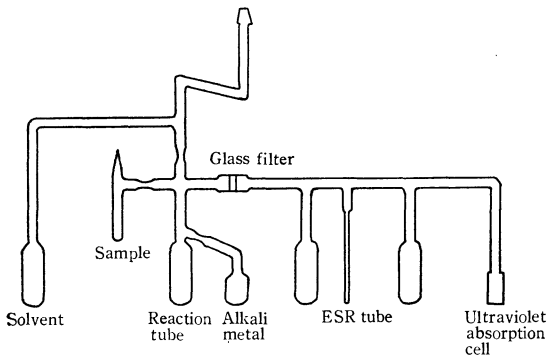

Fig. 1. The vacuum line system.

A Cary recording spectrophotometer model 14 M was used for the measurements of the near infrared, visible and ultraviolet absorption spectra. The ESR spectra were measured with a Hitachi ESR spectrometer model MPU-2B (X band, 100 kc. modulation).

Experimental Results

The Electronic Absorption of the Nitrobenzene Anion. — The DME solution of nitrobenzene turned a shallow brown when in contact with a potassium metal film and showed the ESR spectrum. With the progress of the reaction, the ESR absorption became stronger, the 260 mμ band of neutral nitrobenzene gradually decreased its intensity, and at the same time new absorption bands appeared. The color of the solution changed from brown to reddish orange and then to deep reddish purple. The electronic absorption spectrum and ESR spectrum of this solution were measured in parallel. The observed electronic absorption spectrum is shown in Fig. 2. The observed hyperfine structure of the ESR spectrum was explained well on the basis of the coupling constants determined by Ward et al.[6] The spin concentration of the solution was determined, with the result that 5~10% of nitrobenzene was converted into the radical in the solution.

The observed electronic spectrum of the solution consists of five absorption bands. However, great caution must be used in the identification of the electronic spectrum, since the solution might contain not only the nitrobenzene anion radical but also other by-products. When the solution was exposed to air, it immediately changed color from reddish purple to yellow and no longer showed the ESR signal. The electronic spectrum of the solution of the decomposed products was measured and compared with that of the anion radical solution. From this comparison, it was concluded that, among the five bands shown in Fig. 2, the two bands at 292 and 560 mμ which disappeared when the anion radical solution was in contact with air may safely be ascribed to the nitrobenzene anion.

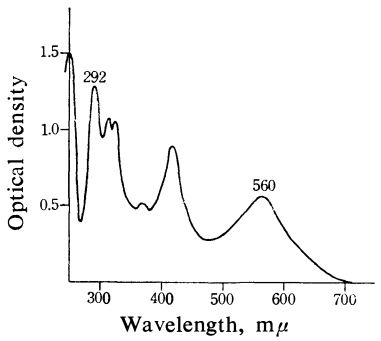

Fig. 2. The electronic spectrum of the DME solution of the nitrobenzene anion.

The Electronic Spectrum of the *p*-Nitrotoluene Anion.—A similar experimental study was also carried out with *p*-nitrotoluene. When in contact with a potassium metal film, the THF solution of *p*-nitrotoluene turned blue and gave the electronic spectrum

shown in Fig. 3. This spectrum is composed of three bands at 302, 607 and 875 mμ. The ESR spectrum was also measured; the result was completely coincident with that obtained by Maki et al.[7] The three electronic absorption bands shown in Fig. 3 and the ESR spectrum disappeared in parallel when the solution was exposed to air. Therefore, the 302, 607 and 875 mμ bands may safely be assigned to the *p*-nitrotoluene anion.

Theoretical

Molecular orbital calculations of the π-electron system of the nitrobenzene anion were carried out in order to clarify the nature of the observed transition bands and obtain some knowledge about the electronic structure of the anion radical. In the actual calculations, the nitrobenzene anion was separated into two components; the benzene anion and the nitro group. The interaction between the components was calculated by taking into account the interaction among such

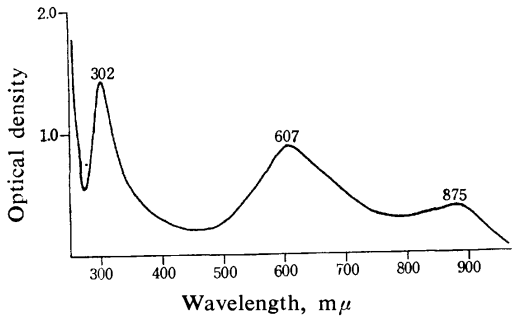

Fig. 3. The electronic spectrum of the THF solution of the *p*-nitrotoluene anion.

π-electron configurations as ground, locally excited and charge-transfer configurations. In order to perform this kind of calculation, we need knowledge about the energy values and wave functions for the respective components. Therefore, first of all, the calculation of the benzene anion was carried out.

The calculation of the energy levels of the benzene anion was carried out by considering the configurational interaction among the two ground and nine excited π-electron configurations which are obtained by putting seven π-electrons into the molecular orbitals of the neutral benzene. The detailed description of our calculations may be omitted, since similar calculations have been made by Hoijtink.[8] In the actual calculation, the approximation of zero differential overlap was adopted.[9] The repulsion integrals of the (AA/AA) and (AA/BB) types necessary for the evaluation of the configuration energies and the interaction energies between the configurations were obtained by the method of Pariser and Parr.[9] The finally-evaluated energy levels and wave functions are given in Table I. These results are in good agreement with those obtained by Hoijtink.[8]

Using the above results about the π-electron structure of the benzene anion, the energy levels and wave functions of the nitrobenzene anion were calculated by a method similar to that used for the theoretical consideration of the π-electron structures of the nitromethyl anion,[10] nitrobenzene,[11] nitroamide, and ethyl nitrate.[12] That is to say, the effect of the nitro group on the energy levels of the benzene anion was considered in terms of the configuration interaction among the ground, locally excited and charge-transfer configurations. The geometrical configuration of the nitrobenzene anion necessary for the actual calculation was assumed to be equal to that of nitrobenzene itself as determined by Trotter.[13]

In the evaluation of the ground configuration energy, electrostatic interaction energy was taken into account. This is because there is a large heterogeneity in the π-electron distribution of the nitro group and the nitrogen atom is positively charged to a great extent. The thirteen locally excited configurations were considered. The energy values of the twelve configurations caused by the local excitation within the benzene anion were calculated by adding electrostatic interaction energy to the calculated excitation energy of the benzene anion given in Table I. The energy of the configuration locally excited within the nitro group was determined from the experimental value of the $\pi \rightarrow \pi^*$ transition energy of the nitromethane[9] and the electrostatic energy.

In addition to these, a charge-transfer configuration which is caused by moving an electron in the highest occupied orbital of the benzene anion to the lowest vacant orbital of the nitro group was taken into consideration. The energy of this configuration was obtained as follows: (Ionization potential of the benzene anion) − (electron affinity of the nitro group) = (electron affinity of benzene) − (electron affinity of the nitro group) = −0.54 −0.4 = −0.94 (eV.) The electron affinity of benzene was taken from the paper by Hush

* φ_a, φ_b, φ_c, are the molecular orbitals of the nitro group evaluated by Tanaka (J. Tanaka, *J. Chem. Soc. Japan, Pure Chem. Soc. (Nippon Kagaku Zasshi)*, **78**, 1636 (1957)).

** S and A mean symmetric and antisymmetric, respectively, with respect to the symmetry plane perpendicular to the plane of the nitrobenzene anion.

and Pople.[14] The electron affinity of the nitro group was taken to be 0.4 eV., the value used for the calculation of a series of nitro compounds.[10-12] The energies and wave functions of the configurations taken up in the present calculations are shown in Table II.

The off-diagonal matrix elements (H_{ij}'s) of the total electronic Hamiltonian which represent the interaction between two appropriate configurations were evaluated by the aid of the method presented by Pople[15] and by Murrell and Longuet-Higgins.[16] The results are shown in Table III. The repulsion integrals necessary for the evaluation of the interaction energies between configurations locally excited in different parts of the molecule were obtained in the same way as in the case of the benzene anion. The interaction energies between the charge-transfer configuration and the others are expressed using the core resonance integral, β_{CN}, between the adjacent nitrogen and carbon atoms. The best value of β_{CN} was estimated to be -2.30 eV. for neutral nitrobenzene.[10] It may be expected that the $|\beta_{CN}|$ of the nitrobenzene anion is larger than that of neutral nitrobenzene. In the present calculations, β_{CN} was estimated to be -3.0 eV. By solving the secular equation composed of the elements given in Tables II and III by the aid of an electronic computer (IBM 7090), the energy levels and wave functions of the nitrobenzene anion were evaluated. (see Fig. 4). Of these, the lowest four energy levels and their wave functions are shown in Table IV.

Furthermore, the oscillator strength (f) values of the three longer wavelength transitions were calculated by means of the usual equation, $f=1.085\times10^{-5}\nu Q^2$, where Q and ν are the transition moment (in units of Å) and the evaluated transition energies (in units of cm^{-1}) respectively. The evaluated oscillator strength values are shown in Table V, together with observed and calculated transition energies.

Discussion

On the basis of the comparison of the calculated transition energies and oscillator strengths with the observed results, the 560 mμ and 292 mμ bands can safely be ascribed to the $W_1 \rightarrow W_2$ and $W_1 \rightarrow W_3$ transitions respectively. As may easily be seen from the wave functions given in Table IV, the W_1 and W_2 states may be said to be mainly caused by the resonance interaction between the ground and charge-transfer configurations, although there are also small contributions from locally excited configurations. Therefore, the strongest 560 mμ band may be regarded as the intramolecular charge-transfer band. In the upper state of the 292 mμ band, the contribution of the local excitation within the benzene anion is large, amounting to 88%. Therefore, this band can be interpreted as the shifted band of the 600 mμ band of the benzene anion. It is noteworthy that the band of the benzene anion shows a large blue shift when the nitro group is introduced. This blue shift phenomenon exhibits a striking contrast to the red shift phenomena usually observed with the 260 mμ band of the neutral benzene molecule.[17] In the case of the nitrobenzene anion, the resonance between the ground and charge-transfer configurations is strong; consequently, the stabilization energy of the ground configuration due to the resonance is larger than that of the locally excited configuration. This is the reason why the 600 mμ band of the benzene anion shows the blue shift when the nitro group is introduced.

In addition to the above-mentioned two bands, the theoretical results show that another weak band, one corresponding to the $W_1 \rightarrow W_{10}$ transition, may appear in the near infrared region, say, the 800 mμ region. Although a weak and broad absorption was found in that region, no clear absorption peak could be observed in the case of the nitrobenzene anion.

This may be due to the fact that the band should be very weak, as is revealed by the small value of the calculated oscillator strength; moreover, the solvent absorption in the expected wavelength region prevents any accurate absorption measurement. In the case of the *p*-nitrotoluene anion, we observed the absorption peak at 875 mμ. This may correspond to the same transition.

TABLE VI. ODD ELECTRON DENSITIES AND COUPLING CONSTANTS OF THE NITROBENZENE ANION

Atom	Odd electron density		Coupling constant, gauss obs.
	Calcd.	Obs.	
N	0.2651	0.212	10.33
C^o	0.0401	0.124	3.46
C^m	0.0401	0.040	1.13
C^p	0.1495	0.138	3.86

The observed coupling constants[6] and the odd electron densities derived from them are shown in Table VI, together with the theoretical values of odd electron densities evaluated by the use of the wave function Ψ_1' in Table IV. The odd electron densities on the ring carbon atoms, ρ_i^C's, were obtained using the usual equation, $\rho_i^C = a_i^H / Q_H$.[18] Here a_i^H is the observed coupling constant of the ring proton adjacent to the carbon atom under consideration and Q_H was taken to be 28 gauss.[19] The odd electron density on the nitrogen atom, ρ^N, was obtained by using a similar equation, $\rho^N = a^N / Q_N$, where a^N the observed coupling constant and Q_N was assumed to be 49 gauss, the mean value of the coupling constants of nitrogen in the anion radicals of several aliphatic nitro compounds.[20] The odd electron densities estimated from the coupling constants are in good agreement with the theoretical ones except in the case of the ortho carbon atom.

NOTES

The Oxidation of (+)-p-Menth-3-ene with Selenium Dioxide

By Takayuki SUGA, Masako SUGIMOTO and Tamon MATSUURA

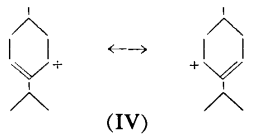
(Received March 8, 1963)

The oxidation of (+)-*p*-menth-3-ene with *t*-butyl chromate has been recorded to afford (+)-*p*-menth-3-en-2-one (major product) and (±)-*p*-menth-3-en-5-one (minor product),[1] but only the latter ketone was produced by oxidation with selenium dioxide in an alcoholic solution.[2,3] The action of selenium dioxide in acetic acid appears not to have been described as yet. We have now investigated this reaction in an 8 : 11 mixture* of glacial acetic acid and acetic anhydride in order to check the position of the oxidative attack.

The oxidation was carried out at 50°C for 40 hr. with an equimolar amount of selenium dioxide. *p*-Menth-3-en-5-yl acetate (I; 35% based on the sample taken), *p*-menth-3-en-5-ol (II; 18%) and *p*-menth-3-en-5-one (III; 8%) were obtained, all of them optically inactive. No oxidation product resulting from the attack on the other allylic methylene (2-position) could be isolated in spite of a careful examination. This finding was further supported by the fact that such successive treatments as saponification of the whole reaction products, oxidation with chromic trioxide-pyridine complex and final dehydrogenation gave thymol as the resultant. Not even a trace of carvacrol, which should be derived from C_2-oxidation products, could be detected.

The hydroxyl group of II and the acetoxy group of I apparently possessed trans-configuration with respect to the methyl group attached to C_1, as II and I were converted into the 3, 5-dinitrobenzoate which coincided with that of the (±)-*trans-p*-menth-3-en-5-ol characterized by Macbeth et al.[4]

In order to explain both the formation of the optically inactive oxidation products and the attack on only C_5-active methylene, we suppose the formation of a carbonium ion intermediate IV in the resonance state, when



(IV)

selenium dioxide attacks *p*-menth-3-ene. The I (major product) is explained as resulting from the reaction between IV and the solvent (i. e., the acetoxy anion). II may be formed when water, which is considered to be produced by the attack of the oxidant, reacts on IV, and then II is party oxidized to yield III.

Experimental

Sample.—(+)-*p*-Menth-3-ene[5] (b. p. 168~169°C, n_D^{25} 1.4490, d_4^{25} 0.8080, $[\alpha]_D^{25}$ +114.9°) was prepared from (−)-menthol by the pyrolysis of methyl (−)-menthylxanthate (m. p. 39.5~40.5°C). The racemization procedure with *p*-toluenesulfonic acid[6] showed the hydrocarbon to consist of (+)-*p*-menth-3-ene (72%) and (+)-*p*-menth-2-ene (28%). However, the isolation of pure *p*-menth-3-ene was so difficult that the hydrocarbon mixture was used without further purification.

Oxidation.—To the sample hydrocarbon (41.5 g.) dissolved in a mixture of glacial acetic acid (41 g.) and acetic anhydride (56 g.), selenium dioxide (33.3 g.) was added in seven portions over a 15-hr. period at 50°C under agitation in an atmosphere of nitrogen. After the mixture had been stirred at the same temperature for a further 25 hr., it was subjected to steam-distillation. The residue seemed to be metallic selenium and a selenium-containing polymerized substance. The distillate, after being treated as usual, gave a neutral oil (26.0 g., $[\alpha]_D^{13}$ +3.7° (l, 1), E. V. 160.3), the chromato-strip chromatogram[7] of which exhibited three spots corresponding to those of I, II and III respectively.

The Identification of Reaction Products.—(1) On treating the neutral oil (8.00 g.) with an excess of 2, 4-dinitrophenylhydrazine in ethanolic hydrochloric acid, only 2, 4-dinitrophenylhydrazone (2.03 g., m. p. and mixed m. p. 145~146°C) of (±)-III was obtained.

(2) The neutral oil (5.00 g.) was treated with a 2 N hydrochloric acid solution of 2, 4-dinitrophenylhydrazine and subjected to steam-distillation in a neutral medium, and an oil (3.98 g.) containing no ketone (by the IR spectrum) was obtained. The oil was chromatographed on a silica gel column with a 17 : 3 (in vol.) mixture of isopropyl ether and *n*-hexane as the eluant, and was separated into three fractions. The first fraction (0.07 g.) was the unchanged hydrocarbon, which was found to consist of *p*-menth-3-ene and *p*-menth-2-ene by infrared spectrum comparison. The second fraction (1.92 g., b. p. 93~94°C/9 mmHg, n_D^{25} 1.4555, d_4^{25} 0.9344, $[\alpha]_D^{20}+0.12°$*, $\nu_{C=O}$ 1736 cm^{-1}, ν_{C-O-} 1239 cm^{-1}) was (±)-I, which was identified by converting it into (±)-II. The third fraction (1.76 g., b. p. 92°C/10.5 mmHg, n_D^{25} 1.4770, d_4^{25} 0.9134, $[\alpha]_D^{20}$ ±0°, ν_{OH} 3344 cm^{-1}, ν_{C-OH} 1028 cm^{-1}) was (±)-II, which was identified by converting it into the 3, 5-dinitrobenzoate (m. p. 141.5~142°C; lit.[4], m. p. 142°C as (±)-*trans*-*p*-menth-3-en-5-yl 3, 5-dinitrobenzoate) and also into (±)-III on chromic trioxide-pyridine complex oxidation.

(3) The neutral oil (3.7 g.) was successively subjected to saponification with 0.5 N alcoholic potassium hydroxide, oxidation with chromic trioxide-pyridine complex, and dehydrogenation with palladium charcoal (palladium content: 30%) at 230°C for 15 hr. A phenolic substance (1.4 g., m. p. 49~51°C) was thus obtained, which was identified as thymol by the mixed melting point determination. The gas chromatogram of the substance did not show the peak corresponding to carvacrol, but a single peak was observed.

* Judging from the gas chromatogram, which exhibited a small peak of the sample hydrocarbon in addition to a main peak of the acetate, the ester was contaminated with a small amount of the unchanged hydrocarbon. Accordingly, this small optical rotation value is due to the hydrocarbon.

Summary

The oxidation of (+)-*p*-menth-3-ene by selenium dioxide in a mixture of glacial acetic acid and acetic anhydride was examined with special attention paid to the position of the oxidative attack, i. e., the C_2- or C_5-position of the hydrocarbon. Careful examination of the reaction product showed that this oxidation yielded only (±)-*p*-menth-3-en-5-yl acetate (major product), (±)-*p*-menth-3-en-5-ol and (±)-*p*-menth-3-en-5-one. Thus, this oxidant selectively attacks an active methylene group at the C_5-position of *p*-menth-3-ene.

The Redetermination of the Lattice Constants of Phenazine 5, 10-Dioxide

By Yoshiyuki NAMBA, Tsutomu ODA and Tokunosuké WATANABÉ

(Received June 6, 1963)

In a previous paper,[1] we have reported on the crystal structure of phenazine 5, 10-dioxide. Quite independently, another paper on the same subject has been published by Curti et al.[2]

The atomic coordinates and the crystal structure derived therefrom agree in both papers in the main. However, there are small differences in the unit cell dimensions between the two investigations. Therefore, we have carried out a careful determination of the unit cell dimensions on two specimens, one prepared by us and another kindly sent to us by Professor Curti. It was not possible to get more accurate values for the spacings on the basis of powder diffractometry because of overlapping. A Weissenberg camera was used, and the Debye-Sherrer reflections from pure sodium chloride were superimposed on reflections from a single crystal of phenazine 5, 10-dioxide. There were no significant differences between the unit cell dimentions obtained from the two specimens. They are:

$$a = 7.75 \pm 0.02\,\text{Å}, \qquad b = 4.09 \pm 0.02\,\text{Å},$$

$$c = 15.36 \pm 0.05\,\text{Å}, \text{ and } \beta = 104°48' \pm 10'.$$

The new data are closer to those of Curti et al. Fortunately, there are no serious changes necessary between the intramolecular atomic distances reported in the previous paper, except

1) Y. Namba, T. Oda and T. Watanabé, This Bulletin, **36**, 79 (1963).
2) R. Curti and V. Riganti, *Instituto Lombardo (Rend. Sc.)*, **A94**, 117 (1960).

that the value of 1.39 Å for the C_6–N bond should be revised to 1.36 Å. There are slightly larger changes in the intermolecular atomic distances between molecules related by the unit translation along the b-axis, namely, +0.09 Å on the average, the largest being between C_5 and O′ (Fig. 5), for which the reported value, 3.45 Å, should be read as 3.59 Å.

The Spectral Dependence of the Photoconduction and the Mobility of the Charge Carrier in a Single Crystal of the Pyrene-Tetracyanoethylene Complex

By Haruo KURODA, Keitaro YOSHIHARA and Hideo AKAMATU

(Received June 13, 1963)

Photoconduction has been observed with solid molecular complexes involving polycyclic aromatic hydrocarbons as an electron donor and 1, 3, 5-trinitrobenzene (TNB), bromanil, or tetracyanoethylene (TCNE) as an electron acceptor.[1] In the electronic spectra of these solid complexes, the absorption bands associated with the intermolecular charge-transfer excitation have been found in the visible region.[2,3] We have shown in a previous paper[1] that a weak photoconductive sensitivity in the wavelength region of the first charge-transfer band is appreciably dependent on the process of the crystal preparation, while the sensitivity in the shorter wavelength region is not. It seemed, therefore, that it would be interesting to examine the photoconduction with a well-grown single crystal of these complexes.

We obtained a single crystal of the pyrene-TCNE complex by slowly evaporating the solvent from a chloroform solution containing equivalent amounts of pyrene and TCNE. The crystal thus prepared showed a marked photoconductive sensitivity, a sensitivity much higher than that of various other charge-transfer complexes. We have examined the spectral dependence of photoconduction with a single crystal a few millimeters square and about one millimeter thick. The results obtained with a surface-type cell are shown in Fig. 1, together with the spectral dependence curve for a polycrystalline specimen which was grown from the melt of the complex. The spectral dependence curve of a single crystal rises steeply in the wave number region from 15000 to 20000 cm^{-1}. No photoconduction could be detected practically in the region corresponding to the first charge-transfer band, in contrast to the spectral dependence for a polycrystalline specimen. The threshold of photoconduction can be located at 13500 cm^{-1} (1.67 eV.), a value which coincides with the energy gap, 1.5~1.6 eV., determined from the temperature dependence of the dark conductivity. It is evident, therefore, that the photoconduction observed in the lower wave number region with a polycrystalline specimen is not an intrinsic one.

The determination of the crystal structure of this complex is now in progress. The preliminary results show, that it is monoclinic, with the cell dimensions $a=14.58$ Å, $b=7.34$ Å $c=8.09$ Å and $\beta=92.4°$, and that it belongs to the $P2_1/a$ space group. Two molecules of pyrene and two molecules of TCNE are contained in a unit cell. The face of a plate-like single crystal is the bc plane, in which the transition moment of the charge-transfer excitation is nearly parallel to the c-axis. However no appreciable anisotropy was found in the dark conductivity or in the photoconductivity.

The drift mobility of the charge carriers in this complex was determined from the observation of the photocurrent pulse[4] produced by an irradiation of a light pulse 1 μ sec. in duration from an air-gap spark. At room temperature, the drift mobility in the direction perpendicular to the bc plane was 0.15~0.2 cm^2/V. sec. for the electron and 0.05~0.08 cm^2/V. sec. for the positive hole. These values are smaller than the drift mobility of charge carriers in an anthracene crystal.[4,5] We could

not detect any appreciable change in the mobility from 5°C to 40°C. These results seem to indicate that the carriers in the pyrene-TCNE complex are of a more localized nature than those in anthracene or in other simple organic solids. This is quite reasonable if we suppose, as we have postulated in the previous papers,[2,3] that in the lowest conduction state of a solid molecular complex such as pyrene-TCNE, an conduction electron moves in the crystal lattice primarily by jumping from one acceptor molecule to another acceptor molecule, while a positive hole moves from one donor molecule to another donor molecule. The height of the photocurrent pulse was almost three times as much for the electron as for the positive hole. The stationary photocurrent was also higher when the light was irradiated through the negative electrode than in the reverse case. These results indicate that electrons make a larger contribution to the photoconduction than positive holes. This is probably the result of the difference in mobility.

SHORT COMMUNICATIONS

*The Solid Complex of Silver Nitrate and Ethylene**

By Kimio TARAMA, Mitsuhiko SANO and Kengo TATSUOKA

(Received August 9, 1963)

The syntheses of a number of solid complexes of silver nitrate with several olefins have been reported in the literatures,[1,2] but there seems to have been no mention of the solid complex with ethylene. In this laboratory, the solid complex of silver nitrate with ethylene has been prepared from an aqueous solution under

suitable temperature and silver-nitrate concentration conditions. In this paper the method of preparation and some properties will be reported.

Experimental.—The silver nitrate used was reagent grade. The purity of the ethylene was 99.6%; no other olefins were detected by gas chromatographic analysis. In the preparation of the solid complex, when ethylene gas was bubbled through the saturated aqueous solution of the silver nitrate (6 N) at 0°C, a white precipitate appeared. This precipitate in solution disappeared when nitrogen gas instead of ethylene was bubbled through this solution, and it was repeatedly regenerated by the repetition of the above-mentioned procedure. The resulting solid precipitate was isolated from the solution and dried on a glass filter cooled at 0°C by passing ethylene over it under a pressure of about 800 mmHg.

The dried samples were stored at the temperature of dry ice in glass containers in an ethylene atmosphere. The equilibrium pressure data were obtained with a manometric apparatus. The ethylene content of the complex was calculated from the amount of gas resulting from the complete decomposition of the samples, and then the amount of silver in the residue was measured gravimetrically in the analytical form of silver chloride and that of nitrate ions, by ultraviolet method.

Results and Discussion.—The solid silver nitrate-ethylene complex is in the form of white needle-like crystals and is stable only at temperature below about −30°C or under higher partial pressures of ethylene, like other silver salt-olefin complexes.[1] This complex dissociates quantitatively to ethylene and crystal silver nitrate without forming polymerized or oxidized products of ethylene at 30°C. The analytical data of this complex are presented in Table I. The quantities of ethylene released from the complex correspond closely to 0.5 mol. of ethylene par mole of silver nitrate for three samples. These samples also indicate no change in the composition of the complex with the contamination of the water. The ratio of nitrate ions to silver is about unity. These analytical data lead to the conclusion that the composition of the complex

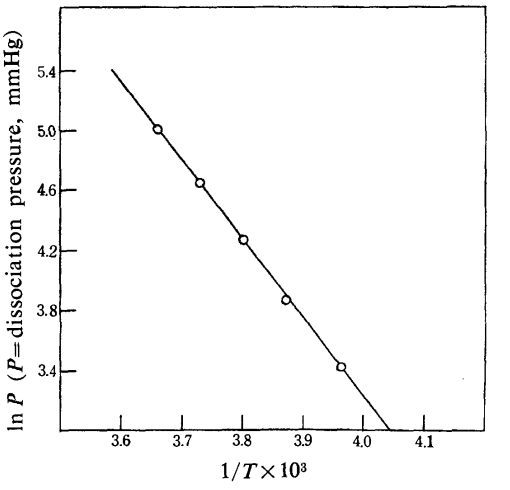

Fig. 1. Dissociation pressure of $(AgNO_3)_2\cdot C_2H_4$.

is $(AgNO_3)_2\cdot C_2H_4$. Equilibrium pressures (P) in the temperature range from 253°K to 273°K are illustrated in Fig. 1. From these data the heat of dissociation is calculated to be 10.6± 0.2 kcal. for $(AgNO_3)_2\cdot C_2H_4$. This is about twice as large as the value (5.8 kcal.)* for $AgNO_3\cdot C_2H_4$ in an aqueous solution.

The complex formation between silver ions and ethylene may be described by the following equations in an aqueous solution.[3]

$$Ag^+ + C_2H_4 \overset{K_1}{\rightleftarrows} Ag^+\cdot C_2H_4 \quad (1)$$

$$Ag^+\cdot C_2H_4 + Ag^+ \overset{K_2}{\rightleftarrows} (Ag^+)_2\cdot C_2H_4 \quad (2)$$

$$Ag^+\cdot C_2H_4 + C_2H_4 \overset{K_3}{\rightleftarrows} Ag^+\cdot (C_2H_4)_2 \quad (3)$$

Trueblood and Lucas found K_1 to be 85.3 and K_2 0.15 at 25°C by distribution methods.[4] These equilibrium constants indicate that the fraction of $(Ag^+)_2C_2H_4$ in silver and ethylene complexes in an aqueous solution is very small, but that in higher concentrations of silver nitrate, the concentration of the species having this composition will rise in accordance with the reaction of Eq. 2; then the species will be

A New Catalyst System for the Polymerization of Tetrahydrofuran

By Iwao YAMASHITA, Minoru SERIZAWA and Takaharu MIYAKAWA

(Received August 21, 1963)

The ring-opening polymerization of tetrahydrofuran (THF) by the use of metal halides or triethyl aluminum as a catalyst has recently been reported by several authors.[1] In such cases, a cocatalyst or comonomer, such as alkyl halides, ortho acid esters, hydrogen halides, alkylene oxides, oxethanes, diketene, β-propiolactone, and phenyl isocyanate, have been used together with the catalyst.

We have now examined the polymerization of THF by the use of organometallic compounds (Et_3Al, Et_2AlCl, Et_2Zn) or metal halides ($BF_3 \cdot Et_2O$, $AlCl_3$, $FeCl_3$) in the presence of phosphorus pentaoxide (P_2O_5) and have found that Et_3Al was the most effective of the substances examined.

Bulk polymerization was carried out in a nitrogen atmosphere in a sealed test tube. The polymeric product was isolated by pouring the reaction mixture into a large quantity of water containing hydrochloric acid. The crude polymer was washed with methanol and then dissolved in THF at room temperature by leaving it standing for 24 hr. The THF-soluble fraction was recovered by again pouring the solution into a large excess of water and then drying it in vacuo. The THF-insoluble fraction was washed with THF and dried in vacuo.

Several results of the polymerization of THF by the use of the P_2O_5-Et_3Al system are shown in Table I and Figs. 1 and 2. The effect of P_2O_5 is obvious. Both the THF-soluble and the THF-insoluble fraction contain a small amount phosphorus.*

When the THF-soluble fraction was compared with polytetrahydrofuran prepared by the method of Muetterlies[3] (catalyst: PF_5), considerable differences in the thermal properties were noticed, whereas the X-ray diffraction patterns and infrared spectra of the two polymers were similar. On the other hand, an apparent difference was found between those of the THF-soluble fraction and those of the

The Electrokinetic Potential and Surface Acidity of Titanium Dioxide

By Tetsuo MORIMOTO and Masashi SAKAMOTO

(Received August 24, 1963)

When an insoluble metal oxide is in equilibrium with water, the solid will be covered with surface hydroxyl groups as a result of surface hydration. The present communication deals with the dependence of the electrokinetic potential and the surface acidity of titanium dioxide on its heat treatment in order to clarify the dissociation of surface hydroxyl groups on titanium dioxide.

Titanium dioxide obtained by the hydrolysis of titanium sulfate was treated with ammonium hydroxide to remove contaminating sulfate groups. After having been sufficiently washed with water, the sample was dried and calcined at given temperatures. The electrokinetic potentials obtained in water by the streaming-potential method are shown in Fig. 1. The charge of titanium dioxide is positive on the samples treated at 100 to 700°C, but it changes to a negative value after treatment at higher temperatures. An isoelectric point appears on a sample treated at about 800°C, which agrees with the transition temperature of anatase to rutile.

In the next place, the surface acidity of these samples was examined by the dye-adsorption method. To prepare the dye solution, 10 mg. of methylred was dissolved in 100 ml. of isooctane.[1] 0.2 g. of titanium dioxide was then shaken with 4 ml. of the dye solution. After the adsorption of dye molecules, the

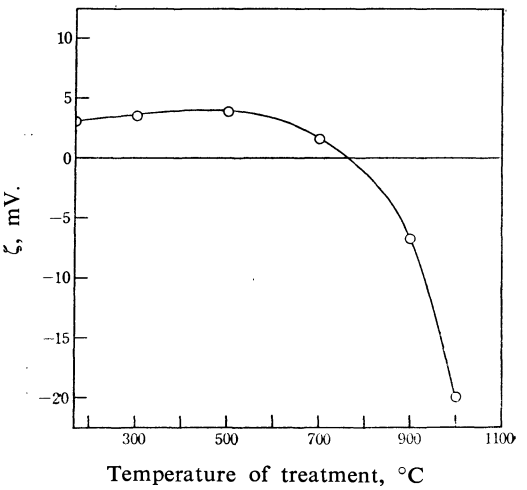

Fig. 1. Electrokinetic potential (ζ) of titanium dioxide.

1) K. Tanabe and M. Katayama, *J. Res. Inst. Catalysis, Hokkaido Univ.*, 7, 106 (1959); C. Walling, *J. Am. Chem. Soc.*, 72, 1164 (1950).

reflectance of the powder was measured by a spectrophotometer. The color of the adsorbed dyestuff was a basic one, yellow, in the samples treated at lower temperatures, but in the samples treated at 1000°C it was an acidic color, red, as is recorded in Fig. 2. Thus the change in the surface acidity of titanium dioxide appears to correspond to the transition temperature of the crystal, as in the case of the electrokinetic potential.

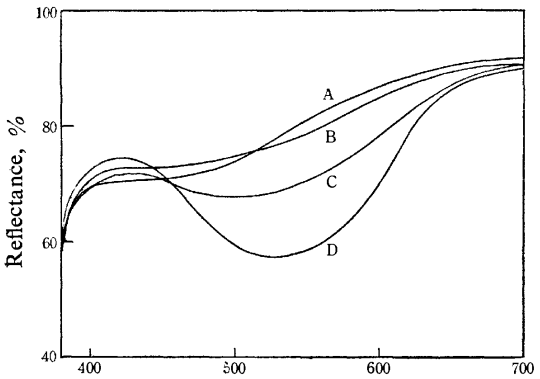

Fig. 2. Reflection spectra of methylred adsorbed on titanium dioxide, treated at A, 100°C; B, 500°C; C, 700°C; D, 1000°C.

It is possibly considered that the surface hydroxyl groups situated on titanium dioxide dissociate as follows:

$$\equiv TiOH \rightarrow \equiv Ti^{+} + OH^{-} \quad (1)$$

$$\equiv TiOH \rightarrow \equiv TiO^{-} + H^{+} \quad (2)$$

Dissociation resulting from Eq. 1 will give a positive charge on the surface and a basic color for the indicator, while that from Eq. 2 a negative charge and an acidic color. Judging from the present investigation, it is plausible that, on treatment at temperatures lower than 800°C, the dissociation of surface hydroxyl groups on titanium dioxide follows Eq. 1, while on treatment at higher temperatures it follows Eq. 2.

It is known that the distances between neighboring oxygens are longer than about 3.00Å in basic metal hydroxide crystals, while in acidic ones they are less than 2.70Å.[2] The crystallographic data on titanium dioxide, described by Cromer and Herrington,[3] are represented in Table I. If we assume that

Table I. Oxygen-oxygen distances in anatase and rutile, Å

Anatase	Rutile
2.802	2.779
2.446	2.526
3.040	

the surface of titanium dioxide is hydrated to form surface hydroxyl groups without varying the O–O distances greatly from those given in Table I, it may be expected that rutile has an acidic surface and anatase, a basic one. Rather we may propose from the present results that the exposed surfaces of anatase are rich in longer O–O bonds. In conclusion, the fact that titanium dioxide may have either a positive or a negative charge according to its modifications should play an important role in the interfacial phenomena of titanium dioxide.

The Separation and Determination of Polycyclic Aromatic Hydrocarbons by Thin Layer Chromatography

By Hidetsuru MATSUSHITA, Yasutomo SUZUKI and Hiroyuki SAKABE

(Received August 28, 1963)

This study presents a method for the separation and the quantitative determination of polycyclic aromatic hydrocarbons by thin-layer adsorption chromatography.

Anthracene, pyrene, 1, 2-benzanthracene, 3, 4-benzpyrene, perylene and 1, 12-benzperylene were used as samples. They were all proved to be chromatographically pure. As the adsorbent layer, silica gel Woelm for thin layer chromatography (M. Woelm · Eschege, Germany) was used in a thickness of about 300 μ. The chromatoplate was activated by heating at 100°C for 15 min. in an electric furnace and then by heating it at 60°C and 0.1 mmHg for 30 min. in a vacuum desiccator. The activated plate was transferred quickly onto a hot metal plate of about 60°C, and 3 μl. of a benzene solution of the test sample were spotted on it. The ascending development was carried out in a chromatographic chamber using as the developing solvent *n*-hexane, *o*-dichlorobenzene and pyridine (10 : 1 : 0.5). The humidity in the chromatographic chamber was about 25%. The developing time was about 60 min., and the height of development was about 12 cm. Spots of the separated hydrocarbons on the plate were detected by fluorescence under a 365 mμ ultraviolet light.

The minimum values of aromatic hydrocarbons detectable by this method were within the range of 0.13 μg. to 0.0017 μg., as Table I shows. As these values obtained by acetylated paper chromatography have been reported to be 2 μg. to 5 μg.,[1] this method is very sensitive in detecting these compounds.

TABLE I. R_f VALUES AND MINIMUM DETECTABLE VALUES OF POLYCYCLIC AROMATIC HYDROCARBONS BY THIN LAYER CHROMATOGRAPHY

Substance	R_f value[1]	Minimum detectable value, μg.
Anthracene	0.51	0.03
Pyrene	0.41	0.13
1,2-Benzanthracene	0.32	0.010
3,4-Benzpyrene	0.23	0.007
Perylene	0.19	0.0017
1,12-Benzperylene	0.15	0.002

1) To obtain these R_f values, samples were spotted in 5 min. on a hot metal plate (ca. 60°C) in a room of 49% relative humidity at 29°C and developed in a chromatographic chamber of 27% relative humidity at 29°C for 60 min.

It must be noticed that the R_f values were highly affected by the humidity in the chromatographic chamber as well as by that in the environmental air in which samples were spotted. An increase in the humidity gave larger R_f values, resulting in an unsatisfactory separation of the aromatic hydrocarbons.

In this study, a linear relationship was found between the area of spot and the logarithm of the amount of aromatic hydrocarbon (Fig. 1). On the basis of this relationship, aromatic hydrocarbons were determined with an accuracy of ±5% if such experimental conditions as activation and humidity were fixed. In this connection, it is recommended that the amount of an unknown sample is calculated using a calibration curve which is drawn from three or more spots of known amounts of pure hydrocarbon on the plate on which the unknown sample is spotted.

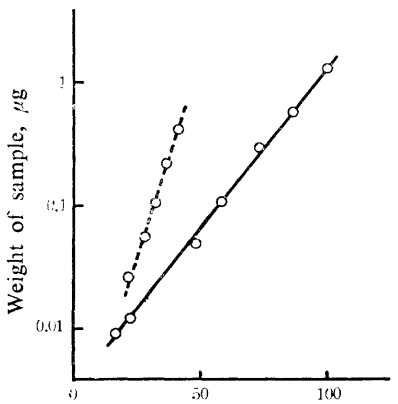

Fig. 1. Relationship between area of spot and logarithm of weight for 3,4-benzpyrene (——) and for 1,2-benzanthracene (----) on the thin layer chromatoplate.

This method might offer a useful tool for the microdetermination of carcinogenic hydrocarbons such as 3,4-benzpyrene in air pollutants, exhaust gases or the smoke of cigarettes.

The Self-diffusion Coefficients of Carbon Dioxide, Hydrogen Carbonate Ions and Carbonate Ions in Aqueous Solutions

By Kunihiko KIGOSHI and Takusei HASHITANI

(Received September 17, 1963)

The distribution of natural radiocarbon and man-made radiocarbon in the atmosphere and the ocean depends on the exchange rate of carbon between the atmosphere and the ocean.[1] In recent publication Bolin[2] has pointed out that this carbon exchange between the atmosphere and the ocean depends on the diffusion of carbonates ions in the sea water.

This short communication will present the results of studies of the self-diffusion of carbon dioxide, hydrogen carbonate ions and carbonate ions in aqueous solutions. The measurements of the self-diffusion coefficients were made using a modified Northrop-McBain type diaphragm cell. Both the upper and the lower compartments of the cell were filled with solutions of the same chemical composition. The solutions contain carbon dioxide, hydrogen carbonate ions, carbonate ions and sodium ions, and they were adjusted to pH 4.0, 8.0 and 12.5. More than 99% of the carbon atoms in the solution were contained as carbon dioxide molecules in the solution of pH 4.0, as hydrogen carbonate ions in the solution of pH 8.0, and as carbonate ions in the solution of pH 12.5. Therefore, each solution could be regarded as a pure solution of these molecules or ions. The concentration of carbon-containing ions in these solutions was held ca. 0.1 F while that of carbon dioxide was ca. 0.06 F. The carbon tracer C-14 was present in the lower compartment of the cell.

After the diffusion had continued for one or two days, barium carbonate was precipitated from the solution in each compartment. By β-rays assays of these precipitates, the diffusion coefficients of carbon dioxide, hydrogen carbonate ions and carbonate ions in aqueous solutions shown in Table I were obtained. The cell constant was determined by the diffusion of a 0.1 F potassium chloride solution into pure water, assuming a standard value of 1.87×10^{-5} cm^2/sec. for the diffusion coefficient of this solution.[3]

TABLE I. SELF-DIFFUSION COEFFICIENTS OF CO_2, HCO_3^- AND CO_3^{2-} (10^{-5} cm^2/sec.)

Temp., °C	CO_2	HCO_3^-	CO_3^{2-}
0.0	0.953±0.013	0.521±0.011	0.414±0.011
25.0	1.94 ±0.023	1.09 ±0.015	0.804±0.008
30.0	2.18 ±0.019	1.28 ±0.015	0.974±0.005

The details of the experimental procedure and a discussion of the hydration of carbon dioxide, hydrogen carbonate ions and carbonate ions in aqueous solutions based on the measured self-diffusion coefficients will be published in the near future in this Bulletin.

*The Separation of Amino Acids with an Ion-exchange Membrane**

By Yujiro HARA

(Received February 8, 1962)

The group separation of a mixture of amino acids obtained from the hydrolysis of gluten has been carried out by electrodialysis, using the homogeneous ion-exchange membrane of the styrene-butadiene copolymer. It has been found that the five-compartment use of a cation-exchange membrane (C-2, with a water content of 50% and a specific resistance of 100 Ω-cm.) and an anion-exchange membrane (A-3, with a water content of 55% and a specific resistance of 120 Ω-cm.) effects a successful separation of amino acids into neutral, basic, and acidic groups. However, 10~20% of the neutral amino acids migrated to the basic and acidic amino acid groups.

The separation of amino acids by electrodialysis using such ordinary semi-permeable membranes as biological and collodion membranes has previously been attempted.[1] However, this method has not yet been carried out on an industrial scale because of the difficulty of manufacturing large-sized membranes with good electric properties and stability for long use. Moreover, ordinary semi-permeable membranes have a very low permselectivity; therefore, they cannot prevent the leakage of the hydrogen and hydroxyl ions formed in the electrode chambers. This makes it difficult to adjust the hydrogen ion concentration of amino acid solutions in the intermediate compartments. The author adopted ion-exchange membranes as diaphragms in the electrodialysis, and the experiments were carried out using homogeneous ion-exchange membranes of the styrene-butadiene copolymer produced by Kuwata and Yoshikawa.[2]

Experimental

The separation of amino acids by electrodialysis using ion-exchange membranes was limited to the separation of such groups as the acidic (AA), neutral (NA), and basic (BA) groups, all with similar isoelectric points. Various ion-exchange membranes have been made by polymerization or condensation.[3] The ion exchange membranes used in the present experiments were derived from the styrene-butadiene copolymer (commercial SBR) which has a styrene content of 50%.

The styrene-butadiene copolymer membrane has an advantage that the pore-size of the membrane can be changed by adjusting the butadiene content of the copolymer and/or by controlling the cross-linking reaction. Consequently, this kind of membrane is preferable over other ion exchange membranes for the separation of amino acids. The properties of these membranes are shown in Table I. The porosity of the membranes is compared in terms of the value of the water content (W), the water permeation ratio[4] (K), and the specific resistance (Ω-cm.) of the membranes.

An electrodialysis apparatus,* separated by two sets of anion- and cation-membranes (7.5×7.5 cm.), as illustrated in Fig. 1 (each intermediate compartment was 7.5×7.5×1.0 cm.), was used, with a nickel plate (7.0×7.0 cm.×0.3 mm.) as a cathode and a carbon electrode 7.5×7.5×0.8 cm.) as an anode. The experiment was carried out by changing the cation-exchange membrane, C_1, and the anion-exchange membrane, A_2, in various ways. The A_1 and C_2 membranes in Fig. 1 were fixed throughout the experiment by A-1 and C-1 respectively. A sodium chloride solution (0.1~0.2%) was placed in the intermediate compartments A and C, and 70 cc. of a solution (pH 5.6) containing 10% of mixed amino acids (Table II) obtained from the hydrolysis of gluten and by adjusting the pH in the vicinity of the isoelectric point of neutral

amino acids, were placed in the intermediate compartment B. Colloidal deposits on the C_1 cation-exchange membrane cause electric resistance when peptide and fumin are present in the feed amino acids, perticularly in the case of imperfect hydrolysis. Therefore, the muddy matter in the feed solution of amino acids was filtered off and purified through an ion-exchange resin bed. A 3~6% sodium sulfate solution was used as an electrolyte solution in the cathodic and anodic chamber and was circulated in the direction of the arrow at the rate of 1.0 l./hr. in order to cancel out the H ions and OH ions produced in the electrode solution at all times and thus to prevent any effect of pH fluctuation on the intermediate solution.

If the electrodialysis is carried out in such a way, sulfate ions will be furnished from the cathode to the A compartment and sodium ions from the anode to the C compartment, and, consequently, the pH of the solution of the B compartment will not be much changed during the electrodialysis.

The experiment was carried out using various kinds of anion- and cation-exchange membranes and under various operating conditions, such as current density, operating time, kind of electrolyte and pH of the solution of each compartment during electrodialysis. The degree of amino-acid separation was measured by two-dimensional paper partition chromatography and was determined quantitatively by the dinitrophenyl-paper chromatography method.[6]

Results and Discussion

To carry out a group separation of amino acids smoothly, it is necessary to keep the feed solution, viz., the solution in the intermediate compartment B at a constant pH during the electrodialysis. The pH fluctuation of the compartment B solution is due to the electrolysis of water within the membrane in addition to the effect of the H ions or OH ions formed on the electrodes. The effect of the H or OH ions can be minimized by mixing electrode solutions during circulation. When the sizes of the amino acid molecules are about as large as or larger than the pore-size of the ion-exchange membrane, the electrolysis of water occurs by forced electric current. Because of this phenomenon, the pH in each intermediate compartment varies markedly during electrodialysis.

The results are summarized in Table III. As No. 1 shows, when membranes having the smallest pore-size, C-1 and A-1, were adopted as membranes C_1 and A_2, respectively electrolysis of water took place apparently at an initial current density of 0.3 amp./dm^2 and the solution in compartment B gradually became acidic. In No. 2, if the initial current density was decreased at 0.1 amp./dm^2 and if the period of dialysis was extended, no electrolysis of water took place, but the results of paper partition chromatography showed that the separation of amino acids was imperfect. In Nos. 3 and 4, when sodium hydroxide or hydrochloric acid and sodium hydroxide were used as the electrolytes, the pH of the solution in the B compartment became unstable and the separation of amino acids was imperfect. In Nos. 5 and 6, when membranes wit ha little larger pore-sizes, C-2 and A-2, were adopted as membranes C_1 and A_2 respectively, the fluctuation of the pH of the solution in the intermediate compartment B was noticeable, even at a low current density, and it was found from the results of paper partition chromatography that a considerable amount of histidine and glutamic acid still remained in the B compartment. When the A-3 membrane, with the largest pore-size, was adopted as membrane A_2 almost no electrolysis of water took place, even at the high initial current density of 0.8 amp./dm^2, as Nos. 7—11 show, and the separation of amino acids took place within a short time. Further, the results of paper partition chromatography showed that no acidic and basic amino acids remained in the solution of the B compartment, although a small amount of remaining histidine was noticed in the feed solution at a current density below 0.2 amp./dm^2.

On the other hand, when the C-1 membrane, which has a smaller pore-size, was adopted as the C_1 membrane insteat of the C-2 membrane, both the basic and acidic groups remained in the solution of the B compartment,

6) S. Blackburm and A. G. Lowther, *Biochem. J.*, 48, 126 (1951).

as shown in Nos. 12 and 13. Therefore, the separation of amino acids was unfavorably achieved. Further, it was found that when a set of C-2 and A-3 membranes, both of which have a larger pore-size, was applied and when electrodialysis was performed by applying a high initial current density (0.5~0.8 amp./dm^2), no electrodialysis of water took place and a favorable result was obtained.

TABLE IV. QUANTITATIVE ANALYSIS OF AMINO ACIDS SEPARATED BY DNP-PPC METHOD (Run No. 11)

Kind of amino acids	Each fraction of separated amino acids in the intermediate compartments, %		
	A	B	C
Glutamic acid	0	0	100
Aspartic acid	0	0	100
Glycine	10.0	81.7	8.2
Alanine	6.9	85.6	7.4
Leucine, Isoleucine	4.3	89.9	6.0
Valine, Methionine	6.7	86.3	7.0
Proline	5.7	89.0	5.1
Serine	7.0	81.5	12.1
Threonine	8.9	75.4	15.7
Phenylalanine	3.3	83.6	13.3
Neutral amino acids	7.2	84.3	9.4
Arginine	100	0	0
Histidine	100	0	0
Lysine	100	0	0

The results of the quantitative analysis on each fraction by means of the dinitrophenyl-paper partition chromatography method as an example (No. 11), are shown in Table IV, where the separation was almost ideal. These results show the complete absence of basic and acidic amino acids in the neutral amino acids remaining in the B compartment and a few per cent of neutral amino-acid transfer to both the basic and the acidic amino acid groups. This tendency is especially noted in neutral amino acids, which have a smaller molecular weight, and is probably due to the electro-osmosis accompanying the electrodialysis. In addition, it is interesting to note that some of the neutral amino acids, such as serine and threonine, which have an hydroxyl group, and phenylalanine, which has a phenyl ring, show a marked tendency to transfer to the acidic amino acid group. This seems to be because these amino acids have a particular affinity for the anion-exchange membrane.

The author is deeply indebted to Dr. Tadashi Yawataya and his co-workers of the Asahi Glass Co., Ltd., for the generous supply of the ion-exchange membranes used in this work, and to Mr. Toshisaburo Yamana of the Daigo Nutritive Chemicals Co., Ltd., for leading some of the experiments reported on in this paper.

The Complex Formation of Boron Fluoride with Lower Olefin at Low Temperatures. I. The Isotope Effects and Absorption Spectra of Boron Fluoride-Propylene and -Ethylene Systems

By Ryohei NAKANE, Tsunao WATANABE, Osamu KURIHARA and Toshiyuki ŌYAMA

(Received December 12, 1962)

The complexes of π donors with vacant-orbital acceptors, e.g., unsaturated hydrocarbons with Friedel-Crafts catalysts, have been considered not likely to be very stable,[1] although mono-olefin can form complexes with such transition metals as platinum(II) and silver(I). Evans et al.[2] denied the possibility of any stable complex of isobutylene with boron fluoride. In a preceding paper,[3] however, we proposed that propylene may form a stable liquid complex with boron fluoride at low temperatures. This proposal has its basis in the fact that the equilibrium constant of the isotopic exchange between boron fluoride gas and boron fluoride in a propylene solution is much larger than the vapor pressure ratio of

isotopic boron fluorides. In other words, the unusual concentration of boron-10 in the liquid phase of boron fluoride with propylene can be explained only by assuming the formation of the liquid complex. In this report more accurate values of the isotopic exchange, as obtained by further measurements, are given, together with the absorption spectra of the complex. Similar measurements of the boron fluoride-ethylene system have also been made.

Experimental

Material. — Tank boron fluoride, propylene, ethylene and propane were purified by repeated bulb-to-bulb distillation in vacuo at temperatures from −112°C (the melting point of carbon disulfide) to that of liquid nitrogen. The inside of the distillation bulb was coated with evaporated sodium to remove any trace of residual oxygen and water. In all cases, good care was taken to assure the purity of the gas, for the purity attained by the boron fluoride and propylene used in the previous work might be somewhat insufficient.

The Measurement of the Isotope Effect. — The equilibrium constant of the isotopic exchange was measured by the shaking method.[4] The apparatus used is shown in Fig. 1. The flask with a break-off seal (a), a stopcock (1) and a universal joint (b) was connected to an appropriate vacuum line. The volume was approximately 300 ml. First the

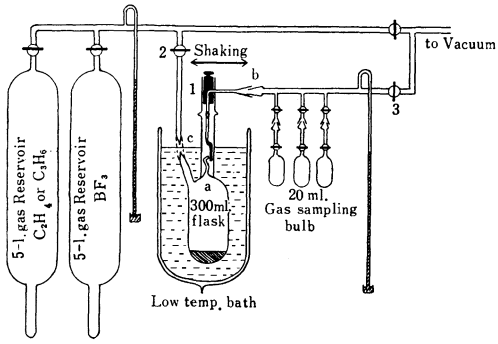

Fig. 1. The shaking type of gas-liquid contactor for the determination of equilibrium constant for low temperature exchange.

entire appartus was evacuated. Known amounts of purified propylene or ethylene and boron fluoride were then introduced through a stopcock (2) into the flask and frozen with liquid nitrogen. The glass tube (c) connecting the flask with the stopcock (2) was sealed off, then the flask was closed and isolated from the vacuum line. The flask was immersed in a low temperature bath at the melting point of carbon disulfide (−112°C). From the known volume of the flask, the total amounts of introduced propylene or ethylene, and of boron fluoride, and the amounts of boron fluoride in the gas phase (m mol.) and in the liquid phase (M mol.) were calculated. Since a large excess of boron fluoride in the liquid phase was used (at least in the ratio of 20 to 1), the value of m/M was small enough to assume that the isotopic composition in the liquid phase remains almost unchanged throughout the experiments. The equilibrium constant was, accordingly, so determined by only measureing the $^{10}B/^{11}B$ ratio in the gas phase before and after the equilibration, that sampling in the liquid phase was not necessary.

The flask was vigorously shaken by a shaker for approximately 2 hr., after which the joint (b) was connected to a set of 20 ml. sampling tubes. After the connecting line to stopcock (1) and the sampling tubes had been evacuated, stopcock (3) was closed. Then the seal (a) was broken by a smart turning of stopcock (1) and the gas in the flask was allowed to flow into the sampling tubes one by one. This way of sampling was suitable for checking whether or not the normal gas boiling from the liquid phase as a result of the sudden drop of pressure affected the isotopic composition of the sampled gas in the flask. The result of the analysis was that only when the pressure of gaseous boron fluoride in the flask was low was the gas sampled last in the three tubes not to be relied upon because of the dilution.

For the boron fluoride-propylene system, the sampled gas was directly analyzed by means of a mass spectrometer, for there was only a very little trace of propylene in it. On the other hand, for the boron fluoride-ethylene system it was necessary to introduce ammonia gas to produce a solid ammonia-boron fluoride complex because about a half of the sampled gas was ethylene. After the unreacted ethylene gas had been evacuated, the ammonia-boron fluoride complex was heated with sulfuric acid to regenerate the boron fluoride, which was then analyzed by means of the mass spectrometer.

The equilibrium constant was obtained from the analyzed values corrected by the m/M effect.

Our 15 cm., 60°-sector-type mass spectrometer, which was made by Mr. Hoshino in our laboratory several years ago, has recently had its electric source improved; thereby more accurate values than in the preceding investigations could be obtained.

The Measurement of the Ultraviolet Absorption Spectrum. — The ultraviolet absorption spectrum was measured on a Cary recording spectrophotometer of the 14 M type. A vessel made of quartz as shown in Fig. 2 was devised for the measurement at low temperatures. The double-wall container, A, was evacuated after the fashion of a Dewar vessel in order to obtain thermal insulation and was filled with a cooling agent, liquid nitrogen or melting carbon disulfide (−112°C). After the center tube, B, had been evacuated, the specimen was let into it through stopcock C from a gas reservoir provided and then condensed. When a large quantity of the specimen had condensed, its temperature at the bottom, B′, of the tube became slightly higher than the temperature of the cooling agent, but it remained constant. A beam of ultraviolet light was passed through B′ in a path length

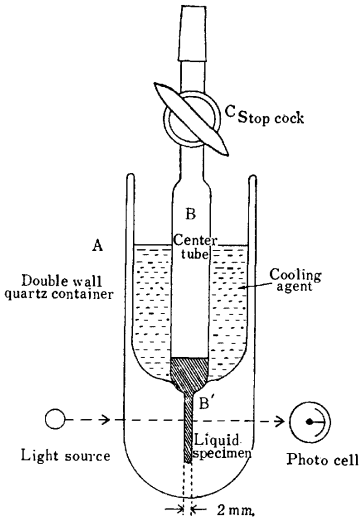

Fig. 2. Apparatus used for obtaining ultraviolet low temperature absorption spectrum.

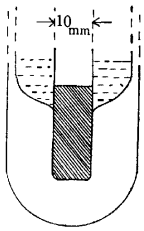

Fig. 2'

of approximately 2 mm. This transmission-type cell has the advantages that it can be used with any spectrometer and that its construction is far simpler than the cells used by Potts[5] and Reid[6]; it is also suitable for a low-temperature liquid measurement, as in the present work.

Results and Discussion

The Isotope Effect.—Results concerning the isotope effect are shown in Table I. The value of the equilibrium constant when propylene is contained in the liquid phase of a system is always larger than when the system has no propylene, but when ethylene is contained in the liquid phase, the value is the same as that of the isotopic exchange between gaseous and liquid boron fluoride, that is, the vapor pressure ratio of isotopic molecules $^{11}BF_3$ to $^{10}BF_3$. These results seem to suggest that boron fluoride forms a stable liquid complex with propylene at $-112°C$, but not with ethylene, which only dissolves into liquid boron fluoride. This is because the equilibrium constant for the isotopic exchange is

Table I. Equilibrium constant of boron isotope exchange in boron fluoride-mono-olefin system at $-112°C$

System	Mole ratio of olefin to BF_3 in the liquid phase	Vapor press. mmHg	Equilibrium constant $\left[\frac{^{10}B}{^{11}B}\right]_{liq}/\left[\frac{^{10}B}{^{11}B}\right]_{gas}$
BF_3	0	300	1.011 ± 0.002
BF_3-Ethylene	1	440	1.011 ± 0.002
BF_3-Propylene	1	170	1.018 ± 0.002
	3	120	1.018 ± 0.002
	4	75	1.018 ± 0.002

well correlated with the energy states of the molecules, especially with their vibration energies. Therefore, the fact that the equilibrium constant of the boron fluoride-ethylene system and the vapor pressure ratio of isotopic molecules have the same value shows that the dissolution of liquid ethylene into liquid boron fluoride has no appreciable effect on the vibrational energy of the molecule; in other words, the structure of boron fluoride in a liquid ethylene solution is not different from that of liquid boron fluoride itself. On the other hand, the fact that the value of the equilibrium constant of the boron fluoride-propylene system is larger than the vapor pressure ratio of isotopic molecules shows that a new molecule, the vibrational energy of which is different from that of boron fluoride, is formed, as in the case of the boron fluoride-ether complex.[7] This can be explained as follows: propylene polarizes as the result of the inductive transfer of the charge from the methyl radical to the double bond. Electron-deficient boron atoms in the boron fluoride act as very strong electron-acceptors. Hence, when boron fluoride is dissolved in liquid propylene, the charge is transferred from β-carbon atoms of propylene to boron atoms, causing the β-carbon atoms to become partially bonded covalently to boron atoms and the structure of boron fluoride molecule to become deformed to some extent from the original planar to tetrahedral. As a result, the interatomic distances between the boron atom and the three fluorine atoms of the molecules are changed, causing a change in the vibrational energy of the molecule. Thus, the results of the experiment made on the isotope effect in the present work prove that, with propylene, at low temperatures, boron fluoride can form stable complexes which are not π-complexes but σ-complexes.

Thus, in the boron fluoride-propylene system, isotopic exchange occurs between gaseous

5) W. Potts, Jr., *J. Chem. Phys.*, 23, 65 (1955).
6) C. Reid, *J. Am. Chem. Soc.*, 76, 3264 (1954).
7) A. Palko, G. Begun and L. Landau, *J. Chem. Phys.*, 37, 552 (1962).

boron fluoride and the liquid boron fluoride-propylene complex as follows:

$$^{10}BF_3(gas) + {}^{11}BF_3 \cdot C_3H_6(liq.) \overset{K}{\rightleftharpoons} {}^{11}BF_3(gas) + {}^{10}BF_3 \cdot C_3H_6(liq.)$$

where $K = 1.018 \pm 0.002$ $(-112°C)$

while in the boron fluoride-ethylene system the isotopic exchange is according to the following equation:

$$^{10}BF_3(gas) + {}^{11}BF_3(\text{in ethylene soln.}) \overset{K}{\rightleftharpoons} {}^{11}BF_3(gas) + {}^{10}BF_3(\text{in ethylene soln.})$$

where $K = 1.011 \pm 0.002$ $(-112°C)$

In a table given in the preceding paper, mention was made of the precipitation of a white solid matter when the mole ratio of boron fluoride in the liquid phase to propylene in a solution was 1:1. This precipitated material was a polymer; its amount increased with the increase of boron fluoride in the liquid phase. When, however, the materials used were sufficiently pure, the amount of the precipitate, the polymer, was not much, which facilitated the measurement of the isotope effect and of the absorption spectrum of a mole ratio 1:1 solution of the propylene-boron fluoride system.

The Absorption Spectrum. — The forming of a complex of propylene with boron fluoride can be established by the measurement of the ultraviolet absorption spectrum.

Figure 3 shows the absorption spectra of liquid propylene from 28000 cm^{-1} to 50000 cm^{-1} at the melting point temperatures of itself and of carbon disulfides.

Potts[5] examined the absorption spectra of methylated ethylenes in a rigid glass form at low temperatures and observed a weak absorption in the 40000~48000 cm^{-1} region, an absorption which he assigned to the $T \leftarrow N$ absorption ($^3B_{1u}$—$^1A_{1g}$). On the contrary, Mulliken[8] asserted that this absorption was not $T \leftarrow N$ band, but $T_R \leftarrow N$ band (state T_R is of $^3B_{3u}$ with the same electron configuration as of the R state of $^1B_{3u}$), because the above bands showed a vibrational frequency interval of about 1400 cm^{-1}, an interval which agrees well with the 1375 cm^{-1} spacing found in the $R \leftarrow N$ transition ($^1B_{3u}$—$^1A_{1g}$), whereas if it is the $T \leftarrow N$ absorption, the vibrational frequency interval should be comparable to that (about 850 cm^{-1}) of the V state.

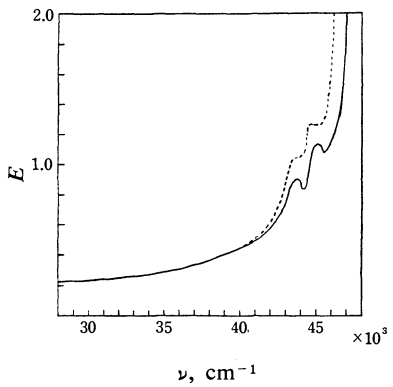

Fig. 3. Absorption spectrum of liquid propylene [solid curve, at the melting point temperature of itself; dashed curve, nearly $-112°C$].

As Fig. 3 shows, two weak absorptions of liquid propylene were found at 45000±100 cm^{-1} and 43650±100 cm^{-1} at low temperatures. The close similarity between the two positions and the vibrational frequency intervals of both the absorption bands of liquid propylene observed by the authors and those of methylated observed by the authors and those of methylethylene shown by Potts indicates that the former bands are none other than those caused by the singlet-triplet transition $T_R \leftarrow N$ ($^3B_{3u}$—$^1A_{1g}$).

When mixtures of boron fluoride with propylene (1:1) are cooled to a low temperature of about $-100°C$, a colorless liquid appears which freezes at a temperature a little higher than $-160°C$. The absorption spectra at the melting point temperatures of itself and of carbon disulfide are shown in Fig. 4. In both cases the main features are the same, and the $T_R \leftarrow N$ absorption in propylene disappeared in the 43650~45000 cm^{-1} region and did not reappear even at longer wavelengths. No blue-shift could be detected, either, for the absorption of a stronger intensity was still observed.

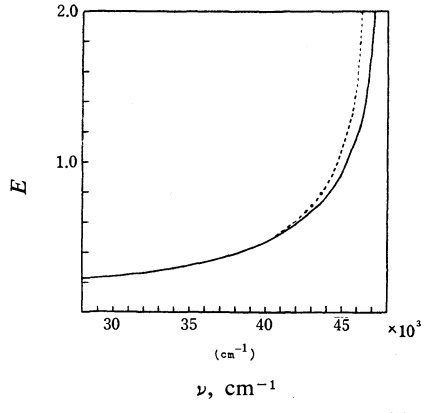

Fig. 4. Absorption spectrum of liquid boron fluorid-propylene system (1:1) [solid curve, at the melting point temperature of itself (nearly $-160°C$); dashed curve, nearly $-112°C$].

8) R. Mulliken, ibid., 33, 1596 (1960).

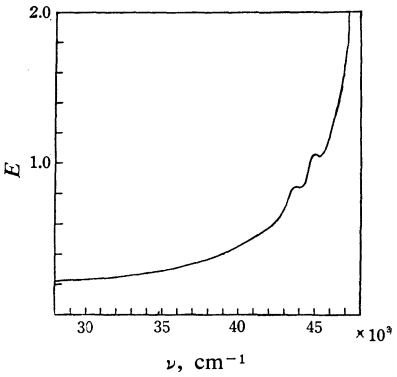

Fig. 5. Absorption spectrum of liquid propylene-propane system (1 : 1) nearly [−185°C].

For the sake of comparison, the absorption spectrum of propylene in a propane solution (1 : 1) was measured at low temperatures, but in this case the $T_R \leftarrow N$ bands of propylene were observed in their original positions, as Fig. 5 shows.

In ordinary circumstances, the Rydberg bands may be expected to become observable in the gas phase but not in liquids or in the liquid phase at low temperatures, for their large-sized orbitals will probably be strongly perturbed by closely-situated solvent molecules.[5] However, the fact that the two absorption bands in 43650 and 45000 cm^{-1} caused by the $T_R \leftarrow N$ transition are observed in liquid propylene or in its propane solution at low temperatures shows that, when the molecules are merely linked by van der Waals' force, Rydberg orbitals are not perturbed by the neighboring molecules, even in the liquid phase, and that electrons can be excited from the π-bonding orbital of the $\rangle C{=}C\langle$ bond to the Rydberg orbital. However, the disappearance of the absorption bands upon the addition of boron fluoride shows that the boron fluoride molecule, being different from the propylene and propane molecules, can closely approach the propylene molecule and strongly perturb the large-sized Rydberg orbitals of propylene molecules.

That the boron fluoride molecules can closely approach propylenes is a sure indication of the smallness of the distance between the boron atom and the β-carbon atom of propylene molecules in a liquid compared with the van der Waals' distance, which causes the formation of a molecular complex. Thus, the disappearance of the $T_R \leftarrow N$ bands of propylene upon the addition of boron fluoride can be attributed to the complex formation.

However, it is considered that the σ-complex formed is not $CH_3{-}\overset{+}{C}H{-}CH_2{-}\overset{-}{B}F_3$, which was formerly assumed to be the intermediate product in polymerization,[9] but $\overset{\delta+}{CH_3{-}CH}{=}CH_2 \rightarrow \overset{\delta-}{B}F_3$ for the $V \leftarrow N$ bands indicating the presence of a double bond were still observed.

On the other hand, in ethylene the $T_R \leftarrow N$ absorption, being obscured by the long-wavelength tail of strong $V \leftarrow N$ bands, is hardly traceable; therefore, the effect of boron fluoride upon ethylene could not be examined.

The Relation between Complex Formation and Polymerization.—Before Evans et al.[2] showed that a co-catalyst such as water is necessary for the polymerization of isobutylene by a boron fluoride catalyst, many investigators assumed hypothetically that unstable complexes are formed as intermediate products in polymerization, condensation and other reactions in which boron fluoride is used as a catalyst. Moreover, they all, including Evans, denied the existence of a stable complex of boron fluoride with mono-olefin, and this conclusion has been generally accepted since. In the present investigation, however, it was found for the first time that boron fluoride, which is a Friedel-Crafts catalyst, can form a stable liquid σ-complex with a polar mono-olefin such as propylene at low temperatures, whereas no σ-complex formation with a non-polar mono-olefin such as ethylene could be detected.

The polymerization of well-purified propylene does not proceed either at a low or at room temperature, but in the presence of a co-catalyst such as water a solid polymer at low temperatures and a liquid polymer at room temperature are produced at atmospheric pressure. Therefore, it is obvious that the formation of the σ-complex has no direct connection with the mechanism of polymerization; at low temperatures, the reaction of σ-complex formation proceeds parallel with the reaction of polymerization. On the other hand, ethylene, which is a non-polar mono-olefin, cannot form a σ-complex with boron fluoride at low temperatures and does not polymerize at atmospheric pressure, even in the presence of a co-catalyst such as water, although an oily polymer is obtained at higher pressure.[10]

Summary

The equilibrium constant of the isotopic exchange between boron fluoride gas and boron fluoride in a propylene solution at −112°C

9) C. Price and J. Ciskowski, *J. Am. Chem. Soc.*, **60**, 2499 (1938).

10) A. Topchiev, S. Zavgorodnii and Ya. Paushkin, "Boron Fluoride and its Compounds as Catalysts in Organic Chemistry," Pergamon Press, London (1959), p. 174.

has been determined by means of a shaking-type gas-liquid contactor. When the mole ratio of propylene to boron fluoride in the liquid phase was larger than 1, the value of the constant obtained was 1.018. In the boron fluoride-ethylene system, the value of the constant is equal to the vapor pressure ratio of the isotopic boron fluorides, i. e., 1.011.

In the measurement of the absorption spectrum of liquid propylene at low temperatures, two weak absorptions were observed at 43650 and 45000 cm^{-1}. They were assigned to the $T_R \leftarrow N$ transition. When boron fluoride was added to liquid propylene at low temperatures, these absorption bands disappeared, although the $V \leftarrow N$ bands were still observed.

The above findings lead to the following conclusion: boron fluoride can form stable liquid σ-complexes with polar mono-olefins such as propylene at low temperatures; these complexes are not the intermediate products in polymerization by a boron fluoride catalyst. On the other hand, ethylene, which is a non-polar mono-olefin and which does not polymerized at atmospheric pressure, cannot form a stable σ-complex with boron fluoride, even at low temperatures.

The authors wish to express their deep thanks to Dr. Shizu Tonomura for her kind advice on measuring the absorption spectra.

*Some Theoretical Considerations of Quasi-reversible and Irreversible Electrode Reactions in Oscillographic Square-wave Polarography**

By Koichi OKAMOTO

(Received March 20, 1963)

The new oscillographic polarograph reported on in a previous paper[1] is a combination of Barker's square-wave polarograph and Randles' single-sweep oscillographic polarograph in which the anodic sweep process was newly equipped in order to observe the anodic wave. By this polarograph, the a.c. polarographic wave (square-wave polarographic wave) in the cathodic process and also in the anodic process under the rapid sweeping of the applied d.c. voltage can be obtained.

The charging current, which appears in a rapid voltage sweep system, as in this oscillographic polarograph, is eliminated by the positive feed-back of the cell current to the d.c. amplifier, as has been described in the previous paper,[1] and also by the gating method proposed by Barker.[2] The a.c. polarographic wave in this polarograph, therefore, can be considered to give the faradaic current independent of the charging current.

The theoretical treatment of the reversible electrode reaction in the oscillographic square-wave polarograph has been reported on in a previous paper.[3] In this paper, some theoretical considerations of the quasi-reversible and the irreversible reactions will be presented.

I. Fundamental Equation.—The generalized equation, which represents the polarographic current, $j(t)$, in this polarograph, is expressed as Eq. 1 :[4,5]

$$\Psi(t) = (k_G f/\sqrt{D}\,)\left\{e^{-\alpha\zeta(t)} - [e^{-\alpha\zeta(t)} + e^{\beta\zeta(t)}] \times (1/\sqrt{\pi}) \int_o^t \Psi(s)\,(t-s)^{-1/2}\mathrm{d}s\right\} \quad (1)$$

where

$$\Psi(t) = j(t)/n\boldsymbol{F}q\sqrt{D_{\mathrm{ox}}}{}^{*}\boldsymbol{C}_{\mathrm{ox}} \quad (2)$$

$$\zeta(t) = (n\boldsymbol{F}/\boldsymbol{RT})\,[E(t) - \boldsymbol{E}^{r}{}_{1/2}] \quad (3)$$

$$k_G = (k_f^0)^{\beta}(k_b^0)^{\alpha}, \quad f = ({}_{\mathrm{ox}}f)^{\beta}(f_{\mathrm{red}})^{\alpha},$$

$$\sqrt{D} = (\sqrt{D_{\mathrm{ox}}})^{\beta}(\sqrt{D_{\mathrm{red}}})^{\alpha}$$

f_{ox} and f_{red}=activity coefficients of the oxidized and the reduced forms of a depolarizer;

k_f^0 and k_b^0=reaction rate of the potential

determinig process of the oxidation and the reduction of a depolarizer under the normal hydrogen potential;

α and β=transfer coefficients ($\alpha+\beta=1$);

E=electrode potential vs. hydrogen electrode;

$E(t)$=applied potential expressed as a function of time and

$E^{r}_{1/2}$=reversible half-wave potential.

The $\Psi(t)$ function can be expanded into the power series of $(nF/RT)\Delta E$.[4] The first term in the series gives the d.c. component of the electrode current and is expressed as Eq. 4 for the cathodic wave and as Eq. 6 for the anodic wave. The second term gives the a.c. component and is expressed as Eq. 5 for the cathodic and as Eq. 7 for the anodic.

The cathodic waves, in which the electrode potential is given by $E(t)=E_o-vt-\Delta E\,V(t/\Theta)$, are expressed as Eqs. 4 and 5:[4,5]

D.c. component:

$$j^{c}_{0}(t)/nFq\sqrt{D_{ox}}{}^{*}C_{ox}=\Psi^{c}_{0}(t)=\lambda\left\{(1+e^{\xi})^{-1}-(1/\sqrt{\pi})\int_{0}^{t}\Psi^{c}_{0}(s)(t-s)^{-1/2}ds\right\} \quad (4)$$

A.c. component:

$$j^{c}_{1}(t)/nFq\sqrt{D_{ox}}{}^{*}C_{ox}=\Psi^{c}_{1}(t)=\lambda\left\{F^{c}(\xi;\lambda)V(t/\Theta)-(1/\sqrt{\pi})\int_{0}^{t}\Psi^{c}_{1}(s)(t-s)^{-1/2}ds\right\} \quad (5)$$

The anodic waves, where $E(t)=E_1+vt-\Delta E\times V(t/\Theta)$, are expressed as Eqs. 6 and 7:[3-5]

D.c. component:

$$j^{a}_{0}(t)/nFq\sqrt{D_{red}}{}^{*}C_{red}=\Psi^{a}_{0}(t)=\lambda\left\{(1+e^{\xi})^{-1}-\left[(1/\sqrt{\pi})\int_{0}^{\theta}\Psi^{c}_{0}(s)(t-s)^{-1/2}ds+(1/\sqrt{\pi})\int_{\theta}^{t}\Psi^{a}_{0}(s)(t-s)^{-1/2}ds\right]\right\} \quad (6)$$

A.c. component:

$$j^{a}_{1}(t)/nFq\sqrt{D_{red}}{}^{*}C_{red}=\Psi^{a}_{1}(t)=\lambda\left\{F^{a}(\xi;\lambda)V(t/\Theta)-\left[(1/\sqrt{\pi})\int_{0}^{\theta}\Psi^{c}_{1}(s)(t-s)^{-1/2}ds+(1/\sqrt{\pi})\int_{\theta}^{t}\Psi^{a}_{1}(s)(t-s)^{-1/2}ds\right]\right\} \quad (7)$$

where

$$\zeta(t)=(nF/RT)[E(t)-E^{r}_{1/2}] \quad (8)$$

$$\lambda=(k_G f/\sqrt{D})(e^{-\alpha\xi}+e^{\beta\xi}) \quad (9)$$

$$F^{c}(\xi;\lambda)=[4\cosh^{2}(\xi/2)]^{-1}+(\alpha-\beta e^{-\xi})[\lambda(1+e^{-\xi})]^{-1}\Psi^{c}_{0}(t) \quad (10)$$

$$F^{a}(\xi;\lambda)=[4\cosh^{2}(-\xi/2)]^{-1}+(\beta-\alpha e^{\xi})[\lambda(1+e^{\xi})]^{-1}\Psi^{c}_{0}(t) \quad (11)$$

$\xi=(nF/RT)vt-\zeta_o$ for Eqs. 4, 5, 9 and 10

$\xi=(nF/RT)v(t-\theta)+\zeta_1$, for Eqs. 6, 7, 9 and 11 (11')

Other variables and constants are used with the same meaning as in the previous paper.[3]

II. Quasi-Reversible Case.—In quasi-reversible reactions, no simplification of Eqs. 10 and 11 can be made. The calculation of the a.c. component, therefore, must be started from the calculation of the d.c. component.

The mathematical procedures for calculating the d.c. component in the cathodic process, $\Psi^{c}_{0}(t)$, under the projected conditions, such as $\alpha=0.3$, 0.5 and 0.7 and $\Lambda=10$, 1, 10^{-1} and 10^{-2} (see Eq. 12), have already been shown by Matsuda.[4] For this paper, the numerical calculations of $\Psi^{c}_{0}(t)$ were carried out by means of the electronic computer, and then the following calculation of the a.c. component $\Psi^{c}_{1}(t)$ in a cathodic process was made using the d.c. component obtained.

1. Cathodic Process.—i) D.C. Component.— The quasi-reversible case[4] can be defined as $15\geqq\Lambda\geqq 10^{-2(1+\alpha)}$. In this case, Eq. 4 can be numerically dissolved by the same mathematical procedures as were used by Matsuda.[4] The results are shown in Figs. 1-a, b and c. The $\Psi^{c}_{0}(-\xi)$ and ξ-values at the summit point of each curve are summarized in Table I.

ii) A.C. Component.—In order to calculate the a.c. component using the d.c. components shown in Fig. 1, Eqs. 9 and 10 are transformed into Eqs. 12 and 13;

$$\Lambda=(k_G f/\sqrt{D})(nFv/RT)^{-1/2} \quad (12)$$

$$\Psi(t)=(nFv/RT)^{1/2}\Psi(\xi) \quad (13)$$

They can be rewritten to Eqs. 14 and 15:

$$\lambda=\Lambda(nFv/RT)^{1/2}(e^{-\alpha\xi}+e^{\beta\xi}) \quad (14)$$

$$F^{c}(\xi;\lambda)=[4\cosh^{2}(\xi/2)]^{-1}+(\alpha-\beta e^{-\xi})\times(1+e^{-\xi})^{-1}(e^{-\alpha\xi}+e^{\beta\xi})^{-1}\Lambda^{-1}\Psi^{c}_{0}(\xi) \quad (15)$$

On the other hand, as has already been shown by Matsuda,[4] by applying Fourier's expansion method, Eq. 5 may be expressed as Eq. 16:

$$j^{c}(\xi)=nFqD_{ox}{}^{1/2}{}^{*}C_{ox}(nF\Delta E/RT)\times\Theta^{-1/2}F^{c}(\xi;\lambda)\,\psi_{sq}(t/\Theta;\lambda\sqrt{\Theta/2\pi}) \quad (16)$$

where ψ_{sq} is the same function as in a previous work;[3] it is graphically shown in Fig. 2.

The theoretical equation of a.c. polarograms, $j^{c}(-\xi)$, are shown in Figs. 3-a, b and

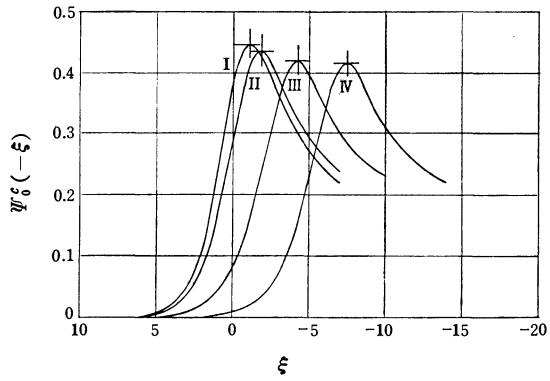

Fig. 1-a. $\alpha=0.7$.

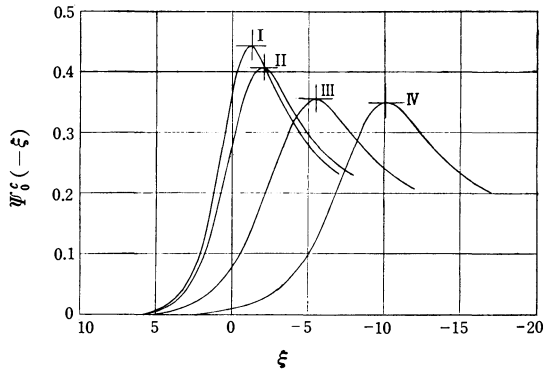

Fig. 1-b. $\alpha=0.5$.

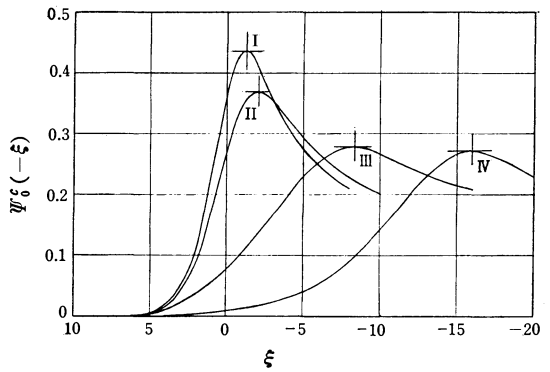

Fig. 1-c. $\Psi_0^c(-\xi)\sim\xi$ Relation (quasi-reversible) $\alpha=0.3$. I: $\Lambda=10^1$, II: $\Lambda=10^0$, III: $\Lambda=10^{-1}$, IV: $\Lambda=10^{-2}$.

c, where the following numerical values are adopted: $n=2$, $q=2\times10^{-2}$cm^2, $D_{ox}=10^{-5}$cm$^2\cdot$sec^{-1}, $\Delta E=5$ mV., $^*C_{ox}=5\times10^{-4}$mol./l., $\Theta=1.667\times10^{-4}$sec., $T=25°$C, $\alpha=0.3$, 0.5 and 0.7, and $\Lambda=10^1$, 10^0, 10^{-1} and 10^{-2}. The summit current values, $(j_s)_{quasi}$, the summit potential values, $(\xi_s)_{quasi}$, and the half-width values, $(\xi_{s/2})_{quasi}$, are summarized in Table II. These values can be expressed as Eqs. 17, 17', 18 and 19:

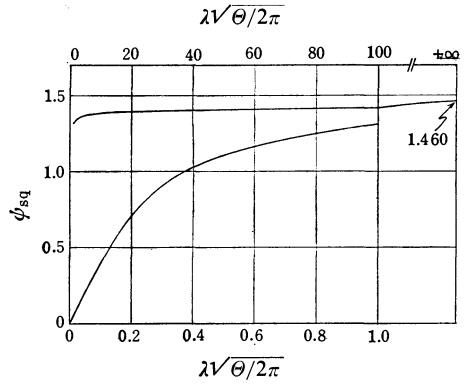

Fig. 2. The relation between ψ_{sq} ($t/\Theta=0.9$ and 1.9; $\lambda\sqrt{\Theta/2\pi}$) and $\lambda\sqrt{\Theta/2\pi}$.

$$(j_s)_{quasi}=K(\Lambda,\alpha)(j_s)_{rev} \tag{17}$$

$$K(\Lambda,\alpha)=[F(\xi;\lambda)\times\psi_{sq}(t/\Theta;\lambda\sqrt{\Theta/2\pi})]_{quasi}/0.365 \tag{17'}$$

$$(\xi_s)_{quasi}=(\xi_s)_{rev}-\Xi(\Lambda,\alpha) \tag{18}$$

$$(\xi_{s/2})_{quasi}=\Delta(\Lambda,\alpha)(\xi_{s/2})_{rev} \tag{19}$$

where

$(j_s)_{rev}=67.15\ \mu$amp

$(\xi_s)_{rev}=0$

$(\xi_{s/2})_{rev}=3.6_0$

The $K(\Lambda,\alpha)$, $\Xi(\Lambda,\alpha)$ and $\Delta(\Lambda,\alpha)$ functions are shown in Figs. 4, 5 and 6. The relation of $(j_s)_{quasi}$ and $(\xi_s)_{quasi}$ of the a.c. waves to $(i_s)_{quasi}$ and $(\xi_s)^{DC}_{quasi}$ of the d.c. waves are also listed in Table II in the form of $(j_s)_{quasi}/(i_s)_{quasi}$ and $(\xi_s)^{DC}_{quasi}-(\xi_s)_{quasi}$.

2. Anodic Process. — The d.c. component $\Psi_0^a(-\xi)$, and the a.c. component, $\Psi_1^a(-\xi)$, can be obtained by Eqs. 6 and 7, but the

integrations in these equations can not be carried out, because the $\Psi_0^c(-\xi)$ values can not be virtually calculated up to the ξ-value of $-\infty$.

In the reversible case, an approximation technique was employed[3] in order to obtain the effect of the change of the turning point of the sweeping d.c. voltage. Namely, when the d.c. voltage is swept to the ξ-value of $-\infty$, the influence from a prior cathodic

sweep upon the following anodic sweep is negligible. For this reason, the anodic waves having a form symmetrical to the corresponding cathodic waves were employed for calculating both the d. c. and a. c. anodic components. The d. c. anodic waves, therefore, have the forms symmetrical to the cathodic waves with respect to the zero point (see Figs. 1-a, b and c).

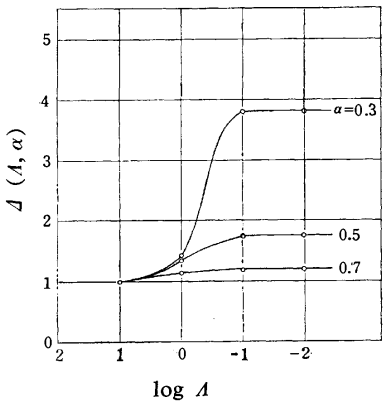

Fig. 6. $\Delta(\Lambda, \alpha)\sim\log \Lambda, \alpha$ relation.

TABLE III. THE SUMMIT POTENTIALS AND THE SUMMIT CURRENTS OF THE D. C. WAVES (irreversible)

	40	1/2	+0.7	−0.407
	80	1/2	+0.7	−0.433

The a. c. anodic waves are expressed as Eq. 20 and are shown in Figs. 3-a, b and c:

$$j^a(\xi)=nFqD_{red}^{1/2}\ {}^*C_{red}(nF\Delta E/RT)\times\Theta^{-1/2}F^a(\xi\,;\lambda)\phi_{sq}(t/\Theta\,;\lambda\sqrt{\Theta/2\pi}) \quad (20)$$

where λ and $F^a(\xi\,;\lambda)$ are given by Eqs. 9 and 11 respectively. The relations between the summit potentials, the summit currents, the half-width and $\ln\Lambda$ and α, and between the

summit potentials of a. c. and of d. c. waves are also the same to those of the cathodic waves (see Table II).

III. Irreversible Case.—*1. Cathodic Process.*—*i) D. C. Component.* — The irreversible case is defined by the condition: $\xi \geqq 4.6$ or $e^{-\xi} \leqq 10^{-2}$, as has already been indicated by Matsuda.[5] Eqnations. 10 and 9 are, therefore, simplified to Eqs. 21 and 22 respectively:

$$F^c(\xi\,;\lambda) = (k_G f/\sqrt{D})\,\alpha\lambda\Psi_0^c(t) \tag{21}$$

and

$$\lambda = (k_G f/\sqrt{D})\,e^{-\alpha\xi} \tag{22}$$

Eq. 4 is also changed to Eq. 23:

$$\Psi_0^c(\xi) = (k_G f/\sqrt{D})\,(nFv/RT)^{-1/2} e^{\alpha\xi} \times \left\{1-(1/\sqrt{\pi})\int_{-\zeta}^{\xi}\Psi_0^c(\eta)\,(\xi-\eta)^{-1/2}\mathrm{d}\eta\right\} \tag{23}$$

In order to eliminate the $(k_G f/\sqrt{D})\,(nFv/RT)^{-1/2}$ term, the transformation as Eqs. 24-a, b and c, Eq. 12 and Eq. 25 are introduced into Eq. 23:

$$\alpha\xi = \xi^* - \ln \Lambda^* \tag{24-a}$$

$$\alpha\eta = \eta^* - \ln \Lambda^* \tag{24-b}$$

$$\Lambda/\sqrt{\alpha} = \Lambda^* \tag{24-c}$$

$$\Psi(\xi)/\sqrt{\alpha} = \Psi_{\mathrm{irr}}(\xi^*) \tag{25}$$

Eq. 26 is then derived:

$$e^{-\xi^*}\Psi_{\mathrm{irr}}(\xi^*) = 1-(1/\sqrt{\pi}) \times \int_{-\alpha\zeta+\ln\Lambda^*}^{\xi^*}\Psi_{\mathrm{irr}}(\eta^*)\,(\xi^*-\eta^*)^{-1/2}\mathrm{d}\eta^* \tag{26}$$

This equation can be dissolved by the numerical integration, as has been shown by Matsuda;[4] the $\Psi_{\mathrm{irr}}(-\xi^*)\sim\xi^*$ curve calculated (again by the author) is shown in Fig. 7-a, while the values at their summit points are listed in Table III.

ii) A. C. Component.—By the use of Fourier's expansion technique in the same manner as Matsuda,[5] Eq. 5 is changed to Eq. 27:

$$j_1^c(\xi) = nFq\ D_{\mathrm{ox}}^{1/2}\,{}^*C_{\mathrm{ox}}(\alpha nF\Delta E/RT) \times \Theta^{-1/2}(nFv/RT)^{1/2}\psi_0^c(\xi)\,(k_G f/\sqrt{D})^{-1}e^{-\alpha\xi} \times \psi_{\mathrm{sq}}(t/\Theta\,;\ (k_G f/\sqrt{D})\,e^{\alpha\xi}\sqrt{\Theta/2\pi}) \tag{27}$$

The final equation, 28, is obtained by introducing Eqs. 24—25 and 12 into Eq. 27; i. e.,

$$j_{\mathrm{irr}}^c(\xi^*) = nFq\ D_{\mathrm{ox}}^{1/2}\,{}^*C_{\mathrm{ox}}(\alpha nF\Delta E/RT) \times \Theta^{-1/2}e^{-\xi}\Psi_0^c(-\xi^*)\psi_{\mathrm{sq}}(t/\Theta\,;\ (\alpha nFv/RT)^{1/2} \times (\Theta/2\pi)^{1/2}e^{\xi^*}) \tag{28}$$

where $\Psi_0^c(-\xi^*)$ is the d. c. component already described in Section III-1-i, while the values of $\psi_{\mathrm{sq}}(t/\Theta\,;\ (\alpha nFv/RT)^{1/2}(\Theta/2\pi)^{1/2}e^{\xi^*})$ can be

* $(i_s)_{irr}$ Values were calculated by the equations:
$(i_s)^c_{irr}=n\boldsymbol{F}qD_{ox}^{1/2}*C_{ox}\ (\alpha n\boldsymbol{F}v/\boldsymbol{RT})^{1/2}\ \Psi_0^c(\xi^*)_{irr}$ for the cathodic wave.
$(i_s)^a_{irr}=-n\boldsymbol{F}qD_{red}^{1/2}*C_{red}(\beta n\boldsymbol{F}v/\boldsymbol{RT})^{1/2}\ \Psi_0^a(\xi^*)_{irr}$ for the anodic wave.
where, n, $\boldsymbol{F}$, q, $D^{1/2}{}_{ox(or\ red)}$, $*C_{ox(or\ red)}$ and T are the same to these in the section II-1-ii, and $v=4$ V. sec^{-1}.

obtained from the $\Psi_{sq}\sim\lambda\sqrt{\Theta/2\pi}$ curve shown in Fig. 2.

Theoretical a. c. polarograms, $j^c_{irr}(\xi^*)$, taken under the same conditions as in Section II-1-ii, except the values of Λ, are shown in Fig. 8. The irreversible polarogram is very much affected by the magnitude of the transfer coefficient, and the wave height becomes very much lower than the reversible case. The variations of the summit potentials, $(\xi_s^*)_{irr}$, the half- widths, $(\xi_{s/2}^*)_{irr}$, the summit currents, $(j_s)_{irr}$, and the ratios to the d. c. summit currents, $(j_s)_{irr}/(i_s)_{irr}$, obtained from Fig. 8 are summarized in Table IV.

2. Anodic Process.—i) D. C. Component.—The second term in Eq. 6 is equivalent to Eq. 4. The first term, designated by $\Psi_0^1(\xi)$, can, on the other hand, be calculated in the following manner: when the variables, t and s, are transformed as Eqs. 11′ and 29,

$$\eta=\zeta_1-n\boldsymbol{F}v(s-\theta)/\boldsymbol{RT} \tag{29}$$

where

$$\zeta_1=(n\boldsymbol{F}/\boldsymbol{RT})(E_1-E^r{}_{1/2})$$

$\Psi_0^1(\xi)$ is expressed as Eq. 30:

$$\Psi_1^0(\xi)=(k_Gf/\sqrt{D})(n\boldsymbol{F}v/\boldsymbol{RT})^{-1/2}e^{\beta\xi}(1/\sqrt{\pi})\times\int_{\zeta_1}^{\zeta_0}\Psi^c(\eta)(\xi+\eta-2\zeta_1)^{-1/2}\mathrm{d}\eta \tag{30}$$

Further transformation of this equation by the use of Eqs. 31-a, b, c, and d, and Eq. 12 leads to a simpler equation, 32:

$$\beta\xi=\xi^*-\ln\Lambda^* \tag{31-a}$$
$$\beta\eta=\eta^*-\ln\Lambda^* \tag{31-b}$$
$$\Lambda/\sqrt{\beta}=\Lambda^* \tag{31-c}$$
$$\Psi(\xi)/\sqrt{\beta}=\Psi_{irr}(\xi^*) \tag{31-d}$$

$$\Psi^1_{irr}(\xi^*)=(1/\sqrt{\pi})\int_{\beta\zeta_1+\ln\Lambda^*}^{\beta\zeta_0+\ln\Lambda^*}\Psi^c_{irr}(\eta^*)\times[\xi^*+\eta^*-2(\beta\zeta_1+\ln\Lambda^*)]^{-1/2}\mathrm{d}\eta^* \tag{32}$$

When the sweeping range of the d. c. voltage is as wide as $\zeta_0\gg10$ and $\zeta_1\ll-10$, Eq. 32 may be approximately expressed by Eq. 33:

$$\Psi^1_{irr}(\xi^*)=(1/\sqrt{\pi})\times\int_{-\infty}^{\infty}\Psi^c_{irr}(\eta^*)(\xi^*+\eta^*-2\xi_1^*)^{-1/2}\mathrm{d}\eta^* \tag{33}$$

where

$$\xi_1^*=\beta\zeta_1+\ln\Lambda^*$$

The $\Psi^c_{irr}(\eta^*)$ function has a maximum value of $\eta^*=0.78$ as Fig. 7-a shows. Therefore, the approximation method used in a previous paper[3] is applied to Eq. 33 under the assumption that the $\Psi^c_{irr}(\eta^*)$ reaches a maximum at $\eta^*=0$; therefore, Eq. 34 can be obtained:

$$\Psi^1_{irr}(\xi^*)\fallingdotseq(1/\sqrt{\pi})(\xi^*-2\xi_1^*)^{-1/2}\times\int_{-\infty}^{\infty}\Psi^c_{irr}(\eta^*)\mathrm{d}\eta^* \tag{34}$$

Since the integral term in Eq. 34 cannot be virtually calculated, the following approximation method is employed. When the $\Psi^c_{rev}(\xi)$ function for the revesible case and $\Psi^c_{irr}(\xi^*)$ for the irreversible case are compared with each other, as in Fig. 7, the arease within ξ or $\xi^-=7\sim-10$ are found to be almost equivalent. Moreover, since the more negative the ξ or ξ^* values, the more reversible the electrode reactions, the integral value of $\Psi^c_{irr}(\xi^*)$ more and more approaches that of $\Psi^c_{rev}(\xi)$ with increasing negative shift of ξ or ξ^*-values. For these reasons, the integral value

of $\Psi^c_{irr}(\xi^*)$ can be considered to be the equivalent to that of $\Psi^c_{rev}(\xi)$ for all ξ or ξ^* values. The integral value in Eq. 33, may, therefore, be approximated by Eq. 35 in a manner similar to the reversible case:[3]

$$\int_{-\infty}^{\infty}\Psi^c_{irr}(\eta^*)d\eta^* \fallingdotseq \int_{-\infty}^{\infty}[\cosh^2(\eta/2)]^{-1}d\eta=4 \quad (35)$$

The d.c. component in an irreversible anodic electrode reaction can be finally expressed as Eq. 36:

$$\Psi^a_{irr}(\xi^*)=(1/\sqrt{\pi})(\xi^*_0-\xi^*_1)^{-1/2}[\xi^*/(\xi_0^*-\xi_1^*)-2\xi_1^*/(\xi_0^*-\xi_1^*)]^{-1/2}-\Psi^c_{irr}(\xi^*) \quad (36)$$

where

$$\xi_0^*=\beta\zeta_0+\ln \Lambda^*$$

The relations between $\Psi^a_{irr}(\xi^*)$ and ξ^* for some ξ_0^* and ξ_1^* values are shown in Figs. 7-b, c, d and e. The values at their summit points are listed in Table III.

ii) A. C. Component.—The first integral term in Eq. 7, which represents the influence of a cathodic sweep upon an anodic process, can be neglected for the same reason as that adapted in the reversible case.[3] The generalized equation can, therefore, be shown as Eq. 37:

$$\Psi^a_1(t)=\lambda\left\{F(\xi;\lambda)V(t/\Theta)-(1/\sqrt{\pi})\times\int_{\Theta}^{t}\Psi^a_1(s)(t-s)^{-1/2}ds\right\} \quad (37)$$

The final equation, 38, which expresses the theoretical a.c. polarographic wave in the anodic process, can be obtained by means of the same mathematical technique as that in Section III-1-ii:

$$j^a_1(\xi^*)=nFqD_{red}^{1/2}{}^*C_{red}(\beta nF\Delta E/RT)\times\Theta^{-1/2}e^{-\xi^*}\Psi^a_0(\xi^*)\psi_{sq}(t/\Theta;\beta nFv/RT)^{1/2}\times(\Theta/2\pi)^{1/2}e^{\xi^*} \quad (38)$$

where $\Psi^a_0(\xi^*)$ is the d.c. component in the range of $\Psi^a_0(\xi^*)\leqq 0$, which was already obtained in Section III-2-i and which is also shown in Figs. 7-b. c. d. and e.

Some of the theoretical polarograms calculated by Eq. 38 under the same conditions as in Section II-1-ii, but in this case using β, D_{red} and C_{red} instead of α, D_{ox} and C_{ox} respectively, are shown in Figs. 8-d—i.

The variations of the summit potentials, $(\xi_s^*)_{irr}$, the half-widths, $(\xi_{s/2}^*)_{irr}$, the summit currents, $(j_s)_{irr}$ and the ratios to the d.c. summit currennts, $(j_s)_{irr}/(i_s)_{irr}$ with the vallues of β and the turning potentials are summarized in Table IV.

As is shown in Fig. 8, the summit potential of the irreversible anodic wave is more positive than that of the cathodic waves. Their wave heights are lower than the cathodic waves because of the influence of the turning point of applied d.c. voltage, and they are affected by the values of the transfer coefficient β.

The asymmetric forms of the anodic a.c. waves such as Figs. 8-d-i, are due to the insufficiently negative value of the turning point of the d.c. applied voltage. If the turning point is selected at the infinite negative value, a symmetric wave may be otained.

IV. Discussion.—The polarographic wave of the quasi-reversible reaction in the author's polarograph is very much influenced by the magnitude of the reaction rate constant and by the transfer coefficient in a manner almost identical with that of the conventional a.c. polarograph.

The summit current, $(j_s)_{quasi}$, decreases with the decrease in the Λ-values and also with that in the α-values, as is shown in Fig. 4. The transition range in the said figure corresponds to the quasi-reversible region, and the decrement of $K(\Lambda, a)$ in this region is comparatively larger than that of the same function for Randles' single sweep polarograph reported by Matsuda.[4] The summit potential, $(\xi_s)_{quasi}$, changes with the changes in the α- and Λ-values in rather a complicated way, as Fig. 5 shows. This relation is not equivalent to that of Randles' polarograph. When the reaction rate, $\Lambda(=(k_af/\sqrt{D})(nFv/RT)^{-1/2})$, is in the range of $10^1\sim10^0$, and also when the transfer coefficient, α, is as small as 0.3, the the summit potential tends to shift to the potentials more positive than that of the reversible wave, $[(\xi_s)_{rev}=0]$. This interesting result is also observed in the conventional a.c. polarographic wave.[5] The value of the half-width, $(\xi_{s/2})_{quasi}$, also changes with the α- and Λ-values, as Fig. 6 shows. The smaller the values of the transfer coefficient and of the reaction rate, the broader the wave. This relation is most predominant in the case of a transfer coefficient with a small value, e.g., $\alpha=0.3$. The summit currents of a.c. waves at $\Lambda=10^1$ are larger than those of d.c. waves independently of the values of α, as is shown in Table II, and they decrease rather remarkably in a manner similar to that of $K(\Lambda, \alpha)$ in Fig. 4.

The $(\xi_s)_{quasi}$ summit potential is always at a potential more positive than the $(\xi_s)^{quasi}_{DC}$ summit potential as is seen in Table II. The difference between them, however, decreases with a decrease in the value of the transfer coefficient; finally it becomes negligibly small at $\alpha=0.3$ and $\Lambda=10^{-2}$, as Table II shows.

The theoretical findings on the quasi-reversible electrode reaction in the author's polarograph may be useful for the estimation of the

reversibility and of the reaction rate constant.

The polarographic wave of an irreversible electrode reaction can not be observed clearly by the conventional a. c. method because of its very low height and its obscure form. This is true also in the oscillographic square-wave polarograph, in which the d. c. applied voltage sweeps very rapidly. However, the measurement of such an irreversible wave can be effectively carried out by the observation of a higher anodic wave instead of that of a lower cathodic wave. This is one of the merits of this equipment.

As is shown in Table IV, the summit potential, $(\xi_s^*)_{\mathrm{Irr}}$, is affected by the magnitude of the transfer coefficient in the manner: $(\xi_s^*)^c_{\mathrm{Irr}} = -0.7$, -0.5 and -0.3 for $\alpha=0.3$, 0.5 and 0.7 in the cathodic process, and $(\xi_s^*)^a_{\mathrm{Irr}}=0.7$, 0.5 and 0.3 for $\beta=0.3$, 0.5 and 0.7 in the anodic process respectively. No effect of the change of the turnnig point of the d. c. applied voltage upon the summit potential is predicted, as the table shows. The summit currents in both cathodic and anodic processes are also affected by the transfer coefficient; and their relations are almost linear, as Fig. 9 shows. The influence of the change of the turning point of the d. c. voltage upon the summit currents of the anodic waves is rather remarkable, as is shown in Table IV. When the voltage is turned back at such insufficiently negative potentials as $\xi^*=-5$ or -10, an asymmetric anodic wave lower in height than the corresponding cathodic wave is obtained, as Fig. 8 shows.

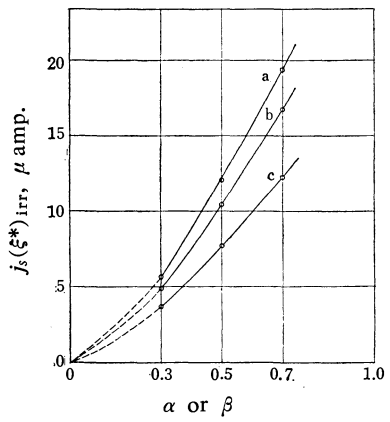

Fig. 9. The dependence of the summit current $j_s(\xi^*)_{\mathrm{Irr}}$ to the transfer coefficient.
a cathodic
b anodic, $\xi_0^*-\xi_1^*=80$, $-(\xi_1^*/\xi_0^*-\xi_1^*)=1/2$
c anodic. $\xi_0^*-\xi_1^*=20$, $-(\xi_1^*/\xi_0^*-\xi_1^*)=1/4$

The discussion or the evaluation of the theoretical results of the a. c. wave could be carried out in more detail if the a. c. wave were expressed in the form of some known and simple function. Such a trial, however, is not easy, so in this paper the discussions were made on the basis of the discontinuous values obtained by the numerical calculations of the integral equations.

Conclusion

Some theoretical considerations of the quasi-reversible and the irreversible electrode reactions in oscillographic square-wave polarograph have been carried out according to a mathematical procedure similar to that used in the reversible reaction.

The equations which represent the quasi-reversible polarographic wave in the cathodic and also in the anodic sweep processes have been derived. The polarographic wave of the quasi-reversible reaction is very much influenced by the magnitude of the transfer coefficient and by that of the reaction rate. Generally speaking, the smaller the above values, the lower the wave height; the summit potential tends to shift to more positive values when $10^0>\Lambda>10^{-1}$ and to more negative values when the Λ-value is less than 10^{-1}.

The theoretical equation of irreversible waves in the cathodic and the anodic sweep processes have also been derived. The wave height of the irreversible electrode reaction is much lower than that of the reversible reaction and is dependent on the transfer coefficient. The summit potentials in two sweep processes do not coincide with each other.

The author is very much indebted to Professor Taichirō Fujinaga, Kyōto University, for his guidance, to Dr. Hiroaki Matsuda, Government Chemical Industrial Research Institute, Tokyo, for his advice, and to Dr. Munetoshi Matsui and to Dr. Akira Itō, both of this laboratory, for affording facilities for this investigation.

Synthesis of Long-chain Aliphatic Compounds from Cyclododecatriene

By Hirosi TAKAHASI and Muneaki YAMAGUCHI

(Received March 21, 1963)

Dialkyl 1, 16-hexadecandioate, a starting material of 16-membered ring compounds, has been synthesized by the following methods: (1) treating α, ω-dibromoalkane with dialkyl sodiomalonate[1] or potassium cyanide[2]; (2) treating the monochloride of α, ω-dicarboxylic acids with organo cadmium compounds;[3] (3) alkylating 1, 3-cyclohexandione with 1, 4-dibromobutene[4] followed by ring opening, and (4) the electrolytic coupling of α, ω-dicarboxylic acids.[5] The present paper reports a synthesis of diethyl 1, 16-hexadecandioate from 1, 5, 9-cyclodecatriene, as well as syntheses of certain long-chain aliphatic compounds as intermediates of the hexadecandioate.

cis, trans, trans-1, 5, 9-Cyclododecatriene was treated with hydrogen peroxide in formic acid to give 2-formoxy-*cis, trans*-5, 9-cyclododecadienol in a 76% yield; its hydrolysis yielded *cis, trans*-5, 9-cyclodecadiene-*cis*-1, 2-diol[6] (I) melting at 160~161°C with small amounts of an isomer melting at 164~165°C.

The 1, 2-diol I gave *cis*-1, 2-cyclododecanediol[7] upon hydrogenation over palladium-charcoal. The configurations of the two olefinic bonds are considered to be cis and trans on the basis of the infrared absorptions of 2-formoxy-*cis, trans*-5, 9-cyclododecadienol and *cis, trans*-5, 9-cyclododecadiene-1, 2-diol isopropylidene ketal (II) near 970 and 700 cm^{-1}.[8] The structure of the isomer melting at 164~165°C is currently under investigation.[9]

The treatment of *cis, trans*-5, 9-cyclododecadiene-*cis*-1, 2-diol with lead tetraacetate yielded *cis, trans*-5, 9-dodecadiene-1, 12-dial (III) in a 63% yield. The compound gave succinic acid in a 91% yield upon ozonolysis followed by oxidative decomposition, thus excluding the possibility of double-bond migration. The configurations of the two olefinic bonds are considered to be cis and trans on the basis of the infrared absorbance of the dialdehyde at 970 cm^{-1} relative to that of *cis, trans, trans*-1, 5, 9-cyclododecatriene.

The dialdehyde was treated with lithium aluminum hydride to give *cis, trans*-5, 9-dodecadiene-1, 12-diol (IV) in a 79% yield.

cis, trans-5, 9-Dodecadiene-1, 12-dial was heated with ethyl hydrogen malonate and catalytic amounts of piperidine in pyridine to give 2, 6, 10, 14-hexadecatetraene-1, 16-dioate (V) in a 71% yield. This compound gave a mixture of oxalic and succinic acid upon ozonolysis followed by hydrolysis. Upon catalytic hydrogenation over palladium-charcoal, the compound absorbed four moles of hydrogen to give diethyl 1, 16-hexadecanedioate (VI). Attempts to prepare diethyl 6, 10-hexadecadiene-1, 16-dioate by partial hydrogenation over palladium-charcoal or Raney-nickel were unsuccessful.

Experimental[10]

2-Formoxy-*cis, trans*-5, 9-cyclododecadienol. — To 1150 g. of formic acid (80%), 1050 g. of acetic anhydride and 3 ml. of concentrated sulfuric acid were added. The solution was then mixed with 440 g. of *cis, trans, trans*-1, 5, 9-cyclododecatriene[11] and hydrogen peroxide (30%) was added dropwise under stirring. The reaction temperature rose to near 100°C after 350 g. of hydrogen peroxide had been added, and the mixture became homogeneous. The solution was stirred until the peroxide disappeared, and then the solvent was removed in a vacuum. From the distillate, 58 g. of cyclododecatriene were recovered unchanged. The residue was distilled to give 398 g. of a fraction boiling at 150~160°C/10 mmHg (76% based on the reacted cyclododecatriene). By redistillation, a fraction boiling at 155°C/10 mmHg was collected.

Found: C, 69.40; H, 8.85. Calcd. for $C_{13}H_{20}O_3$: C, 69.61; H, 8.99%.

The infrared spectrum of the compound showed the absorptions of the trans and cis double bonds near 970 and 700 cm^{-1}.

***cis, trans*-5, 9-Cyclododecadiene-*cis*-1, 2-diol.**—To a mixture of 500 g. of *cis, trans, trans*-1, 5, 9-cyclododecatriene, 1300 g. of formic acid (80%), 1200 g. of acetic anhydride and 3 ml. concentrated sulfuric acid, 390 g. of hydrogen peroxide (31%) were added. The mixture was stirred until the peroxide disappeared, and then the solvent was removed in a vacuum. From the distillate, 62 g. of the starting cyclododecatriene were obtained. The residue was vigorously refluxed with 1.2 l. of a 20% sodium hydroxide solution for 2 hr. After the mixture had cooled the crystals were filtered, washed with water, and recrystallized from 400 ml. of alcohol to give 320 g. of crude *cis, trans*-5, 9-cyclododecadiene-*cis*-1, 2-diol melting at 150~153°C. The filtrate was concentrated to give 30 g. of the crude 1, 2-diol. The total yield was 66%. A pure specimen was obtained by recrystallization from alcohol; m. p. 160~161°C. The compound showed the infrared absorptions of the trans and cis double bonds at 970 and 700 cm^{-1}.

The mother liquor was distilled in a vacuum to give a fraction boiling at 170~190°C/5 mmHg. This fraction partially crystallized after standing overnight at room temperature, and the solids were filtered to give 2 g. of crystals melting at 156~160°C. By recrystallization from acetone, a pure specimen was obtained; m. p. 164~165°C. Mixed melting point with *cis, trans*-5, 9-cyclododecadiene-*cis*-1, 2-diol showed a depression; m. p. 145~157°C.

Found: C, 73.51; H, 10.26. Calcd. for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

***cis, trans*-5, 9-Cyclododecadiene-*cis*-1, 2-diol Isopropylidene Ketal.**—A mixture of 5 g. of *cis, trans*-5, 9-cyclododecadiene-*cis*-1, 2-diol, 50 ml. of acetone and 10 g. of anhydrous copper sulfate was stirred at room temperature for 3 days. After the copper sulfate had been filtered, the acetone was removed and the residue was distilled in a vacuum to give 4.5 g. (69%) of *cis, trans*-5, 9-cyclododecadiene-*cis*-1, 2-diol isopropylidene ketal; b. p. 128~131°C/3 mmHg, m. p. 41~42°C.

Found: C. 76.24; H, 10.27. Calcd. for $C_{15}H_{24}O_2$: C, 76.23; H, 10.24%.

The compound gave the infrared absorptions of the double bonds at 970 and 730 cm^{-1} (liquid).

***cis, trans*-5, 9-Dodecadiene-1, 12-dial.**—Lead tetraacetate was prepared from 450 g. of trilead tetraoxide and 1.4 l. of acetic acid. Into a mixture of 100 g. of *cis, trans*-5, 9-cyclododecadiene-*cis*-1, 2-diol and 150 g. of potassium carbonate in 1 kg. of xylene, lead tetraacetate was stirred in small portions under a nitrogen atmosphere over a 3 hr. period, the mixture was then allowed to stand overnigh after having been stirred for an additional hour. The mixture was filtered, and the solid was washed with xylene. The xylene solutions were washed with water and dried over anhydrous sodium sulfate. After the solvent had been removed, 63 g. of *cis, trans*-5, 9-dodecadiene-1, 12-dial boiling at 140~160°C/4 mmHg were obtained in a 63% yield. A pure specimen was obtained by redistillation; b. p. 147~148°C/4mmHg, n_D^{20} 1.4799, d_4^{20} 0.9625.

Found: C, 73.94; H, 9.42. Calcd. for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

The compound (in a carbon disulfide solution) gave infrared absorptions of the trans and cis double bonds at 970 and 710 cm^{-1} respectively, and the infrared absorbance of this compound in a 6.0 mmol. % carbon disulfide solution at 970 cm^{-1} was of the same degree as that of *cis, trans, trans*-1, 5, 9-cyclododecatriene in a 3.0 mmol. % carbon disulfide solution.

2, 4-Dinitrophenylhydrazone: m. p. 110~111°C.

Found: C, 52.08; H, 4.81; N, 20.09. Calcd. for $C_{24}H_{26}N_8O_8$: C, 51.98; H, 4.72; N, 20.21%.

The Ozonolysis of *cis, trans*-5, 9-Dodecadiene-1, 12-dial.—Ozone was introduced into a solution of 3 g. of the sample and 30 ml. of acetic acid, and the ozonized solution was treated with hydrogen peroxide. When the solution was concentrated, 5 g. of succinic acid melting at 180~182°C was obtained in a 91% yield. Its paper chromatography gave a single spot of succinic acid.

***cis, trans*-5, 9-Dodecadiene-1, 12-diol.**—To a solution of 39 g. of *cis, trans*-5, 9-dodecadiene-1, 12-dial in 100 ml. of ether, 4 g. of lithium aluminum hydride were added over a 2 hr. period; the mixture was then refluxed for 3 hr. while being stirred. After it had stood overnight, the mixture was poured into 100 g. of ice-water and extracted with ether after having been treated with hydrochloric acid. The extracts were washed with water and dried over anhydrous sodium sulfate. After the ether had been removed, the residue was distilled to give 31 g. (79.4%) of a fraction boiling at 165~

170°C/4 mmHg. Redistillation gave *cis, trans*-5, 9-dodecadiene-1, 12-diol; b. p. 167~168°C/4 mmHg, n_D^{20} 1.4889, d_4^{20} 0.9558.

Found: C, 72.81; H, 11.13. Calcd. for $C_{12}H_{22}O_2$: C, 72.68; H, 11.18%.

Bis(phenylurethane): m. p. 72.0~72.5°C.

Found: C, 71.35; H, 7.36; N, 6.35. Calcd. for $C_{26}H_{32}N_2O_4$: C, 71.53; H, 7.39; N, 6.42%.

Diethyl 2, 6, 10, 14-Hexadecatetraene-1, 16-dioate.—A solution of 19 g. of *cis, trans*-5, 9-dodecadiene-1, 12-dial, 50 g. of ethyl hydrogen malonate, and 1 ml. of piperidine in 70 ml. of pyridine was refluxed under a nitrogen atmosphere for 4 hr. The solution was then concentrated, and the residue was distilled in a vacuum to give 23 g. (71%) of a fraction boiling at 220~230°C/6 mmHg. and 4 g. of residue. A pure specimen was obtained by redistillation; b. p. 196~197°C/2 mmHg, n_D^{20} 1.4899, d_4^{20} 0.9919.

Found: C, 71.36; H, 8.98. Calcd. for $C_{20}H_{30}O_4$: C, 71.23; H, 9.04%.

The ozonolysis followed by the hydrolysis of the compound gave a mixture of oxalic and succinic acid.

Attempts to Synthesize Diethyl 6, 10-Hexadecadiene-1, 16-dioate.—An alcohol solution of 6.7 g. (0.02 mol.) of diethyl 2, 6, 10, 14-hexadecatetraene-1, 16-dioate was hydrogenated over palladium-charcoal (or Raney-nickel). After 1 l. (0.045 mol.) of hydrogen had been absorbed, the catalyst was filtered off and the filtrate was distilled to give 5.5 g. of a fraction boiling at 220~240°C/6 mmHg. The fraction gave a mixture of oxalic, succinic and adipic acid by ozonolysis followed by hydrolysis.

Diethyl 1, 16-Hexadecandioate.—An alcohol solution of 6.7 g. (0.02 mol.) of diethyl 2, 6, 10, 14-hexadecatetraene-1, 16-dioate was hydrogenated over palladium-charcoal (or Raney-nickel) for 7 hr. After 1.7 l. (0.08 mol.) of hydrogen had been absorbed, the catalyst was filtered and the filtrate was distilled to give 5.5 g. of diethyl 1, 16-hexadecandioate boiling at 220~240°C/6 mmHg.

By hydrolysis, this compound gave 1, 16-hexadecandioate; m. p. 119~120°C.

The authors wish to express their thanks to Professor Hitosi Nozaki of Kyoto University for his extremely helpful suggestions and his readings of the manuscript.

Sorboses. I. Syntheses of 2, 3-O-Isopropylidene-6-amino-6-deoxy-α-L-sorbofuranoses[1]

By Kanji TOKUYAMA, Masumi KIYOKAWA and Nobuyuki HŌKI

(Received April 9, 1963)

Although 1- and 2-amino derivatives of L-sorbose (I) are known,[2] the 6-amino derivative has not yet been described. In this paper we will report on the synthesis of 6-amino-6-deoxy- and 1, 6-diamino-1, 6-dideoxy-2, 3-*O*-isopropylidene-α-L-sorbofuranoses.

The synthesis was achieved by the schemes outlined in Chart I. For the introduction of an amino group into the C-6 position of a sugar, the tosylation of the hydroxyl group at only this position was desired. At the outset, 1-*O*-acetyl-2, 3-di-*O*-isopropylidene-α-L-sorbofuranose (IV) was prepared to protect all the other hydroxyl groups, and is stable under alkaline conditions and hydrolysable with acid.

The acetylation of 2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (II)[3] with acetic anhydride in pyridine gave 1-*O*-acetyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (III), which was hydrolyzed with 60% acetic acid to give IV. The tosylation of IV with one mole of tosyl chloride in pyridine gave a sirup mixture of the expected 6-tosylate, 1-*O*-acetyl-2, 3-*O*-isopropylidene-6-*o*-tosyl-α-L-sorbofuranose (V) and ditosylate, 1-*O*-acetyl-2, 3-*O*-isopropylidene-4, 6-di-*O*-tosyl-α-L-sorbofuranose (VI). The latter was obtained from IV by treating it with more than 2 mol. of tosyl chloride. The separation of those two tosylates was achieved by alumina chromatography, but with poor yields. The purification of 2, 3-*O*-isopropylidene-6-anilino-6-deoxy-α-L-sorbofuranose (X), which was obtained by the treatment of V with aniline, was also difficult. The deacetylation of V by ethanolic sodium hydroxide gave 2, 3-*O*-isopropylidene-6-*O*-tosyl-α-L-sorbofuranose (VII) as silky crystals. The deacetylation of VI gave a

1) Presented at the Division of Organic Chemistry of the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

2) K. Heynes, H. Paulsen, R. Eichstedt and M. Rolle, *Chem. Ber.*, **90**, 2039 (1957).

Ac=CH_3CO-
Ts=*p*-toluenesulfonyl-

Chart I

crystalline compound, the infrared spectrum of which exhibited no hydroxyl groups, suggesting that the compound is either 2,3-*O*-isopropylidene-6-*O*-tosyl-1,4-anhydro-α-L-sorbofuranose (VIII) or 1,4-anhydro-α-L-psicose (VIII'). Therefore, the deacetylation of the mixture of V and VI, followed by either fractional crystallization or alumina chromatography, was carried out successfully to give two tosylates, VII and VIII (or VIII').

The heating of VII with aniline gave X, while that with liquid ammonia gave 2,3-*O*-isopropylidene-6-amino-6-deoxy-α-L-sorbofuranose (XII) as a sirup, which was converted into a crystalline *p*-nitrobenzoate (XIII).

The structure of anhydrosugar (VIII or VIII') was also investigated. The deacetylation of VI with alcoholic sodium hydroxide gave an anhydrosugar (VIII or VIII'), while that with liquid ammonia at room temperature gave 2,3-*O*-isopropylidene-4,6-di-*O*-tosyl-α-L-sorbofuranose (IX), which was then easily converted into the same anhydrosugar when treated with alcoholic sodium hydroxide. On the other hand, the partial hydrolysis of II to 2,3-*O*-isopropylidene-α-L-sorbofuranose (XVI), followed by tosylation, gave 2,3-*O*-isopropylidene-1,6-di-*O*-tosyl-α-L-sorbofuranose (XVII).[4,5] Reacting with alcoholic sodium hydroxide, XVII was converted into an anhydrosugar which showed an infrared absorption band identical with the above-described anhydrosugar. The latter course has no opportunities for Walden inversion. Therefore, the structure of anhydrosugar was established as VIII. It is noteworthy that no Walden inversion was observed in the reaction of VI to VIII.

The treatment of VIII with aniline gave dianilinosorbose. Under the same conditions, XVII gave the same product. From these results the dianilinosorbose was confirmed to be 2,3-*O*-isopropylidene-1,6-dianilino-1,6-dideoxy-α-L-sorbofuranose (XI). Similarly, the treatment of VIII as well as of XVII with liquid ammonia gave 2,3-*O*-isopropylidene-1,6-diamino-1,6-dideoxy-α-L-sorbofuranose (XIV) as a sirup, which was then converted into a crystalline *p*-nitrobenzoate (XV). The two 1,6-diamino-sorboses, XI and XIV, were also prepared from IX, with the amines via VIII as a probable intermediate.

The infrared absorption spectra of the above-described sorbofuranoses are summarized in Table I. Previously, Barker and Stephens reported that the compounds containing a furanose or hydrofuranol ring exhibit infrared absosption of the A, B, C and D types at 924±

Table I. Infrared absorption bands of sorbofuranoses

Compound	Frequencies (cm^{-1}) of absolute bands				
	Type A	Type B	Type C	Type D	Other peaks
II	945	890	855	830	765
III	980	901	858	835	770
IV	985	888	860	828	770
VII	946	898	870	828	792
VIII	935	895	858	818	780
IX	977	900	865	827	770
X	938	892	866	823	760
XI	934	892	860	812	742
XIII	982	895	863	824	778
XV	944	880	855	830	720
XVI	980	891	864	830	750
XVII	958	890	856	818	765
Mean and standard derivation	958±24	895±7	864±6	823±7	

4) T. I. Temnikova and V. V. Sklyarava, *Zh. Prikl. Khim.*, 27, 1131 (1954); *Chem. Abstr.*, 49, 2952 (1955).
5) H. Ohle, *Ber.*, 71, 562 (1938).

13, 879±7, 858±7 and 799±17 cm^{-1}, respectively.[6] These four types of infrared absorption bands are also characteristic of sorbofuranoses, but their positions then shift to higher frequencies to some extent, appearing at 958±24, 895±7, 864±6 and 823±7 cm^{-1} respectively. 1,2-*O*-Isopropylidene-α-L-sorbopyranose[5] and methyl α-L-sorbopyranoside[7] showed no absorption bands of these four types. Instead, they exhibited absorptions at 910 and 902, 890 and 880, and 772 and 792 cm^{-1}, positions which were identical with those of D-glucopyranose as suggested by Barker et al.[8] These facts are very useful in determining whether or not sorboses are of the furanose type.

Experimental[9]

1-*O*-Acetyl-2,3:4,6-di-*O*-isoproylidene-α-L-sorbofuranose (III).—Into a cooled solution of 200 g. of 2,3:4,6-di-*O*-isopropylidene-α-L-sorbofuranose (II) in 300 ml. of dry pyridine, 200 g. of acetic anhydride in portions were stirred. After having been stirred at 0~5°C for 4 hr. and after standing overnight at room temperature, the reaction mixture was poured onto 800 g. of ice. The product was then extracted with benzene, washed with a sodium bicarbonate solution, dried, and evaporated in vacuo. The residue was distilled to give a colorless sirup, which crystallized immediately. Yield: 204 g. (88%); b. p. 168°C/6 mmHg; m. p. 52°C $[\alpha]_D^{19}$ −16.4 (*c* 1.038, acetone).

Found: C, 55.95; H, 7.51; CH_3CO, 13.96. Calcd. for $C_{14}H_{22}O_7$ (302): C, 55.63; H, 7.29; CH_3CO, 14.23%.

1-*O*-Acetyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (IV).—A solution of 170 g. of 1-*O*-acetyl-2,3:4,6-di-*O*-isopropylidene-α-L-sorbofuranose (III) in 200 ml. of 60% acetic acid was warmed at 80°C for 40 min. The reaction mixture was cooled, made alkaline with sodium carbonate, and then extracted with chloroform. After the removal of the solvent, the residue was distilled to give a colorless sirup. Yield: 88 g. (67.2%); b. p. 205°C/11 mmHg; $[\alpha]_D^{23}$ +7.3 (*c* 0.987, acetone).

Found: C, 50.41; H, 7.07; CH_3CO, 16.26. Calcd. for $C_{11}H_{18}O_7$ (262): C, 50.38; H, 6.87; CH_3CO, 16.41%.

The Tosylation of 1-*O*-Acetyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (IV).—Into a solution of 100 g. of 1-*O*-acetyl-2,3-*O*-isopropylidene-α-L-sorbofuranose (IV) in 300 ml. of dry pyridine, 73 g. of tosyl chloride in small portions were stirred while the mixture was being cooled in ice water. After having been stirred at room temperature for 4 hr., the reaction mixture was poured into 600 ml. of a saturated sodium carbonate solution and then extracted with chloroform, which had been washed with water, dried and evaporated to dryness in vacuo to a sirup (A). Yield: 118 g. i) Ten grams of the A sirup was fractionated by alumina chromatography with chloroform. The first fraction was 0.15 g. of 1-*O*-acetyl-2,3-*O*-isopropylidene-4,6-di-*o*-tosyl-α-L-sorbofuranose (VI), $[\alpha]_D^{23}$ −3.8 (*c* 1.03, acetone).

Found: C, 52.40; H, 5.64; S, 10.80. Calcd. for $C_{25}H_{30}O_{11}S_2$ (570): C, 52.63; H, 5.26; S, 11.22%.

The other compound purely isolated was 0.18 g. of 1-*O*-acetyl-2,3-*O*-isopropylidene-6-*O*-tosyl-α-L-sorbofuranose (V), $[\alpha]_D^{23}$ +4.2 (*c* 0.790, acetone).

Found: C, 52.35; H, 5.88; S, 7.90. Calcd. for $C_{18}H_{24}O_9S$ (416): C, 51.99; H, 5.77; S, 7.69%.

ii) The 4,6-ditosylate VI was also obtained from IV, along with more than 2 mol. of tosyl chloride, by using the same procedure.

iii) A solution of 50 g. of the A sirup in a solution of 8 g. of sodium hydroxide, 60 ml. of water and 280 ml. of ethanol was warmed at 50°C for 40 min. After the solvent had been removed, the residue was extracted with chloroform, which had been washed with water, dried and evaporated to dryness in vacuo to a sirup. a) Recrystallization from ethanol gave 12 g. of 2,3-*O*-isopropylidene-6-*O*-tosyl-1,4-anhydro-α-L-sorbofuranose (VIII). The mother liquor was evaporated to dryness in vacuo. Recrystallization from petroleum ether and ethyl acetate gave 16 g. of 2,3-*O*-isopropylidene-6-*O*-tosyl-α-L-sorbofuranose (VII). b) The sirup dissolved in chloroform was passed through an alumina column and evaporated to dryness. Recrystallization from ethanol gave 12 g. of 2,3-*O*-isopropylidene-6-*O*-tosyl-1,4-anhydro-α-L-sorbofuranose (VIII). The column was eluted out with alcohol. The alcohol solution was evaporated in vacuo. Recrystallization of the residue from petroleum ether and ethyl acetate gave 10 g. of 2,3-*O*-isopropylidene-6-*O*-tosyl-α-L-sorbofuranose (VII).

2,3-*O*-Isopropylidene-6-*O*-tosyl-α-L-sorbofuranose (VII).—A solution of 2 g. of 1-*O*-acetyl-2,3-*O*-isopropylidene-6-*O*-tosyl-α-L-sorbofuranose (V) in 20 ml. of 0.5 N ethanolic potassium hydroxide was warmed at 50°C for 1 hr. To the reaction mixture 100 ml. of chloroform were then added. The chloroform layer was washed with water, dried, and evaporated to dryness. Recrystallization from petroleum ether and ethyl acetate gave 1.1 g. (61.2%) of colorless needles; m. p. 105°C, $[\alpha]_D^{22}$ +15.1 (*c* 1.075, acetone).

Found: C, 51.70; H, 6.05; S, 8.55. Calcd. for $C_{16}H_{22}O_8S$ (374): C, 51.34; H, 5.88; S, 8.56%.

2,3-*O*-Isopropylidene-6-*O*-tosyl-1,4-anhydro-α-L-sorbofuranose (VIII).—This was prepared from 2g. of 1-*O*-acetyl-2,3-*O*-isopropylidene-4,6-di-*O*-tosyl-α-L-sorbofuranose (VI) and 20 ml. of ethanolic potassium hydroxide in a 62% yield by the above-described procedure. M. p. 115°C (recrystallized from ethanol), $[\alpha]_D^{24}$ −11.6 (*c* 1.035, acetone).

Found: C, 53.74; H, 5.62; S, 9.01. Calcd. for $C_{16}H_{20}O_7S$ (356): C, 53.96; H, 5.62; S, 8.99%.

The anhydrosorbose VIII was also obtained from 2,3-*O*-isopropylidene-4,6-di-*O*-tosyl-α-L-sorbofuranose (IX) or 2,3-*O*-isopropylidene-1,6-*O*-tosyl-α-L-sorbofuranose (XVII) in a similar yield by the above-described procedure.

9) All melting points are uncorrected.

2,3-*O*-Isopropylidene-4,6-di-*O*-tosyl-α-L-sorbofuranose (IX).—A solution of 10 g. of 1-*O*-acetyl-2,3-*O*-isopropylidene-4,6-di-*O*-tosyl-α-L-sorbofuranose (VI) in 10 ml. of liquid ammonia was allowed to stand overnight at room temperature. After the liquid ammonia had been removed, a brown sirup was obtained, the solution of which in 50 ml. of chloroform had been washed with water, dried, and evaporated to dryness in vacuo to a sirup. Alumina chromatography with chloroform gave 0.5 g. of colorless needles as a second fraction; m. p. 125°C (recrystallized from ethanol), $[\alpha]_D^{23}$ +8.4 (*c* 1.003, acetone).

Found: C, 52.33; H, 5.48; S, 11.55. Calcd. for $C_{23}H_{28}O_{10}S_2$ (528): C, 52.23; H, 5.34; S, 12.14%.

2,3-*O*-Isopropylidene-6-anilino-6-deoxy-α-L-sorbofuranose (X).—A solution of 2 g. of 2,3-*O*-isopropylidene-6-*o*-tosyl-α-L-sorbofuranose (VII) and 2 g. of potassium carbonate in 20 ml. of aniline was heated while being stirred at 160~170°C for 20 hr. The reaction mixture was then cooled and extracted with three 60 ml. portions of chloroform, which had been washed with water, dried and evaporated in vacuo to get a dark brown sirup. Recrystallization from ethanol gave 0.7 g. of colorless needles; m. p. 140°C, $[\alpha]_D^{24}$ +32.6 (*c* 0.859, acetone).

Found: C, 61.46; H, 7.35; N, 4.59. Calcd. for $C_{15}H_{21}NO_5$ (295): C, 61.02; H, 7.12; N, 4.75%.

2,3-*O*-Isopropylidene-1,6-dianilino-1,6-dideoxy-α-L-sorbofuranose (XI).—This was obtained from 2g. of 2,3-*O*-isopropylidene-6-*O*-tosyl-1,4-anhydro-α-L-sorbofuranose (VIII) and 2 g. of potassium carbonate in 20 ml. of aniline by the above-described procedure for 2,3-*O*-isopropylidene-6-anilino-6-deoxy-α-L-sorbofuranose (X). Recrystallization from ethanol gave 0.8 g. of the sample for analysis; m. p. 151°C, $[\alpha]_D^{25}$ +10.3 (*c* 1.020, acetone).

Found: C, 68.36; H, 7.20; N, 7.78. Calcd. for $C_{21}H_{26}N_2O_4$ (370): C, 68.11; H, 7.04; N, 7.57%.

The dianilino compound XI was also prepared in a similar yield from either 2,3-*O*-isopropylidene-1,6-di-*O*-tosyl-α-L-sorbofuranose (XVII) or 2,3-*O*-isopropylidene-4,6-di-*O*-tosyl-α-L-sorbofuranose (IX) by the same procedure.

2,3-*O*-Isopropylidene-6-amino-6-deoxy-α-L-sorbofuranose (XII).—A solution of 5 g. of 2,3-*O*-isopropylidene-6-*o*-tosyl-α-L-sorbofuranose (VII) in 10 ml. of liquid ammonia was heated on a boiling water-bath for ten days. After the liquid ammonia had been removed, the residue, dissolved in 100 ml. of chloroform, was passed through an alumina column (50 g. of alumina was used) and evaporated to dryness in vacuo. A solution of 1 g. of the residue and 2 g. of *p*-nitrobenzoyl chloride in 15 ml. of dry pyridine was stirred at room temperature for 10 hr. The reaction mixture was poured into a saturated aqueous solution of sodium carbonate while being cooled and was extracted with chloroform which had been washed with water and evaporated to dryness in vacuo. Three recrystallizations from petroleum ether and ethyl acetate gave 1.4 g. of colorless needles (XIII); m. p. 235°C (decomp.), $[\alpha]_D^{30}$ +25.3 (*c* 0.364, acetone).

Found: C, 54.22; H, 3.91; N, 8.32. Calcd. for $C_{30}H_{26}N_4O_{14}$ (666): C, 54.05; H, 3.91; N, 8.41%.

A solution of 1 g. of XIII in 50 ml. of 10% methanolic sodium hydroxide was refluxed for 1.5 hr. After the methanol had been removed, the residue was extracted with chloroform, and the extracts were washed with water saturated with sodium chloride, dried, treated with charcoal, and evaporated to dryness in vacuo to a sirup. Yield: 0.2 g., $[\alpha]_D^{23}$ +28.1 (*c* 1.030, acetone).

Found: C, 49.63; H, 7.69; N, 6.07. Calcd. for $C_9H_{17}NO_5$ (219): C, 49.32; H, 7.76; N, 6.39%.

2,3-*O*-Isopropylidene-1,6-diamino-1,6-dideoxy-α-L-sorbofuranose (XIV).—This was prepared from 5 g. of 2,3-*O*-isopropylidene-6-*O*-tosyl-1,4-anhydro-α-L-sorbofuranose (VIII) and 10 ml. of liquid ammonia by the above-described procedure. *p*-Nitrobenzoate (XV): m. p. 110~115°C (decomp.) (by five recrystallizations from petroleum ether and benzene), $[\alpha]_D^{23.5}$ −69.5 (*c* 0.243, acetone).

Found: C, 53.88; H, 4.24; N, 10.79. Calcd. for $C_{30}H_{27}N_5O_{13}$ (665): C, 54.14; H, 4.06; N, 10.53%.

The 1,6-diaminosorbose (XIV) was obtained as colorless plates. M. p. 52°C, $[\alpha]_D^{30}$ −8.36 (*c* 1.078, acetone).

Found: C, 49.80; H, 7.95; N, 13.01. Calcd. for $C_9H_{18}N_2O_4$ (218): C, 49.54; H, 8.26; N, 12.84%.

The authors wish to express their deep gratitude to Dr. Ken'ichi Takeda, Director of this laboratory, and to Dr. Kaname Hamamoto, Assistant Director of this laboratory, for their encouragement. The authors are also indebted to the other members of this laboratory who measured the optical rotation and made the elementary analysis.

Darstellung und Acetolyse von isomeren Decalylcarbinyltosylaten

Von Nobuo Mori

(Eingegangen am 22. April, 1963)

In der Cyclohexanreihe im allgemeinen solvolysieren sich axiale Tosylate etwa 3~4-mal rascher als die entsprechenden äquatorialen Isomere; die Reaktionsbeschleunigung wird hauptsächlich durch die sogenannte 1, 3-diaxiale Wechselwirkung zwischen der axialen Tosylatgruppe und dem axialen Wasserstoffatom an C_3 order C_5 in den axialen Formen verursacht,[1] und sie steigt ja mit der Zahl der Wechselwirkung.[2] Auch bei der Solvolyse von gewissen äquatorialen Cyclohexyltosylaten, die eine grosse Gruppe wie Methyl in der 1- oder 3-axialen Lage besitzen, wird ähnlich eine ziemlich grosse Beschleunigung trotz der äquatorialen Form erfahren; das kommt daher, dass ihre Ionisierung auch durch Beteiligung der 1- oder 3-axialen grossen Gruppe unterstützt wird. Von einigen Beispielen der Beschleunigung wird zunächst die Solvolyse von *cis*- und *trans*-1, 3-Dimethylcyclohexylbromid[3] angeführt, worin die cis Form mit äquatorialem Bromatom auch mit einer praktisch gleichen Geschwindigkeit wie die der trans Form mit axialem Bromatom acetolysiert wird. Ähnlich acetolysieren sich äquatoriale *cis*-3, 3, 5-Trimethylcyclohexyl-[4] und 2α-Cholestanyl-tosylat[5] rascher als äquatoriale *cis*-3-Methylcyclohexyl- und als 3β-Cholestanyl-tosylat; die Tatsache wurde in ähnlicher Weise auf die grössere Wechselwirkung zwischen der axialen Methylgruppe an C_3 und dem axialen Wasserstoffatom an C_1 in den ersten Verbindungen zurückgeführt.

Im Anschluss an das Problem über solche 1, 3-diaxiale Wechselwirkung, und zwar besonders zur Klärung des Konstellationseinflusses auf die Reaktionsfähigkeit von den axialen und äquatorialen Toluolsulfoxymethylgruppen in der Cyclohexanreihe wurde früher die Acetolyse von *cis*- und *trans*-4-*t*-Butylcyclohexylcarbinyltosylat, die beide das Butyl in Äquatorialstellung enthalten dürfen, aufgeführt, wobei die cis Form ja 4.2-mal rascher als der trans Isomer reagierte.[6] In bezug auf die Untersuchungen erschien es mir interessant und zweckmässig, auch konstellativ einheitliche, isomere Decalylcarbinyltosylate zu studieren.

In der vorliegenden Mitteilung werden somit eine Methode zur Darstellung von bisher unbekannten *cis-cis*-1-, *cis-cis*-2-, *trans-trans*-1- und *trans-cis*-2-Decalylcarbinyltosylaten* und ihre Acetolyse berichtet.

Darstellung von Isomeren Decalylcarbinyltosylaten.—Die vier Tosylate sind in üblicher Weise,[7] mit der praktisch vollständigen Beibehaltung von Konfiguration, aus den entsprechenden Decahydronaphthoesäuren dargestellt worden. Von den acht theoretisch möglichen *cis*- und *tran*-Decahydro-1- und -2-naphthoesäuren sind bisher fünf in reiner Form bekannt.[8] Von denen dürfen vier Verbindungen, nämlich die *cis-cis*-1-, *cis-cis*-2, *trans-trans*-1- und *trans-cis*-2-Säuren, in der rein (die *trans*-Reihe) oder praktisch rein (die *cis*-Reihe) äquatorialen Konstellation vorliegen, somit sind sie zur vorliegenden Untersuchung zweckmässig, während die einzige übrige, nämlich die *cis-trans*-2-Säure, unzweckmässig ist, weil sie etwa in Konstellation uneinheitlich angesehen wird.

In diesem Versuch wurden darum die ersteren vier Säuren als Ausgangsmateriale zur Darstellung der Decalylcarbinyltosylate benützt. Von den Säuren wurden also die *trans-trans*-1- und *trans-cis*-2-Säuren zwar aus den entsprechenden Chlordecalinen in üblicher Weise[8-11] durch Carbonierung ihrer Grignard-Reagenzien hergestellt, während die *cis-cis*-1- und *cis-cis*-2-Isomere durch Hydrierung von 1- und 2-Naphthoesäuren mit Hilfe von Raney-Nickel an Stelle des Platinoxyds[8,12] in ziemlich guter Ausbeute erhalten wurden. Die gereinigten Säuren wurden dann durch Veresterung und

TABELLE I. KONFIGURATIONEN* UND KONSTANTEN DER DARGESTELLTEN DECALINDERIVATE

Substituent X					cis-cis-1	cis-cis-2	trans-trans-1	trans-cis-2
-COOH (Schmp. °C)	125	81	102	106
$-COOC_2H_5$ (n_D^{25})	1.4767	1.4755	1.4700	1.4685
(d_4^{25})	1.0014	0.9988	0.9826	0.9784
$-CH_2OH$ (Schmp. °C)	55	68.8	Flüssig	31.5
$-CH_2OTs$ (Schmp. °C)	67.5	56.2	74.5	62

nachfolgende Reduktion mit Lithiumaluminiumhydrid zu den entsprechenden Decalylcarbinolen umgesetzt, die dann zum Schluss tosyliert wurden.

In der folgenden Tabelle werden nun die dargestellten Decahydronaphthoesäuren, als auch ihre Ester, Carbinole und Tosylate zusammen mit ihren Konstanten angegeben.

Wie man in der Tabelle sieht, sind immer die Brechungsindizes als auch die spezifische Gewichte der Äthylester von der cis-Reihe, deutlich höher als diejenigen der entsprechenden Ester von der trans-Reihe, was wohl von Auwers-Skita Regel[13] erwartet wird.

Acetolyse von Decalylcarbinyltosylaten.—Die Acetolyse der vier Decalylcarbinyltosylate wurde jederzeit bei 110.1°C in Gegenwart von etwas überschüssigem Natriumacetat ausgeführt. Zum Vergleich wurden weiter auch *cis*- und *trans*-4-*t*-Butylcyclohexylcarbinyltosylate, die früher nur in Abwesenheit von der Base solvolysiert wurden, unter den gleichen Bedingungen acetolysiert; die Geschwindigkeiten in beiden Fällen sind beinah dieselben. Die folgende Tabelle zeigt die Verhältnisse von den Acetolysegeschwindigkeitskonstanten zusammen mit ihren als energetisch günstig angesehenen, gestaffelten Konstellationen von I bis zu VI.

Es ist von Interesse, dass die Geschwindigkeitskonstanten der vier Decalylcarbinyltosylate, die hauptsächlich in den entsprechenden äquatorialen Konstellationen von II zu V bzw. in etwas deformierten Formen vorliegen dürfen, zwischen den der *cis*- und *trans*-4-*t*-Butylcyclohexylcarbinyltosylate liegen, trotzdem die Zahl der sogenannten 1, 3-diaxialen Wechselwirkung auf die Tosylatgruppe jedenfalls eins ist, wie später erwähnt werden wird. Wie die gaschromatographische Analyse des Reaktionsprodukts ergibt, treten bei der Acetolyse bei 145~150°C ausschliesslich das Methylenderivat und Carbinylacetat auf. Das Verhältnis von der Eliminierung zu der Substitution zeigt eine regelmässige Zunahme mit der bei 110°C gemessenen Geschwindigkeitskonstante.

Dann könnte man erwarten, dass der Unterschied in den Reaktivitäten vorwiegend von der sterischen Spannung abhängig ist, welche nicht nur auf die Tosylatgruppe, sondern auf die ganze Toluolsulfoxymethylgruppe wirkt und welche bei Ionisierung zu einem Carboniumion nachlässt.

Früher wurde gezeigt,[6] dass sich das axiale *cis*-4-*t*-Butylcyclohexylcarbinyltosylat 4.2-mal rascher als der entsprechende äquatoriale trans-Isomer acetolysiert, und dass die Reaktionsbeschleunigung unter anderm auf die sterische Spannung zurückzuführen ist, welche durch die relative grosse Wechselwirkung zwischen dem Wasserstoffatom in der Methylengruppe und den axialen Wasserstoffatomen an C_3 und C_5 in der Konstellation von I verursacht wird und welche bei Ionisierung zu einem Carboniumion nachlässt. Durch solch eine auf das Methylen-Wasserstoffatom wirkende sterische Spannung kann sich der oben angegebene Unterschied in der Acetolysegeschwindigkeit von den Tosylaten folgendermassen, zahlenmässig, erklären.

Wie man in der Tabelle sieht, bedeutet die Wechselwirkung vom Typus A immer die 1, 3-diaxiale Wechselwirkung zwischen der Tosylatgruppe und dem Wasserstoffatom, während diejenige vom Typus B die 1, 3-diaxiale Wechselwirkung zwischen den Wasserstoffatomen in der Methylengruppe und in 3-Stellung, und auch weiter diejenige vom Typus C die Wechselwirkung zwischen den zwei Wasserstoffatomen in der Methylengruppe und in 4-Stellung. Von diesen drei Wechselwirkungen, könnte die vom Typus C den höchsten Einfluss auf die Ionisierung des Tosylatmoleküls ausüben, weil die an der Wechselwirkung vom Typus C sich beteiligenden zwei Wasserstoffatome zueinander näher als in 1, 3-diaxialer Stellung stehen, somit das Molekül in einem höheren gespannten Zustand sein sollte.

13) K. von Auwers, *Ann.*, **420**, 84 (1920); A. Skita, *Ber.*, **53**, 1792 (1920); A. Skita und W. Faust, ebenda, **64**, 2878 (1931).

* Die Stellen der Wasserstoffatome werden in den Formeln mit schwarzen Tupfen gezeigt, diese Tupfen zeigen, dass ein Wasserstoffatom auf der Fläche des Moleküls liegt.

Tabelle II. Konstellationen, relative Reaktionsgeschwindigkeiten und Verhaltnis vom Olefin zum Acetat

Konstellation vom Tosylat	Wechselwirkung vom Typus A(TsO:H)	B(H:H)	C(H:Ⓗ)	Relative Reaktionsgeschwindigkeiten	Verhaltnis vom Olefin zum Acetat
 (I) *cis*-4-*t*-Butylcyclohexylcarbinyl	1	1	2	4.07	1.0
 (II) *cis-cis*-1-Decalylcarbinyl	1	2	1	3.00	0.92
 (III) *trans-trans*-1-Decalylcarbinyl	1	2	1	2.51	0.80
 (IV) *cis-cis*-2-Decalylcarbinyl	1	3	0	1.60	0.65
 (V) *trans-cis*-2-Decalylcarbinyl	1	3	0	1.14	0.53
 (VI) *trans*-4-*t*-Butylcyclohexylcarbinyl	1	3	0	1.00	0.47

Vorausgesetzt, dass die Abnahme der Wechselwirkung, u. a. vom Typus C, beim Übergang des Grundzustandes in den Carboniumion, hauptsächlich den Nachlass der Spannung im Tosylatmolekül verursacht, so lässt sich die Grösse ihrer Acetolysegeschwindigkeit überhaupt nur auf Grund von der Wechselwirkungszahl vom Typus C leicht erklären.

Wie die Tabelle lehrt, ist die Zahl vom Typus A in allen Konstellationen eins, während die vom Typus C eine regelmässige Zunahme mit der Geschwindigkeitskonstante und die vom Typus B eine Abnahme zeigen. Daraus folgt, dass hauptsächlich die Wechselwirkung vom Typus C die Acetolysegeschwindigkeit kontrolliert.

Vergleicht man noch die drei Tosylate von IV, V und VI miteinander, welche die gleiche Wechselwirkung (A+3B) enthalten, so sieht man, dass die rein äquatoriale *trans-cis*-2-Tosylat-(V) und als rein äquatorial angesehene *trans*-4-*t*-Butyl-verbindungen (VI) fast gleich

schnell reagieren, und zwar verläuft die Reaktion von V rascher nur um den Faktor 1.14 als die von VI, aber das als fast rein äquatorial angesehene *cis-cis*-2-Tosylat (IV) acetolysiert sich 1.6-mal so rasch wie VI. Für diese erhöhte Reaktivität von IV scheint die uneinheitliche Konstellation vorantwortlich zu sein, weil der axiale Konstellationsisomer ziemlich rascher als der äquatoriale Isomer (IV) reagieren will.

Nach einer ähnlichen Ursache acetolysiert sich auch das als fast rein angesehene *cis-cis*-1-Tosylat (II) etwas racher als der rein äquatoriale *trans-trans*-1-Isomer (III), trotz der gleichen Wechselwirkungszahl (A+2B+C).

Beschreibung der Versuche

Alle Schmelzpunkte sind korrigiert.

***cis-cis*-1-Decahydronaphthoesäure.**—Eine schwach alkalische wässrige Lösung von 1-Naphthoesäure (10 g) in einer 5-proz. Natriumhydroxydlösung wurde in Gegenwart von Raney-Nickel (5 g) unter einem anfänglichen Druck von 75 Atom. bei 190～200°C hydriert. Nachdem die Aufnahme des Wasserstoffs beendet war, wurde das Reaktionsgemisch abgesaugt und dann unter Eiskühlung und Umrühren mit konzentrierter Salzsäure angesäuert, um eine sauere Substanz auszufällen. Die Substanz wurde abgesaugt und mit Wasser gewaschen. Das Rohprodukt (9 g) wurde mehrmals aus Ameisensäure umkristallisiert, bis der Schmelzpunkt konstant wurde, dabei wurden Schuppchen (3 g) vom Schmp. 123.5～125.5°C erhalten.

***cis-cis*-2-Decahydronaphthoesäure.**—2-Naphthoesäure (10 g) wurde wie bei der *cis-cis*-1-Säure hydriert. Das Reaktionsgemisch wurde abgesaugt und dann unter Eiskühlung und Umrühren mit Salzsäure angesäuert. Das ausgefallene Öl wurde in Äther aufgenommen, die ätherische Lösung über Natriumsulfat getrocknet und dann verdampft. Der ölige Rückstand erstarrte nach Stehenlassen einige Tage im Kühlschrank zu einer farblosen Kristallmasse, und er wurde aus etwas Hexan zweimal umkristallisiert, wobei Nädelchen (3 g) vom Schmp. 76～79°C erhalten wurden. Ein Teil vom Produkt ergab nach noch einer Umkristallisierung aus etwas Hexan Nadeln vom Schmp. 80.5～81.5°C.

***trans-trans*-2-Decahydronaphthoesäure.**—Reines *trans*-Decalin (300 g) wurde nach der bekannten Methode von Dauben und Tweit,[10] indessen bei einer höheren Temperatur von 10～15°C und im Laufe von einigen Stunden chloriert, wobei ein Gemisch von *trans*-1- und *trans*-2-Chlordecalin (120 g) vom Siedp. 100～117°C/12 Torr. erhalten wurde. Die Grignard-Lösung aus dem Chlordecalingemisch (52 g), Magnesium (12 g) und Jod (0.05 g) in wasserfreiem Äther (300 ccm) wurde unter starkem Umrühren und Kühlen mit Eis-Kochsalz bei −10～−5°C mit getrocknetem Kohlendioxyd so lange behandelt bis die Reaktionstemperatur nicht mehr anstieg, danach unter Kohlendioxyd noch 30 Min gerührt. Das Reaktionsgemisch wurde in der Kälte mit eiskalter verd. Schwefelsäure umgesetzt, und dann wurde die ätherische Schicht einmal mit Salzlösung gewaschen und zweimal mit 10-proz. Natriumhydroxydlösung extrahiert. Die alkalische Lösung wurde unter Eiskühlung mit konz. Salzsäure angesäuert, um ein saueres Öl auszufällen, das in der Kälte sich kristallisierte. Nach einigemaligem Umkristallisieren aus Hexan ergaben sich Blättchen (6 g) vom Schmp. 105.5～106.5°C. Diese Säure gab ein Amid als Blättchen vom Schmp. 205～206°C.

***trans-trans*-1-Decahydronaphthoesäure.**—Aus der Mutterlauge der Umkristallisierung der *trans-cis*-2-Säure wurde wenige reine *trans-trans*-1-Decahydronaphthoesäure (1 g) vom Schmp. 102°C (aus wässrigem Äthanol) nach der chromatographischen Methode von Dauben und Tweit[10] getrennt.

Auch nach der anderen Methode[8] wurde diese Säure durch Carbonierung von einer Grignardlösung des bei Chlorierung vom *trans-trans*-1-Decalol gewonnen reinen *trans-trans*-1-Chlordecalins dargestellet. Nach zweimaligen Umkristallisierungen aus wässrigem Äthanol ergaben sich Nadeln vom Schmp. und Misch-Schmp. 100～101°C. Der Misch-Schmp. mit der bei 106°C schmelzenden *trans-cis*-2-Säure war 85～88°C.

***cis-cis*-1-Decahydronaphthoesäureäthylester.**—Die reine *cis-cis*-1-Säure (4.3 g) wurde in eine Lösung von konz. Schwefelsäure (1 ccm) in absolutem Äthanol (50 ccm) zugesetzt und 1.5 Stdn. unter Rückfluss erhitzt, und dann wurde das Lösungsmittel unter vermindertem Druck abgedampft. Der Rückstand wurde in Äther aufgenommen, mit Wasser und 10-proz. Natriumcarbonatlösung gewaschen und über Natriumsulfat getrocknet. Nach Abdampfen von Äther wurde der ölige Rückstand in Vakuum destilliert. Ausb. 3.8 g, Siedp. 145～151°C/19.5 Torr. Die Hauptfraktion (2.9 g) vom Siedp. 148～150°C/19.5 Torr. hatte n_D^{25} 1.4767, d_4^{25} 1.0014 und MR_D 59.31 (Ber. 59.80).

***cis-cis*-2-Decahydronaphthoesäureäthylester.**—Dieser Ester wurde in ähnlicher Weise wie bei der 1-Ester aus der *cis-cis*-2-Säure (2.5 g) vom Schmp. 76～79°C hergestellt. Ausb. 2.4 g, Siedp. 145～152°C/19.5 Torr. Die Hauptfraktion (1.8 g.) von Siedp. 148～150°C/19.5 Torr. zeigte n_D^{25} 1.4755, d_4^{25} 0.9988 und MR_D 59.32 auf.

***trans-trans*-1-Decahydronaphthoesäureäthylester.**—Die reine *trans-trans*-1-Säure (3.0 g) lieferte den Ester (3.0 g) vom Siedp. 143～146°C/19.5 Torr. Die Hauptfraktion (2.5 g) vom 144～145°C/19.5 Torr. hatte n_D^{25} 1.4700, d_4^{25} 0.9826 und MR_D 59.71.

***trans-cis*-2-Decahydronaphthoesäureäthylester.**—Die reine *trans-cis*-2-Säure (4.5 g) ergab den Ester (4.2 g) vom Siedp. 145～150°C/20 Torr. Die Hauptfraktion (2.2 g) vom Siedp. 145～148.5°C/20 Torr. hatte n_D^{25} 1.4685, d_4^{25} 0.9784 und MR_D 59.37.

***cis-cis*-Decalyl-1-carbinol und dessen Tosylat.**—Zu einer Suspension von Lithiumaluminiumhydrid (1.4 g) in getrocknetem Äther (50 ccm) wurde eine Lösung des *cis-cis*-1-Säureesters (3.7 g) in getrocknetem Äther (30 ccm) unter Eiskühlung bei 0～5°C tropfenweise zugegeben, und nach der Entfernung des Eisbades noch 30 Min bei Raumtemperatur gerührt. Das Reaktionsgemisch wurde unter Eiskühlung mit verd. Schwefelsäure umgesetzt, und die organische Schicht wurde, nach dem Waschen mit Salzlösung, über Kaliumcarbonat getrocknet und

abgedampft. Der ölige Rückstand wurde in Vakuum destilliert, wobei ein zähes farbloses Öl (2.5 g) vom Siedp. 136～139°C/12 Torr. erschien, das im Kühlschrank zu einer Kristallmasse bald erstarrte. Die Ausbeute der Hauptfraktion war 2.5 g, Siedp. 138～138.5°C/12 Torr. Nach Umkristallisieren aus wässrigem Äthanol ergab sie Nadeln von Schmp. 55°C.

Fef. C, 78.66; H, 11.77. Ber. für $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

Das Carbinol (1.5 g) in wasserfreiem Pyridin (5 cc) wurde bei 0～5°C mit pulverisiertem *p*-Toluolsulfochlorid (2.0 g) behandelt und nach Stehenlassen über Nacht im Kühlschrank zu einem Gemisch von Eis und konz. Salzsäure eingegossen. Das ausgefallene Öl erstarrte bald. Nach Absaugen wurde es zweimal aus Äthanol umkristallisiert. Das gereinigte Tosylat (2.0 g) war Blättchen vom Schmp. 67～67.5°C.

Gef. C, 67.15; H, 8.22. Ber. für $C_{18}H_{26}O_3S$: C, 67.06 H, 8.13%.

***cis-cis*-Decalyl-2-carbinol und dessen Tosylat.**—Bei ähnlicher Behandlung des *cis-cis*-2-Säureesters (2.2 g) mit Lithiumaluminiumhydrid (1.0 g) wie bei der *cis-cis*-1-Verbindung ergab sich ein Carbinol (1.4 g) als ein zäher Sirup vom Siedp. 145～148°C/20 Torr. Die Hauptfraktion (1.0 g) vom Siedp. 147～147.5°C/20 Torr. hatte n_D^{25} 1.4983, d_4^{25} 0.9891 und MR_D 49.87 (Ber. 50.56). Nach Stehenlassen einige Tage im Eisschrank erstarrte die Fraktion zu einem Kristallbrei. Nach dem Abpressen auf Ton und Umkristallisieren aus wässrigem Äthanol formten sich Nadeln vom Schmp. 68.6～68.8°C.

Gef. C, 78.61; H, 12.24%.

Das Carbinol (1.1 g) ergab ein Tosylat (1.0 g) als Nadeln, Schmp. 56.0～56.2°C aus wässrigem Äthanol. Der Misch-Schmp. mit dem bei 62°C schmelzenden *trans-cis*-2-Carbinyltosylat deprimiert zu 43.5～45.5°C.

Gef. C, 67.33; H, 8.30%.

***trans-trans*-Decalyl-1-carbinol und dessen Tosylat.**—Aus dem *trans-trans*-1-Säureester (2.8 g) und Lithiumaluminiumhydrid (1.2 g) ergab sich ein Carbinol (1.6 g), ein zäher Sirup vom Siedp. 133～136°C/12 Torr. Die Hauptfraktion (1.6 g) vom Siedp. 132～132.5°C/11.5 Torr. zeigte n_D^{25} 1.4952, d_4^{25} 0.9808 und MR_D 50.05 auf. Das Carbinol (1.0 g) ergab ein Tosylat (1.1 g) als Blättchen vom Schmp. 74.5°C aus wässrigem Äthanol.

Gef. C, 66.80; H, 8.41%.

***trans-cis*-Decalyl-2-carbinol und dessen Tosylat.**—Aus dem *trans-cis*-2-Säureester (4.0 g) und Lithiumaluminiumhydrid (1.5 g) ergab sich ein Carbinol (3.0 g) als ein zäher Sirup vom Siedp. 142～145°C/20 Torr, das im Kühlschrank zu einer Kristallmasse erstarrte. Die Ausbeute der Hauptfraktion war 2.5 g, Siedp. 144～144.5°C/20 Torr., und die Kristallmasse schmolz bei 29～30°C. Nach Umkristallisieren aus wässrigem Äthanol ergaben sich Nadeln vom Schmp. 31～31.5°C.

Gef. C, 78.28; H, 12.22%.

Das Carbinol (2.0 g) lieferte ein Tosylat (2.7 g) als Nadeln vom Schmp. 62°C nach Umkristallisieren aus Äthanol.

Gef. C, 67.12; H, 8.16%.

Messungen

Essigsäure.—Eisessig wurde zweimal durch Gefrieren gereinigt, mit 3% Essigsäureanhydrid und 1% Natriumacetat unter Rückfluss 2 Stdn. erhitzt, und dann fraktioniert.

Messungen von Acetolysegeschwindigkeit.—Das Tosylat und ein wenig Überschüss vom Natriumacetat wurden in 50 ccm Essigsäure gelöst, und auf 7～8 Ampullen verteilt, die sofort zugeschmolzen und in einem auf 110.1 ±0.1°C eingestellten Thermostat gebracht wurden. Nach einer bestimmten Zeit wurde eine Ampulle rasch auf 10°C abgekühlt, 5 ccm der Lösung sofort mit 0.05 N-Essigsäure Perchlorsäure mit Bromphenolblau als Indikator titriert, um das unreagierte Natriumacetat zu bestimmen. Die Geschwindigkeitskonstante (k) wurde nach der Formel erhalten:

$$k = (2.303/t)\log\{a/(a-x)\}$$

hier a: Anfangskonzentration des Tosylats, x: Konzentration der nach der Zeit t verbrauchten Base.

Die berechneten Intervallkonstanten befanden sich jedenfalls innerhalb der Fehlergrenzen

* Wert bei 110.0°C[6])

von 3% aus dem Mittelwert. Beispielsweise wird ein typischer Verlauf der Acetolyse von *trans-cis*-2-Decalylcarbinyltosylat in Tabelle III gezeigt. Tabelle V zeigt die mittelen Acetolysegeschwindigkeitskonstanten erster Ordnung von den Tosylaten.

Acetolyse.—Acetolyse von den Tosylaten und Analyse der Acetolyseprodukte wurden auf jeden Fall in folgender Weise ausgeführt. 1 g Tosylat und 0.3 g Natriumacetat wurden in 35 ccm Essigsäure unter Rückfluss 35 Stdn. bei 145~150°C erhitzt. Die schwach gelbliche oder farblose Lösung wurde mit Wasser und Äther verdünnt, und dann ein grosser Teil der Essigsäure bei 0°C mit einer verdünnten Natriumhydroxydlösung neutralisiert. Die getrennte ätherische Schicht wurde mit Wasser, mit einer Natriumcarbonatlösung und wieder mit Wasser gewaschen. Aus der über Natriumsulfat getrockneten ätherischen Lösung wurde der Äther in Vakuum abgedampft. Ein schwach gelblicher öliger Rückstand wurde jedenfalls in fast quantitative Ausbeute (0.5~0.6 g) erhalten, welcher nach dem Ergebnis der gaschromatographischen Analyse nur aus einem Methylenderivat und Carbinylacetat bestand.

Der gaschromatographische Versuch wurde bei 180°C mit einem Gaschromatograph GCG-2 von Yanagimoto ausgeführt, in welchem eine Thermosol-2-Säule (2 m), Helium als Trägergas und eine aufgegebene Menge 6 μl benützt wurden. Die Gaschromatographiken der Reaktionsprodukte hatten jedenfalls nur zwei Piks mit Retentionszeiten ca. 6 und 60 Min. Der erste Pik war vom Methylenderivat und der letzte Pik vom Carbinylacetat, nach dem Befunde der unter den gleichen Bedingungen erhaltenen Retentionszeiten vom authentischen 2-Methylen-*trans*-decalin und *trans-cis*-2-Decalylcarbinylacetat. Das Flächenverhältnis vom Methylenderivat zum Acetat wurde berechnet, welches in Tabelle II gezeigt wird.

Ich danke herzlich Herrn Prof. Dr. Yojiro Tsuzuki für seinen Rat und Herrn Sadatoshi Akahori im Laboratorium für Organische Chemie der Universität Tokio, für die Elementaranalysen.

Intramolecular Hydrogen Bonding in Some Aliphatic α- and β-Hydroxy-carboxylates

By Nobuo MORI, Satoshi OMURA, Osamu YAMAMOTO, Teruo SUZUKI and Yojiro TSUZUKI

(Received July 19, 1963)

High resolution proton magnetic resonance (NMR) spectroscopy has recently been employed as a powerful means for investigating various types of hydrogen bonds. It is useful when the changes in the chemical shift of a proton involved in the formation of a hydrogen bond are sufficiently large,[1] and it is useful as an indicator of hydrogen-bond formation similar to the changes in X–H stretching frequency due to the formation of a hydrogen bond.[2]

The formation of intramolecular hydrogen bonds in dilute solutions in non-polar solvents is a simple case, since in general only one species is involved. For various *o*-substituted phenols in carbon tetrachloride, the change in the chemical shift of the hydroxyl-proton due to the formation of an intramolecular hydrogen bond has been correlated with the corresponding change in the O–H stretching frequency.[3,4] In addition, the dilution-shift curves of *o*-halophenols[4,5] in carbon tetrachloride, quite different from that of phenol itself, are generally of an s-shape, with a reversal of the curvature at a relatively high concentration.

The intramolecular hydrogen bonding in some aliphatic α- and β-hydroxy-carboxylates, particularly *d*-tartrates, has previously been studied by means of optical rotation[6] and by infrared spectroscopy.[7] The present paper will report on further investigation of the esters carried out by NMR and infrared spectroscopy.

Experimental

All ethyl esters were prepared by Fischer's method from hydroxy-carboxylic acids and ethyl alcohol in the presence of dry hydrogen chloride and were repeatedly fractionated. These esters are of the racemic form, unless otherwise stated, and are listed in Table I.

All the NMR spectra of the esters were measured in pure liquid or in solutions in varions concentrations up to 0.002 mol./l. in carbon tetrachloride at 20°C with a Varian Model DP 60 NMR spectrometer; chemical shifts were read by the sideband method, using tetramethylsilane (TMS) as an internal standard. Each shift in the table is the average of at least two independent measurements. Full analysis of the signals in the spectra could readily be made on the basis of the chemical shift and the relative intensity.

Many data of the infrared measurement were taken from the previous works,[7] while others were obtained in a similar manner at 20°C; the pure liquid measurement, however, was carried out with a Hitachi EPI-002 infrared spectrometer equipped with a sodium chloride prism and the solution measurement, with a Perkin-Elmer 21 spectrometer equipped with a lithium fluoride prism. The infrared and the NMR data obtained for the hydroxyl groups in the esters are shown in Table I.

Results and Discussion

Infrared Measurements of the Hydroxyl Groups. — The infrared spectra of the pure liquid esters display in each case one broad absorption band at a frequency of from 3420 to 3500 cm^{-1}, higher than the 3350 cm^{-1} of the hydroxyl in pure ethanol, as seen in Table I.

7) a) Y. Tsuzuki et al., ibid., **75**, 1030, 1033 (1954); b) N. Mori, Y. Tsuzuki and Tsubomura, ibid., **77**, 459 (1956).

Of particular interest is the steric effect of the methyl group on the O–H frequency. The OH frequency of the α-hydroxy-esters increases in the order of the glycolate (3427 cm^{-1}), the lactate (3436 cm^{-1}) and the α-hydroxy-isobutyrate (3478 cm^{-1}) ; in the β-hydroxy- esters a similar trend is found for the β-hydroxypropionate (3426 cm^{-1}) and the β-hydroxybutyrate (3430 cm^{-1}). This is undoubtedly to be attributed to a weaker intermolecular hydrogen bond resulting from steric hindrance by the methyl group.

Preliminary measurements of the lactate and the tartrate carried out in concentrations of up to ca. 0.002 mol./l. have shown that the position of the O–H band is displaced with a decreasing concentration towards a higher frequency and that, simultaneously, a shoulder or an additional weak band appears, overlapped with the first strong band. At different concentrations below ca. 0.05 mol./l., the positions and relative intensities of the bands were substantially independent of the concentration. Accordingly, the spectra of the other esters were measured in a concentration near 0.03 mol./l. in carbon tetrachloride. The results of the measurement in solution are shown in Figs. 1—5.

In the α-hydroxy-esters, the strong and the weak bands appear at ca. 3545 and 3610 cm^{-1} respectively. The former should be assigned to the hydroxyl group intramolecularly associated with the carbonyl in the carboxylate

group, as has been suggested in a previous paper.[7b] On the other hand, the latter is considerably lower than the 3631 cm^{-1} of the free hydroxyl of ethanol, although near that (3580~3610 cm^{-1}) of the intramolecularly hydrogen-bonded hydroxyl in many aliphatic diols.[8] Nevertheless, it is not evident whether the weak band is due to the hydroxyl associated with the ether-oxygen in the carboxylate group or to the free hydroxyl, because the electron-attracting nature of the carboxylate group would cause the absorption band of the α-hydroxyl to shift towards a lower frequency.

In all the β-hydroxy-esters except the isomeric hexahydrosalicylates, the strong band appears at 3560 or 3582 cm^{-1}; this is due to the hydroxyl intramolecularly associated with the carbonyl in the carboxylate group. The weak band at 3625 cm^{-1} may be due to the hydroxyl, either free or associated in a manner similar to that in the corresponding case of the α-hydroxy-esters. This may be compared with the 3630 cm^{-1} of the free hydroxyl in methyl 3-hydroxyurs-12-en-24-oate:[9]

Further, when the frequencies of the hydroxyls in the α- and β-hydroxy-esters in a liquid (ν_1) and in a dilute solution (ν_0) are compared, the values of ν_0 for the strong band due to the α-hydroxyl are seen to be lower by 15~30 cm^{-1} than those for the β-hydroxyl; an even more remarkable difference is found in the values of $\nu_0-\nu_1$ or $\Delta\nu$. Consequently, this seems to be directly related to the strength of the intramolecular hydrogen bond in the α- and β-hydroxy-esters, which form a five- and a six-membered ring respectively. It is also of interest that, as the number of methyl groups on the carbon atom with the hydroxyl group increases, the frequencies of both the weak and the strong bands decrease and there is a simultaneous decrease in the intensity of the former band relative to that of the latter, as can be seen in Figs. 1 and 2. However, this is not surprising, since the methyl group would bring about a geometry faborable to form a stronger intramolecular hydrogen bond. Similarly, in isomeric ethyl hexahydrosalicylates, the intramolecular hydrogen bond of the hydroxyl formed with the carbonyl in the cis form is considered to be stronger than that of the trans form.

Chemical Shifts of Hydroxyl-protons and Other Protons.—As may be seen in Table I, the signal position (δ_1) of the hydroxyl-proton in each of the α- and β-hydroxy-esters in the pure liquid state moves towards a higher field with the increasing number of methyl groups on the carbon atom with the hydroxyl group. Such a trend is also seen in the series of alcohols except methanol, as may be seen in the table. This is undoubtedly due to a weaker intermolecular hydrogen bond resulting from steric hindrance by the methyl group, as has been pointed out in connection with the infrared measurement. Figure 6 shows the dilution-shift curves for some of the esters investigated. The insert in the figure, plotted on a larger scale, shows the detailed low-concentration measurements extrapolated to infinite dilution. The chemical shifts (δ_0) of the hydroxyl-protons in the table are those extrapolated to infinite dilution. It is of interest that the value of δ_0 in each of the α- and β-hydroxy-esters increases with the increased number of methyl groups on the carbon atom having the hydroxyl group, although no such trend is seen in the series of alcohols except methanol. Consequently, this must be related to the intramolecular hydrogen-bonding strength in the esters.

It is known that a stronger intramolecular hydrogen bond results in a lower value of the dilution shift, as may be seen, for example, in *o*-chlorophenol[5] in a carbon tetrachloride

solution, where the dilution shift of the hydroxyl-proton is only 0.8 p.p.m. as compared with 2.8 p.p.m. of the phenols containing no intramolecular hydrogen bond; also, in β-chloroethanols[10] the value is 3.5 p.p.m., which is lower than the 4.5 p.p.m. of ethanol itself. Accordingly, the relatively low dilution shifts of 1.3~2.8 p.p.m. of the hydroxyl-protons in the esters are substantially caused by the intramolecular hydrogen bond formed in them. However, the curves of the dilution shifts for the esters, as shown in Fig. 6, are generally of an L-shape, differnt from that of *o*-chlorophenol, which features the reversal of the curvature at ca. 20 mol. % in carbon tetrachloride.[5] A similar reversal of curvature was observed even with ethanol itself at a low concentration of 1.5 mol. %[11] and also with some alcohols.[10] This might seem to lead to the conclusion that, even in a concentration as low as 1 mol. % (or ca. 0.01 mol./l.) or below, each of the esters consists of a system of monomers and intermolecularly associated species, with a decreasing proportion of the latter to the former on further dilution. This is strikingly different from the findings based on the infrared measurement of the hydroxyl group in a dilute solution, where substantially all molecules are present as monomer even in a concentration as high as 0.1 mol./l. This contradiction may be settled by a possible assumption that the changes in the chemical shift of the hydroxyl-proton on dilution are caused not only by the dissociation of the polymer, but also partially by some other factors such as those which would bring about the dilution shifts of protons other than the hydroxyl-proton, as will be mentioned later. Consequently, a dilution-shift curve of the hydroxyl-proton resulting from such factors would be superimposed on a real hydrogen-bond-shift curve of the proton to produce the dilution-shift curve of an apparent L-shape without the reversal of curvature.

In all the esters investigated, a similar dilution shift has also been observed for protons other than the hydroxyl-proton, most especially for the proton on the carbon atom with the hydroxyl group. The changes in the chemical shift of such protons in some of the esters are shown in Fig. 7. In general, the dilution shift of the proton on the carbon atom with

either the hydroxyl or carboxylate group, A or B, is ca. 5 c. p. s. towards a higher field, while that of the proton on the carbon atom with both groups C is ca. 10 c.p.s. in the same direction. Further, the signals due to the methyl- and methylene-protons in the ethyl-carboxylate group shift by 3 c.p.s. towards a lower field. These shifts seem to have no direct relation to the hydrogen bonding, since there is a shift of 8 c.p.s. for the α-proton in ethyl α-methoxypropionate, but no shift for the α-proton in isopropanol.

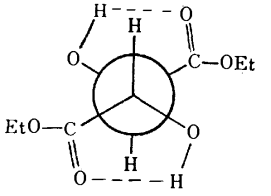
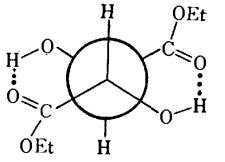
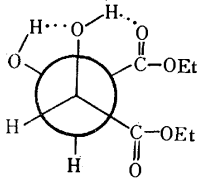
Intramolecular Hydrogen Bonding in Ethyl Tartrates, Malate and Isomeric Hexahydrosalicylates.—*Ethyl meso-Tartrate.*—The infrared spectrum of ethyl *meso*-tartrate in Fig. 3 displays on strong absorption band at 3534 cm^{-1}, with a shoulder at 3584 cm^{-1}; the relative intensity of the former to the latter is ca. 10. As for the form of the intramolecular hydrogen bonding of this ester in a dilute solution in carbon tetrachloride, conformation I seems to be the most preferable of the three I—III given below. This suggestion is based on the facts that the frequency of the strong band is very close to that of the α-hydroxyl group, especially in ethyl lactate and α-hydroxyisobutyrate, but it is almost completely different from those of the β-hydroxyl group and some diols. Furthermore, the chemical shift of the hydroxyl-proton in infinite dilution is substantially equal to those of the α-hydroxy-esters, but quite different from those of the β-hydroxy-esters. On the other hand, the shoulder seems to be due to the hydroxyl associated with the carbonyl in the β-carboxylate group in the same molecule. Conformation III, containing a hydrogen bond between the two hydroxyls, is unlikely, at least in a carbon tetrachloride solution, because of the relatively high steric repulsion between the groups in the conformation.



I



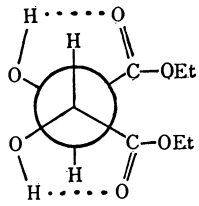
II



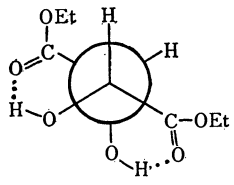
III

Ethyl d-Tartrate.—The infrared spectrum of this ester in Fig. 3 contains two bands, at 3532 and 3588 cm^{-1}, the relative intensity of the former to the latter being ca. 10. The frequencies of the bands and also the chemical shift in infinite dilution are the same as those of

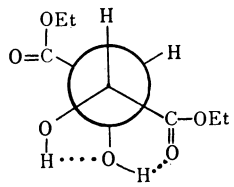
ethyl *meso*-tartrate; therefore, the strong band should be assigned to the hydroxyl associated with the α-carboxylate-carbonyl in conformation IV, as has been suggested in a previous paper.[7b] It is not evident whether or not the weak band is due to the hydroxyl in conformation V or VI.



IV



V

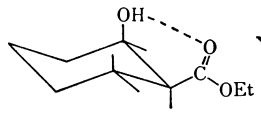


VI

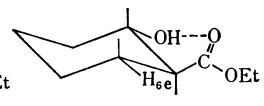
Ethyl Malate.—The strong band at 3535 cm^{-1} in Fig. 4 may be assigned to the hydroxyl forming the same type of intramolecular hydrogen bond as in the α-hydroxy-esters. This assignment is borne out by almost the same chemical shift of the hydroxyl-proton as that of the tartrates. The shoulder near 3590 cm^{-1} may be due to the hydroxyl associated with the β-carboxylate-carbonyl.

Ethyl cis- and trans-Hexahydrosalicylates.—According to the NMR spectra (60 Mc.) of isomeric 4-*t*-butylcyclohexanols[12] and decalols[13], the axial hydrogen on the carbon atom with the hydroxyl group appears in a field higher by ca. 30 c.p.s. than the signal position of the epimeric equatorial hydrogen (−235 c.p.s. from TMS), the two signals being broadened unresolved spin-spin multiplets. This fact is useful in the conformational analysis of the isomeric ethyl hexahydrosalicylates.

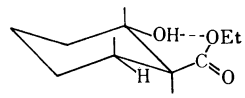
The NMR spectrum of the cis form in carbon tetrachloride in Fig. 8-IX displays a signal at ca. −240 c.p.s. overlapped with that of the methylene protons in the ethylcarboxylate group. On the other hand, the spectrum of the trans form in Fig. 8-X has a broadened signal at ca. −220 c.p.s. The infrared spectrum of the cis ester in Fig. 5 has only one strong absorption band, at 3450 cm^{-1}; consequently, conformation VII, containing an intramolecular hydrogen bond of the axial hydroxyl with the carbonyl in the equatorial carboxylate group, shold be assigned for this isomer. On the other hand, the infrared spectrum of the trans form in Fig. 5 contains two bands at 3560 and 3593 cm^{-1} with the intensity ratio of ca. 3 : 1. The former may be due to the hydroxyl associated with the carbonyl in conformation VIII, and the latter, to one associated with the ether-oxygen in conformation IX.



VII



VIII



IX

The Correlation between Chemical Shifts and Frequencies.—For various *o*-substituted phenols in a dilute solution in carbon tetrachloride, the change in the chemical shift of the hydroxyl-proton on the formation of an intramolecular hydrogen bond has been correlated with the corresponding change in the O–H stretching frequency.[3,4] Gränacher reported a similar correlation for intermolecular hydrogen bonds.[14] In the present work, the chemical shifts of the hydroxyl-proton of the hydroxy-ester in the pure liquid state and in infinite dilution in carbon tetrachloride have been correlated with the stretching frequencies of the O–H band in the respective states. Figure 9 shows graphically the correlation between the above two parameters for all the esters studied as well as for ethanol for the purpose of comparison. All plots of the chemical shifts against the frequencies lie roughly on a straight line between the plots for ethanol in the liquid state and in infinite dilution.

*The Chelating Behavior of Catechol-4-sulfonate with Iron(III) Ion**

By Yukito MURAKAMI and Katsuyuki NAKAMURA

(Received May 11, 1963)

Disodium 1,2-dihydroxybenzene-3, 5-disulfonate (Tiron) was found to form blue, violet and red complexes with iron(III)[1,2] in aqueous media, and these were referred to the 1 : 1, 2 : 1 and 3 : 1 (ligand to metal) complexes respectively.[2] Later, the interaction of Tiron with iron(III) in aqueous media at the ionic strength of 0.1 M was investigated quantitatively by means of both potentiometric and spectrophotometric methods, and the stability constants of the chelates were evaluated.[3] These investigations established the information that two sulfonate groups favor the strong coördinate bond formation and, thus, that Tiron may form various stable chelates with iron(III) in aqueous media.

For the present work, a catechol derivative with only one sulfonate group at the 4-position, monopotassium salt of catechol-4-sulfonic acid, was selected and the effect of a sulfonate group on the chelating behavior of the catechol with iron(III) was investigated.

Experimental

Reagent-grade $Fe(NO_3)_3 \cdot 9H_2O$ produced by the Wako Pure Chemical Industries, Ltd. was used to prepare an aqueous stock solution of iron(III) ions which was standardized by chelatometric titration. The method for the preparation of potassium catechol-4-sulfonate was described in a previous paper.[4]

The procedure for potentiometric titration was largely the same as has been mentioned elsewhere.[5] However, this procedure was modified in some occasions, since equilibrium was reached only slowly in the major pH region of potentiometric titrations when a sufficient amount of the ligand was not present. In the modified procedure (*the batch method*), a series of bottles containing measured amounts of the metal ion, ligand species, and a supporting electrolyte were used; varying amounts of a standard base were added in these bottles. These solutions were allowed to equilibrate at 30±0.1°C for 12~24 hr. in a nitrogen atmosphere, and then the pH of each sample was recorded. The pH readings thus obtained were verified by subsequent pH measurements from time to time.

The visible absorption spectra of the iron(III)-catechol-4-sulfonate system were measured with a Hitachi EPS-2-type recording spectrophotometer at various hydrogen ion concentrations. The hydrogen ion concentrations of the solutions were adjusted by adding proper amounts of a standard base (sodium hydroxide) or a standard acid (nitric acid). The concentrations of iron(III) ion, of catechol-4-sulfonate, and of the supporting electrolyte (potassium nitrate) in stock solutions were adjusted at 2.50×10^{-1} M, 7.50×10^{-4} M, and 0.10 M respectively.

Results and Discussion

Systems with Enough Ligand Present.—The potentiometric titration curve of the iron(III)-catechol-4-sulfonate system at a 10 : 1 molar ratio of ligand to metal ion is illustated in Fig. 1. Alkalimetric titration (from the lower pH region) and acidimetric titration (from the

higher pH region) of the system brought about titration curves which coincide with each other satisfactorily. The equilibrium of the solution at each addition of base or acid was established in a sufficiently short period of time, even though both titrations required some time (approximately 30 min.) for the attainment of the equilibrium in the region of $m=4$. Three inflection regions were observed in titration curve A in Fig. 1; the most significant of these was the one found at the m-value of 4. The first small inflection was observed in the region between 1.5 and 2.0 in m-value, while another one was found around $m=13$. The former corresponds to the formation of the 1 : 1 chelate, while the latter corresponds to the formation of the 3 : 1 chelate and to the liberation of the first proton of the free ligand existing in the solution. The steep jump of the titration curve at $m=4.0$ is undoubtedly ascribed to the completion of the 2 : 1 chelate formation.

Figure 2 shows titration curves for solutions containing a 3 : 1 ratio of ligand to metal ion. No precipitates were observed throughout titrations as in the case of the 10 : 1 system. In the alkalimetric titration of the 3 : 1 system, equilibrium of the titrating solutions was reached quickly in an acidic buffer region lying below $m=1.5$, where the 1 : 1 chelate formation is predominant, while it was established rather gradually in the second buffer region ($2.0<m<4.0$). A very slow establishment of equilibrium was observed in the second inflection region ($m=4.0$); the pH reading did not becomes stationary in a few hours of elapse. Then, the pH equilibration was completed in approximately half an hour for each addition of a base in the third buffer region, lying between 4.0 and 6.0 in m-value. Meanwhile, the 3 : 1 system was also titrated with an acid from the higher pH range. A good agreement of the titration curve with that obtained by alkalimetric titration was observed, except in the second buffer region and in the second inflection range. In order to clarify the extremely noticeable disagreement of both curves in the second inflection range and the minor one in the second buffer region, the third titration curve in Fig. 2 was obtained by the batch method, the procedure for which has been mentioned in the preceding section. It was ascertained that the equilibrium of the system was gained after 12 hr., even in the second inflection region. The pH reading drifted downward in alkalimetric titration in the range of slow equilibration, while it tended upward in acidimetric titration in the same range, so that the truly equilibrated curve may be expected to lie between these two titration curves. During the titration of the iron(III)-catechol-4-sulfonate system, the color of the solution varied remarkably, as in the case of the iron(III)-Tiron system, from a greenish blue in the first buffer region ($m<1.7$; $-\log[H^+]<4.0$) through a violet in the second buffer region ($m=4$; $-\log[H^+]=5.5\sim6.7$) to a deep red in the higher pH range ($m>6$; $-\log[H^+]>9.0$).

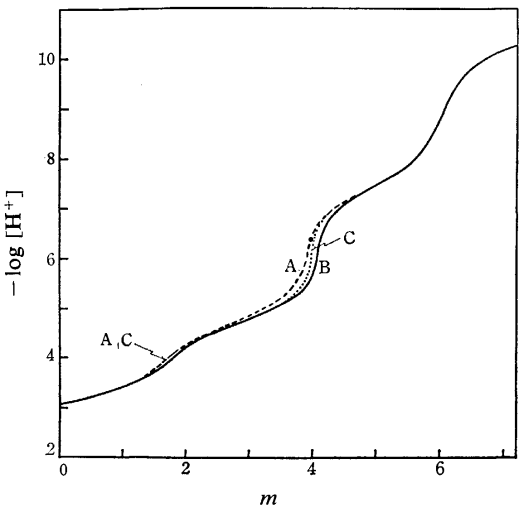

Fig. 2. Potentiometric titration of Fe(III)-catechol-4-sulfonate chelate system at total ligand concentration of 1.00×10^{-3} M with 3 : 1 molar ratio of ligand to metal ion : A, alkalimetric titration; B, acidimetric titration; C, batch method (equilibrated for 12~24 hr.); m=moles of base added per gram-ion of metal; $t=30°C$; $\mu=0.10$ M (KNO_3).

Such a slow establishment of equilibrium reading in the 3 : 1 titration curves may not be due to the hydrolysis of any iron(III) chelates, but to the slow rates of chelate-forming reactions. The following experimental results may support this statement. Firstly, the equilibration rate was accelerated in the presence of enough ligand i. e., in the 10 : 1 system, and no precipitates were observed in solutions of the 3 : 1 system which contained different amounts of base and which were left for a long enough period of time. Secondly, in the 3 : 1 system were observed two distinct inflection regions at $m=4.0$ and 6.0, which may be ascribed to the formation of the 2 : 1 and the 3 : 1 chelate respectively.

1 : 1 and 2 : 1 Systems.—It was rather difficult to examine the behavior of the chelate systems when the amount of ligand species present in the system was not enough to occupy all the coördination sites of the nuclear metal ion. The titration curves for 1 : 1 and 2 : 1 molar ratios of ligand to metal ion are shown in Fig. 3. The pH drifting was observed to start above $m=1.0$ ($-\log[H^+]=3.1$) in the

1 : 1 titration, while such a tendency of pH drifting was extreme above $m \approx 4.0$ in the 2 : 1 titration. The slow rates of both the chelate formation and the hydrolysis reaction of the chelates seem to make the system complex. The extensive hydrolysis of the partially-chelated metal ion conceivably occurs in this case in a manner similar to that in the iron-(III)-kojate chelate system.[5]

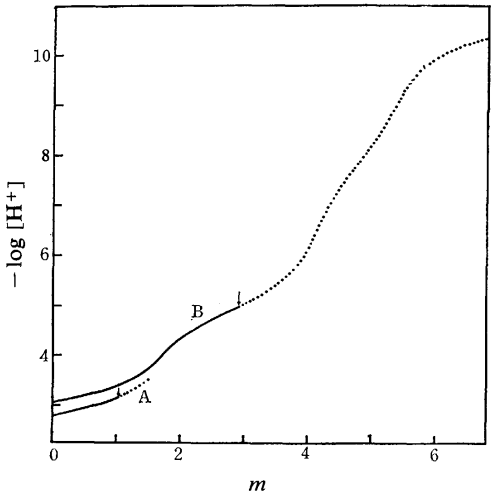

Fig. 3. Potentiometric titration of Fe(III)-catechol-4-sulfonate chelate system at total ligand concentration of 1.00×10^{-3} M, with these molar ratios of ligand to metal ion: A, 1 : 1; B, 2 : 1; t=30°C; μ=0.10 M (KNO_3). Dotted curves represent non-equilibrated titration; arrows indicate points where pH drifting became noticeable.

Stability Constants.—The stability constants calculated by the aid of Bjerrum's method[6] are shown in Table I, along with the data on the corresponding Tiron chelates reported by Schwarzenbach and Willi.[3] Because of the slow establishment of the equilibrium state, the stability constants for the 2 : 1 and the 3 : 1 chelate were evaluated with a lower precision. Moreover, the stability constant for the 1 : 1 chelate was not evaluated with enough accuracy due to some complexity of the system.

TABLE I. STABILITY CONSTANTS OF Fe(III) CHELATES
30.0±0.1°C; μ=0.10 M (KNO_3)

Ligand	$\log K_1$	$\log K_2$	$\log K_3$
Catechol-4-sulfonate	>17	14.0	9.1
Tiron[3]*	20.7	15.2	11.0

* t=20~22°C; μ=0.1 M (KCl)
For the definition of the stability constants, see Ref. 4.

Visible Absorption Spectra.—The visible absorption spectra of the 3 : 1 chelate system were measured at various pH's. The main absorption maximum of the chelate solution, which may be ascribed to the d-d transition of the metal-electron, is plotted as a function of the pH value of the chelate solution in Fig. 4. The color changes of the iron(III)-catechol-4-sulfonate system in aqueous media may be attributed to the stepwise formation of various chelates; the 1 : 1 chelate in the lower, the 2 : 1 in the middle, and the 3 : 1 in the higher pH region. The absorption maxima of these chelates in aqueous media are indicated in Table II, together with those of the Tiron chelates. It seems that the difference in stability constants between the iron(III)-Tiron and the iron(III)-catechol-4-sulfonate chelates does not cause any appreciable spectral shifts among

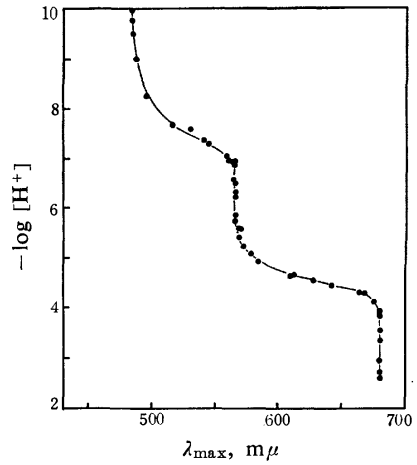

Fig. 4. Variation in absorption maximum of Fe(III)-catechol-4-sulfonate chelate system with hydrogen ion concentration, at total ligand concentration of 7.50×10^{-4} M with 3 : 1 molar ratio of ligand to metal ion; μ=0.010 M (KNO_3).

TABLE II. VISIBLE ABSORPTION SPECTRA OF THE Fe(III) CHELATES

Ligand	Absorption maximum, mμ			Intensity, log ε	
	1 : 1 Chelate	2 : 1 Chetate	3 : 1 Chelate	2 : 1 (565 mμ)	3 : 1 (483 mμ)
Catechol-4-sulfonate	680	565	483	3.62	3.74
Tiron[1,2]	—	560	480	—	—

6) J. Bjerrum, "Metal Ammine Formation in Aqueous Solution," P. Haase & Son, Copenhagen (1942).

the corresponding chelates in these systems. It seems, therefore, that Tiron and catechol-4-sulfonate produce similar ligand fields for the iron(III) ion.

Summary

Both potentionmetric and spectrophotometric measurements have been carried out in order to study the chelating tendencies of catechol-4-sulfonate with iron(III) ions in aqueous media at the ionic strength of 0.10 M. Even in the 3 : 1 (ligand to metal ion) system, the equilibrium of the titrating solution was established gradually, except in the lower pH range. When the amount of the ligand was not sufficient to satisfy the coördination number of the iron(III) ion, the titration system became complicated because of both the slow attainment of equilibrium in the chelate formation and the hydrolysis of the chelates.

The stability of the iron(III)-catechol-4-sulfonate was found to be slightly less than that of the corresponding iron(III)-Tiron chelates. The visible absorption spectral data indicated that Tiron and catechol-4-sulfonate produce similar ligand fields for the iron(III) ion.

The Re-activation Analysis of Aluminum—The Activation Analysis of Aluminum with Special Reference to Yield Determination

By Yuichiro KAMEMOTO and Shigeru YAMAGISHI

(Received May 13, 1963)

In an activation analysis using short-lived nuclides with radiochemical separation, the chemical yield has been determined by, for instance, the gravimetry, volumetry, photometry, polarography and tracer method. The yield determination by these methods requires a long period of time, however; therefore, these methods cannot be used in rapid determination. A method in which the chemical yield is determined by re-irradiating the counted sample and which can be completed in a short time is suitable for rapid determination.

On the other hand, it is not desirable, from the standpoint of the precise determination of the chemical yield, that other methods, such as the gravimetry, volumetry, photometry and polarography, be applied to the yield determination of elements being analyzed after their activity has been counted.

When the correction factor of chemical yield is previously determined by a radioisotope tracer under the same conditions as the practical and is used for the correction of chemical yield in each separation, there is the disadvantage that an error is produced by the difference between the chemical yields obtained in the individual separations.

The present authors have devised an activation analysis in which the chemical yield is easily corrected by the re-activation of the counted sample; they have designated this method "re-activation analysis".[1)]

After the addition of a carrier to the irradiated sample solution, the element to be determined is isolated in a radiochemically pure form by solvent extraction, transferred into a polyethylene tube, and its γ-ray spectrum measured. It is then allowed to decay to a negligible activity level and sealed again in a polyethylene tube. This sample is re-activated with neutrons and counted. The element is determined by the induced activity from the first irradiation, which is corrected for the chemical yield calculated from the induced activity from the second irradiation. In other words, the technique of non-destructive activation analysis is applied to determine the yield of radiochemical separation in normal destructive activation analysis. This method has the advantage of determining the chemical yield without loss of the counted sample.

This method has been satisfactorily applied to the determination of aluminum.

1) Y. Kamemoto and S. Yamagishi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **84**, 291 (1963).

Theoretical

This re-activation technique consists of these steps: the first irradiation of a sample, the addition of a carrier, radiochemical separation, the counting of the induced activity from the first irradiation, the sealing of the counted sample in a polyethylene tube, cooling, a second irradiation, and the counting of the induced activity from the second irradiation. For rapid radiochemical separation, a solvent extraction method was adopted. In this method the carrier to be added is sometimes limited to a rather small amount. Therefore, the amount of the element to be determined cannot be disregarded in the calculation of the chemical yield. From these considerations, an equation for determining the element in the sample from the induced activities from the first and the second irradiation was derived as follows:

$$\text{Chemical yield} = \frac{W_c'}{W_c + W} \tag{1}$$

where

W: weight of the aluminum in the sample (g.),

W_c: weight of the aluminum carrier added to the first irradiated sample (g.),

W_c': weight of the aluminum isolated from the sample after the addition of the carrier (g.).

When the chemical yield is 100%, the induced activity, A, from the first irradiation is:

$$A = A_{sam} \times \frac{W_c + W}{W_c'} \tag{2}$$

where A_{sam} is activity of the ^{28}Al isolated from the first irradiated sample.

The specific activity in the first irradiation is the same in unknown and the standard samples.

Therefore,

$$A/W = A_{st}/W_{st} \tag{3}$$

where

A_{st}: the induced activity of the standard aluminum from the first irradiation,

W_{st}: the amount of the standard aluminum for the first irradiation.

From Eqs. 2 and 3,

$$W = \frac{A_{sam} \times W_c \times W_{st}}{A_{st} \times W_c' - A_{sam} \times W_{st}} \tag{4}$$

The specific activity in the second irradiation is also the same in the unknown and the standard samples.

Therfore,

$$A_{sam}'/W_c' = A_{st}'/W_{st}' \tag{5}$$

where

A_{sam}': the induced activity of the ^{28}Al isolated from the second irradiation,

A_{st}': the induced activity of the ^{28}Al of the standard aluminum from the second irradiation,

W_{st}': the amount of standard aluminum for the second irradiation.

From Eqs. 4 and 5,

$$W = \frac{A_{sam} \times W_c \times W_{st}}{(A_{st} \times A_{sam}' \times W_{st}'/A_{st}') - A_{sam} \times W_{st}} \tag{6}$$

Experimental

Standard Sample.—4.7 mg. of a spectrographically pure aluminum rod made by Johnson Matthey Co., Ltd., was dissolved in 1 ml. of sulfuric acid. After evaporation, the residue was dissolved in water and diluted to 50 ml. This solution was further diluted to give several solutions of different aluminum concentration. Each 1 ml. of the standard solution was sealed in a polyethylene tube and placed in the center of a capsule packed with soft paper.

Sample. — Samples containing different amounts of aluminum, manganese, sodium and magnesium were prepared in the same way as the aluminum standard.

Apparatus. — The JRR-1 reactor was used as a neutron source, while the RCL-256 channel pulse-height analyzer with a 1.75×2 inch NaI (Tl) crystal (well type) attached was used as a counter.

Neutron Irradiation.—All irradiations were made in the No. 16 experimental hole (pneumatic tube) at a neutron flux of about 3×10^{11} n/cm^2/sec. The first irradiation was continued for 3 min., and the second irradiation, for 10 sec.

Procedure. — This method consists of the first irradiation, the addition of the carrier, solvent extraction, counting, the second irradiation, cooling, and counting. The above procedure was repeated for each sample with the reactor always in the same stationary state.

The sample solution irradiated in the reactor for 3 min. was transferred into a separating funnel. An aluminum carrier solution (94.0 μg. Al) was added to this solution. After the further addition of 50 ml. of an oxine solution containing 30 mg. of oxine, 1.5 ml. of an acetic acid solution and 2.5 g. of sodium acetate, aluminum was extracted with 5 ml. of benzene.[2-4] The organic phase was transferred into a polyethylene tube, which was then mounted in the NaI (Tl) crystal 5 min. after the end of the irradiation; it was counted for 2 min., and the resultant γ-ray spectrum was measured. The polyethylene tube containing the benzene phase was sealed again and was kept sufficiently long to allow the aluminum-28 activity decay. It was then irradiated again for 10 sec. and cooled for 2 min., and the γ-ray spectrum was measured for one minute.

2) E. Sudo, ibid., 72, 718 (1951).
3) H. Nishida, *Japan Analyst* (*Bunseki Kagaku*), 4, 39 (1955).
4) S. Yokosuka, ibid., 5, 71 (1956).

In the first irradiation, the standard sample was irradiated for 3 min. and measured for the γ-ray spectra 5 min. after irradiation in the same manner as for the unknown sample. In the second irradiation, the standard sample was irradiated for 10 sec., cooled for 2 min., and counted for one minute.

In each of the resultant gamma spectra, the height of the photopeak due to the 1.78 MeV. γ-ray from the ^{28}Al was measured.

Results and Discussion

γ-Ray Spectrum.—An example of the γ-ray spectrum of ^{28}Al, which was measured after irradiation and extraction, is shown in Fig. 1.

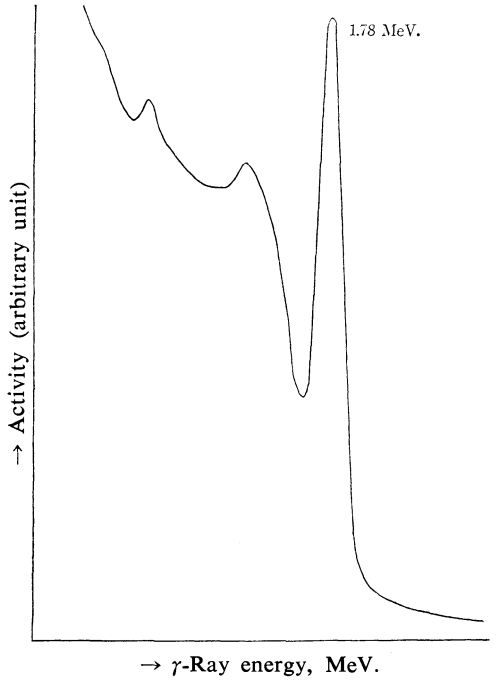

Fig. 1. γ-Ray spectrum of ^{28}Al of sample No. 10.

Calibration Curve. — The calibration curves of aluminum for the first and the second irradiation are shown in Figs. 2 and 3 respectively.

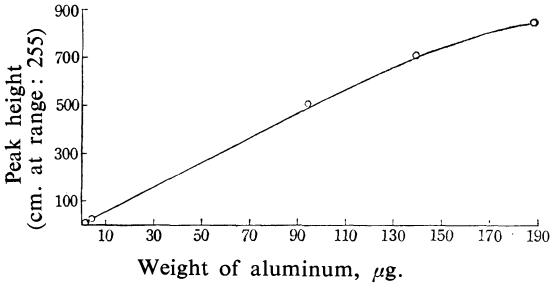

Fig. 2. Calibration curve of aluminum for the first irradiation.

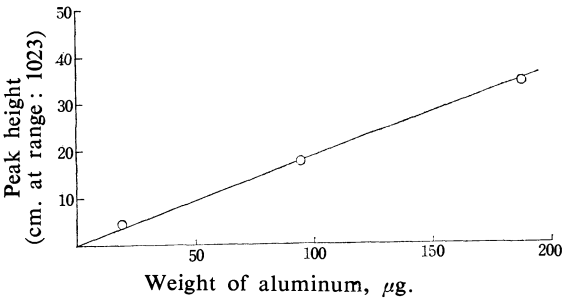

Fig. 3. Calibration curve of aluminum for the second irradiation.

In the concentration ranges of aluminum of 0~100 and 0~190 μg. for the first and the second irradiation respectively, the relation between activity and concentration was linear. Therefore, in these concentration ranges aluminum could be determined with each standard sample in the first and the second irradiation.

Result.—The determination results of aluminum by this method are shown in Table I.

Table I. Analytical results by this method

Sample No.	Sample: Al added μg.	Sample: Other element added, mg.	Al found μg.
1	3.76	0	3.34
2	3.76	0	3.97
3	3.76	0	3.73
4	3.76	0	3.81
5	3.76	0	3.72
6	1.88	0	1.92
7	0.94	0	0.99
8	3.76	Mn, 1	4.64
9	3.76	Mn, 0.1	4.45
10	3.76	Mg, 1	3.69
11	3.76	Mg, 0.1	3.80
12	3.76	Na, 1	3.78

The coefficient of the variation was 1.22% for the determination of 3.76 μg. of aluminum. This value is the total error produced in this method, including the error due to the neutron flux variation in the reactor.

Interference.—The γ-rays which may be confounded with the γ-ray of aluminum at 1.78 MeV. are that at 1.734 MeV. of ^{90}Y, at 1.81 MeV. of ^{56}Mn, and at 1.853 MeV. of ^{88}Rb. The interefence by ^{56}Mn, ^{24}Na and ^{166}Ho must also be taken into account because of their high activation cross sections and saturation factors.[5]

The present authors also examined the interference by sodium and manganese which

5) T. Nakai, S. Yajima, M. Okada, K. Shiba and T. Moki, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **81**, 104 (1960).

was sometimes observed in the non-destructive determination of aluminum.

Since sodium and rubidium were not extracted with an oxine-benzene solution, these elements did not affect the determination of aluminum in the present method. It could be considered that manganese did not affect it either because of its non-extractability with an oxine-benzene solution. However, some interference by manganese was found. This interference may be due to some precipitation of manganese hydroxide at the pH value of the extraction step.

The induced activities of sodium and manganese obstruct the photopeak of aluminum or cause a pile-up phenomena in the γ-ray spectrum when the amount of these elements in the sample material is 25$\sim$250 times as much as that of the aluminum. In such cases, the non-destructive determination of aluminum is not practicable. In the proposed method, sodium does not affect the determination of aluminum. Manganese causes an error of about 18% in the determination of aluminum, but a semi-quantitative determination is possible. These results show the advantages of the present method over other non-destructive methods.

*The Nuclear Magnetic Resonance Spectra of Olefinic Protons and the Substituent Effects. III. Trans-forms of Methyl β-Substituted Acrylates, β-Substituted Vinyl Methyl Ketones and β-Substituted Acryloyl Chlorides**

By Jun NIWA and Hazime KASIWAGI

(Received June 4, 1963)

It was reported in Part I that a Hammett-type relationship was applicable to the chemical shifts of olefinic protons situated at the cis-position to terminal substituents in the trans-forms of ω-substituted styrenes and in those of 1-substituted propenes ($RCH_A=CH_BX$, invariable substituent; R=C_6H_5, CH_3).[1] In these systems, the invariable substituent was an electron-repulsive methyl group or an aromatic ring which might constitute a conjugated system with the olefinic part. The present authors are concerned with such systems in which the invariable substituent of a series of compounds is strongly electron-attractive and conjugates with the olefinic part.

As examples of such systems, a series of trans-forms of methyl β-substituted acrylates, β-substituted vinyl methyl ketones and β-substituted acryloyl chlorides were chosen. The authors have investigated the results of the NMR absorption of these compounds from the viewpoint of a Hammett-type relationship. Moreover, the trends of the proton shifts in these compounds have been compared with those of ω-substituted styrenes and 1-substituted propenes.

Experimental

Two Varian 4300-B type spectrometers operating at 56.4 Mc. and 60 Mc. were used in obtaining the spectra. The conditions of measurement were the same as described in Part I.[1]

All the compounds examined have a trans-configuration. The acrylate derivatives are as follows: Methyl β-methylcrotonate, methyl crotonate, methyl acrylate, methyl cinnamate, methyl β-bromoacrylate, methyl β-chloroacrylate, dimethyl fumarate, methyl β-acetylacrylate and β-methoxycarbonylacryloyl chloride. The spectra of the corresponding free acids were also measured in glacial acetic acid. The methyl vinyl ketone derivatives are as follows: Methyl vinyl ketone, methyl styryl ketone and methyl acetylacrylate. As for the acryloyl chloride derivatives, crotonyl chloride, cinnamoyl chloride and β-methoxycarbonylacryloyl chloride were used. The synthesized compounds had the following properties: β-Methyl crotonic acid, m. p. 66~67°C; its ester, b. p. 132°C; β-chloroacrylic acid, m. p. 83.5~84°C; its ester, b. p. 22°C under 12 mmHg; β-bromoacrylic acid, m. p. 115~116°C; its ester, b. p. 20°C under 5 mmHg; β-methoxycarbonylacryloyl chloride, b. p. 65°C under 15 mmHg. Methyl

acrylate (b. p. 80.5°C), methyl crotonate (b. p. 118~119°C), crotonic acid (m. p. 71~72°C), fumaric acid (m. p. 286~287°C), methyl β-acetyl acrylate (b. p. 196.8~197.3°C) and methyl vinyl ketone (b. p. 33~34°C under 130 mmHg) were commercially obtained and purified.* The physical properties of the other compounds were described in Part I.

Results and Discussion

The spectra of olefinic protons of methyl β-substituted acrylates, β-substituted vinyl methyl ketones and β-substituted acryloyl chlorides are of the simple AB-type, with the exception of those of methyl crotonates, methyl acrylate and methyl vinyl ketone. Methyl crotonate gives the spectra corresponding to the ABX_3-type, while the spectra of methyl acrylate and methyl vinyl ketone are attributed to the ABC-type. In the spectra of β-methoxycarbonylacryloyl chloride, a single signal was observed for the olefinic protons. The analyses of the spectra of methyl acrylate and methyl vinyl ketone have been compared with the results obtained by Castellano and Waugh[2] and by Brügel et al.[3] respectively. The chemical shifts obtained by the analysis of the spectra are summarized in Table I.

In series of compounds here examined ($RCH_A{=}CH_BX$, $R{=}CO_2CH_3$, $COCH_3$, COCl), since the invariable substituent (R) conjugates with the olefinic part, it may be expected that the olefinic proton shifts would be governed by Hammett's substituent effect, at least qualitatively. Meanwhile, the authors have observed that a qualitative relationship exists between the shifts of protons (H_A) situated at the cis-position to substituents in mono-substituted ethylenes[4] ($RCH_A{=}CH_BX$, R=H) and Hammett's σ. The τ-values of the proton shifts are shown in the table. The authors examined Hammett's substituent effects for the proton shifts in these four systems, comparing the former systems with the latter. In this case, it must be taken into account that the magnetic anisotropy of the substituents and other magnetic effects act as disturbing factors in the investigation of polar substituent effects. As has been considered in Part I, however, such disturbing factors do not seem to be much for the shifts of H_A, with the exception of a few cases. This would imply that the chemical shifts of H_A in these compounds are governed mainly by the polar substituent effects.

Similarly, as in Part I, Fig. 1 shows the relationship between the τ-values of H_A in these compounds and Hammett's σ_p. Figure 2 also shows the relationship between the τ-values of H_A and Taft's parameter, $0.40\,\sigma_I + 0.70\,\sigma_R$.[5] In the figures, the plot for the H_A of styrene is corrected to 4.79 p. p. m.[1,4,6] and that of acrylonitrile, to 3.80 p. p. m.[7] In the series of β-substituted acrylates, the H_A of methyl cinnamate may also be lowered by the

long-range shielding effect of the benzene ring, which is situated at the cis-position to H_A. If the magnitude of the lowering effect is estimated as in styrene, the τ-value of H_A may be corrected to 4.19 p. p. m. This correction may, however, be overestimated, because the methoxycarbonyl group in this compound is strongly electron-attractive, which would diminish the effect of the benzene ring current. As for the Cl, Br, CO_2CH_3 and $COCH_3$ groups, the consideration made in Part I would hold in the present systems. In Figs. 1 and 2 a rough correlation may be observed, but it seems to be somewhat disintegrated compared with ω-substituted styrenes and 1-substituted propenes. Moreover, it is also observed that the plots for the corresponding substituents in the ethylene derivatives and in the β-substituted acrylates deviate similarly from the correlation line. Therefore, the same kind of correlation may be expected among the H_A-shifts themselves in both systems. In Fig. 3 a fairly clear

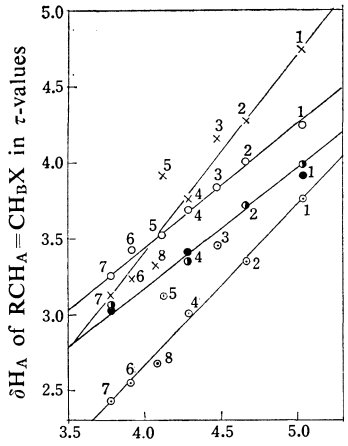

Fig. 3. The correlation among δH_A of methyl β-substd. acrylates (○), β-substd. vinyl methyl ketones (◑), β-substd. acryloyl chlorides (●), ω-substd. styrenes (⊙) and 1-substd. propenes (×). The substituents X are; 1, CH_3; 2, H; 3, Cl; 4, C_6H_5; 5, Br, 6, $COCH_3$, 7, CO_2CH_3, 8, CN.

correlation among them may be observed. This suggests that, in these systems, the modes of the transmission of substituent effects are essentially similar. Figure 3 also shows the relation between the H_A-shifts of ω-substituted styrenes (and 1-substituted propenes) and those of the ethylene derivatives. In this case, however, the correlation is considerably disintegrated. Especially, the plots for halogen substituents deviate largely from the correlation line. (With regard to the origin of the anomalous behavior of the H_A-shifts caused by halogen atoms, further invetigation is necessary.) On the other hand, it was reported in Part I that a fairly clear correlation existed between the H_A-shifts of ω-substituted styrenes (and 1-substituted propenes) and the ortho-proton shifts of mono-substituted benzenes. From what has been stated above with regard to the modes of the transmission of substituent effects, these six olefinic systems may be classified into two types — one is the system rather resembling the benzene derivatives, and the other, the ethylene derivatives. This may correspond to the difference between the natures of the conjugated systems, of which the former has the electron-repulsive invariable substituents and the latter, the electron-attractive. Also, the slope of each correlation line decreases, on the whole, in the order of the σ-value of the invariable substituent, namely, $CH_3 > H \simeq C_6H_5 > CO_2CH_3 \simeq COCH_3 \simeq COCl$. This probably illustrates how the overall trends of the H_A-shifts in each system are uniformly governed by the polar nature of the invariable substituent.

As for the shielding of the H_B protons at the β-position, their behavior can not be discussed concurrently with those of the H_A-shifts from the viewpoint of Hammett's substituent effect. Moreover, there is no clear correlation between the H_B-shifts of β-substituted acrylates and those of the ethylene derivatives. Similarly to what has been reported in Part I, however, the order of the H_B-shifts of these compounds may be qualitatively determined by both the electronegativity of the first atom and the magnetic anisotropy of the substituent group.

As is shown in Fig. 4, in trans-forms of methyl β-substituted acrylates the chemical shifts of the methyl proton of the methoxycarbonyl group are determined by Hammett's σ_p, although their spread does not exceed about 0.2 p. p. m. in any of the derivatives. This relation corresponds with the fact that the pK_a-values of the trans-forms of β-substituted acrylic acids are represented by the usual Hammett equation.[8]

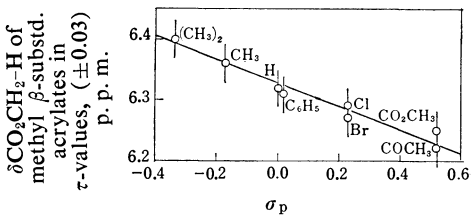

Fig. 5. The methyl proton shifts of methoxycarbonyl groups of methyl β-substituted acrylates, plotted vs. Hammett's substituent constants, σ_p.

Summary

In the NMR absorption of the trans-forms of β-substituted acrylates, β-substituted vinyl methyl ketones and β-substituted acryloyl chlorides, the chemical shifts of protons situated at the cis-position to the substituents have been roughly determined by Hammett's σ_p and Taft's parameter, $0.40\,\sigma_I + 0.70\,\sigma_R$. From a comparison of the H_A-shifts of the six olefinic systems ($RCH_A{=}CH_BX$, R = CH_3, C_6H_5, H, CO_2CH_3, $COCH_3$, COCl), these systems have been classified into two types—one, systems resembling the benzene derivatives, and the other, resembling the ethylene derivatives. Nevertheless, it has also been observed that the slope of each correlation line, on the whole, decreased in the order of the σ-value of the invariable substituent. The methyl proton shifts of β-substituted *trans*-acrylates, too,

8) M. Charton and H. Meislich, ibid., **80**, 5941 (1958).

depend upon Hammett's σ_p. The shifts of the proton (H_B) at the β-positon can not be discussed from the viewpoint of Hammett's substituent effect. However, they relate qualitatively with the electronegativity of the first atom of the substituent group.

The authors wish to take this opportunity to thank Dr. Naoya Nakagawa of the University of Electro-Communications for his helpful discussions. Thanks are also due Dr. Yo-ichiro Mashiko of the Government Chemical Research Institute and Dr. Ichiro Yamaguchi and Dr. Naohiro Hayakawa of the Japan Atomic Research Institute for kindly giving permission to use the spectrometers of those institutions.

The Rheological Properties of Concentrated Suspensions. I. Some Theoretical Considerations Based on a Network Model

By Masaharu TAKANO*

(Received June 6, 1962)

At very small deformations, certain concentrated disperse systems show viscoelastic properties resembling these of polymer solutions. The elasticity of disperse systems is not that of an entropic nature as that of polymer systems. It is generally accepted that the elastic properties of such disperse systems are due to a three-dimentional network formed by the flocculation or aggregation of the dispersed solid particles. Tobolsky and Eyring[1] have derived a theory of the viscoelastic deformation of a polymer network. This theory is based essentially on a generalized Maxwell model as modified by Eyring's non-linear viscous elements. Recently van den Tempel[2] has extended this theory to the creep behavior of plastic disperse systems at very small deformations.

It is the purpose of this paper to extend this theory in order to explain the stationary flow properties of concentrated suspensions at very low rates of shear and their dynamic properties at low frequencies on the basis of a network model.

A. The Flocculation of Spherical Particles

The typical mechanical properties of fluocculated systems are originated from the network structure formed by their dispersed particles. They are evidently influenced by the concentration, surface characteristics, shape, and size distribution of the dispersed particles. The mechanical and thermal conditions during the preparation and the storage of the system are also of great influence. For the sake of simplicity, let us consider the particles to be uniform spheres.

The kinetics of the flocculation of spherical particles has been discussed theoretically by von Smoluchowski,[3] Overbeek,[4] Goodeve and Whitfield[5] and others. The rate of flocculation and the stationary size-distribution of the flocculate in the flowing suspension are generally determined by three factors: the Brownian motion of the particles, the effect of the shearing force, and the interaction energy between neighboring particles.

Flocculates increase in size by linking upon collision with each other and decompose by the breaking of the internal links. The rate of increase of the number of the k-fold flocculates† by collision per unit volume is given by the following equation, at finite concentrations:[4]

† The k-fold flocculate means a flocculate constituted of k particles.

$$\mathrm{d}\nu_k/\mathrm{d}t=(1/2)\sum_{\substack{i=1\\j=k-i}}^{i=k-1}4\pi D_{ij}R_{ij}\nu_i\nu_j-\nu_k\sum_{i=1}^{\infty}4\pi D_{ki}R_{ki}\nu_i+(2\dot{\gamma}/3)\times\{\sum_{\substack{i=1\\j=k-i}}^{i=k-1}R^3_{ij}\nu_i\nu_j-2\nu_k\sum_{i=1}^{\infty}R^3_{ki}\nu_i\} \quad (1)$$

where ν_i is the number of the i-fold flocculates per unit volume, D_{ij} and R_{ij} are the mutual diffusion constant and the radius of interaction between the i-fold flocculates and the j-fold flocculates respectively, and $\dot{\gamma}$ is the rate of shear. The first and the second term represent the increase and the decrease of the k-fold flocculates by thermal collision respectively. The third and the fourth term correspond to the rates of change of the number of flocculates by shearing force. For unlinked particles, the first and the third term vanish. Therefore,

$$\mathrm{d}\nu_1/\mathrm{d}t=-\nu_1\sum_{i=1}^{\infty}4\pi D_{1i}R_{1i}\nu_i-(4\dot{\gamma}/3)\nu_1\sum_{i=1}^{\infty}R^3_{1i}\nu_i \quad (2)$$

Some of the flocculates decompose to smaller flocculates as the result of thermal and mechanical actions. The rate of loss of the k-fold flocculates per unit volume is

$$-\mathrm{d}\nu_k/\mathrm{d}t=\nu_k(\boldsymbol{kT}/\boldsymbol{h}\sigma)\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\}-\sum_{j=k+1}^{\infty}\{2\nu_j/(j-1)\}(\boldsymbol{kT}/\boldsymbol{h}\sigma)\times\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (3)$$

where $\boldsymbol{k}$ and $\boldsymbol{h}$ are the constants of Boltzmann and Planck respectively, T is the absolute temperature, ΔF, the mean free energy of activation for breaking a link between particles in a flocculate, λ, the critical distance for breaking a link, and f, the mean shearing force on a link. σ is the mean number of links to be broken for generating two smaller fragments from a flocculate. It is effectively larger than one when some circular structures are involved in the flocculates. In Eq. 3 the first term represents the decomposition of the k-fold flocculates, while the second term represents the generation of the k-fold flocculates by the decomposition of larger flocculates. For unlinked particles, the first term vanishes; therefore,

$$-\mathrm{d}\nu_1/\mathrm{d}t=-\sum_{j=2}^{\infty}\{2\nu_j/(j-1)\}\times(\boldsymbol{kT}/\boldsymbol{h}\sigma)\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (4)$$

For $k\geqq 2$, the net rate of the increase of the k-fold flocculates per unit volume is given by the summation of Eqs. 1 and 3:

$$\mathrm{d}\nu_k/\mathrm{d}t=(1/2)\sum_{\substack{i=1\\j=k-i}}^{i=k-1}4\pi D_{ij}R_{ij}\nu_i\nu_j-\nu_k\sum_{i=1}^{\infty}4\pi D_{ki}R_{ki}\nu_i+(2\dot{\gamma}/3)\{\sum_{\substack{i=1\\j=k-1}}^{i=k-1}R^3_{ij}\nu_i\nu_j-2\nu_k\sum_{i=1}^{\infty}R^3_{ki}\nu_i\}-\{\nu_k-\sum_{j=k+1}^{\infty}2\nu_j/(j-1)\}(\boldsymbol{kT}/\boldsymbol{h}\sigma)\times\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (5)$$

For unlinked particles, it is given by the summation of Eqs. 2 and 4:

$$\mathrm{d}\nu_1/\mathrm{d}t=-\nu_1\sum_{i=1}^{\infty}4\pi D_{1i}R_{1i}\nu_i-(4\dot{\gamma}/3)\nu_1\sum_{i=1}^{\infty}R^3_{1i}\nu_i+\sum_{j=2}^{\infty}\{2\nu_j/(j-1)\}(\boldsymbol{kT}/\boldsymbol{h}\sigma)\times\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (6)$$

The summations in Eqs. 5 and 6 are very complicated and can not be carried out without any assumptions or approximations. When the radii of the i-fold flocculates and of the j-fold flocculates are not too widely different, we obtain the following approximation:[4]

$$D_{ij}R_{ij}\fallingdotseq 2D_1R_1$$

where D_1 is the diffusion constant of an unlinked particle and R_1 the distance of interaction between unlinked particles. Under the same conditions, we have another approximation:

$$R^3_{ij}\fallingdotseq R^3_1(i+j)/2\phi_c$$

where ϕ_c is the mean fraction of volume occupied by particles in a multiple flocculate.

Substituting these approximations into Eqs. 5 and 6, we have, for $k\geqq 2$:

$$\nu_k/\mathrm{d}t=4\pi D_1R_1\{\sum_{\substack{i=1\\j=k-i}}^{i=k-1}\nu_i\nu_j-2\nu_k\sum_{i=1}^{\infty}\nu_i\}+(\dot{\gamma}R^3_1/3\phi_c)\{\sum_{\substack{i=1\\j=k-i}}^{i=k-1}(i+j)\nu_i\nu_j-2\nu_k\sum_{i-1}^{\infty}(k+i)\nu_i\}-\{\nu_k-\sum_{j=k+1}^{\infty}2\nu_j/(j-1)\}\times(\boldsymbol{kT}/\boldsymbol{h}\sigma)\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (7)$$

and for $k=1$:

$$\mathrm{d}\nu_1/\mathrm{d}t=-8\pi D_1R_1\sum_{i=1}^{\infty}\nu_i\nu_1-(2\dot{\gamma}R^3_1/3\phi_c)\nu_1\sum_{i=1}^{\infty}(1+i)\nu_i+\{\sum_{j=2}^{\infty}2\nu_j/(j-1)\}(\boldsymbol{kT}/\boldsymbol{h}\sigma)\times\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (8)$$

The total rate of the increase of flocculates per unit volume is obtained by summing up Eq. 7 with respect to k and by then adding Eq. 8:

$$\mathrm{d}\sum_{k=1}^{\infty}\nu_k/\mathrm{d}t = -4\pi D_1 R_1\Big(\sum_{k=1}^{\infty}\nu_k\Big)^2 - (2\dot{\gamma}R_1^3/3\phi_c)\nu_0\Big(\sum_{k=1}^{\infty}\nu_k\Big) + \Big(\sum_{k=1}^{\infty}\nu_k-\nu_1\Big)(\boldsymbol{kT}/\boldsymbol{h}\sigma) \times \exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (9)$$

where $\nu_0=\sum_{k=1}^{\infty}k\nu_k$ is the total number of primary particles per unit volume.

As $\mathrm{d}\sum_{k=1}^{\infty}\nu_k/\mathrm{d}t=0$ at a stationary state, the number of flocculates per unit volume is

$$\sum_{k=1}^{\infty}\nu_k = \frac{\left(\begin{array}{c}(\boldsymbol{kT}/\boldsymbol{h}\sigma)(1-\nu_1/\sum_{k=1}^{\infty}\nu_k)\\ \times\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\}-(2\dot{\gamma}R_1^3/3\phi_c)\nu_0\end{array}\right)}{4\pi D_1 R_1} \quad (10)$$

In concentrated disperse systems, the number of unlinked particles may be negligible compared with the total number of flocculates. Therefore,

$$\sum_{k=1}^{\infty}\nu_k = \frac{\left(\begin{array}{c}(\boldsymbol{kT}/\boldsymbol{h}\sigma)\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\}\\ -(2\dot{\gamma}R_1^3/3\phi_c)\nu_0\end{array}\right)}{4\pi D_1 R_1} \quad (11)$$

The diffusion constant of the unlinked particles, D_1, and the total number of primary particles, ν_0, are expressed by the following equations respectively:

$$D_1=\boldsymbol{kT}/3\pi\eta R_1$$

and

$$\nu_0=6\phi/\pi R_1^3$$

where R_1 is the diameter of the primary particles, η, the viscosity of the medium, and ϕ, the volume fraction of solid dispersed particles.

Therefore, Eq. 11 can be rewritten as follows:

$$\sum_{k=1}^{\infty}\nu_k=(3\eta/4\boldsymbol{h}\sigma)\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} -3\eta\dot{\gamma}\phi/\boldsymbol{kT}\pi\phi_c \quad (12)$$

If no flocculates have any circular structures, the total number of the links between particles per unit volume is

$$L_o=\sum_{k=1}^{\infty}(k-1)\nu_k=\nu_0-\sum_{k=1}^{\infty}\nu_k \quad (13)$$

This equation holds in the case of linear or branched structures. However, actually, certain circular structures may be formed in flocculates. Let n_k equal the average number of links involving a given particle in an k-fold flocculate;

$$\mathrm{d}n_k/\mathrm{d}t=K(k-1)/V_k-\beta n_k$$

where K is the rate constant of link formation and β is the rate constant of the link rupture without any generation of smaller fragments. V_k is the volume occupied by a k-fold flocculate and is given approximately by $k\pi R_1^3/6\phi_c$. At a stationary state,

$$n_k=K(k-1)/\beta V_k=6K\phi_c(k-1)/k\pi\beta R_1^3$$

Considering the fact that each link is shared by two particles, the number of links in a k-fold flocculate is

$$b_k=3K\phi_c(k-1)/\pi\beta R_1^3$$

The total number of the links between particles per unit volume is, therefore:

$$L'=\sum_{k=1}^{\infty}b_k\nu_k=(3K\phi_c/\pi\beta R_1^3)\Big(\nu_0-\sum_{k=1}^{\infty}\nu_k\Big) \quad (14)$$

The rate constants, K and β, are given approximately by the following equations:[4]

$$K=4\pi D_1' R_1+(4\dot{\gamma}/3)R_1^3$$

and

$$\beta=(1-1/\sigma)(\boldsymbol{kT}/\boldsymbol{h})\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\}$$

where D_1' is the mutual diffusion constant of the particles involved in a multiple flocculate.

As σ is the mean number of links between two fragments of a flocculate, the total number of links between particles per unit volume is

$$L'=\sum_{k=1}^{\infty}\sigma(k-1)\nu_k=\sigma\Big(\nu_0-\sum_{k=1}^{\infty}\nu_k\Big) \quad (14')$$

When we compare Eq. 14' with Eq. 14,

$$\sigma=3K\phi_c/\pi\beta R_1^3 \quad (15)$$

and when we substitute the β given above into Eq. 15,

$$\sigma=1+3K\phi_c/\pi R_1^3(\boldsymbol{kT}/\boldsymbol{h})\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (15')$$

Combining Eq. 15 with Eq. 12, we obtain

$$L'=\{(6/\pi R_1^3)+(3\eta\dot{\gamma}/\boldsymbol{kT}\pi\phi_c)\}\sigma\phi - (3\eta/4\boldsymbol{h})\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\} \quad (16)$$

In this equation the second term is independent of the concentration. Therefore, a critical concentration, ϕ_{crit}, above which links between particles would appear, is

$$\phi_{crit}=\frac{(3\eta/4\boldsymbol{h})\exp\{-(\Delta F-f\lambda)/\boldsymbol{kT}\}}{\{(6/\pi R_1^3)+(3\eta\dot{\gamma}/\boldsymbol{kT}\pi\phi_c\}\sigma} \quad (17)$$

This critical concentration may be lowered with the increase in the ΔF value.

B. The Mechanical Properties of Concentrated Suspensions

In order to explain the viscoelastic properties of suspensions, van den Tempel[2] assumed that at very small deformations the interparticle links could be distinguished into two kinds: the primary links, which remain intact during measurement, and the secondary links, which may break and reform during an experiment. However, van den Tempel did not give the precise nature of the primary links and neglected the shearing force acting on the medium; this force can not be ignored in suspensions of a highly viscous medium.

In the model considered here, the primary links may be explained by considering the circular structures in the flocculate. The flocculates are distributed homogeneously in the system. In a stationary state, the total number of the links, L', between dispersed particles is held constant, but the sizes of the flocculates are changed incessantly by interactions between the flocculates.

For the sake of simplicity, let us assume, as van den Tempel did, that the flocculate is an assembly of chains, each chain consisting of a linear array of dispersed perticles placed very close together and oriented in three mutually-perpendicular directions in the cube. In such an equivalent model, linkages between neighboring perticles in a chain may be considered to be composed of σ links on the average when we accept the presence of circular structures in the flocculates, as stated in the definition of σ in Section A. Moreover, if the mutual distance between neighboring particles in a chain is negligible compared to the diameter of the particles, the number of links in one direction is $L'R_1/3$ per unit area; in other words, a cross section of the cube perpendicular to the chains cuts through $L'R_1/3$ links per unit area. In the present equivalent model, the σ links between two neighboring perticles must be broken simultaneously in order to separate them. Two kinds of behavior of the bonds between particles may be considered upon deformations of the system: the one is the breaking of bonds following the re-formation of another bond between another pair of particles, and the other is the elongation of bonds without the separation of particles, in the stationary state. The probability of the simultaneous breaking of σ links, which is necessary for breaking the bonds, may be $1/\sigma$; therefore, that of the other type of deformation may be $(1-1/\sigma)$. The former corresponds to the secondary bonds and the latter to the primary bonds proposed by van den Tempel. However, he considered a special case in which σ equals one and in which all particles in the system are involved in a flocculate.

When the shearing force acting on the medium can not be ignored, the total shear stress, S, tangential to the cross section considered is expressed as follows:

$$S=\eta\dot{\gamma}+f_1N_1+f_2N_2 \tag{18}$$

where η is the effective viscosity of the medium involving the hydrodynamic effect of particles, and f_1 and f_2 are the mean forces acting on the primary links and on the secondary links respectively. N_1 and N_2 are the numbers of links cut by a cross section of unit area. In the present model,

$$N_1=(1-1/\sigma)L'R_1/3 \tag{19}$$

$$N_2=(1/\sigma)L'R_1/3 \tag{20}$$

The rate of shear of the primary links is governed by the rate of the stretching of unbroken links, while that of the secondary links in expressed as a sum of the rate of link-stretching and the rate of the breaking of the links:[1,2]

$$\dot{\gamma}_1=(n_1/g_1)(\mathrm{d}f_1/\mathrm{d}t) \tag{21}$$

$$\dot{\gamma}_2=(n_2/g_2)(\mathrm{d}f_2/\mathrm{d}t)+(2n_2\lambda_2\boldsymbol{kT}/\boldsymbol{h}) \times\exp(-\Delta F_2/\boldsymbol{kT})\sinh(f_2\lambda_2/\boldsymbol{kT}) \tag{22}$$

where it has been assumed that the strain is increased by λ_2 whenever two particles separate. The number of links per unit chain length in the direction normal to the shear plane and the the mean stiffness of the links are called n and g respectively.

According to the definitions,

$$n_1=(1-1/\sigma)(1/R_1) \tag{23}$$

$$n_2=(1/\sigma)(1/R_1) \tag{24}$$

So long as coherence in the sample is maintained, the shear stress is distributed over the medium, the primary links and the secondary links in such a way that the rate of shear is the same throughout:

$$\dot{\gamma}=\dot{\gamma}_1=\dot{\gamma}_2 \tag{25}$$

Stationary Flow Properties. — In stationary flow experiments, the total shear stress and the rate of shear are constant during measurement:

$$\mathrm{d}S/\mathrm{d}t=0 \tag{26}$$

and

$$\mathrm{d}\dot{\gamma}^2/\mathrm{d}t^2=0 \tag{27}$$

As L' and σ may be assumed not to be changed in the stationary flow, n_1, n_2 N_1 and N_2 are considered, from Eqs. 19, 20, 23 and 24, to be constant during measurement.

Consequently, from Eqs. 26, 27, 18 and 21,

$$N_1\mathrm{d}f_1/\mathrm{d}t=-N_2\mathrm{d}f_2/\mathrm{d}t=N_1g_1\dot{\gamma}/n_1 \tag{28}$$

Therefore, integrating Eq. 21, we have the mean force acting on primary links at an instant as follows:

$$f_1=\int_0^{t_1}(g_1\dot{\gamma}/n_1)\mathrm{d}t=\int_0^{\gamma_1}(g_1/n_1)\mathrm{d}\gamma=(g_1/n_1)\gamma_1 \tag{29}$$

where it has been assumed that n and g are independent of the strain and where γ_1 means the mean strain of primary links at the instant, t_1.

Substituting Eqs. 28 and 29 into Eq. 22, and combining the result with Eq. 18, we obtain

$$S=\eta\dot{\gamma}+(N_2\boldsymbol{k}T/\lambda_2)\sinh^{-1}\{\dot{\gamma}\tau_2\lambda_2(N_1g_1/n_1+N_2g_2/n_2)/N_2\boldsymbol{k}T\}+(N_1g_1\gamma_1/n_1) \tag{30}$$

where the relaxation time, τ_2, is defined by Eq. 31.

$$\tau_2=(\boldsymbol{h}/2g_2\lambda_2^2)\exp(\Delta F_2/\boldsymbol{k}T) \tag{31}$$

At very low rates of shear, approximately,

$$S=\eta\dot{\gamma}+(N_1g_1/n_1+N_2g_2/n_2)\tau_2\dot{\gamma}+(N_1g_1/n_1)\gamma_1 \tag{32}$$

The (N_1/n_1) and (N_2/n_2) parameters are generally given by functions of the concentration and the rate of shear. According to Eqs. 19, 20, 23 and 24, the parameters are

$$(N_1/n_1)=(N_2/n_2)=L'R_1^2/3 \tag{33}$$

When Eq. 33 is combined with Eqs. 16 and 17,

$$(N_1/n_1)=(N_2/n_2)=(R_1^2/3)(6/\pi R_1^3+3\eta\dot{\gamma}/\boldsymbol{k}T\pi\phi_c)\sigma(\phi-\phi_{crit}) \tag{34}$$

where σ is the same as that given by Eq. 15'.

Substituting Eq. 34 into Eq. 32, we obtain

$$S=\eta_{pl}\dot{\gamma}+S_o \tag{35}$$

where η_{pl} and S_o are the plastic viscosity and the yield value, respectively, given by

$$\eta_{pl}=\eta+(R_1^2/3)(g_1+g_2)\tau_2(6/\pi R_1^3+3\eta\dot{\gamma}/\boldsymbol{k}T\pi\phi_c)\sigma(\phi-\phi_{crit}) \tag{36}$$

and

$$S_o=(R_1^2/3)g_1\gamma_1(6\pi R_1^3+3\eta\dot{\gamma}/\boldsymbol{k}T\pi\phi_c)\sigma(\phi-\phi_{crit}) \tag{37}$$

The plastic viscosity and the yield value will increase linearly above the critical concentration, ϕ_{crit}, given by Eq. 17. However, after all particles are involved in a flocculate in all the space available in the system, the ϕ_c included in σ must be equal to ϕ; therefore, σ increases linearly with the concentration ϕ. In such a region, the plastic viscosity and the yield value must be quadratic functions of the concentration.

If the terms concerning the shearing force in Eqs. 15', 16 and 17 are negligibly small at very low rates of shear, the (N_1/n_1) and (N_2/n_2) parameters may be considered to be independent of the rates of shear. In such a case, we have

$$(N_1/n_1)=(N_2/n_2)=(2/\pi R_1)\sigma'(\phi-\phi'_{crit}) \tag{34'}$$

where

$$\sigma'=1+(12D'\boldsymbol{h}\phi_c/R_1^2\boldsymbol{k}T)\exp(\Delta F/\boldsymbol{k}T) \tag{15''}$$

and

$$\phi'_{crit}=(\eta\pi R_1^3/8\boldsymbol{h})\exp(-\Delta F/\boldsymbol{k}T)/\sigma' \tag{17'}$$

When we substitute Eq. 34' into Eq. 32, and combine the result with Eq. 35,

$$\eta_{pl}=\eta+(g_1+g_2)\tau_2(2/\pi R_1)\sigma'(\phi-\phi'_{crit}) \tag{36'}$$

and

$$S_o=(2/\pi R_1)g_1\gamma_1\sigma'(\phi-\phi'_{crit}) \tag{37'}$$

In this case, the plastic viscosity and the yield value, η_{pl} and S_o, are independent of the rates of shear; therefore, Eq. 35 represents the typical behavior of a Bingham body.

Dynamic Properties at Very Small Deformations.—We consider dynamic properties when the network structure formed by particles is not broken irreversibly by the shearing force.

When the network is subjected to a sinusoidal shear strain,

$$\gamma=\gamma_0\exp(\boldsymbol{j}\omega t) \tag{38}$$

the mean shear force acting on the primary links is given, by integrating Eq. 21 with Eqs. 25 and 38, as follows:

$$f_1=(g_1/n_1)\gamma_0\exp(\boldsymbol{j}\omega t) \tag{39}$$

Similarly, the force on the secondary links is given by integrating Eq. 22 with the first order approximation that $\sinh(f_2\lambda_2/\boldsymbol{k}T)$ equals $(f_2\lambda_2/\boldsymbol{k}T)$ at very small shear stresses:

$$f_2=(g_2/n_2)\gamma_0\exp(\boldsymbol{j}\omega t)(\boldsymbol{j}\omega\tau_2+\tau_2^2\omega^2)/(1+\tau_2^2\omega^2) \tag{40}$$

where τ_2 is the same as that given by Eq. 31 and where it has been assumed that the values of n_2 and g_2 are independent of the shear strain.

If the medium shows its own viscoelasticity, Eq. 18 alters:

$$S=\eta'_m(\omega)\dot{\gamma}+G'_m(\omega)\gamma+f_1N_1+f_2N_2 \tag{41}$$

where $G'_m(\omega)$ and $\eta'_m(\omega)$ are the dynamic modulus and the dynamic viscosity of the medium involving the hydrodynamic effect of particles.

Substituting Eqs. 39 and 40 into Eq. 41, we have

$$S=\{\eta'_m(\omega)+(N_2g_2/n_2)\tau_2/(1+\tau_2^2\omega^2)\}\boldsymbol{j}\omega\gamma_0\times\exp(\boldsymbol{j}\omega t)+\{G'_m(\omega)+(N_1g_1/n_1)+(N_2g_2/n_2)\tau_2^2\omega^2/(1+\tau_2^2\omega^2)\}\times\gamma_0\exp(\boldsymbol{j}\omega t) \tag{42}$$

If we denote the dynamic modulus and the dynamic viscosity of the whole system at very small deformations as $G'_s(\omega)$ and $\eta'_s(\omega)$ respectively, the shear force is expressed by

$$S=\eta'_s(\omega)\boldsymbol{j}\omega\gamma_0\exp(\boldsymbol{j}\omega t)+G'_s(\omega)\gamma_0\exp(\boldsymbol{j}\omega t) \tag{43}$$

Comparing Eq. 42 with Eq. 43, we have

$$G'_s(\omega)=G'_m(\omega)+(N_1g_1/n_1)+(N_2g_2/n_2)\tau_2^2\omega^2/(1+\tau_2^2\omega^2) \tag{44}$$

$$\eta'_s(\omega)=\eta'_m(\omega)+(N_2g_2/n_2)\tau_2/(1+\tau_2^2\omega^2) \tag{45}$$

In the case of a simply viscous medium, the first term in Eq. 44 vanishes and the first term in Eq. 45 is independent of the frequency.

At very small deformations, the network may be considered not to be changed by the shearing force. In Eqs. 44 and 45, the (N_1/n_1) and (N_2/n_2) parameters may, therefore, be given by Eq. 34' as functions of the concentration. Consequently, at very small deformations, we have

$$G'_s(\omega)=G'_m(\omega)+(2/\pi R_1)\times\{g_1+g_2\tau_2^2\omega^2/(1+\tau_2^2\omega^2)\}\sigma'(\phi-\phi'_{crit}) \tag{46}$$

$$\eta'_s(\omega)=\eta'_m(\omega)+(2/\pi R_1)g_2\times\{\tau_2/(1+\tau_2^2\omega^2)\}\sigma'(\phi-\phi'_{crit}) \tag{47}$$

where σ' and ϕ'_{crit} are the same as those given by Eqs. 15'' and 17'.

When we compare Eqs. 46 and 47 with Eqs. 36' and 37', we recognize similarities between the concentration dependence of dynamic properties and that of the plastic viscosity at very low rates of shear. The dynamic properties will increase linearly above a critical concentration, ϕ'_{crit}, given by Eq. 17' and after all the particles are involved in a flocculate in all the space available in the system, the dynamic properties must be be quadratic functions of the concentration.

The Correlation between the Dynamic Properties and the Stationary Flow Properties.—The correlation of the dynamic properties and the stationary flow properties can be deduced by comparing the derived equations with one other. The dynamic viscosity and the dynamic modulus at very small deformations are given by Eqs. 46 and 47. On the other hand, the plastic viscosity and the yield value in stationary flow experiments are generally given by Eqs. 36 and 37, while they are given by Eqs. 36' and 37' at infinitesimal rates of shear.

By comparing Eq. 47 with Eqs. 36 and 36', we can deduce the following relations between the viscosities: (i) when the primary links are absent in the system, the dynamic viscosity at lower frequencies coinsides with the plastic viscosity at very low rates of shear, and (ii) when the primary links exist, the plastic viscosity at infinitesimal rates of shear may be larger than the dynamic viscosity at lower frequencies. However, in the latter case, the plastic viscosity at finite rates of shear may be practically larger or smaller than the dynamic viscosity at lower frequencies, depending on the sensitivity of links to the shear force, since σ and ϕ_{crit} depend on the shearing force exponentially, as Eqs. 15' and 17 show.

When we compare Eq. 46 with Eqs. 37 and 37', we can see that the dynamic modulus at lower frequencies also relates to the yield value in simple shear experiments. At infinitesmal rates of shear, the yield value may be given by a product of γ_1 and the dynamic modulus at lower frequencies.

The Dependence of the Dynamic Properties on Amplitude.—The mean stiffness of links in Eqs. 39 and 40 may be decreased with an increase in the amplitude of shear strain, since the links between solid particles generally have a non-linear dependence of the stiffness on the particle separation. Besides, the network formed by particles may be changed by the shearing force and the rate of shear at larger deformations, as predicted by Eq. 9 in Section A. At larger stresses, therefore, the (N_1/n_1) and (N_2/n_2) parameters in Eqs. 44 and 45 are not given by Eq. 34'. In such a case, the parameters may be approximated to those mean values through sinusoidal motions and may be given by functions of the amplitudes of the shear rate and of the shearing force acting on the links.

If we denote the parameters at the amplitudes of the shear rate $\dot{\gamma}_0$ and of the shearing force f_0 as $(N_1/n_1)_{\dot{\gamma}_0,f_0}$ and $(N_2/n_2)_{\dot{\gamma}_0,f_0}$, so long as a first order approximation that $\sinh(f_2\lambda_2/\boldsymbol{kT})$ equals $(f_2\lambda_2/\boldsymbol{kT})$ is acceptable, the dependence of the dynamic properties on the amplitude of the shearing force is given by the following equations:

$$\{G'_s(\omega)-G'_m(\omega)\}_{\dot{\gamma}_0,f_0}/\{G'_s(\omega)-G'_m(\omega)\}_{\dot{\gamma}_0\fallingdotseq 0,f_0\fallingdotseq 0}=\psi(\dot{\gamma}_0,f_0)\{g_1+g_2\tau_2^2\omega^2/(1+\tau_2^2\omega^2)\}_{\dot{\gamma}_0,f_0}/\{g_1+g_2\tau_2^2\omega^2/(1+\tau_2^2\omega^2)\}_{\dot{\gamma}_0\fallingdotseq 0,f_0\fallingdotseq 0} \tag{48}$$

and

$$\{\eta'_s(\omega)-\eta'_m(\omega)\}_{\dot{\gamma}_0,f_0}/\{\eta'_s(\omega)-\eta'_m(\omega)\}_{\dot{\gamma}_0\fallingdotseq 0,f_0\fallingdotseq 0}=\psi(_0,\dot{\gamma}f_0)\{g_2\tau_2/(1+\tau_2^2\omega^2)\}_{\dot{\gamma}_0,f_0}/\{g_2\tau_2/(1+\tau_2^2\omega^2)\}_{\dot{\gamma}_0\fallingdotseq 0,f_0\fallingdotseq 0} \tag{49}$$

where

$$\psi(\dot{\gamma}_0,f_0)=(N_1/n_1)_{\dot{\gamma}_0,f_0}/(N_1/n_1)_{\dot{\gamma}_0\fallingdotseq 0,f_0\fallingdotseq 0}=(N_2/n_2)_{\dot{\gamma}_0,f_0}/(N_2/n_2)_{\dot{\gamma}_0\fallingdotseq 0,f_0\fallingdotseq 0} \tag{50}$$

As $\tau_2g_2=(\boldsymbol{h}/2\lambda_2^2)\exp(\Delta F_2/\boldsymbol{kT})$ in Eq. 49 may be independent of the amplitude of the shearing force, Eqs. 48 and 49 can be rewritten as

follows at lower frequencies:

$$\{G'_s(\omega)-G'_m(\omega)\}_{\dot{\gamma}_0,\ f_0}/\{G'_s(\omega)-G'_m(\omega)\}_{\dot{\gamma}_0\fallingdotseq 0,\ f_0\fallingdotseq 0}=\psi(\dot{\gamma}_0,\ f_0)(g_1)_{\dot{\gamma}_0,\ f_0}/(g_1)_{\dot{\gamma}_0\fallingdotseq 0,\ f_0\fallingdotseq 0} \tag{48'}$$

and

$$\{\eta'_s(\omega)-\eta'_m(\omega)\}_{\dot{\gamma}_0,\ f_0}/\{\eta'_s(\omega)-\eta'_m(\omega)\}_{\dot{\gamma}_0\fallingdotseq 0,\ f_0\fallingdotseq 0}=\psi(\dot{\gamma}_0,\ f_0) \tag{49'}$$

In conclucion, it is thought that the dynamic modulus is influenced by the amplitude more remarkably than is the dynamic viscosity at lower frequencies.

Summary

The rheological properties of concentrated suspensions have been considered theoretically by the use of a network model in which the particles are linked at random by thermal and mechanical actions.

The effects of particle size, the viscosity of the medium and the mean free energy of the activation for breaking links between particles have been taken into account in the calculation of the number of interparticle links.

The links between particles have been conveniently distinguished into two kinds in stationary states: the primary links, which are elongated without the separation of neighboring particles in an instant, and the secondary links, which are broken and reformed reversibly in an instant. The primary links originate from circular structures in the flocculates.

The dynamic properties at very small deformations and the stationary flow properties have been derived theoretically as functions of the concentration and of the frequency or the rate of shear by assuming a generalized Maxwell model modified by Eyring's non-linear viscous elements.

The correlation of the dynamic properties and the stationary flow properties and the dependence of the dynamic properties on amplitude have been considered theoretically by the use of the present network model.

The author is much indebted to Professor Hirotaro Kambe of the Aeronautical Research Institute, The University of Tokyo, for his many stimulating discussions and suggestions.

The Rheological Properties of Concentrated Suspensions. II. Stationary Flow Properties and the Influence of Additives and of Particle Size

By Masaharu TAKANO and Hirotaro KAMBE

(Received July 2, 1963)

It is generally accepted that the rheological properties of concentrated suspensions are connected with the state of flocculation and that the contribution of larger flocculates to the properties is predominant at low shearing stresses.[1,2] The rheological behavior of such flocculated systems is appreciably influenced by a trace of an adsorbate as well as by the size distribution of particles, which changes the energy of the interaction between particles. There is yet, however, no definite interpretation of the relations between the rheological properties and structures of the flocculates formed by particles in the ststem. In such concentratrated suspensions, it would be reasonable to assume that dispersed particles are partially linked with each other by weak attractive forces and that the links between particles are broken by a shearing force depending on the rate of shear.[2-5] A network model composed of links with various relaxation times would be an appropriate base for an explanation of the plastic behavior of such concentrated suspensions at low rates of shear where links between particles are not appreciably broken by the shearing force.[6,7]

In a previous paper,[8] several equations were proposed for the stationary flow properties of concentrated suspensions at low rates of shear, assuming that there are certain circular structures in flocculates and that the links between particles can be conveniently distinguished into two parts at any instant in the stationary flow: the primary links, which are elongated without the separation of neighboring particles, and the secondary links, which are broken and reformed with the separation of particles.

It is the purpose of this paper to measure the stationary flow properties of various concentrated suspensions at very low rates of shear and to compare the findings with the theoretical predictions.

Experimental

Materials.—The characteristics of the pigments and media used in this work are listed in Table I. Barium sulfate-III was the same as barium sulfate-I except that the former was covered by sodium stearate. Linseed oil contains free fatty acids in itself and is more polar than polyisobutylene, which consists essentially of linear hydrocarbons with short methyl side chains, as shown in Table I.

The Preparation of Suspensions.—First a paste containing 70% pigments by weight was made. This paste was then passed through a paint mill three times and diluted by a medium to give a suspension of the required concentration. The diluted suspension was passed once more through the mill. Additives were added to the pigment before the pigment was mixed with the medium. An exact concentration of pigment was determined by igniting the suspension. Pigments had not been dried before being mixed with the medium except when the effect of water was examined experimentally.

Apparatus.—The stationary flow properties were measured with capillary viscometers and a rotational viscometer.

(a) Capillary Viscometers.—The capillary viscometers used in this work are improved Bingham viscometers, as illustrated in Fig. 1. The radii of the capillaries are 0.1493 and 0.1079 cm. and their lengths are 5.0 and 4.5 cm. respectively. The flow volume of measurement was selected so small as 0.10 cm^3 in order that the effects of head difference might be ignored during measurement. Measurements were made, alternately under pressure and by suction, in a water bath controlled at 30±0.02°C after the sample had been kept in it for 30 min.

The shear stress, S_a, and the shear-rate, $f(S_a)$,

at the wall of the capillary are given by the following equations:

$$S_a = a\Delta P/2L$$

$$f(S_a) = (1/\pi a^3)\{3Q + S_a(dQ/dS_a)\}$$

where a and L are the radius and the length of capillary respectively, ΔP is the pressure, and Q, the flow volume per unit time. The apparent shear rate is given as follows:

$$\dot{\gamma}_a = 4Q/\pi a^3$$

For the Bingham flow, the yield value, S_0, and the plastic viscosity, η_{pl}, are:

$$S_0 = a\Delta P_0/2L$$

$$\eta_{pl} = (\pi a^4/8QL)\{\Delta P - 4\Delta P_0/3 + (\Delta P_0/3)(\Delta P_0/\Delta P)^3\}$$

$$\fallingdotseq (\pi a^4/8QL)(\Delta P - \Delta P_0)$$

where ΔP_0 is the pressure below which the sample does not flow.

(B) Brookfield Rotational Viscometer.—The Brookfiedl viscometer used in this work is a commercial instrument which has a cylinder driven at the four constant speeds of 2, 4, 10 and 20 rev./min. However, three cylinders are exchangeable. The diameters of the cylinders are 3.039, 5.027 and 7.059 mm., and the lengths are 4.995, 5.053 and 5.009 cm. respectively. A container which had a radius of about 5 cm. and a depth of about 8 cm. was used directly as a vessel for the measurements.

Measurements were made after the sample had been kept for three hours in a water bath controlled at 30±0.02°C.

The stationary flow curves were obtained by using Engelhardt's extrapolation method.[9] The yield value and the plastic viscosity for Bingham flow have been calculated by means of the following equations:

$$S_0 = M_0/2\pi a^2 L$$

$$\eta_{pl} = (M/4\pi\omega L)(1/a^2 - 1/b^2) + (S_0/\omega)\ln(a/b)$$

where M is the torque acting on the inner cylinder, M_0, the critical torque below which the sample does not flow, L, the immersed length of the inner cylinder, ω, the angular velocity of the inner cylinder, and a and b, the radii of the inner and outer cylinder respectively. The apparent rate of shear, $\dot{\gamma}_a$, is given as follows:

$$\dot{\gamma}_a = 2\omega/\{1 - (a/b)^2\}$$

Experimental Results

Typical Newtonian and Bingham behavior was observed at lower rates of shear, as illustrated in Figs. 2 and 3.

The plastic viscosity and the yield value of various suspensions are listed in Tables II and III. The values listed in the tables were mainly obtained with capillary viscometers. However, some data were obtained by the Brookfield viscometer at 2 and 4 rev./min., as it was very difficult to obtain reproducible data at a stationary flow for thixotropic suspensions when capillary viscometers were used. The dependences of the relative plastic viscosity and the yield value are shown in Figs. 4 and 5.

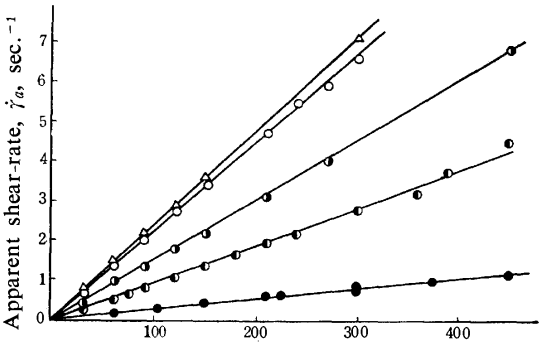

Fig. 2. Newtonian flow of suspensions of barium sulfate-I in linseed oil-II at various concentrations: (△) 0 vol.%, (○) 2.26vol. %, (◑) 8.18 vol.%, (◐) 17.14 vol.% and (●) 30.86 vol.%.

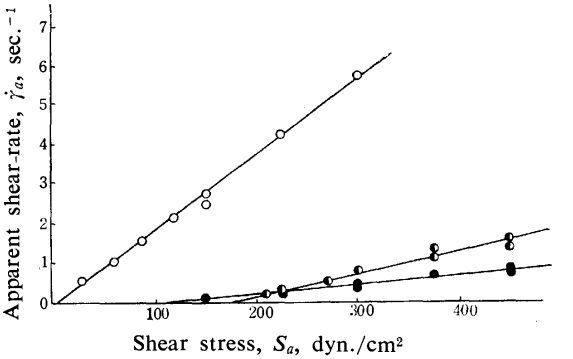

Fig. 3. Bingham flows of various suspensions: (○) 2.40 vol.% barium sulfate-III in linseed oil-II, (◐) 7.14 vol. % barium sulfate-III in linseed oil-II and (●) 2.09 vol.% barium sulfate-I in polyisobutylene-II.

When linseed oil was used as the medium, the yield value was not observed and the dependence of the relative plastic viscosity on the concentration was relatively simple, except when the particles were covered by sodium stearate. The adsorption of sodium stearate on the surfaces of particles increases the plastic viscosity and generates the yield value at lower concentrations.

When polyisobutylene is used as the medium, the yield value appears above the critical concentration determined by the particle size, and the plastic viscosity also increases remarkably above the critical concentration. The coating of the particles by sodium stearate

do those of barium sulfate-II. In these cases, it seems not to be important that the particles had not been dried before being mixed with the medium. The effect of the adsorption of water on the stationary flow properties of suspensions of barium sulfate-I in linseed oil was examined experimentally; the findings are listed in Table IV. A minor quantity of water below 2 wt.% based on pigment does not appreciably change the flow properties of the system.

According to electron-microscopic observations, the shapes of these particles are approximately hexahedral, but the size distribution of particles differs from particle to particle, as shown in Table I-b. The weight losses of these particles by their being dried and by ignition are listed in Table I-b.

Sedimentation volumes of the particles in various media are listed in Table V. Barium sulfate-I shows a larger volume than barium sulfate-II in polar and non-polar media.

The time dependence and shear-rate dependence of the flow properties were examined qualitatively by the Brookfield viscometer.

When linseed oil was used as medium, thixotropic behavior was observed slightly in suspensions of barium sulfate-I and -II, and remarkably in suspensions of barium sulfate-III.

When polyisobutylene was used as the medium on the other hand, anti-thixotropic behaviors[10] were observed, as illustrated in Figs. 6 and 7. Suspensions of barium sulfate-I have a greater tendency toward anti-thixotropic behavior than do those of barium sulfate-II. The anti-thixotropic behavior, however, disappears and normal thixotropic behavior is

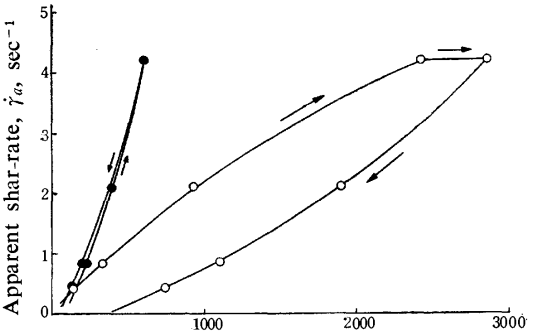

Fig. 6. Time dependence of flow property: (○) 4.54 vol.% suspension of barium sulfate-I in polyisobutylene-II and (●) 4.57 vol.% suspension of barium sulfate-III in polyisobutylene-II. Each point was obtained after rotating of the inner cylinder at a given speed for 5 min.

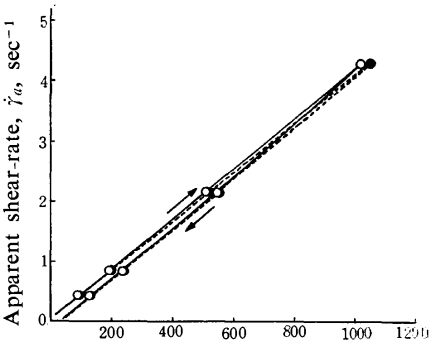

Fig. 7. Time dependence of flow property for a 4.47 vol.% suspension of barium sulfate-II in polyisobutylene-I: (○) after the sample was kept still for 30 min., and (●) after the sample was kept still for three weeks. observed when the particles are covered by sodium stearate.

Discussion

According to the experimental results described above, it is evident that the particle sizes and the polarities of the medium and of the additive appreciably influence the state of flocculation and the flow properties of the system.

In the previous paper,[8] it was proposed that the plastic viscosity and the yield value of flocculated systems at very low rates of shear may be given by the following equations:

$$\eta_{pl}=\eta+(g_1+g_2)\tau_2(2/\pi R_1)\sigma'(\phi-\phi'_{crit}) \quad (1)$$

and

$$S_o=(2/\pi R_1)g_1\gamma_1\sigma'(\phi-\phi'_{crit}) \quad (2)$$

where η is the effective viscosity of a medium involving the particles, g_1 and g_2 are the mean stiffnesses of the primary links and of the secondary links between particles respectively, τ_2 is the relaxation time of the secondary links, R_1, the diameter of the particles, ϕ, the volume fraction of the particles, σ', the mean number of links to be broken in order to separate two particles, γ_1, the mean strain of primary links in a stationary flow, and ϕ'_{crit}, the critical concentration above which stationary links between particles appear appreciably.

In Eqs. 1 and 2, the parameters, τ_2, σ' and ϕ'_{crit}, are given as follows at very low rates of shear:

$$\tau_2=(\boldsymbol{h}/2g_2\lambda_2^2)\exp(\Delta F/\boldsymbol{kT}) \quad (3)$$

$$\sigma'=1+(12D_1'\boldsymbol{h}\phi_c/R_1^2\boldsymbol{kT})\exp(\Delta F/\boldsymbol{kT}) \quad (4)$$

and

$$\phi'_{crit}=(\eta\pi R_1^3/8\boldsymbol{h})\exp(-\Delta F/\boldsymbol{kT})/\sigma' \quad (5)$$

where $\boldsymbol{h}$ and $\boldsymbol{k}$ are the constants of Planck and Boltzmann respectively, ΔF is the mean free energy of activation for breaking the links between particles (which equals those of secondary links effectively), λ_2 is the distance increased whenever the secondary links are broken, T, the absolute temperature, D_1', the mutual diffusion constant of particles involved in a flocculate, and ϕ_c, the volume fraction occupied by particles in flocculates.

According to theoretical considerations, the plastic viscosity and the yield value must increase linearly above the critical concentration, ϕ'_{crit}, given by Eq. 5. After all particles are involved in one flocculate occupying the entire space available in the system, these flow properties must be quadratic functions of the concentration, since the ϕ_c included in σ' must be equal to the ϕ in such a region. These theoretical predictions seem to agree with the experimental findings, at least qualitatively, in flocculated systems.

The critical concentration, ϕ'_{crit}, can be obtained experimentally, and the mean free energy of activation for breaking the links between particles ΔF can be evaluated by using Eq. 5 with an assumption of the value of σ'. The critical concentration and the energy, ΔF, evaluated in this way are listed in Table VI. In these flocculated systems, the mean free energy of activation for breaking the links between particles seems to have the order of $30\sim36\boldsymbol{kT}$, slightly depending on the assumed value of σ'. The order of energy, ΔF, agrees with the values, $38\sim46\boldsymbol{kT}$, obtained by van den Tempel for suspensions of glyceryltristearate in either groundnut oil or paraffin oil.[7]

Table VI. Critical concentration and the mean free energy of activation for breaking the links between particles

Flocculated system	Critical concn. ϕ'_{crit}, vol. %	ΔF, $\boldsymbol{kT}$ $\sigma'=1$	$\sigma'=2$	$\sigma'=3$
Barium sulfate -III in linseed oil-II	5.0	31.0	30.3	29.8
Barium sulfate -I in polyisobutylene-II	0.8	34.0	33.3	32.8
Barium sulfate -II in polyisobutylene-I	5.6	36.0	35.3	34.9
Barium sulfate -III in polyisobutylene-II	0.5	34.4	33.7	33.3

In non-polar mediums, the most generally occurring type of interaction between particles may be considered to be the van der Waals-London attraction. For solvated spherical particles, the mean free energy of activation for breaking the links between two neighboring particles, ΔF, is given approximately by the following equation:[11-13]

$$\Delta F=(A_m^{1/2}-A_p^{1/2})^2R_1/24(\delta+2\Delta) \quad (6)$$

where A_m and A_p are the Hamaker parameters of medium and particles, δ is the distance between the surfaces of solvated particles, and Δ is the thickness of the layer of the bound medium.

For particles adsorbed by an additive, the interaction energy is[13]

11) H. C. Hamaker, *Physica*, 4, 1058 (1937).
12) M. J. Vold, *J. Colloid Sci.*, 9, 451 (1954).
13) M. J. Vold, ibid., 16, 1 (1961).

$$\Delta F=(A_s^{1/2}-A_m^{1/2})^2(R_1+2\Delta)/24\delta + (A_s^{1/2}-A_p^{1/2})^2R_1/24(\delta+2\Delta) + (A_s^{1/2}-A_p^{1/2})(A_m^{1/2}-A_s^{1/2}) \times R_1(R_1+2\Delta)/12(\delta+\Delta)(R_1+\Delta) \quad (7)$$

where A_s is the Hamaker parameter of the additive and Δ, the thickness of the layer of the additive.

The parameter, A, of a given homogeneous material with q_i, q_j atoms per cubic centimeter is defined as

$$A=\pi^2\sum_i\sum_j q_iq_j\lambda_{ij} \quad (8)$$

where λ_{ij} is the van der Waals parameter between two kinds, i and j, of atoms depending mainly on the polarizabilities of the atoms concerned. However, there is no simple method evaluate the value of A.

For the sake of simplicity, we will consider the van der Waals-London attraction between molecules. In this way, we have the approximate parameter for a given homogeneous material:

$$A=\pi^2q^2\lambda \quad (8')$$

and the parameter, λ, between two molecules:[14]

$$\lambda=(3/4)\alpha^2eI \quad (9)$$

where q is the number of molecules per cubic centimeter, α, the polarizability of the molecule, e, the charge of an electron, and I, the first ionization potential of the molecule. The polarizabilities of non-polar molecules can be evaluated by measurement of the dielectric constant:

$$\alpha=(3M/4\pi dN)(\varepsilon-1)/(\varepsilon+2) \quad (10)$$

where M is the molecular weight, N, Avogadro's constant, d, the density, and, ε, the dielectric constant at sufficiently higher frequencies.

By substituting Eqs. 9 and 10 into Eq. 8', and by combining the result with the following relation:

$$q=(dN/M)$$

we obtain

$$A=(3/4)^3eI(\varepsilon-1)^2/(\varepsilon+2)^2 \quad (11)$$

For non-polar materials, Eq. 11 will give an approximate value of the A parameter. For polar materials, however, Eq. 11 may only give an approximate order of the parameter.

Assuming $I=13.5$ eV., which is the first ionization potential of hydrogen atom for linseed oil, polyisobutylene and water, and using the dielectric constants listed in Table I-a, we estimated the magnitudes of A for each material. Similarly, for barium sulfate and sodium stearate, we assumed $I=5.21$ eV. for $Ba \rightarrow Ba^+$ and $I=5.09$ eV. for $Na \rightarrow Na^+$. The resultant evaluated values are listed in Table VII. Although these values were roughly estimated as described above, their orders of magnitudes of A agreed with those estimated in another way.[13]

TABLE VII. ORDERS OF THE MAGNITUDES OF PARAMETERS A

Material	A, erg.
Linseed oil	1.81×10^{-12}
Polyisobutylene	4.88×10^{-13}
Barium sulfate	2.00×10^{-12}
Sodium stearate	5.91×10^{-13}
Water	8.55×10^{-12}

By substituting these values of A into Eqs. 6 and 7 and by comparing the results with the experimental results stated above, we can estimate the distance between particles as shown in Table VIII. The thickness of the layer of sodium stearate was calculated from the concentration, ca. 1 wt.% based on pigment. In suspensions of barium sulfate-I and -II in linseed oil, the energy of the interaction between particles owing to the van der Waals-London attraction is very small when the distance between the surfaces of solid particles is larger than 10Å. The critical concentration, ϕ'_{crit}, given by Eq. 5 does not appaer up to the closest packing. This evaluation agrees with the experimental finding that no critical concentration can be observed up to the highest concentration.

The inefficiency of the addition of water to the suspensions in linseed oil can also be explained by assuming the van der Waals-London attraction between particles.

TABLE VIII. INTERACTION PARAMETERS BETWEEN PARTICLES

	$BaSO_4$-III in linseed oil-II	$BaSO_4$-I in P.I.B. -II	$BaSO_4$-II in P.I.B. -I	$BaSO_4$-III in P.I.B. -II

14) F. London, *Z. Phys.*, 63, 245 (1930)

The mean stiffness of links between particles may be given by the following equation:

$$g=(1/3)(\mathrm{d}^2\Delta F/\mathrm{d}\delta^2) \qquad (12)$$

If we assume the D_1' in Eq. 4 can be approximated by the diffusion constant of unlinked particles $D_1=kT/3\pi\eta R_1$, and that ϕ_c may be approximated by ϕ'_{crit}, the other parameters, σ', γ_1 and λ_2, may be evaluated from the concentration dependences of the plastic viscosity and the yield value by using Eqs. 1, 2, 3 and 4. The results are listed in Table VIII. However, it has been assumed that g_1 equals g_2 and that the interaction between particles is merely the van der Waals-London attraction.

Summary

The stationary flow properties of concentrated suspensions of barium sulfate in linseed oil and of those in polyisobutylenes have been measured at very low rates of shear with capillary viscometers and a Brookfield viscometer.

The dependence of the plastic viscosity and the yield value on the concentration, the particle sizes, and the polarizabilities of the medium and of the additive have been measured and explained by using a network model and by assuming van der Waals-London attraction between particles.

In suspensions of barium sulfate in linseed oil, the plastic viscosity and the yield value do not change on the addition of water below 2 wt. % based on pigments, and their dependence on the concentration of particles is monotonous. However, these values increase when the particles are covered with sodium stearate above a critical concentration.

In suspensions of barium sulfate in polyisobutylene, the plastic viscosity and the yield value appreciably increase above the critical concentration determined by the particle sizes, and these values decrease when the particles are covered with sodium stearate.

In both cases, a higher plastic viscosity and yield value are observed for suspensions of smaller particles in the same medium.

In suspensions of barium sulfate in polyisobutylene, antithixotropic behavior is observed at very low rates of shear. When the particles were covered by sodium stearate, the abnormal behavior disappears and normally thixotropic behavior is observed.

For plastic systems, the mean free energy of activation for breaking links between particles has been evaluated at $30\sim36kT$. If we assume van der Waals-London attraction between particles, the distance between the surfaces of solid particles is within the range of 10～55 Å, depending on the particle sizes and the presence of an additive.

Other parameters, the mean number of links to be broken for separating particles, the mean stiffness of links and other data have been approximately evaluated by assuming van der Waals-London attraction between particles.

The authors would like to express their gratitude to Professor Emeritus Bunnosuke Yamaguchi for his kind advice and also to Mr. Sentaro Yoshimoto for assisting in the experimental work described in this paper.

The Gas Chromatographic Separation and Characterization of δ-Cyclogeraniolene and α-Cyclogeraniolene Formed from Isophorone by Wolff-Kishner Reduction[1]

By Atsuaki ARAI, Ching-Chung YAO and Iwao ICHIKIZAKI

(Received June 6, 1963)

Some isomers of cyclogeraniolene are known to serve as starting substances applicable[2-4] in the synthesis of ionone analogs. These isomers have been prepared by the cyclization of geraniolene[5,6] or by the dehydrative cyclization of 2, 6-dimethyl-5-hepten-2-ol[7,8] in the presence of various acidic catalysts; they have not, however, hitherto been separated in a pure state except in a single case in which δ- and ε-isomers,[8] i. e., 3, 5, 5- and 3, 3, 5-trimethylcyclohexene, were isolated in a reliable purity[9] from the dehydration products of dihydroisophorol.

A recent publication[10] describing how the modified Wolff-Kishner reduction of isophorone gave only the α-isomer, 2, 4, 4-trimethylcyclohexene, has prompted us to report on the isolation and characterization of δ- and α-isomers from the reaction products obtained during our independent studies.

We have found that the above reduction carried out at 160~170°C produces, in a 55% yield, an inhomogeneous hydrocarbon along with a small amount of isophorone hydrazone and isophorone azine. The hydrocarbon mixture thus obtained gave, on gas chromatography, two large peaks which accounted for ca. 30 and 70% of the total. A very small peak at a much lower retention time was also detected thereby, but it has not yet been identified. The relative amounts of the two main components scarcely changed under the reaction conditions programmed from 140 to 200°C, while that of the minor component varied over a range of 0~3%. The separation of these isomers was not sufficiently achieved even by careful distillation techniques, whereas the two principal components were completely isolated from the above mixture by preparative scale-gas chromatographic trapping.

The faster-eluted cyclogeraniolene gave, on ozonolysis, 2, 4, 4-trimethylhexanedioic acid, and the other major isomer yielded isogeronic acid in a high yield. Therefore, the former was considered to be δ-cyclogeraniolene and the latter to be α-cyclogeraniolene. The structural assignment was further confirmed by the NMR spectra, as will be described in the Experimental section.

The formation of the δ-isomer in the above reaction is not unexpected, as it has previously been recognized[11,12] that the Wolff-Kishner reduction of α, β-unsaturated carbonyl compounds in an alicyclic series gives essentially two olefinic isomers, of which one possesses the olefinic bond at the same position as before, while the other has a bond which has migrated to the site of the original carbonyl group.

We have found a linear relationship between the refractive indices and mole ratios for several mixtures of α- and δ-cyclogeraniolenes. The observed refractive values of both pure isomers (α, n_D^{25} 1.4433; δ, n_D^{25} 1.4383) were in good agreement with those estimated by graphical extrapolation. Alkonyi's "α-cyclogeraniolene," [10] n_D^{25} 1.4408, is possibly inhomogeneous and is contaminated by an appreciable amount of δ-isomers and/or other substances.

Finally, isophorone azine,[10] which was obtained on the Wolff-Kishner reduction, as has been mentioned, was also formed when isophorone hydrazone was allowed to stand for a long period at room temperature.

Experimental[13]

The Wolff-Kishner Reduction of Isophorone. — A mixture of isophorone (69 g.), triethylene glycol (300 g.), 80% hydrazine hydrate (140 g.) and potassium hydroxide (93 g.) was heated at a bath temperature of 160~170°C for 2 hr. The reaction mixture was distilled at the same temperature to separate the product, which was obtained as an azeotropic mixture with a b. p. range of 123~135°C. The residue was again refluxed for 2 hr. and distilled. There was also obtained a pale yellow product boiling at 125~165°C. The combined distillates were then separated, and the water layer was extracted with ether. The extract and the organic layer were combined, washed with a saturated sodium chloride solution, dried over sodium sulfate and concentrated in vacuo. Distillation through a 20 cm. Vigreux column gave (1) a colorless liquid (39 g.) (b. p. 65~67°C/80 mmHg), (2) a pale yellow oil (8.5 g.) (b. p. 120~127°C/20 mmHg) and (3) a viscous yellow oil (8.3 g.) (b. p. 143~145°C/3 mmHg), which solidified immediately to give yellow prisms.

The low boiling fraction 1 was redistilled over sodium (1 g.) using a small Vigreux column to give a mobile liquid (38.2 g.) (b. p. 67.5~68°C/80 mmHg, n_D^{25} 1.4420), which on gas chromatography employing a 9 m., 30% PEG-6000-on-Celite DM-14A column at 128°C with a hydrogen flow rate of 35 ml./min. gave three peaks with the retention times of 18 min. 18 sec., 21 min. 18 sec. and 24 min. 42 sec. respectively. The second and third peak, accounting for 29 and 69% of the above fraction, are due to δ- and α-cyclogeraniolene respectively. The first peak, accounting for 2%, is due to the hydrocarbon, which has not yet been characterized. The relative amounts of this compound changed over a range of only 0~3% under several W.-K. reduction conditions (4~13 hr. at 140~200°C).

The distillation of fraction 2 gave a pale yellow oil (7.8 g.) which boiled at 125~127°C/21 mmHg and which solidified gradually when left standing. Crystallization from ether-petroleum ether (5 : 1) yielded isophorone hydrazone as colorless needles (m. p. 72~73°C), which was treated with the Brady reagent to give isophorone 2,4-dinitrophenylhydrazone as dark-red needles (m. p. 146~147°C) (Lit. m. p. 147~148°C[14]).

Isophorone hydrazone was unstable and, on exposure to air, yielded an orange-yellow tarry product with an isophorone-like odor from which isophorone azine, identified by the mixture melting point determination and by infrared comparison with an authentic sample, was obtained.

The yellow solid obtained from the high boiling fraction 3 was recrystallized from methanol to give isophorone azine in the form of yellow leaflets; m. p. 148.5~149°C (Lit. m. p. 147~148°C[10]). ν_{max}^{KBr} 3034, 1641 (C=N), 1580 (conju. C=C), 1381, 1362 (*gem*-dimethyl), 1121, 898 and 835 cm^{-1}.

Found: C, 79.54; H, 10.07; N, 9.91. Calcd. for $C_{18}H_{28}N_2$: C, 79.36; H, 10.36; N, 10.28%.

The treatment of this compound with the Brady reagent gave, in a quantitative yield, isophorone 2,4-dinitrophenylhydrazone; m. p. 146~147.5°C.

The Gas Chromatographic Separation of δ-Cyclogeraniolene and α-Cyclogeraniolene from the Hydrocarbon Mixture.—The hydrocarbon mixture (59 g., n_D^{25} 1.4419) consisting of 0.5% an unknown component, 28.5% δ-isomers and 71.0% α-isomers was injected in 6 ml. portions into a Beckmann "Megachrom" equipped with a 12 ft.×5/8 in.φ, Apiezon "J" on a firebrick column at 123°C with a 135°C pre-heated inlet and a nitrogen flow (inlet/outlet=15/1 (p. s. i.)). After the usual procedure, there were finally obtained three fractions: (1) 11.4 g. (retention time, 27 min. 48 sec.), (2) 34.0 g. (32 min. 32 sec.), and (3) 6.3 g. (the mixed hydrocarbon recovered). The distillation of fraction 1 through a 40 cm. Vigreux column over sodium (1 g.) gave δ-cyclogeraniolene (9.9 g.) as a colorless mobile liquid (b. p. 132.4~132.6°C/760 mmHg, n_D^{25} 1.4384, n_D^{15} 1.4428), which was gas chromatographed on a 2.5 m. column of 25% PEG-6000 substrate to show a single peak. (Lit. b. p. 133.58°C, n_D^{20} 1.4406[9]). ν_{max}^{film} 3014, 1653, 714, 672 (cis -CH=CH-), 1461 ($-CH_2-$), 1398, 1387 and 1367 cm^{-1} (CH_3). NMR absorptions:[13] a multiplet in the 8.40~8.88 τ region (2H, CH_2 in the 4-position); an apparent triplet at 8.26 τ (2H, allylic CH_2 in the 6-position); a multiplet at 7.94 τ (1H, allylic CH in the 3-position); two peaks at 9.12 and 9.09 τ (6H, *gem*-dimethyl); a doublet at 9.04 τ (3H, CH_3 in the 3-position, J=5.01 c.p.s.), and an apparently unresolved doublet at 4.59 τ (2H, vinyl CH=CH, J=0.9 c.p.s., half-width=3.5 c.p.s.).

Found: C, 86.98; H, 12.92. Calcd. for C_9H_{16}: C, 87.02; H, 12.98%.

Fraction 2 was distilled through the same column to afford α-cyclogeraniolene (32.1 g.) as a colorless mobile liquid (b. p. 137~138°C/760 mmHg, n_D^{25} 1.4433), which was proven to be completely homogeneous by gas chromatographic analysis. (Lit. b. p. 103~105°C/200 mmHg;[7] b. p. 135°C, n_D^{25} 1.4408;[10] b. p. 54°C/40 mmHg[15]). ν_{max}^{film} 3042, 1679, 805 (>C=CH-), 1458 ($-CH_2-$), 1381 and 1363 cm^{-1} ($-CH_3$). NMR absorptions:[13] a triplet at 8.64 τ (2H, CH_2 in the 5-position); a multiplet at 7.91 τ (4H, two allylic CH_2 in the 3- and 6-positions); two peaks at 9.03 and 8.97 τ (6H, *gem*-dimethyl); a singlet at 8.27 τ (3H, CH_3 in the 2-position), and a multiplet at 4.33 τ (1H, olefinic C-H).

Found: C, 87.05; H, 13.03. Calcd. for C_9H_{16}: C, 87.02; H, 12.98%.

The retention time ratios to cyclohexene as the standard of the two isomeric cyclogeraniolenes and related substances, when measured at 136°C by a 3 m., 30% PEG-6000-on-Celite DM-14B column with

13) All melting points were measured on a Kofler block and are uncorrected. The infrared spectra were recorded on a Nippon Bunkô, model IRS, recording spectrometer using sodium chloride optics, while the gas chromatographic analyses were performed with a Kotaki Super Fractioner, model GU-21. The NMR spectra were determined at 56.4 Mc./s. with a Varian V-4300C high resolution NMR spectrometer using a 20 vol. % solution in carbon tetrachloride and tetramethylsilane as the internal standard.

a 25 ml./min. rate of hydrogen flow, are: the unknown hydrocarbon, 1.26; ε-cyclogeraniolene, 1.37; δ-cyclogeraniolene, 1.45, and α-cyclogeraniolene, 1.67.

2,4,4-Trimethylhexanedioic Acid.—Ozonized oxygen (*c* 17 g./m³) was passed through a solution of δ-cyclogeraniolene (1.5 g.) in carbon tetrachloride (10 ml.) at a flow rate of 30 l./hr. over a period of 2.5 hr. The temperature was maintained at −10°C by cooling. Acetic acid (5 ml.) and 30% hydrogen peroxide (1.5 ml.) were added, and the resulting solution was allowed to stand overnight at room temperature. After the bulk of solvent had been removed in vacuo, the residue was treated as usual to give a colorless, viscous oil (0.65 g.) (b. p. 160～180°C/6 mmHg (bath temp.)), which solidified when stored for a week in a refrigerator. Crystallization afforded colorless prisms; m. p. 71°C (Lit. m. p. 69.7～70.0°C,[9] 72～73.5°C[16]). The dianilide crystallized from benzene in the form of colorless prisms; m.p. 165°C (Lit. m.p. 164～165°C,[16] 162.8～163.3°C[17]).

Isogeronic Acid.—α-Cyclogeraniolene (1.5 g.) in carbon tetrachloride (15 ml.) was ozonized, and the reaction mixture was treated in the manner described for δ-isomer. A colorless viscous oil (1.0 g., 67.0%) (b. p. 162～165°C/5 mmHg) was obtained.

Found: C, 62.32; H, 9.42. Calcd. for $C_9H_{16}O_3$: C, 62.76; H, 9.36%.

The semicarbazone crystallized from methanol in the form of colorless prisms; m. p. 200～201°C (Lit. m. p. 197～198°C,[10] 198°C[18]).

The authors wish to express their deep appreciation to Dr. Yo-ichiro Mashiko and Dr. Hiroshi Tomita of the Government Chemical Industrial Research Institute of Tokyo for their help in the use of the Beckmann "Megachrom" and to Dr. Naohiro Hayakawa of the Japan Atomic Energy Research Institute for his measurement of the NMR spectra. They are also indebted to Dr. Toshiaki Nishida of this laboratory for his valuable discussions of the NMR spectra and for his kind supply of a pure sample of ε-cyclogeraniolene.

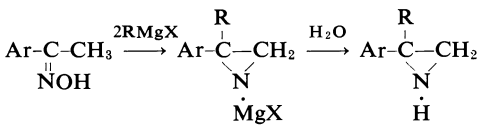
The Mechanism of Ethylenimine Formation by the Action of Grignard Reagents on Ketoximes

By Shoji EGUCHI and Yoshio ISHII

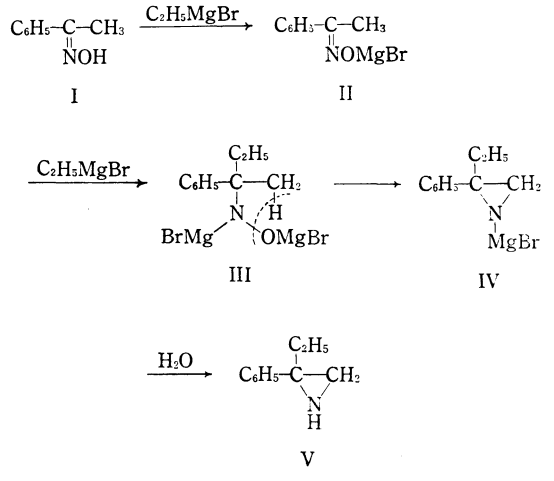
(Received June 7, 1963)

It has been known that certain substituted ethylenimines are obtained by the action of aliphatic or aromatic Grignard reagents on aryl alkyl ketoximes, followed by the non-acidic decomposition of Grignard complexes.[1]

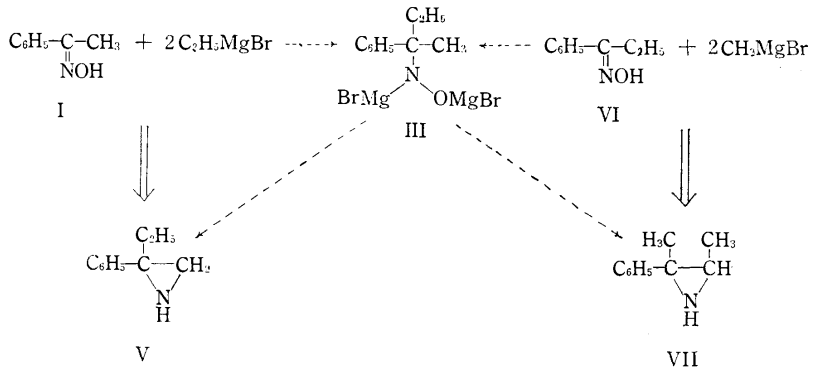


In this paper this cyclization reaction will be examined using acetophenone oxime I as a ketoxime and ethylmagnesium bromide as a Grignard reagent; as will be seen, an azirine derivative VIII has been found to be an intermediate in these reactions.

Campbell et al.[1] proposed the following reaction process involving the Grignard complex III as an intermediate:



1) K. N. Campbell and J. F. Mckenna, *J. Org. Chem.*, **4**, 198 (1939); K. N. Campbell, B. K. Campbell and E. P. Chaput, ibid., **8**, 99 (1943); K. N. Campbell, B. K. Campbell, J. F. Mckenna and E. P. Chaput, ibid., **8**, 103 (1943); K. N. Campbell, B. K. Campbell, L. G. Hess and I. J. Schaffner, ibid., **9**, 184 (1944).



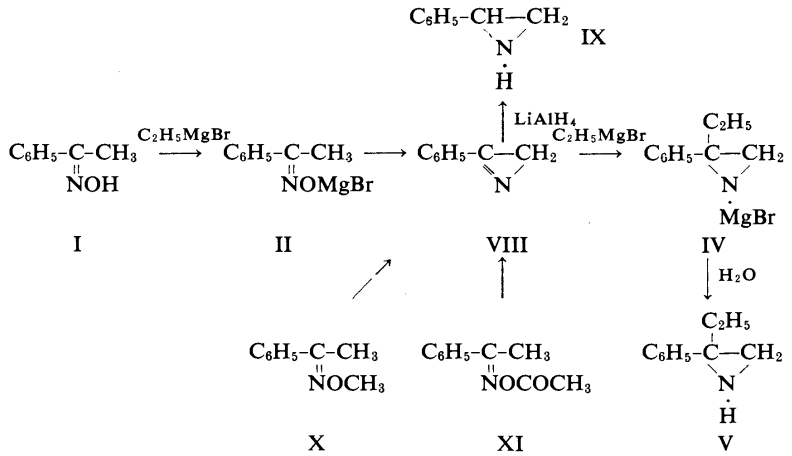
If this were actually the case, the same product would be expected from the reaction of acetophenone oxime (I) and ethylmagnesium bromide as from that of propiophenone oxime (VI) and methylmagnesium bromide, since the same intermediate complex III should be formed from these two reaction systems.

However, Henze and Compton[2] reported that the former reaction system afforded 2-phenyl-2-ethylethylenimine (V), while the latter yielded 2-phenyl-2, 3-dimethylethylenimine (VII). By gas chromatographic analysis we have confirmed their findings.

From these results, it may be concluded that an α-carbon atom of the alkyl group in the oxime becomes a member of the ethylenimine ring.

An explanation of this fact has been suggested based on the configuration of the starting oxime and the proximity of the OMgBr group to the hydrogen of the alkyl group.[2] In the intermediate complex III, however, the carbon-nitrogen single bond can not be fixed and no allylic hydrogen exists any longer; accordingly it is difficult to explain the selective cyclization in these reactions since the hydrogen atoms of the two alkyl groups become more or less equivalent.

An alternative and more plausible formulation is that the acidic hydrogen of the alkyl group is abstracted by an excess of the Grignard reagent, followed by cyclization to an azirine ring VIII, and that the reaction of the Grignard reagent on this azirine intermediate finally affords the substituted ethylenimine compounds as follows:



The Neber rearrangement[3] of an oxime tosylate by a base is an example similar to this cyclization process. The mechanism of the Neber rearrangement has been reported by Cram and his co-workers,[4] who proved the intermediate to be an azirine derivative.

When the phenylazirine (VIII) was treated with ethylmagnesium bromide and the resultant complex was decomposed by ice-ammonium chloride, 2-phenyl-2-ethylethylenimine (V) was obtained as expected. Lithium aluminum hydride reduction of the C=N double bond of the azirine gave styrenimine (IX).

The reaction of acetophenone oxime with

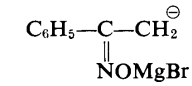
2) H. R. Henze and W. D. Compton, ibid., **22**, 1036 (1957).

3) P. W. Neber and A. Friedolsheim, *Ann.*, **449**, 109 (1926); P. W. Neber and G. Huh, ibid., **515**, 283 (1935); P. W. Neber, A. Burgard and W. Thier, ibid., **526**, 277 (1936).

4) D. J. Cram and M. J. Hatch, *J. Am. Chem. Soc.*, **75**, 33, 38 (1953).

ethylmagnesium bromide containing lithium aluminum hydride was examined, and the reaction products were analyzed by gas chromatography. It was found that 2-phenyl-2-ethylethylenimine (V) was produced in this reaction, together with a small amount of styrenimine (IX). On the other hand, from the reaction of lithium aluminum hydride with acetophenone oxime, no trace of styrenimine could be detected.

The intermediate complex II was obtained by the addition of one mole of ethylmagnesium bromide to the oxime I in ether. The complex II was stable upon being heated at 150°C without a solvent, but it yielded the ethylenimine V when treated with an excess of ethylmagnesium bromide (about 2 mol.) at about 95°C in a toluene-ether (1 : 1) mixture. The second mole of the Grignard reagent presumably reacts with the complex II as a base to produce a carbanion:



Acetophenone oxime methyl ether (X) and its acetate XI also reacted with an excess of the Grignard reagent under the same conditions to afford the ethylenimine V in a relatively high yield.

These findings clearly support the proposed mechanism for the ethylenimine formation from the action of the Grignard reagent on oximes.

Experimental

The infrared absorption spectra were measured with a Nippon Bunko IRS infrared spectrometer, using rock salt prisms. The gas chromatographic analyses were carried out on a Shimazu gas chromatograph, Model GC-1B.

2-Phenyl-2-ethylethylenimine (V).—Almost the same procedure as that of Campbell[1] was employed in the reactions of oximes and Grignard reagents. One mole of ethylmagnesium bromide in 250 ml. of ether and 250 ml. of toluene was prepared. With the solution kept at ca. 100°C, 34 g. (0.25 mol.) of acetophenone oxime was added dropwise with stirring. After the addition of the oxime, the mixture was kept at 105°C for 1 hr. The reaction mixture was then poured onto a cracked ice-ammonium chloride mixture, and the organic layer was extracted with ether several times. The combined ether extracts were dried over anhydrous magnesium sulfate. After the mixture had stood overnight, the solvent was removed under reduced pressure (water aspirator) below 80°C. The vacuum distillation of the oily residue gave about 15~20 g. of 2-phenyl-2-ethylethylenimine (V); yield 40~54%; b. p. 85~87°C/7 mmHg, n_D^{20} 1.5319 [lit.,[1] b. p. 85~86°C/7 mmHg, n_D^{20} 1.5318]. The infrared spectrum of V exhibited prominent bands at 3200, 3000, 2900, 1600, 1495, 1450, 1370, 1230, 1145, 870, 770, and 710 cm^{-1}. Phenyl thiourea, m. p. 98~99°C [lit.,[1] m. p. 99~100°C], $\nu_{C=S}^{KBr}$ 1590 cm^{-1}. The gas chromatographic analyses of V through a 1.5 m. column packed with 30% Cerite-545 and PEG-6000 revealed a single peak.

Acetophenone oxime methyl ether (b. p. 80~81°C/10 mmHg) and acetophenone oxime acetate (m. p. 53~55°C, $\nu_{C=S}^{KBr}$ 1770 cm^{-1}) were also treated with the Grignard reagent under the same conditions, to give 2-phenyl-2-ethylethylenimine (V) in yields of 63% and 64%, respectively.

2-Phenyl-2, 3-dimethylethylenimine (VII).—Propiophenone oxime (VI) (0.25 mol.) was treated with 1 mol. of methylmagnesium bromide under conditions similar to those when I was treated with ethylmagnesium bromide. A 50% yield of VII resulted; b. p. 89~91°C/7 mmHg; n_D^{20} 1.5242 [lit.,[2] b. p. 85~95°C/10 mmHg, n_D^{20} 1.5288]; phenyl thiourea, m. p. 120~122°C [lit.,[2] m. p. 122~123°C], $\nu_{C=S}^{KBr}$ 1590 cm^{-1}. Gas chromatography showed two peaks which may correspond to a 98 : 2 mixture of the cis and trans isomers. No peak corresponding to 2-phenyl-2-ethylethylenimine (V) was observed.

The Reaction of Acetophenone Oxime with Lithium Aluminum Hydride-Grignard Reagent Mixture.*—Acetophenone oxime, 13.5 g. (0.1 mol.) in 50 ml. of toluene, was added drop by drop at 85°C to a Grignard reagent-lithium aluminum hydride mixture which had been prepared from 9.6 g. of magnesium (0.4 mol.), 50 g. of ethyl bromide and 1.0 g. (0.026 mol.) of lithium aluminum hydride in 300 ml. of an ether-toluene (1 : 1) mixture. After the addition, the mixture was refluxed for about 1 hr. The reaction mixture was poured onto a cracked ice-ammonium chloride mixture, and the organic layer was extracted with ether 5 times. The extracts were dried over anhydrous magnesium sulfate, and then the solvent was removed under reduced pressure (water aspirator). Distillation of the remaining oily material gave 6 g. of an amine-imine mixture, b. p. 94~95°C/10 mmHg, n_D^{20} 1.5352. Gas chromatographic analysis showed that this was a mixture of 64% 2-phenyl-2-ethylethylenimine, 1% styrenimine and 35% α-phenylethylamine.

The same reaction of acetophenone oxime with the Grignard reagent-lithium aluminum hydride mixture in ether at a lower temperature was also carried out, but gas chromatography showed the basic products were then 72% ethylaniline and 28% α-phenylethylamine. The lithium aluminum hydride reduction of acetophenone oxime in ether produced 60% α-phenylethylamine and 40% ethylaniline.[5]

The Reaction of Phenylazirine (VIII) **with Lithium Aluminum Hydride and the Grignard Reagent.**—2-Phenylazirine (VIII), which had been obtained from the pyrolysis of α-azidostyrene,[6] was treated with lithium aluminum hydride in the

* It has been reported that the reducing properties of an ether solution of $Mg(AlH_4)_2$, formed from $LiAlH_4$ and the Grignard reagent, are similar to those of the ether solution of $LiAlH_4$; E. Wiberg and R. Bauer, *N. Naturforsch.*, **5b**, 397 (1950); *Chem. Abstr.*, **45**, 4593 (1951).

5) D. R. Smith, M. Maienthal and J. Tipton, *J. Org. Chem.*, **17**, 294 (1952).

6) G. Smolinsky, ibid., **27**, 3557 (1962).

usual manner. Styrenimine (IX) was obtained in a 30% yield; b. p. 88~90°C/9 mmHg, n_D^{20} 1.5610 [lit.,[7] b. p. 94~95°C/10 mmHg, n_D^{20} 1.5588]. Gas chromatography showed a single peak. The reaction of phenylazirine with ethylmagnesium bromide in ether gave 2-phenyl-2-ethylethylenimine (V) in a 55% yield. The relatively low yield of styrenimine and V from these reactions may be due to the dimerization of phenylazirine, since an unidentified, yellow, high-boiling material (b. p. 140~145°C/2 mmHg) was also obtained.

The Isolation of Complex II. — When one mole of ethylmagnesium bromide in ether was introduced into an ethereal solution of acetophenone oxime at room temperature, a white solid was obtained in a high yield (ca. 95%). This solid showed $\nu_{C=N}^{KBr}$ 1613 cm^{-1} (very strong[8]), and by hydrolysis acetophenone oxime was reproduced. When the complex II was treated with an excess of ethylmagnesium bromide in a manner described before, 2-phenyl-2-ethylethylenimine (V) was obtained (65%). However, complex II neither reacts with one mole of the Grignard reagent nor changes upon being heated at 150°C for 1 hr. without a solvent.

Summary

The reactions of aryl alkyl ketoximes with aliphatic Grignard reagents have been carried out under various conditions.

Gas chromatographic analyses of the reaction products showed the formation of an ethylenimine ring in which an α-carbon of the alkyl group in oximes constitutes a member of the ethylenimine ring. The reaction of acetophenon oxime with ethylmagnesium bromide containging lithium aluminum hydride produced 2-phenyl-2-ethylethylenimine, together with styrenimine.

A reaction process similar to that of the Neber rearrangement has then been proposed on the basis of the above findings.

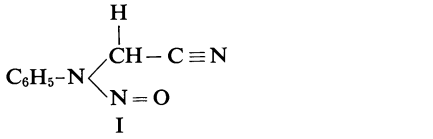
The Synthesis of New Meso-ionic Compounds from Cyanomethyl Dithiobenzoate[1]

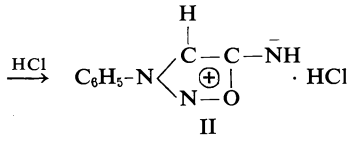
By Masaki OHTA and Masatoshi SUGIYAMA

(Received June 8, 1963)

In our previous paper on meso-ionic compounds,[2] it was reported that 3-phenylsydnoneimine hydrochloride (II) was prepared by the action of hydrogen chloride upon *N*-nitrosoanilinoacetonitrile (I). Recently, the synthesis of sydnoneimine hydrochlorides and sydnoneimines substituted with an acyl-, carbamoyl- or thiocarbamoyl- group at the exocyclic nitrogen atom has been reported by Daeniker and Druey.[3]



I



II

The formation of a sydnoneimine ring involves both a bond formation by the intramolecular addition between polar groups, i. e., a nitroso and a cyano group, and a proton transfer to a nitrogen of the cyano group. As the thioketo group is a strong polar group like the nitroso group, it is reasonable to expect that ring formation would occur with cyanomethyl dithioesters by means of a similar mechanism. The present paper reports the synthesis of a new type of meso-ionic compound, "dithioloneimine,"* containing two sulfur atoms in a ring.

The reaction of potassium dithiobenzoate

1) This paper is the part XVII of studies on meso-ionic compounds.

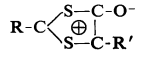
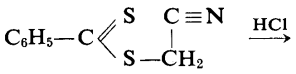
3) H. U. Daeniker and J. Druey, *Helv. Chim. Acta*, **45**, 2426 (1962).

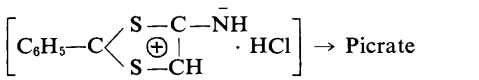
* The free base of IV is referred to as "dithioloneimine" and was derived from an unknown "dithiolone" with the structure written below. The synthesis of dithiolone is now under way in our laboratory.



with chloroacetonitrile in ethanol or in methanol gave a red, oily product, identified as cyanomethyl ester III, which could be purified neither by crystallization nor by distillation even in a nitrogen atmosphere because of decomposition; therefore, the oily intermediate was used for further experiments. When dry hydrogen chloride was passed into an ethereal solution of III, dithioloneimine hydrochloride was separated out; it was very hygroscopic in air and was identified as the picrate.

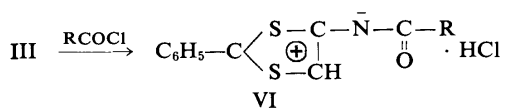


III

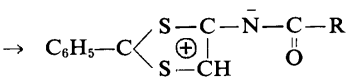


IV V

In contrast to sydnoneimine hydrochloride, which is easily acylated with acyl chlorides in the presence of alkali, IV seemed to be very unstable towards alkali and could not be acylated in the presence of weak alkali. By the action of benzoyl chloride on III in an ethereal solution, the hydrochloride of the *N*-benzoyl derivative VIa was obtained. When acetyl chloride was used in place of benzoyl chloride, the hydrochloride of the *N*-acetyl derivative VIb was obtained.



VI

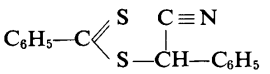


VII

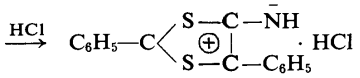
VIa $R=C_6H_5$ VIb $R=CH_3$

These hydrochlorides of *N*-acyldithioloneimines are yellow, but their free bases are brilliant red. It is known that some dithioesters show thermochromism in a solution. For example, a solution of methyl α-dithionaphthoate in ethyl benzoate is yellow-orange, but it becomes red-orange when heated.[4] Yellow crystals of VIa or of its solution in benzene or in xylene turn red when heated and then become yellow again when cooled.

When α-chlorophenylacetonitrile was treated with potassium dithiobenzoate, an oily intermediate VIII was obtained which gave 2, 5-diphenyldithioloneimine hydrochloride when treated with hydrogen chloride. Unexpectedly, when VIII was treated with benzoyl chloride, the same dithioloneimine hydrochloride was obtained. The reason for the formation of this hydrochloride instead of the *N*-benzoyl derivative is not clear.



VIII



IX

The structural evidence for dithioloneimines based on elementary analysis and its infrared spectrum. The disappearance of the C≡N stretching band at 2260 cm^{-1} and the appearance of a CH stretching band at 3020~3050 cm^{-1} suggest the formation of a meso-ionic ring. A CO stretching band of *N*-acylsydnoneimine hydrochlorides was observed at 1720 cm^{-1},[3] but in case of *N*-acyldithioloneimine hydrochlorides, this band shifts to 1650~1670 cm^{-1}.

Experimental

2-Phenyldithioloneimine Picrate (V). — Thirty-eight grams of chloroacetonitrile were added drop by drop below 40°C to an ethanol solution (500 ml.) of potassium dithiobenzoate prepared from 98 g. of benzotrichloride by Crawholl's procedure;[5] the mixture was then stirred for an hour at room temperature under a slow stream of nitrogen. The filtration of the reaction mixture and the removal of the ethanol from the filtrate gave 47 g. of a red oil which was identified as III by its infrared spectrum but which could not be purified by distillation because it decomposed when heated above 80°C.

The red oil was dissolved in 100 ml. of ether and dried with sodium sulfate. Dry hydrogen chloride was passed through 10 ml. of an ethereal solution of III, the hygroscopic precipitate obtained was quickly dissolved in 10 ml. of ethanol, and 1 ml. of a saturated alcoholic solution of picric acid was added to the resulting solution. Then the alcoholic solution was heated to a boil; when it had cooled, there separated out red needles, which were recrystallized from ethanol (m. p. 157.5~158.5°C).

Found: C, 42.50; H, 2.30; N, 13.09. Calcd. for $C_{15}H_{10}N_4O_7S_2$: C, 42.66; H, 2.39; N, 13.26%.

2-Phenyl-1-*N*-benzoyldithioloneimine Hydrochloride (VIa).—To 20 ml. of the ethereal solution of III prepared above, 7.2 g. of benzoyl chloride were added while the mixture was shaken well, the mixture was then kept standing for a day at room temperature. The precipitate was filtered off and crystallized three times from ethanol to give 4.3 g. of yellow needles (m. p. 214~215°C (decomp.)), which showed λ_{max}^{EtOH} 398 mμ (ε 15100).

4) A. Schoenberg, S. Nickel and D. Cernik, *Ber.*, 65, 289 (1932).

5) J. C. Crawholl and D. F. Elliott, *J. Chem. Soc.*, **1951**, 2071.

Found: C, 57.42; H, 3.62; N, 4.28. Calcd. for $C_{16}H_{12}NOS_2Cl$: C, 57.57; H, 3.62; N, 4.19%.

2-Phenyl-*N*-acetyldithioloneimine Hydrochloride (VIb).—To 20 ml. of the ethereal solution of III, 4 g. of acetyl chloride were added while the solution was being cooled and shaken; the mixture was then kept standing for a day. The precipitate was filtered off, crystallized from ethanol, and recrystallized from isopropyl alcohol to give 4.5 g. of yellow crystals (m. p. 207°C (decomp.)), which showed λ_{max}^{EtOH} 398 mμ (ε 13800).

Found: C, 48.43; H, 3.45; N, 5.38. Calcd. for $C_{11}H_{10}NOS_2Cl$: C, 48.60; H, 3.71; N, 5.15%.

2-Phenyl-*N*-benzoyldithioloneimine (VIIa).—To 100 ml. of an aqueous solution of VIa (1 g.) 10 ml. of a saturated aqueous solution of sodium hydrogen carbonate was added, and the mixture was shaken with benzene. The benzene layer was then dried with sodium sulfate. The removal of the benzene gave 0.6 g. of red needles (m. p. 176~177°C (decomp.)), which showed λ_{max}^{EtOH} 472 mμ (ε 9090).

Found: C, 64.30; H, 3.48; N, 4.73. Calcd. for $C_{16}H_{11}NOS_2$: C, 64.63; H, 3.73; N, 4.71%.

2-Phenyl-*N*-acetyldithioloneimine (VIIb). — To 100 ml. of an aqueous solution of VIb (1 g.), 10 ml. of a saturated aqueous solution of sodium hydrogen carbonate was added, and the mixture was shaken with benzene. The benzene layer was then dried with sodium sulfate. The removal of the benzene gave 0.55 g. of red crystals, which was recrystallized twice from benzene-petrolium ether; m. p. 184~185°C (decomp).

Found: C, 55.63; H, 3.16; N, 5.56. Calcd. for $C_{11}H_9NOS_2$: C, 56.10; H, 3.86; N, 5.95%.

2, 5-Diphenyldithioloneimine Hydrochloride (IX).—7.6 g. of α-chlorophenylacetonitrile[6] which had been prepared from mandelonitrile[7] and thionyl chloride were added under a slow stream of a nitrogen current below 40°C to 100 ml. of potassium dithiobenzoate in ethanol prepared from 9.8 g. of benzotrichloride; the mixture was then stirred for an hour at room temparature. The filtration of the reaction mixture and the removal of ethanol of the filtrate gave a red oil, to which 20 ml. of water was added and extracted with two portions of ether of 50 ml. each. The ethereal layer was dried with sodium sulfate, and dry hydrogen chloride was passed through one-half of the ethereal layer. When the solution was kept standing for two days at room temparature, gave dark red crystals which were recrystallized from acetone (m. p. 166~167° (decomp.)), the crystals showed λ_{max}^{EtOH} 487 mμ (ε 21800).

Found: C, 58.42; H, 3.74; N, 4.52. Calcd. for $C_{15}H_{12}NS_2Cl$: C, 58.92; H, 3.92; N, 4.58%.

To the other half of the ethereal solution, benzoyl chloride was added; after the mixture had been kept standing over night, red crystals were filtered off. Recrystallization from acetone gave dark red needles which were identified as IX by their infrared spectrum and by elementary analysis.

The authors are indebted to Miss Toshiko Aoyagi for her elementary analysis and to Mr. Yutaka Hachimori for his ultraviolet spectral data.

The Separation and Structure Determination of an Eicosatrienoic and an Eicosadienoic Acid in Nagi Seed Oil[*1]

By Suketaka ITO,[*2] Yoshito KOYAMA[*3] and Yoshiyuki TOYAMA[*4]

(Received June 8, 1963)

The presence of an eicosatrienoic acid in the seed oil of Nagi, *Podocarpus Nagi*, has been reported in a previous study by Koyama and Toyama.[1] However, the structure of this acid has not yet been determined; it is only known that this acid, after isomerization with alkali, shows the characteristic absorption of conjugated dienes without showing that of conjugated trienes.

In this study, the presence of an eicosadienoic

*1 A Synopsis of this paper has already been published in Japanese; *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **84**, 92 (1963).

1) Y. Koyama and Y. Toyama, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **78**, 1223 (1957). The eicosatrienoic acid of Nagi seed oil was carelessly named "podocarpic acid" by these authors, but this nomenclature should be withdrawn since the same name had already been given to a different resin acid (cf. A. C. Oudemans, *Ber.*, **6**, 1122, 1125 (1873)).

acid besides the eicosatrienoic acid in Nagi seed oil has been indicated by gas-liquid chromatography (GLC). For the separation of these two acids, the methyl ester of the fatty acids of Nagi seed oil was subjected to repeated urea-adduct segregation; a crude eicosatrienoate fraction and a fraction rich in eicosadienoate were thus separated. The crude eicosatrienoate fraction was purified further by column chromatography to give the eicosatrienoate fraction. The fraction rich in eicosadienoate was fractionally distilled to give the eicosadienoate fraction. The positions of the double bonds in the eicosatrienoate and in the eicosadienoate were determined by the oxidative ozonolysis of the respective methyl ester fractions and also, in the case of the eicosatrienoate, by the oxidative ozonolysis of the nonadecatrienyldimethylcarbinol and the hydroxyeicosadienoate derived from it.

Experimental

Properties of the Oil.—The Nagi seed oil used in this study was extracted with acetone from Nagi seeds collected in Nara in late November, 1960. The yield of the oil from 3 kg. of seeds was 270 g. It is a pale yellow liquid with a faint aroma. The characteristics of the oil and of its fatty acids are as follows:

Oil: n_D^{20} 1.4802, acid value 1.2, saponification value 188.0, iodine value 151.4, and nonsaponifiable matter 0.64%.

Fatty acids: n_D^{20} 1.4704, neutralization value 193.5, and iodine value 162.4.

Fatty Acid Composition.—The methyl ester of fatty acids, freed from nonsaponifiable matter, was prepared from the oil in the usual way. It had a refractive index (n_D^{20}) of 1.4634, a saponification value of 186.5 and an iodine value of 153.9, and it was analyzed by GLC. All GLC analyses were performed using a conventional GLC apparatus with a thermoconductivity detector. Column: 225 cm. in length and 6 mm. in diameter, packed with 60~80 mesh Celite 545 coated with 20% diethylene glycol succinate polyester. Temperatures: 230°C for the methyl ester fractions of fatty acids, 200°C for the methyl esters of the dibasic cleavage products of ozonolysis, and 170°C for the benzyl esters of monobasic cleavage products of ozonolysis. Helium flow rate: 80 ml./min. The peaks on the chromatogram were identified by the addition of reference samples or by a comparison of the retention times. With diethylene glycol succinate polyester as the fixed liquid phase, the retention time of the methyl eicosenoate is almost equal to that of the linolenate, whereas with propylene glycol succinate polyester as the fixed liquid phase, the retention times for these two methyl esters are significantly different.[2] The chromatogram of the fatty acid methyl esters of Nagi seed oil using propylene glycol succinate polyester as the fixed liquid phase showed the peak corresponding to the eicosenoate but no peak corresponding to the linolenate. The composition of the fatty acid methyl esters was calculated by the half-band width method. The results are shown in Table I.

TABLE I. THE COMPOSITION OF THE FATTY ACID METHYL ESTERS OF NAGI SEED OIL

Methyl ester	Wt. %[a)]
Palmitate	3.8
Stearate	1.9
Oleate	21.4
Linoleate	37.8
Eicosenoate	1.8
Eicosadienoate	9.6
Eicosatrienoate	23.7

a) Corrected. Cf. Ref. 2.

The Urea-adduct Segregation of Methyl Esters. —Methyl esters were prepared by refluxing 200 g. of oil with 600 ml. of methanol and 0.6 g. of metallic sodium for 30 min., and then by extracting them with hexane after the solution had been cooled to room temperature. A 180 g. portion of the methyl esters thus obtained was treated with 180 g. of urea and 1350 ml. of methanol; the crystalline urea-adduct (Fr. 1) was then filtered off at room temperature and washed with hexane. The material recovered from the hexane washing was added to the methanol filtrate and then treated with another 150 g. of urea. The urea-adduct (Fr. 2) was filtered and washed as before. The filtrate was treated further with urea in a similar manner to give urea-adduct fractions (Fr. 3 and Fr. 4) and the final filtrate fraction (Fr. 5) as shown schematically in Fig. 1. The methyl ester fractions regenerated from Frs. 1—5 were analyzed by GLC to ascertain the relative distribution of the eicosatrienoate and of the eicosadienoate in these fractions. It was found that, although Fr. 2 contained more oleate and linoleate than eicosadienoate and eicosatrienoate, the proportion of the amount of eicosadienoate to eicosatrienoate in this fraction was relatively large. Fraction 4 contained eicosatrienoate and linoleate but no eicosadienoate. Fraction 5 appeared to contain almost exclusively the eicosatrienoate as a regular methyl ester, but oxidized and polymerized methyl esters and some other impurities were also concentrated in this fraction. Fractions 2 and 4 were subjected to further fractionation using urea, as Fig. 1 shows.

Methyl Eicosatrienoate and Eicosadienoate. — The methyl ester fraction regenerated from Fr. 6 in Fig. 1 was found by GLC to contain no methyl ester other than the eicosatrienoate. It was purified further by elution chromatography using hexane and hexane-ether (100 : 0.5) as the eluants and an adsorption column, 20.6 cm. in height and 3.0 cm. in diameter, packed with 70 g. of activated silica.

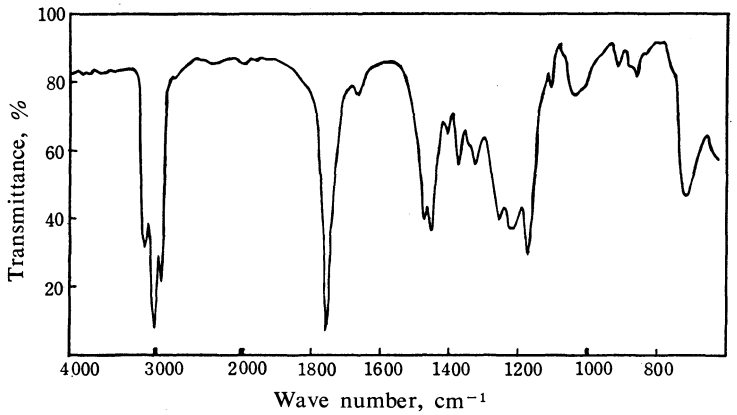

Fig. 2. Infrared spectrum of the fraction I (film on NaCl flats).

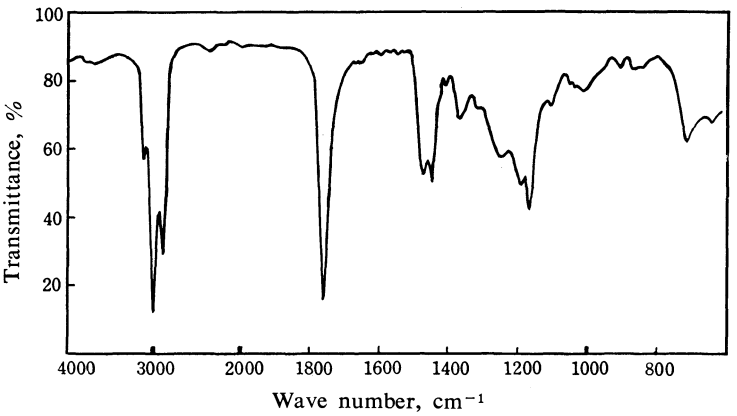

Fig. 3. Infrared spectrum of the fraction II (film on NaCl flats).

When the first and last eluates were removed, 6.1 g. of the methyl eicosatrienoate fraction (I) was obtained.

The methyl ester fractions regenerated from Fr. 7 and Fr. 8 in Fig. 1 were united, and the united fraction was fractionally distilled under 2 mmHg using a fractionating column, 90 cm. in height and 1.8 cm. in diameter, packed with stainless steel rings, 4 mm. in diameter. Thirteen fractions were separately collected. The lower boiling fractions consisted predominantly of the methyl ester of C_{18}-acids. The 12th fraction, 1.2 g., was used as the methyl eicosadienoate fraction (II) in this study. The chromatograms of GLC indicated that, while fraction I consists almost exclusively of methyl eicosatrienoate, fraction II is not a pure methyl eicosadienoate fraction but is contaminated more or less with other unsaturated methyl esters. The characteristics of fractions I and II are shown in Table II.

Table II. The characteristics of methyl eicosatrienoate (I) and eicosadienoate (II)

	I[a]	II[b]
n_D^{32}	1.4660	1.4572
Saponification value	174.9 (175.1)	175.6 (174.0)
Iodine value	235.5 (237.6)	154.7 (157.4)
Hydrogen absorption ml./mmol.	67.2 (67.5)	—

a) The figures in parentheses are the values calculated for $C_{21}H_{36}O_2$.
b) The figures in parentheses are the values calculated for $C_{21}H_{38}O_2$.

The hydrogenation of fractions I and II with palladium black in ether gave methyl arachidate. The infrared spectra of I and II exhibited no absorption at 965 cm^{-1} (Figs. 2 and 3). The ultraviolet absorptions of fractions I and II after isomerization with 21% potassium hydroxide in ethylene glycol at 180°C for 15 min. were measured. After the isomerization both fractions exhibited the characteristic absorptions of conjugated dienes, $k_{233}=85.0$ for fraction I and $k_{233}=71.5$ for fraction II. In the region of conjugated trienes, 268 mμ, fraction II after the isomerization exhibited no absorption, while fraction I after the isomerization exhibited only a minor absorption, one which is possibly to be ascribed to the presence of a small amount of preformed conjugated trienes in fraction I.

The Ozonolysis of Fractions I and II.—A 100 mg. portion of I was ozonized in 3 ml. of methylene chloride at −15°C by passing ozonized oxygen (4.5%) through the solution for 2 hr. at a flow rate of 80 ml. per min. Then, 2 ml. of 30% hydrogen peroxide and 5 ml. of a 5% aqueous solution of potassium hydroxide were added to the ozonide solution, and the mixture was gradually heated to 80°C in the course of 2 hr., during which period nitrogen bubbles were allowed to pass through the mixture. The reaction mixture was then distilled, and the distillate was neutralized with a 0.1 N solution of potassium hydroxide and evaporated to dryness. The residue was taken up with 20 ml. of ethanol, and the ethanol solution was concentrated to a volume of 2~3 ml. Finally, benzyl bromide in an amount equivalent to the amount of potassium hydroxide required to neutralize the distillate was added to the concentrated ethanol solution, and the mixture was refluxed for 20 min. After the mixture had cooled, the extraction of the reaction mixture with ether gave 94 mg. of benzyl esters. Benzyl formate, acetate and caproate were identified by GLC. Another 100 mg. portion of I was ozonized in the same way, and the ozonide was decomposed by gradually heating the ozonide solution with 2 ml. of 30% hydrogen peroxide and 5 ml. of water up to 90°C in the course of 3 hr., during which period nitrogen bubbles were allowed to pass through the mixture. The reaction product was then evaporated in vacuo for the removal of the bulk of the water, and the residue was taken up with ether. The ether solution was dried over anhydrous sodium sulfate. After distilling off the ether, the residue was esterified with sulfuric acid and methanol to give methyl esters of dibasic acids (68 mg.), in which methyl glutarate and adipate were identified as the main components by GLC.

A 100 mg. portion of II was ozonized, and the ozonide was treated in the same way as has been described for I. From the distillate, benzyl esters were obtained in a yield of 92 mg. Benzyl formate, acetate and caproate were identified by GLC. The distillation residue was extracted with ether, and the ether extract was converted to methyl esters with sulfuric acid and methanol. Yield: 63 mg. Methyl undecanedioate was identified as the main component by GLC.

The Preparation and Ozonolysis of Nonadecatrienyldimethylcarbinol. — A solution of 400 mg. of fraction I in 10 ml. of ether was added to a Grignard reagent prepared from 400 mg. of methyl iodide, 70 mg. of magnesium turnings, and 5 ml. of ether in the usual way. The mixture was then refluxed for 1 hr., and the reaction product was hydrolyzed by the successive addition of water and of dilute hydrochloric acid. The product was obtained by extraction with ether in a yield of 402 mg. It could be recognized as nonadecatrienyldimethylcarbinol by the pattern of the preparation and by the infrared spectrum shown in Fig. 4. This tertiary, unsaturated alcohol was subjected to ozonolysis, and the ozonide was treated in the same way as has been described for fraction I. From 200 mg. of alcohol 97 mg. of methyl esters of dibasic acids were obtained; in these esters methyl adipate and succinate, together with glutarate, were identified by GLC.

Methyl Hydroxyeicosadienoate.—A 4.0 g. portion of the fatty acid obtained from fraction I by saponification was dissolved in 30 ml. of ether and brominated at −15°C, yielding 1.35 g. of an ether-insoluble bromide which had a m. p. of 152~152.5°C (reported,[1] 152~152.5°C) after recrystallization from carbon tetrachloride and which was regarded as hexabromoarachidic acid. A solution of 1.10 g. of recrystallized hexabromide in 80 ml. of ethanol-ether (1 : 1) was neutralized with a solution of potassium hydroxide and refluxed for 4 hr. After 1.5 to 2 hr. from the beginning of this refluxing, potassium bromide was formed and precipitated

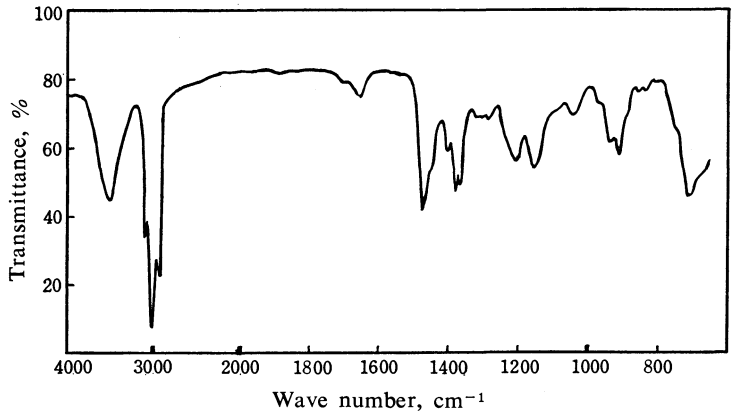

Fig. 4. Infrared spectrum of nonadecatrienyldimethylcarbinol derived from the fraction I (film on NaCl flats).

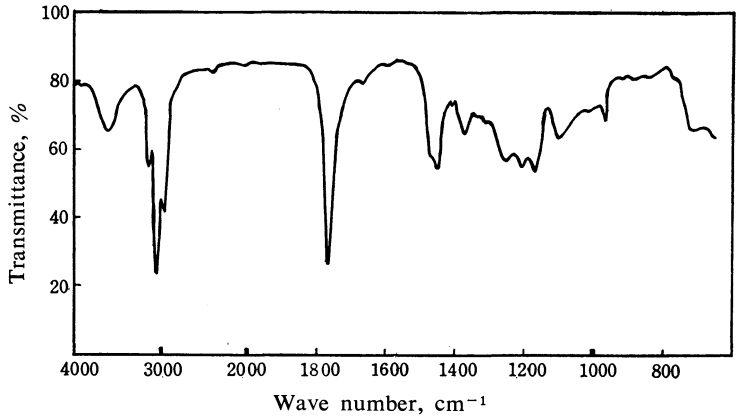

Fig. 5. Infrared spectrum of methyl hydroxyeicosadienoate derived from the fraction I (film on NaCl flats).

from the solution. The reaction product was extracted with ether, and the ether solution was washed with alkali to remove the unchanged hexabromoarachidic acid. After distilling off the ether from the ethereal solution, 634 mg. of a neutral substance (bromolactone) was obtained. Yield: 64% of theory. To 625 mg. of this substance were added 500 mg. of zinc powder and 13 ml. of methanol, and the mixture was refluxed for 1 hr. Then, 250 mg. of zinc powder, 7 ml. of methanol and 1 ml. of concentrated sulfuric acid were added, and the mixture was refluxed further for 1 hr. The reaction product obtained by extraction with ether was found to be free from bromine. Yield: 334 mg. The debromination product could be recognized as methyl hydroxyeicosadienoate by the pattern of the preparation and by the infrared spectrum (Fig. 5). It had a refractive index (n_D^{31}) of 1.4772 and an iodine value of 155.6 (calcd. for $C_{21}H_{38}O_3$: 149.9). The isomerization product obtained under the same conditions as have been described for fractions I and II exhibited the characteristic absorption of conjugated dienes, $k_{233}=70.8$.

A solution of 100 mg. of the debromination product in 3 ml. of methylene chloride was ozonized at −15°C for 1.5 hr. Then, 10 ml. of a 5% solution of potassium hydroxide and 500 mg. of silver oxide were added to the ozonide solution, and the mixture was heated at 70°C for 3 hr. during which period nitrogen bubbles were allowed to pass through the mixture. The alkaline solution was filtered. The filtrate was acidified with diluted sulfuric acid and then distilled. The distillate was subjected to a procedure similar to that described for fractions I and II to give 103 mg. of benzyl esters. Benzyl formate, acetate and caproate were identified by GLC.

Discussion

Both methyl eicosatrienoate (I) and eicosadienoate (II), upon hydrogenation, give methyl arachidate. Accordingly, I and II have no branched chain. The ethylenic linkages in I and II are of the all-cis form, since the infrared spectra of I and II (Figs. 2 and 3) show no absorption at 965 cm^{-1}. After isomerization with alkali, I and II show the characteristic absorption of conjugated dienes at 233 mμ.,

indicating that both I and II have the $=CHCH_2CH=$ group of the divinylmethane type.

The ozonolysis of II gives formic, acetic and caproic acids as the monobasic acids and *n*-undecanedioic acid as the dibasic acid. Among these cleavage products, formic and acetic acids may be regarded as secondary decomposition products of malonic acid or of its precursor resulting from the $=CHCH_2CH=$ group. Accordingly, $CH_3(CH_2)_4CH=$ and $=CH(CH_2)_9COOCH_3$ are the terminal groups of II.

From these results, the free fatty acid corresponding to II may be concluded to be all-*cis*-11, 14-eicosadienoic acid.

The ozonolysis of I gives formic, acetic and caproic acids as the monobasic acids, and adipic and glutaric acids as the dibasic acids. Formic and acetic acids are considered to be secondary decomposition products originating from the $=CHCH_2CH=$ group. Hence, the free fatty acid of I is found to have the terminal group $CH_3(CH_2)_4CH=$ on the methyl side and either $=CH(CH_2)_4COOH$ or $=CH(CH_2)_3COOH$ as the terminal group on the carboxyl side. However, the oxidative ozonolysis of the nonadecatrienyldimethylcarbinol derived from I gives succinic acid in a large proportion, together with glutaric and adipic acids as the dibasic cleavage products. Hence, the terminal group on the carboxyl side should be $=CH(CH_2)_3COOH$. As for the arrangement of the two intermediate groups, $=CHCH_2CH=$ and $=CH(CH_2)_4CH=$, the results of the ozonolysis of hydroxydienoate (I') derived from I indicate that the $=CHCH_2-CH=$ group is adjacent to the terminal group, $CH_3(CH_2)_4CH=$, since the hydroxydienoate contains an alkali conjugatable diene, $=CHCH_2-CH=$, and since on ozonolysis it gives formic, acetic and caproic acids as the monobasic cleavage products. On the basis of these findings, the free fatty acid corresponding to I may be concluded to be all-*cis*-5, 11, 14-eicosatrienoic acid. The hydroxydienoate I' is methyl 5-hydroxy-11, 14-eicosadienoate.

Univalent-Bivalent Ion-exchange Equilibria on Some Permselective Membranes

By W. G. B. MANDERSLOOT

(Received June 3, 1963)

This study was undertaken in connection with preferential ion transport in electrodialytic ion transfer through permselective membranes and therefore the ion pairs studied were selected from those encountered in natural waters: Cl/SO_4 in the case of anion exchange resins and Na/Ca in the case of cation exchange resins.

In the equilibrium state the electrochemical potential of each mobile particle is equal inside and outside the resin. If a constant partial molar volume is assumed for each particle it may be shown[1] that for the ion i:

$$E_i=\bar{\varphi}_i-\varphi_i=\frac{1}{z_i\boldsymbol{F}}\left[\boldsymbol{RT}\ln\frac{a_i}{\bar{a}_i}-\pi V_i\right] \quad (1)$$

in which E is the Donnan potential, φ the electrical potential, z the electrovalency of the ion, $\boldsymbol{F}$ Faraday's constant, $\boldsymbol{R}$ the gas constant, T the absolute temperature, a the single ion activity, π the swelling pressure and V the partial molar volume; barred symbols refer to the resin phase. Helfferich[1] applies Eq. 1 to both the competing counterion species i and j, assuming $\bar{\varphi}_i=\bar{\varphi}_j$ and therefore $E_i=E_j$, and assuming a constant π. Tye[2] has pointed out that counterions and co-ions are on different electrical potentials and the same, although possibly less so, should hold for two different counterions i and j. Therefore we will equate φ_i and φ_j rather than E_i and E_j:

$$\varphi_i=\varphi_j \quad (2)$$

Combining Eqs. 1 and 2:

$$\ln\left[\frac{a_j}{\bar{a}_j}\right]^{z_i}\left[\frac{\bar{a}_i}{a_i}\right]^{z_j}=-\frac{\pi}{\boldsymbol{RT}}[z_jV_i-z_iV_j]-\frac{z_iz_j\boldsymbol{F}}{\boldsymbol{RT}}[\bar{\varphi}_i-\bar{\varphi}_j] \quad (3)$$

1) F. Helfferich, *Ionenaustauscher*, Vol. 1, *Verlag Chemie*, Weinheim/B (1959), pp. 133, 154.

2) F. L. Tye, *J. Chem. Soc.*, **1961**, 4784.

In the exchange of i and j not only the two counterions are involved but also a certain amount of water and therefore we replace in Eq. 3 the difference in partial molar volumes by the total volume change (in the resin) involved in the exchange of i and j, $(z_j\overline{V}_i - z_i\overline{V}_j)$. Furthermore, it will be assumed that π is proportional to the equivalent fraction $\overline{X}_j$ of j in the resin:

$$\pi = \pi_i + \overline{X}_j(\pi_j - \pi_i) \tag{4}$$

in which π_i and π_j denote the swelling pressures in the single ionic forms of the resin. When the single ion activities in Eq. 3 are replaced by molalities according to

$$a_i = f_i m_i, \text{ etc.} \tag{5}$$

and the molalities are in turn replaced according to

$$X_i = \frac{z_i m_i}{z_i m_i + z_j m_j}, \text{ etc.} \tag{6}$$

and defining the relative affinity coefficient K_j^i by:

$$K_j^i \equiv \left[\frac{X_j}{\overline{X}_j}\right]^{z_i}\left[\frac{\overline{X}_i}{X_i}\right]^{z_j} \tag{7}$$

then, combination of 3–7 and conversion to logarithms gives:

$$\ln k_j^i = (z_j - z_i)\ln\frac{z_i m_i + z_j m_j}{z_i\overline{m}_i + z_j\overline{m}_j} + \ln\frac{f_i^{z_j}}{f_j^{z_i}} + \ln\frac{\overline{f}_j^{z_i}}{\overline{f}_i^{z_i}} - [z_j\overline{V}_i - z_i\overline{V}_j] \times \frac{\pi_i + \overline{X}_j[\pi_j - \pi_i]}{RT} - \frac{z_i z_j F}{RT}(\overline{\varphi}_i - \overline{\varphi}_j) \tag{8}$$

The first term on the right hand side is the external/internal concentration ratio term which disappears when $z_i = z_j$. This term is mainly responsible for the increase in affinity for multivalent ions (compared with univalent ions) when the external total electrolyte concentration is decreased. The term varies slightly with $\overline{X}_j$ because of the amount of water involved in the exchange, which causes m_i and m_j to change with $\overline{X}_j$.

The second term is the external activity coefficient ratio term which is somewhat dependent on X_j and therefore also on $\overline{X}_j$ and, depending on the ionic species involved, the term can change considerably with external concentration.

The thired term is the internal activity coefficient ratio term which is difficult to estimate; one should be very cautious when considering an analogy with concentrated electrolyte solutions.

The fourth term is the pressure-volume term which is dependent on $\overline{V}$ and therefore on total external concentration (increased swelling of the resin at lower external concentration) and, as shown, it is also dependent on $\overline{X}_j$.

The last term is the electrical term which can be expected to be quite independent of external concentration and $\overline{X}_j$.

Experimental

Ion exchange resin membranes used were:

	Cation exchanger	Anion exchanger
Permaplex[3]	C-20	A-20
T. N. O.[4]	C-60	A-60
A. M. F.[5]	3129 B-56	3129 B-96
A. C. I.[6]	Yes	Yes
C. S. I. R.[7]	—	TA

From each membrane four circular pieces with a diameter of 1.5 in. were cut and brought to the sodium or chloride form with several amounts of 2 N sodium chloride after which the samples were rinsed with distilled water. The pieces were then equilibrated for two days with renewed amounts of mixed solutions of sodium chloride and calcium chloride (0.15N) or sodium chloride and sodium sulfate (0.5N, 0.15N or 0.01N). In a number of cases ohmic resistance measurements were carried out on the membranes in the equilibrating solution. On each piece of membrane measurements were made on two different small areas (2.3 cm^2) and for each material the reported values are the average of eight measurements.

Equilibration and Resistance Measurements at 25°C. —The four pieces of each material were weighed together after thorough blotting with filter paper. Calcium was then displaced from the cation exchange resins by leaching with 25 ml. amounts of 1N sodium chloride and calcium was determined by complexometric titration with EDTA. Chloride and SO_4 were displaced from the anion exchange resins by leaching with 25 ml. amounts of 2 N sodium nitrate. Chloride in the leach was determined by Mohr titration and SO_4 by complexometric titration using photometric endpoint detection. The NO_3 form of the membranes was weighed. The membranes were in the complete sodium or chloride form before each new equilibration with a mixed solution. All equilibrations were carried out with the same four pieces of material. Finally, the membranes were rinsed free of absorbed electrolyte and dried to constant weight sodium or chloride form in a vacuum desiccator over phosphorus(V) oxide.

Results and Discussion

Change in Water Content.—The weight of the samples varied linearly with internal

counterion composition, examples being shown in Fig. 1. After correcting for the change due to the counterions themselves it was possible to arrive at the constant amount of water involved in the exchange of i and j. The constancy is the basis for Eq. 4. As indicated by Boyd et al.[8] the amount of water involved is not necessarily constant in resins with low degrees of crosslinking; the resin membranes are usually highly crosslinked.

The observed water content changes have been summarized in Table I. In the cation exchange resins the amount of water involved in the Ca/Na exchange tends to be low in the resins of high internal molality. The hydration of the ions in the resin decreases with increasing internal molality (degree of crosslinking).[9]

The result for Permaplex C-20 seems to deviate, but it should be remembered that these heterogeneous membranes contain liquid interstices between the ion exchange resin grains embedded in the inert matrix. This leads to a higher water content for the membrane than for the resin itself[10] and consequently to a low calculated internal molality. It may also lead to low values for the change in water content, if the volume changes of the resin particles are partly compensated by changes in the size of the interstices.

In the anion exchange resins the amount of water involved in the Cl/SO_4 or NO_3/SO_4 exchange decreases, in general, with increasing external electrolyte concentration, i. e., with decreasing swelling of the resin and consequently an increasing internal molality. The correlation of water content change with the internal molalities of the different membranes is less clear and it should be remembered that, although in general the high concentration of fixed ions is due to crosslinking, the degree of crosslinking itself should still be taken into account. The C. S. I. R.-T. A. resin, for instance, is very highly crosslinked but does not have the highest concentration of fixed ions.

In general, we may conclude that the amount of water involved in ion exchange is dependent

on the amount of water present in the resin and on the rigidity (crosslinking) of the polymer network.

Conductivity.—Conductances were measured only in 0.15 N solutions. The results are given in Figs. 2 and 3. In the cation exchange resins interaction is noticeable only at high calcium loading. The calcium form of the resin is less swollen and the observed effect could be explained by an uneven distribution of counterions through the resin, caused by heterogeneity in the crosslinking of the resin.

The form of the curve obtained for the heterogeneous Permaplex C-20 membranes can be explained as follows. At low $\overline{X}_{Ca}$ the calcium ions in the membrane will be located mainly inside the resin particles and then they cannot hinder the movement of Na^+ on the particle surface. If surface transport makes up a large portion of total transport, the conductivity of the membrane decreases little when only a small amount of calcium is present. Evidence that surface transport is indeed important in heterogeneous membranes comes from selective ion transport in a d.c. field, in which the transport ratios are more in favor of the common monovalent ions than would be expected from the ratios of internal concentrations and mobilities. At high $\overline{X}_{Ca}$ the calcium ions are present on the particle surface as well (area of little crosslinking) and the interaction is then similar to, though possibly less than, that in homogeneous membranes.

In the anion exchange resins the interaction is strong at any $\overline{X}_{SO_4}$, particularly in the A. C. I. membrane. The chloride form of the resin is less swollen and the observed effect could again be explained by an uneven distribution of counterions through the resin. In this case the ions causing the highest swelling of the resin are the less mobile (bivalent) ions, and the differences in the conductivities of the two single ionic forms of the resin are considerably smaller than in the case of Ca/Na in the cation exchange resins in which the less mobile (bivalent) ions cause the lowest swelling. Conductivities appear to give some indication of the electrostatic forces between fixed ions and counterions.

Ion Exchange Equilibrium. — The relative affinity coefficient K_{Ca}^{Na} is given in Fig. 4 and $K_{SO_4}^{Cl}$ is given in Fig. 5. In both types of resin K varies with $\overline{X}$ and in the discussion of Eq. 8 several reasons have already been indicated. This equation does not incorporate the influence of heterogeneity in the resin. This heterogeneity can have several causes. If the fixed ions are of a different chemical nature (e.g., $-COO^-$ and $-SO_3^-$), then the resin is bifunctional[11] and K_j^i changes sharply at $\overline{X}$ corresponding to the fraction of fixed ions of one kind; or, fixed ions of identical chemical nature are attached to the polymer network in different positions.[12-14] Reichenberg and McCauley[15] attributed the strong dependence of K on $\overline{X}$ in highly crosslinked resins to heterogeneity in the degree of crosslinking through the resin (sometimes interpreted as a range of pore sizes[16,17]); the result

is a multifunctional resin. Högfeldt[18] has shown that both a bifunctional and a multifunctional treatment can be used to explain the same set of experimental data. Glueckauf and Watts[19,20] indicated that heterogeneous crosslinking is an important factor with respect to some other resin (or membrane) properties as well, i. e., electrolyte uptake and salt diffusion. It was also shown[21] that their approach does not lead to a quantitative theory of ion exchange equilibra.

The most remarkable feature in Fig. 4 is the strong decrease in K^{Na}_{Ca} at high $\overline{X}_{Ca}$; the more calcium is present in the resin the higher the affinity for calcium. The deviating result for the A. M. F. membrane remains unexplained.

Between $X_{Ca}=0$ and $X_{Ca}=1$ the concentration ratio term in Eq. 8 varies only by 5～10%. Changes in the external activity coefficient term can be estimated at 0.3%. There is no *a priori* reason why the internal activity coefficient term should decrease greatly at high $\overline{X}_{Ca}$. The electrical term in Eq. 8 can be assumed to remain approximately constant and the pressure-volume term should bring about a gradual decrease in K^{Na}_{Ca} with increasing $\overline{X}_{Ca}$.

If the resin is heterogeneous with respect to crosslinking, then at high $\overline{X}_{Ca}$ the few sodium ions will be situated preferentially in the areas of least crosslinking, forming islands of high swelling, which are squeezed by the elastic forces in the surrounding more crosslinked area. A serious deviation from proportionality between π and $\overline{X}_{Ca}$ may then occur. In should be noted that the strong decrease in K^{Na}_{Ca} occurs in the same range of $\overline{X}_{Ca}$ in

18) E. Högfeldt, *Ark. f. Kemi*, **13**, 491 (1959).

which interaction with respect to conductivity was observed.

With respect to the Cl/SO_4 equilibria on the anion exchange resins (Fig. 5) attention is drawn to the sharp increase in affinity for chloride at high $\overline{X}_{SO_4}$ and low external concentration. This affinity is generally higher in the highly crosslinked resins (A. C. I. and C. S. I. R.-T. A.) where the sharp increase starts at $\overline{X}_{SO_4}=0.6$ and $\overline{X}_{SO_4}=0.4$ respectively, while in the other resins it starts only at approximately $\overline{X}_{SO_4}=0.75$. In the shape of the curves for higher external concentrations there is some indication that the increase is then less sharp but starts at a much lower $\overline{X}_{SO_4}$. In all casses less swelling is connected with a higher affinity for chloride.

The contribution of the concentration ratio term to $K^{Cl}_{SO_4}$ changes by 15~30% with $\overline{X}_{SO_4}$ across the ranges of $\overline{X}_{SO_4}$ investigated at each exteral concentration. The external activity coefficient term can be estimated from

$$\frac{f^2_{Cl}}{f_{SO_4}}=\frac{f^2_{Cl}\cdot f^2_{Na}}{f_{SO_4}\cdot f^2_{Na}}=\frac{\gamma^4_{NaCl^*}}{\gamma^3_{Na_2SO_4^*}} \qquad (9)$$

in which γ is the mean ion activity coefficient. [At the same ionic strength $I=(1+1/2X_{SO_4})\times(m_{Cl}+2m_{SO_4})$]. Values derived from listed data[22] are given in Table II. The increase

Table II. Estimated values for $\frac{f^2_{Cl}}{f_{SO_4}}$

External concn., N	$X_{SO_4}=0$	$X_{SO_4}=1$
0.01	1.8	2.0
0.15	5.1	6.5
0.50	10.7	16.8

in affinity for chloride with external concentration is due not only to the concentration ratio term but also to a considerable change in the external activity coefficient ratio.

In a resin with hetrogeneous crosslinking the chloride ions are preferentially situated in regions with relatively high crosslinking and, when at high $\overline{X}_{SO_4}$ the SO_4 ions invade these regions, pressure-volume effects increase the affinity for chloride. The influence of heterogeneity can be expected to be strongest when the resin is in its most swollen state (low external concentration or high $\overline{X}_{SO_4}$); in regions of low crosslinking the swelling changes more with external concentration than in regions of high crosslinking.[23]

The high affinity for chloride does not occur in the resins with the highest internal molality (see Table I) but in the resins with the highest degree of crosslinking. This is a strong indication that the pressure-volume term is of relative importance.

Summary

The relative affinity coefficient K^i_j is shown to be dependent on the ratio of external and internal total concentrations, the ratio of the external activity coefficients and of the internal activity coefficients, a pressure-volume term and an electrical term. K^i_j is therefore dependent on the "loading" of the resin $\overline{X}_j$.

Several cation exchange resins exhibit a very strong affinity for calcium at high calcium loading and this affinity increases sharply with $\overline{X}_{Ca}$; this effect is attributed to heterogeneity in the crosslinking of the resin and it is a strong indication that here the pressure-volume term plays a decisive rôle.

The pressure-volume term appears to be of relative importance also in the Cl/SO_4 equilibrium on anion exchange resins, particularly when these are highly crosslinked. Heterogeneity in the crosslinking probably causes the sharp increase in affinity for Cl at high SO_4 loading and low (0.01N) external concentration.

Conductivity measurements on the resins in single and mixed forms is useful to get an indication of the binding forces between counterions and fixed ions and these measurements can also reveal interactions which may have a bearing on ion exchange equilibrium.

The author wishes to express his sincere thanks to Mr. J. Venlet who carried out the experimental work and who assisted in the data evaluation.

A Molecular Orbital Treatment of Phosphate Bonds of Biochemical Interest. II. Metal Chelates of Adenosine Triphosphate

By Kenichi FUKUI, Akira IMAMURA and Chikayoshi NAGATA

(Received June 20, 1963)

In our previous paper[1] attempts were made by way of the simple LCAO MO method to correlate the energy-donor ability of adenosine triphosphate (ATP) with the π electronic energy of this compound. However, it was found that, so far as only the phosphate part is considered, the π electronic energy change of ATP in the course of hydrolysis, the reactivity index, and the π electron density at the phosphorus atom are not significantly different from those of such other high energy phosphate compounds as adenosine diphosphate (ADP), phosphoenol pyruvate (PEP) and acetyl phosphate (ACP), nor from those of such low energy phosphate compounds as adenosine monophosphate (AMP) and glycerol 1-phosphate (GLP).

These findings could not explain the efficiency of ATP as a biological specific. That is, among many so-called high energy phosphate compounds, ATP holds a unique position in the sense that ATP alone is, in general, used as an energy source in *in vivo* energy transfer reactions. Therefore, some other factors must be taken into consideration in order to explain the biochemical characteristic of ATP. This was pointed out by the present authors in the previous paper, where the possible importance of the metal chelate formation of ATP in the *in vivo* reaction was suggested. In fact, the participation of metal ions in the biological functions of ATP has been established in many experiments. In line with these experiments, various models of ATP-metal complex have been proposed. However, no detailed discussion and calculation have yet been carried out.

In the present paper, a comparison will be made of such theoretical indices as the stabilization energy due to the formation of metal chelate, the reactivity index and the π electron density for various models with the experimental facts, especially with the enzymatic hydrolysis of ATP. On the basis of this comparison, the most probable structure of the ATP-metal complex will be sought.

The Method of Calculation and the Models Adopted

As in the previous paper, the calculations were carried out by means of the simple LCAO MO method. For the sake of comparison, the same values for the parameters of the Coulomb and the resonance integrals of phosphorus and oxygen atoms have been adopted as in the previous paper. However, in these calculations it was necessary to determine the parameters for the chelate-forming part of the ATP-metal complex. The resonance integrals between the metal and the oxygen atom or the nitrogen atom, $l_{M-O}\beta$, or $l_{M-N}\beta$, are both taken to be $0.4\,\beta$, where β is the resonance integral of two adjacent carbon atoms in benzene. This value was determined by considering the distance of the chelate bond and also the nature of the orbitals participating in the π conjugation.*

The value of Coulomb integral for the metal, α_M, is difficult to determine. Therefore, calculations have been carried out for model 2 for various values, for $\alpha+3\beta$, $\alpha+\beta$, $\alpha-\beta$ and $\alpha-3\beta$. The theoretical indices obtaiaed by utilizing these varying parameters are not very different from one another, and the qualitative conclusion is not changed with these varying parameters. Therefore, the calculations for some models have been carried out for two parameters, $\alpha+\beta$, and $\alpha-\beta$. For model 1, rather tedious calculations are required, therefore, the calculations have been carried out for the $\alpha+\beta$ parameter value.

By utilizing these parameters, such theoretical indices as the stabilization energy due to the chelate formation, the superdelocalizability and the total π electron density at the phosphorus atoms have been calculated for the following models (Fig. 1).

* The resonance integrals between oxygen and metal have been tentatively determined to be 0.4β, which may be an intermediate value between that of oxygen-phosphorus bond in ATP, 0.6β, and that of the usual hydrogen bond. For many kinds of metals, the values of resonance integral are probably different. But so far as the relative comparison on the stability of chelate compounds is concerned, the change in the resonance integral can be included in the change in the Coulomb integral, so that the approximate estimation of the resonance integral may not cause any serious errors in these calculations.

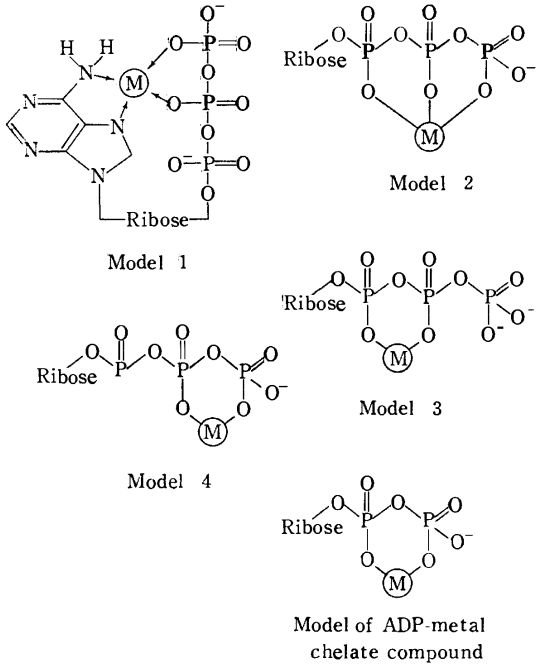

Fig. 1. The models of metal chelate compounds adopted in the calculation.

Model 1 represents the ATP-metal complex making a chelate between the adenine and the phosphate parts. Taking the metal as the magnesium cation, Szent-Györgyi[2] postulated a quadridentate chelate. Epp[3] et al. suggested, on the basis of their infrared data of ATP in the presence of and in the absence of Mg^{2+}, that such a complex formation could be recognized, although no direct evidence was obtained as to whether the complex formation was intramolecular or intermolecular.

In addition, James,[4] on the basis of the data on the rotatory dispersion of ATP, ADP and AMP, suggested the existence of some interaction between adenine and phosphate parts. Model 2 was proposed by Melchior[5] in view of the higher stability of the ATP-metal complex than those of ADP and AMP.

Theoretically there exist two other possible chelate complex structures between the polyphosphate chain and the metal. They are designated as models 3 and 4; the theoretical indices have been calculated with respect to these structures, and also for the ADP-chelate complex for the sake of comparison.

In ATP there are two sites at which chelation can take place, that is, the amino group of the purine ring or the polyphosphate chain. In order to decide the site where the metal ion combines with the ATP molecule, Khan and Martell[6] measured the equilibrium constant of the ATP complex with various metal ions and concluded that the amino group of the purine ring is probably not involved in the chelate formation of ATP, because little or no interaction was observed between metal ions and adenosine. In view of these experiments, there is no need to consider the ATP-metal chelation on the purine ring only. Needless to say, however, model 1 can not be eliminated by this experiment, because in that model the participation of both the purine ring and the polyphosphate parts are considered.

Results and Discussion

Stabilization Energy Due to the Metal Chelate Formation.—In Table I, the stabilization energies calculated with regard to various models for ATP-metal complexes are indicated. For the sake of comparison, the calculated results for the ADP-metal complex are also included. As may clearly be seen in this table, the stabilization energies for models 3 and 4 are considerably smaller than those for models 1 and 2. Therefore, the latter two models are more plausible than the former two. The propriety of models 3 and 4 is, moreover, threatened conclusively by the fact that the stabilization energies for models 3 and 4 are smaller than that of the ADP-metal complex; this finding contradicts the fact that the ATP

Table. I. Stabilization energy due to metal chelate formation

complex has a higher stability than those of ADP or AMP. Hence, from the standpoint of the stabilization energy, model 1 or 2 remains the most favorable.

Reactivity Indices and Enzymatic Hydrolysis. —As reactivity indices such as the superdelocalizability for nucleophilic attack, $S_r^{(N)}$, and the π electron density at the phosphorus atoms of ATP- and ADP-metal complexes have been calculated; they are indicated in Tables II and III. Superdelocalizability, S_r, is

	$\alpha-\beta$	1.100	1.107	1.099
ATP-metal chelate compound model 4	$\alpha+\beta$	1.182	1.101	1.180
	$\alpha-\beta$	1.182	1.108	1.188

a good index representing the reactivity of atom r in conjugated molecules, the greater the value of a position, the more reactive that position. Accordingly, from Table II, a prediction for the most susceptible position in ATP for the nucleophilic attack is possible. That is, for models 1 and 4, the innermost and the terminal phosphorus atoms (they are referred to as P_1 and P_3, respectively) are expected to be most susceptible to nucleophilic attack, whereas model 2 predicts the following order of reactivity: $P_3 > P_2 > P_1$, where the middle phosphorus atom is designated as P_2. For model 3 and also for free ATP, P_2 is predicted as the most reactive.

In comparing these theoretical predictions with the experimental positions of enzymatic hydrolysis, we can choose the model 1 as the most probable chelate complex of ATP, because the theoretical indices for this model explain well the experimental position of enzymatic hydrolysis. That is, the most commonly encountered type of reaction of ATP is the cleavage of the terminal phosphate group, P_3; moreover, not a few reactions involving the cleavage of the innermost group, P_1, have also been recognized. On the other hand, the middle phosphate group is very resistant to such enzymatic attacks. These situations are schematically shown in Fig. 2, in which the position of cleavage is shown by an arrow. The theoretical values for model 4 explain well the experimental position of enzymatic hydrolysis, but this model is not suitable in view of the stabilization energy, as has been stated in the previous section.

TABLE III. TOTAL π ELECTRON DENSITY, q_r, OF THE PHOSPHORUS ATOM

Compound	The value of the Coulomb integral of the metal α_M	q_{P_1}	q_{P_2}	q_{P_3}
ADP (phosphate part only)		0.270	0.329	
ADP-metal chelate compound	$\alpha+\beta$	0.279	0.272	
	$\alpha-\beta$	0.276	0.268	
ATP (phosphate part only)		0.269	0.268	0.329
ATP-metal chelate compound model 1	$\alpha+\beta$	0.270	0.277	0.272
ATP-metal chelate compound model 2	$\alpha+3\beta$	0.278	0.276	0.270
	$\alpha+\beta$	0.279	0.277	0.272
	$\alpha-\beta$	0.276	0.275	0.268
	$\alpha-3\beta$	0.277	0.275	0.269
ATP-metal chelate compound model 3	$\alpha+\beta$	0.279	0.278	0.329
	$\alpha-\beta$	0.276	0.275	0.329
ATP-metal chelate compound model 4	$\alpha+\beta$	0.269	0.277	0.272
	$\alpha-\beta$	0.269	0.274	0.268

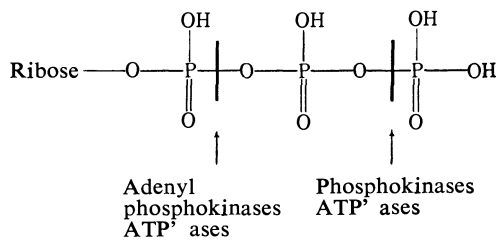

Fig. 2. Positions of the enzymatic cleavage of ATP (After Ref. 7).

In Table III the total π electron densities for various models are indicated. The smaller the value in the table, the more reactive the position for the nucleophilic attack. Also, in this case an identical conclusion is obtained as in the case of the superdelocalizability. That is, model 1 remains the most probable structure in *in vivo* reactions.

A Comparison of the Theoretical Indices with the Nuclear Magnetic Resonance Spectra of ATP.—Recently an ever-increasing number of data have been accumulated regarding the nuclear magnetic resonance (NMR) spectra of ATP, but no quantitative data for the theoretical analysis is available. Therefore, in this paper some qualitative discussions will be undertaken in comparison with the results of Cohn's experiment.[7] Cohn measured the shift in resonance frequency of the three phosphorus atoms in ATP relative to that of H_3PO_4. The shift for P_2 was largest and appeared at higher magnetic fieldes, while the spectra of P_1 and P_3 were superimposed upon each other and appeared at lower magnetic fields than those of P_2. If the chemical shift is exclusively influenced by the electron density, we can expect, on the basis of the above experiment, the following order of electron density at the phosphorus atoms in ATP: $P_2 > P_1 \sim P_3$. However, as may be seen in Table III, the degree of the electron densities in free ATP is $P_3 > P_2 \sim P_1$. This discrepancy means that the chemical shift of phosphorus atoms is influenced not only by the electron density around them, but also by other factors. That is, the contribution from the terms of the diamagnetism as well as the paramagnetism should be taken into consideration in order to explain correctly the shift of the phosphorus atom in ATP.

Kinetics of the Catalytic Hydrogen Peroxide Oxidation of Thiodiglycol in Aqueous Solutions

By Yoshiro OGATA and Yasuhiko SAWAKI

(Received June 27, 1963)

In order to compare the catalytic activities of various inorganic compounds and to discover new catalysts in the aqueous hydrogen peroxide oxidation, the catalytic oxidation of thiodiglycol (TDG) was investigated.

$$(HOCH_2CH_2)_2S + H_2O_2 \rightarrow (HOCH_2CH_2)_2SO + H_2O \quad (1)$$

The rate of the uncatalyzed hydrogen peroxide oxidation of TDG has been reported by Ross[1] to follow the second-order kinetics. We found that molybdate exhibited a stronger catalytic activity than well-known tungstates and selenous acid. The kinetics of sodium molybdate (SM)-catalyzed oxidation has also been investigated, since the mechanism of the catalysis of molybdates had not previously been clarified in detail.[2]

The present paper describes the rate data and a probable mechanism of the SM-catalyzed hydrogen peroxide oxidation of TDG in aqueous solution. In the course of this study, the rate of the oxidation of TDG by yellow sodium peroxymolybdate (YPM), together with the absorption spectra of the SM-hydrogen peroxide system, were measured.

2) Molybdates have been used in the hydrogen peroxide oxidation of organic compounds in the following experiments: a) I. D. Raacke-Fels, C. H. Wang, R. K. Robins and B. E. Christensen, *J. Org. Chem.*, **15**, 627 (1950); b) A. R. Bader, *J. Am. Chem. Soc.*, **73**, 3731 (1951); c) K. Kahr and C. Berther, *Chem. Ber.*, **93**, 132 (1960); d) G. Toennies and J. T. Kolb, *J. Biol. Chem.*, **140**, 131 (1941); e) J. C. Ghosh and B. C. Kar, *J. Indian Chem. Soc.*, **11**, 485 (1934).

Experimental

Materials.—TDG was purified by vacuum distillations; b. p. 131~134°C/3 mmHg. YPM was synthesized according to the Kobosev-Sokolov procedure.[3] All the catalysts used were commercial reagents of G. R. grade.

Typical Procedure for Kinetic Measurements.—A buffered aqueous solution containing TDG, a catalyst, sodium acetate and acetic acid was thermostated at the reaction temperature; the reaction was started by adding a known amount of aqueous hydrogen peroxide. Aliquots were taken out at appropriate intervals of time, and their peroxide contents were determined iodometrically.

The SM-catalyzed oxidation was carried out in aqueous media at pH 0.5~6.2 and in aqueous sulfuric acid. No appreciable change in the rates was observed when the oxidation was started by mixing TDG with a prepared mixture of SM and hydrogen peroxide, or when the reaction was carried out in a brown flask.

The kinetics of oxidation by YPM was studied by means of the iodometry of active oxygen in a buffered reaction mixture of YPM and TDG.

Ultraviolet Absorption Spectra.—Absorption spectra (210~500 mμ) were measured with a SM-H_2O_2 system in order to obtain some information on active species in the SM-catalyzed hydrogen peroxide oxidation. An absorption maximum was observed at the wavelength of 310 mμ with a solution at pH 4.7 or at 326 mμ with one at pH 0.8. No absorption maximum appeared in 210~500 mμ with an aqueous solution of hydrogen peroxide-TDG and with an aqueous solution of TDG-SM.

Reaction Products Criterion.—To examine the reaction products, a mixture of SM (0.002 mol.), hydrogen peroxide (0.12 mol.) and TDG (0.1 mol.) in 100 ml. of water was kept standing at 25° for two hours. After the evaporation of the water under reduced pressure, the residue was dissolved in alcohol, the SM being filtered off. On recrystallization from alcohol crystals (11.3 g.) of thiodiglycol sulfoxide (82%) were obtained; m. p. 110.5~111.5°C (lit.[4] m. p. 111°C).

Upon the treatment of thiodiglycol sulfoxide (15×10^{-3} M), the reaction product, with a mixture of SM (1×10^{-4} M) and H_2O_2 (8×10^{-3} M) at 25°C and pH 4.7 or 0.8 for 4 hr., no appreciable oxidation occurred.

Results and Discussion

The Examination of the Catalyst Activity.—Sulfides, in general, can be oxidized to sulfoxides by hydrogen peroxide at room temperature.[5] Ross[1] has reported that the second-order rate constant for the uncatalyzed hydrogen peroxide oxidation of thiodiglycol (TDG) in aqueous solutions of pH 4~6 was 2.17×10^{-3} l. mol^{-1} sec.$^{-1}$ at 25°C.

Our examinations of the catalytic activities of various inorganic compounds at 25°C and pH 4.7 gave the following data:

Compounds with some activity:

$Na_2MoO_4 > Na_2WO_4 \gg H_2SeO_3 \gg NH_4VO_3$, Na_2TeO_4, $UO_2(OAc)_2$, and $Cu(OAc)_2$

Compounds with no activity:

$AgNO_3$, $MgCl_2$, $BaCl_2$, $CaCl_2$, $Zn(OAc)_2$, $ZnSO_4$, $CdCl_2$, $HgCl_2$, $Hg(OAc)_2$, $Al_2(SO_4)_3$, $Na_2B_4O_7$, $NaBO_3$, $NaBO_2$, Tl_2SO_4, $Zr(OAc)_4$, $NaHCO_3$, Na_2CO_3, $Pb(OAc)_2$, $NaNO_3$, NaH_2PO_4, $Na_2P_2O_7$, Na_2HPO_3, $(NaPO_3)_n$, $Cr_2(SO_4)_3$, Cr_2O_3, K_2SO_4, $Na_2S_2O_3$, $KHSO_4$, $Mn(OAc)_2$, $KClO_3$, $KClO_4$, $NaClO_2$, $NaBrO_3$, KIO_3, KIO_4, $CoSO_4$, $Co(OAc)_2$, $Ni(OAc)_2$, and V_2O_5

TABLE I. CATALYZED HYDROGEN PEROXIDE OXIDATION OF TDG IN AQUEOUS SOLUTIONS AT 25°C AND pH 4.7

Initial concn.: H_2O_2, 0.02570 M; TDG, 0.03960 M

Catalyst	Concn. of catalyst M$\times10^{-4}$	Rate constant[a]		Catalyst coeff.[a]	
		$k_2\times10^3$ l. mol^{-1} sec^{-1}	$k_1\times10^3$ sec^{-1}	k_2^c l^2 mol^{-2} sec^{-1}	k_1^c l. mol^{-1} sec^{-1}
Na_2MoO_4	1	—	6.56	—	6.54
Na_2WO_4	1	69.2	—	670	—
H_2SeO_3	10	4.12	—	1.93	—
NH_4VO_3	10	2.54	—	0.35	—
Na_2TeO_4	10	2.42	—	0.23	—
$UO_2(OAc)_2$	10	2.39	—	0.20	—
$Cu(OAc)_2$	10	2.37	—	0.18	—
None	0	2.17	—	—	—

a) $v=k_2[H_2O_2][TDG]=(k_0+k_2^c[Catalyst])[H_2O_2][TDG]$ or $v=k_1[TDG]=k_1^c[Catalyst]-[TDG]$.

3) N. J. Kobosev and N. N. Sokolov, *Z. anorg. u. allgem. Chem.*, **214**, 321 (1933).
4) J. Bougault and P. Robin, *Compt. rend.*, **171**, 355 (1920).
5) M. Gazdar and S. Smiles, *J. Chem. Soc.*, **93**, 1833 (1908).

Compounds with side reactions:

$CuCl_2$, $CuSO_4$, $Ce_2(SO_4)_3$, $ZrOCl_2$, $NaNO_2$, $NaHSO_3$, KSCN, $K_2Cr_2(SO_4)_4$, $Fe_2(SO_4)_3$, $K_3Fe(CN)_6$, $K_4Fe(CN)_6$, $NaBiO_3$, and Na_2TeO_3

It is evident in Table I that molybdate and tungstate are both active catalysts, while selenous acid is less active. However, the other four, NH_4VO_3, Na_2TeO_4, $UO_2(OAc)_2$ and $Cu(OAc)_2$, show only a small activity. It is of interest to note that the rate of SM-catalyzed oxidation is independent of the concentration of hydrogen peroxide, following the first-order kinetics with TDG, while the oxidations with other catalysts satisfy the second-order kinetics. The comparison of the catalytic activities of sodium molybdate (SM) and tungstate seems less significant, since their kinetics are different. It is obvious, however, that the completion of oxidation with molybdate is faster than that with tungstate. The SM-catalyzed oxidation will be discussed in detail later.

a) Acidity function, $-H_0$.
b) Second-order rate constant ($l.\,mol^{-1}\,sec^{-1}$); $v=k_2\,[H_2O_2]\,[TDG]$.

Peroxytungstates have been suggested as active oxidation species in the tungstate-catalyzed epoxidation of olefins,[6] and peroxyselenious acid, in the selenium dioxide-catalyzed oxidation of dimethyl aniline[7] and ketones.[8]

No catalytic action of vanadic acid, a well-known catalyst,[9] was observed under these conditions, although a faint activity was appreciable with ammonium vanadate. Faint catalytic activities were also observed with sodium tellurate, cuprous acetate and uranyl acetate. The uranyl acetate is known to catalyze the hydrogen peroxide oxidation of primary amines.[10] Ferric and ferrous salts showed no appreciable activity.

The Mechanism of SM-catalyzed Oxidation. —*Rate Equations.*—The rate of SM-catalyzed oxidation is independent of the concentration of hydrogen peroxide and is first-order with respect to TDG if the concentration ratio of hydrogen peroxide vs. SM exceeds 2, as Table II-A and Fig. 1 show. These pseudo-first order rates are proportional to the concentration of SM (Fig. 2). Thus, if $[H_2O_2] > 2$ [SM], the rate equation is expressed as:

$$v = k_1 [TDG] = k_1^c [SM] [TDG] \quad (2)$$

([SM] is the initial concentration of Na_2MoO_4.) However, if $[H_2O_2]/[SM]$ is less than 2, the rate is second-order (Table III and Fig. 1):

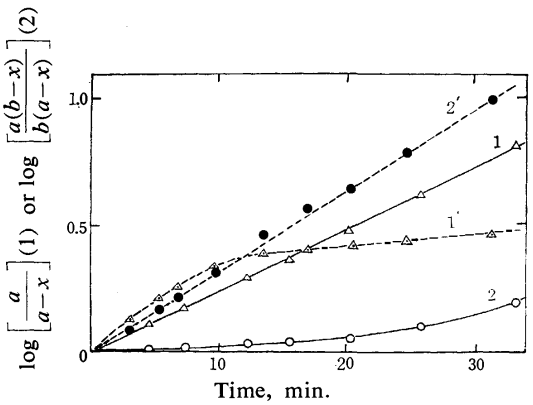

Fig. 1. Comparison of first-order (1) and second-order (2) rate equations at 0°C and pH 4.7.

	$[TDG]_{Init}$ (a), M×10³	$[H_2O_2]_{Init}$ (b), M×10³	[SM] M×10³

1'(▲), 2'(●) ------	5.42	3.70	2

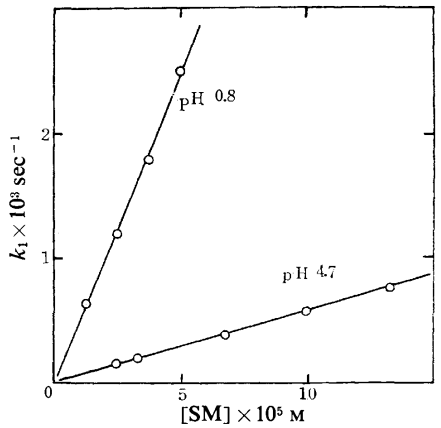

Fig. 2. Effect of concentration of SM on the rate in the range of $[H_2O_2] > 2[SM]$ at 25°C.

TABLE III. RATE DATA ON THE OXIDATION OF TDG WITH SM-H_2O_2 IN THE RANGE OF $[H_2O_2] < 2[SM]$; pH=4.7 (AcOH-AcONa) at 0°C

Initial concn. M×10³			k_2' a) 1. mol^{-1}. sec^{-1}
[SM]	$[H_2O_2]$	[TDG]	
2.0	0.924	1.806	0.856
2.0	1.924	1.806	0.862
2.0	2.879	1.806	0.749
2.0	2.879	2.709	0.706
2.0	2.879	4.514	0.786
2.0	3.611	1.924	0.860
2.0	3.695	5.417	0.711
4.0	2.879	4.514	0.856
6.0	2.879	4.514	0.783

a) $v = k_2'$ [Active oxygen] [TDG]

$$v = k_2' [\text{Active oxygen}] [TDG] \quad (3)$$

Here, [Active oxygen] expresses the concentration of active oxygen determined iodometrically. The value of k_2' holds constant while [SM] is vavied, in so far as $[H_2O_2] < 2[SM]$.

The pseudo-second order rate constant of the uncatalyzed oxidation is calculated from Table II-C and Table VI to be acout 2.0×10^{-3} l. mol^{-1} sec^{-1}, which is about 1/400 of the value of k_2', 0.797 l. mol.$^{-1}$ sec^{-1}. Hence, k_2' is not the rate for hydrogen peroxide itself, but that for other active oxidizing species.

It is quite probable that one mole of SM is transformed quantitatively to a reactive intermediate by two moles of hydrogen peroxide:

$$SM + 2H_2O_2 \overset{\text{fast}}{\rightleftarrows} \text{intermediate}$$

$$\frac{1}{2}\text{(intermediate)} + (HOCH_2CH_2)_2S \xrightarrow{\text{slow}} (HOCH_2CH_2)_2SO$$

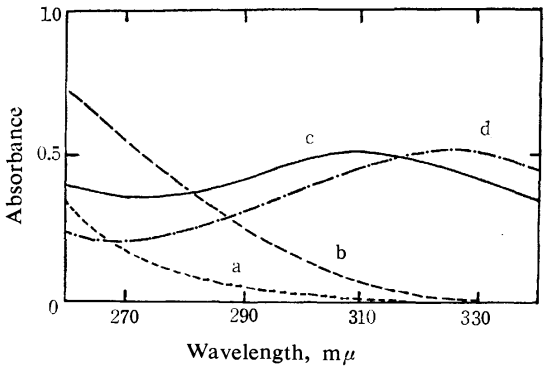

Fig. 3. Absorption spectra of SM-H_2O_2 in aqueous solutions (a) SM at pH 4.7 (AcOH-AcONa) (b) SM at pH 0.8 (H_2SO_4) (c) SM-H_2O_2 at pH 4.7 (AcOH-AcONa) (d) SM-H_2O_2 at pH 0.8 (H_2SO_4).

Assuming that the formation of the intermediate is rapid and complete and that excess hydrogen peroxide has no effect on the rate, the rate sould be independent of the concentration of hydrogen peroxide when $[H_2O_2]>2[SM]$.

Reactive Species in Solutions.—The formation of the complex, YPM, was expected from the previous equations; this expectation was confirmed by the identification of YPM by means of ultraviolet spectrophotometry, together with the comparison of the data on oxidation by SM-H_2O_2 with those on oxidation by YPM.

As shown in Fig. 3, an absoption maximum appeared at 310 mμ (pH 4.7) or at 326 mμ (pH 0.8) in the aqueous hydrogen peroxide-SM system, each maximum being identical with that of synthetic YPM at the corresponding pH. The absorbance of the aqueous hydrogen peroxide-SM system was determined at pH 4.7 with various concentrations of hydrogen peroxide while [SM] was kept constant (Table IV). The absorbance at 310 mμ did not increase with an increasing amount of hydrogen peroxide in the range of $[H_2O_2]>2[SM]$. Therefore, two moles of hydrogen peroxide and one mole of SM react almost quantitatively to yield YPM. The shift of the absorption maximum up to 326 mμ (pH 0.8) suggests that YPM may exist in another form in the realm of higher acidity.

TABLE V. OXIDATION OF TDG WITH YPM AT 0°C AND pH 4.7 (AcOH-AcONa)

Initial concn., M×10³		k''_2[a]
[Active oxygen]	[TDG]	l. mol^{-1} sec^{-1}
0.831	1.806	0.824
1.661	1.806	0.694
1.661	3.612	0.792

a) $v=k''_2$ [Active oxygen] [TDG]

Table V shows the rate data on the oxidation of TDG by YPM, data which satisfy the second-order kinetics:

$$v=k_2''\ [\text{Active oxygen}]\ [\text{TDG}] \quad (4)$$

Here, [Active oxygen] means the concentration of the active oxygen determined iodometrically. This pseudo-second order rate constant, k_2'', is identical with k_2' in Eq. 3 within the range of experimental error. These facts suggest the following mechanism at pH 3~6:

$$Na_2MoO_4 \overset{\text{fast}}{\rightleftarrows} 2Na^+ + MoO_4^{2-} \quad (5)$$

$$MoO_4^{2-} + 2H_2O_2 \overset{\text{fast}}{\rightleftarrows} HMoO_6^- + H_2O + OH^- \quad (6)$$

$$HMoO_6^- + (HOCH_2CH_2)_2S \overset{\text{slow}}{\longrightarrow} HMoO_5^- + (HOCH_2CH_2)_2SO \quad (7)$$

$$HMoO_5^- + (HOCH_2CH_2)_2S \overset{\text{fast}}{\longrightarrow} H^+ + MoO_4^{2-} + (HOCH_2CH_2)_2SO \quad (8)$$

Assuming that all the SM is converted to $HMoO_6^-$ in this pH range and that a and b are the initial concentrations of $HMoO_6^-$ and TDG respectively, and x, the decrease of TDG at time t, the rate is expressed as:

$$v=k_2''\ [HMoO_6^-]\ [\text{TDG}]$$
$$=k_2''\left(a-\frac{x}{2}\right)(b-x)$$

or

$$k_2''t=\frac{2}{b-2a}\ln\frac{2a(b-x)}{b(2a-x)} \quad (9)$$

Equation 9 is equal to Eqs. 3 and 4, and satisfies Eq. 2, if $[HMoO_6^-]$ is constant and equal to the initial concentration of SM.

SM reacts with two moles of hydrogen peroxide to form Na_2MoO_6 (YPM) and with four moles of hydrogen peroxide to form red sodium peroxymolybdate Na_2MoO_8, an unstable peroxide decomposing to YPM at room temperature.[3,11] It has been found that YPM exists in a neutral aqueous solution in the form of monoanion II.[12]

$$\underset{\text{(I)}}{MoO_2(OOH)(OOH)} \rightleftarrows \underset{\text{(II)}}{MoO_2(OO^-)(OH)}+H^+$$

Here the first ionization constant of I, K_1, is 3×10^{-3} and the second ionization constant, K_2, is 7×10^{-10}; hence the dissociation of II is almost negligible in a neutral solution.[12] When [SM] exceeds 2×10^{-3} M, SM exists in the form of polymolybdate,[13] which reacts also with hydrogen peroxide to give II.[14] These facts strongly suggest that the active species at pH 3~6 is $HMoO_6^-$.

The Effect of Acidity.—The effect of the acidity of the solution on the SM-catalyzed oxidation rate is shown in Table II-B and Fig. 4. The rate increases with the increasing acidity of the solution; the plot of log k vs. pH in the pH range of 2~3 fits a line of the unit slope (Fig. 4).

The rate constant at pH below 2 becomes independent of the acidity, as is obvious from the data obtained in dilute aqueous sulfuric acid (Table II-B). However, the uncatalyzed oxidation is accelerated by acid at pH below 2, and this is probably the well-known acid catalysis in the hydrogen peroxide oxidation. The plot of log k_2 vs. $-H_0$ gave a straight line with a slope of 0.90. The activation energies were calculated to be 11.2 kcal. mol^{-1} at a pH above 3 and 9.21 kcal. mol^{-1} at a pH below 2 (Table VI).

These facts imply two distinct active species, those at pH values below 2 and those above 3. Furthermore, the ultraviolet absorption spectrophotometry described above also endorses the presence of two active species at different pH's. It is most probable that YPM at pH above 3 exist as $HMoO_6^-$ (II), while at pH below 2 they exist as H_2MoO_6 (I), which should be more active than $HMoO_6^-$. The ratio of $[H_2MoO_6]$ to $[HMoO_6^-]$ was calculated to be 100 : 3 at pH 1 and 1 : 30 at pH 4 by means of the first ionization constant of H_2MoO_6 as determined by Csányi.[12] The shift of the absorption maximum from 310 to 326 mμ with a decreasing pH value is explicable by the transformation of $HMoO_6^-$ to H_2MoO_6. Considering the ionization constants of H_2MoO_6, H_2MoO_6 should be about nine times as active as $HMoO_6^-$ at 25°C.

2.5	0.8	9.21	−41.0

Summary

The catalytic activities of some inorganic compounds for the hydrogen peroxide oxidation of thiodiglycol (TDG) have been examined in aqueous media at 25°C and at pH 4.7. It has been found that the order of catalytic activities was: Na_2MoO_4, $Na_2WO_4 \gg H_2SeO_3 > NH_4VO_3$, Na_2TeO_4, $UO_2(OAc)_2$, $Cu(OAc)_2$. The rates of oxidation using all these catalysts, except sodium molybdate, may be expressed as $v=k_2[H_2O_2][TDG]$.

The kinetics of this reaction has been

studied in detail, especially with the sodium molybdate (SM) catalyst, by means of iodometry. The oxidation in the range $[H_2O_2] > 2[SM]$ follows the pseudo-first-order kinetics: $v = k_1^c[SM][TDG]$. The rate at pH below 2 is several times faster than that at pH 3~6, the energies of the activation at pH's below 2 and at 3~6 being 9.21 and 11.2 kcal. mol^{-1} respectively. The oxidation in the range of $[H_2O_2] < 2[SM]$ follows the second-order kinetics: $v = k_2'$[Active oxygen][TDG]. The values of k_2' were identical with the second-order rate constants obtained in the oxidation of thiodiglycol by yellow sodium peroxymolybdate. It is probable that dihydroperoxymolybdate, $HMoO_6^-$, produced rapidly from Na_2MoO_4 and hydrogen peroxide, oxidizes thiodiglycol. The increase in the rate with a decreasing pH may be due to the transformation of $HMoO_6^-$ to more active H_2MoO_6, since the Na_2MO_4-hydrogen peroxide system gave two different ultraviolet absorption maxima corresponding to $HMoO_6^-$ and H_2MoO_6 at pH 4.7 and 0.8 respectively.

Polymerization and Polymers of Itaconic Acid Derivatives. V. The Copolymerization Reactivity of Itaconic Acid in an Aqueous Solution[1,2]

By Susumu NAGAI

(Received July 12, 1963)

Studies of the copolymerization of itaconic acid have been reported by several workers.[3-7] Concerning the effect of pH value on the copolymerization reactivity of itaconic acid, however, no information has been produced in the literature available to the author.

In the preceding report[1] on the homopolymerization of itaconic acid in an aqueous solution, it was shown that an increase in the pH values of the solution caused a great decrease in the rate of polymerization. For the interpretation of this phenomenon, it was suggested that itaconic acid in the dianionic form polymerizes poorly.

Therefore it became of interest to determine whether or not itaconic acid in the dissociated state is able to copolymerize with other monomers. In the present paper, the effect of pH value on the copolymerization reactivity of the acid with acrylonitrile is described.

Experimental

Materials.—Acrylonitrile was purified by Thomas' method.[8] Itaconic acid was recrystallized two times from water. Potassium persulfate was also recrystallized from water and was used as a polymerization initiator. Deionized water, prepared by treating water with ion-exchange resin, was used as the solvent of the copolymerization.

The Copolymerization Procedure and the Treatment of the Copolymer.—Three pH values, 1.5, 4.6 and 9.5, were selected for the copolymerization systems of itaconic acid and acrylonitrile in an aqueous solution. In order to adjust the pH, hydrochloric acid or potassium hydroxide was added to the solution of itaconic acid.

Potassium persulfate, the itaconic acid solution with its pH adjusted, and acrylonitrile were charged for the polymerization into a clean glass tube. The total volume of the solution in each batch was 50 ~60 cc. After they had been flushed with nitrogen, the tubes were sealed and immersed in a water-bath regulated to the polymerization temperature of 50°C. and then kept still for several hours.

The copolymer formed was soluble or insoluble to the solution depending on both the composition of the copolymer and the pH value of the system. For the system in which the copolymer precipitated, it was easy to separate the copolymer from the unreacted monomers by filtration. When, however, the

copolymer did not precipitate in the copolymerization medium at the acid pH, the solution was first neutralized by the addition of potassium hydroxide to pH 7, and then an excess amount of calcium chloride solution was rapidly stirred in at about 50°C to form the calcium salts of the itaconic monomer and the copolymer.[9] The calcium salt of the copolymer obtained was a fine powder and was insoluble to the solution, while that of the monomer was soluble. The copolymer salt was so finely suspended in the solution that it was difficult to isolate the salt by suction filtration through a glass filter. Accordingly, the suspension was centrifuged to recover the precipitates, and the upper solution was then decanted. The precipitates were washed with hot water and centrifuged again. This procedure was repeated several times until no chlorine ions were found in the washings. Then the copolymer was dried.

After copolymerization at a slightly alkaline pH, the solution of this system changed its color to yellow; the addition of a calcium chloride solution caused no recovery of the copolymer. In this case, however, the addition of hydrochloric acid precipitated the copolymer, with a yellow color, at about pH 3~4. Before being dried, the precipitate was dissolved again in water and reprecipitated by the addition of hydrochloric acid.

The Analysis of the Copolymer.—The acrylonitrile content of the copolymer was determined by nitrogen analysis using Kieldahl's method. The ash obtained from the copolymer was analyzed for calcium by the titration of EDTA and for potassium by the gravimetric method or by flame photometry.* Then the itaconic acid content was calculated from that of acrylonitrile, considering the calcium and potassium content of the copolymer.

Results and Discussion

The results of the copolymerization of three systems I, II and III, at different pH values are presented in Table I. In these cases, itaconic acid is designated as monomer 2, while acrylonitrile is monomer 1.

The Relationship between the pH of the System and the Dissociation of Itaconic Acid.—The copolymerization was carried out in the pH ranges of 1.0~2.2 (I), 4.7~5.3 (II) and 9.8~7.1 (III). It can be considered on the basis of Fig. 1,[10] which shows the relationship between the pH value and the degree of dissociation of itaconic acid, that the compositions of the acid in these systems are as follows:

(I) $IA > 97\%$

(II) $IA^- \simeq 80\%$, $IA \simeq IA^{2-} \simeq 10\%$

(III) $IA^{2-} > 97\%$

where IA means the undissociated form, IA^- means the first step dissociated monoanion, and IA^{2-} means the second-step dissociated dianion.

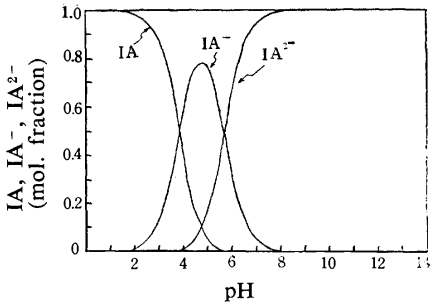

Fig. 1. Dissociation curves of itaconic acid against pH. IA, IA^- and IA^{2-} mean undissociated, first step dissociated and second step dissociated forms of itaconic acid, respectively.

The Precipitation of the Copolymer in the Copolymerization System.—In the cases of both I and II, the copolymer rich in acrylonitrile precipitated during the polymerization, while the copolymer rich in itaconic acid did not precipitate. The copolymer of an intermediate composition was partly precipitated and partly dissolved in the solution. (Cf., e.g., Table I, I-3.) However, in the case of III, no precipitates were found, presumably because of the great solubility of the copolymer composed, even though only in part, of itaconic dianion, whose water solubility is very large.

The Rate of Copolymerization.—In the acid pH copolymerization, a great decrease in the rate of copolymerization was observed as the composition of itaconic acid increased. This phenomenon had already been reported and explained by Uchida;[5] itaconic acid acts as a retarder in the emulsion copolymerization with acrylonitrile. Thus, itaconic acid monomers (M_2) add predominantly to the polymer radicals in competition with acrylonitrile monomers, i.e., $r_1 < 1 < r_2$. This results in a yield of polymer radicals with the itaconic units whose homopropagation ability is comparatively poor added at the growing ends.

However, in the neutrallized solution of the present work, rates of copolymerization which were rather large in comparison with those in acid pH copolymerization were observed in the range of 0.2~0.4 mol. fractions of M_2. The most probable interpretation of this phenomenon is that the relationship between r_1 and r_2 is now changed, as will be mentioned below; i.e., $r_1 > r_2 \simeq 0$, with a larger r_1

9) This method has previously been described by H. Ito and S. Suzuki in the case of the copolymerization of acrylonitrile with acrylic acid; *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zassi*), **58**, 627 (1955).

I	1.0～2.2	IA >97%	0.25	1.57	0.55	0.22
II	4.7～5.3	IA^- ≃max.	0.30	0.60	—	—
III	9.8～7.1	IA^{2-} >97%	0.43	0.1	0.12	−0.58

* The Q and e values of acrylonitrile used for this calculation are 0.41 and 1.2 respectively.

and a smaller r_2 than those for the acid pH copolymerization, thus accelerating the consumption of M_1 and increasing the rate of copolymerization.

When more than a 0.4 mol. fraction of itaconic acid was used, the rate of conversion became very small.

The Composition of the Copolymer and the Copolymerization Parameters.—The calculation of the monomer reactivity ratios was carried out according to Lewis and Mayo's method, as shown in Fig. 2, except for runs which yielded precipitated copolymers, because the unexpected absorption of the unreacted monomers to the precipitated polymers might have occurred.

Figures 3—5 show the relationship between the monomer and the copolymer compositions. The curve represents the calculated values for

r_1 and r_2, while the points represent the experimentally-determined compositions. Each curve rides sufficiently on the respective experimental points, except for those systems excluded from the calculation.

Figure 3 shows that when itaconic acid is undissociated, copolymers with acrylonitrile always contain an excess fraction of itaconic acid compared with the fraction of the acid in the monomer mixtures. On the other hand, when itaconic acid is ionized to the second step dissociated form, the "azeotropic" points are observed on a composition of about 0.4 mol. fraction of M_2, as shown in Fig. 5. Figure 4 shows an example of the results obtained by the copolymerization at intermediate pH values when IA, IA^- and IA^{2-} are all involved in the reaction.

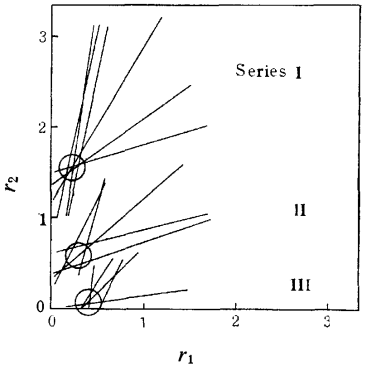

Fig. 2. Calculation diagram of reactivity ratios.

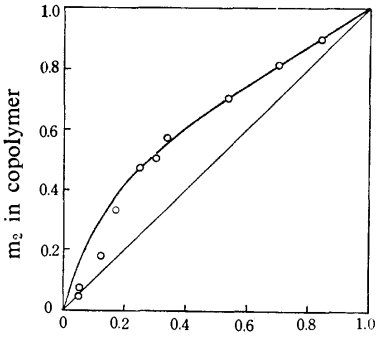

Fig. 3. Relationship between monomer composition and the initial copolymer composition. (Series I)

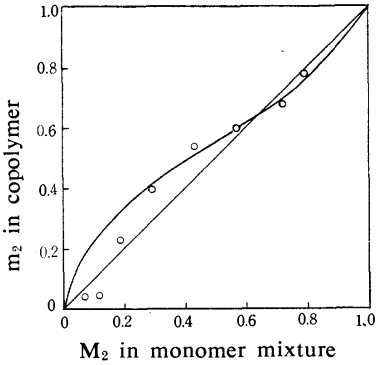

Fig. 4. Relationship between monomer composition and the initial copolymer composition. (Series II)

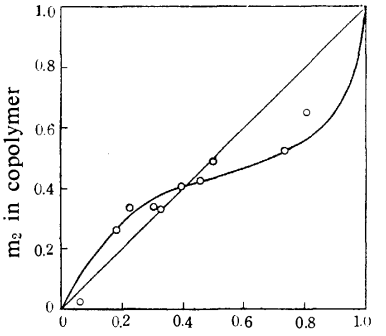

Fig. 5. Relationship between monomer composition and the initial copolymer composition. (Series III)

The monomer reactivity ratios and the Q-e values calculated according to the method of Alfrey and Price are summarized in Table II.

As for the monomer reactivity ratios, it is observed that r_2 decreases from 1.57 to 0.1 according as itaconic acid changes from the undissociated form to the second-step dissociated anion. This fact suggests that, in accordance with the finding reported in the previous paper,[1] for all practical purposes the second-step dissociated itaconic dianion does not homopolymerize.

During the considerable change in r_2 above mentioned, however, a comparatively small change is observed in r_1, one ranging from 0.25 to 0.43. This finding demonstrates that the itaconic dianion has yet a considerable reactivity to copolymerization.

Concerning the corresponding changes in Q and e values, Q_2 varies from 0.55 to 0.12, while e_2 varies from 0.22 to -0.58, according as itaconic acid changes from IA to IA^{2-}. If this finding is compared with that of acrylic acid, some interesting facts are observed. In the case of acrylic acid, Ito and Suzuki reported[9] that Q varies from 0.40 to 0.11, while e varies from 0.25 to -0.15, according as the acid changes from the undissociated form to the anion. It may be due to the similar structures of acrylic and itaconic acid from the point of view of resonance stabilization that the two monomers have similar Q values,

showing similar changes in response to the changes in the dissociation degree. Further, probably responsible for the second step dissociation of itaconic acid against the only one step dissociation of acrylic acid is the fact that the change in the *e* value of itaconic acid is much larger than the change of that of acrylic acid.

Summary

The copolymerization of itaconic acid with acrylonitrile has been carried out in aqueous solutions of three different pH values. From the composition data obtained, the monomer reactivity ratios and the *Q-e* values have been calculated. The results indicate that itaconic acid, when ionized to the second-step dissociated form, is able to copolymerize with other monomers, while it is almost completely unable to homopolymerize.

The author wishes to express his gratitude to Dr. Keinosuke Yoshida and Dr. Taizo Uno for their encouragement and to Mr. Yasushi Yoshinaga for his cooperation in the experiments.

The Nuclear Magnetic Resonance Spectra of Triethylaluminum and Diethylaluminum Monohalides

By Osamu YAMAMOTO

(Received July 5, 1963)

The high resolution proton magnetic resonance spectra of a considerable number of metal alkyls have been studied in recent years; special attentions has been directed to ethyl compounds[1-4] in an attempt to correlate the electronegativity of the metal with the internal chemical shift of the ethyl group. An empirical linear relation between them was first proposed by Dailey and Shoolery[5] and later modified by Shoolery[6] for substituents of lower electronegativity through altering the empirical constants of the equation. The modified form of the equation is:

$$x = 0.62\delta + 2.07 \qquad (1)$$

where x is the electronegativity of the metal atom and δ is the internal chemical shift in p. p. m., i. e., the difference between the methyl and the methylene proton shifts.

It can easily be predicted from the equation that if x is equal to the constant term, the δ value is zero, and that if x is less than the constant term, δ is negative; that is, the methyl protons will be less shielded than the methylene protons. The spectrum shows the "inverted ethyl signals." These have clearly been demonstrated by Baker for tetraethyllead and diethylaluminum chloride respectively.[1]

Aluminum alkyls occupy an interesting position in structural chemistry because of their dimeric forms;[7,8] consequently, they have been studied extensively by means of X-ray[9] and electron diffraction[10] as well as by Raman[11-15] and infrared[12,14,16-18] spectroscopy. Some studies of the proton magnetic

resonance spectra of these compounds have also been reported.[1,19,20] These compounds, however, except for methyl derivatives, give moderately complicated spectra, and the reported values of the chemical shifts, δ, and the coupling constant, J, are based on the firstorder approximation of the analysis.

In the present paper, the δ and the J values for triethylaluminum and diethylaluminum monohalides will be revised by a rigorous A_3B_2 analysis of the spectra; moreover, some consideration will be given for the internal chemial shifts and the coupling constants of the compounds. At the same time, the dilution effect on the δ values will be considered.

Experimental

The proton magnetic resonace spectra were obtained by means of a Varian Associate DP-60 spectrometer equipped with V-4311 R-F units of 40 and 60 Mc./sec., the usual sideband technique being employed. The spectra were obtained with pure liquid samples as well as solutions in benzene.

The solvent was dehydrated and purified by the conventional methods. All the materials used were prepared by Grosse and Mavity's methods.[21] Since aluminum alkyls are in general very reactive with air and moisture, the purified samples were transferred into cylindrical sample tubes (5 mm. o. d.) in a high vacuum apparatus; appropriate amounts of solvent, if employed, were directly distilled therein, and then the tubes were sealed off.

Results

The spectra obtained at 40 Mc./sec. using the pure liquid samples are reproduced in Figs. 1—4. The triplet-like signals on the lower field side are due to the methyl protons, and the higher field side signals, to the

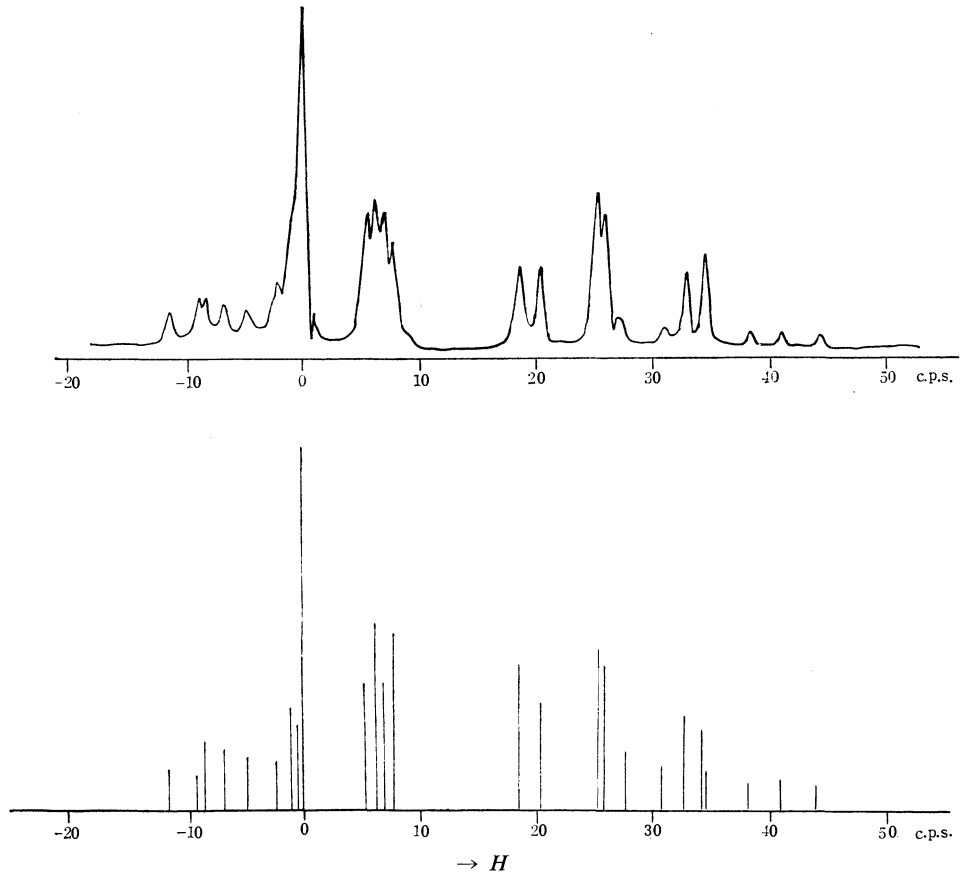

Fig. 3. Observed and calculated spectra of diethylaluminum bromide in pure liquid state at 40 Mc./sec.

methylene protons, so the spectra show "inverted ethyl signals." The individual spectral lines are somewhat broadened, probably because of the nuclear spin of aluminum ($I=5/2$).

The analysis of the spectra as an A_3B_2 system was accomplished using a NEAC-2101 digital computor. Three equivalent protons of the methyl group and two of the methylene group were treated as composite spin particles which have total spin angular momenta of 3/2 and 1 respectively. The initial assignment of the signals was determined by comparison with the theoretical spectra calculated for various J/δ values in advance. Since the observed spectra were not very muth deformed from the first-order triplet-quartet spectra (when J/δ is quite small), the assignments were rather easy. All the data from the observed lines according to the tentative assignment were fed into the input of the computor, and calculations were made to obtain the stationary state energies and the transition intensities. The program further proceeded to iteration, using the least-squares method for the difference between the observed and the calculated frequencies.

TABLE II. δ AND J_{CH_3, CH_2} VALUES OBTAINED FROM A_3B_2 ANALYSIS OF THE SPECTRA EOR TRIETHYLALUMINUM AND DIETHYLALUMINUM MONOHALOGENIDES IN THE PURE LIQUID STATE

Compound	δ, p.p.m.		J_{CH_2, CH_3} c.p.s.	
	40 Mc.	60 Mc.	40 Mc.	60 Mc.
$Al(C_2H_5)_3$	−0.72	−0.72	7.9_3	8.0_1
$Al(C_2H_5)_2Cl$	−0.81	−0.82	8.1_1	8.1_2
$Al(C_2H_5)_2Br$	−0.73	−0.73	8.0_8	8.0_7
$Al(C_2H_5)_2I$	−0.60	−0.60	8.0_5	8.1_1

The numerical details of the calculation are shown in Table I for only the 40 Mc. spectrum of triethylaluminum, while schematic illustrations of the theoretical spectra for each compound are given at the bottom in Figs. 1—4. The δ and the J values obtained both at 60 and 40 Mc./sec. for the pure liquid samples are summarized in Table II.

The spectra of benzene solutions were obtained only with 60 Mc./sec.; similar calculations were made to obtain the δ values,

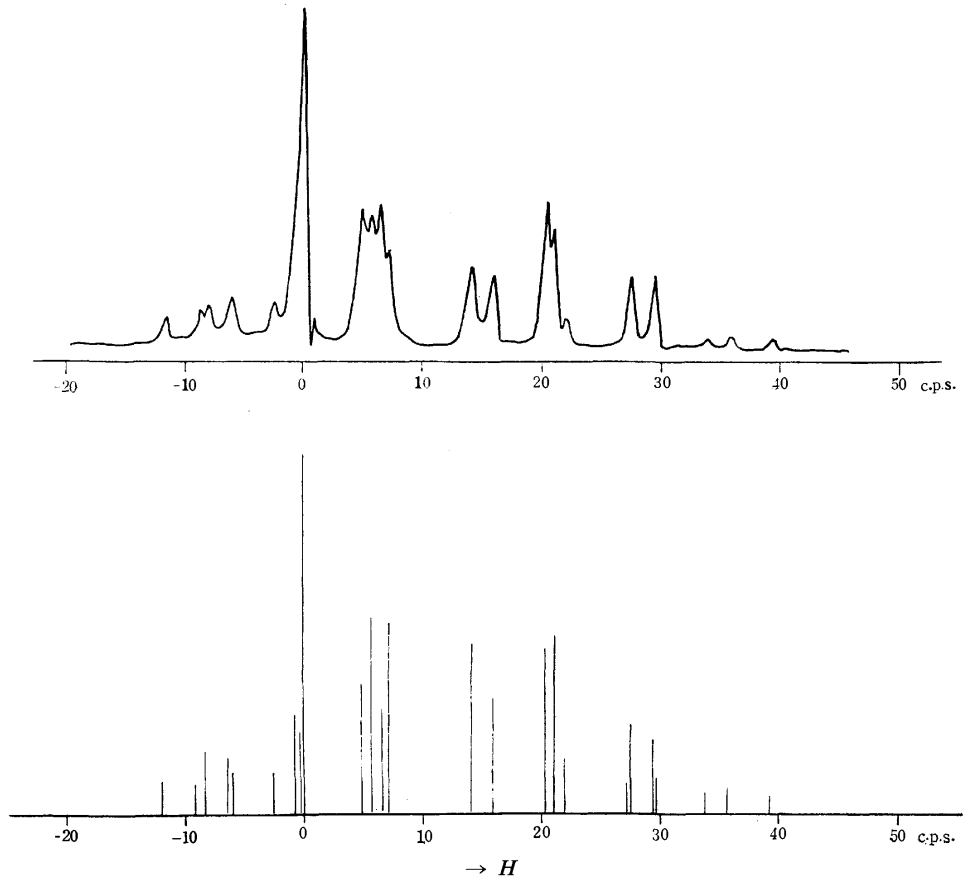

Fig. 4. Observed and calculated spectra of diethylaluminum iodide in pure liquid state at 40 Mc./sec.

which are shown in Fig. 5 plotted against the concentration.

Discussion

Coupling Constants. — The agreement in the J values at 40 Mc./sec. and at 60 Mc./sec. assures the accuracy of the obtained spin-spin coupling constants between the methyl and the methylene protons, J_{CH_3, CH_2}. All of the values are found to be near 8.0 c. p. s. and to be approximately the same as those obtained with other metal compounds (See Table III). Hence, it seems that the coupling constants, J_{CH_3, CH_2}, in the ethyl groups of such metal compounds are independent of the nature of the metal atoms attached to the ethyl groups.

The Dilution Effect of Benzene on δ Values.— Narasimhan and Rogers[3] have suggested that it would be preferable to obtain the δ values at infinite dilution in an inert solvent. Originally Dailey and Shoolery[5] employed 50 volume % benzene solutions in correlating the δ values with the electronegativity of metals. Although benzene is not necessarily an adequate solvent because of its considerable solvent effect, other solvents commonly used in NMR measurements cannot be employed in the case of metal alkyls because of the overlap of the signals and/or the reaction between the solvent and the solutes.

Thus, it is necessary to obtain the δ values at infinite dilution using benzene as the solvent and to observe their differences from those obtained with pure liquid samples for each

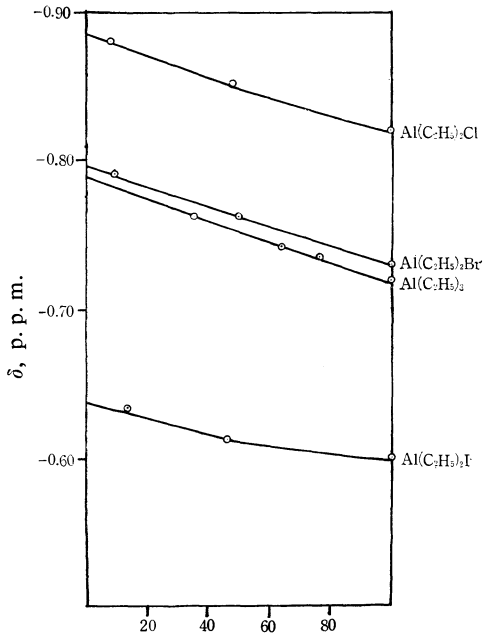

Fig. 5. Solvent effect benzene on δ values of $Al(C_2H_5)_3$ and $Al(C_2H_5)_2X$.

particular metal compound. Figure 5 shows the dilution effect on the δ values obtained in the present work. It may be seen from this figure that the maximum difference is about 0.1 p. p. m., the extent being quite large.

As far as the electronegativity of the metal itself is concerned, it is not so much affected by such a change in δ values as indicated by Narasimhan and Rogers.[3] However, when the effect of substituents attached to the metal atom on the δ values, as will be described below, is involved, the dilution effect plays more or less a significant role; in these instances, one must discuss the problem using δ values obtained under substantially the same conditions.

The Effects of Substituents Attached to the Metal Atom on the δ Values. — As is shown in Fig. 5 and Table II, the δ values of the diethylaluminum monohalides increase as the substituents change from chlorine through bromine to iodine. (Throughout the discussion below, the sign of δ is taken into account when the δ values are compared.) Figure 6 shows that the methyl protons, which are at the γ-position to the halogens, do not change in the resonance position throughout the compounds under the same conditions of dilution. Thus, the difference in δ values for these compounds is due to the methylene proton shifts. The methylene protons are at the β-position to the halogens and are, hence, influenced by the substituents.

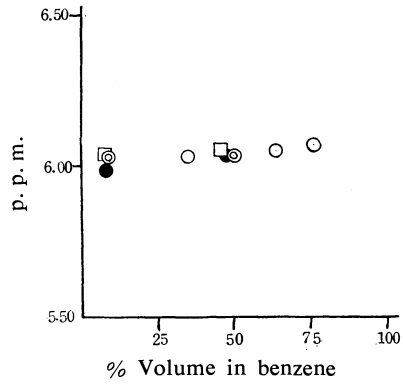

Fig. 6. Chemical shifts of the methyl signals in $Al(C_2H_5)_3$ and $Al(C_2H_5)_2X$ in benzene (referred to solvent benzene).

○ $Al(C_2H_5)_3$ ◎ $Al(C_2H_5)_2Br$
● $Al(C_2H_5)_2Cl$ □ $Al(C_2H_5)_2I$

In the CH_3-CH_2-X type compounds it has already been found that, for a simple atomic substituent, the shift to a lower field of the protons at the β-position, i. e., the methyl proton shift, increases in the order of the substituent from upper to lower down the periodic table.[22] The shielding by a β group to the methyl protons is largely controlled by the diamagnetic anisotropy of the substituent, with a smaller contribution from its inductive effect. Thus, the extents of the low field shifts increase in the descending order of chlorine, bromine and iodine. This order is contrary to that of the electronegativity but is consistent with that of the diamagnetic polarizability of the atom.

The same is true for the methylene protons of diethylaluminum monohalides. Thus, since the methylene protons in these compounds are shifted to lower fields in the order of chloride, bromine, and iodine by the diamagnetic anisotropy of the halogen atoms and since the methyl signals are substantially invariant, diethylaluminum monohalides have δ values increasing in the order of chlorine, bromine and iodine.

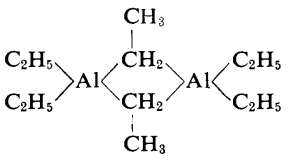
Triethylaluminum, which has a larger δ value than diethylaluminum monochloride, provides another problem. As was mentioned above, the substitution of the halogen atom at the β-position to a certain group of protons causes the proton signal or signals to shift to a lower field. This can be interpreted in terms of the electron-withdrawing power of the halogen atoms. For example, diethylsilane dichloride has a larger δ value (+0.01 p.p.m.)

22) L. M. Jackman, "Applications of Nuclear Magnetic Resonance Spectroscopy in Organic Chemistry," Pergamon Press, New York (1959), p. 53.

than tetraethylsilane (−0.42 p. p. m.).[3,23] A similar consideration will lead to a larger expected value for δ in diethylaluminum monochloride than in triethylaluminum, but actually the reverse is true.

Growenewege, Smidt, and de Vries[20] reported that trimethylaluminum, which gives a sharp singlet signal at room temperature, shows two separate signals at −78°C, one of which appears at higher and the other at lower fields than that of the original one. They assigned the higher signal to the terminal methyl protons and the lower one to the bridged methyl protons of trimethylaluminum dimer. The fact that trimethylaluminum gives only one singlet signal at room temperature was attributed to the rapid exchange between the terminal and the bridged methyl groups.

Since triethylaluminum has also been reported to have a dimeric form in liquid or in solutions,[7,8] the fact that the obtained spectra can be interpreted by a simple A_3B_2 system rather than by the superposition of two different A_3B_2 spectra must be responsible for the rapid exchange between the terminal and the bridged ethyl groups, as in the trimethylaluminum. In these circumstances the observed signals will be a weighted mean of the two A_3B_2 signals. If it is assumed that in this case also both the methyl signals are at approximately the same position and that the ethyl bridge is formed through the methylene group, i. e.,



then the terminal methylene signals which are observed when the rapid exchange does not occur may be expected to appear at higher fields than the methylene signals observed at room temperature; therefore, the δ value of the terminal ethyl groups would be smaller than the δ value of diethyl aluminum monochloride. Then the apparent abnormality of the δ values of triethylaluminum may be eliminated. The confirmation of this assumption requires the low temperature spectra of triethylaluminum, work on which is now proceeding in this laboratory.

Baker in his early paper[1] suggested that the aluminum atom in triethylaluminum has a greater tendency to donate an electron to the methylene group than in diethylaluminum chloride, so that the former has a larger δ value. However, this conception seems to be improbable to judge the discussion of tetraethylsilane and diethylsilane dichloride mentioned above.[3]

The Electronegativity of Aluminum. — The electronegativity of the aluminum atom evaluated from Eq. 1 with the δ value of triethylaluminum at infinite dilution turns out to be 1.58. The electronegativity of metals can be obtained by various methods, including the method using the vibrational frequency of the methyl derivatives of the metals.[24-28] Several relationships between the electronegativity and the symmetric deformation frequency of the methyl group have been proposed. The following experimental formula, for instance, has been presented by Takenaka:[26]

$$\delta_{CH_3} = 375 \log(x/r^2_{cx}) + 1366 \qquad (2)$$

where δ_{CH_3} is the symmetric deformation frequency of the methyl group in cm^{-1}, x is the electronegativity of the metal atom, and r_{cx} is the distance between carbon and the metal atom in Å.

If the obtained values, 1.58 for the electronegativity of aluminum and 2.00Å for the terminal Al–C distance,[9] are used, one obtains 1215 cm^{-1} for δ_{CH_3}, which agrees approximately with the observed value, 1200 cm^{-1}, for the symmetric deformation of the methyl group in trimethylaluminum.[12] When the electronegativity which would be obtained for the terminal ethyl signal of triethylaluminum is substituted into formula 2 above, one can expect a smaller δ_{CH_3} value and the agreement between the observed and the expected values will be much improved.

The author wishes to express his hearty thanks to Dr. Shinnosuke Saëki of the Government Chemical Industrial Research Institute, Tokyo, for his kind advice and discussions regarding computor calculation, and to Mr. Joseph Yamada of the same Institute for his experimental work.

23) Assuming the bridge structure in the aluminum compounds and comparing the substituents attached to the metal atom, diethylsilane dichloride rather than triethylsilane monochloride is appropriate, the δ value of the latter having not yet been reported but predicted to be −0.215 p. p. m. by Narasimhan and Rogers.[3]

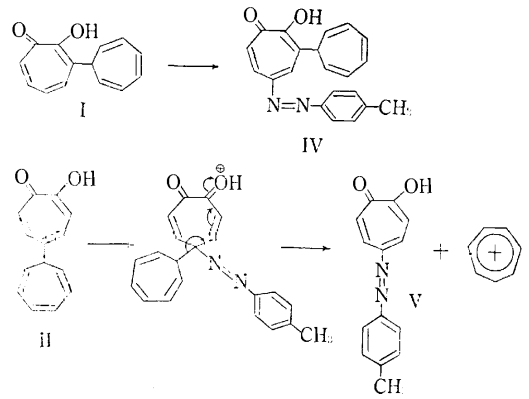
Reaction of Tropylium Ion with Tropolone[1]

By Tetsuo NOZOE, Takahiro TEZUKA and Toshio MUKAI

(Received July 12, 1963)

In a previous paper[2] the authors reported on the reaction of tropylium ion with β-naphthol. Since tropolone is regarded as a compound analogous to phenols in its chemical behavior, especially toward electrophilic reagents,[3] it is to be expected that a reaction would take place between tropylium ion and tropolone. The present paper will describe this reaction and the structure and reactions of the products obtained.

The reaction of equimolecular amounts of tropylium bromide and sodium salt of tropolone affords three kinds of acidic substances with recovery of tropolone. They are yellowish needles, (I) $C_{14}H_{12}O_2$ (m. p. 89°C), (II) $C_{14}H_{12}O_2$ (m. p. 127°C) and (III), $C_{21}H_{18}O_2$ (m. p. 137°C), which were obtained in 20, 18 and 36% yields respectively. From their analytical values, the red coloration with ferric chloride, which is characteristic of tropolone derivatives, and a consideration of the preferential attack of the electrophilic reagent at the 3- and 5-positions of the tropolone ring, I and II have been assumed to be 3- or 5-(7-tropyl)tropolone. The coupling of I with *p*-toluenediazonium chloride results in the formation of a crystalline azo dye (IV) $C_{21}H_{18}O_2N_2$ (m. p. 159°C), which indicates that I is 3-(7-tropyl)tropolone with no substituent at the 5-position.[4] II also affords an azo dye (V) $C_{14}H_{12}O_2N_2$ (m. p. 200°C) by coupling with *p*-toluenediazonium chloride. However, its analytical value reveals that the tropyl group of the 5-position of II would be replaced by the *p*-tolylazo group. In fact, V is found to be identical with the known 5-(*p*-tolylazo)tropolone[5] by a comparison of their infrared absorption spectra; there is no depression of their mixed melting point. Since the reaction is considered to proceed as depicted below, II is certainly 5-(7-tropyl)tropolone. There are some examples of the same type of replacement reaction in tropolone derivatives; that is, the 5-hydroxymethyl[6] and 5-morphorinomethyl groups[6] at the 5-position are replaced with the *p*-tolylazo group.



As Figs. 1, 2 and 3 show, the ultraviolet spectra and nuclear magnetic resonance spectra[7] of I and II support the correctness of the structure of I and II. In their nuclear magnetic spectra, I and II exhibit five groups of signals, a, b, c, d and e, which have intensity ratios corresponding to 1, 2, 4, 4 and 1 protons respectively. The triplet signal, a, the quartet, b and the multiplet, c, are ascribed to the C_7, $C_{1,6}$ and $C_{2,3,4,5}$ protons of the tropyl group, and d and e are attributed to the tropolone-ring proton and that of the hydroxyl group respectively. The symmetrical signal d of II is especially characteristic of the A_2B_2 system,[8] indicating II to be 5-(7-tropyl)tropolone. The e signal shifts to a lower field when one drop of acetic acid is added.

The acidic compound III couples with *p*-toluenediazonium salt in pyridine, affording an azo dye (VI) $C_{28}H_{24}O_2N_2$ (m. p. 188°C). III also gives a crystalline sodium salt and a hydrazine salt which readily regenerates III on acidifying. From these facts and from the

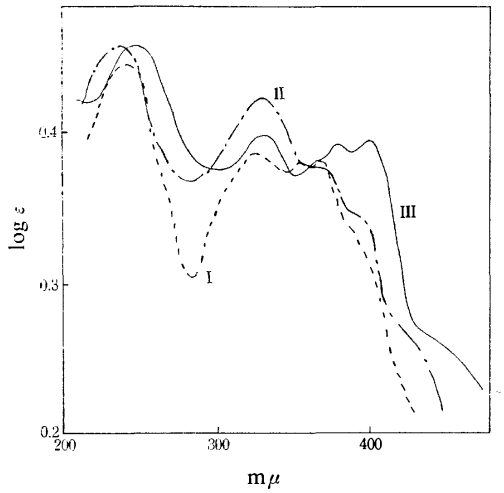

Fig. 1. UV spectra of I, II and III in methanol.

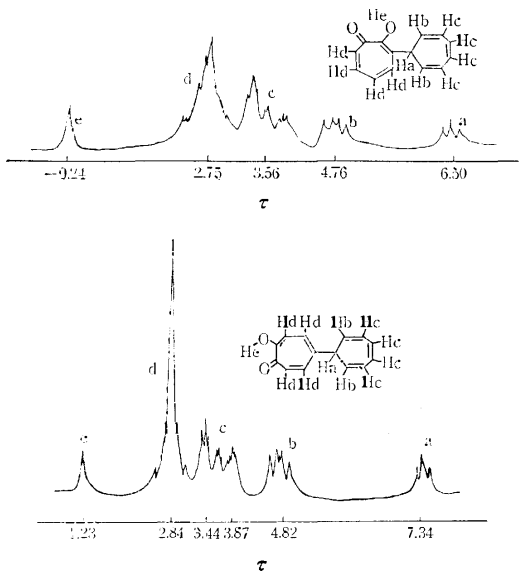
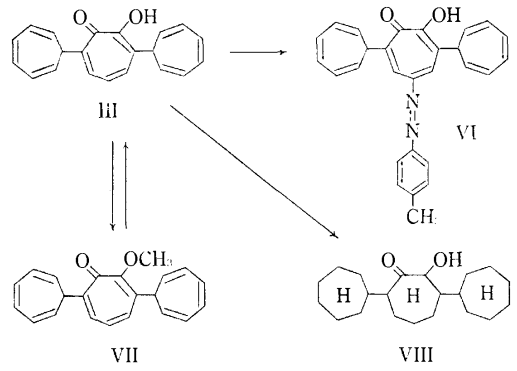


Figs. 2 and 3. NMR spectra of I and II in carbon tetrachloride (40 Mc.), with cyclohexane as an internal reference.

analytical value, III is assumed to be 3, 7-di-(7-tropyl)tropolone. The ultraviolet spectrum shown in Fig. 1 supports the assignment of III as a tropolone derivative. In the infrared spectrum, however, there is no absorption band due to the hydroxyl group and III does not show any coloration with ferric chloride in an organic solvent, such as benzene and chloroform; it does, however, show a red coloration in *n*-butanol. Since III is 3, 7-di(7-tropyl)tropolone, not a 3, 5-derivative, these abnormalities concerning the infrared spectrum and coloration can be understood from the steric hindrance of the tropyl groups situated in the 3- and 7-positions. Actually, III gives only one methyl ether (VII) (m. p. 86°C), upon being treated with diazomethane. Nine moles of hydrogen are absorbed when III is hydrogenated over platinum oxide, yielding a compound (VIII) $C_{21}H_{36}O_2$ (m. p. 60°C) which shows a band at 3500 cm^{-1} for a hydroxyl and at 1700 cm^{-1} for a carbonyl group.



The NMR spectrum of III, shown in Fig. 4, furnishes additional evidence concerning its structure. There are also five groups of absorption signals, a, b, c, d and e. The symmetrical shape of the a triplet which appears at 6.48τ, at almost the same field as a of I, supports the theory that the two tropyl groups are situated in equivalent positions, that is, the 3- and 7-positions. If they were not at equivalent positions, they would give rise to the double triplet in this region of field. The signal d at 2.69τ, ascribed to the tropolone-ring proton, shows AB_2 type coupling.[8] This fact also supports the idea that III is 3, 7-di-(7-tropyl)tropolone.

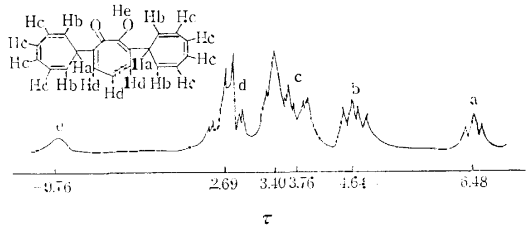


Fig. 4. NMR spectrum of III in carbon tetrachloride (40 Mc.), with cyclohexane as an internal reference.

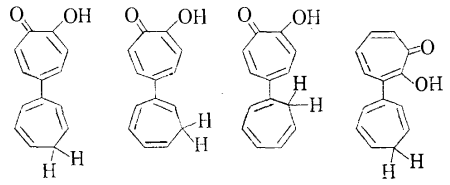
The distillation of the mixture obtained from the reaction of tropylium ions and tropolone at the bath temperature of 180°C, before separating I, II and III, affords two additional acidic compounds; (IX) $C_{14}H_{12}O_2$ (m. p. 98°C) and (X) $C_{14}H_{12}O_2$ (m. p. 60°C). They are assumed to be isomeric monotropyltropolones resulting from a shift of the hydrogen during heating, because of their

analytical values and the red coloration with ferric chloride characteristic of tropolones. On coupling with *p*-toluenediazonium chloride, IX does not afford any crystalline azo compound, but X does afford an azo dye, (XI) $C_{21}H_{18}O_2N_2$ (m. p. 148°C).[4]



IXa IXb IXc X

This fact indicates that IX is 5- and that X is 3-tropyltropolone isomeric to II and I. In the case of IX, there are three possible formulas in which double bonds of the tropyl group are conjugated to the tropolone ring; IXa, IXb and IXc. In fact, the ultraviolet spectra of IX and X are shifted to a longer wavelength region than those of I and II, as Fig. 5 shows. However, IXc can be ruled out, because its NMR spectrum shows a triplet with the area of two protons at 7.71τ which is attributed to the C_7 proton of the tropyl group. Recently, ter Borg, Kloosterziel and Van Meurs[9] reported that 7-deuterocycloheptatriene, when heated at 100~140°C, rearranged to 3-deuterocycloheptatriene as a result of the 1, 5-transannular shift of hydrogen. Nozoe and his co-workers also reported that 7-tropylbenzene[10] and 4-(7-tropyl)phenol[11] rearranged to the corresponding 2 or 3-tropyl derivatives upon being heated with or without a base. According to ter Borg et al., IXa would be a more favorable formula than IXb, while X would have the similar isomeric formulas. It is necessary to do more detailed study in order to elucidate the structure of IX and X and to clarify the thermorearrangement of I, II and III. The results of this series of studies will be published in this Bulletin.

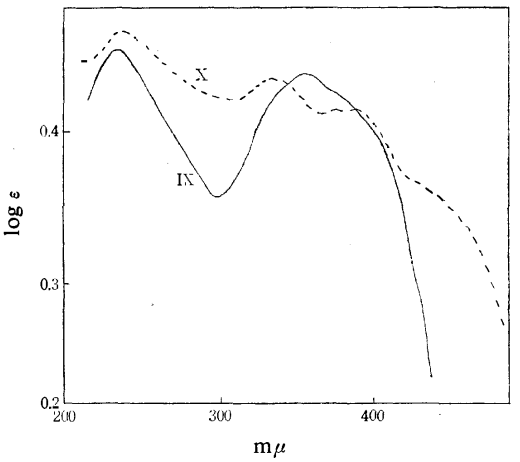


Fig. 5. UV spectra of IX and X in methanol.

Experimental[12,13]

The Reaction of Tropylium Bromide and Tropolone Sodium Salt: The Formation of 3-(7-Tropyl)- (I), 5-(Tropyl)- (II) and 3, 7-Di(7-tropyl)tropolone (III).—To a suspension of the sodium salt prepared from 10 g. of tropolone (0.0821 mol.) in 80 ml. of absolute ethanol, 13.6 g. (0.0795 mol.) of tropylium bromind were added. The reaction mixture was refluxed for 5.5 hr. After the sodium bromide had been filtered off, the evaporation of the solvent afforded 17 g. of an oil, which was found by paper chromatography to be a mixture of four kinds of tropolone derivatives. The fractional recrystallization of the sodium salt obtained from the oil from a water-ethanol mixture gave five fractions as follows. (1) The acidification of 2.8 g. of the most sparing soluble portion by 2 N hydrochloric acid afforded 2.2 g. of yellow crystals (m. p. 125~131°C), which on recrystallization from a benzene-ethanol mixture gave yellow needles (III) (m. p. 137°C). IR (KBr): no OH group, 1600, 1550 (C=O and C=C), 748, 695 cm^{-1} (7-tropyl group).[14]

Found: C, 83.44; H, 5.86. Calcd. for $C_{21}H_{18}O_2$: C, 83.42; H, 6.00%.

Treating III with hydrazine hydrate gave hydrazine salt (m. p. 160°C (decomp.)) as pale yellow needles.

Found: N, 8.80. Calcd. for $C_{21}H_{22}O_2N_2$: N, 8.38%.

(2) The acidification of 2.0 g. of the second sparing soluble portion afforded 1.2 g. of crystals (m. p. 60~65°C), the recrystallization of which from ethanol gave yellow needles (I) (m. p. 88~89°C). IR (Nujol): 3120 (OH), 1615, 1600, 1550 (C=O, C=C) 755, 704 cm^{-1} (7-tropyl group).[14]

Found: C, 79.25; H, 5.70. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

(3) The acidification of 2.3 g. of sodium salt afforded 1.1 g. of crystals (m. p. 100°C), the recrystallization of which from benzene gave yellow needles (II) (m. p. 126~127°C). IR (Nujol): 3200 (OH) 1615, 1550 (C=O and C=C) 755 and 704 cm^{-1} (7-tropyl group).[14]

Found: C, 79.69; H, 5.71. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

(4) The acidification of 1.6 g. of sodium salt afforded crystals (m. p. 40~45°C), which were identified as tropolone by a comparison of the infrared spectra.

(5) The acidification of 1 g. of the most easily soluble portion afforded 0.85 g. of oil, which was not studied in more detail.

The Coupling of 3-(7-Tropyl)tropolone (I) with *p*-Toluenediazonium Chloride. The Formation of Azo Dye (IV).—To a solution of 60 mg. of I dissolved in 0.3 ml. of pyridine, an aqueous solution of *p*-toluenediazonium chloride prepared from 30 mg. of *p*-toluidine in the usual way was added drop by drop while the solution was cooled by ice. The reaction mixture was then stirred for 1 hr., diluted with water, and extracted with chloroform. After the mixture had been dried on sodium sulfate, the evaporation of the solvent afforded 90 mg. of red crystals (IV) with a melting point of 157 ~158°C after recrystallization from the benzene-ethanol mixture.

λ_{max}^{MeOH} mμ (log ε): 233 (4.13), 297 (3.88), 390 (4.37) and 440 (sh).

Found: C, 76.31; H, 4.25; N, 8.33. Calcd. for $C_{21}H_{18}O_2N_2$: C, 76.34; H, 5.49; N, 8.48%.

The Reaction of 5-(7-Tropyl)tropolone (II) with *p*-Toluenediazonium Chloride. The Formation of Azo Dye (V).—To a solution of 38 mg. of II dissolved in 0.2 ml. of pyridine, an aqueous solution of *p*-toluenediazonium chloride prepared from 15 mg. of *p*-toluidine was added drop by drop while the solution was being cooled by ice, and stirring was continued for 1.5 hr. The crystals precipitated were collected by filtration to give 25 mg. of red crystals (m. p. 145~150°C). Recrystallization from a benzene-ethanol mixture afforded orange needles (V) (m. p. 199~200°C), which were identified with authentic 5-(*p*-tolylazo)tropolone[5] by a comparison of their infrared spectra and by a mixed melting point determination.

The Coupling of 3, 7-Di(7-tropyl)tropolone (III) with *p*-Toluenediazonium Chloride. The Formation of Azo Dye (VI). — To a solution of 100 mg. of sodium salt of III dissolved in 2 ml. of pyridine, an aqueous solution of *p*-toluenediazonium chloride prepared from 60 mg. of *p*-toluidine was added drop by drop while the solution was being cooled by ice. After the mixture had been stirred for 1.5 hr. at 0~5°C, the filtration of the reaction mixture afforded 135 mg. of red crystals (m. p. 155~160°C), the recrystallization of which from benzene gave orange needles (VI) (m. p. 187~188°C).

λ_{max}^{MeOH} mμ (log ε): 265 (4.35), 295 (4.27), 402 (4.49) and 436 (4.45).

Found: C, 80.34; H, 5.41; N, 5.79. Calcd. for $C_{28}H_{24}O_2N_2$: C, 79.97; H, 5.75; N, 6.66%.

The Formation and Hydrolysis of Methyl Ether (VII) of 3, 7-Di(7-tropyl)tropolone (III). — To 5 ml. of a 2.8% ether solution of diazomethane containing a few drops of methanol, 100 mg. of III were added and the mixture was allowed to stand overnight at room temperature. The removal of the ether afforded 70 mg. of crystals (m. p. 80~82°C), which on recrystallization from methanol gave yellowish crystals (VII) (m. p. 85~86°C). IR (Nujol): no OH group, 1590, 1560 (C=O and C=C), 745, 704 cm^{-1} (tropyl group).

λ_{max}^{MeOH} mμ (log ε): 322 (3.80).

Found: C, 83.51; H, 5.79. Calcd. for $C_{22}H_{20}O_2$: C, 83.51; H, 6.37%.

The solution of 7 mg. of VII dissolved in 1 ml. of ethanol containing five drops of 6 N hydrochloric acid was refluxed for 30 min. After the removal of the ethanol and dilution with water, the reaction mixture was extracted with benzene. Evaporation of benzene extract, after it had been dried on sodium sulfate, afforded 5 mg. of crystals (m. p. 130°C), which were found to be identical with III by a comparison of their infrared spectra.

The Catalytic Hydrogenation of 3, 7-Di(7-tropyl)-tropolone (III). — A solution of 38 mg. of III dissolved in 2 ml. of ethanol was catalytically reduced in the presence of 10 mg. of platinum oxide at an ordinary temperature and pressure. 26 ml. of hydrogen (9 molar equivalent) were absorbed over a 70 min. period. After the removal of the catalyst by filtration, evaporation of the ethanol afforded 32 mg. of colorless crystals (m. p. 52~55°C), the recrystallization of which from ethanol gave colorless needles (VIII) (m. p. 59~60°C). IR (oily state): 3500 (OH), 2900, 2850 (CH) 1700 cm^{-1} (C=O).

Found: C, 78.77; H, 10.87. Calcd. for $C_{21}H_{36}O_2$: C, 78.69; H, 11.32%.

The Separation of Isomeric Compounds (IX and X) from the Reaction of Tropylium Bromide and Tropolone. — The reaction of 13.6 g. of tropylium bromide and 10.0 g. of tropolone was carried out in as the way described above. The oily product thus obtained was distillated under reduced pressure to give three fractions as follows. (1) 3.94 g. of an oil (b. p. 90°C/3 mmHg) which crystallized to colorless crystals (m. p. 40°C). Recrystallization from benzene gave crystals, melting at 47°C, which were identified as recovered tropolone by a comparison of their infrared spectra. (2) 1.21 g. of an oil (b. p. ~190°C/3 mmHg). (3) 2.41 g. of an oil (b. p. 190~192°C/3 mmHg). Fractions 2 and 3 were found to be almost the same by a comparison of their infrared spectra and by paper chromatography which showed the existence of two major components. The sodium salt obtained from 2 g. of fraction 3 was fractionally recrystallized from a water-ethanol mixture to give the following fractions. From the most sparing fraction, 635 mg. of the salt was obtained, which on acidification with 2 N hydrochloric acid it gave 350 mg. of crystals (m. p. 65~67°C). Recrystallization from petroleum ether afforded yellow needles (IX) (m. p. 97~98°C). IR (KBr): 3180 (OH), 1602, 1550 (C=O, C=C), 750, 732 cm^{-1}.

Found: C, 79.03; H, 5.64. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

The acidification of 1.02 g. of the second fraction of the salt afforded 750 mg. of crystals (m. p. 40~50°C), which on recrystallization from ethanol gave yellow needles (X) (m. p. 59~60°C). IR (KBr): 3235 (OH), 1600, 1594, 1545 (C=O, C=C) 725, 704 cm^{-1}.

Found: C, 78.04; H, 5.36. Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

The oil, obtained from 300 mg. of the most easily soluble salt by acidifying it with acid, could not be identified because of its lability.

The Coupling of 3-Tropyltropolone (X) with *p*-Toluenediazonium Chloride.—To a solution of 160

mg. of X dissolved in 1 ml. of pyridine, *p*-toluenediazonium chloride prepared from 97 mg. of *p*-toluidine was added drop by drop while the solution was being cooled by ice. After it has been stirred and ice-cooled for 2 hr. and had been diluted with water, the reaction mixture was extracted with chloroform. The extract was washed with water, dried on sodium sulfate and evaporated to give 120 mg. of red crystals (m. p. 120~125°C), the recrystallization of which from a benzene-ethanol mixture afforded yellow needles (XI) (m. p. 148~149°C).

λ_{max}^{MeOH} mμ (log ε): 233 (4.22), 307 (4.13), 400 (4.53) and 440 (sh).

Found: C, 76.91; H, 5.43; N, 7.82. Calcd. for $C_{21}H_{18}O_2N_2$: C, 76.34; H, 5.49; N, 8.43%.

The authors wish to express their gratitude to Professor Genjiro Hazato and his colleagues of the Chemical Institute of Non-aqueous Solutions, Tohoku University, for their measurement of the NMR spectrum and to the Sankyo Co. for its donation of a research fund which covered a part of the expenses for this work. The infrared and ultraviolet spectrophotometers used in this study were purchased with a grant-in-aid for Fundamental and Technical Research from the Toyo Rayon Co., Ltd., to whom the authors are grateful.

*Absolute Configuration of Nupharamine**

By Ichiro KAWASAKI, Shigeru MATSUTANI and Takeo KANEKO

(Received July 12, 1963)

Nupharamine is a minor alkaloid isolated from the root of *Nuphar japonicum* DC. Although structure I was assigned to nupharamine by Arata and Ohashi,[1,2] the configurations of the three asymmetric carbons involved in this alkaloid have not yet been ascertained.

A number of natural products containing a piperidine ring have been isolated, and their chemical structures, together with their stereochemistry, have been elucidated. Leonard and Ryder[3] synthesized 2-butyl-3-methyl piperidine, which had been obtained from lupinane by cyanogenbromide degradation,[4] and found that the infrared spectra of its trans and of its cis isomer differ from one other. This finding led us to guess that the conformation of nupharamine could be determined through its spectral behavior. Recent studies of methyl quinolizidine have indicated that an axial and an equatorial group showed peaks at different positions in the NMR spectra.[5,6] This finding played a important role in the determination of the configuration of deoxynupharidine, the main alkaloid of this plant.[6] As will be described in the following scheme, we wish here to elucidate the conformation of nupharamine by the chemical correlation of it with deoxynupharidine and its diastereoisomer.

Anhydronupharamine was obtained from nupharamine by heating it with hydrochloric acid and then neutralizing it with sodium hydrogen carbonate according to Ohashi's procedure. As this product seemed to be a mixture of two isomers which have double bonds at different positions, it was separated into IIIA and IIIB isomers by chromatography on an alumina column. While the infrared spectrum of the IIIB isomer showed bands at 1360 cm^{-1} and 1380 cm^{-1}, both assigned to the *gem*-dimethyl group, that of the other isomer, IIIA, showed no such bands, but, rather, two distinctive bands at 875 cm^{-1} and 880 cm^{-1}. On the other hand, only the latter band was recognized in the infrared spectrum of anhydrotetrahydronupharamine (VIIIA), which had been derived from tetrahydronupharamine by a similar procedure and no longer contained a furan ring. Therefore, this band (880 cm^{-1}) should be assigned to a double bond of the $CH_2=C<$ type, while the former band (875 cm^{-1}) should be assigned to the furan ring.

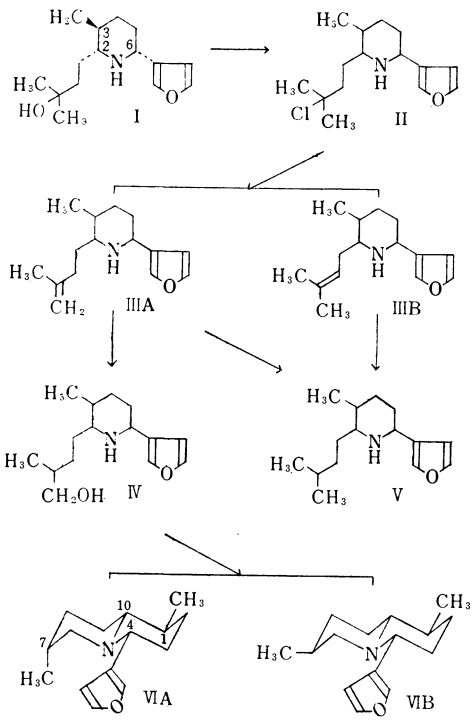

Fig. 1

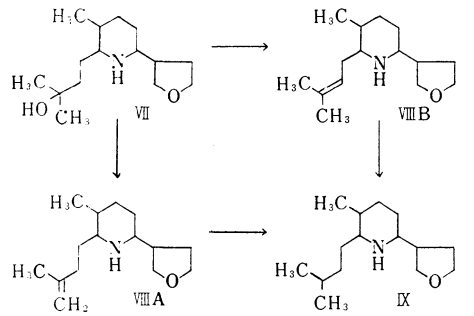

Fig. 2

When the isomer VIIIA or VIIIB was hydrogenated, the same compound, tetrahydrodeoxynupharamine (IX), was obtained in both cases. Similarly, the isomers IIIA and IIIB gave the same hydrogenation product, deoxynupharamine.

These facts indicate that IIIA contains a terminal double bond and that IIIB, an internal double bond in their molecules. With diborane in tetrahydrofuran, IIIA was converted to an organoborane compound, which was then oxidized to isonupharamine (IV) by alkaline hydrogen peroxide. IV was chlorinated with thionyl chloride and then cyclized with methanolic potassium hydroxide to afford a quinolizidine derivative. It was a mixture of diastereoisomers at C-7. The separation of both isomers was carried out by chromatography on an alumina column. From the observation of the infrared spectrum and of the levo rotatory power, one isomer, VIA, was found to be identical with natural deoxynupharidine. The other isomer, VIB, gave an infrared spectrum identical with that of 1(e), 7(e)-dimethyl-4(e)-[furyl-(3)]-quinolizidine[7] and a showed 1-equatorial methyl doublet at 0.86 p.p.m. and a 7-equatorial one at 0.68 p.p.m. in the NMR spectrum. The NMR spectra of isomer of deoxynupharidine are shown in the following table:**

Deoxynupharidine		Axial p.p.m.	Equatorial p.p.m.
1-epi	1-Me	1.19	
	7-Me	1.09	
Natural	1-Me		0.89
	7-Me	1.10	
7-epi	1-Me		0.86
	7-Me		0.68

The difference between the chemical shifts of the axial and equatorial methyl groups may be due to the long-range shielding effect of a magnetically-anisotropic carbon-carbon single bond or to the diamagnetic anisotropy which arises from furan ring currents. The C-methyl proton resonance signal for the equatorial methyl group (0.89~0.68 p. p. m.) was found to be at a higher field than the signal for the axial methyl group (1.19~1.09 p. p. m.). This observation indicates that the compound VIB must carry both methyl groups on equatorial conformation.

From the results obtained, it was concluded that the configurations of the asymmetric carbons, C_2, C_3, and C_6, of nupharamine are identical with those of the C_{10}, C_1 and C_4 of *l*-deoxynupharidine respectively and that, therefore, their absolute configurations may be deduced to be C_2(R), C_3(S) and C_6(R).

Experimental

Chloronupharamine (II).—a) A solution of 2 g. of nupharamine in 20 ml. of 10% hydrochloric acid was heated on a steam bath for 40 min. and then evaporated in vacuo. The residue was dissolved in small amounts of acetone and kept in a refrigerator. The deposited hydrochloride was recrystallized from acetone or ethanol-ether (1 : 5); 0.3 g.; m. p. 194°C (decomp.).

b) To a solution of 1 g. of nupharamine in 15 ml. of anhydrous ether, 0.7 g. of ice-cooled thionyl

7) F. Bohlmann, E. Winterfeld, P. Studt, H. Lautrent, G. Boroshewoki and K-M. Kleine, *Chem. Ber.*, **94**, 3151 (1961).

** These values were determined at 60 Mc. with a Varian A-60 spectrometer in a benzene solution (using TMS as the internal standard).

chloride were added and then kept at 50°C for 15 min. The solvent was evaporated. The residue was dissolved in 5 ml. of ethanol-ether (1 : 5) and kept in a refrigerator. The obtained hydrochloride (0.7 g.) melted at 196°C (decomp.).

Found : C, 58.59 ; H, 8.17. Calcd. for $C_{15}H_{25}O_2$-NCl_2 : C, 58.82 ; H, 8.27%.

Anhydronupharamine, IIIA and IIIB.—A solution of 1 g. of chloronupharamine-hydrochloride in water was carefully made basic with sodium carbonate and extracted with ether. The ether solution was dried and the ether was removed by distillation. The product was obtained as an oil (b. p. 113～120°C/3 mmHg, 0.75 g ; 91.4%) which was negative in a Beilstein test. The oil (1.55 g.) obtained was dissolved in petroleum ether and chromatographed on an alumina (55 g.) column.

Fraction	Elute	Volume ml.	Weight g.
1	Petr. ether	280	0
2	Petr. ether : ether (5%)	155	0.33
3	Petr. ether : ether (5%)	150	0.28
4	Petr. ether : ether (5%)	250	0.28
5	Petr. ether : ether (1 : 1)	200	0.29
6	Ether	250	0.31
7	Ethanol	100	0.43

The infrared spectrum of fraction 2 showed bands at 1505 and 875 cm^{-1} (the furan nucleus) and at 1380 and 1360 cm^{-1} (*gem*-dimethyl), and that of fraction 5 at 1505 and 875 cm^{-1} (the furan nucleus) 880 cm^{-1} (CH_2=C<) and 1380 cm^{-1}.

Deoxynupharamine (V).—A solution of 0.95 g. of anhydronupharamine (IIIA) in 20 ml. of alcohol was hydrogenated over 10% of palladium-on-charcoal at room temperature and in an ordinary atmosphere. After 98 ml. of hydrogen (one equivalent 90 ml.) had been absorbed over a 14 hr. period, the reduction product was taken up in the usual manner and crystallized as hydrochloride ; m. p. 232～233°C.

Found : C, 66.14 ; H, 9.60. Calcd. for $C_{15}H_{25}ON$-HCl : C, 66.27 ; H, 9.64%.

The hydrogenation of IIIB gave hydrochloride (m. p. 232～233°C) ; these crystals were shown to be identical with those obtained from IIIA (mixed m. p. 232～233°C). The infrared spectra of both hydrochloride were also identical.

Anhydrotetrahydronupharamine, VIIIA and VIIIB.—Tetrahydronupharamine VII (1.7 g. ; its perchloride, m. p. 212°C (decomp.)) was dissolved in 40 ml. of ether ; then a solution of 0.8 g. of thionyl chloride in 20 ml. of ether was slowly added while being ice-cooled. The mixture was warmed at 40～50°C for 3 hr. and then evaporated. The residue was made basic with an aqueous sodium bicarbonate solution and extracted with ether. The ether solution was dried, and the solvent was removed by evaporation. The residual oil (1.3 g.) was chromatographed on an alumina column (80 g.).

The infrared spectrum of fraction 5 showed a band at 880 cm^{-1}, indicating the presence of a CH_2=C< group.

Fraction	Elute	Volume ml.	Weight g.
1	Petr. ether : ether (5%)	200	0
2	Petr. ether : ether (10%)	200	0.14
3	Petr. ether : ether (20%)	250	0.48
4	Ether	100	0.26
5	Ether	400	0.30
6	Ethanol	200	0.04

Tetrahydrodeoxynupharamine (IX).—The anhydrotetrahydronupharamines, VIIIA and VIIIB, gave identical tetrahydrodeoxynupharamine (IX) when reduced over a platinum catalyst. Its hydrochloride was recrystallized from acetone to give colorless needles (m. p. 195°C).

Isonupharamine (IV).—To a mixture of 1.66 g. of anhydronupharamine (IIIA) and 0.61 g. of sodium borohydride in 80 ml. of tetrahydrofuran, a solution of 3.07 g. of boron trifluoride etherate in 10 ml. of tetrahydrofuran was added slowly under an nitrogen atmosphere. After being kept at room temperature for 4 hr., the reaction mixture was decomposed with 2 ml. of water, and then 2 ml. of 6 N sodium hydroxide and 2 ml. of 30% hydrogen peroxide were stirred in. After the mixture had been kept at 45～50°C for 30 min., the solvent layer was separated from a precipitate, which was extracted several times with boiling ether. The solvent layer and the combined ether extracts were mixed up, and the solvent was evaporated. The residue was dissolved in ether, washed with water and dried. On distillation, 1.0 g. of IV (b. p. 145～152°C (bath temp.)/0.001 mmHg.) was obtained. The perchlorate was recrystallized from ethyl acetate to give colorless needles (m. p. 164～166°C).

Found : C, 51.35 ; H, 7.47 ; Cl, 10.07. Calcd. for $C_{15}H_{23}ON$-$HClO_4$: C, 51.20 ; H, 7.44 ; Cl, 10.07%.

Deoxynupharidine, VIA and VIB.—To a solution of 1 g. of isonupharamine (IV) in 10 ml. of ether, 0.5 g. of thionyl chloride in 5 ml. of ether was added slowly. After being kept at 40～50°C for 30 min., the reaction mixture was mixed with 10 ml. of water and 40 ml. of methanol ; it was then made basic potassium hydroxide. The mixture was refluxed for 2 hr. The precipitated inorganic salt was filtered off. The filtrate was made acidic with hydrochloric acid and evaporated in vacuo. Then the residue was neutralized and extracted with ether. The ether extract was dried and evaporated to give an oil (0.6 g.), which was dissolved in petroleum ether ; an insoluble substance (0.07 g.) was then filtered off. The chromatography of this petroleum ether solution on an alumina column (80 g.) resulted in the separation of the following fractions :

Fraction	Elute	Volume ml.	Weight g.
1	Petr. ether	100	0.02
2	Petr. ether	100	0.02
3	Petr. ether	100	0.01
4	Petr. ether : ether	100	0.39
5	Ether	100	0.07

Fraction 4 was rechromatographed on an alumina column (65 g.).

Fraction	Elute	Volume ml.	Weight g.
4-1	Petr. ether : ether (5%)	120	0
4-2	Petr. ether : ether (10%)	65	0.05
4-3	Petr. ether : ether (15%)	105	0.12
4-4	Petr. ether : ether (20%)	105	0.07
4-5	Petr. ether : ether (30%)	65	0.05
4-6	Ether	130	0.10

The infrared spectrum of fraction 4-2 was identical with that of natural deoxynupharidine. The optical rotation of this fraction showed $[\alpha]_D$ $-76.8°$ (*c* 5.6 in ethanol). The corresponding fraction of another run showed $[\alpha]_D$ $-97.11°$ (*c* 1.7 in ethanol), and the hydrochloride melted at 256~258°C (cf. natural deoxynupharidine: $[\alpha]_D$ $-109.86°$).

Found: C, 66.98; H, 8.91; N, 5.00. Calcd. for $C_{15}H_{23}ON$-HCl: C, 66.77; H, 8.97; N, 5.19%.

The infrared spectrum of fraction 4-3 was identical with that of *dl*-7(epi)-deoxynupharidine: $[\alpha]_D$ $-110°$ (*c* 1.06 in ethanol); the hydrochloride, m. p. 246~248°C.

Found: C, 66.50; H, 8.86; N, 5.22.

The authors wish to express their thanks to Dr. Kenichi Takeda and Dr. Kazuo Tori of the Shionogi Research Laboratory for his measurement of the NMR spectra. Part of the expenses for this study were defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

Compounds Related to Acridine. I. Condensation of Acridine Derivatives Having Active Methyl Group and Aromatic Nitroso Compounds*

By Otohiko TSUGE, Minoru NISHINOHARA and Masashi TASHIRO

(Received July 13, 1963)

The basic condensation of the active methylene or the methyl group and the aromatic nitroso compound in general has been known as the Ehrlich-Sachs reaction[1] and has been considered a useful synthetic route to the corresponding ketone or aldehyde. It has been established in recent years that this reaction is accompanied by an oxidative reaction to form the nitrone, besides the anil, as a by-product. It is also known that these two products are difficult to separate.

Recently,[2] we found that the reaction of 7-methyl-4, 5-dihydroindeno [1, 7-bc] acridine (I) with *p*-nitrosodimethylaniline did not take place in the presence of an alkaline catalyst (sodium carbonate, potassium carbonate or piperidine) ; on the other hand, the presence of a catalytic amount of a mineral acid, especially hydrochloric acid, afforded the nitrone compound in a fairly good yield, while only a small amount of the anil compound was formed.

The present investigation was undertaken in order to elucidate the role of hydrochloric acid (HA) as a condensation agent in the reaction of 9-methyl- (II), 2, 9-dimethyl- (III), 4, 9-dimethyl- (IV), 2-chloro-9-methyl- (V), 7-methylbenz [c] - (VI) or 12-methylbenz [a] acridine (VII), which are similar to I in their chemical structures, with several nitroso compounds : nitrosobenzene (VIII), *p*-nitrosodimethyl- (IX), *p*-nitrosodiethylaniline (X) and *p*-nitrosophenol (XI).

These compounds and their reaction products are depicted in Chart 1.

Although the reaction of II with nitroso compounds, especially IX, in the presence of an alkaline catalyst has been investigated by a number of workers, Chardonnens and Heinrich[3] first successfully separated and identified acridine-9-carboxaldehyde anils and *N*-(*p*-substituted phenyl)-α-(9-acridyl) nitrones ; the major product was found to be the anil in most cases.

On the other hand, only a little information has been available regarding the condensation of substituted 9-methylacridines or methylbenzacridines and the nitroso compound. Porai-Koshits and others[4] reported that a

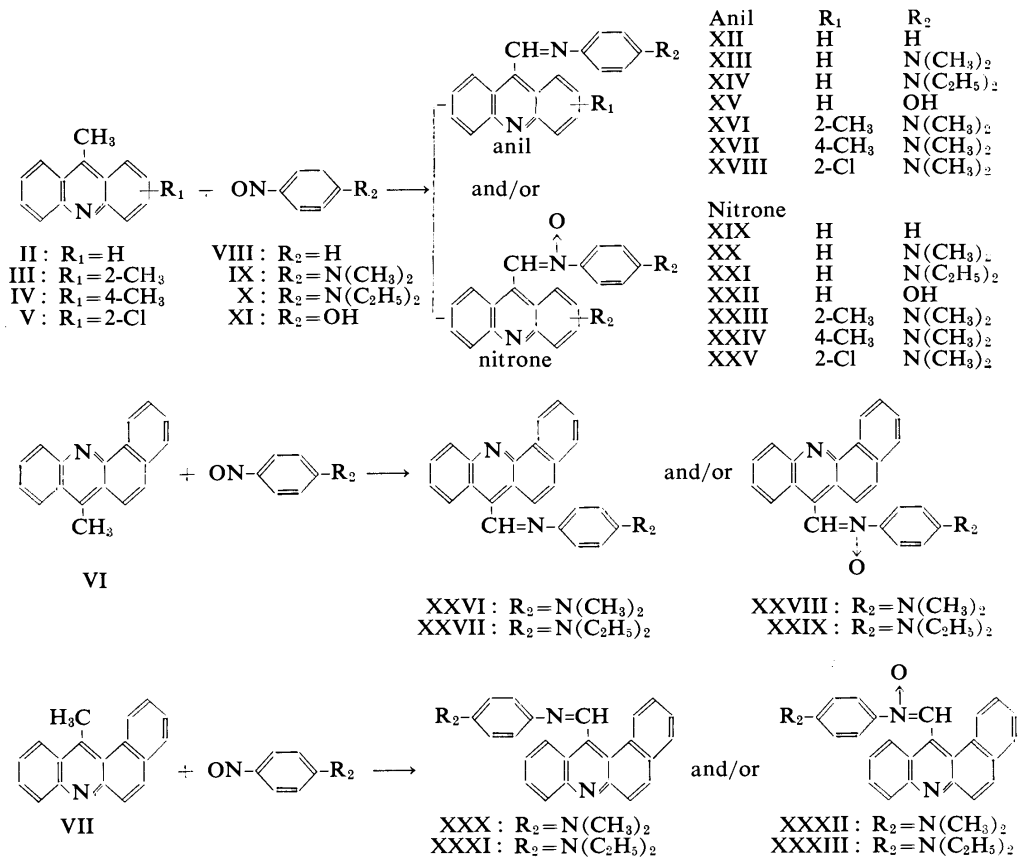

Chart 1

nitrone compound was formed by the reaction of the dimethylsulfate of VI with IX. It was reported by Mikhailov and Ter-Sarkisyan[5] that the condensation of III and IX with sodium carbonate or the ultraviolet illumination of a mixture of VII and the hydrochloride of IX in methanol gave the corresponding nitrone compounds in a poor yield.

Now, the addition of a small amount of HA in place of an alkaline catalyst to the reaction mixture of the acridine derivatives and nitroso compounds mentioned above in ethanol, revealed interesting results, as had been expected. In addition, this paper will also deal with the infrared spectra of the anil and nitrone compounds.

Results and Discussion

As the optimum conditions for obtaining a nitrone compound by the reaction of I with IX in the presesnce of HA had not been determined, in the reaction of II with IX the effect of reaction conditions on the yield of

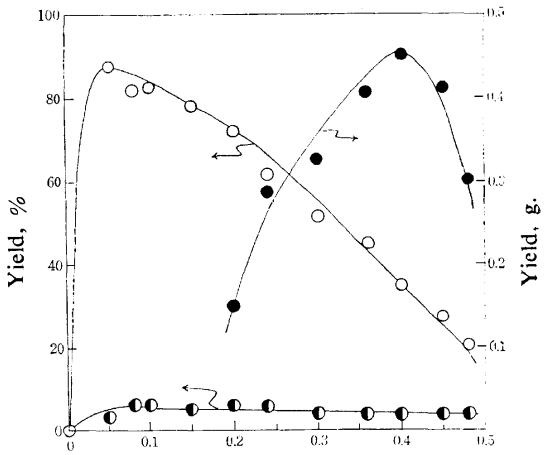

Fig. 1. Effect of hydrochloric acid.

Mixtures of II (1.0 g.) and IX (1.6 g.) in the presence of the specified amounts of HA (d^{27} 1.1748) in ethanol (50 ml.) were refluxed for 2 hr.

-○-○- Nitrone (XX)
-◐-◐- Anil (XIII)
-●-●- Higher melting compound (XXXIV)

5) B. M. Mikhailov and G. S. Ter-Sarkisyan, ibid., 1954, 656.

acridine-9-carboxaldehyde *N*-(*p*-dimethylaminophenyl)anil (XIII) or of *N*-(*p*-dimethylaminophenyl)-α-(9-acridyl)nitrone (XX) was first examined.

Effect of the Amount of Hydrochloric Acid.—The results are given in Fig. 1. In contrast with the condensation in the presence of sodium carbonate, the main product was the nitrone XX, whose yield was greatly affected by the amount of HA. The maximum yield of XX was obtained when the molar ratio of HA to II was about 0.08 (0.03 ml. in Fig. 1); its yield rapidly decreased with the increase in the amount of the HA. While the yield of the anil XIII was little affected by the HA, it was very poor.

On the other hand, if the molar ratio of HA to II was over about 0.5 (0.2 ml. in Fig. 1), the higher melting substance (XXXIV)[6] (m. p. over 300°C) began to be formed. When equimolecular amounts of II and of HA were used, the maximum yield of XXXIV was obtained. On the other hand, a large amount of a resinous material came to be formed as the amount of the HA increased.

Effect of the Reaction Time.—The effects of the reaction time on the yields of XIII and XX in the presence of HA or sodium carbonate are shown in Fig. 2. It is clear that HA greatly accelerated the rate of the condensation of II and IX in comparison with sodium carbonate, and that the nitrone XX was formed in a good yield in a short while. In the case of sodium carbonate, more of the anil XIII was obtained than of the nitrone XX, but both yields were very poor, as had been reported by Chardonnens and Heinrich.[3]

Effect of the Amount of *p*-Nitrosodimethylaniline (IX).—The results are given in Table I. The treatment of II with two or three molecular amounts of IX afforded the nitrone XX in an excellent yield. In particular, it is to be emphasized that even when an equimolecular amount of IX was used, XX was formed in a fairly good yield.

Table I. Effect of the amount of IX*

IX**	Product, %	
	Anil (XIII)	Nitrone (XX)
1	4.1	74.8
2	5.0	85.3
3	4.5	90.0

* Mixtures of II (1.0 g.) and the specified amounts of IX in the presence of HA (0.05 ml., d^{27} 1.1748) in ethanol (50 ml.) were refluxed for 3 hr.
** Moles per mole II

Kröhnke and his co-workers[7,8] have suggested the mechanism for the formation of the anil and nitrone in the presence of an alkaline catalyst depicted in Chart 2:

$$R\text{-}CH_3 + ON\text{-}R' \longrightarrow$$

$$R\text{-}CH_2\text{-}\underset{\displaystyle OH}{\underset{|}{N}}\text{-}R' \text{-(A)-} \begin{cases} \xrightarrow{-H_2O} R\text{-}CH{=}N\text{-}R' \\ \xrightarrow{-H_2} R\text{-}CH{=}\overset{\displaystyle O}{\hat{N}}\text{-}R' \end{cases}$$

Chart 2

That is, the aldol-type intermediate (A) is formed by the condensation of active methyl and the nitroso compound, and the dehydration of the intermediate (A) chiefly proceeds to give the anil. Simultaneously, the nitrone compound is formed as a by-product by the dehydrogenation. The dehydrogenation is mainly ascribed to the oxidative property of the nitroso compound according to the following scheme:

$$R\text{-}CH_2\text{-}\underset{\displaystyle OH}{\underset{|}{N}}\text{-}R' + 2\ ON\text{-}R' \longrightarrow R\text{-}CH{=}\overset{\displaystyle O}{\hat{N}}\text{-}R' + R'\text{-}N{=}\overset{\displaystyle O}{\hat{N}}\text{-}R'$$

Furthermore, they proposed that the intermediate (A) may be dehydrogenated in a certain degree by air, and that the corresponding phenylhydroxylamine, which is yielded by the reduction of the nitroso compound, is disproportionate to the original nitroso compound and aniline derivative: $2R'\text{-}NO + H_2 \rightarrow 2R'\text{-}NHOH \rightarrow R'\text{-}NO + R'\text{-}NH_2$.

According to this mechanism, at least two moles of the nitroso compound are needed to form one mole of the nitrone compound.

* Moles per mole II

** Data with sodium carbonate as a catalyst were quoted from Ref. 3.

*** Yields based on II and a plus-sign, +, means a small amount.

However, the fact that the nitrone XX was obtained in a good yield, even if an equimolecular amount of IX was used, as Table I shows, does not appear to be explained by Kröhnke's mechanism. The mechanism will be considered elsewhere in the near future.

Effect of the Substituent in Aromatic Nitroso Compounds.—Chardonnens and Heinrich[3] also reported that the kind of aromatic nitroso compound affected the relative amounts of the products, the anil and the nitrone. As has been described above, contrary to the case of sodium carbonate, the nitrone XX was chiefly afforded when the mixture of II and IX with a catalytic amount of HA in ethanol was refluxed. Accordingly, it seemed of interest to clarify the variation in the relative amounts of the anil and of the nitrone when the condensations of II and several nitrosobenzenes VIII—XI were carried out in the presence of a catalytic amount of HA in a boiling ethanol solution. The results are summarized in Table II.

Table II shows interesting features regarding the relative amounts of the anil and of the nitrone compound. In the treatment of II and nitrosobenzene (VIII) with sodium carbonate, *N*-phenyl-α-(9-acridyl)nitrone (XIX) was obtained as a major product in place of acridine-9-carboxaldehyde *N*-phenylanil (XII). On the other hand, when HA was used the product ratio of these two compounds was reversed, and the anil XII was formed as the main product.

As has been mentioned above, IX reacted with II in the presence of HA to give the nitrone compound in an excellent yield. The condensation of II and *p*-nitrosodiethylaniline (X) with HA or sodium carbonate afforded acridine-9-carboxaldehyde *N*-(*p*-diethylaminophenyl)anil (XIV) as the major product. In the case of the former, however, *N*-(*p*-diethylaminophenyl)-α-(9-acridyl)nitrone (XXI) was also formed in a fairly large amount.

Drozdov and Yavorskaya[9] have reported that the condensation of II and *p*-nitrosophenol (XI) with sodium carbonate leads to the formation of *N*-(*p*-hydroxyphenyl)-α-(9-acridyl)-nitrone (XXII) (m. p. 230~231°C) in a 60% yield. We carried out the reaction of II with XI in the presence of HA or potassium carbonate as a condensation agent; acridine-9-carboxaldehyde *N*-(*p*-hydroxyphenyl)anil (XV) (m. p. 275°C) or the nitrone compound (XXII) (m. p. 235°C (decomp.)) was obtained in a 82.3 or a 47.1% yield respectively. The melting point of the anil XV reported by Drozdov and Yavorskaya[9] was 225°C (decomp.), but XV prepared by the condensation of acridine-9-carboxaldehyde and *p*-aminophenol melted at 275°C.

Reaction of Other Acridines with Nitroso Compounds. — We have attempted to clarify the relation between the effect of HA and sodium carbonate on the condensation of other acridines and nitroso compounds. It has been reported that the treatment of 2, 9-dimethylacridine (III) with IX in the presence of sodium carbonate in boiling methanol for 5 hr. afforded *N*-(*p*-dimethylaminophenyl)-α-(2-methyl-9-acridyl)nitrone (XXIII) in about a 26% yield.[5] We carried out the reaction of III with IX in the presence of HA or sodium carbonate in boiling ethanol. In the case of HA, 2-methylacridine-9-carboxaldehyde *N*-(*p*-dimethylaminophenyl)anil (XVI) was obtained in a good yield, but XXIII, in only a trace amount. As reported by Mikhailov and Ter-Sarkisyan,[5] in the presence of sodium carbonate only the nitrone XXIII was obtained in a poor yield.

4, 9-Dimethyl- (IV) or 2-chloro-9-methylacridine (V), treated with IX in the presence of HA, condensed to afford 4-methylacridine- (XVII) or 2-chloroacridine-9-carboxaldehyde *N*-(*p*-dimethylaminophenyl)anil (XVIII) in a fairly

TABLE III. CONDENSATION OF OTHER ACRIDINES AND NITROSO COMPOUNDS

Acridine	Nitroso* compound	Catalyst	Reaction time, hr.	Anil	Product** Yield, %	Nitrone	Yield, %
III	IX	HCl	3	XVI	77.4	XXIII	+
III	IX	Na_2CO_3	3	XVI	—	XXIII	22.2
IV	IX	HCl	3	XVII	36.6	XXIV	44.9
IV	IX	Na_2CO_3	3	XVII	—	XXIV	15.2
V	IX	HCl	3	XVIII	54.8	XXV	37.7
V	IX	Na_2CO_3	3	XVIII	43.6	XXV	+
VI	IX	HCl	3	XXVI	15.5	XXVIII	14.6
VI	X	HCl	3	XXVII	37.4	XXIX	—
VII	IX	HCl	1	XXX	+	XXXII	82.6
VII	X	HCl	1	XXXI	—	XXXIII	61.5

* Two moles per mole acridine compounds were used.

** Yields based on acridines and a plus-sign, +, means a trace amount.

good yield; the corresponding nitrone, *N*-(*p*-dimethylaminophenyl)-α-(4-methyl-9-acridyl)-(XXIV) or *N*-(*p*-dimethylaminophenyl)-α-(2-chloro-9-acridyl)nitrone (XXV), was also produced. However, the basic condensation of IV or V with IX afforded only the nitrone XXIV or anil XVIII respectively in a low yield.

The methylbenzacridines VI—VII, as well as I, did not react with IX or X in the presence of an alkaline catalyst, but they did react to give the anil and/or nitrone with HA. In the condensation of VI and IX, benz[c]acridine-7-carboxaldehyde *N*-(*p*-dimethylaminophenyl)anil (XXVI) and *N*-(*p*-dimethylaminophenyl)-α-(7-benz[c]acridyl) nitrone (XXVIII) were obtained in almost the same yield, but both yields were poor. However, VI with X reacted to give only the corresponding anil, benz[c]acridine-7-carboxaldehyde *N*-(*p*-diethylaminophenyl)anil (XXVII).

On the other hand, VII with IX or X smoothly reacted to afford the nitrone, *N*-(*p*-dimethylaminophenyl)- (XXXII) or *N*-(*p*-diethylaminophenyl)-α-(12-benz[a]acridyl)nitrone (XXXIII) respectively, in a fairly good yield, although the corresponding anil was not formed. These results are summarized in Table III.

Mikhailov and Ter-Sarkisyan[10] have reported that the order of the reactivity of the methyl component in the reaction with *m*-nitrobenzaldehyde was as follows: II>VI>VII; 4-picoline>4-quinaldine>1-methylbenzo[f]quinoline>4-methylbenzo[h]quinoline.

When the reactivity of the methyl group in VI and VII in the reaction with IX or X is compered, the latter is greater than the former. This seems to be the same as with the relationship of benzoquinoline derivatives mentioned above; it shows that the steric factor alone is not always predominate.

The structure assignments of all anils and nitrones described above were made on the basis of the infrared spectra as well as of elemental analyses.

Furthermore, all the anils or nitrones were almost quantitatively hydrolyzed to afford the corresponding formyl derivatives, which formed the anils by condensation with anilines.

Infrared Spectra of the Anils and Nitrones.— The infrared spectra of the above-mentioned anils and nitrones were measured in Nujol mull; the characteristic absorption bands for the C=N bond of the Schiff base type and for the *N*-oxide group were thus established. The observed frequencies are summarized in Table IV. The spectra of the anil XIII and nitrone XX as one example are shown in Fig. 3. In general, the C=N stretching frequency in the nitrone compounds was observed at a lower frequency region than that in the anil compounds; this shows that the double-bond

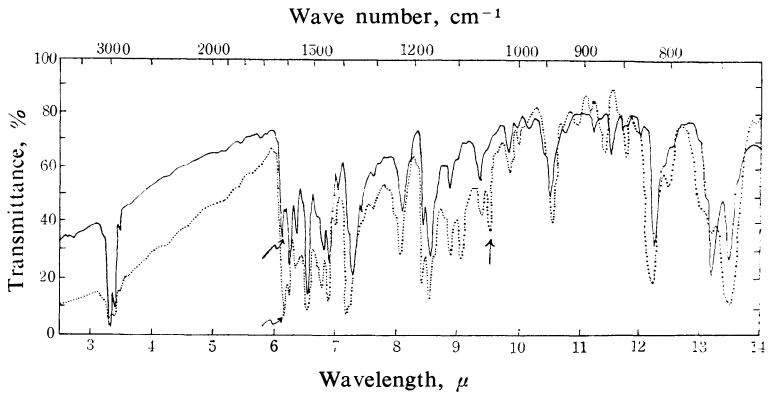

Fig. 3. Infrared spectra of the anil (XIII) and nitrone (XX) in Nujol mull.
—— (XIII), ···· (XX)

character of C=N in the former is smaller than that in the latter, as was expected.

In all nitrone compounds, the moderate absorption band always appeared around 1050 cm^{-1}. The N–O stretching frequency in aliphatic tertiary amine *N*-oxides,[11] aromatic nitroso compounds[12] or pyridine *N*-oxides[13] is assigned to the region of 950, 1380~1340 or 1200~1300 cm^{-1} respectively.

Since the N–O bond in the above-mentioned nitrone compounds is considered by mesomerism to have a greater double-bond character than that in aliphatic tertiary amine *N*-oxides and a smaller one than that in aromatic nitroso compounds or pyridine *N*-oxides, it is expected that the N–O band of the present nitrones will appear at a higher frequency region than that of aliphatic *N*-oxides and at a lower region than the aromatics.

Consequently, it seems to be appropriate for the observed band at around 1050 cm^{-1} to be assigned to the N–O streching frequency in the nitrone compounds.

Experimental[14]

Preparation of Methylacridines II—VII.—The reaction conditions in the preparation of 9-methylacridine (II) by the Bernthsen method were examined.[15] It was found that the yield of II became better as the amount of zinc chloride increased and that the following procedure afforded II in a fairly good yield in spite of the relatively short reaction time.

A mixture of diphenylamine (10.0 g.) and glacial acetic acid (10 ml.) in the presence of anhydrous zinc chloride (40.0 g.) was heated to 220°C, while being stirred; the excess acetic acid was thus evaporated, and the mixture was then held at 220~230°C for 6 hr. The reaction mixture was digested with hot 10% aqueous sulfuric acid and then strongly alkalified with concentrated aqueous ammonia to dissolve zinc chloride. The insoluble residue was extracted with benzene and, after separation, the benzene layer was extracted again with 10% aqueous sulfuric acid. The extract with dilute sulfuric acid was alkalified by the addition of aqueous ammonia, upon which yellow crystals separated out. Filtration gave 10.0 g. (87.5%) of crude II (m. p. 103~110°C), which on chromatography on alumina and then recrystallization from petroleum benzine afforded pale yellow needles (m.p. 118~118.5°C) (reported, 117~118°C[16]). (Found: C, 87.02; H, 5.71; N, 7.60%).

According to this procedure, the following acridines were prepared from the corresponding diarylamine, 2-methyl-, 4-methyl-, 2-chlorodiphenylamine, 1-phenyl- or 2-phenylnaphthylamine; 2, 9-dimethylacridine (III): pale yellow needles (from petroleum benzine), m. p. 89.5~90°C (reported, 90°C[16]). Yield, 45.5%. (Found: C, 86.62; H, 6.44; N, 6.86 %). 4, 9-Dimethylacridine (IV): pale yellow needles (from petroleum benzine), m. p. 53.5~54°C. Yield, 51.2%.

Found: C, 86.51; H, 6.03; N, 6.72. Calcd. for $C_{15}H_{13}N$: C, 86.92; H, 6.33; N, 6.76%.

2-Chloro-9-methylacridine (V): pale yellow needles (from petroleum benzine), m. p. 124~125°C (reported, 124°C[17]). Yield, 71.5%. (Found: C, 73.92; H, 4.50; N, 6.18%). 7-Methylbenz[c]acridine (VI): pale yellow scales (from benzene), m. p. 124~125°C (reported, 125.5°C[4]). Yield, 68.4%. (Found: C, 88.76; H, 5.09; N, 5.98%). 12-Methylbenz[a]acridine (VII): pale yellow scales (from benzene), m. p. 144~145°C (reported, 144~145°C[18]). Yield,

17) A. Campbell et al. have reported that they obtained V by the reaction of 2, 9-dichloroacridine with ethyl sodiomalonate (*J. Chem. Soc.*, **1958**, 1145).
18) A. E. Porai-Koshits and G. S. Ter-Sarkisyan, *Izvest. Akad. Nauk S. S. S. R., Otdel. Khim. Sci.*, **1951**, 771. VI or VII was prepared by the reaction of the corresponding diarylamine with acetic anhydride in a 48.8 or a 26.8% yield respectively.

83.7%. (Found: C, 88.95; H, 5.21; N, 5.80%).

Reaction of 9-Methylacridine (II) with Nitrosobenzene (VIII).—To a solution of II (1.0 g.) and VIII (1.1 g.) dissolved in ethanol (50 ml.), HA (0.03 ml.) was added.[19] The resultant solution was refluxed on a water bath and, after one hour, additional VIII (0.5 g.) was placed into the reaction mixture: it was then refluxed for another hour. A large part of the ethanol was evaporated in vacuo, and the residue was allowed to stand overnight. Filtration gave the anil (XII) (0.52 g.) as yellowish brown crystals; m. p. 158~160°C. The filtrate was evaporated to dryness, and the residue obtained was dissolved in benzene. The benzene solution was chromatographed on alumina to separate XII (0.18 g.) (m. p. 159~160°C) and the nitrone (XIX) (m. p. 200°C (decomp.)) in a small amount. The combined anil (XII) was recrystallized from ethanol to give yellow scales; m. p. 161.5°C (reported, 163°C[3]). This compound was identical with the authentic substance which had been prepared by the condensation of acridine-9-carboxaldehyde (XXXV) and aniline. (Found: C, 85.15; H, 5.06; N, 9.88%). The recrystallization of the crude nitrone from ethanol afforded yellow prisms; m. p. 227°C (decomp.) (reported, 220°C (decomp.)). (Found: C, 80.04; H, 4.88; N, 9.45%).

Reaction of II with *p*-Nitrosodimethylaniline (IX).—To a solution of II (1.0 g.) and IX (1.6 g.) in ethanol (50 ml.), HA (0.2 ml.) was added. The refluxing of the reaction mixture resulted in the precipitation of reddish brown crystals in several minutes. After having been refluxed for 2 hr., the mixture was allowed to stand overnight. Filtration gave reddish brown crystals (1.39 g.) which, on washing with hot benzene (5ml.×2), left the nitrone (XX) (1.26 g.) (m. p. 240°C (decomp.)). Recrystallization from a large amount of benzene afforded reddish brown prisms; m. p. 243°C (decomp.) (reported, 243°C (decomp.)[3]). (Found: C, 77.90; H, 5.83; N, 12.31%). The benzene washings were evaporated to give a small amount of the anil (XIII) as red crystals which, on recrystallization from ethanol, afforded red prisms; m. p. 248°C (reported, 248°C[3]). (Found: C, 80.98; H, 5.86; N, 13.01%). The ethanol filtrate after reaction was concentrated in vacuo and then cooled to give 0.15 g. of a higher melting compound (XXXIV); m. p. over 300°C. (Found: C, 79.39, 79.29; H, 4.78, 4.71; N, 7.31, 7.71%).

The results of other reactions under varying conditions are shown in Figs. 1 and 2 and Table I.

Reaction of II with *p*-Nitrosodiethylaniline (X).—A solution of II (1.0 g.), X (1.7 g.) and HA (0.03 ml.) in ethanol (50 ml.) was refluxed for 2 hr. After a large part of the ethanol had been evaporated in vacuo, filtration afforded brown crystals (1.2 g.). The crystals were washed with 15 ml. and then with 5 ml. of hot benzene to leave 0.5 g. of the nitrone XXI, which, on recrystallization from ethanol, gave orange prisms (m. p. 207~208°C (decomp.)) (reported, 208°C (decomp.)[3]). (Found: 77.94; H, 6.30; N, 11.37%). The benzene washings were evaporated to give the anil XIV (0.4 g.), which, on recrystallization from ethanol, afforded dark violet prisms (m. p. 168~169°C (reported, 165°C[3])). (Found: C, 81.38; H, 6.66; N, 11.90%).

Reaction of II with *p*-Nitrosophenol (XI).—*With HA.*—A solution of II (1.0 g.), XI (1.3 g.) and HA (0.03 ml.) in ethanol (50 ml.) was refluxed for 3 hr. After the mixture had stood overnight, filtration afforded dark brown crystals (1.21 g.); m. p. 265~269°C. Recrystallization from chlorobenzene gave brown plates; m. p. 274~275°C. This compound was proved, by the admixed m. p. and by the infrared spectrum, to be identical with the anil (XV) (m. p. 275°C (reported, 225°C (decomp.)[9])) which was obtained from the condensation of the aldehyde XXXV and *p*-aminophenol.

Found: C, 80.20; H, 4.93; N, 9.24. Calcd. for $C_{20}H_{14}ON_2$: C, 80.52; H, 4.73; N, 9.39%.

With Potassium Carbonate.—The similar reaction of II (0.55 g.) with XI (0.7 g.) in the presence of potassium carbonate (40 mg.) in ethanol (30 ml.) gave 0.42 g. of the nitrone (XXII), which, on recrystallization from chlorobenzene, afforded dark yellowish green scales (m. p. 235°C (decomp.)) (reported, 230~231°C[9]).

Found: C, 75.99; H, 4.65; N, 9.09. Calcd. for $C_{20}H_{14}O_2N_2$: C, 76.42; H, 4.49; N, 8.91%.

Reaction of 2,9-Dimethylacridine (III) with IX.—A mixture of III (0.5 g.), IX (0.7 g.) and HA (0.02 ml.) in ethanol (50 ml.) was refluxed for 3 hr. and then allowed to stand overnight. Filtration gave crystals which, on being washed with hot benzene (5 ml.×8), left 30 mg. of red crystals; m. p. 217~219°C (decomp.). Recrystallization from chlorobenzene afforded red prisms of the nitrone (XXIII) (m. p. 220°C (decomp.)) (reported, 224~225°C[5]).

Found: C, 77.47; H, 5.70; N, 12.04. Calcd. for $C_{23}H_{21}ON_3$: C, 77.72; H, 5.96; N, 11.82%.

The benzene washings were evaporated in vacuo to give red crystals (0.65 g.), which, on recrystallization from benzene, afforded dark red prisms (m. p. 223°C). This compound was identical with the anil XVI obtained by the condensation of aldehyde XXXVI and *p*-dimethylaminoaniline, as will be mentioned below.

Found: C, 81.48; H, 6.53; N, 12.07. Calcd. for $C_{23}H_{21}N_3$: C, 81.39; H, 6.24; N, 12.38%.

In the presence of concentrated aqueous sodium carbonate (4 drops) in place of HA, the same reaction afforded the nitrone (0.19 g.).

2-Methylacridine-9-carboxaldehyde (XXXVI).—A mixture of XXIII (0.5 g.) in 12% aqueous hydrochloric acid (10 ml.) was heated on a water bath for 30 min. After the mixture had cooled, the precipitated crystals were filtrated and washed with aqueous ammonia. Yield, 0.295 g. (94.8%); m. p. 137~139°C. Recrystallization from the benzene-petroleum benzine mixture gave the aldehyde (XXXVI) as orange needles; m. p. 145°C (reported, 136~138°C[5]).

Found: C, 81.50; H, 5.23; N, 6.48. Calcd. for $C_{15}H_{11}ON$: C, 81.43; H, 5.01; N, 6.33%.

A mixture of XXXVI (0.1 g.), *p*-dimethylaminoaniline (0.1 g.) and acetic acid (1 drop) in ethanol

19) HA used in this experiment: d^{17} 1.1748.

(10 ml.) was refluxed for 2 hr. After the mixture had cooled, filtration afforded 0.14 g. (90.0%) of the anil XVI as dark red prisms (m. p. 223°C).

Reaction of 4, 9-Dimethylacridine (IV) with IX.—The similar treatment of IV (1.0 g.), IX (1.5 g.) and HA (0.03 ml.) in ethanol (50 ml.) gave benzene-soluble dark red crystals (0.61 g.) (m. p. 188~189°C) and benzene-insoluble orange crystals (0.75 g.) (m. p. 204~205°C (decomp.)). The recrystallization of the former from benzene afforded dark red prisms; m. p. 188~189°C. This compound was proved, by the admixed m. p. and infrared spectrum, to be identical with the anil XVII prepared by the condensation of the corresponding aldehyde XXXVIII and *p*-dimethylaminoaniline, as will be described below.

Found: C, 81.48; H, 6.53; N, 12.07. Calcd. for $C_{23}H_{21}N_3$: C, 81.39; H, 6.24; N, 12.38%.

The latter was recrystallized from chlorobenzene to afford orange plates (m. p. 207~208°C (decomp.)), whose infrared spectrum and elemental analyses showed the nitrone XXIV.

Found: C, 77.73; H, 5.99; N, 11.81. Calcd. for $C_{23}H_{21}ON_3$: C, 77.72; H, 5.96; N, 11.82%.

The reaction of IV (0.5 g.) with IX (0.75 g.) in the presence of concentrated aqueous sodium carbonate (4 drops) in ethanol (25 ml.) afforded 0.13 g. of the nitrone XXIV (m. p. 207~208°C (decomp.)).

4-Methylacridine-9-carboxaldehyde (XXXVIII).—The hydrolysis of 0.5 g. of the mixture of the anil XVII and nitrone XXIV obtained above with 12% aqueous hydrochloric acid (10 ml.) afforded the aldehyde XXXVIII (0.27 g.) (m. p. 112~113°C), which, on recrystallization from petroleum benzine, gave yellow needles (m. p. 114°C).

Found: C, 81.51; H, 5.34; N, 6.55. Calcd. for $C_{15}H_{11}ON$: C, 81.43; H, 5.01; N, 6.33%.

The anil XVII (m. p. 189°C) was quantitatively obtained by a condensation of the aldehyde XXXVIII and *p*-dimethylaminoaniline similar to that in the case of XXXVII.

Reaction of 2-Chloro-9-methylacridine (V) with IX.—A mixture of V (1.0 g.), IX (1.32 g.) and HA (0.03 ml.) in ethanol (50 ml.) was refluxed for 3 hr. After the mixture had stood overnight, the obtained crystals were dissolved in hot chlorobenzene (100 ml.). After they had cooled, filtration gave orange scales (0.62 g.) (m. p. 230°C (decomp.)), which, on recrystallization from chlorobenzene, showed a m. p. of 235°C (decomp.). This compound was confirmed as the nitrone XXV from the infrared spectrum and elemental analyses.

Found: C, 70.25; H, 5.14; N, 11.25. Calcd. for $C_{22}H_{18}ON_3Cl$: C, 70.30; H, 4.83; N, 11.18%.

The filtrate was evaporated in vacuo to give dark red crystals (0.86 g.), which, on recrystallization from chlorobenzene, showed a m. p. of 207~208°C. This compound was identical with the anil XVIII prepared from the corresponding aldehyde XXXIX and *p*-dimethylaminoaniline.

Found: C, 73.35; H, 5.23; N, 11.49. Calcd. for $C_{22}H_{15}N_3Cl$: C, 73.43; H, 5.04; N, 11.68.

The similar reaction of V (0.5 g.) with IX (0.66 g.) in the presence of concentrated aqueous sodium carbonate (4 drops) afforded the anil (0.34 g.) (m. p. 202~204°C), and a small amount of the nitrone.

2-Chloroacridine-9-carboxaldehyde (XXXIX).—The hydrolysis of 0.5 g. of the above mixture of the anil and nitrone with 12% aqueous hydrochloric acid gave 0.31 g. of the aldehyde XXXIX (m. p. 162~163°C), which, on recrystallization from petroleum benzine, afforded yellow needles (m. p. 169°C).

Found: C, 69.72; H, 3.35; N, 5.88. Calcd. for $C_{14}H_9ONCl$: C, 69.58; H, 3.34; N, 5.80%.

The condensation of XXXIX and *p*-dimethylaminoaniline similar to that in the case of XXXVII afforded the anil XVIII (m. p. 209°C) quantitatively.

Reaction of 7-Methylbenz[c]acridine (VI) with Nitroso Compound.—*With IX.*—To a solution of VI (2.0 g.) and IX (2.5 g.) in ethanol (70 ml.), HA (2 drops) was added, and the mixture was refluxed for 3 hr. After the mixture had stood overnight, filtration gave yellowish brown crystals (0.47 g.) (m. p. 220~228°C (decomp.)), which, on recrystallization from benzene, afforded the nitrone XXVIII as orange prisms (m. p. 240°C (decomp.)) (reported, 236~237°C (decomp.)[4]). (Found: C, 79.68; H, 5.40; N, 10.56%). The filtrate was evaporated to give a resinous material, which was then dissolved in benzene. The benzene solution was chromatogaphed on alumina to separate unreacted VI (0.79 g.) and red crystals (0.48 g.) (m. p. 188~197°C). The latter was recrystallized from benzene to give the anil XXVI as red prisms (m. p. 214~215°C).

Found: C, 83.24; H, 5.88; N, 11.24. Calcd. for $C_{26}H_{21}N_3$: C, 83.17; H, 5.64; N, 11.19%.

With X.—The similar treatment of VI (1.0 g.) with X (1.25 g.) in the presence of HA (1 drop) in ethanol (50 ml.) afforded unchanged VI and red crystals (0.61 g.) (m. p. 156~160°C), which, on recrystallization from ethanol, showed a m. p. of 167~168°C and appeared as red prisms. This red compound was proved to be the anil XXVII by its elemental analyses and infrared spectrum.

Found: C, 83.11; H, 6.23; N, 10.36. Calcd. for $C_{28}H_{25}N_3$: C, 83.34; H, 6.22; N, 10.41%.

Reaction of 12-Methylbenz[a]acridine (VII) with a Nitroso Compound.—*With IX.*—A solution of VII (1.0 g.) and IX (1.24 g.) in a mixture of ethanol (50 ml.) and HA (1 drop) was refluxed for 1 hr. After the mixture had cooled, filtration gave yellow needles (1.33 g.) (m. p. 234°C (decomp.)), which, on recrystallization from *o*-dichlorobenzene, showed a m. p. of 235°C (decomp.). This compound was proved to be the nitrone XXXII by its elemental analytical values and infrared spectrum.

Found: C, 79.62; H, 5.70; N, 10.75. Calcd. for $C_{26}H_{21}ON_3$: C, 79.77; H, 5.41; N, 10.73%.

The filtrate was then evaporated, and the residue was dissolved in benzene. The benzene solution was chromatographed on alumina to afford red prisms (m. p. 168~169°C) in a small amount. This compound was proved to be the anil XXX by its elemental analyses and infrared spectrum.

Found: C, 83.09; H, 5.60; N, 11.23. Calcd. for $C_{26}H_{21}N_3$: C, 83.17; H, 5.67; N, 11.19%.

With X.—A mixture of VII (1.0 g.), X (1.25 g.) and HA (1 drop) in ethanol (50 ml.) was heated

under reflux for 1 hr. After the reaction mixture had been concentrated in vacuo, filtration afforded yellow crystals (1.12 g.) (m. p. 204~205°C (decomp.)), which, on recrystallization from ethanol, gave yellow needles (m. p. 208~209°C (decomp.)). This compound was the nitrone XXXIII.

Found: C, 79.93; H, 5.89; N, 10.26. Calcd. for $C_{28}H_{25}ON_3$: C, 80.14; H, 6.00; N, 10.02%.

The authors are deeply grateful to Messrs. H. Matsui and K. Hikida of the Institute of Pharmaceutical Sciences of this university for their measurement of the infrared spectra, and to the staff of the Analytical Service Centre of this university for their elemental analyses.

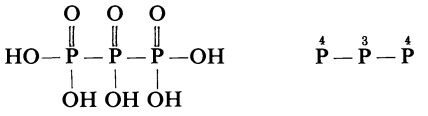
The Ultraviolet Absorption Spectra and the Hydrolysis of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-Acid[1]

By Norimasa YOZA and Shigeru OHASHI

(Received July 15, 1963)

It is well known that the popular and fundamental oxo acids of phosphorus, i. e., hypophosphorous, phosphorous, hypophosphoric, orthophosphoric, and condensed phosphoric acid, do not show any remarkable absorption in the ultraviolet wavelength region of 220~400 mμ. However, in the course of a systematic spectrophotometric study of the oxo acids of phosphorus, the authors found that some of the compounds which contain P–P linkages exhibit absorption spectra in that ultraviolet region. One of them is the oxo acid of phosphorus with lower oxidation numbers, which has the following structural formula and which is represented by the abbreviated formula indicated below (A chemical name has not yet been given to this acid):



Acid form Abbreviated formula

The present investigation revealed that the absorption spectra of the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid vary remarkably with the pH of the solution and that this variation of the spectra can be explained in connection with a pH titration curve of this acid reported by Blaser and Worms.[2]

Blaser and Worms performed the hydrolysis of the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid in nitric acid solutions; its rates were measured by means of iodometric and bromometric titrations. In the present investigation, the hydrolysis of this acid was carried out in perchloric acid solutions in order to minimize the hindrance arising from the complex formation between an acid as a medium and metal ions, a formation of which will be encountered in a future study concerning the effect of the metal ions on the hydrolysis of the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid. The rates of its hydrolysis were readily determined by the ultraviolet spectrophotometric method. By the present investigation it was found that the rate constant of the hydrolysis of the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid increases linearly with the activity of perchloric acid.

Experimental

Materials.—The salts* of $\overset{1}{P}$-, $\overset{3}{P}$-, $\overset{5}{P}$-, and $\overset{5}{P}\text{-O-}\overset{5}{P}$-acid were commercial reagents, while the salts* of $\overset{3}{P}\text{-O-}\overset{3}{P}$, $\overset{2}{P}\text{-}\overset{4}{P}$-, $(\text{-}\overset{3}{P}\text{-})_6$-ring, $\overset{3}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}$-, $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-, $\overset{3}{P}\text{-O-}\overset{5}{P}$-, $\overset{4}{P}\text{-}\overset{4}{P}$-, $(\text{-}\overset{4}{P}\text{-}\overset{4}{P}\text{-O-})_2$-ring, $\overset{4}{P}\text{-}\overset{4}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}$-, and $\overset{5}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}$-acid were supplied by Blaser and Worms.

Buffer Solutions. — The pH of the solutions was adjusted with perchloric acid, citric acid, sodium acetate, sodium monohydrogen orthophosphate, sodium dihydrogen orthophosphate, sodium tetraborate decahydrate, sodium carbonate, and sodium hydroxide.[3]

1) Abbreviated formulas of this kind have been proposed by Blaser and Worms. The Arabic numerals attached to the phosphorus atoms represent their oxidation numbers. See B. Blaser and K.-H. Worms, *Z. anorg. u. allgem. Chem.*, **300**, 225 (1959).

2) B. Blaser and K.-H. Worms, ibid., **300**, 250 (1959).

* The chemical formulas of these salts were shown in a previous paper; cf. Ref. 4.

3) R. A. Robinson, "The Structure of Electrolytic Solutions," John Wiley & Sons Inc., New York (1959), p. 253.

The Measurement of Absorbances. — The measurement of absorbances was carried out with a Shimadzu photoelectric spectrophotometer QB-50 with 1.00 cm. silica cells. In order to keep the cell temperature constant, water of a constant temperature was circulated into a cell mount.

The Determination of the Rate Constants. — Hydrolytic reactions were started by mixing perchloric acid solutions and sample solutions, both of which had been preequilibrated thermally in a constant-temperature bath. The rate constants were calculated from the data obtained by measuring the decrease of the absorbances at 215 mμ with time.

Paper Chromatography and Colorimetry.—The ascending technique was employed for paper chromatographic identification[4] of reaction products. ^{3}P- and ^{4}P-^{4}P-acid were determined colorimetrically with a molybdenum(V)-molybdenum(VI) reagent.[5]

Results and Discussion

There have been no studies of the ultraviolet absorption spectra of oxo acids of phosphorus, especially of the lower oxo acids of phosphorus, which have been recently discovered. Therefore, it was first tested whether any of the oxo acids of phosphorus in aqueous solutions give absorption spectra in the ultraviolet region of 220~400 mμ. It was verified that, of ^{1}P-, ^{3}P-, ^{3}P-O-^{3}P-, ^{2}P-^{4}P-, ^{3}P-O-^{4}P-^{4}P-, ^{3}P-O-^{5}P-, ^{4}P-^{4}P-, ^{4}P-^{4}P-O-)$_2$-ring, ^{4}P-^{4}P-O-^{4}P-^{4}P-, ^{5}P-O-^{4}P-^{4}P-, ^{5}P-, and ^{5}P-O-^{5}P-acid in aqueous solutions none afford any ultraviolet absorption spectra. However, it was found that ^{4}P-^{3}P-^{4}P- and (-^{3}P-)$_6$- ring acid in aqueous solutions show characteristic absorption spectra in the ultraviolet region. It may be possible to analyze the ^{4}P-^{3}P-^{4}P- or (-^{3}P-)$_6$- ring acid quantitatively or qualitatively in the presence of other oxo acids of phosphorus by means of the ultraviolet absorption spectra. It is interesting to note that both of these acids have more than two P-P linkages in their structures.

In this paper only the absorption spectra of the ^{4}P-^{3}P-^{4}P-acid will be discussed. As for the (-^{3}P-)$_6$-ring acid, there are two maxima at 206 and 221 mμ in its absorption spectrum when the pH of the solution is 6.7. For the complete explanation of the absorption spectra of this acid, however, further investigation is required.

The Absorption Spectra of ^{4}P-^{3}P-^{4}P-Acid.—The absorption spectra of the ^{4}P-^{3}P-^{4}P-acid were measured at various pH values. As Figs. 1 and 2 show, the shapes of the absorption spectra vary remarkably with the pH change of the solutions.

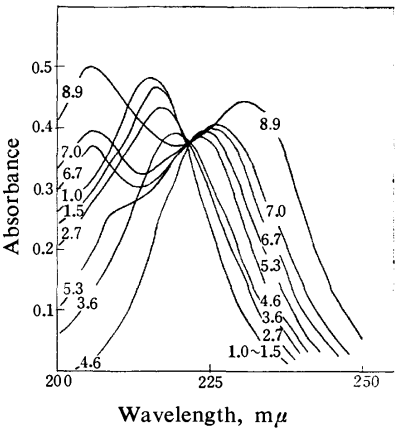


Fig. 1. pH dependence of the absorption spectra of ^{4}P-^{3}P-^{4}P-acid (1.54×10^{-4} M) in aqueous solutions (pH 1.0~8.9).

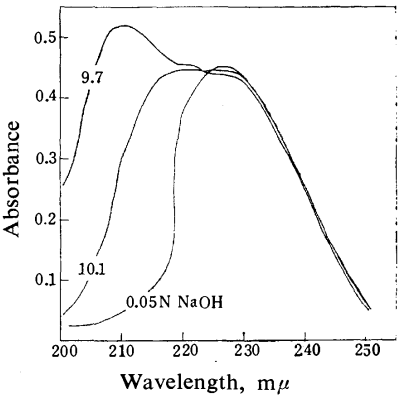

Fig. 2. pH dependence of the absorption spectra of ^{4}P-^{3}P-^{4}P-acid (1.54×10^{-4} M) in aqueous solutions (pH 9.7—0.05 N NaOH).

In an alkaline solution with a pH higher than 11, the spectrum exhibit the maximum absorption at the wavelength of 226 mμ. With the decreasing pH of the solution, the absorbance in the range of the shorter wavelengths increases. Thus, for instance, the absorption spectrum taken at pH 8.9 has two maxima at 205 and 230 mμ. With a further decrease of pH, the peak at 205 mμ diminishes, the maximum at 230 mμ shifts towards the shorter wavelength, and at last the absorption spectrum with only one peak appears. For example, at pH 4.6 one can observe a spectrum with its maximum at 224 mμ only.

When the pH of the solution decreases further, the maximum shifts more and more towards the shorter wavelength side while, at

4) S. Ohashi and N. Yoza. This Bulletin, 36, 707 (1963).
5) N. Yoza and S. Ohashi, report presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

the same time, its absorbance increases. At pH 1 the spectrum indicates a maximum at 215 mμ. In the range of pH lower than 1, the absorption maximum at 215 mμ is always observed. However, in this range, the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid is unstable, and the intensity of the absorbance decreases with time.

There have been reports on the pH dependence of the absorption spectra of some dibasic acids, such as sulfurous acid.[3] In these cases the variations of the absorption spectra with the pH value have been attributed to the transformation between ionized and unionized species of the molecule in question.

As for $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid, an analogous discussion is possible in comparison with the pH titration data for this acid. The pH titration curve[2] of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$ acid exhibits three inflection points at pH values, ca. 11, 9 and 5, corresponding to $P_3O_8^{5-}$, $HP_3O_8^{4-}$ and $H_2P_3O_8^{3-}$ respectively.

It is reasonable to assign the characteristic ultraviolet absorption spectra of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid to three successively ionized species, $P_3O_8^{5-}$, $HP_3O_8^{4-}$, and $H_2P_3O_8^{3-}$, and to one unionized species, $H_5P_3O_8$, as indicated in Table I. The peak at 226 mμ is attributed to the negatively-charged anion formed by the removal of five protons from the unionized molecule, while the spectrum with the maxima at 205 and 230 mμ is assigned to the unsymmetrical species with four negative charges. Similarly, the spectrum with the maximum at 224 mμ is ascribed to the species with three negative charges, and the spectrum with the maximum at 215 mμ, to the unionized species of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid.

Table I. Relation between the ultraviolet absorption spectra of the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid and pH of the solutions

Species	Stability	Maximum of the spectrum mμ	pH of the solution
	Stable	226	11
	Stable	205 230	9
	Stable	224	5
	Unstable (hydrolysis)	215	1

The Hydrolytic Decomposition of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-Acid.—The rate of the hydrolysis of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid is quite slow in a solution of low acidity, but it is catalytically accelerated by the addition of acid. It was confirmed by Blaser and Worms[2] that the hydrolysis of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid in 1.5 N nitric acid proceeds by the following two paths;

$$\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}\text{-Acid} \rightarrow \overset{3}{P}\text{-Acid} + \overset{4}{P}\text{-}\overset{4}{P}\text{-Acid} \quad \text{(A)}$$

$$\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}\text{-Acid} \rightarrow \overset{5}{P}\text{-Acid} + \overset{2}{P}\text{-}\overset{4}{P}\text{-Acid} \rightarrow \overset{5}{P}\text{-Acid} + 2\overset{3}{P}\text{-Acid} \quad \text{(B)}$$

Table II. Rate constants of the hydrolysis of the $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid in perchloric acid solutions of various concentrations (measured at 215 mμ and 30.4°C)

No.	Concentrations of perchloric acid, N	Rate constants, min^{-1}
1	0.240	6.98×10^{-4}
2	0.480	1.73×10^{-3}
3	0.720	2.50×10^{-3}
4	0.960	3.30×10^{-3}
5	1.20	4.07×10^{-3}
6	1.44	4.90×10^{-3}
7	1.68	7.16×10^{-3}
8	1.92	8.92×10^{-3}
9	2.16	1.04×10^{-2}
10	2.40	1.34×10^{-2}
11	2.64	1.61×10^{-2}
12	2.88	1.88×10^{-2}

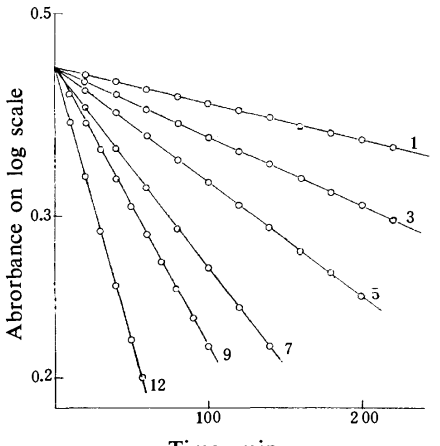

Fig. 3. The hydrolysis of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid ($1.64\times10^{-4}$ M) in perchloric acid.
The numbers in this figure correspond to the numbers in Table II.

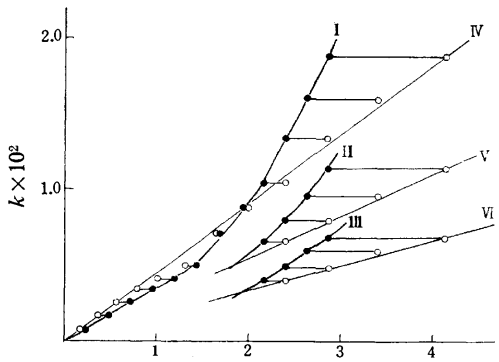

Fig. 4. Relationship between the rate constant, k, of the hydrolysis of $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid and the concentration of perchloric acid.
I, II and III; k vs. normality at 30.4, 25.0 and 20.0°C
IV, V and VI; k vs. activity at 30.4, 25.0 and 20.0°C

and that 82% of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid is decomposed by Path A and 18% of it by Path B.

However, it was found by the present investigation, paper chromatographically and colorimetrically, that equimolar amounts of $^{3}_{}\text{P}$ and $^{4}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid are produced by the hydrolysis of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid in perchloric acid solutions. Therefore, it was concluded that the hydrolysis of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid in perchloric acid solutions proceeds only by Path A. The difference between the reaction mechanisms for the hydrolysis of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid in nitric acid and in perchloric acid solutions can not be explained at the present state of knowledge.

The decrease in the concentration of $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid by hydrolysis can be readily pursued by measuring the absorbances at 215 mμ due to the unionized species of this acid, because the hydrolysis products, $^{3}_{}\text{P}$- and $^{4}_{}\text{P}\text{-}^{4}_{}\text{P}$- acid, do not show any absorption. As shown in Fig. 3, the hydrolysis of $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid follows the first order rate law. Thus, the rate constant, k, is calculated from the equation:

$$k=\{2.303/(t_2-t_1)\}\log(E_1/E_2)$$

where E_1 and E_2 represent the absorbances at 215 mμ measured at the times t_1 and t_2 respectively. The rate constants obtained for the disappearance of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid in the perchloric acid solutions of various concentrations at 30.4°C are presented in Table II, from which it can be seen that the rate constant increases considerably with the increase in the acidity.

In Fig. 4, the rate constants measured at 30.4, 25.0 and 20.0°C are plotted against the normalities and activities of perchloric acid. Since there are not sufficient data on the activity coefficients of perchloric acid, some of them have been obtained graphically by interpolation from the known data[6] for 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.2, 1.4, 1.6, 1.8, 2.0, 2.5, and 3.0 N perchloric acid. It can be concluded that there is a linear relationship between the rate constant of the hydrolysis of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid and the activity of perchloric acid.

Activation Energy.—From the rate constants measured at three different temperatures, one can estimate the activation energy for the hydrolysis of $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid to be 16.6 kcal. per mol. This value is considerably smaller than that for the hydrolysis at the P–P linkage of hypophosphoric acid, 20~25 kcal. per mol.[7]

Summary

It has been found that $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid in aqueous solutions shows characteristic ultraviolet absorption spectra, which vary remarkably with the pH change of the solutions. The spectra having absorption maxima at 226, both 205 and 230, 224, and 215 mμ can be assigned to $P_3O_8^{5-}$, $HP_3O_8^{4-}$, $H_2P_3O_8^{3-}$, and $H_5P_3O_8$ respectively.

The rates of the hydrolysis of the $^{4}_{}\text{P}\text{-}^{3}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid in the perchloric acid solutions have been determined by measuring the absorbance at 215 mμ. The hydrolysis follows the first order rate law. The hydrolysis products are $^{3}_{}\text{P}$- and $^{4}_{}\text{P}\text{-}^{4}_{}\text{P}$-acid. The rate constant is in the linear function with the activity of perchloric acid. The activation energy has been estimated to be 16.6 kcal. per mol.

The authors wish to express their hearty thanks to Professor Jun Yoshimura for his kind suggestions made in the course of this work. The authors also wish to thank Dr. Bruno Blaser and Dr. Karl-Heinz Worms for supplying the samples used in this study.

The Chemical Compositions of Crystals and Glasses of the $NaPO_3$-Na_2SiO_3 and $NaPO_3$-SiO_2 Systems

By Shigeru OHASHI and Fumio OSHIMA*

(Received July 20, 1963)

Several attempts to prepare condensed phosphates containing other oxoacid anions have been made. Thilo and his coworkers[1-7] have, for instance, succeeded in making condensed arsenate-phosphates,** which are composed of P-O-P, As-O-P, and As-O-As linkages. Some investigations have been carried out of the chemical compositions of condensed sulfate-phosphates[8] and condensed vanadate-phosphates,[9] which contain S-O-P and V-O-P linkages respectively.

Silicic acid has a tendency toward polymerization, which in turn leads to the formation of various condensed silicates. From the structural analogy between condensed phosphates and condensed silicates, it is to be expected that condensed phosphate-silicates containing P-O-Si linkages will be formed. Investigations[10-12] of the reaction of silicic acid with orthophosphoric acid have revealed the existence of silicon diphosphate, SiP_2O_7. An investigation of the CaO-P_2O_5-SiO_2 system by du Plessis[13] has disclosed that when a glass of calcium phosphate-silicate is dissolved in water, it gives a mixture of polyphosphates the average chain length of which decreases with the increase in the silicon dioxide content of the glass. Some physical and chemical properties of glasses of the Na_2O-P_2O_5-SiO_2, Na_2O-P_2O_5-B_2O_3, and Na_2O-P_2O_5-Al_2O_3 systems have recently been reported by Takahashi.[14] Although the $NaPO_3$-SiO_2 and KPO_3-SiO_2 systems have also been studied by du Plessis,[13] there have not been sufficient data available on the chemical compositions of the substances belonging to these systems.

The present investigation was undertaken to determine the chemical compositions of crystals and glasses of $NaPO_3$-Na_2SiO_3 and $NaPO_3$-SiO_2 systems. It was found by this work that glassy substances of these systems contain P-O-Si linkages, but not crystalline substances.

Experimental

Glassy Substances. — In a platinum crucible a certain amount (4~12 g.) of monosodium dihydrogen orthophosphate dihydrate was dehydrated and melted by heating and then converted into a glass of sodium metaphosphate (Graham's salt) by cooling the melt in the platinum crucible. In the case of the $NaPO_3$-Na_2SiO_3 system, after the weight of the glass had been measured, calculated amounts of silicon dioxide and of sodium carbonate were placed on the glass in the crucible. As for the $NaPO_3$-SiO_2 system, a mixture of only sodium metaphosphate and silicon dioxide was used. Then, the mixture of these two or three materials was melted at 1400°C for 1.5 hr. The melt was quenched by pouring it onto a copper plate and by pressing it with another copper plate. By this procedure, glasses of the $NaPO_3$-Na_2SiO_3 system with P/Si ratios of 6, 10, 15, 20, 30, 50, 75, 100 and 200, and glasses of the $NaPO_3$-SiO_2 system with P/Si ratios of 10, 20 and 50 were prepared. All the glasses thus obtained were colorless.

Crystalline Substances. — A mixture of sodium metaphosphate, silicon dioxide, and sodium carbonate or a mixture of sodium metaphosphate and silicon dioxide was heated at 1500°C for 1.5 hr. The melt was crystallized by cooling it slowly down to 200°C at the rate of 100°C/hr. By this treatment, crystals of the $NaPO_3$-Na_2SiO_3 system with P/Si ratios of 0.5, 0.7, 0.85, 1, 1.15, 1.3, 1.5, 2, 3 and 4, and crystals of the $NaPO_3$-SiO_2 system with P/Si ratios of 0.5, 1, 2, 3 and 4

were prepared. All the crystals thus obtained were white.

X-Ray Diffractometry. — The samples were ground with an agate mortar until they could pass through a 150 mesh screen. Their diffraction patterns were taken with a Rigaku Denki Geigerflex diffractometer with nickel-filtered CuK_α radiation.

Paper Chromatography. — Solvents A and B as reported by Bernhart and Chess[15] were used. Solvent A was made by mixing 25 ml. of a 20% trichloroacetic acid solution, 10 ml. of water, and 65 ml. of acetone. Solvent B was made by mixing 25 ml. of a 20% trichloroacetic acid solution, 17 ml. of water, and 58 ml. of acetone.

Solvent A was used for the separation of ortho-, di-, tri-, trimeta-, and long-chain- phosphates. A sample solution was placed at the center of a circular paper, 18 cm. in diameter, of Toyo No. 51A and developed for 2 hr. at 10~12°C.

Solvent B was used for the separation of individual chain phosphates from ortho- through tridecaphosphate and long-chain phosphates. Filter paper of Toyo No. 51A was cut into a sheet of 60 by 8 cm., with one end tapered to leave a central 5 by 0.8 cm. strip. The sample solution was placed at the upper end of the central strip of the paper sheet and developed for 5 days at 5°C.

After it had dried, the paper was sprayed with a perchloric acid-molybdate solution so as to convert the phosphates into molybdophosphate. After it had again dried, the paper was exposed to ultraviolet radiation in order to reduce the molybdophosphate a blue complex. Each phosphate species on the paper chromatogram was identified by the similar treatment of a reference solution of a known mixture of phosphates.

The demarcation between the bands was made close to the rear edge of each band in order to minimize the effects of hydrolysis, and the elution of each band was carried out by Smith's[16] method. The paper was cut at the demarcation line, and each band was placed in a 25 ml. Erlenmeyer flask, to which 10 ml. of 0.1 N ammonia was added. The resulting solution was transferred into a 25 ml. volumetric flask, and 10 ml. of water and 2 ml. of Lucena-Conde and Prat's reagent[17] were added. All the bands from each paper must be treated in the same way. Therefore, all the flasks containing solutions from one paper were placed in a boiling water bath at one time, removed at the same time after they had been heated for 1 hr., cooled, and diluted to the mark with water. The absorbance of the solution was measured with a Hirama electrophotometer at 800 mμ.

Lucena-Conde and Prat's Reagent.[17] — Ammonium molybdate tetrahydrate (8.15 g.) was dissolved in 60 ml. of water. To 30 ml. of this solution, 50 ml. of 12 N hydrochloric acid and 56 ml. of 36 N sulfuric acid were slowly added. After the mixture had cooled, 12 N hydrochloric acid was added to bring the volume back to 136 ml. To 25 ml. of the initial molybdate solution, 12.5 ml. of 12 N hydrochloric acid, 12.5 ml. of water, and finally, 10 ml. of mercury were added in turn. The mixture was shaken for 5 min. and filtered to obtain 40 ml. of a ruby-red solution of molybdenum (V). This ruby-red solution was stirred into the acid solution of molybdenum(VI) mentioned above and diluted to 200 ml. to give an emerald green solution.

The Measurement of the Average Chain Length of Polyphosphates. — In a 250 ml. Erlenmeyer flask, 0.1~1 g. of a glass was dissolved in about 150 ml. of water. After most of the silicate ions in the sample solution had been deposited, the deposit was filtered off. According to the pH titration method proposed by Van Wazer, Griffith, and McCullough,[18,19] the average chain length (polymerization degree) of the polyphosphates produced by the hydrolysis of a given sample was measured as follows.

An appropriate amount of the filtrate was acidified with dilute hydrochloric acid and then titrated with 0.1 N sodium hydroxide. The volume of the 0.1 N sodium hydroxide consumed between two inflection points located at approximately pH 4.5 and 9.5 was measured. Another suitable amount of the filtrate was mixed with 0.2 g. of potassium chloride and boiled with hydrochloric acid in order to hydrolyze completely all the condensed phosphates. The residue was treated with water and then titrated with the 0.1 N sodium hydroxide. If the titer for the first titration per unit weight of the sample is A and if the titer for the second one is A_h, the average chain length, $\bar{n}$, is given by the equation, $\bar{n}=2A_h/A$, on the assumption that ortho- and ring phosphates are not present.

Results and Discussion

The samples of both $NaPO_3$–Na_2SiO_3 and $NaPO_3$-SiO_2 systems with P/Si ratios smaller than 4 were obtained as crystalline substances containing amorphous substances. The chemical compositions of these crystalline substances can be estimated from the data obtained by the X-ray diffractometry and the paper chromatography. When the samples are treated with water, all the phosphates are dissolved in it. As for silicon, crystalline silicon dioxide is not dissolved in water, while a greater part of the soluble silicates deposits, only a smaller part of it remaining in the solution. Although the paper chromatographic behavior of silicate ions in the sample solution has not been confirmed, silicate ions do not interfere at all with the separation of condensed phosphates.

The data for the $NaPO_3$–Na_2SiO_3 system with P/Si ratios of 0.5~4.0 are given in Table I. In the X-ray diffraction patterns of the samples with P/Si ratios of 0.85~1.50,

* High temperature form

there are unknown peaks of a strong intensity at spacings of 2.63 and 4.29 Å and of a medium intensity at spacings of 2.79 Å. According to an unpublished paper by Ohashi and Ikeda, these unknown peaks, which have been observed for certain samples of the $NaPO_3$-Na_2SO_4 system, are assumed to be due to one of the modifications of trisodium orthophosphate. The discussions below are based on this assumption.

The crystalline substance of the sample with the P/Si ratio of 1.00 is composed of trisodium orthophosphate and α-cristobalite. Therefore, it is quite evident that when a mixture of sodium metaphosphate and sodium metasilicate with a mole ratio of 1 : 1 is melted, the following reaction occurs:

$$NaPO_3 + Na_2SiO_3 \rightarrow Na_3PO_4 + SiO_2 \quad (1)$$

The crystalline substances of the samples with P/Si ratios smaller than 1.00 contain trisodium orthophosphate but not α-cristobalite. For these samples, the silicon dioxide produced by Eq. 1 reacts further with an excess of sodium metasilicate to form a glassy sodium silicate. The crystalline substances of the samples with P/Si ratios larger than 1.00 contain α-cristobalite and two of the following three phosphate species; trisodium orthophosphate, tetrasodium diphosphate, and pentasodium triphosphate (high-temperature form). The α-cristobalite content in these samples, of course, decreases with the increase in the P/Si ratio. The orthophosphate content decreases and that of diphosphate increases when the P/Si ratio increases from 1.00 to 2.00. With the further increase in the P/Si ratio, the diphosphate content decreases and that of triphosphate increases. These facts indicate that the trisodium orthophosphate produced by Eq. 1 reacts further with an excess of sodium metaphosphate to form di- and triphosphate.

Small amounts of chain phosphates longer than triphosphate were found in the aqueous solutions of the samples with P/Si ratios of 3.00 and 4.00. Since anhydrous crystals of such chain phosphates as hexasodium tetraphosphate and heptasodium pentaphosphate have not been obtained as yet, it is reasonable to consider that the chain phosphates longer than triphosphate in the samples mentioned above compose an amorphous phase, in which di- and triphosphate are probably incorporated to some extent.

The data for the $NaPO_3$-SiO_2 system with P/Si ratios of 0.5~4.0 are given in Table II. The crystalline phases of all the samples are composed of α-cristobalite and trisodium trimetaphosphate. Some of them also contain small amounts of α-tridymite. Ortho-, di-, and triphosphates were found by paper chromatography in the aqueous solutions of the samples. These ortho- and chain phosphates may be derived from amorphous substances, because the X-ray diffraction patterns of these samples do not exhibit any peaks due to phosphates other than trisodium trimetaphosphate. However, the structure of these amorphous substances can not be determined from only the data presented here. It was disclosed that the crystalline substances of neither system contains P–O–Si linkages.

When the samples of the glassy substances with P/Si ratios larger than 6 are treated with water, almost all of the silicate ions deposit as silicic acid. All phosphate species and a trace amount of silicate ions come into the solution. The compositions of the phosphate species in the sample solutions were determined

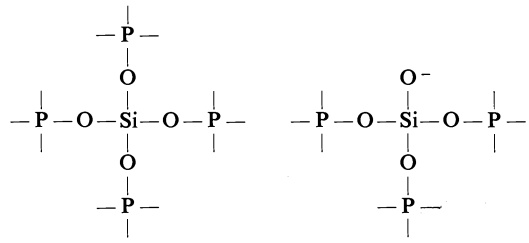
by paper chromatography. The results for the samples of the $NaPO_3$-Na_2SiO_3 and $NaPO_3$-SiO_2 systems are given in Table III. By the technique employed in the present investigation, it was possible to separate each member of the chain phosphates from orthophosphate through tridecaphosphate. The contents of the chain phosphats longer than tridecaphosphate were determined as a whole and are given as high polyphosphates in Table III.

Paper chromatograms developed with Solvent B for the reference solutions of trimeta- and tetrametaphosphate reveal that trimeta- and tetrametaphosphate have the same R_f values as penta- and heptaphosphate respectively. The paper chromatographic analysis by the use of Solvent A disclosed that the sample solutions contain small quantities of trimeta-, tetrametaphosphate, and, probably, ring phosphates larger than tetrametaphosphate. For instance, in the solutions of the samples of the $NaPO_3$-Na_2SiO_3 system with P/Si ratios of 10 and 20, 2.1 and 2.0 percent of the phosphorus are present as trimetaphosphate, and 1.1 and 1.5 per cent of the phosphorus, as tetrametaphosphate respectively. Therefore, the true penta- and heptaphosphate contents are considered to be a little smaller than the values given in Table III. Although it is not sure where the ring phosphates larger than tetrametaphosphate are located on the paper chromatograms developed with Solvent B, their quantities are probably small enough to be disregarded. When the P/Si ratio increases, the contents of the chain phosphates from ortho- to hexaphosphate decrease, while those of the high polyphosphates increase. With the increase in the P/Si ratio, the contents of the chain phosphates from hepta- to tridecaphosphate first increase and then decrease. If all the distributions of the phosphate species are considered, it is evident that the average chain length of the polyphosphates increases with the increase in the P/Si ratio. Conversely speaking, when the quantity of sodium metasilicate added to a sodium metaphosphate

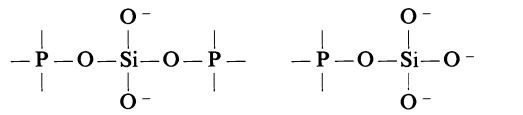
glass increases, the contents of the shorter chain phosphates in the sample solutions increase.

The average chain lengths of the polyphosphates in the sample solutions were determined by the pH titration method. Since the quantities of orthophosphate and ring phosphates in the sample solutions are less than several per cent, the effect of their presence on the calculation of the average chain length of the polyphosphates is disregarded in the following discussion. The fact that the average chain length, $\bar{n}$, increases in the P/Si ratio is indicated by curves A and B in Fig. 1. It is well known that the average chain length, $\bar{n}$, of polyphosphates in a sodium phosphate glass is given by the equation, $Na/P=(\bar{n}+2)/\bar{n}$, where Na/P is the atomic ratio of both the elements. Assuming that there is no interaction between a sodium phosphate glass and silicon dioxide in a melted state, one can calculate the average chain length of polyphosphates in the sample solution. If the P/Si ratio of the $NaPO_3$-Na_2SiO_3 system is x, the Na/P ratio is equal to $(x+2)/x$ and, therefore, $\bar{n}$ is equal to x. Curve C in Fig. 1 indicates this relation, $\bar{n}=x$. The great discrepancy between curves A and C means that the above assumption is not correct. As for the $NaPO_3$-SiO_2 system, the average chain length of polyphosphates based on the same assumption should be the same as that of a sodium metaphosphate glass, approximately 80~200. Curve B again indiate that the above assumption can not be employed.

Therefore, a sodium phosphate glass seems to react with silicon dioxide at a high temperature to form P–O–Si linkages. There are four types of possible structures containing one or more P–O–Si linkages.



Structure A Structure B



Structure C Structure D

The average chain length, $\bar{n}$, of polyphosphates produced by the hydrolytic scission of P–O–Si linkages in condensed phosphate-silicate of the $NaPO_3$-Na_2SiO_3 system is given by Eq. 2:

$$(\bar{n}+2)/\bar{n}=(x+y+2-z)/x \qquad (2)$$

where x, y, or z is the number of phosphorus atoms, P–O–Si linkages, or $Si-O^-$ linkages per atom of silicon respecctively. Similarly, $\bar{n}$ for the $NaPO_3$-SiO_2 system is given by Eq. 3:

$$(\bar{n}+2)/\bar{n}=(x+y-z)/x \qquad (3)$$

For structure A, B, C, or D, y is 4, 3, 2, or 1 and z is 0, 1, 2, or 3 respectively. The average chain lengths of polyphosphates derived from the condensed phosphate-silicates with various P/Si ratios, x, were calculated by Eq. 2 or 3. As is shown in column I of Table IV, even the calculated values of the average chain length based on structure A are considerably larger than the experimental values when x is greater than 50.

Other factors that shorten the average chain length of the polyphosphates produced from the condensed phosphate-silicates are the existence of branching points in phosphate chains and the presence of composition water and of other impurities. If all these factors are represented by the factor b, Eqs. 2 and 3 are modified into Eqs. 4 and 5 respectively:

$$(\bar{n}+2)/\bar{n}=(x+y+2-z+bx)/x \qquad (4)$$

$$(\bar{n}+2)/\bar{n}=(x+y-z+bx)/x \qquad (5)$$

where b is given with respect to an atom of phosphorus. If b is arbitrarily set at 0.04, the average chain lengths shown in column II of Table IV are obtained by means of Eqs. 4 and 5. When b is zero, Eqs. 4 and 5 are reduced to Eqs. 2 and 3 respectively. Therefore, if $0<b<0.04$, the average chain length

calculated by Eq. 4 or 5 for a sample with a certain P/Si ratio lies between the corresponding values of $\bar{n}$ given in columns I and II of Table IV. The average chain length of a pure sodium metaphosphate (Graham's salt) is usually in the range from 80 to 200, depending on the conditions of the preparation. Hence, the b factor for Graham's salt is calculated by the equation, $(\bar{n}+2)/\bar{n}=(1+b)/1$, to be 0.025~0.01. Therefore, the assumption that b is less than 0.04 in the present discussion is not unreasonable. As can be seen in Table IV, the calculated values for the average chain lengths printed in boldface type are close to the experimental values. Structure D appears unlikely to occur. In view of the above discussion, it seems reasonable to conclude that, with the increase in the P/Si ratio, the structural framework of the glasses of the condensed phosphate-silicates is transformed successively from structure C to structure B and then to structure A.

Summary

Crystals and glasses of the $NaPO_3$–Na_2SiO_3 and $NaPO_3$–SiO_2 systems with various P/Si ratios have been prepared from sodium metaphosphate, silicon dioxide, and sodium carbonate. The samples with P/Si ratios in the range from 0.05 to 4.00 have been obtained as crystalline substances containing amorphous substances, while those with P/Si ratios in the range from 6.00 to 200 have been obtained as glassy substances. By the X-ray diffractometry and the paper chromatography, it has been revealed that the crystals of neither system contains any P–O–Si linkages. By the paper chromatography and the pH-titration method, it has been disclosed that the glassy substances of either system with P/Si ratios higher than 6 are hydrolyzed to give mixtures of polyphosphates when dissolved in water. The lower the P/Si ratio, the more shorter chain polyphosphates are formed. The variation in the average chain length of the polyphosphates with the P/Si ratio indicates that these glassy substances are condensed phosphate-silicates containing P–O–Si linkages. Three structural types of P–O–Si linkages have been proposed for the condensed phosphate-silicates.

The Thermal Condensation of Formaldehyde with Aliphatic Olefins

By Shoji WATANABE and Kyoichi SUGA

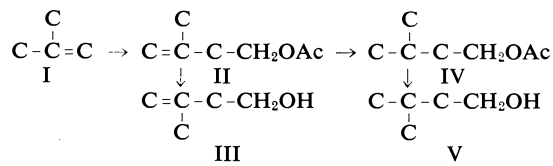
(Received July 18, 1963)

The addition of formaldehyde to olefins is known as the Prins reaction.[1] In a previous paper,[2] the preparation of a limonenylcarbinol, 1,8(9)-*p*-menthadien-10-yl-carbinol, and its various derivatives was reported. The present paper describes the thermal condensation of paraformaldehyde with aliphatic olefins in the presence of acetic anhydride.

Various workers have shown that the principal products of thermal olefin-formaldehyde condensations are unsaturated primary alcohols in which the double bond is located at a position adjacent to its original site in the starting olefins.[3] In this study all condensations were carried out in acetic anhydride, at temperatures varying from 180 to 210°C, the products obtained being mainly acetates.

$$R\text{-}\overset{3}{C}H_2\text{-}\underset{R'}{\overset{2}{C}}\text{=}\overset{1}{C}H_2 + CH_2O \rightarrow R\text{-}\overset{3}{C}H\text{=}\underset{R'}{\overset{2}{C}}\text{-}\overset{1}{C}H_2\text{-}CH_2OH$$

The isoprene process is in two stages. The first stage involves the use of the Prins reaction, in which isobutylene is reacted with formaldehyde under mild conditions to give 4,4-dimethylmethadioxane as the principal product. The 4,4-dimethyl-methadioxane is then decomposed to isoprene in the second stage, with a recycle of the by-product formaldehyde. This method is used as the industrial process for making isoprene.[4,5] In the presence of acetic acid and acetic anhydride, the reaction of isobutylene with formaldehyde was studied.[6] The authors also studied the thermal condensation of isobutylene (I) with paraformaldehyde under various reaction conditions in an attempt to prepare an unsaturated primary alcohol, 3-methyl-3-buten-1-ol (III).



From the condensation of isobutylene (I) with paraformaldehyde in the presence of acetic anhydride (at 180°C), 3-methyl-3-butenyl-acetate (II) was obtained in ca. a 30% yield. The hydrolysis of this II gave 3-methyl-3-buten-1-ol (III). The structure of III was established as (1) by reduction and hydrolysis or by hydrolysis and reduction, giving 3-methyl-butan-1-ol (V). II and III showed strong absorption in their infrared spectra at 890 cm^{-1}, indicating that they possessed the end methylene group.

In this condensation reaction, some etheric compounds, the structure of which was not determined, were obtained in ca. 13% yield.

As catalysts, aluminum chloride, zinc chloride, boron trifluoride etherate, iron carbonyl, titanium tetrachloride and anhydrous stannic chloride were used, and the products were analyzed with gas-liquid chromatography. The results are shown in Table I. From this results, it is established that the condensation gave the acetate of the unsaturated primary alcohol 3-methyl-3-buten-1-ol (III) and etheric compounds.

The condensation of 2-ethyl-1-hexene (VI) with paraformaldehyde at 220°C in the presence of acetic anhydride gave an acetate VII in ca. a 66% yield. By the saponification of this acetate VII, the corresponding alcohol VIII was obtained. Analysis, the hydroxy value and the bromine value indicated that the product was an adduct of one mole of formaldehyde to VI ($C_9H_{18}O$ VIII). The infrared absorption spectrum showed the absorption band characteristic of a primary alcohol type at 1050 cm^{-1}, and those characteristic of a trisubstituted ethylene type at 1660 cm^{-1} and 830 cm^{-1}. The gas liquid chromatogram of VIII showed two peaks, the areas of which were nearly equal. From these facts, it is thought that VIII is a mixture of $VIII_A$ and $VIII_B$. The reduction of VIII gave a saturated primary alcohol (IX), the gas-liquid chromatogram of which showed only one peak. The

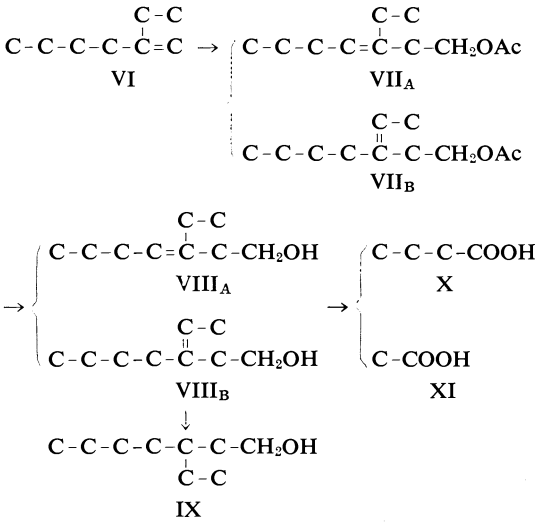
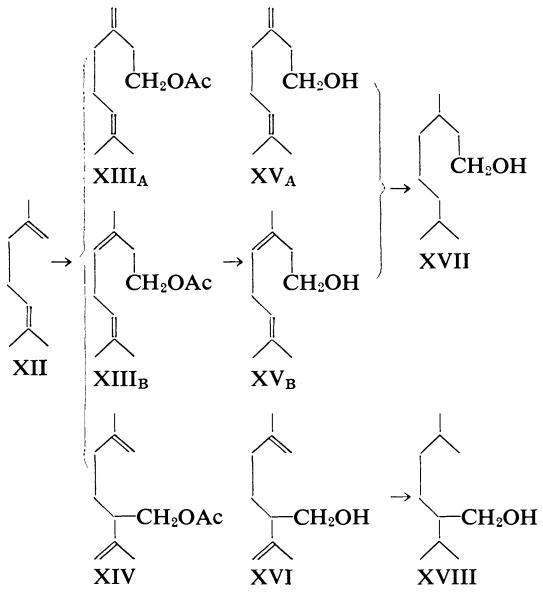
* The initial pressure with H_2 was 100 kg./cm^2.

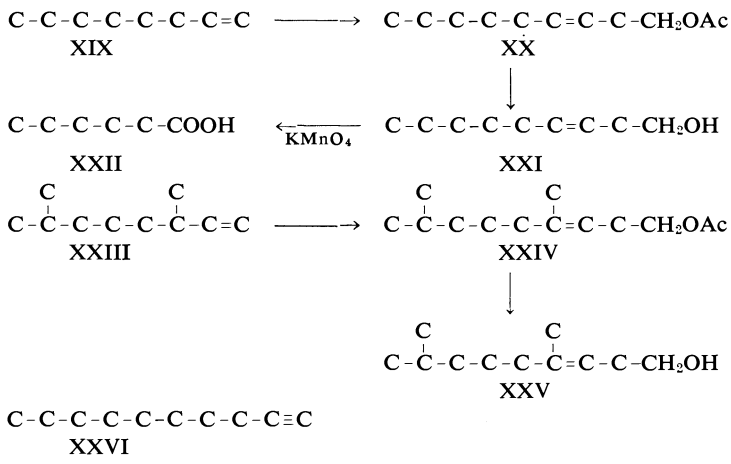




oxidation of VIII with potassium permanganate gave lactic acid (X) and acetic acid (XI). From the above results, it has been concluded that the alcohol VIII was an equivalent mixture of 3-ethyl-3-heptenol ($VIII_A$) and 3-ethylidene-heptanol ($VIII_B$).

The condensation of formaldehyde with 2, 6-dimethyl-1, 5-heptadiene (XII) under conditions similar to those used for 2-ethyl-1-hexene gave a mixture of three unsaturated alcohols, XV_A, XV_B and XVI, in ca. a 40% yield. This product, which showed a narrow boiling point range, gave no solid derivatives, and its direct separation into the three isomeric components with fractional distillation was unsuccessful. The reduction of the mixture of the alcohols, XIII and XIV, gave a product composed of 65% tetrahydrogeraniol (XVII) and 35% tetrahydrolavanduol (XVIII). This composition was established by comparing the gas-liquid chromatogram of the reduction product with those of known mixtures of pure XVII and XVIII. The mixture of XVII and XVIII was separated by means of column chromatography, using activated alumina gel. XVII and XVIII were identical in infrared spectra with authentic XVII and XVIII. Similarly, the mixture of XV and XVI was separated by means of liquid chromatography, using activated alumina gel.

The infrared absorption spectrum of XV indicates the presence of a primary alcohol group (absorption peak at 1050 cm^{-1}), an end methylene group (at 890 cm^{-1}) and a trisubstituted ethylene group (at 825 cm^{-1}). These results suggest a mixture of 3-methylene-7-methyl-6-octen-1-ol (XV_A) and 3, 7-dimethyl-3, 6-octadien-1-ol (XV_B) for the XV. Similarly, the infrared absorption spectrum of XVI indicates the presence of a primary alcohol group (absorption peak at 1050 cm^{-1}) and an end methylene group (890 cm^{-1}). These results



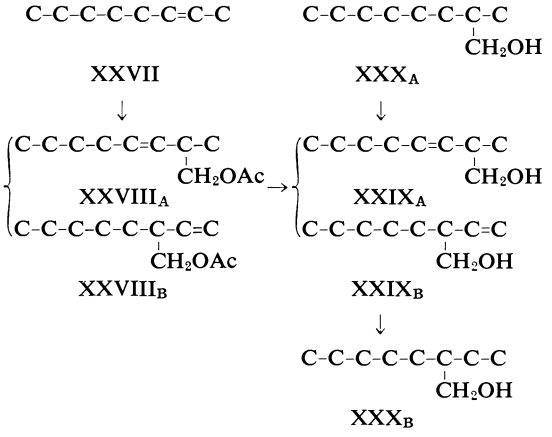
suggest the structure of 2-isopropenyl-5-methyl-5-hexenol for the XVI. As has been mentioned above, the procedure for synthesizing C_{10}-terpene alcohols from C_9-unsaturated olefins and formaldehyde with thermal condensation is a new method. The preparation of various terpene alcohols using this method is now in progress at our laboratory.

From the condensation of octene-1 (XIX), 3-nonen-1-ol acetate (XX) was obtained in ca. a 30% yields. The hydrolysis of this product gave 3-nonen-1-ol (XXI). The oxidation of this alcohol with potassium permanganate gave the known hexanoic acid, indicating that the structure was 3-nonen-1-ol. The infrared absorption spectrum of XXI indicates the presence of a trans configuration (at 965 cm^{-1}).

Similarly, from the condensation of 3, 7-dimethyl-1-octene (XXIII), 4, 8-dimethyl-3-nonen-1-ol (XXV) was obtained in ca. a 30% yield through the acetate XXIV. Analysis, quantitative acetylation, the bromine value and the infrared absorption spectrum (825 cm^{-1}, 1050 cm^{-1}) indicated that the structure was 4, 8-dimethyl-3-nonen-1-ol (XXV).

The condensation of paraformaldehyde with decyn-1 (XXVI) under conditions similar to those above mentioned did not give any alcoholic compounds.

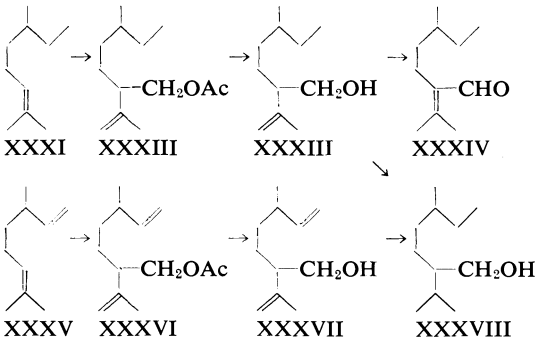
From the condensation of octene-2 (XXVII), an unsaturated acetate (XXVIII) was obtained in ca. an 11% yield. The saponification of XXVIII gave an unsaturated primary alcohol XXIX. The gas liquid chromatography of XXIX showed that it consisted of two components, and the saturated alcohol XXX consisted of two components, too. This product, which showed a narrow boiling point range, gave no solid derivatives, however, and its direct separation into the two isomeric components by means of fractional distillation and liquid chromatography was unsuccessful. The



infrared absorption spectrum indicates the presence of a primary alcohol group (absorption peak at 1040 cm^{-1}), an end vinyl group (absorption peaks at 910 cm^{-1} and 990 cm^{-1}) and a trans configuration of –CH=CH– (absorption peak at 967 cm^{-1}) The product III prepared by the catalytic hydrogenation of XXIX had no double bonds as an end vinyl group and a trans configuration visible in the infrared absorption spectrum. These results suggest the mixture of 2-methyl-3-octen-1-ol ($XXIX_A$) and 3-oxymethyl-1-octene ($XXIX_B$) for the original unsaturated alcohol.

Under conditions similar to those used for XXVII, the condensations of oleic acid, methyl oleate, oleylalcohol and oleylacetate, which has a disubstituted double bond (–CH=CH–), yielded no good results.

From the condensation of 2, 6-dimethyl-2-octene (XXXI), an acetate (XXXII) was obtained. The saponification of this acetate gave an unsaturated primary alcohol XXXIII. Analysis ($C_{11}H_{22}O$), the hydroxyl value and the bromine value indicated that the product was an adduct of one mole of formaldehyde



to XXXI. The infrared absorption spectrum showed the absorption bands characteristic of a primary group (absorption peak at 1040 cm^{-1}) and of an end methylene group (strong band at 855 cm^{-1}). Formula XXXIII was established on the basis of a comparison with the infrared spectrum of the product XXXVIII prepared by the catalytic hydrogenation of the end methylene group of the carbinol XXXIII. The hydrogenated carbinol XXXVIII showed remarkable doublet absorption peaks at 1380 cm^{-1} arising from an isopropyl radical. From the above results, it was concluded that the structure of the alcohol XXXIII is 3-methyl-2-(3'-methyl-1'-pentyl)-3-buten-1-ol. By the action of chromic anhydride in glatial acetic acid, an α,β-unsaturated aldehyde, 3-methyl-2-(3'-methyl-1'-pentyl)-2-buten-1-al (XXXIV), was obtained. It gives positive reactions with Schiff's reagent and with Tollen's reagent. The major absorption peaks at 243 mμ in the ultraviolet absorption spectrum suggested the presence of a conjugated enal grouping.

When the proportions of XXXI, paraformaldehyde and acetic anhydride were changed, the yields of XXXII were examined by means of gas-liquid chromatography (Table II). The use of 0.5 mol. of acetic anhydride and 1.25 mol. of paraformaldehyde per mole of XXXI gave the best results.

Similarly, from the condensation of 2, 6-dimethyl-2, 7-octadiene (XXXV), 2, 6-dimethyl-3-oxymethyl-1,7-octadiene (XXXVII) was obtained. The infrared absorption spectrum showed the absorption bands characteristic of a primary alcohol at 1040 cm^{-1}, of an end methylene group at 890 cm^{-1}, and of an end vinyl group at 910 and 990 cm^{-1}. The product prepared by the catalytic hydrogenation of XXXVII was identical in infrared absorption spectrum, gas-liquid chromatogram and other physical constants with the XXXVIII which had been prepared from the known XXXIII. These results suggest the structure of 2, 6-dimethyl-3-oxymethyl-1, 7-octadiene (XXXVII) for the original alcohol.

From the condensation of 2, 3-dimethyl-2-pentene (XXXIX), which has a tetrasubstituted double bond, an unsaturated alcohol was obtained in a poor yield, but the structure was not determined.

Finally, from the condensation of myrcene (XXXX), which has a conjugated diene, no alcoholic compound was obtained, only an unsaturated hydrocarbon as the main product

in ca. a 35% yield. The molecular weight (280), the boiling point (140~150°C/3 mmHg), and the bromine value indicated that the product was a dimer of XXXX. The infrared absorption spectrum did not show the existence of an oxygenated compound.

The foregoing observations indicate that the thermal condensation of paraformaldehyde with aliphatic olefins in the presence of acetic anhydride occurs most readily with end methylene-type olefins, $CH_2=CR_1R_2$, and that trisubstituted olefins ($R_1CH=CR_2R_3$), disubstituted olefins and vinyl olefins ($CH_2=CHR_1$ and $R_1CH=CHR_2$) and tetrasubstituted olefins ($R_1R_2C=CR_3R_4$) are less reactive in these orders.

Experimental

Materials.—The properties of the materials used are summarized in Table III.

The Condensation with Paraformaldehyde (General Method).—A mixture of 1 mol. of an olefin, 1 mol. of paraformaldehyde, and 0.5 mol. of acetic anhydride was heated at 180~220°C in an stainless autoclave for several hours. The reaction mixture was extracted with ether. The ethereal solution was then washed with water and drid over anhydrous sodium sulfate. Fractional distillation gave a crude acetate. By saponification with the alcoholic potassium hydroxide of the acetate, the corresponding alcohol was obtained.

The Condensation of Isobutylene (I) with Formaldehyde.—From a mixture of 19 g. of isobutylene (I), 11 g. of paraformaldehyde, and 15 g. of acetic anhydride (reaction temperature, 200~210°C; reaction time, 4 hr.), 15 g. of a crude product was obtained. The crude product (150 g.) fractionally distilled to give the following fractions: (a) 24 g. of the forerun (b. p. 70~140°C); (b) 60 g. of II (b. p. 144°C; d_4^{30} 0.8910; n_D^{29} 1.4150; molecular refraction, 36.00 (calcd. for $C_7H_{12}O_2$, F_1, 35.713); bromine value, 115.01 ($C_7H_{12}O_2$, F_1, 124.7); (c) 33 g. of higher condensation products (b. p. 144~160°C); (d) 30 g. of residue.

The infrared spectrum of the II compound showed strong absorption at 890 cm^{-1} (an end methylene group) and at 1740 cm^{-1} and 1240 cm^{-1} (acetate).

The quantitative hydrogenation of II in methanol using a Raney nickel catalyst required 98% of one molar equivalent of hydrogen. The product was identical with an authentic isoamyl acetate (IV) in infrared absorption spectrum, gas chromatogram and other physical constants.

The saponification of II in the usual way gave 3-methyl-3-butene-1-ol (III); b. p. 132°C, n_D^{20} 1.4340; d_4^{20} 0.8533. The infrared spectrum of III showed strong absorption at 890 cm^{-1} (an end methylene group) and at 1050 cm^{-1} (a primary alcohol group). The quantitative hydrogenation of II in ethyl alcohol using a palladium-carbon catalyst required one molar equivalent of hydrogen. The product was identical with an authentic isoamyl alcohol (V) in infrared absorption spectrum, gas chromatograph and other physical constants.

The Condensation of 2-Ethyl-1-hexene (VI) with Formaldehyde. — From a mixture of 112 g. of VI, 36 g. of paraformaldehyde and 51 g. of acetic anhydride (reaction temperature, 220°C; reaction time, 6 hr.), 122 g. of the crude VII was obtained. The saponification of VII gave a mixture of $VIII_A$ and $VIII_B$. B. p. 81°C/6 mmHg; d_4^{15} 0.8345; n_D^{22} 1.4541; molecular refraction, 45.84 (Calcd. for $C_9H_{17}OH$, F_1, 44.95); hydroxy group, 11.97% (Calcd. for monohydric alcohol, 11.96%); bromine value, 128.4 (Calcd. for $C_9H_{17}OH$, 112.4); infrared absorption spectrum, 1045 cm^{-1}, 1660 cm^{-1} and 830 cm^{-1}.

Found: C, 76.01; H, 12.32. Calcd. for $C_9H_{18}O$: C, 76.02; H, 12.76%.

2-Ethyl-heptanol (IX).—Upon the hydrogenation of VIII in methanol at 130°C under high pressure (40 kg./cm^2) using a Raney nickel catalyst, one molecular equivalent of hydrogen was absorbed. The reduced product IX was carefully distilled. B. p. 79~80°C/6 mmHg.

The Oxidation of VIII with Potassium Permanganate.—A mixture of 29 g. of potassium permanganate, 35 g. of concentrated sulfuric acid and 300 cc. of water was added to a mixture of 10 g. of VIII and 30 cc. of acetone over an hour's time. After the mixture had been left alone overnight,

the precipitated part was filtered off. After the reaction-mixture had been alkalined with sodium carbonate, it was evaporated. The concentrated solution was then acidified with sulfuric acid and extracted with ether. After the ether had been evaporated, the residue was an analyzed by gas liquid chromatography; lactic acid (X) and acetic acid (XI) were recognized by comparing then with authentic samples.

The Condensation of 2, 6-Dimethyl-1, 5-heptadien (XII) with Formaldehyde. — From a mixture of 41 g. of XII, 10 g. of paraformaldehyde and 17 g. of acetic anhydride (reaction temperature, 220°C; reaction time, 4 hr.), 25 g. of crude acetate (b. p. 89～90°C/2 mmHg) was gained. The saponification of this product gave 20 g. of a mixture of XXV and XXVI. This was distilled to give the fractions in Table IV.

The Hydrogenation of XV and XVI.—Upon the hydrogenation of 4 g. of Fr. 2 (Table IV) in methanol at 120°C using a Raney nickel catalyst, two molecular equivalents of hydrogen were absorbed. The reduced product was shown to be a mixture of tetrahydrogeraniol (XVII) (40%) and tetrahydrolavanduol (XVIII) (60%) by gas-liquid chromatography.

The Separation of Mixture of XVI and XVII. —The chromatography of 2 g. of the above-mentioned saturated alcohol (XVII, XVIII) with an activated alumina using benzene (150 cc.) and acetone (150 cc.) gave 100 mg. of tetrahydrogeraniol (purity, 90%) and 100 mg. of tetrahydrolavanduol (XVIII) (purity, 90%) from the elution of acetone. XVII and XVIII were identified by a comparison of the infrared absorption spectra and the gas-liquid chromatography results with those of authentic samples.

Found: C, 75.57; H, 13.53. Calcd. for $C_{10}H_{22}O$ (XVII): C, 75.88; H, 14.01%.

Found: C, 75.62; H, 13.92. Calcd. for $C_{10}H_{22}O$ (XVIII): C, 75.88; H, 14.01%.

Separation of a Mixture of XV and XVI.— The chromatography of 2 g. of the mixture of XV and XVI with an activated alumina using benzene (150 cc.) and acetone (150 cc.) gave 200 mg. of a mixture of XV_A and XV_B (purity, 80%) and 70 mg. of XVI (purity, 80%) from the elution of acetone.

Condensation of Octene-1 (XIX) with Formaldehyde.—From a mixture of 45 g. of XIX, 20.5 g. of acetic anhydride and 14.5 g. of paraformaldehyde (reaction temperature, 220°C; reaction time, 5.5 hr.), 22 g. of a crude acetate (XX) (b. p. 110～120°C/20 mmHg) was gained. The saponification of the product gave 14 g. of XXI. B. p. 114～116°C/25 mmHg; d_4^{12} 0.8630; n_D^{12} 1.4550; molecular refraction, 44.90 (Calcd. for $C_9H_{18}O$, F_1, 44.82); hydroxy group, 11.50% (Calcd. for monohydric alcohol, 11.95%); bromine value, 103.2 (Calcd. for $C_9H_{18}O$, F_1, 112.3); the gas chromatogram shows one peak.

α-Naphthylurethan. — This was prepared as usual and was recrystallized from petroleum benzine. M. p. 75.5°C.

Found: N, 4.42. Calcd. for $C_{20}H_{25}NO_2$: N, 4.498%.

Oxidation of XXV with Potassium Permanganate.—A mixture of 25 g. of potassium permanganate, 21 g. of sulfuric acid and 300 cc. of water was added to 10 g. of XXV over an hour's time while the mixture was agitated. After the mixture had then been left alone overnight, the precipitated material was filtered off. The filtrate was alkalined with potassium hydroxide and then evaporated. After the concentrated solution had been acidified with sulfuric acid, it was extracted with ether. The ether solution was distilled to give 2 g. of caproic acid (XXII), which was identical with the IR and GC of the authentic sample of XXII.

p-Bromphenatylester.—This was prepared as usual and was recrystallized from methanol. It has a m. p. of 72°C, which does not depress the m. p. of an authentic XXII *p*-bromphenatylester with an m. p. of 72°C.

The Condensation of 3, 6-Dimethyl-1-octene (XXIII) with Formaldehyde.—From a mixture of 31 g. of XXIII, 6,7 g. of paraformaldehyde and 11 g. of acetic anhydride (reaction temperature, 220°C; reaction time, 10 hr.), 7 g. of a crude acetate XXIV was obtained. The saponification of XXIV gave 4 g. of XXV. B. p. 120～124°C/20 mmHg; d_4^{29} 0.8363; n_D^{30} 1.4462; molecular refraction, 54.21 (Calcd. for $C_{11}H_{22}O$, F_1, 54.26); bromine value, 75.2 (Calcd. for $C_{11}H_{22}O$, F_1, 93.9); hydroxy group, 9.91% (Calcd. for monohydric alcohol, 9.98%).

Found: C, 76.88; H, 12.85. Calcd. for $C_{11}H_{22}O$ (XXV): C, 77.58; H, 13.02%.

The Condensation of Decyn-1 (XXVI) with Formaldehyde.—From a mixture of 30 g. of XXVI, 6.7 g. of paraformaldehyde and 13.5 g. of acetic anhydride (reaction temperature, 220°C; reaction

time, 10 hr.), no acetate was obtained.

The Condensation of Octene-2 (XXVII) with Formaldehyde.—From a mixture of 40 g. of XXVII, 12.5 g. of paraformaldehyde and 18.17 g. of acetic anhydride (reaction temperature, 200~210°C; reaction time, 11 hr.), 7 g. of a crude acetate (XXVIII) (b. p. 80~88°C/9 mmHg) were obtained. The saponification of 20 g. of XXVIII in the usual way gave 14 g. of XXIX (b. p. 92~95°C/7 mmHg; $n_D^{29.5}$ 1.4430; $d_4^{29.5}$ 1.1864; bromine value, 103 (Calcd. for $C_{19}H_{18}O$, F_1, 112); hydroxy group, 13.5% (Calcd. for monohydric alcohol 11.98%); the gas chromatogram shows one peak). The infrared spectrum of the compound XXIX showed a strong absorption at 1040 cm^{-1} (a primary alcohol group) and at 967 cm^{-1}, 910 cm^{-1} and 990 cm^{-1} (a terminal vinyl group and a disubstituted trans-type double bond).

Found: C, 76.01; H, 12.71. Calcd. for $C_9H_{18}O$ (XXIX): C, 76.02; H, 12.75%.

The hydrogenation of XXIX in a methanol solution using a Pd-C catalyst absored one molar equivalent of hydrogen. This infrared absorption spectrum showed no absorption peaks of any double bonds.

Condensation of 2, 6-Dimethyl-2-octene (XXXI) with Formaldehyde. — From a mixture of 32 g. of XXXI, 16 g. of acetic anhydride and 6 g. of paraformaldehyde (reaction temperature 220°C; reaction time, 5 hr.), 10 g. of a crude acetate XXXII were obtained (b. p. 90~97°C/7 mmHg). This (137 g.) was distilled to give the following fractions: (a) 59 g. of XXXII (b. p. 81~81.5°C/3 mmHg; n_D^{10} 1.4504; d_4^{10} 0.8913; molecular refraction, 64.06 (Calcd. for $C_{13}H_{24}O_2$, 63.42); saponification value, 240 (Calcd. for $C_{13}H_{24}O_2$, 264); bromine value, 65.3 (Calcd. for $C_{13}H_{24}O_2$: F_2, 75.3); the gas chromatogram shows one peak); (b) 12 g. of higher condensation products (b. p. 120~130°C/2 mmHg.; d_4^{21} 0.9313; n_D^{21} 1.4745; bromine value, 85.8; hydroxyl group, 13.5%).

The saponification of XXXII (20 g.) gave an alcoholic compound, XXXIII (12 g.). B. p. 92~93°C/5 mmHg; n_D^{10} 1.4615; d_4^{10} 0.8598; molecular refraction, 54.43 (Calcd. for $C_{11}H_{22}O$: F_1, 54.06%); hydroxyl group, 9.15% (Calcd. for $C_{11}H_{22}O$, 9.99%); bromine value, 80.5 (Calcd. for $C_{11}H_{22}O$, 93.9); the gas chromatogram shows one peak.

Found: C, 76.60; H, 13.11. Calcd. for $C_{11}H_{22}O$ (XXXIII): C, 77.46; H, 13.00%.

2, 6-Dimethyl-3-oxymethyl-octane (XXXVII). — The quantitative hydrogenation of XXXIII in methanol using a Raney nickel catalyst in an autoclave (initial H_2 pressure, 35 kg./cm^2) required 99% of one molar equivalent of hydrogen. From 3 g. of XXXIII there were obtained 2 g. of XXXVII (b. p. 89~91°C/5 mmHg; n_D^8 1.4520; the gas chromatogram shows one peak).

3-Methyl-2-(3'-methyl-1'-pentyl)-2-buten-1-al (XXXIV).—To a mixture of 6 g. of XXXIII, 10 g. of acetone and 10 g. of glacial acetic acid, a mixture of 12 g. of chromic anhydride, 30 g. of acetic acid, 5 g. of water and 2 g. of concentrated sulfuric acid was added over a 30 minute period at 0°C while the mixture was being vigorously agitated. After the mixture had then been stirred for 4.5 hr., it was poured into a large amount of water and extracted with ether. The extracts were washed with water and dried over anhydrous sodium sulfate. By fractional distillation, 2 g. of XXXIV were obtained (b. p. 68~72°C/1~2 mmHg; λ_{max} 243 mμ, ε 1310). This substance gave a positive reaction with Schiff's reagent and reduced an ammoniacal silver nitrate solution.

2,4-Dinitrophenylhydrazone.—This was prepared as usual and was recrystallized from a mixture of pyridine and methanol. M. p. 209°C: λ_{max} 390 mμ ε 4080.

Found: N, 17.69. Calcd. for $C_{17}H_{24}O_4N_4$: N, 16.56%.

The Condensation of 3, 7-Dimethyl-1, 6-octadiene (XXXV) with Formaldehyde.—From a mixture of 79 g. of XXXV, 17 g. of paraformaldehyde and 28.5 g. of acetic anhydride (reaction temperature, 200°C; reaction time, 4 hr.), 25 g. of crude XXXVI (b. p. 100~130°C/4 mmHg) were obtained. The saponification of this product (92 g.) gave 71 g. of a crude alcohol. This was distilled to give the following fractions: (a) 28 g. of XXXVII (b. p. 81.5°C/3 mmHg; n_D^{26} 1.4645; d_4^{26} 0.8590; molecular refraction, 54.36 (Calcd. for $C_{11}H_{20}O$: F_2, 53.59); hydroxyl group, 9.06% (Calcd. for monohydric alcohol, 10.1%); bromine value, 201 (Calcd. for $C_{11}H_{20}O$: F_2, 189.9); the gas chromatography shows one peak).

Found: C, 77.49; H, 12.19. Calcd. for $C_{11}H_{20}O$ (XXXVII): C, 78.49; H, 11.98%.

(b) 5 g. of higher condensation products (b. p. 100~110°C/3 mmHg).

Hydrogenation of 2, 6-Dimethyl-3-oxymethyl-1, 7-octadiene (XXXVII).—The quantitative hydrogenation of XXXVII in isopropylalcohol using Raney nickel in an autoclave (initial H_2 pressure, 38 kg./cm^2) required 98% of two molar equivalents. B. p. 93°C/3 mmHg; n_D^5 1.4523. The infrared spectrum and the gas-liquid chromatogram of this product agreed with XXXVIII, which had been similarly prepared from XXXIII.

The Condensation of 2, 3-Dimethyl-2-pentene (XXXIX) with Formaldehyde.—From a mixture of 26 g. of XXXIX, 9 g. of paraformaldehyde and 13 g. of acetic anhydride (reaction temperature, 220°C; reaction time, 8 hr.), 3 g. of a crude acetate (b. p. 120~125°C/3 mmHg) were obtained. The saponification of this product gave 0.5 g. of an alcoholic compound, the structure of which was not determined.

Condensation of Myrcene (XXXX) with Formaldehyde.—From a mixture of 45 g. of XXXX, 10 g. of paraformaldehyde and 17 g. of acetic anhydride (reaction temperature, 210~220°C; reaction time, 5 hr.), the following main fraction was obtained: (a) 13.7 g. of an unsaturated hydrocarbon (b. p. 140~150°C/3 mmHg: d_4^{25} 0.8793; n_D^{25} 1.5001; bromine value, 205; molecular weight, 280).

Absorption Spectra. — The infrared absorption spectra were measured by using a Koken IRS spectrophotometer, while the ultraviolet absorption spectrum were measured with a "Shimadzu" photometric spectrophotometer Type QB-50 using isopropyl alcohol as the solvent.

Gas-Liquid Chromatography. — Gas-liquid chromatography was measured under the following

conditions: II, III, IV, V, VI, XII, XIX, XXI, XXIII, XXVI, XXVII, XXXI, XXXV, XXXIX and XXXX: column; LAC-2R-446 (20%) on Celite 545, 2 m.; temperature, 120°C; carrier gas He 45 ml./min.

VII, VIII, IX, XIII, XIV, XV, XVI, XVII, XVIII, XX, XXI, XXIV, XXV, XXVIII, XXIX, XXX, XXXII, XXXIII, XXXIV, XXXVI, XXXVII and XXXVIII: Temperature, 180°C; the other conditions were the same as above.

X, XI and XXII: column; Silicone D C 200 on Celite 545, 2 m.; temperature, 150°C; carrier gas, He 45 ml./min.

The authors are indebted to the Takasago Perfumery Co., Ltd., for providing materials.

Remark on the Solvent Effects upon the Electronic Spectra of Naphthalene Derivatives

By Noboru MATAGA

(Received July 20, 1963)

In one of our previous papers[1] we reported on the absorption and fluorescence spectra of naphthylamines and isomeric aminobenzoic acids in various organic solvents. This sort of study, in which the effects of solvents on both the absorption and fluorescence spectra are investigated, is important in order to obtain detailed information on the electronic structures of complex aromatic molecules as well as on the nature of the molecular interaction in solutions.

It has been observed that the hydrogen bonding between the solute and the solvent molecules, especially that between the alcohol and amino nitrogen of naphthylamines or aminobenzoic acids, affects the electronic spectra of the latter two quite remarkably. This fact has been ascribed to the rearrangement of the hydrogen bond between the solute and solvent molecules during the lifetime of the excited solute molecule.

In the present report, we shall describe additional experimental findings concerning the electronic spectra of some aromatic hydrocarbon derivatives, such as naphthylamines, naphtholate ions and aniline in aqueous and alcohol solutions; we shall also discuss the rearrangement of the solute-solvent interaction in the excited state and the role of the Franck-Condon principle in the spectral shifts.

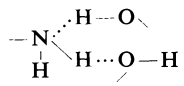
Experimental

The details of the apparatus for the measurement of the absorption and fluorescence spectra have been described elsewhere.[1-3] The samples of the solutes were the same as were used before.[1,3]

Experimental Results and Discussion

The Importance of the Franck-Condon Principle in the Solvent Shifts of π-π^* Spectra.— As has been demonstrated in our previous report,[1] the solute-solvent interactions in alcohol solutions affect the absorption spectra of naphthylamines only slightly, whereas they cause a very large red shift of the fluorescence spectra compared to the case of *n*-hexane or cyclohexane solutions.

The hydrogen-bonding interaction in alcohol solutions of naphthylamines probably involves the following types of hydrogen bonds:



The hydrogen bond of the $-H-H\cdots O<$ type (type D) causes a red shift of the absorption spectrum, whereas the $-N\cdots H-O<$ type (type A) hydrogen bond causes a blue shift of the absorption spectrum; this is because the former is favorable while the latter is unfavorable to the charge migration from the substituent to the aromatic ring.

The hydrogen-bonding interaction of the A type is certainly much weaker in the excited

TABLE I. THE WAVE NUMBERS OF THE BAND MAXIMA OF ANILINE, α- AND β-NAPHTHYLAMINES IN ETHANOL AND IN AQUEOUS SOLUTIONS (IN UNITS OF $10^4\,cm^{-1}$)

Solvent	Aniline		α-Naphthylamine		β-Naphthylamine	
	σ_a^m	σ_f^m	σ_a^m	σ_f^m	σ_a^m	σ_f^m
EtOH	3.52	2.95	3.13	2.31	2.96	2.46
H_2O	3.58	2.91	3.30	2.19	3.02	2.43

state,*1 while that of the D type is a little stronger in the excited state than in the ground state. The former circumstance is related to the fact that the basicity of the amino nitrogen is much weaker in the excited state than in the ground state, as has been demonstrated by Förster[4] in the case of naphthylamines in an aqueous solution. Moreover, the type D hydrogen bond may be strengthened by the cooperative interaction between alcohol molecules in the hydrogen-bonded chain.

These hydrogen-bonding interactions, as well as the dipole-dipole and dipole-polarization interactions with the surrounding solvent molecules, which are much stronger in the excited state than in the ground state, may cause the very large $\Delta\sigma$ value (the wave number difference between the maxima of the absorption, (σ_a^m), and of the fluorescence spectra, (σ_f^m), respectively) of the alcohol solution.

The effects of the solute-solvent interactions on the spectral shifts described above may be far greater in the aqueous solution than in the alcohol solution because of the more extensive hydrogen bonding interactions and dipolar interactions in the former solution.

As an example of very large spectral shifts in the hydroxylic solvent, the absorption and fluorescence spectra of α-naphthylamine in ethanol and water (neutral), together with those in 60% (weight) sulfuric acid solution, are shown in Fig. 1. In the last solvent, the amino nitrogen is protonated in both the ground state and the fluorescence state.

The wave numbers of the band maxima of α- and β-naphthylamines in ethanol and in an aqueous solution are collected in Table I. The wave numbers of the band maxima of naphthylamines in some of the other organic solvents have been given elsewhere.[1]

As can be seen from Fig. 1 and Table I, the σ_a^m values of naphthylamines in aqueous (neutral) solutions are greater than those in alcohol solutions, whereas the σ_f^m values in the aqueous solutions are much smaller than those in alcohol solutions. Therefore, the $\Delta\sigma$ value is quite large in the aqueous solution. For example, $\Delta\sigma\sim11100\,cm^{-1}$ in the aqueous

*1 In the potential energy curve for the type A hydrogen bonding which was given in our previous report (Fig. 7 of Ref. 1), the equilibrium distance between the proton donor and the acceptor in the case of the type A hydrogen bond was assumed to be larger in the excited state than in the ground state. However, this assumption is rather doubtful. Because the extent of the charge migration from the nitrogen lone pair orbital to the ring is much greater in the excited state than in the ground state, the lone pair orbital may be more contracted in the excited state than in the ground state. Accordingly, the equilibrium distance between the donor and the acceptor may be a little smaller in the excited state than in the ground state. This circumstance is analogous to the case of the blue shift of the absorption and the red shift of the emission in the n-π spectra shown by Krishna and Goodman (V. G. Krishna and L. Goodman, *J. Chem. Phys.*, 33, 381 (1960)), although the extent of the orbital contraction may be smaller in the present case than in the case of the n-π^* transition.

4) Th. Föster, *Z. Elektrochem.*, 54, 531 (1950).

neutral solution compared to $\sim 8200\,cm^{-1}$ in ethanol and $\sim 4800\,cm^{-1}$ in *n*-hexane in the case of α-naphthylamine.*2 This wave number difference is greater, the larger the sum of the Franck-Condon destabilization energies in the excited and ground states. The present experimental results, which demonstrate the blue shift of the absorption spectrum and the large red shift of the fluorescence spectrum in a more polar solvent, indicate that the Franck-Condon principle, including the various solute-solvent interactions, plays a very important role in the solvent shifts of the electronic spectra.

Table I also contains the σ_a^m and σ_f^m values of aniline in ethanol and in the aqueous neutral solution. We can observe from Table I that the solvent shifts of the spectra in this case are quite analogous to those in the case of naphthylamines.

If we take the spectrum in such non-polar aliphatic hydrocarbons as *n*-hexane and cyclohexane as a reference, then the sum of the Franck-Condon destabilization energies resulting from the solute-solvent interactions in the excited and ground states may be expressed as the difference between the $\Delta\sigma$ value in a polar solvent and that in the hydrocarbon solvent. The Franck-Condon destabilization energy of aniline in an aqueous solution amounts to $3400\,cm^{-1}$. This value is much smaller than the corresponding quantity for α-naphthylamine ($6300\,cm^{-1}$), although it is larger than that for β-naphthylamine ($2900\,cm^{-1}$).

The Similarity of the Electronic Spectra of Naphtholate Ions to Those of Naphthylamines. —Before ending the present article, we would like to note the similarity between the electronic spectra of naphtholate ions in the aqueous solution and those of naphthylamines in the aqueous solution. The conjugation power of $-O^-$ seems to be only a little larger than that of the amino group, as one can see from the electronic absorption spectra of many aromatic hydrocarbon derivatives which have $-O^-$ and $-NH_2$ substituents. Actually, the most appropriate values of the Coulomb parameter for the calculation of Hückel MO's seem to be 0.8[5] for $-O^-$ and 1.2[6] for the amino nitrogen.

The σ_a^m values of α- and β-naphtholate ions are $30300\,cm^{-1}$ and $29000\,cm^{-1}$ respectively*3. These σ_a^m values are smaller than the corresponding values of naphthylamines, in accordance with the stronger conjugation power of $-O^-$ than the amino group. However, the $\Delta\sigma$ values for the naphtholate ions ($9300\,cm^{-1}$ for the α-isomer and $5200\,cm^{-1}$ for the β-isomer) are rather close to those of naphthylamines. The value for the β-naphthol molecule in an aqueous solution is $2200\,cm^{-1}$, which is much smaller than that of the ion (α-naphthol molecule is not fluorescent in an aqueous solution).

Thus, although the wave numbers of the maxima of both the absorption and the fluorescence spectra of naphtholate ions are a little smaller than those of naphthylamines, the spectra of each isomer of naphtholate ions and naphthylamines are similar to each other and the characteristics[1] of the spectrum of each isomer are well maintained in naphtholate ions as well.

Summary

The importance of the Franck-Condon principle in the solvent shifts of π–π^* spectra has been discussed with reference to aniline and naphthylamines in alcohol and aqueous solutions. The blue shift of the absorption spectra and the red shift of the fluorescence spectra in these polar solvents have been interpreted in terms of the Franck-Condon destabilization energies, including the solute-solvent hydrogen bonding interactions and the dipolar interactions. In addition to this, the similarity of the electronic spectra of naphtholate ions to those of naphthylamines has been pointed out with reference not only to the absorption spectra but also to the fluorescence spectra.

*2 As has been discussed in the previous report,[1] the fluorescent state of α-naphthylamine is plausibly ^1L_a, although the lowest absorbing singlet state seems to be ^1L_b. In the case of β-naphthylamine, ^1L_b is the relevant excited state for both light absorption and fluorescence. Therefore, the σ_a^m value indicated in the text for α-naphthylamine is that of ^1L_a.

5) N. Mataga, This Bulletin, **36**, 1109 (1963).
6) H. Baba, ibid., **34**, 76 (1961); H. Baba and S. Suzuki, ibid., **34**, 82 (1961).

*3 As has been discussed in Ref. 1, the ^1L_a band shifts strongly to the red in constrast to the ^1L_b band, which shifts to the red only slightly upon the substitution of an electron-donating group at the α position.

The ^1L_b band of α-naphtholate ion is overlapped by the ^1L_a band more extensively than that of α-naphthylamine because the red shift of the ^1L_a band relative to that of the ^1L_b band is greater for the $-O^-$ substitution than for the amino substitution. In view of this, the σ_a^m value for α-naphtholate ion indicated in the text can quite plausibly be assigned to ^1L_a.

Formaldehyde Resins. LXVI.[1] *The Base-catalyzed Reaction of Benzamides with Formaldehyde*

By Minoru Imoto and Mitsue Kobayashi

(Received July 21, 1963)

Three years ago, the present authors stated[2] that the rate of the reaction of amide with formaldehyde in the presence of hydrochloric acid was represented by the following equation:

$$R = k[\mathrm{HCl}][\mathrm{R\text{-}CONH_2}][\mathrm{CH_2O}]$$

For the reaction, an S_E2 mechanism was proposed, illustrated by the following two steps:

i) $\mathrm{CH_2O + HCl \rightarrow {}^{+}CH_2OH + Cl^-}$

ii) $\mathrm{R\text{-}CONH_2 + {}^{+}CH_2OH \rightarrow R\text{-}CO^{-}\overset{\overset{+}{\mathrm{CH_2OH}}}{\underset{\underset{\mathrm{H^+}}{}}{\mathrm{NH}}}}$

$$\rightarrow \mathrm{R\text{-}CONHCH_2OH + H^+}$$

In the present paper, the base-catalyzed reaction of monosubstituted benzamides with formaldehyde will be studied kinetically. The following results have been obtained: (i) The rate of the reaction increased linearly with the concentration of formaldehyde, until the concentration reached a certain value. Above this value, the rate remained constant; i.e., the rate was independent of the concentration of formaldehyde. (ii) The reaction rate constants fit Hammett's equation. (iii) An S_E1 mechanism is proposed for the base-catalyzed reaction of benzamide with formaldehyde.

Experimental

Materials.—The preparation of six kinds of *m*- or *p*-substituted benzamides and the purification of dioxane have been described in the previous paper.[2] As a catalyst, a 0.0428 N aqueous solution of sodium hydroxide was used.

Kinetic Procedures.—All reactions were carried out at 30°C (±0.05°C). A required amount of amide was weighed into a 50 ml. volumetric flask. The amide was dissolved in 25 ml. of dioxane. The flask was placed in a thermostat kept at 30°C for at least 30 min. The formaldehyde solution and distilled water were also kept at the same temperature. A 0.6 ml. volume of the catalyst and then a required amount of the formaldehyde solution were added to the flask. In order to avoid the effect of carbon dioxide in the atmosphere, the catalyst solution was added through a microburette in an atmosphere of air freed from carbon dioxide. The solution was then immediately diluted to 50ml. with distilled water. After a thorough mixing, the solution was brought into a reaction vessel which had been placed in the thermostat. The rate of the consumption of formaldehyde was determined by the KCN-method, as has been described in the case of an acid-catalyzed reaction.[2]

Experimental Errors Anticipated. — (1) The *N*-methylol amide produced may decompose to formaldehyde and amide in the presence of the base. However, Ugelstadt has concluded that the back reaction could be neglected until the reaction reached the consumption of ca. 10% of formaldehyde.[3]

(2) The benzamide may be hydrolyzed with the base catalyst into benzoic acid and ammonia. Ugelstadt has also concluded that this hydrolysis was negligible.

(3) As is known, formaldehyde is changed into formic acid and methanol by the Cannizzaro reaction. However, under the conditions described above, this reaction was so small as to be negligible, as Table I shows.

Table I. The consumption of formaldehyde at 30°C

($[\mathrm{CH_2O}]_0 = 0.05$ mol./l., catalyst 0.6 ml./50 ml.)

Reaction time min.	Decrease in $[\mathrm{CH_2O}]_0$ content $\times 10^{-3}$ mol./l.	Decrease in $[\mathrm{CH_2O}]_{\mathrm{OCH_3}}$ content $\times 10^{-3}$ mol./l.
2	0	0.5
5	0.1	1.8
25	0.1	2.6
45	0.28	6.0
60	0.28	—

In Table I, the decrease in $[\mathrm{CH_2O}]_0$ content indicates the concentration of formaldehyde consumed by the Cannizzaro reaction in the absence of amide. The decrease in $[\mathrm{CH_2O}]_{\mathrm{OCH_3}}$ content was the result of the consumption of formaldehyde by the reaction of formaldehyde with *p*-methoxybenzamide. In the present reaction, the *p*-methoxybenzamide was the most inactive amide. Even in this case, however, the $[\mathrm{CH_2O}]_0$ decrease was only a twentieth of that of $[\mathrm{CH_2O}]_{\mathrm{OCH_3}}$.

An Estimation of the Initial Rate of Reaction. —Figure 1 shows a typical example of the reaction course. The ordinate, -[F], showed the concentration of consumed formaldehyde. Extrapolating the

3) J. Ugelstadt, Dissertation, Leiden University (1955).

remaining concentration of formaldehyde, [F], to time zero, the initial concentration of formaldehyde, $[F]_0$, was estimated. The inclination of the curve of -[F] vs. time at time zero gave the rate of the reaction, $-d[F]/dt$.

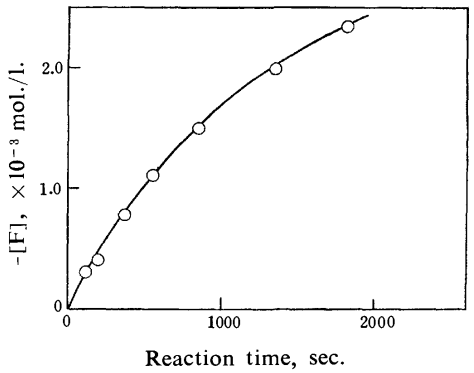

Fig. 1. The consumption of formaldehyde vs. the reaction time.
($[F]_0=0.0955$ mol./l., $[C_6H_5CONH_2]_0=0.05$ mol./l., at 30°C)

Results and Discussion

Reaction-orders of the Reactants.—Ugelstadt[3] has previously given the following rate equation for the base-catalyzed reaction of benzamide with formaldehyde:

$$R=-d[F]/dt$$
$$=k[C_6H_5CONH_2][CH_2O][OH^-] \quad (1)$$

To confirm Ugelstadt's formula, the rate of the consumption of formaldehyde, R, was investigated at various concentrations of benzamide and formaldehyde.

The Reaction-order of Benzamide.—While the concentrations of formaldehyde and of the catalyst were kept at 0.05 mol./l. and 0.60 ml./50 ml. respectively, the rate was measured in various concentrations of benzamide over the range from 0.0125 to 0.05 mol./l. As Fig. 2 shows, a linear relationship was obtained.

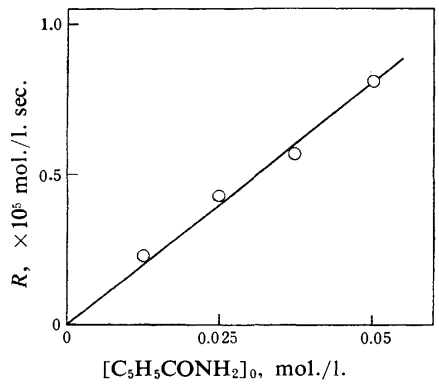

Fig. 2. The relationship between R and $[C_6H_5CONH_2]_0$.

The reaction, therefore, was of the first order with benzamide.

The Reaction-order of Formaldehyde.—While the concentration of benzamide was kept at 0.05 mol./l., the concentration of formaldehyde was changed from 0.013 to 0.200 mol./l. The result obtained was peculiar, as is shown in Fig. 3. Such a relationship between $[F]_0$ and R was found for the first time.

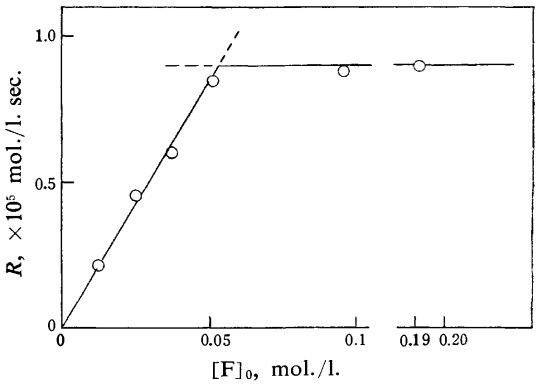

Fig. 3. The relationship between R and $[F]_0$.
0.6 ml. of the catalyst was added.

When the concentration of formaldehyde was less than ca. 0.05 mol./l., the reaction was of the first order with formaldehyde. However, in a higher concentration of formaldehyde than this characteristic concentration, the reaction order of formaldehyde became zero. A similar bending point in the curve of R vs. $[F]_0$ was also observed in the reaction of every substituted benzamide, as Fig. 4 shows.

The Reaction-order of Sodium Hydroxide.—According to the paper by Ugelstadt, it may be assumed that the reaction-order of $[OH^-]$ was first under the conditions described above. This will also be confirmed by us in a later paper.[4]

From the results obtained, the experimental rate equation can be represented as follows: In the case of a lower concentration of formaldehyde than usual:

$$R_2=\frac{-d[F]}{dt}$$
$$=k_2[C_6H_5CONH_2][CH_2O][OH^-] \quad (2)$$

By a higher concentration of formaldehyde than usual;

$$R_1=\frac{-d[F]}{dt}=k_1[C_6H_5CONH_2][OH^-] \quad (3)$$

The Effect of the Polar Character on the Reaction Rate. — The electron-releasing or attracting group substituted in the benzene

4) Part LXVII of this series: M. Imoto and A. Ninagawa, This Bulletin, 36, 1508 (1963).

nucleus of benzamide was expected to have a strong effect on the rate of the reaction. While the concentration of the substituted benzamide was kept constant (0.05 mol./l.), the relationship between R and $[F]_0$ was measured. The results obtained are illustrated by Fig. 4.

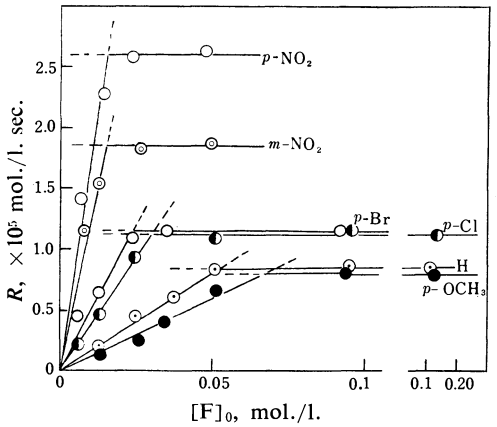

Fig. 4. The relationship between the initial concentration of formaldehyde and R. $[X\text{-}C_6H_4CONH_2]=0.05$ mol./l. Catalyst=0.6 mi./50 ml.

From the results of the experiments illustrated in Fig. 4, the reaction constants, $k_1[OH^-]$ and $k_2[OH^-]$, were calculated. (Table II).

These values of $k[OH^-]$ were correlated with Hammett's equation. The linear relationship shown in Fig. 5 was obtained.

TABLE II. RATE CONSTANTS FOR SUBSTITUTED BENZAMIDE

Benzamide	$k_1[OH^-]$	$k_2[OH^-]$	σ
p-OCH_3	1.60	1.92	−0.268
H	1.80	3.51	0.0
p-Cl	2.32	6.91	+0.227
p-Br	2.40	9.61	+0.232
m-NO_2	3.72	38.5	+0.710
p-NO_2	5.28	41.8	+0.778

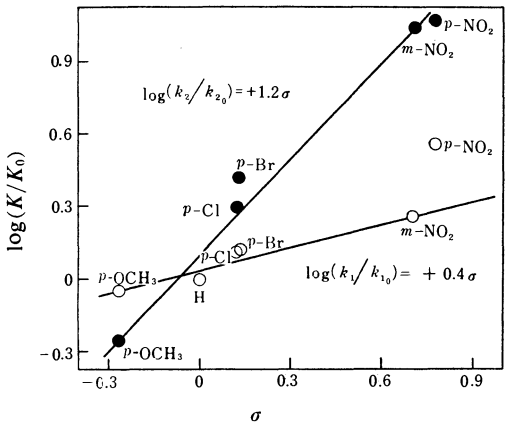

Fig. 5. Plots for Hammett's equation.

The Reaction Mechanism of Benzamide with Formaldehyde in the Presence of a Base Catalyst.—Ugelstadt has concluded that the reaction of benzamide proceeded via three steps:

i) $R\text{-}CONH_2 + B \rightarrow R\text{-}CONH^- + BH^+$

ii) $R\text{-}CONH^- + CH_2O \rightarrow RCONH\text{-}CH_2O^-$

iii) $RCONHCH_2O^- + BH^+ \rightarrow RCONHCH_2OH + B$

Of these three steps, it is clear that iii is not the rate-determining step. Ugelstadt considered step ii to be rate-determining and kinetically derived Eq. 1. However, this conception can not completely interpret the present results.

Step i may be concluded to be the slowest step from the consideration that, when an electron-attracting group is introduced into the phenyl nucleus, the release of protons from the NH_2 group of benzamide by the attack of hydroxyl ions becomes easier. This conception may be experimentally demonstrated, as in Fig. 5. In the range of the lower, and also of the higher, concentrations of formaldehyde, the signs of ρ were positive. The values of ρ were estimated to be +1.2 and +0.4 respectively.

The mechanism presented above may be classified as S_E1, namely, a unimolecular electrophilic substitution. The existence of Eq. 2 in the range of the lower concentration of formaldehyde was, apparently, consistent with the theory of S_E2. However, a new conception was applicable as follows: By step ii $X\text{-}C_6H_4CONH^-$ reacts immediately with formaldehyde, which exists in the solvated cage. Accordingly, until formaldehyde reaches the saturating concentration in the solvated cage, the rate of the consumption of formaldehyde is dependent on the added amounts of formaldehyde. In case the concentration of formaldehyde is higher than the saturated concentration in the solvated cage, the rate of the consumption of formaldehyde is independent of the amounts of formaldehyde.

It can be accepted that the bending points in the curves in Fig. 5 may be indicative of the saturated concentration of formaldehyde in the solvated cage. These points were obtained by extending the upward and lying lines to the crossing points. The concentrations of formaldehyde at this point were denoted as $[F]_c$.

In the ion of $X\text{-}C_6H_4CONH^-$, if X is an electron-attracting group, the electron-density about the nitrogen atom becomes smaller than when an electron-releasing group such as X is present. It is to be anticipated that the smaller

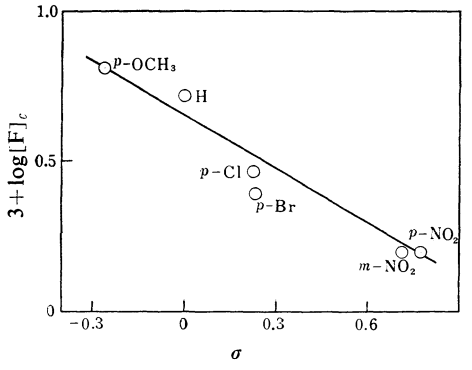

Fig. 6. The relation of the saturating concentration of formaldehyde in solvated cage with Hammett's constants.

the electron-density about the nitrogen atom, the smaller the solvating ability of the ion of $X\text{-}C_6H_4CONH^-$. The values of $[F]_c$ were estimated as follows: *p*-OCH_3 0.065 mol./l., H 0.052, *p*-Cl 0.0305, *p*-Br 0.024, *m*-NO_2 0.015, and *p*-NO_2 0.015. The results obtained here were applied to Hammett's equation, as Fig. 6 shows. These results strongly supported the conception of S_E1.

Summary

The mechanism of the reaction of the substituted benzamides with formaldehye in dioxane-water (1 : 1) in the presence of sodium hydroxide has been studied kinetically. Equations 2 and 3 have been obtained. An electron-attracting group increased the rate of the reaction, while an electron-releasing group decreased it. The reaction rates fit Hammett's equation. It was concluded that the S_E1-mechanism is suitable for interpreting the results obtained.

Formaldehyde Resins. LXVII.[1] *On the Reaction Order of Sodium Hydroxide and on the Salt-effect of Sodium Bromide in the Base-catalyzed Reaction of Benzamide with Formaldehyde*

By Minoru IMOTO and Akira NINAGAWA

(Received July 26, 1963)

In the preceding paper,[1] the base-catalyzed reaction of benzamide and its para-substituted derivatives was investigated, and the following results were obtained. The rate equation was found to be:

$$R_2 = \frac{-d[CH_2O]}{dt} = k_2[C_6H_5CONH_2][CH_2O][OH^-] \quad (1)$$

at a lower concentration of formaldehyde than usual and

$$R_1 = \frac{-d[CH_2O]}{dt} = k_1[C_6H_5CONH_2][OH^-] \quad (2)$$

at a higher concentration of formaldehyde than usual, moreover, the reaction mechanism was assumed to be as follows:

i) $R\text{-}CONH_2 + B \rightleftarrows R\text{-}CONH^- + BH^+$

ii) $R\text{-}CONH^- + CH_2O \rightarrow R\text{-}CONHCH_2O^-$

iii) $R\text{-}CONHCH_2O^- + BH^+ \rightleftarrows R\text{-}CONHCH_2OH + B$

For k_2 and k_1 of Eqs. 1 and 2, Hammett's rule was applied, and a linear relationship was established. The reaction constants, ρ, were +1.2 and 0.4 respectively. The positive ρ values indicated an easiness of the loss of the proton from an amide group when the substituent was of the electron-withdrawing type. Granted that step i was the slowest step, the reaction was interpreted as S_E1. The change in the reaction order of formaldehyde from one to zero was explained by the idea of the "solvated cage."

The present paper concerns the determination of the reaction order of sodium hydroxide and the relationship between the concentration of sodium hydroxide and the bending concentration of formaldehyde, $[F]_c$, which corresponds to the critical point of the reaction order of formaldehyde. Also, studies of the salt-effect of sodium bromide and of the constancy of the pH value through the reaction will be reported on.

1) LXVI: M. Imoto and M. Kobayashi, This Bulletin, **36**, 1505 (1963).

Experimental

Reagents.—The methods used in the preparation and purification of benzamide and dioxane have already been described in a previous paper.[2] An aqueous solution of sodium hydroxide was used as the catalyst. In order to avoid a change in its concentration due to carbon dioxide absorption from air, the storing bottle was directly connected to a microburette and the solution was pushed into the burette by air pressure through a potassium hydroxide absorber tube. Sodium bromide was of a commercially special grade.

Experimental Procedures. — The reaction was carried out at 15±0.05°C, and the rate was determined by the following procedure. Benzamide (0.657 g.) was weighed into a 50 ml. graduated flask so as to produce a 0.1 mol./l. solution; this was dissolved in 35 ml. of dioxane, and then a repuired amount of the catalyst was added. While the mixture was kept in a constant-temperature bath at 15°C for twenty minutes, a formaldehyde solution and purified water were also kept at the same temperature in the same bath. The formaldehyde solution was then pipetted into the benzamide solution, and the whole mixture was then diluted to a total volume of 50 ml. immediately and mixed well by shaking it in the bath. The reaction mixture was then transferred to a reaction vessel that had also been kept in the constant-temperature bath. The addition of formaldehyde was taken as the start of the reaction; after that time aliquot samples were taken at a constant time intervals. The aliquot was then mixed with the quenching solution, which had been cooled in ice water for twenty minutes, and then the amount of residual formaldehyde was determined by the KCN-method, which has been described in a previous paper.[1]

When a salt was present in the reaction system, a water solution of sodium bromide was added just before the addition of the catalyst.

The values of pH were measured by means of a Hitachi-Horiba potentiometer Type P.

Quenching of the Reaction.—Among the number of tests made to quench the reaction, the best results were obtained with a mixture of a buffer solution (0.1 N KH_2PO_4 and 0.1 N Na_2HPO_4) and potassium cyanide with a pH value of 10.0 cooled in ice water for twenty minutes before use. The results obtained are shown in Fig. 1.

After the quenching, the titration of formaldehyde had to be done immediately, for the reaction was stopped for a short period only, after which the reverse reaction took place.

The Start of the Reaction. — The following two methods had been considered to be the start of the reaction:

(a) The time of the addition of formaldehyde, following the addition of the sodium hydroxide solution to the benzamide.

(b) The time of the addition of the sodium hydroxide solution, following the addition of formaldehyde.

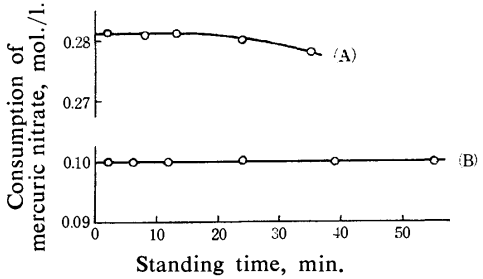

Fig. 1. The standing time in the quenching solution vs. the amount of mercuric nitrate consumed.
(A) The titration of the reacting solution; $[Benzamide]_0=0.100$ mol./l., $[CH_2O]_0=0.100$ mol./l., $[NaOH]=4.0\times10^{-4}$ mol./l., reaction time=29 min.
(B) The titration of the formaldehyde solution, as a blank test; $[CH_2O]_0=0.100$ mol./l.

Both were found to be the same; method a was chosen.

Calculation of the Reaction Rate.—The amount of formaldehyde consumed was given by the difference between the amounts of mercuric nitrate needed for an aliquot sample and for a blank test in which no benzamide was present. The rate of the disappearance of formaldehyde was computed in the manner described in the foregoing paper. Figure 2 shows some typical examples of the consumption of formaldehyde.

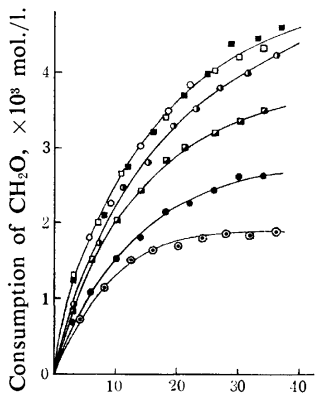

Fig. 2. The consumption of formaldehyde vs. reaction time at 15±0.05°C.

Results

The Order of the Reaction with Respect to Each Reactant.—The reaction was carried out with various concentrations of formaldehyde

2) Part LIII of this series: M. Imoto and M. Kobayashi, This Bulletin, 33, 1651 (1961).

between 0.011 and 0.155 mol./l. for each concentration of sodium hydroxide of 6.12×10^{-4}, 4.48×10^{-4}, 3.28×10^{-4}, and 2.18×10^{-4} mol./l., and their relation with the initial rate of the consumption of formaldehyde (R) was obtained as in Fig. 3, from which the order of the reaction with respect to formaldehyde and sodium hydroxide, and the relationship of the sodium hydroxide concentration to the bending concentration of formaldehyde $[F]_c$ were studied. Of these the reaction had already been reported in a previous paper to be of the first order with respects to formaldehyde; the present study was undertaken in order to reconfirm it.

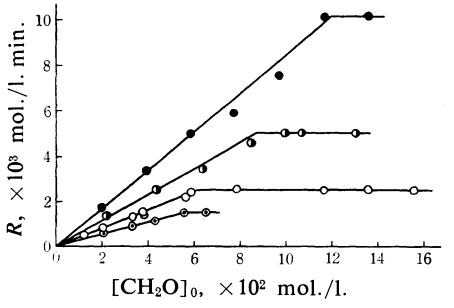

Fig. 3. Consumption rate (R) vs. the concentration of formaldehyde in the presence of various amounts of sodium hydroxide.
$[Benzamide]_0=0.100$ mol./l.
$[NaOH]=6.12\times10^{-4}$ mol./l. (●), 4.47×10^{-4} mol./l. (◑), 3.28×10^{-4} mol./l. (○), and 2.18×10^{-4} mol./l. (⊙)
The same symbols used in Figs. 4, 5 and 6 to represent these same [NaOH] value.

Order of the Reaction with Respect to Formaldehyde. — At each concentration of sodium hydroxide, a linear relationship between the lower concentrations of formaldehyde and R was obtained; at the higher concentrations of formaldehyde, it had no effect on the rate, showing the order of the reaction to be zero. The logarithmic plots of low formaldehyde concentrations and R are shown in Fig. 4. The values of tan α were found to be 1.00, 0.82, 0.97 and 0.93 at the respective concentrations of sodium hydroxide. The reaction, therefore, was found to be of the first order with respect to formaldehyde in the range of lower concentrations.

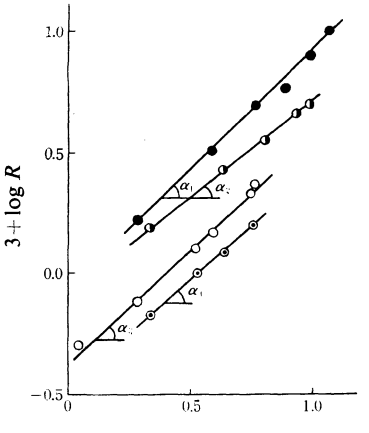

Fig. 4. The relationship between R and the concentration of formaldehyde before the bending point.
tan $\alpha_1=1.00$ tan $\alpha_3=0.97$
tan $\alpha_2=0.82$ tan $\alpha_4=0.93$

The Order of the Reaction with Respect to Sodium Hydroxide.—The logarithmic plots of sodium hydroxide concentration and R at the formaldehyde concentration of 0.40 mol./l., shown already in Fig. 3, gave the straight line in Fig. 5, and tan α was found to be 1.00. Thus the order of the reaction with respect to sodium hydroxide was found to be of the first order.

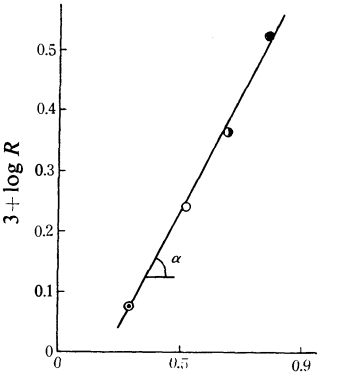

Fig. 5. The relationship between sodium hydroxide concentration and R at $[CH_2O]_0=0.40$ mol./l.
tan $\alpha=1.00$

The Relationship between the Bending Concentration of Formaldehyde and Sodium Hydroxide Concentration.—Figure 6 shows the relationship between the logarithmic plots of the bending concentration of formaldehyde, where the order of the reaction turned from first to zero, and the sodium hydroxide concentration. It was made clear that the slope was 0.93 and that the relationship between the bending concentration of formaldehyde, $[F]_c$, and the sodium hydroxide concentration was of the first order.

Measurement of pH.—As Figs. 7 and 8 show, the pH values of the reaction systems were found to be constant throughout the reaction. Therefore, it was not necessary to consider the various sub-reactions which could cause a change in pH value.

The Salt Effect of Sodium Bromide. — The results obtained are illustrated in Fig. 9. The pH value was constant through the reaction in the presence of sodium bromide.

Activation Energy. — The activation energy of the reaction of benzamide with formaldehyde in the presence of sodium hydroxide was computed as 8.25 kcal./mol. on the basis of the experiments at 15, 20, 25, and 30°C (Fig. 10).

Discussions

The rate equation derived from the present experimental results has shown a good agreement with Eqs. 1 and 2 obtained by Imoto and Kobayashi in the foregoing paper.[1] On the basis of the formation of $RCON^-H$ anions by the reaction of OH^- with the amide, Imoto and Kobayashi have concluded that the mechanism of this reaction was like S_E1, and that thus the anion formed was caged by the solvent and by other molecules to form a so-called "solvated cage," in which formaldehyde reacted with the anion to introduce methylol groups. If this were the reaction, the rate of the disappearance of formaldehyde in a solvated cage had to be proportional to the formaldehyde concentration, unless it reached the saturation

concentration in the cage. When added formaldehyde gave a higher concentration than the saturation concentration in a solvated cage, it existed at the outer side of the cage, missing the reaction with the anion, and the rate of the consumption of formaldehyde was not affected by the formaldehyde concentration. If the reaction proceeds in that fashion, the concentration of $RCON^-H$ increases with an increase in the sodium hydroxide concentration. In other words, the number of solvated cages increases with an increase in the sodium hydroxide concentration, and when the formaldehyde concentration increases, the amount of formaldehyde coming into the solvated cages also increases, therefore, it can be expected that the saturation concentration of formaldehyde will be increased linearly with an increase in the sodium hydroxide concentration. There should be a linear relationship between the critical bending concentration of formaldehyde in Fig. 3 and the sodium hydroxide concentration. As is shown in Fig. 6, the experimental results agreed well with what had been expected. The peculiar effect of sodium bromide shown in Fig. 9 can also be explained by the solvated cage theory. With the concentration of sodium bromide, the concentration of sodium ions in the cage increases, resulting in a decreas in the formaldehyde concentration in the cage. Inevitably the consumption rate of formaldehyde decreases rapidly, until sodium ions reach an equilibrium concentration in the cage. After the equilibrium is achieved, the rate may be kept constant. As the lower two curves in Fig. 9 show, the bending point of a' with respect of sodium bromide is situated at a higher concentration than that of a. This phenomenon can be understood by the cage theory, considering that the concentration of formaldehyde in a' is 0.1 mol./l. and that in a is 0.04 mol./l. The equilibrium concentration of sodium cations should be lower in the case of a' than in that of a.

Those results strongly support the S_E1 mechanism of the reaction of benzamide with formaldehyde in the presence of a base catalyst.

Summary

A kinetic study of the reaction of benzamide with formaldehyde in the presence of sodium hydroxide has been made. The following results have been obtained: (1) A linear relationship is obtained between the concentration of sodium hydroxide and the critical bending concentration of formaldehyde where the reaction-order changes from one to zero. (2) The pH value is constant throughout the reaction. (3) The rate of the reaction decreases upon the addition of sodium bromide. However, the decrease reaches a miuimum at a definite concentration of sodium bromide. After this point, the salt has no effect on the rate. (4) The activation energy has been computed as 8.25 kcal./mol. The findings (1) and (3) have been explained by the solvated cage theory.

Charge Mobility in Pyrene Crystals

By Kenji OHKI, Hiroo INOKUCHI and Yusei MARUYAMA

(Received August 6, 1963)

Recently, Murrell has calculated the overlap integrals between the molecular orbitals of different anthracene molecules in the crystal lattice.[1] Further, LeBlanc has reported on the band structure of anthracene.[2] In this report, we will extend Murrell's study to the pyrene crystal in order to find a correlation between the calculated and experimental values of charge mobility in a direction perpendicular to its ab plane.*

2) O. H. LeBlanc, *J. Chem. Phys.*, **35**, 1275 (1961).

Theoretical

The Coordinates.—The crystal structure of pyrene is monoclinic prismatic with a space group $C_{2h}^5-P2_1/a$ and with $a=13.60\pm0.05$ Å, $b=9.24\pm0.03$ Å, $c=8.37\pm0.10$ Å and $\beta=100.2\pm0.2°$; its detailed analysis has been obtained by the X-ray method by Robertson and White.[3]

* The calculation of overlap integrals in a direction parallel to the ab plane will be reported on elsewhere.
3) J. M. Robertson and J. G. White, *J. Chem. Soc.*, **1947**, 358.

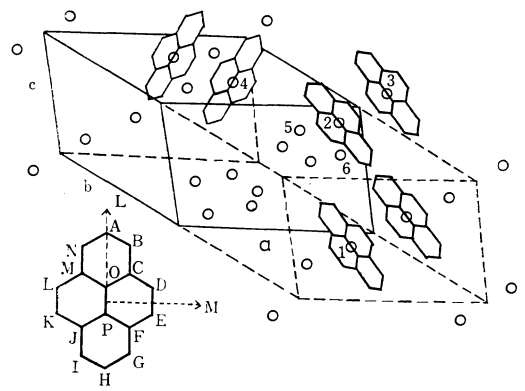

Fig. 1. Arrangement of pyrene molecules in the crystal lattice.

Employing their findings, the relation between neighbouring molecules in the crystal is drawn in Fig. 1; the numbers 1, 2,···, 6 denote pyrene molecules in the crystal. Further, the terms of A, B, C, ···, O and P are carbon atoms in the pyrene molecule, as the same figure shows. From the orthogonal coordinates (X, Y, Z) of the sixteen atoms of the pyrene molecule in the crystal lattice, the distances between two atomic centres in a perpendicular direction to the ab plane are estimates as follows:

(a) Distances between molecule 1 and molecule 2.

N_1G_2**$=3.541$ Å $M_1E_2=4.945$ Å $N_1F_2=4.032$ Å

$M_1F_2=4.703$ Å $N_1E_2=3.827$ Å $L_1G_2=3.827$ Å

$N_1D_2=4.921$ Å $L_1F_2=4.945$ Å $M_1G_2=4.032$ Å

$K_1G_2=4.921$ Å

(b) Distances between molecule 1 and molecule 3. All distances are more than 5 Å.

(c) Distances between molecule 1 and molecule 4.

$N_1N_4=4.899$ Å $B_1M_4=4.672$ Å

$B_1N_4=4.042$ Å $B_1L_4=4.366$ Å

(d) The distance between molecule 1 and molecule 5.

$N_1I_5=4.356$ Å

(e) Distances between molecule 1 and molecule 6.

$N_1B_6=4.042$ Å $B_1M_6=4.612$ Å

$N_1N_6=4.899$ Å $L_1B_6=4.366$ Å

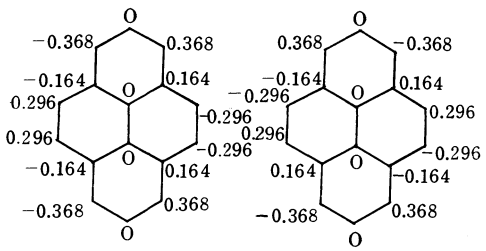
When the overlap integrals between two atomic orbitals are calculated, any integrals between two orbitals which are more than 5.0Å are disregarded, for the integrals decrease exponentially with the distances of the two atomic centres. Therefore, none of intermolecular distances greater than 5 Å are indicated in the above chart. Furthermore, as is described in the following section, the density of the unpaired electrons at the A, H, O or P atom positions is null. Thereby, all terms including A, H, O and P are also disregarded.

The Calculation of Overlap Integrals. — The overlap integral (S) between two molecules, a and b, are

$$S=\int \phi_k^a \phi_k^b \, d\tau = \sum_{ij} C_{ki}C_{kj} \int \chi_i^a * X_j^b d\tau \qquad (1)$$

because ϕ_k^a, the molecular orbital, is derived from a linear combination of atomic orbitals, χ_i^a.

To obtain C_{ki} and $k(C_{kj})$, the simple Hückel theory has been applied. The Hückel functions for the hole and the electron are given in Fig. 2.[4]



For hole For electron

Fig. 2. The Hückel functions for hole and electron.

Further, the terms of $\int \chi_j^a * \chi_j^b \, d\tau$ are calculated in association with Mulliken's method.[5] On the basis of this work on a master formula for the Slater-AO overlap integral, two of the terms are considered to find the overlap integral between two molecules:

$$S(2p\pi, 2p\pi) = (120)^{-1} p^5 [5A_4 - 6A_2 + A_0] \quad (t=0) \qquad (2)$$

$$S(2p\sigma, 2p\sigma) = (120)^{-1} p^5 [5A_4 - 18A_2 + 5A_0] \quad (t=0) \qquad (3)$$

where $A_k(p) \equiv \int_1^\infty \xi^k e^{-p\xi} d\xi$

$$= e^{-p} \sum_{\mu=1}^{k+1} \left[k!/p^\mu (k-\mu+1)! \right];$$

in the above equation $\mu (=Z_n/(n-\delta))$ is 1.45 for C^-, 1.625 for C, and 1.80 for C^+. Further, $p \equiv 1/2(\mu_a+\mu_b)R/a_H$, $t \equiv (\mu_a-\mu_b)/(\mu_a+\mu_b)$, R is the distance between atoms, and a_H is the

** N_1G_2 denotes the distance between the N atom of molecule 1 and the G atom of molecule 2.

4) C. A. Coulson and R. Daudel, "Dictionary of Values of Molecular Constants," Vol. II, Centre de la Recherche Scientifique and ICI (1955).

5) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

Bohr radius.

From these relations, $S(2p\pi, 2p\pi)$ and $S(2p\sigma, 2p\sigma)$ have been calculated as in Table I.

As Table I shows, the overlap integral, S, monotonously decreases with an increase in the parameter, p. In association with the curve of relation, p-S, the values of S for the atomic pair have been evaluated.

These atomic orbitals are defined by the vectors $\boldsymbol{n}_a$ and $\boldsymbol{n}_b$, and the separation of the orbitals, by $\boldsymbol{R}$. Thereby, the overlap integral, S_{ab}, is described as:

$$-S_{ab}=\frac{(\boldsymbol{n}_a\boldsymbol{R})(\boldsymbol{n}_b\boldsymbol{R})}{\boldsymbol{n}_a\boldsymbol{n}_b{}^2\boldsymbol{R}}\,S(2p\sigma, 2p\sigma)-\left[\frac{\boldsymbol{n}_a\boldsymbol{n}_b}{n_an_b}\cdot\frac{(\boldsymbol{n}_a\boldsymbol{R})(\boldsymbol{n}_b\boldsymbol{R})}{n_an_bR}\right]S(2p\pi, 2p\pi) \tag{4}$$

In this consideration, we must calculate the directions of the π-orbital vectors in the pyrene crystal lattice. In accordance with the crystallographical study by Robertson and White, the orientations of molecules in the lattice are:

$$\chi_L=61.1^\circ:\ \chi_M=52.2^\circ:\ \chi_N=128.7^\circ$$
$$\cos\chi_N=-0.6248$$
$$\psi_L=77.7^\circ:\ \psi_M=52.4^\circ:\ \psi_N=40.2^\circ$$
$$\cos\psi_N=0.7630$$
$$\omega_L=31.9^\circ:\ \omega_M=120.1^\circ:\ \omega_N=80.5^\circ$$
$$\cos\omega_N=0.1648$$

where χ, ψ and ω are the angles at which the molecular axes L and M (Fig. 1) and their perpendicular, N, make the a, b and c′ crystallographic axes (c′ is perpendicular to a and b). Thereby, the directions of the π-orbital vectors for molecules 1, 2 and 3 are (−0.6248, 0.7630, 0.1648) or (0.6248, −0.7630, −0.1648), and for molecules 4, 5 and 6, (−0.6248, −0.7630, 0.1648) or (0.6248, 0.7630, −0.1648).

On the basis of the above calculations, the overlap integrals for the hole and the electron in the pyrene crystal are summarized in Table II. These integrals may be proportional to the mobility of the charge carriers.

Experimental and Discussion

Fairly large single crystals of purified pyrene, the method of preparation of which has already been described in a previous report,[6] were studied to find their carrier mobilities. The apparatus to find them was designed following suggestion by Kanzaki.[7] A pyrene crystal (4) approximately 1 to 2 mm. thick (d) was mounted between a pair of Mylar insulating sheets (3) serving as blocking layers. Between two metal electrodes, one of them a copper electrode (1) and the other a conducting glass one (5), an electrical potential (V) was applied, and a short light pulse with μ sec. along was illuminated on the surface of the crystal, as is shown in Fig. 3 schematically. Under the influence of a polarity of the electric field, one of the charge carriers drifted through the crystal. Therefore, the mobilities (μ) of both carriers, the electron (μ_e) and the hole (μ_h),

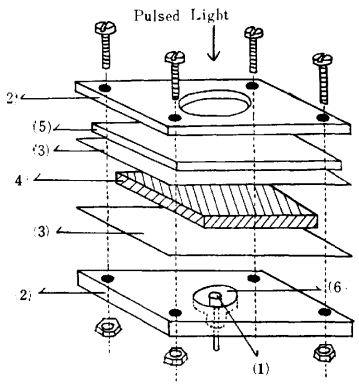

Fig. 3. The apparatus to observe the charge mobility in organic crystals. (1) Copper electrode, (2) copper holder, (3) Mylar sheet as blocking layer, (4) pyrene crystal, (5) conducting glass electrode and (6) teflon insulating bush.

6) H. Inokuchi and K. Ohki, This Bulletin, 36, 105 (1963).

7) H. Kanzaki, T. Ninomiya and K. Kido, *J. Phys. Chem. Solids*, 22, 309 (1961).

were calculated from the relation $\mu=d^2/Vt$, where t is the time of drift in crystal.* In accordance with the above equation, the mobilities were observed to be $\mu_e\sim3.0\,cm^2/V.sec.$ and $\mu_h=1.2\pm0.1\,cm^2/V.sec.$ at room temperature respectively.

LeBlanc has found from the transient photocurrent with cathode illumination that the hole mobility in the polycrystalline pyrene is $\mu_h=0.35\pm0.03\,cm^2/V.sec.$ at 100°C and $\mu_h=0.28\pm0.03\,cm^2/V.sec.$ at 149°C.[8] The same author has also reported that the photocurrent with an illuminated cathode, which was fifty times smaller than that with an illuminated anode, is too weak to use to estimate the electron mobility. In contrast with his work, in this experiment, the electron mobility (μ_e) could be estimated from the weak photocurrent using cathode illumination, although with difficulty.

To judge from the theoretical calculations in Table II, the hole mobility was larger than that of the electron. This discrepancy between experimental and theoretical works may result from a rough approximation of the above calculation applying the overlap integral; in the future we hope to have a more reliable theoretical treatment for organic semiconductors.

* To avoid the effect of the time constant of the apparatus on the preceding relation, the value of the resistor as an input impedance was $10^5\,\Omega$, the applied potential was 10^3 V., and the thickness of the crystal was 1.4 mm.

8) O. H. LeBlanc, *J. Chem. Phys.*, **37**, 916 (1962).

Summary

To estimate the charge mobility in a direction perpendicular to the ab plane in the sixteen atoms of the aromatic hydrocarbon crystal, pyrene, the overlap integrals between two molecules have been calculated. On the basis of these results, the hole mobility (μ_h) has been found to be twice that of the electron mobility (μ_e). However, judging from the transient photocurrent of the pyrene crystal, μ_e ($\sim3\,cm^2/V.sec.$) was considerably larger than μ_h ($1.2\,cm^2/V.sec.$). This discrepancy may be eliminated by the introduction of a more accurate theoretical treatment.

The Application of Intermittent Illumination to the Bleaching of Dye. I. A General Consideration of the Method

By Masao KOIZUMI and Yoshiharu USUI

(Received June 17, 1963)

It is well-known that intermittent illumination (the sector method) has been successfully applied to kinetic studies of polymerization, but it has not yet been introduced in the photobleaching reaction of dye solutions. It is certain, however, that this method would also afford valuable information about the behavior of the intermediate produced by the irradiation of the dye solution. For example, if a certain intermediate with a lifetime of τ absorbs light, there is a possibility that the reaction is accelerated by an intermittent illumination with a frequency comparable with $1/\tau$, as compared with the case in which it is illuminated by a light with a lower frequency. There will be many other cases in which such specific effects may be anticipated. We undertook such experiments by employing the stroboscope light as a light source. This consists of successive flashes, the duration of which is several microseconds and the frequency of which can be changed within a certain region. Furthermore, one flash can emit a considerable amount of light. It is expected that such a light source has, in some cases, certain advantages over an intermittent light source by means of a sector.

The object of the present paper is to discuss the basic points necessary for such a quantitative application. For example, two factors, the intensity and the frequency of the flash, when varied over a wide range, may have some specific effects on the reaction which may be attributed to the method itself; therefore, it is necessary to consider them beforehand. For example, when the intensity of the flash is increased beyond a certain limit,

the quantity of the reaction will become independent of the intensity. The present paper will first discuss four subjects which are closely connected with the experimental results to be presented later.

The Establishment of the Steady State.—When a certain intermediate with a rather long life, τ, is generated by an illumination, its concentration will rise with a successive flash. It is desirable to know the number of flashes which are necessary to get the maximum concentration of the intermediate (X) and the value of the latter when the net reaction does not take place. These findings will be helpful in considering the situation in which the eventual reaction proceeds.

The Effect of ν on the Quantity of Reaction at Various Flash Intensities when $\nu \ll 1/\tau$.—Even when the frequency of the (successive) flashing ν is substantially smaller than $1/\tau$, the quantity of the reaction is still affected by ν in a specific manner depending on the flash intensity. This effect may be said to be due to the method itself. The general features may perhaps be summarized as follows:

A) At a constant light quantity per second, the larger ν may increase the quantity of the reaction per second more or less according to the intensity.

B) At a constant light intensity of one pulse, the quantity of reaction per each successive flash is independent of ν. However, the average quantity of reaction per flash decreases with ν.

The Effect of ν when $\tau \approx 1/\nu$.—A complicated effect due to the method itself may be anticipated.

Some Relations between I and ν Effects when a Genuine Frequency Effect exists.—For example, the case in which X absorbs light and induces an additional reaction will be considered.

I. The Establishment of the Steady State

Let us consider the case in which no net reaction takes place and yet an intermediate, X, with a suitable lifetime, τ, is produced. Upon successive flashes, the concentration of X increases until X^o_n and X^f_n practically reach the constant value (see Fig. 1).

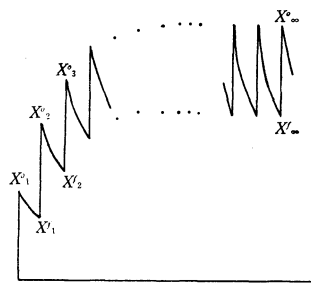

Fig. 1. Change in the concentration of X when no net reaction occurs.

The number of flashes necessary to realize this situation can be derived as follows:
Put the initial concentration of dye as C_o and the concentrations of dye immediately after each flash and just before the next flash, respectively, as C^o_n and C^f_n.

$$\left.\begin{array}{l} C_o \rightarrow C^o_1 \rightarrow C^o_2 \rightarrow \cdots\cdots \\ \qquad X^o_1 \rightarrow X^o_2 \rightarrow \cdots\cdots \end{array}\right\}$$

$$\left.\begin{array}{l} C^f_1 \rightarrow C^f_2 \rightarrow \cdots\cdots \\ X^f_1 \rightarrow X^f_2 \rightarrow \cdots\cdots \end{array}\right\}$$

If $(1-f)$ fraction of dye is changed to X by each flash and if the ratio of X^f_n to X^o_n is g, the following relations hold:

1st pulse

$$C^o_1 = C_o f \qquad X^o_1 = C_o(1-f)$$
$$C^f_1 = C_o - X^f_1 \qquad X^f_1 = C_o(1-f)g$$
$$= C_o(1-g+fg)$$

2nd pulse

$$C^o_2 = C_o\{1-(1-f)g\}f$$
$$X^o_2 = C_o\{1-(1-g+fg)f\}$$
$$C^f_2 = C_o\{1-g+fg(1-g)+f^2g^2\}$$
$$X^f_2 = gX^o_2$$

3rd pulse

$$C^o_3 = C^f_2 f$$
$$X^o_3 = C_o[1-\{1-g+fg(1-g)+f^2g^2\}f]$$
$$C^f_3 = C_o[(1-g)+fg(1-g)$$
$$+f^2g^2(1-g)+f^3g^3]$$
$$X^f_3 = gX^o_3$$

n-th pulse

$$C^f_n = C_o\{(1-g)+fg(1-g)+\cdots$$
$$\cdots+(fg)^{n-1}(1-g)+f^ng^n\}$$
$$= \frac{C_o}{1-fg}\{(1-f)f^ng^{n+1}+(1-g)\}$$

Changing $(1-f)$ to f for convenience:

$$C^f_n = \frac{C_o\{(1-f)^ng^{n+1}f+(1-g)\}}{1-(1-f)g} \tag{1a}$$

$$X^f_n = \frac{C_ofg\{1-(1-f)^ng^n\}}{1-(1-f)g} \tag{1b}$$

$$C^o_n = \frac{C_o\{(1-f)(1-g)+(1-f)^ng^n\}}{1-(1-f)g} \tag{1c}$$

$$X^o_n = \frac{C_of\{1-(1-f)^ng^n\}}{1-(1-f)g} \tag{1d}$$

For $n \rightarrow \infty$:

$$C^f{}_\infty = \frac{1-g}{1-(1-f)g} C_o \qquad (1'a)$$

$$C^o{}_\infty = \frac{(1-f)(1-g)}{1-(1-f)g} C_o \qquad (1'c)$$

$$X^f{}_\infty = \frac{C_o f g}{1-(1-f)g} \qquad (1'b)$$

$$X^o{}_\infty = \frac{C_o f}{1-(1-f)g} \qquad (1'd)$$

If X returns to the ground state dye according to the first order reaction, then $g = \exp(-k/\nu)$, where k is a rate constant and ν, the frequency of the flash.

If the light absorption is proportional to $C\varepsilon$ (assuming the cell length to be 1 cm.), f can be written as $\Phi\varepsilon\alpha$, where α is a fraction of the excited dye which reaches X, and Φ is the light quantity per pulse (see II).

As an example, let us consider the case when $f=0.1$ and $k \approx 10\ \mathrm{sec}^{-1}$. For 100 pulses per sec. (100 pps),

$$g = e^{-k/\nu} \approx 0.9 \qquad X^f{}_\infty \approx 0.47 C_0$$

It can be estimated that the second term in Eqs. 1a, b, c and d becomes less than 1% of the first term when $n=20$. For 10 pps, g is ca. 0.4, $X^f{}_\infty$ is ca. 6% of C_o, and two or three flashes would be enough for X^f to get within 10% of this $X^f{}_\infty$ value.

If $f=0.01$, $k \approx 10\ \mathrm{sec}^{-1}$, and $\nu=100$, $X^f{}_\infty$ would be about 8% of the concentration of the ground state dye, and the second term in Eq. 1b becomes one per cent of the first term when n equals 40.

II. Intensity Effect ($\nu \ll 1/\tau$)

The high intensity of the flash is favorable to a large reaction rate. However, if it is too large, the absorption of light is so close to the saturation point that a quantitative treatment is rather troublesome. What kind of effect may be expected when the intensity approaches the saturation value? How is it influenced by the frequency of the flash? What is the largest possible intensity which is not accompanied with complicating effects? These questions must be answered before we can deal with our problem quantitatively.

Let us take the case when the reaction proceeds through X with a rather long τ. At first, however, only the $\nu \ll 1/\tau$ region, where no genuine kinetic effect is expected, will be considered. The scheme is written as follows:

$$\mathrm{D} \rightarrow \mathrm{D}^* \rightarrow \mathrm{X} \overset{k_d}{\rightarrow} \mathrm{D}, \qquad k_s = k_r + k_d$$
$$\downarrow k_r$$
$$\text{Product}$$

a) The 1 pulse per sec., total light quantity; Φ_o (photons per cm^2).

In case the absorption is more or less close to the saturation ($1000\,\Phi_o\varepsilon\alpha \lessapprox 1$; see below), the fractions of light absorbed are a little different in the earlier and in the later stages of one flash, although its duration is as short as several microseconds. Differentiating Φ_o into small parts, one can put

$$\mathrm{d}\Phi_{ab} = \varepsilon C \mathrm{d}\Phi_o$$

assuming C to be small enough. If α part of the molecules excited is transferred to X,

$$\alpha \mathrm{d}\Phi_{ab} = -\mathrm{d}C/1000$$

Hence:

$$-\mathrm{d}C = 1000\,\alpha C \varepsilon \mathrm{d}\Phi_o$$

Integration gives

$$\ln \frac{C_o}{C} = 1000\,\alpha\varepsilon\Phi_o$$

Putting the decrease of C during the flash as ΔC,

$$\Delta C = \alpha\Phi_{ab} = C_o(1 - e^{-1000\Phi_o\alpha\varepsilon})$$

The quantity of reaction by one flash (R_o) is

$$R_o = \Phi_{ab}\ \alpha\frac{k_r}{k_s} = C_o\frac{k_r}{k_s}(1 - e^{-1000\Phi_o\alpha\varepsilon}) \qquad (2)$$

Now let us treat the case in which the following approximation holds, i.e., the case in which f in I, where f is approximated by $\Phi_o\alpha\varepsilon$, must be replaced by $f - f^2/2$. Besides, $1000\Phi_o$ will be replaced by Φ from now on.

$$R_o = \Phi_{ab}\alpha\frac{k_r}{k_s} \approx C_o\frac{k_r}{k_s}\left\{\Phi\alpha\varepsilon - \frac{(\Phi\alpha\varepsilon)^2}{2}\right\}$$
$$= C_o\frac{k_r}{k_s}\left(f - \frac{f^2}{2}\right) \qquad (3)$$

b) The ν times illumination for one second with the flash of Φ.

For the first flash:

$$\Delta C = C_o\frac{k_r}{k_s}\left(f - \frac{f^2}{2}\right) = C_o f'$$

For each successive flash, the initial concentration, C_n, and the quantity of reaction, R_n, may be given as follows:

Flash No.	Initial concn.	R_n*	$\sum R_n$**
1	C_o	$C_o f'$	$C_o f'$
2	$C_o(1-f')$	$C_o(1-f')f'$	$\{C_o f'(1-f')+1\}$
3	$C_o(1-f')^2$	$C_o(1-f')^2 f'$	$\{C_o f(1-f')^2 + (1-f')+1\}$
4	$C_o(1-f')^3$	⋮	⋮
⋮	⋮	⋮	⋮
ν	$C_o(1-f')^{\nu-1}$	$C_o(1-f')^{\nu-1}f'$	$C_o(1-(1-f')^\nu)$

* R_n: Quantity of reaction to each flash
** $\sum R_n$: Total quantity of the reaction

The total quantity of the reaction for one second when $\nu f' < 1$:

$$\sum_{n=1}^{\nu} R_n = C_0\{1-(1-f')^{\nu}\}$$
$$= C_0\left\{\nu f' - \frac{\nu(\nu-1)}{2!}f'^2 + \frac{\nu(\nu-1)(\nu-2)}{3!}f'^3 + \cdots\right\}$$

and

$$\nu f' = \nu\frac{k_r}{k_s}\left(f - \frac{f^2}{2}\right)$$
$$= \nu\frac{k_r}{k_s}\left\{\Phi\alpha\varepsilon - \frac{(\Phi\alpha\varepsilon)^2}{2}\right\}$$
$$\frac{\nu(\nu-1)}{2!}f'^2 = \frac{\nu(\nu-1)}{2}\left(\Phi^2\alpha^2\varepsilon^2\frac{k_r^2}{k_s^2} + \cdots\right)$$

Hence,

$$\sum_{n=1}^{\nu} R_n \doteqdot \nu\frac{k_r}{k_s}C_0\left[\Phi\alpha\varepsilon - \frac{(\Phi\alpha\varepsilon)^2}{2}\left\{1+(\nu-1)\frac{k_r}{k_s}\right\}\right] \quad (4)$$

In order for $\sum_{n=1}^{\nu} R_n$ to be proportional to the light intensity (within 10 %), the second term must be less than 10 % of the first term.

So,

$$\Phi\alpha\varepsilon < \frac{0.2}{1+(\nu-1)\frac{k_r}{k_s}} \quad (5)$$

This shows that the limit for the linearity largely depends on k_r/k_s. For small values of k_r/k_s, the critical value of Φ does not depend on ν, and for the value of k_r/k_s close to 1, it approaches to $1/\nu$ of that for 1 pps. For instance, in the case of 100 pps, $\Phi_0\varepsilon\alpha$ must be less than 0.004 when $k_r/k_s \approx 0.5$. It is desirable to perform the experiment in the Φ region where the linearity holds approximately irrespective of ν. In the region of Φ treated here, $(1/\nu)\sum_{n=1}^{\nu} R_n$ decreases with the larger ν, and so a correction is needed to get a genuine effect if it is observed.

For example, in the case of 100 pps,

$$\sum_{n=1}^{\nu} R_n = 100\frac{k_r}{k_s}\Phi\alpha\varepsilon C_0\left[1-\frac{1}{2}\left\{1+99\frac{k_r}{k_s}\right\}\Phi\alpha\varepsilon\right] \quad (6)$$

and in case of 10 pps,

$$\sum_{n=1}^{\nu} R_n = 10\frac{k_r}{k_s}\Phi\alpha\varepsilon C_0\left[1-\frac{1}{2}\left\{1+9\frac{k_r}{k_s}\right\}\Phi\alpha\varepsilon\right] \quad (6')$$

c) The light quantity per second $I_0=\nu\Phi$ is kept constant.

The critical intensity (light quantity per second) below which the linearity holds, increases remarkably with the value of ν. Putting the light quantity per second as $I_0=\nu\Phi$, the quantity of reaction per second, $\sum_{n=1}^{\nu} R_n$, is given by:

$$\sum_{n=1}^{\nu} R_n = C_0\frac{k_r}{k_s}I_0\alpha\varepsilon\left[1-\frac{I_0\alpha\varepsilon}{2\nu}\left\{1+(\nu-1)\frac{k_r}{k_s}\right\}\right] \quad (7)$$

Thus, for 1 pps,

$$\sum_{n=1}^{\nu} R_n = C_0\frac{k_r}{k_s}I_0\alpha\varepsilon\left\{1-\frac{1}{2}I_0\alpha\varepsilon\right\}$$

for 10 pps,

$$\sum_{n=1}^{\nu} R_n = C_0\frac{k_r}{k_s}I_0\alpha\varepsilon\left\{1-\frac{I_0\alpha\varepsilon}{10}\left(\frac{1}{2}+\frac{9}{2}\frac{k_r}{k_s}\right)\right\}$$

for 100 pps,

$$\sum_{n=1}^{\nu} R_n = C_0\frac{k_r}{k_s}I_0\alpha\varepsilon\left\{1-\frac{I_0\alpha\varepsilon}{100}\left(\frac{1}{2}+\frac{99}{2}\frac{k_r}{k_s}\right)\right\}$$

III. Specific Effect When the Lifetime of X is Comparable with $1/\nu$

Even when no genuine kinetic effect is present, a certain frequency effect may be expected when the lifetime of X is comparable with $1/\nu$. Therefore, it is necessary to examine such an effect before the quantitative investigation can be made. It is, however, perhaps impossible to get an exact expression generally applicable to all cases. Here one has to be satisfied with treating two problems approximately.

a) An approximate expression for the quantity of reaction by n pulses when $nf<1$.

b) An appoximate expression for the quantity of reaction in unit time as a function of ν when $f_0=\nu f=$const. (<1).

a) X produced by each flash goes to the product by the fraction $q=k_r/k_s$. The remaining portion returns to the original dye step by step according to the flashing condition and contributes further to the total quantity of reaction. Thus, if X_n represents the quantity of X produced by the nth flash, then $(1-q)(1-g)X_n$ goes back to the original dye before the commencement of the $(n+1)$th flash. gX_n represents the portion of X_n at the commencement of the $(n+1)$th flash. In the same way, $gX_n(1-g)(1-q)$ returns to the original dye during the period between $(n+1)$-th and the $(n+2)$th flash. These processes continue until the end of all flashings; the situations are similar for all X_n.

On the basis of the above reasoning, one gets a general expression for X_n produced*

* The meaning of X_n is different from X^0_n or X^f_n.

by the nth flash. For the sake of simplicity, $(1-g)(1-q)$ is set as r.

For the 1st flash,

$$X_1=C_of$$

for the 2nd flash

$$X_2=\{C_of(1-f)+X_1fr\}$$

for the 3rd flash,

$$X_3=\{C_of(1-f)^2+X_1f(1-f)r+X_1fgr\}+X_2fr$$

for the 4th flash,

$$X_4=C_of(1-f)^3+X_1fr\{(1-f)^2+g(1-f)+g^2\}+X_2fr\{(1-f)+g\}+X_3fr$$

for the 5th flash,

$$X_5=C_of(1-f)^4+X_1fr\{(1-f)^3+g(1-f)^2+g^2(1-f)+g^3\}+X_2fr\{(1-f)^2+g(1-f)+g^2\}+X_3fr\{(1-f)+g\}+X_4fr$$

Hence, for the nth flash,

$$X_n=C_of(1-f)^{n-1}+X_1fr\{(1-f)^{n-2}+g(1-f)^{n-3}+g^2(1-f)^{n-4}+\cdots+g^{n-2}\}+X_2fr\{(1-f)^{n-3}+g(1-f)^{n-4}+g^2(1-f)^{n-5}+\cdots+g^{n-3}\}$$
$$\vdots$$
$$+X_{n-2}fr\{(1-f)+g\}+X_{n-1}fr$$

This is simplified as follows:

$$X_n=C_of(1-f)^{n-1}+rf\left[X_1\frac{\{(1-f)^{n-1}-g^{n-1}\}}{1-f-g}+X_2\frac{\{(1-f)^{n-2}-g^{n-2}\}}{1-f-g}\cdots+X_{n-2}\frac{\{(1-f)^2-g^2\}}{1-f-g}+X_{n-1}\frac{\{(1-f)-g\}}{1-f-g}\right] \quad (8)$$

Similarly,

$$X_{n-1}=C_of(1-f)^{n-2}+rf\left[X_1\frac{\{(1-f)^{n-2}-g^{n-2}\}}{1-f-g}+X_2\frac{\{(1-f)^{n-3}-g^{n-3}\}}{1-f-g}\cdots+X_{n-3}\frac{\{(1-f)^2-g^2\}}{1-f-g}+X_{n-2}\frac{(1-f-g)}{1-f-g}\right]$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$X_3=C_of(1-f)^2+rf\left[X_1\frac{\{(1-f)^2-g^2\}}{1-f-g}+X_2\frac{1-f-g}{1-f-g}\right]$$

$$X_2=C_of(1-f)+rfX_1\frac{(1-f-g)}{1-f-g}$$

$$X_1=C_of$$

To get a simple expression, one has to draw attention to the condition $nf<1$ and has to cut down all the terms higher than f^3.

Then, $X_n=C_of(1-f)^{n-1}+C_orf^2\left[\frac{(1-f)^{n-1}-g^{n-1}}{1-f-g}+\frac{(1-f)\{(1-f)^{n-2}-g^{n-2}\}}{1-f-g}+\frac{(1-f)^2\{(1-f)^{n-3}-g^{n-3}\}}{1-f-g}+\cdots+(1-f)^{n-2}\frac{(1-f-g)}{(1-f-g)}\right]$

This is reduced to the following equation:

$$X_n=C_of(1-f)^{n-1}+\frac{C_orf^2}{1-f-g}\left\{(n-1)(1-f)^{n-1}+\frac{g^n-g(1-f)^{n-1}}{1-f-g}\right\}$$

In the same way,

$$X_{n-1}=C_of(1-f)^{n-2}+\frac{C_orf^2}{1-f-g}\left\{(n-2)(1-f)^{n-2}+\frac{g^{n-1}-g(1-f)^{n-2}}{1-f-g}\right\}$$

$$\cdots\cdots\cdots\cdots\cdots\cdots$$

$$X_3=C_of(1-f)^2+\frac{C_orf^2}{1-f-g}\left\{2(1-f)^2+\frac{g^3-g(1-f)^2}{1-f-g}\right\}$$

$$X_2=C_of(1-f)+\frac{C_orf^2}{1-f-g}\left\{(1-f)+\frac{g^2-g(1-f)}{1-f-g}\right\}$$

$$X_1=C_of$$

By means of the formula of the geometric progression, one gets

$$\sum X_n = C_o\{1-(1-f)^n\} + \frac{C_o r f^2}{1-f-g}\left[\frac{(1-f)-(n-1)(1-f)^n}{f} + \frac{(1-f)^2-(1-f)^n}{f^2} + \frac{g^2-g^{n+1}}{(1-f-g)(1-g)} - \frac{g(1-f)\{1-(1-f)^{n-1}\}}{(1-f-g)f}\right] \quad (9a)$$

and the quantity of the reaction, R, is given by:

$$R \equiv q\sum X_n \quad (9b)$$

It is to be added that when $g=0$, the above equation leads to

$$q\sum X_n = C_o\left\{nfq - \frac{n(n-1)}{2}f^2q^2\right\} \quad (10)$$

This is just the expression obtained from $C_o\{1-(1-f)^n\}$, which is the quantity of reaction when the interval of flash is long enough. From Eq. 9a one can easily calculate the quantity of reaction by n flashes for arbitrary values of f, g and q. These calculations must be performed for a set of successive flashes irrespective of the time spent by n flashes. For example, if one sets $f=0.001$, $n=101$, $g=0.5$, and $q\approx 0$, then the quantity of reaction is about 5 % smaller than when $g=0$. Thus, it is expected generally that the shorter the period of flash, the less the quantity of the reaction. It is worth mentioning here that the above formulas (9) hold only when $nf \ll 1$; a much larger effect would be expected if f is larger.*

b) The quantity of reaction per second when $f_o=\nu f=$const. (<1), where ν is the frequency of flash, is easily obtained by an extension of the treatment given in a). The case in which ν is very small need not be considered, since the situations are just the same as with a). When ν is large, g is approximately equal to 1 and is written as follows:

$$g = e^{-k_s/\nu} \approx 1-\frac{k_s}{\nu}, \quad 1-g=\frac{k_s}{\nu}$$

Further, one can replace $(1-f)^\nu$ by e^{-f_o}. Starting from Eq. 8, one can derive following expression by substituting the above relations. (It should be added that all terms higher than f^3 are disregarded.)

$$q\sum_{n=1}^{\nu} X_n = C_0\{1-e^{-f_o}\}q + \frac{C_o q(1-q)k_s f_o^2(\nu-1)}{2(k_s-f_o)\nu} - \frac{C_o q(1-q)k_s f_o^2(\nu-1)}{2\nu(k_s-f_o)}\left\{1+\frac{k_s f_o}{\nu(k_s-f_o)}\right\} \quad (11)$$

If ν is large enough, Eq. 11 is simplified as follows (in the approximation to f_o^2):

$$q\sum_{n=1}^{\nu} X_n = C_o\{1-e^{-f_o}\}q \doteqdot C_o\left\{f_o q - \frac{f_o^2}{2}q\right\} \quad (12)$$

This is to be compared with the quantity of reaction per second obtained under the assumption of a steady state illumination, when X and the product, P, are respectively, produced according to the following relations:

$$\frac{dX}{dt} = \alpha\varepsilon I_o C = k_s X \quad (13)$$

$$\frac{dP}{dt} = -\frac{dC}{dt} = k_r X \quad (14)$$

Equation 13 is restricted to the case where $\alpha\varepsilon C$ is small enough. When I_o is moderately large, the quantity of the reaction per second, R, may be approximately given as follows:

$$R = C_o\left\{\frac{k_r}{k_s}I_o\alpha\varepsilon - \frac{1}{2}\frac{k_r^2}{k_s^2}I_o^2\alpha^2\varepsilon^2\right\} = C_o\left\{f_o q - \frac{1}{2}f_o^2 q^2\right\} \quad (15)$$

Thus, when ν is large enough, the quantity of reaction per second is $(1/2)f_o^2 q(1-q)$ less than that of the steady illumination. It is to be noted that Eq. 15 is different from Eq. 12 in the f_o^2 term and that it is equal to Eq. 10 if one replaces n with ν and takes it large enough. Comparing Eq. 15 with Eq. 7, one can say that when $\tau < 1/\nu$, the quantity of reaction per second (when $I_o=\nu\Phi=$const.) for the frequency ν is $(1/2\nu)(1-k_r/k_s)I_o^2\alpha^2\varepsilon^2(k_r/k_s)$ less than that of the steady illumination at I_o.

Summing up the results obtained in III and II, one can say as follows. As the frequency of flashing is made larger under the condition $\nu f = f_o =$const., then the quantity of reaction per second increases and tends to the value of the steady illumination in the $\tau < 1/\nu$ region, but it decreases when τ becomes larger than $1/\nu$. Further, one can say that when $f_o \approx 0.1$, the ordinary kinetic treatment may be used as in the steady illumination. Thus, it would be better to deal with the rate constant evaluated by the usual method rather than with the quantity of reaction per pulse or per second. The condition for linearity is more stringent for the latter (see IV).

IV. A Model Case

One model case will be considered as an example in which a genuine kinetic frequency effect is to be expected. It is the case in which X absorbs light and then reacts. For this case, an argument similar to that given in III can be made.

* f represents $\Phi\alpha\varepsilon$, but this is an approximation. An exact expression for $(1-f)$ is e^{-f}.

The first flash produces the intermediate X in the amount $X_1=C_of$. During the dark period, the fraction of X_1 which goes to the product is $(1-g)q$ and $r=(1-g)(1-q)$ returns to the ground state. The second flash then produces X in the amount $C_of(1-f)+X_1rf$. The situations up to this point are just the same as in III. The difference appears during the second flash, in which the remaining fraction of X_1, i.e., gX absorbs light and some portion of it contributes to the reaction. Thus the g included explicitly in Eq. 8 is reduced to some extent and should be replaced by such a quantity as $g'=g(1-\varepsilon'\alpha'\Phi)$ (when $\varepsilon'\alpha'\Phi$ is small enough). This implies that the fraction $g\varepsilon'\alpha'\Phi$ goes to the product by the absorption of light. Analogous processes go on to the end of all the flashings and the situations are similar for all X_n.

However, the above situations are too complicated to be considered exactly; one must here be content with the treatment of the extreme case in which all the gX reacts upon the absorption of light. In this case one has only to put $g=0$ in Eq. 9. The contribution of X_n to the quantity of reaction is in general given by $X_n\{(1-g)q+g\}$. Another point to be noted, however, is that the summation must be done to the $(n-1)$th flash, because X_n produced by the last flash goes to the product by the amount of X_nq.

Thus, the quantity of the product is given by;

$$R'=\sum_1^{n-1}X_{n-1}\{(1-g)q+g\}+X_nq$$

By applying Eq. 9 (putting $g=0$) and Eq. 8, one gets:

$$\begin{aligned}R'=&C_o\{1-(1-f)^n\}q+C_o\{1-(1-f)^{n-1}\}\\&\times g(1-q)+C_orf^2q\left\{\frac{1-(n-2)(1-f)^{n-2}}{f}\right.\\&\left.+\frac{(1-f)-(1-f)^{n-2}}{f^2}+(n-1)(1-f)^{n-2}\right\}\\&+C_orf^2g(1-q)\left\{\frac{1-(n-2)(1-f)^{n-2}}{f}\right.\\&\left.+\frac{(1-f)-(1-f)^{n-2}}{f^2}\right\}\end{aligned}\tag{16}$$

Apart from f^2 terms, one gets from Eqs. 16, 9 and 10:

$$\begin{aligned}R'-R&=C_o\{1-(1-f)^{n-1}\}g(1-q)\\&\fallingdotseq(n-1)C_ofg(1-q)\end{aligned}\tag{17}$$

and

$$\frac{R'-R}{R}=\frac{n-1}{n}\frac{g(1-q)}{q}\tag{18}$$

The above two formulas are, of course, the maximum values possible for given g and q values, but they make some general features clear. Thus, according to them, the effect is zero when $q=k_r/k_s=1$ and increases with the value of g. Since $g=\exp(-k_s/\nu)$, the effect becomes apparent in the frequency region where $\nu\gtrsim k_s$. Equation 17 does not, however, indicate the intensity effect correctly. This is natural since the above treatment concerns only the extreme case when the light absorption by X is large enough. If one treats the general case, a complicated function involving $g\varepsilon'\alpha'\Phi$ in both denominator and numerator would result.

The situations will be clarified, at least approximately, by the steady state treatment. Thus, if one assumes that $\alpha'\varepsilon'I_oX(=k'\varepsilon'I_oX)$ of X undergoes the photo-reaction, then

$$I_o\alpha\varepsilon(C-X)=k_sX+\alpha'\varepsilon'I_oX$$

and if one assumes X is very small compared with C,

$$\frac{-dC}{dt}=\frac{I_o\alpha\varepsilon C_o(k_r+k''I_o)}{k_s+k''I_o}\tag{19}$$

In the absence of any extra reaction,

$$\frac{-dC}{dt}=I_o\alpha\varepsilon C_o\frac{k_r}{k_s}\tag{20}$$

Hence, the ratio R'/R in this case is given approximately by

$$\frac{R'}{R}=\frac{1+(k''/k_r)I_o}{1+(k''/k_s)I_o}\tag{21}$$

and

$$\frac{R-R'}{R}=\frac{k''I_o(1/k_r-1/k_s)}{1+(k''/k_s)I_o}\tag{22}$$

These values are, in general, not independent of I_o. To sum up, the genuine effect begins to appear at such a frequency when $\nu\gtrsim k_s$ and, in addition, $k''I_0(=\alpha'\varepsilon'I_0)$ should be at least comparable with k_r. The intensity exponent for $R'-R$ lies between the first and the second order.

Summary

The method of intermittent illumination by means of flashes of very short duration has been criticized, particularly with regard to the frequency and intensity of the flash. It has been concluded that when f_o (the fractional decrease of the starting substance per second due to the absorption of light) is less than 0.1, the kinetics for the steady illumination will hold within a few per cent. A model case in which a certain intermediate absorbs light and causes an addition reaction has been discussed.

The authors wish to thank Professor Shunji Kato for his helpful discussions.

The Application of Intermittent Illumination to the Bleaching of Dye. II. The Methylene Blue-Amine System

By Shunji KATO, Yoshiharu USUI and Masao KOIZUMI

(Received June 17, 1963)

The method of intermittent illumination has been successfully applied to the kinetic studies of photopolymerization in which the termination consists of the mutual interaction of two growing radicals. However, the method has not yet been introduced into the field of the photobleaching of dye. Although the situation in dye chemistry is quite different from that of photopolymerization, there seems to be, among the published results, some cases which suggest certain intermittent light effects. For example Ainsworth[1] observed a saturation effect in the photobleaching of thiazine dyes by ferrous ion and attributed it to the formation of a certain complex which is susceptible to photobleaching but which requires a rather long time to form. According to him, the scheme can be shown as follows:

$$\begin{array}{ccccc} (D-A)^* & \longrightarrow & \cdots\cdots & \longrightarrow & Y \longrightarrow \text{Product} \\ h\nu\uparrow & & & & \downarrow \\ (D-A) & \longleftarrow & A & \longleftarrow & D+A \end{array}$$

where (D—A) is a labile complex of the dye D and the electron donor A.

If the frequency of flash is great enough, then the $D+A \rightarrow (D—A)$ process cannot respond and the quantum yield should decrease with the increase in frequency.

Another case is the photobleaching of methylene blue by means of trimethylamine.[2] In this case the existence of a certain intermediate with the lifetime of the order of minutes and with absorption spectra in the region neighboring that of the dye has been suspected. The scheme can be written as follows:

$$D \xrightarrow{h\nu} D' \longrightarrow X \longrightarrow \text{Product}$$
$$\downarrow \qquad \downarrow$$
$$D \qquad D$$

X is the intermediate in question. In this case, the quantity of the reaction should increase when the interval of flash, $1/\nu$, becomes smaller than the lifetime of X. In both these cases, some kind of intensity effect is also to be expected if the intensity is varied over a wide range. However, the intermittent light method is more direct and affords more detailed information.

In this paper some findings on the methylene blue-trimethylamine system will be reported, along with the details of the apparatus and the procedures for checking the method. As a light source a flash of short duration (several micro-seconds) was used. Its merit was that it gave a considerable amount of light in a very short time and so made the interval of successive flashes easily controllable. Such a light source, we believe, has in these cases some advantages over the intermittent light obtained by means of a sector.

Experimental

Materials. — *Methylene Blue.* — Merck's dye was recrystallized twice from *n*-butyl alcohol and then from redistilled water, and then dried in a vacuum for ten hours. The molar extinction coefficient at 665 mμ is 7.12×10^4.

Trimethylamine.—The trimethylamine (TMA) free base was prepared by the reaction of ammonium chloride with paraformaldehyde by the ordinary method. It was purified by removing the moisture and a trace of ammonia by high vacuum distillation from the dry ice-methanol to liquid air bath four times. The purity of TMA was checked by a Shimadzu gas chromatograph; and the sample could be stored without any change as long as it was degassed and kept in a refrigerator.

Sodium Borate. — A commercial G. R. reagent was recrystallized from redistilled water two or three times.

Intermittent Irradiation Apparatus.—A stroboscope by Nihon Denshi Sokki (Japan Electronic Instrument, Co.), with a xenon flash unit attached was used. It made possible the intermittent illumination of any frequency from 1 to 500 p.p.s (pulse per second). For lower frequency illumination (1 p.p.s.~1 p.p.m.), triggering was done with a microswitch driven by a synchronous motor (p.p.m. denotes pulse per minute). The xenon flash lamp was a U-shaped glass tube, 70 mm. long and 8 mm. in diameter. The separation of its legs was 15 mm. It was connected to a 1 μF capaciter charged up to about 1500 V. The voltage was almost constant for frequencies lower than 1 p.p.s., but it dropped appreciably for higher frequencies. The light intensity was varied by means of neutral filters.

The Cell Compartment.—A sample cell and an actinometer cell were placed side by side, separated

1) S. Ainsworth, *Z. Electrochem.*, **64**, 93 (1960).
2) H. Obata and M. Koizumi, This Bulletin, **30**, 136, 142 (1957); **32**, 125 (1959).

by a dark sheet, in a water-circulating thermostat. The cell was rectangular, $1\times1\times4$ cm., and was connected to a glass tube, which was sealed at the top. Figure 1 shows the top view. The cells, filters and lamp were placed as close together as possible. As is shown in the figure, the sample was illuminated with red light, while the actinometer was illuminated with full light.

Actinometry.—A ferrioxalate actinometer was used to measure the relative light quantity. However, there were two questions to solve beforehand. One was that the antinometer itself may have a frequency effect. If the reaction under pulse irradiation proceeded in a way different from the ordinary way, its quantum yield would depend on the pulse frequency. Another is that the wavelength region sensitive to the actinometer is different from that absorbed by methylene blue. Thus, if the wavelength distribution of the flash light varies with the frequency, the ratio of the intensity of red light to the shorter one, which is effective on the actinometer, will not be constant. This can result in a false frequency effect. These two problems were solved in the following ways.

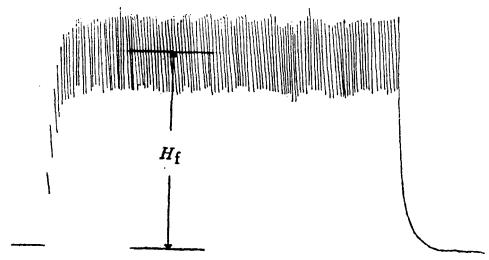

Fig. 2. Oscillogram for 1 p.p.s. The height (H_f) is proportional to the light quantity.

The actinometer was irradiated by the strobo-flash and, at the same time, the current of a photo-tube receiving the same light through a red filter was recorded with an electromagnetic oscillograph. A cathode follower with an integrating circuit was used to smooth out the pulse signal. It was found that the conversion in the actinometer, irrespective of the frequency, was just proportional to the light quantity measured from the oscillogram, as Fig. 2 shows. The area under the trace gives a measure of the light quantity received by a photo-tube during the period. Thus, it was established that the light quantity from the ferrioxalate actinometer can be safely used as a measure of the light quantity absorbed by methylene blue. The factor to convert the former to the latter was measured at 3~4.

Procedure.—An aqueous borate buffer solution (3×10^{-2} M, pH=9.18), containing 1×10^{-5} M methylene blue and 5.0×10^{-3} M TMA, was sealed into a reaction cell after having been degassed by means of repeated pumping in a liquid air bath.

The sample cell and an actinometer cell were illuminated in the cell compartment at 30°C, and the spectral change was followed with a Hitachi EPU-2A spectrophotometer. Since it was confirmed that in the present case there was no shift in the absorption peak in the course of photobleaching, the reaction was followed by the decrease in absorbancy at the peak.

Results

Some Reaction Features. — First, some features of the reaction under pulse illumination were compared with those under steady illumination. In the case of the photobleaching of methylene blue (MB) in the evacuated buffer solution or in alcohol under steady illumination, the shift in the absorption peak of the remaining dye was, to some extent, accompanied by bleaching. This point was, therefore, examined. However, there proved to be no such phenomenon in the present system. Thus, the spectrum of the remaining dye after appreciable bleaching had its maximum peak in exactly the same position as that in the original dye. It was further established that almost all the bleaching reaction consists of the formation of leuco dye; this was established by the absorption spectra of the product and by the fact that the introduction of air to an almost completely bleached solution recovers all of the dye. Another point which was examined concerns the fact that, in steady illumination, a slight increase in the absorption peak of the dye was observed after the interruption. After the 10 p.p.s. irradiation of a sample containing 1.0×10^{-5} M MB, 5×10^{-3} M $(CH_3)_3N$ and 3×10^{-2} M borate by an Xe-lamp by the use of a WR-2 red filter, the absorption spectrum of the sample in the 500~800 mμ region was examined, within 100 sec. and after a long lapse of time in the dark. The examination showed no

change within the range of experimental error, unlike the results obtained under steady illumination. Similar experiments were also conducted using the solution bleached to about one-half by flashes of 10 and 100 p.p.s.; the absorption spectra did not show any change after the sample had been stored 100 hr. in the dark. The cause of such a different behavior under the present conditions is unknown.

However, except for such trivial differences, there is no doubt that quite a similar photoreduction takes place under intermittent illumination and under steady illumination.

Kinetic Results.— It has been shown in the previous paper that the kinetic law for steady illumination can be applied approximately, with a range of error of only a few percent, for pulse illumination in the case of a first order reaction if $f_0 \leq 0.1$. This situation does not alter in other cases.

Now, the kinetics of the reaction of the present system under steady illumination can be better described as of the second order than as of the first order*. Hence, the experimental results in this paper were dealt with in the same way.

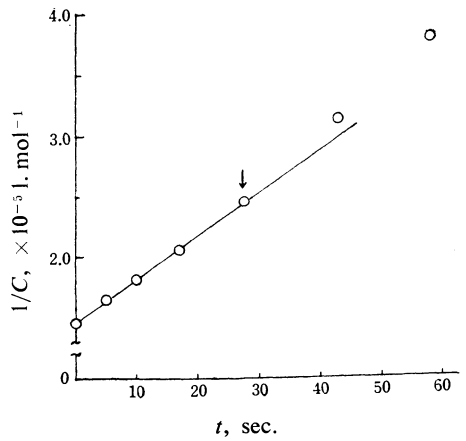

Fig. 3. Applicability of the second order rate formula.

[TMA] $=5.0\times10^{-3}$ M [MB] $=6.7\times10^{-6}$ M
Intermittent frequency; 100 p.p.s.
↓ Marks forty percent bleaching point

As Fig. 3 shows, the reciprocals of the concentration (C) give a good straight line against the time (t) in the initial stage up to about forty percent bleaching, although a slight deviation becomes apparent when the bleaching proceeds further.

From the above results it is clear that the rate formula for the steady illumination really holds for the pulse illumination. Therefore, one can discuss the frequency effect in terms of the second order rate constant, k. To do so, however, a comparison of k must be made at the same light quantity per second.

Hence, the intensity of the flash was controlled by means of neutral filters, and several experiments were performed at various intensities for each frequency. Figure 4 and Table I show the results for 1, 10 and 100 p.p.s. To make the comparison easier, a multiple scale was employed. It is evident from the figure that k in all cases gives a linear plot. This implies that k is proportional to I_0; i.e.,

* To be published shortly. Quite a different rate formula had previously been proposed,[2] but later works including the present one, have disproved it.

$$k = k_0 I_0 \quad (1)$$

where k_0 depends only on ν. To show this it will better to denote k_0 by $k_0^{(\nu)}$.

Equation 1 is exactly the relation that holds for steady illumination. This again supports the similarity in kinetics in the two case. Figure 4 further shows that the inclinations in the case of 10 and 100 p.p.s. are appreciably larger than that for 1 p.p.s. In other words, $k_0^{(100)}$ and $k_0^{(10)}$ are larger than $k_0^{(1)}$. Although there seems to be some inconsistency between relation 1 and the dependence of k_0 on ν in view of formula 21 given in the previous paper (see Discussion), there is no doubt that the frequency effect can be discussed in terms of k_0.

When relation 1 had been established, it was utilized to obtain the values of k_0 in the region of 1 p.p.m. to 1 p.p.s. in a few experiments. The $k_0^{(\nu)}$ values thus obtained are given in Table II. It is evident that in the range from 1 p.p.s. to 1 p.p.m. there is no intermittent light effect beyond the range of experimental error, which is somewhat larger than that in the higher frequency region.

Figure 5 shows the plot of $k_0^{(\nu)}/k_0^{(1)}$ against $\log \nu$. It is apparent that $k_0^{(\nu)}$ is nearly

constant below 1 p.p.s., while it increases by about fifty percent between 1 and 10 p.p.s.

Similar experiments were conducted using a solution of methylene blue (1×10^{-5} M) and trimethylamine (5.0×10^{-3} M). The analysis was made in the same way. The results are shown in Tables III and IV, and in Figs. 6 and 7. $k_0^{(\nu)}$ in this case increases considerably between 10 p.p.s. and 100 p.p.s.

Discussion

It is evident from the above results that there is a certain frequency effect, although the frequency interval, in which the effect becomes apparent, differs slightly at pH=9.2 (a borate buffer solution) and at pH=10.3 (without borate ions).

The following discussion mainly concerns the former case, which was studied in more detail, but the discussion will also be applicable to the latter, at least in its essential points. In the first place, there is no doubt that a genuine frequency effects, since, as was discussed in the previous paper, a silght decrease in $k_0^{(\nu)}$ should be expected in the $\nu\approx1/\tau$ region when I_0=const. and in the absence of a genuine effect (see II and III of the previous paper). The positive effect is to be expected in the following two cases.

a) The case in which certain intermediate X absorbs light and induces a reaction according to the following scheme.—If the lifetime (τ_X) of X is longer than the period of pulse $1/\nu$, additional photoreaction occurs; if the lifetime is shorter, it does not.

$$\mathrm{D} \xrightarrow{h\nu} \mathrm{D}^{\prime} \longrightarrow \mathrm{X} \xrightarrow[k_r]{(h\nu')} \text{Prod.}$$
$$\mathrm{D}^{\prime} \xrightarrow{k_d} \mathrm{D}$$

b) The case where a bimolecular reaction of X occurs.—In this case the effect is due rather to the increase in intensity accompanied by the rise in frequency. However, the present results can not be interpreted by this scheme for the following reason. The experimental results show that $k_0^{(10)}$ is about ten percent larger than $k_0^{(1)}$. Hence, it should be possible to observe a somewhat larger effect by making the intensity of the 1 p.p.s. flash about ten times. However, this is not the case, as is evident from Fig. 5. On the other hand, all the experimental results can be comprehended by scheme a) on the basis of the arguments given in the previous paper. The details will be described below, along with the important conclusions derived from them. First of all, the lifetime of X is estimated to be about one second on the basis of the finding that $k_0^{(\nu)}$ is nearly constant at frequencies below 1 p.p.s. but sharply rises between 1 to 10 p.p.s. In other words, k_s ($=k_d+k_r$) is estimated to be about 1. There is no other intermediate with a longer lifetime. The authors would like to deny the existence of an intermediate with a lifetime as long as a minute, as has been claimed.[2] This is due perhaps to a subsidiary process such as the photoadsorption of dye on the wall.

Another important conclusion is that the intermediate has quite a large absorbance. Thus for the effect to be observed, $\alpha'\varepsilon' I_0$ (ε'; the absorbance of X, α; the probability of the photoreaction of X) should be comparable with k_r (see IV of the preceeding paper). If k_r is 0.1~0.01, then from I_0 for 10 p.p.s., ε' ought to be $10^4\sim10^5$, assuming that $\alpha'\approx1$.

Two other comments must be made. One is about the finding that $k_0^{(\nu)}$ is approximately proportional to I_0 for the 100, 10, and 1 frequencies respectively (see Fig. 4); the other is about the unexpectedly small difference in the effect for 10 p.p.s. and for 100 p.p.s.

From the argument given in III of the previous paper, when the genuine effect does not exist, $k_0^{(\nu)}$ should decrease to some extent in the $\tau\approx1/\nu$ region (if $f_0\approx1$) and the decrease should be larger with the increase in f_0. In the present work, the maximum f_0 for 10 p.p.s. and for 100 p.p.s. is 0.1α and 0.6α respectively, and if α is not too small, a moderate deviation from linearity, especially in the latter case, is to be expected. When the genuine effect exists, however, relation 22 in the previous paper must hold approximately. From the values of k_s, k_r and $\alpha'\varepsilon' I_0$ estimated above, however, the deviation from linearity (opposite to that mentioned above) would not be very large.

Taking into consideration the two opposite effects, one may understand the approximate linearity observed. At any rate, the accuracy of the experiment is not good enough to detect this deviation.

As for the equal magnitude of the effects for 10 p.p.s. and for 100 p.p.s., it is due partially to the fact that f_0 in the latter case is quite close to 1. Alternatively, it is possible that the value of g lies quite close to 1, even at $\nu=10$.

In summary, the above scheme seems to be consistent with all the experimental results.

A slight difference between the effect of the system containing borate ion (pH=9.2) and that of the one without it suggests the dependence of the character of X on some anion. There is, however, one curious point: X has quite a large absorption in the visible region. It is possible that X is not an intermediate essentially connected with the reaction but rather the ground state dye observed immediately after having been recovered from some excited

species or some intermediate.* In connection with this, it is worth mentioning that no transient absorption spectrum with a life near one second has ever been observed in our laboratory** in the 300～500 mμ region.

In order to clarify the nature of X, further studies of the systems containing anions other than the borate ion are desirable.

Summary

A new apparatus for intermittent illumination has been designed and applied to the system of methylene blue and trimethylamine. A frequency effect has been discovered and established to be genuine. Thus, when the frequency is raised, the rate constant for the buffered and for the non-buffered solution shows an increase of about forty percent, but in the former case, between 1 p.p.s. and 10 p.p.s., and in the latter one between 10 p.p.s. and 100 p.p.s.

If it is assumed that a certain intermediate X absorbs light and induces the additional reaction, the extinction coefficient of X ought to be 10^4～10^5 in order to interpret the observed effect. Hence, it is likely that the intermediate in question is not an intermediate in true sense of the word, but the ground state dye in a slightly modified state.

* Such a modified form of dye was assumed by Ainsworth and Havemann. Thus, Ainsworth proposed the formation of a complex by the dye and the ferrous ion; he thought that the dye, just when recovered from the triplet, is in a somewhat different state. Havemann assumes a similar complex formation. However, the effect in such cases would be opposite to the one in the present case. (R. Havemann and H. Pietsch., *Z. physik. Chem.*, **211**, 26, 61 (1959).

** To be reported in the near future.

NOTES

The Synthesis of Ethyl β-Ionylideneacetate by the Wittig Reaction

By Yozo Ishikawa

(Received June 14, 1963)

β-Ionylideneacetate is an important key intermediate for preparing Vitamin A and related compounds. The chief difficulty encountered in the synthesis of this ester lies in maintaining the conjugated polyene system in the molecule. The Wittig reaction using triphenylphosphine has been reported by Pommer and his coworkers[1] to be a favorable method for preparing this ester and its vinylogs, in which the formation of *retro*-compounds has scarcely ever been observed.

This paper will describe the synthesis of ethyl β-ionylideneacetate by means of a Wittig reaction using diethyl carbethoxymethylphosphonate prepared from triethyl phosphite and ethyl bromoacetate.

Ethyl *trans*-β-ionylideneacetate (I) was obtained by the reaction of β-ionone with diethyl carbethoxymethylphosphonate carbanion prepared from the phosphonate and sodium amide in tetrahydrofuran.[2] I was reduced with lithium aluminum hydride to *trans*-β-ionylideneethanol, which was then oxidized with manganese dioxide to *trans*-β-ionylideneacetaldehyde for purposes of identification. The properties of these derivatives were in good agreement with those reported in the literature.

An attempt to synthesize β-ionylideneacetaldehyde diethylacetal by the reaction of β-ionone with diethyl β,β-diethoxyethylphosphonate carbanion derived from monochloroacetaldehyde diethylacetal and diethyl phosphite was unsuccessful.

2) H. Takahashi, K. Fujiwara and M. Ohta, This Bulletin, **35**, 1498 (1962). An analogous reaction of diethyl carbethoxymethylphosphonate with ketones has been reported by B. C. Kovalev, L. A. Yanovskaya and V. F. Kucherov, *Izv. Akad. Nauk SSSR, Otd. Khim. Nauk*, 1876 (1962); *Chem. Abstr.*, **58**, 9148 (1963). These authors showed that β-ionone failed to react and was recovered unchanged.

Experimental[3]

Ethyl *trans*-β-Ionylideneacetate (I).—In a dry nitrogen atmosphere, a solution of 11.2 g. of diethyl carbethoxymethylphosphonate in 10 cc. of tetrahydrofuran was stirred into a suspension of 2 g. of sodium amide in 30 cc. of tetrahydrofuran while the suspension was being cooled in a water bath. After the stirring had continued for 6 hr., during which period scarcely any evolution of ammonia could be observed, a solution of 10 g. of β-ionone in 20 cc. of tetrahydrofuran was added drop by drop. The resulting mixture was stirred for an additional 2 hr. and then allowed to stand overnight at room temperature. After the solvent had been distilled off, the residual resinous product was decomposed with water and extracted with ether. The ethereal layer was washed with water and dried over anhydrous sodium sulfate. The solvent was evaporated, and the residue was distilled in vacuo to give ethyl *trans*-β-ionylideneacetate (I). Yield: 11 g. (80.4%); b. p. 148~154°C/2 mmHg; d_4^{17} 0.9700; λ_{max} 257, 300 mμ (lit.,[4] 257, 302 mμ); IR-spectrum (liq.): 965 cm^{-1} (*trans* -CH : CH-), 1715, 1240 cm^{-1} (ester).

Found: C, 77.98; H, 10.14; Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99%.

3) The UV absorption spectra were measured in isopropyl alcohol. Elementary analyses were performed at the Institute of Physical and Chemical Research, Tokyo.

trans-β-Ionylideneethanol (II).—I was reduced with lithium aluminum hydride to II;[4] b. p. 120~130°C/0.1 mmHg; λ_{max} 240, 267 mμ (lit.,[5] λ_{max} 240, 265 mμ); IR-spectrum (liq.): 3340, 995 cm^{-1} (prim. alcohol), 965 cm^{-1} (*trans* -CH : CH-).

trans-β-Ionylideneacetaldehyde (III).—II was oxidized with manganese dioxide to III;[4] b. p. 105~110°C/0.01 mmHg; λ_{max} 275, 327 mμ (lit.,[5] 273, 327 mμ); 2, 4-dinitrophenylhydrazone: m. p. 198°C (lit.,[4] 198°C); λ_{max} 413 mμ.

Found: N, 14.10; Calcd. for $C_{21}H_{26}N_4O_4$: N, 14.07%; semicarbazone: m. p. 194~195°C (lit.,[4] 194~195°C); λ_{max} 324 mμ.

Found: N, 15.20; Calcd. for $C_{16}H_{25}N_3O$: N, 15.26%.

The Reaction Products from Resorcinol Dimethyl Ether and Cinnamoyl Chloride by the Friedel-Crafts Reaction

By Sumu MATSUEDA, Kazuo SANNOHE and Yoshinori SAITO

(Received June 19, 1963)

In 1926 Simonis and Danischewski[1] synthesized 2, 6-dimethoxychalcone (I) (m. p. 80°C) by the Friedel-Crafts reaction between resorcinol dimethyl ether and cinnamoyl chloride over aluminum chloride in carbon disulfide; I was then converted into 6-methoxy-2-hydroxychalcone (II) (m. p. 108°C). In 1947 Seshadri and Venkoteswarln[2] obtained 6-methoxy-2-hydroxychalcone (III) (m. p. 127~129°C) by the Kostanecki's method, treating 6-methoxy-2-hydroxyacetophenone with benzaldehyde in an alkaline medium. In 1950 Oliverio and Schiavello[3] reported that 6-methoxy-2-hydroxychalcone (IV) (m. p. 64°C) could be obtained by letting 6-methoxy-2-hydroxyacetophenone react with benzaldehyde in an ethanolic sodium hydroxide solution. They noticed the different melting points of II, III and IV, but they suggested that these differences might be attributed to the polymorphism, which is often observed in chalcones. The present paper will discuss the structure of II, III and IV. We have found that I and II are not 2, 6-derivatives but 2, 4-derivatives.

In the Friedel-Crafts reaction of resorcinol dimethyl ether, the substitution reaction at the 4-position (*o*, *p*-orientation) is perhaps more suitable than that at the 2-position (*o*,*o*-orientation) from the standpoint of the steric effect of these methoxy groups. A normal substitution reaction can take place at

1) H. Simonis and S. Danischewski, *Ber.*, **59**, 2914 (1926).

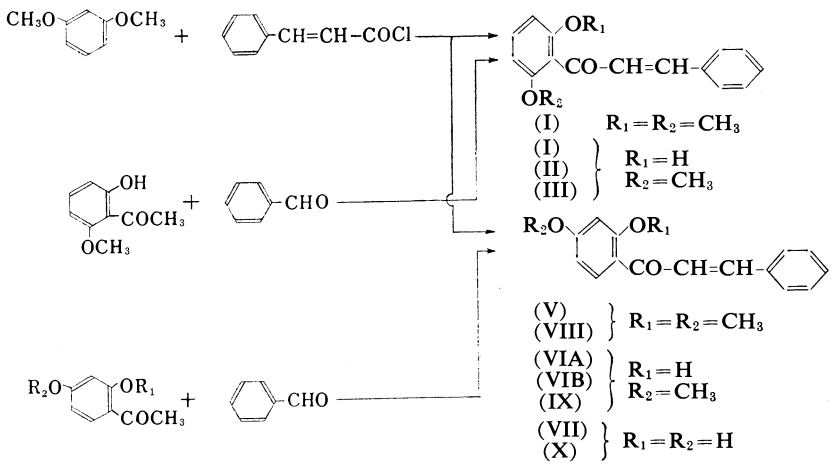
3) Aleardo Oliveris and Aldo Schiavello, *Gazz. Chim. Ital.*, **80**, 788 (1950).



the 4-position, as in the case of Simonis and Danischewski, giving 2, 4-dimethoxychalcone and 4-methoxy-2-hydroxychalcone.

A product (V) in the form of yellow needles (m. p. 79~80°C) is obtained by means of the same procedure as Simonis and Danischewski. This product is comfirmed to be equal to I by converting V into monomethoxymonohydroxychalcone (VIB) (m. p. 107~108°C), which is identified as the II obtained by Simonis and Danischewski. On the other hand, by means of comparison of their mixed melting point and ultraviolet and infrared absorption spectra, the compound V is identified as 2, 4-dimethoxychalcone (VIII) (m. p. 79~80°C), an authentic sample of which is synthesized by means of Geismann's method.[4] 4-Methoxy-2-hydroxychalcone (IX) (m. p. 107~108°C), which is identical with an authentic sample,[5] is obtained from VIII under the same conditions as with Simonis and Danischewski. The identity of IX and VIB (=II) is established by the mixed melting point and absorption spectra of ultraviolet and infrared. It is concluded that cinnamoyl chloride does not attack the 2-position of the benzene nucleus of resorcinol dimethyl ether but rather attacks the 4-position, producing not 2, 6-dimethoxychalcone but 2, 4-dimethoxychalcone.

We also obtained, from the reaction of Simonis and Danischewski, 4-methoxy-2-hydroxychalcone (VIA) (m. p. 107~108°C) and 2, 4-dihydroxychalcone (VII) (m. p. 150~151°C) by means of elution chromatography on alumina. These compuonds show the typical ultraviolet absorption spectra of the chalcone structure and the absence of any flavanones, which isomerize easily from these chalcones. The average ratio of the yield of V, VIA and VII is about 70 : 10 : 5. Resorcinol dimethyl ether is carefully purified, confirming that it does not contain any trace of either monomethyl ether or raw resorcinol by means of gas chromatography. Therefore, the formation of VIA and VII may be attributed to a catalytic demethylation of aluminum chloride.

Experimental

The authentic compounds, 2, 4-dimethoxychalcone (VIII), 4-methoxy-2-hydroxychalcone (IX) and 2, 4-dihydroxychalcone (X), are prepared from the corresponding acetophenone derivatives and benzaldehyde by means of the usual chalcone syntheses.

Resorcinol Dimethyl Ether.—A sample of the dimethyl ether of resorcinol purified by repeated fractional distillations, was shown by gas chromatography (Silicone D. C. 550) to contain no such impurities such as the monomethyl ether of resorcinol and raw resorcinol.

Friedel-Crafts Reaction.—Forty grams of resorcinal dimethyl ether and 50 g. of cinnamoyl chloride were dissolved in 270 ml. of carbon disulfide. Into this solution 38 g. of fine pulverized aluminum chloride were then added while all were cooled with ice. After having been stirred for 1 hr. at room temperature, the reacted mixture was refluxed for 3 hr. at 50°C. Then the aluminum complex was filtered off, washed with carbon disulfide and ether. The complex was decomposed with ice water containing hydrochloric acid. The product dissolved in benzene and was purified by chromatography on alumina. The first eluted compound Vl was recrystallized from alcohol, yielding 56 g. of yellow needles (m. p. 79~80°C).

Found : C, 76.07 ; H, 5.86. Calcd. for $C_{17}H_{16}O_3$: C, 76.10 ; H, 6.01%.

λ_{max} (in alcohol) 230, 280 and 300~320 (plain curve) mμ. The major bands in the infrared absorption spectrum (KBr-disk) are : 3100 m, 3066 m, 2996 m, 2950 m, 2846 m, 1665 s, 1620 s, 1590 s, 1500 s, 1460 m, 1455 m, 1442 m, 1337 s, 1320 m, 1292 s, 1257 s, 1223 s, 1205 m, 1186 m, 1165 m, 1152 m,

1135 s, 1072 w, 1050 w, 1029 m, 1020 m, 1000 m, 987 m, 925 w, 865 w, 830 s, 806 m, 773 w, 768 s, 733 w and 698 w cm^{-1}

V showed no melting point depression when combined with authentic 2, 4-dimethoxychalcone (VIII), and it showed the same infrared absorption spectra as VIII. The second elute VI was recrystallized from petroleum benzine, to give 7.2 g. of yellowish orange needles (m. p. 107~108°C).

Found : C, 75.50 ; H, 5.62. Calcd. for $C_{16}H_{14}O_3$: C, 75.57 ; H, 5.55%.

λ_{max} (in alcohol) 220, 255 and 310~340 (plain curve) mμ. The major bands in the infrared absorption spectrum (KBr-disk) are : 3510 m, 3100 w, 3020 w, 3000 w, 2960 w, 2935 m, 2840 m, 1630 s, 1580 s, 1570 s, 1505 m, 1490 m, 1475 w, 1455 m, 1413 m, 1365 s, 1320 m, 1298 m, 1278 m, 1225 s, 1130 s, 1070 w, 1015 m, 998 m, 982 w, 975 m, 955 m, 850 m, 838 w, 807 m, 789 w, 765 s, 735 w and 674 w cm^{-1}.

VI showed no melting point depression when mixed with authentic 4-methoxy-2-hydroxychalcone (IX). The infrared absorption spectra of these compounds were quite similar. On the other hand, by means of methylation with dimethyl sulfate and sodium hydroxide, VI was converted into dimethoxy derivatives in the form of yellow needles (m. p. 80°C), which agreed with VIII. The last elute VIII was recrystallized from benzene, yielding 4.5 g. of yellowish orange needles (m. p. 150~151°C).

Founb : C, 74.85 ; H, 5.11. Calcd. for $C_{15}H_{12}O_3$: C, 74.99 ; H, 5.03%.

λ_{max} (in alcohol) 240, 255 and 310~350 (plain curve) mμ. The major bands in the infrared absorption spectrum (KBr-disk) are : 3360 s, 3080 m, 3000 w, 2930 m, 2850 w, 1640 s, 1630 s, 1590 s, 1520 s, 1498 m, 1442 s, 1420 m, 1382 s, 1333 m, 1283 m, 1200 broad, 1143 s, 1065 m, 1022 w, 985 m, 950 m, 838 m, 825 w, 785 m, 752 s, 728 w and 710 w cm^{-1}.

VII showed the same infrared absorption spectra as and no melting point depression when combined with authentic 2, 4-dihydroxychalcone (X). VII was then converted into VIII by means of methylation with dimethyl sulfate and sodium hydroxide.

The Reaction of Sodium Metaphosphate with Disodium Sulfate at a High Temperature

By Shigeru OHASHI and Kozo IKEDA*

(Received June 20, 1963)

Poni and Cernătescu[1] have reported that a new compound with the formula Na_3SPO_7 which has an S–O–P linkage, can be prepared by the fusion of an equimolar mixture of sodium hydrogen sulfate and disodium hydrogen orthophosphate. The investigation of the same reaction by Audrieth, Mills, and Netherton[2] has revealed that the reaction proceeds according to Eqs. 1 and 2:

$$n\mathrm{NaHSO_4} + n\mathrm{Na_2HPO_4} \xrightarrow{200^\circ\mathrm{C}} n\mathrm{Na_2SO_4} + n\mathrm{NaH_2PO_4} \quad (1)$$

$$n\mathrm{NaH_2PO_4} \xrightarrow{600\sim800^\circ\mathrm{C}} (\mathrm{NaPO_3})_n\text{-glass} + n\mathrm{H_2O} \quad (2)$$

where n is the average chain length of the polyphosphates in the glass. It has been concluded that the final products are disodium sulfate and a glass of sodium metaphosphate and that a sulfate-phosphate copolymer such as Na_3SPO_7 can not be formed by this reaction, at least in the temperature range of 200~800°C.

The present authors have investigated the reaction of equimolar mixtures (S/P=1) of glassy sodium metaphosphate and disodium sulfate at temperatures higher than 800°C. The mixtures were melted in platinum crucibles at 1300 and 1400°C for 1 hr. and then rapidly cooled. The products were white crystalline substances.

It was found that when the mixture is heated at such high temperatures, a considerable amount of sulfur trioxide is expelled from the melt, while phosphorus pentaoxide is not expelled. Chemical analyses of the reaction

TABLE I. DATA OBTAINED BY THE X-RAY DIFFRACTOMETRY AND THE PAPER CHROMATOGRAPHY FOR THE SAMPLES OF THE $NaPO_3$-Na_2SO_4 AND $NaPO_3$-Na_2SiO_3 SYSTEMS

	X-Ray diffractometry				Paper chromatography P%	
	Unknown	Diphosphate	Na_2SO_4	α-Cristobalite	Orthophosphate	Diphosphate
The $NaPO_3$-Na_2SO_4 system, prepared at						
1300°C	+++	++	+	−	39.5	60.5
1400°C	+++	++	+	−	50.8	49.2
The $NaPO_3$-Na_2SiO_3 system P/Si						
1.00	+++	±	−	+++	100	0
1.15	+++	+	−	+++	85.8	14.2
1.30	+++	++	−	+++	65.1	34.9
1.50	+++	+++	−	+++	51.7	48.3
2.00	+	++	−	+++	16.4	83.6

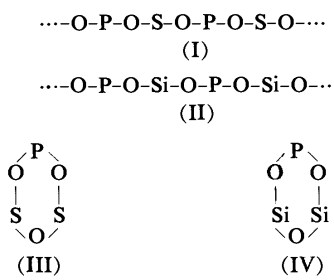
products revealed that 63.5 or 80.75% of the total sulfur was expelled as sulfur trioxide when the mixture was prepared at 1300 or 1400°C respectively. If one assumes that no compounds with S–O–P linkages are produced in the sample, the reaction can be represented by Eq. 3:

$$(NaPO_3)_n + nNa_2SO_4 \rightarrow Na_{n+2nx}P_nO_{3n+nx} + n(1-x)Na_2SO_4 + nxSO_3 \quad (3)$$

where x is a fraction of the sulfur expelled as the sulfur trioxide with respect to the total sulfur, while $Na_{n+2nx}P_nO_{3n+nx}$ represents a mixture of sodium phosphates.

The X-ray diffraction pattern of the sample exhibits peaks due to considerable amounts of tetrasodium diphosphate and an unknown species with a small amount of disodium sulfate. The following three peaks are characteristic of the unknown species; two peaks of strong intensity at spacings of 2.63 and 4.29 Å, and a peak of medium intensity at a spacing of 2.79 Å. On the other hand, it was found in the laboratory of the present authors that there were three peaks, with spacings quite identical to those described above, in the X-ray diffraction patterns of certain samples of a sodium metaphosphate-sodium metasilicate system, which will be described in a separate paper.

The data obtained by the X-ray diffractometry and the paper chromatography of the samples of both the systems are shown in Table I. The latter data indicate that considerable amounts of orthophosphate are present in the sample solutions of both the systems. It may be possible to assume that crystalline substances with structural frameworks such as I, II, III, or IV are hydrolyzed to give orthophosphate when dissolved in water. However,



it is difficult in general to assume that a substance containing S–O–P linkages and one containing P–O–Si linkages both give a group of peaks located at quite identical spacings. Therefore, it seems reasonable to assume that the unknown peaks in question may be due to a kind of trisodium orthophosphate.

Therefore, it may be concluded that the main reaction of an equimolar mixture of sodium metaphosphate and disodium sulfate at a high temperature proceeds according to Eq. 3 and that no compound with S–O–P linkages, at least as a major component in the crystalline substances, is formed by this reaction. A pattern of normal trisodium orthophosphate exhibits three characteristic peaks at spacings of 2.55, 2.70, and 4.25 Å. The discrepancy between the spacings of the peaks due to normal trisodium orthophosphate and those due to the unknown species discussed in this paper remains an unsolved problem.

The Catalytic Activity of Metal Oxides of the Fourth Period in the Hydrogen-Oxygen Reaction. A Commentary on a Paper by Popovskii and Boreskov

By Isamu KOMURO,* Haruhiko YAMAMOTO and Takao KWAN

(Received July 1, 1963)

In spite of many efforts[1] to correlate the catalytic activity of metal oxides with such electronic properties of the corresponding oxides as the semiconductivity and the electronic configuration of the metal ion, there still remain some cases where the classical oxidation-reduction concept[2] sounds better than modern electronic interpretations. Undoubtedly, the catalyst activity of metal oxide is so sensitive to the mode of preparation or to the surrounding atmosphere that difficulty is often encountered in interpreting the observed activity data, the temperature threshold for a reaction in a majority of cases being a conventional measure of the catalyst activity.

Recently Popovskii and Boreskov[3] investigated the hydrogen-oxygen reaction on the metal oxides of the fourth period in a systematic and careful manner. Excess oxygen was used so that the catalyst activity might be compared at a certain oxidation level. The rate data were given in terms of the volume of hydrogen consumed per unit hour and per unit area of the metal oxides at temperatures of 150 and of 300°C respectively.

Their data are reproduced in Fig. 1 in relation to the atomic number of the constituent metal ion in the way they adopted.

The order of the catalyst activity was found to be:

$$Co_3O_4 > CuO > MnO_2 > NiO > Fe_2O_3 > Cr_2O_3 > V_2O_5 > ZnO > TiO_2$$

at 150°C. The activity at 300°C was nearly parallel with this. While such an activity series was consistent with the familiar relationship in respect to the type of semiconductor, i. e., *p*-type>*n*-type, Popovskii and Boreskov favored the parallel relationship with a work function series of these oxides proposed as:

$$CuO > NiO > V_2O_5 > ZnO > TiO_2$$

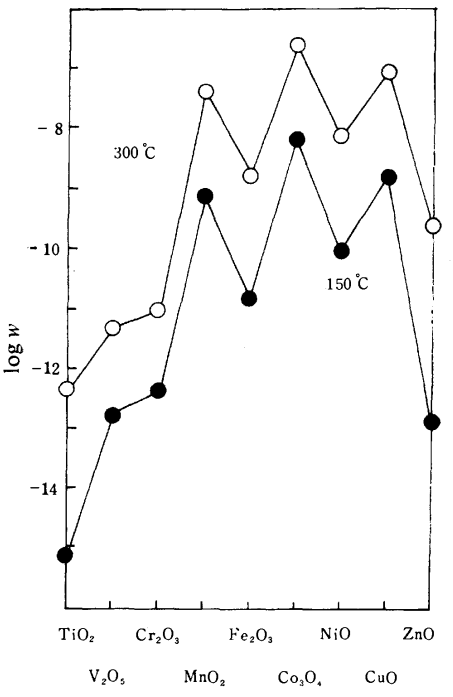

Fig. 1. The catalytic activity of metal oxides of the fourth period for the hydrogen-oxygen reaction after Popovskii and Boreskov.[3]

suggesting that the electron transfer from the substrate to the oxide is rate-controlling.

It should be noted, however, that the work function of metal oxide is in general sensitively dependent on the pretreatment of the oxide as well as on the atmosphere. At present the value of the work function, as far as metal oxide is concerned, does not seem to be well-established. It has been reported[4] that the work function of zinc oxide is, at an oxidation level, greater by 1.0 eV. or even more than that of nickel oxide, contrary to the above order proposed by Popovskii and Boreskov.

On the other hand, it would be interesting to see if the relative catalytic activity of the

oxides quoted above accords with the relative reducibility of the corresponding oxide by hydrogen. Let us, therefore, investigate how the bond strength of oxygen with the surface may be correlated with the catalyst activity.

The chemisorption of hydrogen would be instantaneous under the experimental conditions; the H_2–D_2 exchange reaction is known to occur on the metal oxides at much lower temperatures.[5] The same may perhaps be true with the oxygen chemisorption. It is assumed that the act of depriving the chemisorbed oxygen atom to yield water is rate-controlling. Let us assume, moreover, that the heat of the formation of metal oxide per g. atom oxygen is a measure of the strength of the oxygen-surface bond. The heat of formation of metal oxide per g. atom oxygen does not depend appreciably on the valency state of the constituent metal ion, at least for the metal oxides under investigation. Current investigations[6] fortunately indicate that there is a close correspondence between the chemisorption and the formation of the bulk compounds. Thus, one may expect some kind of regular relation between the catalyst activity of the metal oxides of the fourth period and the heat of the formation of the corresponding metal oxide. Table I shows the heats of formation of metal oxides per g. atom oxygen,

TABLE I. THE HEAT OF FORMATION OF METAL OXIDE PER G. ATOM OXYGEN AND THE KINETIC DATA FOR THE HYDROGEN-OXYGEN REACTION AT 150°C

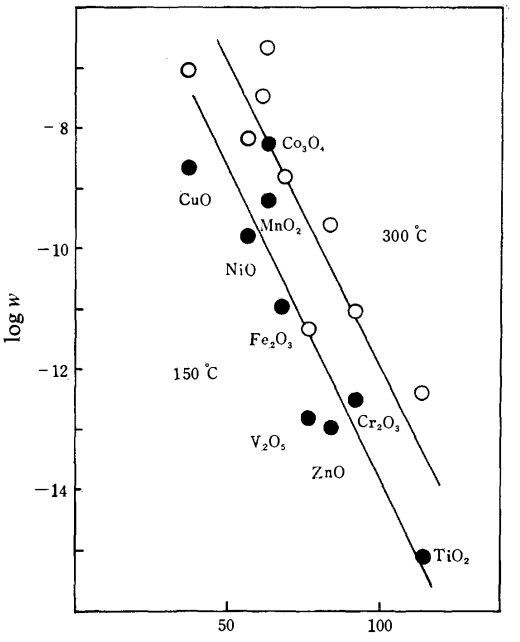

Fig. 2. The relation between the catalytic activity of metal oxides and the heat of formation of metal oxides per g. atom oxygen.

together with the kinetic data for the hydrogen-oxygen reaction obtained by Popovskii and Boreskov.

An attempt was made to plot the rate data ($\log w$) against the heat of formation of metal oxide as given by the third column of Table I. This plot is shown in Fig. 2.

It may be seen from Fig. 2 that an approximately linear relationship exists between the catalyst activity of the metal oxides and the heat of formation of these oxides at 150 and 300°C respectively. It is shown, in other words, that the weaker the oxygen-surface bond, the faster the rate of hydrogen-oxygen reaction.

Sachtler et al.[7] described the relative catalytic activity of metals in the decomposition of formic acid by the use of the heat of formation of metal formate, arriving at a so-called volcano-shaped curve. The present approach is quite similar to this. The use of the heat of formation in any way instead of the strength of the surface bond must, of course, be only approximate. However, it does seem useful as one can readily correlate the kinetic data in terms of the thermodynamic quantities available in the "Handbook."

6) M. W. Roberts, *Nature*, **188**, 1020 (1960); D. Brennan, D. O. Hayward and B. M. W. Trapnell, *Proc. Roy. Soc.*, **A256**, 81 (1960); W. M. H. Sachtler and L. L. van Reijen, *Shokubai*, **4**, 147 (1962); K. Tanaka and K. Tamaru, ibid., **4**, 328 (1962).
7) J. Fahrenfort, L. L. van Reijen and W. M. H. Sachtler, *Z. Elektochem.*, **64**, 716 (1960); W. M. H. Sachtler, Lecture read before the Catalysis Club of Japan, July 26, 1961, Sapporo.

Indeed, there is a rough parallelism between the activation energy of the hydrogen-oxygen reaction given in the fifth column and the heat of formation of metal oxide per g. atom oxygen given by the third column of Table I. It is hoped that modern electronic theory will be successfully applied on the basis of knowledge gained from the classical viewpoint.

One of the authors (I. K.) especially wishes to thank Dr. Yoshio Murata, the General Manager of The Research Laboratory, Mitsubishi Petrochemical Co., Ltd., for his support of this survey.

Note added in proof.—An explanation compatible with this commentary was put forward very recently by Boreskov, Dzisyak and Kasatkina (*Kin. Kata.*, **4**, 388 (1963)) in the homomolecular exchange of oxygen isotope on metal oxides; these authors noted that the calalytic activity of metal oxides of the fourth period in the above-mentioned reaction or in the hydrogen-oxygen reaction may be determined by the bond energy of oxygen with the surface and not by the electronic work function of the oxides.

The Chelating Behavior of β-Aminoethylmercaptan with Alkaline Earth Metals[*1]

By Yuichi TSUCHITANI,[*2] Takeshi ANDO and Keihei UENO

(Received July 22, 1963)

During the course of our investigation into the syntheses of new chelating agents, an intermediate product, β-aminoethylmercaptan (hereafter referred to as AEM), drew our attention as a masking agent in the chelatometric titration.[1] This investigation also made it necessary that we get basic information on the chelating behavior of this bidentate ligand with various metal ions.

Many papers have been published on the chelate-forming properties of AEM in solid[2,3], as well as in solution states;[4-7] the reported data on the chelate stability constant include data on such metal ions as cadmium(II), cobalt(II), nickel(II), lead(II) and zinc(II).[8] However, no information is available on its chelating behavior with alkaline earth metals. This paper will report the results of the chelate stability measurement of AEM with alkaline earth metals.

Experimental

Reagents. — AEM which had been obtained as hydrochloride from the Evans Chemitics, Inc., New York, was recrystallized repeatedly from ethanol in a nitrogen atmosphere. The material was very hygroscopic and had to be stored in nitrogen over phosphorus pentaoxide. It melted at 70~70.5°C in a sealed tube (reported m. p. 70.2 ~70.7°C[9]).

Found: C, 20.81; H, 6.90%. Calcd. for $C_2H_7NS \cdot HCl$: C, 21.13; H, 7.10%.

The purity of the material was also checked by the iodometry of the -SH group; it was found to be 99.37±0.40%. The strength of the aqueous solution of the reagent decreased by 0.5~1.0% over a 3-day period even when it was kept in nitrogen in a refrigerator; therefore, the exact strength of the solution was estimated by taking the mean value of the strengths before and after measurement.

All the metal ions used in this study were in nitrate form; the concentration of their solutions was determined by the EDTA titration.

The Measurement of the Dissociation and the Chelate Stability Constants. — The experimental method consisted of the potentiometric titration of the ligand in the absence and in the presence of

the metal ions, using a 0.10 N sodium hydroxide solution as the titrant. The ionic strength was kept constant at $\mu=0.10$ with potassium nitrate, while the concentrations of the ligand and the metal ions were kept at $1\sim2\times10^{-3}$ M. Titrations were carried out with solutions with 1 : 1 and 1 : 2 metal ligand ratios at 25 ± 0.1°C in a current of nitrogen in the absence of atmospheric and dissolved oxygen.

The hydrogen ion concentration was measured by means of a Hitachi Horiba Model P pH-meter with a glass and a calomel electrode. A fluctuation in the pH value was seen when a fresh glass electrode was used; only reproducible readings were taken as the titration data.

Results and Discussion

The acid dissociation constant of the ligand was calculated, according to Bjerrum's method, from the titration curve of the ligand in the absence of metal ions (Fig. 1). The equilibria and the dissociation constants to be determined are expressed as:

$$H_2A^+ \rightleftharpoons H^+ + HA\,;\ k_1=(H^+)(HA)/(H_2A^+)$$

$$HA \rightleftharpoons H^+ + A^-\,;\ k_2=(H^+)(A^-)/(HA)$$

where H_2A^+ represents the protonated ligand ($HSCH_2CH_2N^+H_3$). The values of pk_1 and pk_2 were obtained from Bjerrum's formation curve, and their accuracies were checked by the successive approximation method of Carlson, McReynolds and Verhoek.[10] As Table I shows, these values agree fairly well with the reported values when the differences in experimental conditions are taken into account.

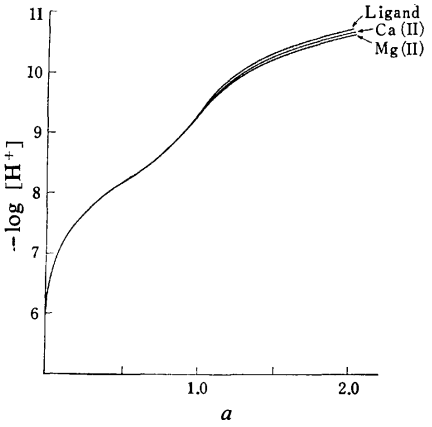

Fig. 1. Titration curves of AEM with and without the metal ions.
$t=25$°C; $\mu=0.10$ (KNO_3); Concentration of ligand, about 1×10^{-3}

The titration curves of the solutions with a 1 : 1 metal to ligand ratio for calcium(II) and magnesium(II) are shown in Fig. 1. Although the titration of solutions with a 1 : 2 ratio was also carried out, no indication of the formation of a 1 : 2 chelate was found. The chelate stability constant for the 1 : 1 may be defined as follows:

$$M^{2+} + A^- \rightleftharpoons MA^+\,;$$

$$K_{MA}=(MA^+)/(M^{2+})(A^-)$$

where M^{2+} and A^- represent alkaline earth metal ions and the deprotonated ligand $H_2NCH_2CH_2S^-$ respectively. The chelate stability constants for alkaline earth metals were calculated from these titration curves according to the method developed by Chaberek and Martell.[11] When the data obtained from the titration curves in a range of $a=1.4\sim1.7$ were employed, the agreement of the calculated values on each metal ion were not satisfactory. Therefore, fairly consistent values from the narrower range of $a=1.48\sim1.57$ were taken as the chelate stability constants. The main reasons for such a deviation may be an error

in pH measurement, an error which would increase with decreasing chelate stability, and the decomposition of ligands in the alkaline region. As is shown in Table I, the chelate stability constants for alkaline earth metals are not very high, but they are still appreciable. These values are comparable to those of iminodiacetic acid and are somewhat higher than those of glycolic acid and glycine. The same order of increasing stability, barium< calcium<magnesium, is observed for AEM, glycine and iminodiacetic acid, all of which have nitrogen as one of the donor atoms. These findings suggest that the coordination of nitrogen in AEM is effective, even in the case of alkaline earth metals. In the chelate stability investigation into the marcaptoethyl derivative of iminodiacetic acid,[12] it has been found that the coordination of the $-S^-$ group contributes very little to the chelate stability in the case of alkaline earth metals. Therefore, it is very likely that the chelate formation of AEM with alkaline earth metals takes place mainly through the coordination of the amino nitrogen of the ligand.

Part of the expense of this investigation have been defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

*The Polymerization of 3,3-Bis(chloromethyl)oxetane with Boron Trifluoride-Diethyl Etherate in the Presence of Glycidyl Methacrylate**

By Takayuki Otsu, Shuzo Aoki and Minoru Imoto

(Received July 27, 1963)

Recently Saegusa and his colaborators[1] reported that three-membered cyclic ethers, such as propylene oxide and epichlorohydrin, showed a cocatalytic effect on the polymerization of tetrahydrofuran and 3,3-bis(chloromethyl)oxetane with Lewis acid catalysts. We also found that glycidyl methacrylate and glycidyl acetate could serve as both cocatalyst and comonomer in the polymerization of tetrahydrofuran catalyzed by boron trifluoride-diethyl etherate.[2] Several copolymers of tetrahydrofuran and 3,3-bis(chloromethyl)oxetane with some other three-membered cyclic ethers have been prepared.[3] This paper is concerned with the polymerization of 3,3-bis(chloromethyl)oxetane with boron trifluoride-diethyl etherate in the presence of glycidyl methacrylate.

Experimental

3,3-Bis(chloromethyl)oxetane, glycidyl methacrylate and boron trifluoride-diethyl etherate were carefully distilled in nitrogen atmosphere under reduced pressure. The middle fraction was collected and used. Methylene chloride was washed with aqueous sodium carbonate and then with distilled water, dried over calcium chloride, and distilled. The polymerization and copolymerization were carried out in a glass-stoppered tube. After a specified time, the polymerization mixture was poured into methanol. The polymer precipitated was filtered off on a glass filter, washed with methanol, and dried under vacuum. The composition of the copolymer was calculated from the results of the chlorine analysis.

Results and Discussion

The effects of the catalyst concentration and of the polymerization temperature on the polymerization rate of 3,3-bis(chloromethyl)-oxetane in the presence of glycidyl methacrylate and boron trifluoride-diethyl etherate were investigated. The results are shown in Table I. The yield of the polymer increased with the increases in the concentration of

boron trifluoride-diethyl etherate-glycidyl methacrylate and in the polymerization temperature; therefore, it was clear that glycidyl methacrylate serves as a cocatalyst for the polymerization of 3,3-bis(chloromethyl)oxetane as well as for that of tetrahydrofuran.[2)]

Table II shows the results of the copolymerization of 3,3-bis(chloromethyl)oxetane with glycidyl methacrylate at −78 and 0°C. As can be seen from Tables I and II, the yield of the polymer decreased as the concentration of glycidyl methacrylate increased relative to the concentration of boron trifluoride-diethyl etherate. These results may be interpreted in terms of the decreased reactivity of the oxonium cation derived from glycidyl methacrylate, since the carbon-carbon double bond in glycidyl methacrylate was quite inert for

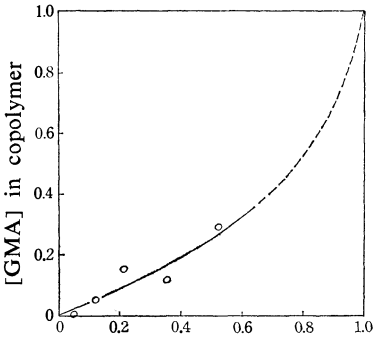

Fig. 1. Monomer-copolymer composition curve for copolymerization of 3,3-bis(chloromethyl)oxetane with glycidyl methacrylate at 0°C.

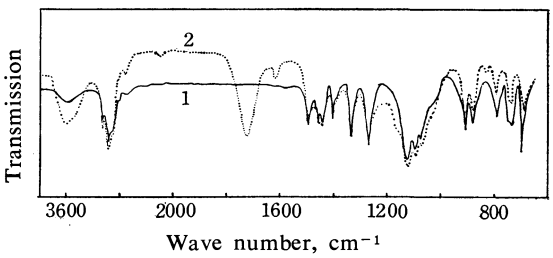

Fig. 2. Infrared spectra of poly-3,3-bis(chloromethyl)oxetane (1) and 3,3-bis(chloromethyl)-oxetane-glycidyl methacrylate copolymer (2) in KBr disk.

the cationic polymerization of tetrahydrofuran, as has been reported in a previous paper.[2)]

From the chlorine contents in the copolymer (Table II), a monomer-copolymer composition curve for this copolymerization at 0°C was drawn (cf. Fig. 1). The apparent monomer reactivity ratios were calculated to be:

r(3, 3-bis(chloromethyl)oxetane) = 2.6

r(glycidyl methacrylate) = 0.2

These values are the same as those obtained for the tetrahydrofuran-glycidyl methacrylate copolymerization.[2)]

The infrared spectrum of the copolymer (Fig. 2) shows absorption bands at 1730 and 1640 cm^{-1} due to a carbonyl group and a carbon-carbon double bond respectively, evidently arising from the glycidyl methacrylate unit of the polymer chain. Accordingly, it has been concluded that only the three-membered cyclic ether (epoxy) group in glycidyl methacrylate participated in the copolymerization with the 3,3-bis(chloromethyl)oxetane catalyzed by boron trifluoride-diethyl etherate.

SHORT COMMUNICATIONS

The Free Radical of Quinone Formed on Active Alumina

By Tsutomu TAKAMURA and Jiro KASHIWAKURA

(Received August 21, 1963)

It has been observed that violet or pink coloration is produced by the absorption of *p*-benzoquinone, Q, or chloranil on active alumina. This has led to the assumption that quinones changed to semiquinone, because a similar coloration has been observed in the course of semiquinone formation in a homogeneous alkaline solution.[1)]

Pure active alumina (99.99% purity after complete drying) obtained by the amalgam method was heated at about 400°C to expel adsorbed water and was then cooled in air. The white alumina thus treated turned pink or violet when it was suspended in a carbon tetrachloride solution of chloranil. The color tone was found to depend upon the water content of the alumina. A low water content gave an orange or pink color, and a high water content, violet or brown. When Q was used instead of chloranil, a brownish violet coloration developed.

When the near-ultraviolet spectrum of Q absorbed on the alumina was measured by the KBr disk method, two adsorption bands were observed, at 415 and 430 mμ. This indicates the formation of semiquinone, whose characteristic bands are known to appear at 407 and 430 mμ in an aqueous solution.[2)] The ESR spectrum was recorded for the alumina degassed at 400°C for 3 hr. under the pressure of 10^{-5} mmHg, followed by the adsorption of Q in vacuo. The spectrum of alumina showed a single absorption band whose peak-to-peak separation of the derivative form was approximately 10 gauss and the *g* value of which was

2) M. Eigen and P. Matthies, *Chem. Ber.*, **94**, 3309 (1961).

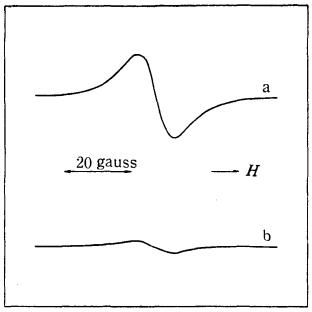

Fig. 1. ESR spectra of *p*-benzoquinone adsorbed on the alumina treated with (curve b) and without (curve a) antimony trichloride.

2.00 (Fig. 1, curve a), while only a very weak signal could be obtained when the alumina had previously been treated with Lewis acid composed of antimony trichloride or maleic anhydride (Fig. 1, curve b).

Although no detailed ESR spectrum of semiquinone could be obtained, the findings regarding the near-ultraviolet and ESR spectra seem to indicate the formation of a semiquinone. Two mechanisms can generally be considered in the formation of a semiquinone from Q. One is the charge-transfer mechanism, where some Lewis base transfers one electron to the delocalized π orbital of Q; the other is that one proposed by Eigen and Matthies,[2] where the hydroxide ion attaches to the 2-position of Q, after which a porton is released and an equimole is formed of hydroxy-*p*-benzosemiquinone and *p*-benzosemiquinone.

If the formation of a semiquinone on active alumina occurs through the above-mentioned mechanisms, some basic sites must be present on the alumina surface. The ESR results of Lewis acid-treatment support the assumption that the basic sites which cause semiquinone formation are present on the alumina. It has been reported that water or oxygen plays an important role in the formation of a semiquinone in a homogeneous solution.[1,2] Since the present findings regarding the ESR signal obtained for the sample prepared in vacuo indicate little influence by oxygen, a further study of the influence of water in connection with the basicity of active alumina has since been conducted.

Electron Spin Resonance Spectra of Nitrophenol Anion Radicals

By Kisaburo UMEMOTO, Yasuo DEGUCHI and Taitiro FUJINAGA

(Received September 3, 1963)

Though the electron spin resonance of the nitrophenol anion radical could not be studied by the reduction method using alkali metals, we have observed the ESR spectra of *p*-, *m*- and *o*-nitrophenol anion radicals generated by electrochemical reduction by following a method similar to that of Maki et al.[1] Electrolysis was carried out in a 10^{-3} molar acetonitrile solution containing 0.1 N tetra-*n*-propylammonium perchlorate as the

TABLE I. COUPLING CONSTANTS OF NITROPHENOL ANION RADICALS

Substance	Coupling constants* (in gauss)
 *p*-Nitrophenol	$a_N = 13.8$ $a_{H_1} = 3.14$ $a_{H_2} = 0.72$
 *m*-Nitrophenol	$a_N = 12.3$ $a_{H_1} = 3.33$ $a_{H_2} = 2.98$ $a_{H_3} = 2.76$ $a_{H_4} = 0.92$
 *o*-Nitrophenol	$a_N = 12.5$ $a_{H_1} = 3.59$ $a_{H_2} = 3.59$ $a_{H_3} = 1.01$ $a_{H_4} = 0.61$ $a_{H_5} = 0.46$

* The assignment of these coupling constants was not confirmed by the deuterium substitution but supposed from the results of the Hückel MO calculations.

supporting electrolyte.

The spectrum of *p*-nitrophenol is shown in Fig. 1a. The three major groups are presumably the hyperfine structures due to the nitrogen splitting, each of them consisting of three triplets caused by two pairs of equivalent protons. These protons are considered to be those which are attached to the ortho- and meta-positions of the benzene ring. The proton hyperfine structure of the hydroxyl group was not observed in this case. The hyperfine coupling constants are shown in Table I, where the results of the Hückel MO calculations have been referred to for the assignment of the coupling constant in each position of the molecule.

The ESR spectrum of *m*-nitrophenol is shown in Fig. 2a. It seems that the proton hyperfine siructure of the hydroxyl group does not show up as in the case of *p*-nitrophenol, and that the two protons in the ortho-positions with respect to the nitro group are not equivalent. Thus this spectrum can be explained well on the basis of the obtained coupling constants shown in the table. The results seem particularly interesting when compared with those obtained with *m*-nitrotoluene, *m*-chlorobenzene and *m*-bromonitrobenzene, in which the ortho-protons are equivalent.[2)]

The ESR spectrum of *o*-nitrophenol is shown in Fig. 3a. There is a distinct nitrogen triplet, each element of which consists of from nineteen to twenty-one lines. These absorption lines can not be understood without taking account the hyperfine coupling of the proton in the hydroxyl group. Though proton splitting constants have not yet been definitely assigned to each of the protons, this spectrum can be explained fairly well on the basis of the splitting constants shown in the table. The participation of the hydroxyl-group proton in the hyperfine coupling of *o*-nitrophenol might

2) T. Fujinaga, Y. Deguchi and K. Umemoto., unpublished results.

be caused by the hydrogen bonding of the hydroxyl-group proton to the nitro-group.

The hydrogen bonding effect in *o*-nitrophenol has already been observed from its infrared spectra,[3] but we believe that the present report is the first ESR observation of the hydrogen bonding in *o*-nitrophenol.

Other anion radicals of substituted nitrobenzenes have also been prepared electrolytically, and a good deal of information on the electrode process has been obtained by the use of ESR spectroscopy. These findings will be reported in due course.

A Nonenzymatic Approach to the Selective Cleavage of Threonine Peptides

By Takeo KANEKO and Toshishige INUI

(Received September 4, 1963)

It has previously been reported that threonine was easily cyclized with phosgene in an alkaline solution to an oxazolidone carboxylic acid.[1] It has also been found that the cyclization of *N*-benzoyl-DL-threonine methyl ester with phosgene to an *N*-benzoyl oxazolidone derivative through a chlorocarbonyl intermediate proceeded in a similar way when the methods of Bergel[2] and Ben-Ishai[3] were applied. In this case, the *N*-benzoyl oxazolidone derivative produced could be hydrolyzed to the oxazolidone carboxylic acid in one step.* In this hydrolysis, only the benzoyl group could be removed in safety from the oxazolidone ring. In connection with this finding, it seemed that it would be of great interest to investigate whether threonine dipeptide, which involves a piptide linkage between the amino group of threonine and the carboxyl group of another amino acid, can be cyclized to an oxazolidone derivative and then cleft to an oxazolidone carboxylic acid and free amino acid.

From a reaction of *N*-benzyloxycarbonyl-(Z)-DL-ananyl-DL-threonine methyl ester[4] (DL-DL-I; m. p. 103.5~105°C) with phosgene, an *O*-chlorocarbonyl compound (m. p. 103.5~104.5°C; Found: C, 51.12; H, 5.26; N, 6.91. Calcd. for $C_{17}H_{21}N_2O_7Cl$: C, 50.94; H, 5.28; N, 6.99%) was obtained. It was cyclized to DL-*trans*-3-(Z-DL-alanyl-)-4-methoxycarbonyl-5-methyl-2-oxo-oxazolidine (DL-DL-II; m.p. 129.5~130°C; Found: C, 56.16; H, 5.52; N, 7.60. Calcd. for $C_{17}H_{20}N_2O_7$: C, 56.40; H, 5.53; N, 7.69%). To a solution of 2.46 g. of the oxazolidone derivative (DL-DL-II) in 38 ml. of methanol, 15.1 ml. (2 eq.) of 0.90 N potassium hydroxide were added. The reaction mixture was kept at room temperature for 1.5 hr. After evaporating the methanol in vacuo, the aqueous solution which remained was acidified with hydrochloric acid to pH 3 and then extracted with ethyl acetate. From the extract, Z-DL-alanine[5] (DL-DL-III; m. p., 113.5~114.5°C; yield: 1.32 g. (88%)) was isolated. An additional amount of hydrochloric acid was added to the remaining acidic aqueous solution (pH 1), which was then evaporated to dryness in vacuo. From an extract of the

residue with ethyl acetate, DL-*trans*-oxazolidonecarboxylic acid[1] (DL-IV; m. p. 126.5~127.0°C; yield: 0.89 g. (91%)) was obtained. In the case of the reaction of an optically-active peptide (L-L-I; m. p. 131.7~132.2°C; $[\alpha]_D^{16.5}$ −23.6° (MeOH)), the oxazolidone peptide (L-L-II) obtained was hydrolyzed in a way similar to that used for DL-DL-II to L-III[6] (m. p., 86~87°C; $[\alpha]_D^{13}$ −13.8° (AcOH)) and L-IV[7], (m. p. 139.0~139.8°C; $[\alpha]_D^{11}$ +40.7° (H_2O)) in yields of 71% and 60% respectively.

Z-Glycyl-DL-threonine methyl ester (m. p., 110.5~111.8°C) was also cyclized to the corresponding oily oxazolidone peptide by the action of phosgene; this was followed by hydrolysis to give Z-glycine[5] and DL-IV in yields of 71% and 76% respectively.

Similarly, a tripeptide, Z-L-alanyl-L-alanyl-L-threonine methyl ester (m. p. 181.0~181.5°C; $[\alpha]_D^{11}$ −56.5° (MeOH)) was also cyclized to the corresponding oily oxazolidone peptide ester, which afforded Z-L-alanyl-L-alanine[8] (m. p., 149.5~151.0°C; $[\alpha]_D^{13.5}$ −32.5° (MeOH)) and L-IV by a mild alkaline hydrolysis.

These results indicated that this selective cleavage of threonine peptide occurred with no recemization at the peptide linkage in which an amino group of the threonine residue participated.

NMR Studies of Rates of the Inversion of o, o'-Bridged Biphenyls[1]

By Michinori Ōki, Hiizu Iwamura and Naohiro Hayakawa

(Received September 17, 1963)

In the course of infrared spectral study, it became necessary to know the rates of the inversion of 9, 10-dihydrophenanthrene (I), 2, 7-dihydro-3, 4 : 5, 6-dibenzoxepin (II), and their derivatives. Since the half-lives of the inversion of these samples are expected to be too short to allow the conventional optical resolution which is inevitable for the polarimetric method,[2,3] the authors adopted the NMR technique,[4] which has lately been successfully applied to the analyses of the rate processes.[5,6]

If I and II are fixed as non-planar or if the half-lives of their inversion are relatively long, the spectra of the bridging methylene groups will be composed of the A_2B_2- and AB-spin patterns respectively, since the two protons on a methylene group are situated in a different magnetic environment. This is the case in III, IV and VI.[7] III shows a broad signal at τ, 7.38, δ_{AB} being less than 5 c. p. s., while IV shows an exact AB-quartet at τ, 6.00 (center), with $\delta_{AB}=19.6$ c. p. s. and $J_{AB}=11.0$ c. p. s.

On the contrary, I, II and V show a singlet

3) R. Adams and H. C. Yuan, *Chem. Revs.*, **12**, 261 (1932).

4) The NMR spectra were measused on a Varian V-4300 spectrometer operating at 56.4 Mc./sec., and variable with a temperature probe accessory and a Dewar probe insert attached. The samples were dissolved in carbon disulfide containing 1% tetramethyl silane to make a 5% solution.

5) A typical example can be seen in the study of the chair-chair interconversion of cyclohexane (F. R. Jensen, D. S. Noyce, C. H. Sederholm and A. J. Berlin, *J. Am. Chem. Soc.*, **84**, 386 (1962)).

6) Lately, Meyer and Meyer (ibid., **85**, 2170 (1963)) have shown the applicability of the NMR method to the study of the rates of rotation of 2, 2'-bis(hydroxymethyl)biphenyls; their report prompted the present authors to report these preliminary findings.

7) K. Mislow and M. A. W. Glass (ibid., **83**, 2780 (1961)) were the first in observing the non-equivalent methylene-bridge protons in VI.

methylene signal at room temperature and retain the singlet at temperatures as low as $-90°C$. The rates of the inversion are estimated to be not less than $10^2\ sec^{-1}$ at $-90°C$, and by assuming $\log A=12$,[8] the activation energy of the inversion is obtained as less than 9 kcal./mol.

VII, at room temperature, also gives two singlet signals at τ, 7.20 and τ, 5.75; these signals are due to the protons on the $-CH_2CH_2-$ and $-CH_2OCH_2-$ groups respectively. Interestingly, the latter signal begins to lower and broaden gradually as the temperature goes down to $-50°C$, and at $-55°C$, separation into vague multiplet sets in. At $-60°C$, a resonance pattern of a characteristic AB-quartet is clearly recognized. At $-80°C$ or lower, the signal is rigorously determined as $\delta_{AB}=25.9$ c. p. s. and $J_{AB}=11.4$ c. p. s. Even at this temperature, the signal at the higher applied magnetic field will not separate into an apparent multiplet but is only broadened a little. Since the δ_{AB} of the methylene protons on the $-CH_2CH_2-$ group is smaller, the averaging of the resonance signals is still occurring in the rate process through which the signal due to $-CH_2OCH_2-$ with a larger δ_{AB} does not coalesce. Assuming that the relation, $\tau=\sqrt{2}/2\,\pi\delta_{AB}=1/2k$, holds when the quartet signal coalesces to a broad singlet, k is found to be $58\ sec^{-1}$ at $-55°C$. The exchange broadening of two interacting nuclear spin resonance signals has been treated theoretically by Alexander.[9] For the fast exchange limit, the height of the coalesced singlet relative to that at $\tau\rightarrow 0$, can be related to the mean life-time. From the limiting slope, $\tau\rightarrow 0$, together with the velocity obtained above at the very temperature of coalescence, the energy of activation and the Arrhenius factor of inversion are determined:

$E=11.2\pm 2$ kcal./mol., and $\log A=12.9\pm 1.5$.

Since the two methylene groups in VIII are no longer equivalent, VIII exhibits double AB-quartets at room temperature; CH_2 substituting the benzene ring without a nitro group, τ, 5.77 (center), $\delta_{AB}=27.0$, and $J_{AB}=11.80$ c. p. s.; and CH_2 substituting the benzene nucleus with a nitro group τ, 5.61 (center), $\delta_{AB}=15.1$, and $J_{AB}=11.4$ c. p. s. Thus the rate of inversion may be estimated to be less than $50\ sec^{-1}$ at room temperature. As the temperature rises, the quartet singnal at a lower applied magnetic field begins to broaden and coalesce (at 48°C) earlier than that at a higher magnetic field (at 56°C). From the two coalescence temperatures of the resonance signals with a different chemical shift, the kinetic parameters of the rate process are determined as follows: $E=15.5\pm 2$ kal./mol. and $\log A=12.0\pm 1.5$.

The Absolute Configuration of the Tris-l-propylenediamine Cobalt(III) Ion, L-[Co l-pn$_3$]$^{3+}$

By Yoshihiko SAITO, Hitoshi IWASAKI and Hiroko OTA

(Received September 19, 1963)

The absolute configuration of the optically-active tris-*l*-propylenediamine cobalt(III) ion has been determined. Crystals of L-[Co *l*-pn$_3$]-Br_3 (pn: propylenediamine, $NH_2CHCH_3CH_2$-NH_2) were prepared, and their crystal structure was completely determined.[1] Commercial *d, l*-propylenediamine was resolved with *d*-tartaric acid according to the method described by O'Brien and Toole.[2] The *l*-pn was heated with purpureo-chloride, $[CoCl(NH_3)_5]Cl_2$. The reaction mixture was then dissolved in a small amount of water. When concentrated hydrobromic acid was added to the solution, crystals of the bromide were precipitated. By recrystallization from water, well-formed prismatic crystals deep orange-red in color were obtained. They are hexagonal, with the space

2) T. D. O'Brien and R. C. Toole, *J. Am., Chem. Soc.*, **76**, 6009 (1954).

group $P6_3$; $a=11.03\pm0.03$, $c=8.59\pm0.03$ Å and $Z=2$ (Cu$K\alpha$, $\lambda=1.542$ Å).

The structure is essentially ionic, consisting of positively-charged complex ions and bromide anions. The arrangement of these ions in the crystals is closely related to that found in 2D $[Co\,en_3]Cl_3\cdot NaCl\cdot 6H_2O$.[3] A perspective drawing of the complex ion, $[Co\,l\text{-}pn_3]^{3+}$ is presented in Fig. 1.

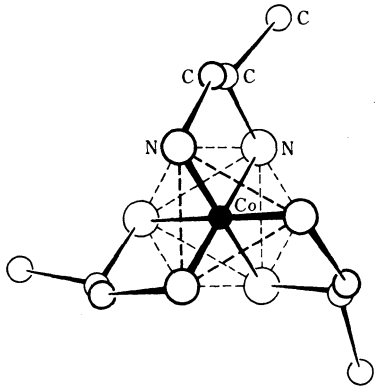

Fig. 1. A perspective drawing of the complex ion, $[Co\,l\text{-}pn_3]^{3+}$.

The complex ion has a three-fold axis of symmetry through the central cobalt atom. All the three ligands, therefore, should have identical configurations. The general features of the complex ion are very similar to those of $[Co\,en_3]^{3+}$ (en: ethylenediamine).[3,4] The five-membered Co-pn rings are puckered, and the C–C bonds in these rings are nearly parallel to the three-fold axis, taking "lel" forms in Bailar's notation.[5] The presence of the substituted methyl groups does not seem to disturb the five-membered ring. The methyl carbon bonds are equatorial with respect to the plane of the ring. The absolute configuration of the complex ion was determined by using absorption-edge technique.[6] Anomalous dispersion effects were taken into account for both the cobalt and bromine atoms, the correction factors for the f-values being:

$$\Delta f'(\mathrm{Co}) = -2.2 \qquad \Delta f''(\mathrm{Co}) = 3.9$$
$$\Delta f'(\mathrm{Br}) = -0.9 \qquad \Delta f''(\mathrm{Br}) = 1.5$$

for Cu$K\alpha$ radiation.[7] The atomic parameters and Bijvoet inequalities were refined on the differential Fourier program at the same time. Some of the observed and calculated relations between $I(h\,k\,l)$ and $I(h\,k\,\bar{l})$, the latter being equivalent to $I(\bar{h}\,\bar{k}\,\bar{l})$ because of the symmetry of the space group, are compared in Table I.

Table I. Determination of the absolute configuration

$h\,k\,l$	Calcd.		Obs.	
	I_{hkl}	$I_{hk\bar{l}}$	I_{hkl}	$I_{hk\bar{l}}$
1 3 1	378	124	>	
1 5 1	85	48	>	
1 6 1	42	101	<	
1 8 1	27	2	>	
3 1 1	934	721	>	
3 5 1	19	75	<	
4 6 1	5	34	<	
5 1 1	0	38	<	

From these accordances in the table, it may be found that the complex ion $[Co\,l\text{-}pn_3]^{3+}$ shown in Fig. 1 corresponds to the laevorotatory form with respect to the Na D lines. If the three methyl groups of $[Co\,l\text{-}pn_3]^{3+}$ are replaced by hydrogen atoms, the absolute configuration of the complex ion, L-$[Co\,en_3]^{3+}$,[8] is obtained. In fact, the optical rotatory dispersion curves of L-$[Co\,en_3]^{3+}$ and L-$[Co\,l\text{-}pn_3]^{3+}$ correspond to one another.[9] The absolute configuration of the propylenediamine, which has an asymmetric carbon atom in the molecule, could be determined at the same time. The results confirm the previous conclusion of our X-ray investigation[10] and agree with the chemical convention.[11,12]

The calculation of the structure factors was carried out on the PC-2 computer of this Institute.

*An Ion Exchange Method for the Determination of Cesium-137 and Strontium-90 in Fallout**

By Hiroyuki TSUBOTA

(Received March 20, 1963)

Several methods for the determination of cesium-137 and strontium-90 in fallout deposits have been reported,[1-6] some of them including ion-exchange techniques. The main aim of the radiochemical analysis of fallout has been the determination of cesium-137 and strontium-90, the most important radionuclides among the fission products because of their long half-lives. It is, therefore, necessary to develop a more rapid and less tedious method for these important radionuclides than the conventional ones.

The methed reported here for the determination of cesium-137 and strontium-90 from the same sample is based on three previous studies by the the present author and his coworker. The first work dealt with the phenomena of the hydrolysis of metal ions adsorbed on cation exchange resin.[7] The second described the ion-exchange separation of a small quantity of strontium from a large quantity of calcium.[8] The third presented fundamental data for the specific adsorption of cesium by a phenol-sulfonic acid type cation-exchange resin.[9]

Experimental

Chemicals. — *Cation Exchange Column A.* — H^+-form of Amberlite CG-120 (sulfonic-acid type cation exchange resin), 100~200 mesh, 2.0×15 cm. column.

Cation Exchange Column B.—Diaion BK (phenol-sulfonic-acid type cation exchange resin), 100~120 mesh, equilibrated with "solution II," 1.0×4 cm. column.

Elutriant I. — 1 : 1 mixture of a 2 M ammonium acetate solution and methanol.

Elutriant II.—2 M ammonium acetate solution.

Solution I.—A mixture of a 5 M ammonium formate solution and 5 M aqueous ammonia in the ratio of 1 : 40 (pH 11.3).

Solution II.—A tenfold diluted solution of solution I (pH 11.0).

All chemicals used were of reagent grade.

Radioactivity Measurement. — Gamma-activity was measured by a scintillation counter with a single-channel pulse height analyzer, and the β-activity by an anti-coincidence low-background Geiger-Muller counter.

Procedure.—As a result of extensive studies of the analytical procedure, the following method was established for the analysis of monthly fallout deposits collected on a 50×50 cm. tray.

An extract of the fallout deposit with 6 N hydrochloric acid was subjected to analysis after organic matter had been decomposed with nitric acid and after silica had been removed by a conventional procedure. The extract was evaporated to dryness, and then the residue was dissolved in 5~10 ml. of 3 N hydrochloric acid and diluted with water to 30~50 ml. The solution was passed through column A and the column was washed with 50 ml. of water. Then, 300 ml. of elutriant I was passed through the column at the flow rate of 2~3 ml./min. Sodium, potassium, magnesium and calcium were eluted in this portion. In the next step, cesium and strontium were eluted with 225 ml. of elutriant II. The effluent was evaporated to dryness on a water bath, and the residue was heated under an infrared lamp; thus the ammonium formate in the residue could be sublimed.

Two milliliters of solution I and 10 ml. of water were added to the vessel to dissolve the residue. The total strontium content of the solution was determined by titration with a 0.01 M EDTA standard solution adding 1 ml. of a 0.01 M magnesium-EDTA solution, and Eriochrome Black T as an indicator. After the titration, a volume of EDTA nearly equal to the titre was further added, and the solution was diluted to 20 ml. with water. The solution was poured into column B. The column was washed with 20 ml. of a mixture of 2 ml. of solution I, a volume of EDTA equal to the titre, and water.

Strontium-90 activity in the effluent was determined with a low-background Geiger-Muller counter by the usual yttrium-milking method after the EDTA had been decomposed with nitric acid and hydrogen peroxide. The γ-activity of the cesium-137 remaining in the column was measured with

9) H. Tsubota, ibid, **36**, 1038 (1963).

a scintillation counter, by taking the resin out from the column into a suitable vessel with water and by drying under an infrared lamp. Alternatively, cesium-137 was eluted from the column with 30 ml. of a 1 : 1 mixture of 1 M formic acid and a 1 M ammonium formate solution. The effluent was evaporated to dryness, and the residue was sublimed under an infrared lamp. The vessel was rinsed thoroughly with 5 ml. of a 1 : 1 mixture of 1 M formic acid and 1 M ammonium formate to dissolve the cesium. The solution was transferred to a stainless steel counting dish and again evaporated to dryness under an infrared lamp to expel the ammonium formate completely. The β-activity of cesium-137 in the dish was measured with a low-background Geiger-Muller counter.

Examination of the Procedure

To check the efficiency of separation, an artificial solution with a composition similar to the extract of fallout was used. Its composition is shown in Table I.

TABLE I. CHEMICAL COMPOSITION OF ARTIFICIAL FALLOUT SAMPLE

Metal ion	Content, mg.
Na^+	200
K^+	50
Mg^{2+}	50
Ca^{2+}	120
Fe^{3+}	80
Al^{3+}	40

Total: About 1.5 g. as chlorides (ca. 30 meq.)

The Behavior of Metal Ions which Tend to be Hydrolyzed.—The artificial fallout solution containing cerium and zirconium labeled with cerium-144 and zirconium-95 was passed through column A. The column was treated with elutriants I and II by the procedure mentioned above, and the effluent was divided into 10 ml. fractions. The radioactivity measurement of cerium and zirconium and the colorimetrical determination of ferric and aluminum ions were carried out in each fraction. Very small amounts of these metal ions were sometimes detected in the fraction collected before the calcium fractions but not in other fractions. It was thus verified that metal ions which tend to be hydrolyzed are not eluted from the cation exchange column with elutriant I (containg methanol), a finding which is in accordance with the former findings with aqueous elutriants.[7]

The Elution of Strontium and Cesium from Column A.—Figures 1 and 2 show the elution curves from column A for artificial fallout solutions containing varying amounts of cesium labeled with cesium-137 and for those containing various amounts of calcium. The elutriants

used are specified along each curve in the figures. From the figures, it is evident that strontium is eluted together with cesium and that both ions are eluted later than and are well separated from calcium. The effect of the change in calcium concentration, as actually encountered in the fallout, can also be shown. The increasing calcium concentration makes the separation more complete. These findings are in agreement with the former findings.[8]

The Capacity of Column A.—The column dimensions were decided upon by assuming that the maximum dimensions would be required if all the cations in the artificial solution were to be replaced by calcium. By using a column 15 cm. long and 2 cm. in diameter, fallout extract, the cation content of which is equivalent to at least 30 meq., would be treated. A sample of greater cation content than that

of the artificial solution can be treated by a larger column. The length of the column (L cm.) necessary to treat W g. (as chlorides) of a sample is given by:[8]

$$L=10+5\frac{W}{1.5}$$

and the volume of elutriant (V ml.) by:

$$V=V_0\frac{L}{15}$$

where V_0 is the volume of elutriant required when the value of W is 1.5. Actually, 2 g. of chlorides can be treated with a column 15 cm. long, as will be shown later in Table III. Hence, L calculated in this manner has reasonable allowance.

The Separation of Cesium and Strontium with Column B.—Cesium is adsorbed on a phenol-sulfonic-acid type cation exchange resin from an ammoniacal solution.[9] When solution II containing strontium labeled with radioactive strontium was passed through column B and the column was washed with solution II, a considerable amount of strontium remained in the column, as is shown in Table II. When EDTA was added to the sample solution and washing solution, however, no strontium (nor yttrium) remained. Even when twice as much EDTA as strontium was added to solution II, cesium was not eluted until 150 ml. of the washing solution had passed.

The cesium adsorbed on the resin could not be eluted with water, and was eluted very slowly with a neutral solution of sodium or ammonium salt, but it was eluted easily and completely with acidic solutions. Elution curves for cesium from column B with different elutriants are shown in Fig. 3. The elution

curve with 0.5 N hydrochloric acid consists of two parts, a high peak probably due to elution from the phenolic group, the tailing part probably due to elution from the sulfonic group. Elution curves with concentrated acids, such as 3 N hydrochloric acid or a 2 M formate buffer solution, had a typical form of favorable elution.

Results

The analysis was carried out by using an artificial fallout solution containing labeled strontium and cesium. The results are shown in Table III. The recovery was 98±4% for strontium and 99±3% for cesium.

The results of analyses of monthly fallout deposits are shown Table IV. In this case, samples were collected on the roof of the

National Institute of Health in Tokyo, Japan, and the hydrochloric acid extracts of the sample were divided into two portions, one being analyzed by the present method and the other by the usual fuming acid-tungsto-silicate-perchlorate method.[2] The agreement between the results of these two methods was satisfactory as a whole.

The author wishes to thank Professor Yasuo Miyake of Tokyo Kyoiku University, Professor Hidetake Kakihana of the Tokyo Institute of Technology, Professor Yasushi Kitano of Nagoya University, and Dr. Masami Izawa, the Chief of the Chemistry Division, the National Institute of Radiological Sciences, for their helpful discussions of this work. Special thanks are given to Mr. Takashi Nagai of the National Institute of Health, who made many data available for the analysis of radiocesium.

Oxidation of Alicyclic Compounds with Pernitrous Acid

By Tadao INOUE, Noboru SONODA and Shigeru TSUTSUMI

(Received May 4, 1963)

It has been reported by many workers[1-5] that the reaction of hydrogen peroxide with nitrous acid, nitrate, nitrite, etc. produces unstable peroxy compounds of nitrogen. Baeyer and Villiger[1] inferred the formation of an unstable pernitrous acid as an intermediate during the reaction between hydrogen peroxide and nitrous acid, and Rasig[2] showed the presence of pernitric acid (formulated as HNO_4) from the fact that a mixture of hydrogen peroxide and nitrous acid was a stronger oxidizing agent than either of its components. Kortum and Finckh[3] observed that the transient yellow color solution, prepared by mixing acidified hydrogen peroxide with sodium nitrite, had an ultraviolet absorption band with a maximum close to that of nitrate ions, but about fifteen times more intense and much broader. Halfpenny and Robinson[4] suggested the formation of pernitrous acid and further proposed the homolytic fission of pernitrous acid to give a hydroxy radical and nitrogen dioxide on the grounds of the polymerization of methylacrylate or reaction with simple aromatic compounds.

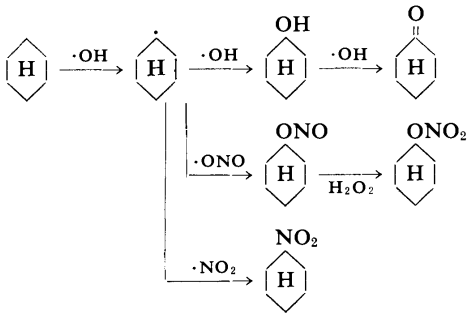
Laville et al.[5] supported the above considerations and postulated the nitration process of quinoline by the free radical mechnism. Recently, Johnson and Lockett[6] reported the mechnism of pernitrous acid formation from their observation of the effect of oxygen and hydrogen peroxide on the oxidzing action of nitrous acid. This investigation was carried out in order to obtain some information about the oxidation behavior of aliphatic compounds with the pernitrous acid produced as an active oxidizing species in the reaction system. Cyclohexane and cyclohexene were chosen as the starting materials.

Results and Discussion

When cyclohexane and cyclohexene were oxidized by hydrogen peroxide containing nitrous acid in a slightly acidic solution, several compounds were obtained as the reaction products. When cyclohexane was treated with pernitrous acid at 0~2°C, cyclohexanol was obtained as the main product, and cyclohexanone, cyclohexyl nitrate and nitrocyclohexane were also confirmed by gas chromatography, infrared spectra and/or the identification of derivatives. It was assumed that these products would be produced by the following course, in which the hydroxy radical resulting from the homolytic fission of pernitrous acid initially attacks cyclohexane and in which, after the abstraction of the hydrogen atom, the cyclohexyl radical formed reacts with the ·OH, ·ONO and ·NO_2 radicals.

$$H_2O_2 + HNO_2 \rightarrow HOONO + H_2O$$

$$HOONO \rightarrow \cdot OH + \cdot ONO \leftrightarrow \cdot NO_2$$



It seems to us that the reaction proceeds step by step and that cyclohexyl nitrate and cyclohexanone would be formed by the oxidation with the ·OH radical and H_2O_2 respectively. Halfpenny and Robinson[4] suggested that the reaction of pernitrous acid with aromatic compounds might proceed by homolytic processes involving the successive addition of the ·OH and ·NO_2 radicals to the aromatic nucleus and that the abstraction of nuclear hydrogen by the hydroxy radical would not occur. However, the reaction of saturated hydrocarbons with these agents may proceed via the immediate hydrogen abstraction, followed by recombination with other radicals.

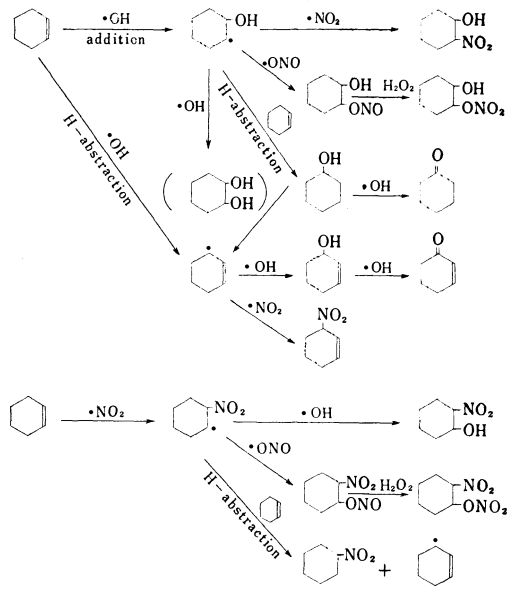
Cyclohexene was treated with pernitrous acid prepared from nitrous acid and an excess amount of hydrogen peroxide. From the water-insoluble part of the reaction products, cyclohexanol, cyclohexanone, cyclohexene-3-ol and cyclohexen-3-one were detected as oxygen-containing components; they were considered to be formed by the attack of the hydroxy radical on the double bond or the α-hydrogen atom of cyclohexene. The presence of nitrocyclohexane, 3-nitrocyclohexene and cyclohexyl nitrate as nitrogen-containing components may be assumed on the basis of the analysis of the infrared spectrum and the physical properties. *trans*-2-Nitrocyclohexyl nitrate was also isolated as a higher boiling product which might be formed by the hydrogen peroxide oxidation of the *trans*-2-nitrocyclohexyl nitrite produced by the reaction of the nitro radical with cyclohexene.[7] *trans*-2-Nitrocyclohexanol was obtained as a main product from the water-soluble part. The reduction of this part with lithium aluminum hydride gave *trans*-2-aminocyclohexanol and *trans*-cyclohexan-1, 2-diol, which was considered to be derived from *trans*-hydroxycyclohexyl nitrate. The presence of the nitrite was also detected by the infrared spectrum of the water-soluble part. In this experiment, no cis-isomers of these products were detected. The formation of *trans*-2-nitrocyclohexanol indicated that the simultaneous hydroxylation and nitration of the olefinic double bond with pernitrous acid might be possible. The yield of α-nitroalcohol was fairly low for the synthetic purpose because of the less selectivity of the reaction. The whole reaction might be interpreted by the free radical mechanism shown below. The hydroxy radical formed by the homolytic fission of pernitrous acid may attack an olefinic double bond or an α-hydrogen, and then the α-hydroxycyclohexyl radical or the cyclohexyl radical will be formed as the respective first intermediates, whereas the nitro radical may add to a double bond or may recombine with free radicals formed in this reaction system. These intermediate radicals may react with other radicals or may disproportionate to produce various products.

When an excessive amount of sodium nitrite was used to prepare the pernitrous acid, 1-nitrocyclohexene and cyclohexane-φ-nitrosite were isolated in addition to the products described above. There products may be derived from the reaction of free nitrous

$$HOONO \rightarrow \cdot OH + \cdot ONO \leftrightarrow \cdot NO_2$$



acid.[8]

Cyclohexane-φ-nitrosite is produced in addition to the reaction product of pernitrous acid, so the excess amount of hydrogen peroxide must be used to avoid these side reactions.

Experimental

Materials.—The cyclohexane used was purified by treating it with fuming sulfuric acid and then by fractional distillation: b. p. 80.7°C, $n_D^{20}=1.4263$ (lit.[9] b. p. 80.7°C). Cyclohexene was prepared by the dehydration of cyclohexanol, and it was purified by fractional distillation before used: b. p. 82.5°C, $n_D^{20}=1.4449$ (lit.[10] b. p. 82.6°C).

These materials were confirmed to be pure by gas chromatography.

The Reaction of Cyclohexane with Pernitrous Acid.—Cyclohexane (1 mol.) was emulsified with a solution containing 100 ml. of 6% hydrogen peroxide, 5 ml. of 3 N hydrochloric acid and 80 ml. of water in 1 l. four-necked flask in a nitrogen atmosphere. A 5% sodium nitrite solution (150 ml.) and a 6% hydrogen peroxide solution (288 ml.) were simultaneously vigorously stirred drop by drop into the emulsion for about 1 hr. at 0~2°C. The stirring was continued a further 4 hr. The organic layer from four runs experiments was separated and dried over anhydrous sodium sulfate. After the removal of the unreacted cyclohexane, the residual liquid was distilled under reduced pressure and 1 g. of an oily liquid (b. p. 39~60°C/10 mmHg) was obtained; this was assumed to be

a mixture of mono-functional cyclohexane derivatives. Four peaks were detected in this fraction by gas chromatography; two of them were identical with the those of cyclohexanol and cyclohexanone respectively; (column, silicon-550; 130°C). The fraction showed infrared absorption bands at 3320 cm^{-1} (OH); 1690 cm^{-1} (C=O); 1620, 1280, and 868 cm^{-1} (ONO_2) and 1545 and 1375 cm^{-1} (NO_2).[11] The reduction of this fraction with lithium aluminum hydride gave cyclohexylamine, which was identified as the hydrochloric acid salt (m. p. 203~204°C (lit.[12] m. p. 203~204°C)). This showed the presence of nitrocyclohexane in the above fraction. Cyclohexyl nitrate was assumed to be present on the basis of the infrared spectrum.

The Reaction of Cyclohexene with Pernitrous Acid.—A 5% sodium nitrite solution (150 ml.) and a 6% hydrogen peroxide solution (288 ml.) were added to an emulsion containing a 6% hydrogen peroxide solution (100 ml.), water (80 ml.) 3 N-hydrochloric acid (5 ml.) and cyclohexene (82 g.) in the manner described in the reaction of cyclohexane. The organic layer separated from ten runs was extracted with an aqueous sodium bicarbonate solution and was washed with water. After being dried over sodium sulfate, the organic layer was distilled to remove unreacted cyclohexene, and the residual oil was distilled under reduced pressure. From the fraction (1.2 g.) with a b. p. of 45~57°C/3 mmHg, cyclohexanol, cyclohexanone, cyclohexyl nitrate and nitrocyclohexane were identified by gas chromatography, and 3-nitrocyclohexene was assumed to be present on the ground of its characteristic bands in the infrared spectrum: 1545 and 1368 cm^{-1} (NO_2) and 1665 cm^{-1} (C=C). The infrared analysis of this nitro-compound agreed with that of Brown.[13] The fraction (1.3 g.) (b. p. 58~120°C/3 mmHg) was purified by chromatography using a silica gel column according to the procedure of Stevens;[14] it was judged to be *trans*-2-nitrocylohexyl nitrate from a comparison of its infrared spectrum with that of an authentic sample.[13] A mixture of the sodium carbonate solution and the washed water was acidified with N hydrochloric acid and mixed with the aqueous layer from ten runs. The resultant aqueous solution was extracted with chloroform, and the extract was dried over anhydrous sodium sulfate. The chloroform was evaporated, and 18.5 g. of the oily residue was distillated under reduced pressure; the following fractions were obtained:

Fraction 1: 7.8 g., b. p. 39~64°/3 mmHg
Fraction 2: 7.7 g., b. p. 65~104°C/3 mmHg
Residue: 2.9 g.

Fraction 1 was divided into three portions by preparative gas chromatography using a silicon-550 packed column. Each portion was distilled under reduced pressure. Cyclohexanol (3.4 g.) was isolated and identified as its α-naphthylurethane: (m. p. 128~128.5°C (lit.[15] m. p. 128°C)); a mixed melting point with an authentic sample was not depressed.

Found: C, 57.79; H, 6.88. Calcd. for $C_{17}H_{19}NO_2$: C, 57.81; H, 7.11%.

The second portion (0.6 g. of liquid; b. p. 42~43°C/3 mmHg) was identified as cyclohexen-3-ol by the infrared spectrum and its α-naphthylurethane derivative (m. p. 154~155°C (lit.[16] m. p. 155°C)); a mixed melting point with an authentic sample showed no depression.

Found: C, 76.19; H, 6.15. Calcd. for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41%.

The third portion (1.4 g. of liquid; b. p. 54~56°C/3 mmHg) was assumed to be cyclohexen-3-one on the basis of the bromine test and its infrared spectrum, which showed the strong characteristic band at 1680 cm^{-1} (conjugated carbonyl). Fraction 2 showed characteristic bands at 3320 cm^{-1} (OH); 1548 and 1375 cm^{-1} (NO_2); and 1625, 1275, 865, 760, and 690 cm^{-1} (ONO_2). Fraction 2 was reduced with lithium aluminum hydride. Fraction 2 (7.7 g.) was added drop by drop to a well-stirred solution of lithium aluminum hydride (9.0 g.) in ether (200 ml.). After the reaction mixture had been kept at 33°C for 5 hr., water (50 ml.) and a 20% aqueous solution of sodium potassium tartrate (150 ml.) were stirred in. The aqueous layer which separated was saturated with sodium chloride and then extracted with ether and ethanol. After these extracts had been mixed with the organic layer, the resultant mixture was dried over magnesium sulfate and the solvent was evaporated. The residual liquid was distilled under reduced pressure and 3 g. of a liquid (b. p. 70~94°C/3 mmHg) was obtained. This fraction was cooled at 0°C, and the deposited crystalline solid was filtered. Recrystallization from a *n*-hexane-ligroin mixture gave *trans*-cyclohexan-1, 2-diol (0.7 g.), which was considered to be derived by the reduction of *trans*-hydroxycyclohexyl nitrite or *trans*-2-hydroxycyclohexyl nitrate (m. p. 103~104°C (lit.[17] m. p. 103~103.5°C)); a mixed melting point with an authentic sample showed no depression.

Found: C, 62.09; H, 10.40. Calcd. for $C_6H_{12}O_2$: C, 62.04; H, 10.41%.

The filtrate was dissolved in 50 ml. of benzene, and dry hydrogen chloride was passed through the solution. Recrystallization of the deposited solid gave 2 g. of *trans*-2-aminocyclohexanol hydrochloride (m. p. 175~176°C (lit.[18] m. p. 176~177°C)).

Found: C, 47.56; H, 9.29. Calcd. for $C_6H_{14}NOCl$: C, 47.52; H, 9.31%.

The Reaction of Cyclohexene with Hydrogen Peroxide and a Concentrated Sodium Nitrite Solution. — Cyclohexene (82.1 g.) was emulsified with a mixture of sulfuric acid (10 ml.) and water (80 ml.), and a sodium nitrite solution (69 g. in 250 ml. of water) and a 6% hydrogen peroxide solution (450 ml.) containing 17 ml. of water and 3 ml. of concentrated sulfuric acid were simultaneously added drop by drop to the emulsion at equal rate

over a 2 hr. period while dry nitrogen was passed at −5∼−10°C. The products, obtained from the two runs described above, were separated into three parts: a crystalline solid (1.6 g.) water-soluble products (10.0 g.) and water-insoluble products (5.5 g.). This solid was identified as cyclohexane-φ-nitrosite from its infrared spectrum which was in full accordance with that of Brown[19] (m. p. 153°C (decomp.)); it recrystallized from ethyl acetate; and a mixed melting point with an authentic sample showed no depression.

Found: C, 45.69; H, 6.52. Calcd. for $C_{12}H_{20}N_4O_6$: C, 45.56; H, 6.37%.

Distillation of the water-insoluble products gave 3-nitrocyclohexene (b. p. 54∼56°C/1 mmHg Found: C, 56.82; H, 7.28. Calcd. for $C_6H_{10}NO_2$: C, 56.68; H, 7.14% and 1-nitrocyclohexene (b. p. 64∼65°C/1 mmHg.

Found: C, 56.61; H, 7.29. Calcd. for $C_6H_{10}NO_2$: C, 56.68; H, 7.14%.

The infrared spectra of these nitro-compounds agreed with those of Brown.[11] Treatment of 1-nitrocyclohexene with semicarbazide acetate in methanol gave 2-nitrocyclohexylsemicarbazide after several days (m. p. 163∼163.5°C (decomp.), from ethanol (lit.[20] m. p. 163°C)).

Found: C, 41.77; H, 6.97. Calcd. for $C_7H_{14}N_4O_3$: C, 41.62; H, 6.98%.

A small amount of *trans*-2-nitrocyclohexanol was obtained from the water-soluble products (b. p. 94∼95°C/1 mmHg).

Found: C, 49.62; H, 7.91. Calcd. for $C_6H_{11}NO_3$: C, 49.64; H, 7.64%.

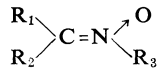
The Electronic Spectra of Nitrones and the Solvent Effect on Them[*1]

By Tanekazu KUBOTA,[*2] Masumi YAMAKAWA[*2] and Yutaka MORI[*3]

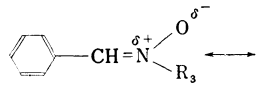
(Received May 7, 1963)

The spectroscopic behavior and the electronic states of such heterocyclic *N*-oxides as pyridine and quinoline *N*-oxides have been reported by the present authors[1-3] and by other workers.[4] Nitrone, the general formula of which can be expressed as I, may also be considered to be a kind of conjugated tertiary amine *N*-oxide. If the oxygen atom in I shows considerable resonance interaction with the rest of the molecule, a spectroscopic behavior similar to that of heterocyclic *N*-oxides may be expected for nitrones. For example, in

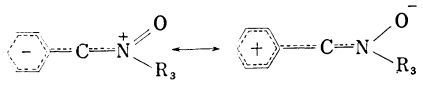


(I)

aldonitrones, where R_1 and R_2 in I are an aryl group and a hydrogen atom respectively, the above-mentioned resonance structure may be written as II–IV.



(II)



(III) (IV)

Although a few reports on the electronic spectra of nitrones have been published by several workers,[5-7] a detailed spectroscopic investigation from the above view-point has not been made. For this paper, the electronic spectra of a total of fifteen nitrones, all of which contain a benzene ring as at least one

substituent of R_1, R_2 and R_3 in I, and such related compounds as anils and oximes, have been extensively examined in various solvents. The results thus obtained will be compared with the findings on spectroscopic behavior obtained previously on heterocyclic *N*-oxides. In addition, the configurations of the typical nitrones were also assumed from the measurement of the dipole moments and from their reactivities.[8]

Experimental

Measurement.—The ultraviolet absorption spectra were measured with a Hitachi recording spectrophotometer, model EPS-2 at 23°C and at a slow scanning speed, using matched quartz cells with a 1 cm. light path. The infrared spectra were measured with a Perkin-Elmer 12-C recording spectrometer provided with LiF optics and with a Nippon-Bunko DS-201-B recording spectrometer with NaCl optics. Special care was taken in the region of the OH-stretching frequency. The dipole moments were measured at 25°C in benzene or dioxane. The dielectric constants of dilute solutions were measured by the heterodyne beat method, using a platinum cell.[9] The experiments were made for concentrations lower than 1%, a good linear relationship between the dielectric constants and the weight fractions of a sample being obtained within the range of experimental error. the slope of this straight line, the molar polarization of the solute was calculated by a method similar to that of Halverstadt-Kumlar.[10] The deformation polarization of nitrones was assumed to be 1.05 times the molar refraction estimated as the sum of the bond refractions.

Materials.—The solvents were purified by the method recommended by Weissberger and Proskauer;[11] special care was taken to remove contaminating water from the organic solvents. The synthetic method, microanalytical data, estimated configurations and physical properties of the nitrones and the related compounds are shown in Tables I and II, together with the numbering of the samples.

Results and Discussion

On the Electronic Spectra of Nitrones.—Figures 1 and 2 give the absorption spectra of nitrones and the related compounds in nonpolar solvents, while Table III lists the absorption maxima and the intensities of the compounds measured in various solvents. As may clearly be seen in Fig. 1, nitrones apparently show a characteristic strong π-π^* band in the region of 280～370 mμ as well as one or two additional bands with a relatively low intensity in the region of 200～260 mμ, the positions of which bands are dependent upon the kind of substituent. The molecular extinction coefficient (ε) of the former is about 20000. With regard to the examination of the character of the spectra of nitrones, a comparison of the spectra of the corresponding anils, oximes, etc., with those of nitrones would seem to be very important and interesting. Detailed investigations of the electronic spectra of anil-type compounds were carried out by Ebara,[12] by Brocklehurst,[7] and by other workers,[13-15] with results consistent with ours (see Fig. 2).

The spectra of compounds 17–24, which are oxime or anil-type compounds with no benzene ring on the *N*-atom, apparently consist of a rather weak band with vibronic structures at the longest wavelength region, a strong band continuing from the above weak band, and a strong band in the 200～230 mμ region. Each of these spectra is essentially similar to

Platt's notation and in the order given above, as Figs. 2a–2d show. In the case of the absorption spectra of nitrones, we could not explicitly find the band corresponding to ^1L_b, but it may be hidden below the strongest π-π^* band.[20] Moreover, in the case of oximes or anils, we could not obviously find the absorption band corresponding to those of nitrones appearing in the 200~250 mμ region with relatively low intensity and fine structures. These facts clearly suggest that the difference in electronic structures between nitrones and anil-type compounds is fairly large, and that the resonance structures, for example as shown in II–IV, must be taken into consideration.

Recently, the abnormal electronic spectra of such anils as benzylidene aniline have been found by several authors[7,12] and have been discussed from the standpoint of steric hindrance by comparison with the spectra of stilbene or azobenzene. These authors concluded that benzylidene aniline has no planar structure and that two benzene rings are considerably twisted with regard to each other. Spectral curves similar to those obtained by previous authors were also recorded by us for the benzylidene aniline. As may be understood from Figs. 1a, 1b, 1c and 1d, however, in the case of *N*-phenyl benzaldoxime and its analogous nitrones distinctly different spectra from those of, for instance, the benzylidene aniline were observed. These spectra are analogous to those of nitrones with no benzene ring on the *N*-atom in molecules and show, at the longest wavelength region, the strongest π-π^* band, which depends on the nature of the substituent introduced in the benzene ring, as may be seen in Figs. 1a, 1b, and 1c and Table I. This character is similar to that of the spectra shown by normal nitrones, as has been mentioned before, where the steric hindrance may be inferred to be small. This fact indicates that the electronic structure of these nitrones differs considerably from that of, for instance, the benzylidene aniline and that these nitrones may be closely represented by a planar structure, although some steric hindrance may be inferred from the the molecular model shown in Fig. 3.[21]

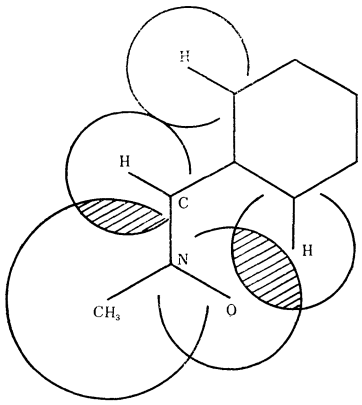

Fig. 3. Molecular model of *N*-methyl benzaldoxime.

Steric Effect on the Electronic Spectra of Nitrones.—It should be clearly noted in Fig. 1d that the intensity of the π-π^* band of *N*-methyl or *N*-phenyl benzophenonoxime is much lower than that of *N*-phenyl benzaldoxime. The same tendency can also be found in the spectra of *N*-methyl acetophenonoxime, the intensity of the π–π^* band of which is much lower than that of *N*-methyl benzaldoxime.

As an example, Fig. 4 shows the molecular model of *N*-methyl benzophenonoxime drawn by the aid of Pauling's van der Waals radii.[21] From this figure it is evident that these nitrones have a considerable steric hindrance for planar structure and that, as is often the case,

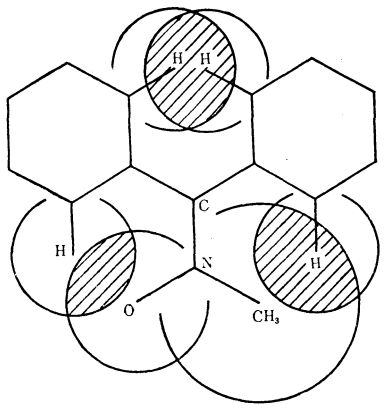

Fig. 4. Molecular model of *N*-methyl benzophenonoxime.

such a steric hindrance is the main reason for the decrease in the intensity of the characteristic strong π-π^* band of nitrones because the resonance among such canonical structures as II–IV may be hindered by the steric hindrance. The spectroscopic behavior of *N*-methyl acetophenonoxime is of especial interest. This compound can be obtained only by the replacement of the side chain C–H group of *N*-methyl benzaldoxime by a C–CH_3 group.

It is well known that the effect of methyl substitution on the electronic spectra of conjugated systems is rather small. Nevertheless, a serious difference was observed between the

20) Detailed theoretical calculation results on this point will be published in the next paper.

21) L. Pauling, "The Nature of the Chemical Bond," 3rd Edition, Cornell University Press, New York (1956), p. 260. C–H, 1.08Å; C–C (aromatic), 1.40; C–C (–Ph), 1.43; C–CH_3, 1.52; C–N, 1.48; N→O, 1.33; C=N 1.32.

spectra of *N*-methyl benzaldoxime and those of *N*-methyl acetophenonoxime. Namely as may be seen in Figs. 1a and 1d, the intensity of the latter is very weak. It seems probable that the steric effect is the main reason for this, as may, for example, be seen in Fig. 5. In this molecule the configuration of the benzene part and the side chain part may depart more from the coplanar structure than from the structure of *N*-methyl benzaldoxime.[22]

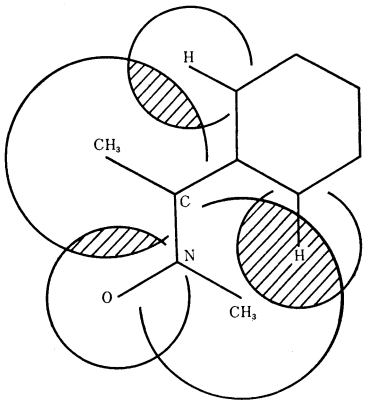

Fig. 5. Molecular model of *N*-methyl acetophenonoxime on the assumption of the "anti" form of phenyl group against N→O bond.

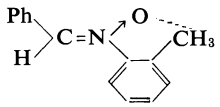
The fact that compound 10 absorbs light at a shorter wavelength than the π-π^* bands of compounds 11 and 12 may also be explained by considering the structure.



Solvent Effect on the Electronic Spectra of Nitrones and Their Related Compounds.—As may clearly be seen in Table I, the blue shift of the absorption bands of all nitrones is caused by the increasing polarity of those solvents which contain active hydrogen atoms which can form hydrogen bonds. This phenomenon is analogous to that discovered generally in heterocyclic *N*-oxides and may be considered to be due to the reason discussed in detail in our previous papers.[1,3] It is conceivable that hydrogen bonding, such as $\gg$N→O···H (solvent), plays an important role in the blue shift phenomenon. In order to make a more detailed study concerning the contribution of the hydrogen-bonding effect, we made an experiment on three component systems (*N*-methyl benzaldoxime, methanol and *n*-heptane). The change in the spectra of *N*-methyl benzaldoxime upon the addition of methanol is shown in Fig. 6. The behavior

of the spectra suggests that the equilibrium shown in Eq. 1 may exist.[27]

$$N\rightarrow O + HO\text{–}CH_3 \rightleftarrows N\rightarrow O\cdots HO\text{–}CH_3 \qquad (1)$$

This fact is also supported by the behavior of the OH-stretching band of methanol when nitrone is added, as is shown in Fig. 7. From Eq. 1, the following equation is obtained:

$$K=\frac{[C_{NO\cdots H}]}{[C_{NO}-C_{NO\cdots H}]\ [C_{CH_3OH}-C_{NO\cdots H}]} \qquad (2)$$

where C_{NO}, C_{CH_3OH} and $C_{NO\cdots H}$ are the concentrations of nitrone, methanol and the associated compound respectively. Under the experimental conditions shown in Fig. 6, $C_{CH_3OH}\gg C_{NO\cdots H}$. Then, Eq. 3 is easily obtained by appling the Lambert-Beeer law.

22) The configuration shown in Fig. 5 is also supported by the fact that mutual interaction like $\gg$N-O···H_3C- can be expected. The interaction of this type has often been reported in the heterocyclic *N*-oxides, such as α-picoline *N*-oxide.[4,23-25] Furthermore, this structure is more reasonable from the stand-point of chemical reactivities.[26]

26) Y. Mori, to be published.

27) In this case, it was found that the fine structure at about 293.4 mμ disappeared rapidly upon the addition of a small amount of methanol, and no fine isosbestic point could be obtained. This shows some contribution from effects other than the hydrogen bonding. However, it is clear that the shift due to the hydrogen-bonding effect is the largest. This fact is also supported by the behavior of the infrared spectra shown in Fig. 7.[27a]

27a) See also footnote 3, and the following paper concerning the investigation of infrared spectra: H. Shindo and B. Umezawa, *Chem. Pharm. Bull.*, **10**, 492 (1962).

$$\varepsilon=\frac{1}{K}\left(\frac{\varepsilon_{NO}-\varepsilon}{C_{CH_3OH}}\right)+\varepsilon_{NO\cdots H} \qquad (3)$$

where ε is an apparent molecular extinction coefficient, and ε_{NO} and $\varepsilon_{NO\cdots H}$ are the molecular extinction coefficients of nitrone and the hydrogen-bonding compound respectively. The relations of Eq. 3 at various wavelengths are shown in Fig. 8 and Table IV. The averaged value of K is 5.6 l./mol., while the degree of blue shift caused by hydrogen bonding (1:1) is about 642 cm^{-1}. In addition, the degree of the red shift of the OH-stretching band resulting from this hydrogen bonding effect is about 238 cm^{-1}. In the case of *N*-methyl acetophenonoxime, its absorption bands shift largely to blue upon the addition of a small quantity of methanol, as is shown in Fig. 9, where no good isosbestic point could be obtained. The absorption bands of oximes and anils did not show such a large blue shift with the increasing polarity of solvents as was found for

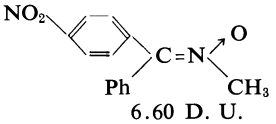
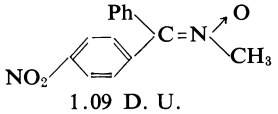
nitrones or heterocyclic *N*-oxides.[1] Generally, the solvent effect on the spectra of these compounds is very small. These results suggest that the blue shift is characteristic of conjugated *N*-oxides; this phenomenon was always observed in both heterocyclic *N*-oxides and nitrones. It seems that hydrogen bonding, such as N→O···H–O– (solvents), plays an important role in this phenomenon.[28]

On the Configuration of Nitrones.—Whether the conjugated system of nitrones is a syn or an anti form is very important for the analysis of these spectra, which has been described before and which will be discussed in the next paper more fully, and for the problem of the steric hindrance, which was discussed in the previous section. The configurations of nitrones are inferred from the methods of synthesis,[29] their reactivities,[29] and the measurement of the dipole moments which are



6.60 D. U.



1.09 D. U.

28) After we finished work on this paper, we learned of the paper by Kinko Shinzawa, of the Tokyo Institute of Technology, read at "The Symposium on Photochemistry" held by the Chemical Society of Japan, in Nagoya, October 17, 1962, in which she found that free nitrone (benzylidene aniline *N*-oxide) and hydrogen-bonded nitrone clearly show a different behavior in the quantum yield of the photochemical reaction.
29) Y. Mori, to be published.

TABLE V. THE DIPOLE MOMENTS OF COMPOUNDS 1, 5, AND 8*

Compound	α	β	$P_{2\infty}$, cc.	MR_D, cc.	μ, D.	Solvent
1	10.02	0.21	290.24	39.89	3.49	Benzene
5	26.88	0.30	835.5	45.56	6.20	Dioxane
8	20.98	0.31	886.58	65.31	6.32	Dioxane

*: In this Table, α and β denote the changes in the dielectric constant and in the density of the solutions with the weight fraction of the solute respectively, and other notations have their usual meaning.

shown in Table V. The dipole moments of the following compounds were measured by Taylar and Sutton.[30]

The dipole moment of the compound in which the nitrophenyl group is cis against the *N*-oxide group is 6.60 D. U., but that for the trans form is 1.09 D. U. The measured dipole moments of  and  are 6.20 D. U. and 6.32 D. U. respectively. Therefore, it may reasonably be considered that these configurations are the anti form, that is, that the nitrophenyl group is cis to the *N*-oxide group. The nitrone configurations shown in Table I have been decided on the basis of the reasonable assumption that the nitrones synthesized with the same method have the same configuration. This rule may be safely applied for compounds of this type.

It seems that these configurations give a reasonable explanation of the steric effect on the spectra of nitrones and for the reactivity of these compounds.[29]

Summary

The ultraviolet spectra of nitrones, the configurations of which were assumed from their dipole moments and chemical reactivities, and their related compounds have been measured in various solvents. The following results have been obtained:

(1) Nitrones show a characteristic strong π–π^* band in the 280~370 mμ region as well as one or two additional bands with a relatively low intensity in the 200~260 mμ region. The molecular extinction coefficient (ε) of the former is about 20000. The decrease in intensity of the π-π^* band is observed in the spectra of the sterically-hindered compounds.

(2) These bands always show a blue shifs with the increasing polarity of the solvent. The general rule of solvent effect on heterocyclic *N*-oxides applies also to nitrones, the conjugated *N*-oxide band of which has the same property as that of heterocyclic *N*-oxides.

(3) It has been confirmed by ultraviolet and infrared spectra that the formation of a hydrogen bond such as N→O···H (solvent) plays an important role in this blue shift phenomenon.

The authors wish to express their deep gratitude to Professor Emeritus Eiji Ochiai of The University of Tokyo for his kind guidance throughout the course of this work; to Professor Saburo Nagakura of the Institute for Solid State Physics, The University of Tokyo, for his valuable discussions and for reading the manuscript; to Dr. Ken'ichi Takeda, Director of this Research Laboratory, and Dr. Noboru Mataga of Osaka Municipal University for their valuable advice; to Dr. Haruyuki Watanabe of this Research Laboratory for the measurement of the dipole moments and for valuable advice, and to Mr. Mamoru Takasuka for the measurement of the infrared spectra.

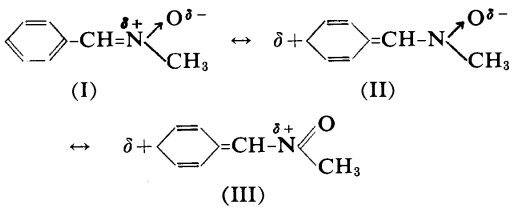
The Electronic Structures and Electronic Spectra of Benzylidene Methyl Amine N-Oxide[*2] and Its Related Compounds*[*1]

By Tanekazu KUBOTA[*3] and Masumi YAMAKAWA

(Received May 9, 1963)

In a previous paper,[1] the electronic spectra of many nitrones and their related compounds were recorded, and the configurations of some nitrones were determined by measuring their dipole moments. As a result, we found that the behavior of the electronic spectra of nitrones, especially with regard to solvent effects, is very similar to that of heterocyclic *N*-oxides. That is, in hydrogen-bonding solvents, a remarkable blue shift of the electronic spectra is always observed with an increase in solvent polarity. In addition, it was established that the electronic spectra of nitrones without a large steric hindrance exhibit a behavior which can be expressed as resonance hybridization, such as I, II and III.



(I) (II) (III)

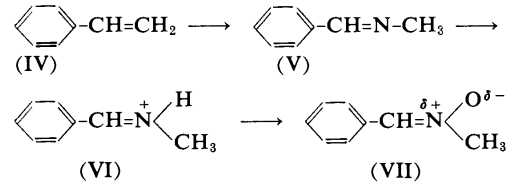
It seems important to make more detailed studies of the above points from the theoretical and experimental points of view. This paper will report the theoretical results obtained on the basis of the molecular orbital theory (MO). These results will be compared with those of experiments on benzylidene methyl amine *N*-oxide, which is a basic nitrone, and its related compounds.

Experimental

The ultraviolet absorption spectra were measured with a Hitachi recording spectrophotometer, Model EPS-2. Measurements were usually carried out at room temperature and at a slow scanning speed, using a 1 cm. light path quartz cell. The organic solvents used were purified according to the methods recommended by Weissberger and Proskauer;[2] special care was taken to remove any contaminating water. The anhydrous ethanol containing hydrogen chloride was prepared by introducing hydrogen chloride gas, which has been carefully dried with concentrated sulfuric acid, into anhydrous ethanol. The concentration of hydrochloric acid was decided by titration with a sodium hydroxide solution. The samples used were benzylidene methyl amine, its *N*-oxide, and benzaldoxime *O*-methyl ether.[3] The synthetic and purification methods and the physical properties of these compounds were reported in a previous paper.[1]

Experimental Results

The electronic structure and the spectrum of benzylidene methyl amine *N*-oxide were analyzed according to the following system, where styrene was selected as the basic compound, because the electronic structure and the electronic spectra of styrene have been investigated in detail by several authors, as will be mentioned later. Figure 1 shows the spectra of styrene[4] and benzylidene methyl amine and its *N*-oxide, these spectra being measured by a method previouly reported.



(IV) (V) (VI) (VII)

The Absorption Spectra of Proton-Addition Compounds of Benzylidene Methyl Amine (V) and Its Related Compound.—Compound V is relatively unstable in an acid solution and decomposes easily to each component, benzaldehyde, etc. This is easily detected by the fact that the absorption spectrum of V varies considerably with time, the final one being the same as that of benzaldehyde.

However, the spectrum corresponding to VI

can be obtained by recording the spectra as soon as possible after dissolving V in sulfuric acid solutions of various concentrations. The recorded spectra are shown in Figs. 1 and 2. The absorption spectra of V dissolved in anhydrous ethanol containing hydrochloric acid also show a time dependence, but the mechanism of decomposition may be considered to be different from that in the acidic aqueous solution mentioned above,[5] because the spectrum obtained after 2 hr. is completely different from that of benzaldehyde. As has been stated above, however, the spectrum of VI was also obtained by recording it quickly after the sample had been dissolved. The spectra in various acid concentrations are shown in Fig. 3.

5) Considering that weter may play an important role in the decomposition of V to benzaldehyde, etc., in an acidic aqueous medium, we carried the experiment out under the anhydrous condition.

On the other hand, benzaldoxime *O*-methyl ether is stable in an acidic medium, and the spectra of the proton-addition compound could be recorded easily, as may be seen in Fig. 4. In this case it may reasonably be thought that the proton addition will occur at the nitrogen atom in the molecule.

A comparison of the spectrum of benzaldoxime *O*-methyl ether with that of V shows that the former absorbs light at a longer wavelength than the latter. The resonance effect of the OCH_3 group may be the main reason for this.

Theoretical

In order to analyze the electronic structure and the spectrum of benzylidene methyl amine *N*-oxide (VII), MO methods were applied to the IV, V, VI and VII compounds. As VII is quite a complex molecule, in practice it is difficult to treat it under higher order conditions. In this paper, the theoretical calculations were based on the π-electron approximation, partly taking electron repulsion terms into account and including the zero differential overlap approximation, proposed by Goodman and Shull[6] and by Baba and Suzuki,[7] to interpret the spectra of benzene derivatives.

Electronic State and Spectroscopic Exchange Integrals, β_s's, of Styrene.—The electronic spectrum and the electronic structure of styrene have been reported by many workers, and the spectrum has reasonably been assigned.[4a,8-11] As is shown in Fig. 1, the absorption bands of styrene have been assigned to ^1L_b, ^1L_a and ^1B_b (Platt's notation) in the order of decreasing wavelength. It may reasonably be considered that these bands are related to the four orbitals ϕ_3, ϕ_4, ϕ_5 and ϕ_6 in the Hückel MO's of styrene shown in Fig. 5.[12,13] Here, the configuration $^1\chi_{4\to5}$ arising from the one electron transition from ϕ_4 to ϕ_5 has the symmetry of $^1A_1$ and the lowest transition energy. The other transitions belonging to the $^1A_1$ symmetry have far larger transition energies than that of $^1\chi_{4\to5}$ (cf. Fig. 5). The interaction between $^1\chi_{4\to5}$ and other $^1A_1$ configurations seems to be relatively small. Assuming that the transition energy, $1.3243\,\beta$, of the $^1\chi_{4\to5}$ configuration, obtained from the simple molecular orbital (SMO) calculations, is equal to the observed value, 5.009 eV., for the ^1L_a band, we can obtain 3.78 eV. for the spectroscopic exchange integral β_s belonging to $^1A_1$. This value was applied to the calculations for V, VI and VII. The configurations, $^1\chi_{4\to6}$ and $^1\chi_{3\to5}$, belonging to $^1B_1$ have the same energy, since styrene is an alternant hydrocarbon. Therefore, the two excited states corresponding to Eqs. 1 and 2 may be written:

$$\Psi_1=\frac{1}{\sqrt{7}}(^1\chi_{3\to5}-{}^1\chi_{4\to6}) : {}^1B_1^- \tag{1}$$

$$\Psi_2=\frac{1}{\sqrt{2}}(^1\chi_{3\to5}+{}^1\chi_{4\to6}) : {}^1B_1^+ \tag{2}$$

These correspond to the ^1L_b and the ^1B_b bands respectively. The interaction between $^1\chi_{3\to5}$ and $^1\chi_{4\to6}$ was calculated by means of Eq. 3:

$$(^1\chi_{4\to6}|H|{}^1\chi_{3\to5})=2(36|G|54)^{MO}-(36|G|45)^{MO} \tag{3}$$

The values of (pp/pp) and (pp/qq), which are one-center and two-center π-coulomb repulsion integrals respectively, were calculated on the basis of Pariser-Parr's Ball approximation.[14] The quantity (pp/pp) is obtained from the relation: $(pp/pp)=I_p-E_A$.

In the case of the $2p\pi$-electron in the carbon atom, as was seen in a previous paper,[15] the ionization potential (I_p) and the electron affinity (E_A) on the valence state of sp^3 (V_i) were taken from the data of Pritchard and Skinner.[16] These data lead to $(pp/pp)_c=11.42-0.58=10.84$ eV.

When the distance (γ) between nuclei $\geqq 2.80$ Å, the quantity (pp/qq) is given by Eq. 4 on the basis of the Ball approximation:[14]

$$(pp/qq)_{eV}=\frac{7.1975}{\gamma}\left[\left\{1+\left(\frac{1}{2\gamma}\right)^2(R_p-R_q)^2\right\}^{-1/2}+\left\{1+\left(\frac{1}{2\gamma}\right)^2(R_p+R_q)^2\right\}^{-1/2}\right] \tag{4}$$

Since Slater's effective nuclear charge of the $2p\pi$-electron in the carbon-atom is 3.25, $R_p=R_q=1.4145$ Å is obtained by the aid of the Pariser-Parr method. However, for the case of $\gamma<2.80$ Å, the quantity (pp/qq) is obtained by

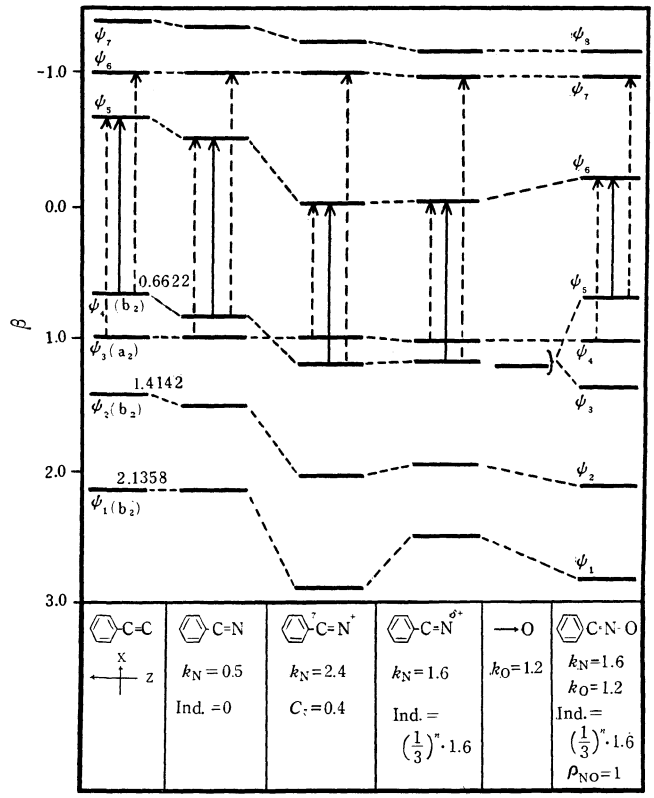

Fig. 5. The orbital energies of styrene, benzylidene methyl amine and its related compounds, and benzylidene methyl amine *N*-oxide.

extrapolating the values evaluated at longer distances to $\gamma=0$, using Eq. 5 as determined by the method of quadratic equation:

$$(pp/qq)=0.2463\gamma^2-2.8237\gamma+10.84 \qquad (5)$$

The values of $(pp/qq)_c$ and of Eq. 3 thus obtained are shown in Table I.

On the basis of the SMO approximation, $E(^1\chi_{4\to6})$ and $E(^1\chi_{3\to5})$ are equal to 1.66215 β, as can be understood from Fig. 5. The interaction between them leads to the two states shown in Fig. 6, in which the observed values of ^1L_b and ^1B_b are also given.[4a]

Table I. The values of various integrals
(Unit is in eV.)

Now, the spectroscopic exchange integral, β_s, is evaluated to satisfy the observed values in Fig. 6.[17] $\beta_s=3.04$ eV. is obtained to reproduce the observed value of ^1L_b, whereas $\beta_s=3.31$ eV. is obtained from that of the ^1B_b band. The difference between these two β_s values apparently results from the fact that

17) The dimensions of styrene were estimated on the basis of the bond order-bond length relation derived by Coulson.[18,24] We assumed that the benzene ring is a regular hexagon, the bond distance of which is 1.40 Å. It should be noted that the terms (pp/qq) necessary to calculate Eq. 3 are reduced to those consisting of the carbon atoms appearing in the benzene ring in the molecule because of the assumed C_{2v} symmetry.

$C_{i2}=\pm C_{i6}$: $C_{i3}=\pm C_{i5}$ (+ and − represent b_2 and a_2 orbitals respectively). $\varepsilon_8=-1.18828$: $\varepsilon_9=-2.02446$

the calculated values of Eq. 3 are not suitable. If one calculates the value of Eq. 3 so as to reproduce the observed ^1L_b and ^1L_a bands, one obtains 0.8307 eV., which is a little greater than that listed in Table I. The main reasons for this discrepancy are as follows: (a) The MO's used here are not the SCF-MO, which are believed to be most desirable. (b) We assumed that the symmetry of styrene is C_{2v}. (c) In these calculations, only the configuration interaction (C. I.) between $^1\chi_{3\to5}$ and $^1\chi_{4\to6}$ was evaluated. If we are rigorous we must consider the C. I. among the other configurations. Therefore, 3.17 eV., that is, the mean value between 3.04 eV. and 3.31 eV., was adopted here as the approximate value for the β_s corresponding to the $^1B_1$ bands. This value was applied to the calculations of V, VI and VII.

The SMO Calculations for Benzylidene Methyl Amine (V) and Its Proton-Addition Compound (VI).—The SMO's on V and VI were calculated by a method analogous to that used for styrene. In this case, the selection of the Coulomb integral is important for the N-hetero atom in Eq. 6:

$$\alpha_{hetero} = \alpha + k_{hetero}\beta \qquad (6)$$

So far, much information about the Coulomb integral for the heterocyclic nitrogen atoms has been obtained by many authors. It has been reported that the value 0.4~0.5 is the best for the parameter, k_N, of the sp^2 type, just as for the nitrogen atom in pyridine.[19] Assuming that the parameter of the nitrogen atom in V is nearly equal to that in pyridine, we used $k_N = 0.5$.[19a] For the $k_N{}^+$ of the $\rangle\overset{+}{N}$–H type, we made use of 2.4 (0.4 β is adopted on the carbon atom adjacent to the N^+-atom), which was decided by the SCF-MO calculations for the pyridine cation.[20] The results are listed in Table II.

The SMO Calculation of Benzyliden Methyl Amine *N*-Oxide (VII).—This compound is the simplest and most typical nitrone. Previously, we studied the electronic structure of such heterocyclic *N*-oxides as pyridine *N*-oxide and determined reasonable parameters to describe the hetero atoms of these molecules. Here, in order to compare the results of nitrones with those of heterocyclic *N*-oxides, the parameters,[21] except for that of the oxygen atom of VII, were taken to be equal to those of the heterocyclic *N*-oxides derived previously by us: $k_N = 1.6$, and inductive effects $= (1/3)^n \cdot k_N$.

Furthermore, under the conditions mentioned above, we also calculated the SMO of the hypothetical molecule  , which is obtained by dividing the VII into the composite systems consisting of the oxygen atom and its residual part.[22] The MO's thus obtained are listed in Table II. Next, the parameter of the oxygen atom in VII was determined so as to reproduce the observed dipole moment (3.49 D. U.) of VII.[1] As was described in a previous paper,[1] although VII is probably distorted somewhat from a planar structure, for the sake of simplicity the planar structure was assumed for the calculation of the dipole moment. The molecular dimensions of VII were obtained by a method analogous to that used in the calculation of styrene. The bond-order bond-length relation was used, where the order-length relationships of the N–O and C–N bonds are the same as those of our previous papers,[15] and as those used in Kobayashi's and in Cox and Jeffrey's papers respectively.[23] Moreover, we assumed that each of the C–C–N and C–N–O angles is 120°, the configuration of the molecule being the same as that discussed in a previous paper,[1,24] and that the benzene ring is a regular hexagon.

The values of the σ-moments were determined with reference to those obtained by the analysis of the dipole moments of, for instance, pyridine *N*-oxide, and diazine mono *N*-oxide[15,26] and by the analysis of the NMR

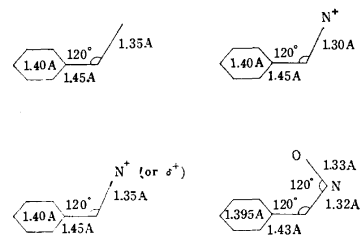
20) S. Mataga and N. Mataga, *Z. physik. Chem. N. F.*, **19**, 231 (1959).

21) The effect based on the methyl group was neglected.

22) It seems to be very useful to compare the energy level of the oxygen atom with those of the residual part stated above.

23) a) E. G. Cox and G. A. Jeffrey, *Proc. Roy. Soc.*, **A207** 110 (1951); b) H. Kobayashi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **82**, 272 (1961).

24) The dimensions and configurations for V, VI and VII are as follows:



The dimensions of VII were estimated by averaging the molecular diagrams obtained by using the following two sets of parameters: $k_N = 1.6$, inductive effects $= (1/3)^n k_N$, $\rho_{NO} = 1$ and $k_O = 0.8$; $k_N = 1.6$, $k_O = 0.8$, $\rho_{NO} = 0.7$, and inductive effects $= 0$.[15,25] These averaged values are almost the same as those in the molecular diagram shown in Fig. 10.

25) The latter set of parameters is nearly equal to that adopted by W. Maier, A. Saupe and A. Englert, *Z. physik. Chem. N. F.*, **10**, 273 (1957).

26) T. Kubota and H. Watanabe, This Bulletin, **36**, 1093 (1963), where the symbol "N–O" in Table II must be read as H–C because of misprint.

spectra of pyridimine:[27] $\overset{(+)}{N}\rightarrow\overset{(-)}{O}$ (dative bond) $=4.55$ D., $\overset{(+)}{H}-\overset{(-)}{C}=0.40$ D., $C(sp^2)-N(sp^2)=0.0$ D., and the lone pair moment of the $N(sp^2)$ atom is 1.0 D. Under these conditions, the MO's were calculated by using the various parameters of the oxygen atom. It was found that $k_O=1.2$ is a suitable value. The results thus obtained are shown in Table II. It is important to point out that 1.2 is larger than the value decided previously for pyridine *N*-oxide (0.8β). This fact shows that the electron migration from the oxygen atom to the conjugated system in VII is smaller than that in heterocyclic *N*-oxides, as will be mentioned in a later section.

The Calculation of the Transition Energy and the Oscillator Strength of Benzylidene Methyl Amine (V), Its Proton-Addition Compound VI, and Benzylidene Methyl Amine *N*-Oxide (VII).—These values are calculated by using the MO's and the eigen values shown in Table II and the spectroscopic exchange integrals, β_s, mentioned in the preceding section. The one electron transition from the highest occupied orbital to the lowest vacant orbital belongs to the $^1A_1$ symmetry (shown with a solid arrow line in Fig. 5); this state may be expressed by a single configuration as in the case of styrene. Both transitions shown with a dotted arrow line in Fig. 5 belong to the $^1B_1$ symmetry, and these will interact with each other, as may be seen in Table I. The observed and calculated values of electronic spectra are shown in Fig. 7, in which the observed values are indicated by a circle. The transition moment corresponding to each excited state was also computed. The numbers shown in Fig. 7 indicate the square value of $\vec{Q}$:

$$\vec{Q}=\int \Psi_g(^1\Gamma)\,\vec{\gamma}\,\Psi_{exc.}\ (^1\Gamma)d\tau \qquad (7)$$

where $\Psi_{exc.}$ ($^1B_1^{\pm}$) is as shown in Table III. Under our approximation, $\vec{Q}$ is reduced to each term expressed as $q_{i-j}=\sqrt{2}\sum_\nu C_{i\nu}\cdot C_{j\nu}\cdot\vec{\gamma}_\nu$.[28] Assuming that side chain group in the molecules has the bent structure (120°), the calculation of the transition moments for the $^1A_1$ species was carried out.[24] The $^1A_1$ level has a transition moment along the long axis of molecules, while the $^1B_1$ levels have their transition moments parallel with the X-axis, as Fig. 5 shows. The character of the $^1B_1$ bands may be considered to be localized in the benzene ring.

Discussion and Results

On the Electronic Spectra of Benzylidene Methyl Amine *N*-Oxide (VII) and Its Related Compounds.—As is shown in Fig. 7, the calculated values of V agreed well with the observed values. It should be noted that the level arising from $^1B_1^-$ increases to an intensity slightly more than that of styrene[29] because the MO is disordered when the nitrogen atom is introduced.

The calculated transition energy and intensity of the $^1A_1$ level of VI are also in good agreement with the experimental results, as may be seen in Fig. 7. Furthermore, on the basis of this calculation, it is thought that a band having the $^1B_1$ symmetry will exist in the longest wavelength region. An inspection of the experimental curve of VI in Figs. 1, 2 and 3 will show that the curve in the above wavelength region has a considerably prolonged tail, where an absorption band may be hidden. In the light of the calculated results, this hidden band may conceivably be ascribed to the $^1B_1^-$ band, although the calculated value does not thoroughly agree with the observed value. The main reason for this disagreement on the $^1B_1^-$ level may be attributed to the selection of Coulomb parameters (i.e., the $k_{N^+}=2.4$ used here for N^+ is relatively large). Therefore, the MO values, ψ_4 and ψ_5, of styrene shown in Fig. 5 are largely stabilized in spite of the small change of the ψ_3 and ψ_6 MO's. As a result, the $^1B_1^-$ level undergoes a large red shift. When a large net charge such as N^+ is introduced into the molecule, it is believed that the same treatment of the VI as of the pyridine cation is not totally valid. The calculated results of VII shown in Fig. 7 differ from those of other compounds in the following points: a band having the $^1B_1$ symmetry and a lower intensity than that of the strong $^1A_1$ band existing at about 4 eV. must appear in the region of 5.35 eV. In fact, we can find a new band having vibrational structures at about 5.35 eV., as may be seen in Figs. 1, 7 and Table III.[30] On the basis of the above findings, we may reasonably conclude

27) W. Seiffert, H. Zimmermann and G. Sheibe, *Angew. Chem.*, 74, 249 (1962).

29) On this approximation, if the vibronic interaction is not considered, the $^1B^-_1$ of styrene is forbidden by accident.

30) We could not obviously conclude from this calculation whether or not the absorption band arising mainly from the $^1\chi_{3\rightarrow6}$ configuration ($^1A_1$) is overlapped in this band. A problem analogous to this was discussed by Inuzuka in the case of the compound:

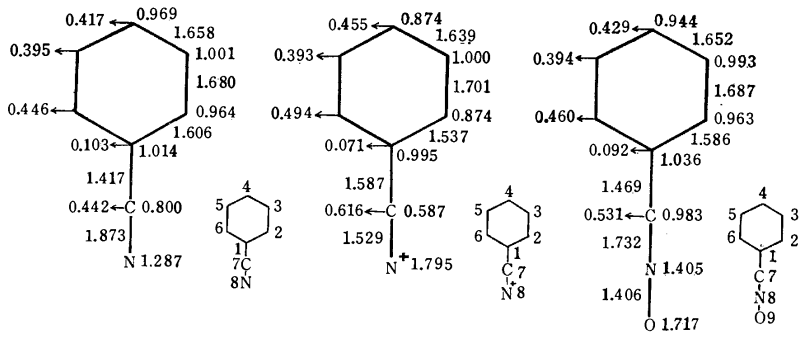
that the characteristic strong π-π^* band of VII can be assigned to a $^1A_1$ band superposed on a weak $^1B_1$ band, although the calculated energy levels do not perfectly agree with the observed levels because of various approximations and assumptions made in carrying out the calculations. From the standpoint of what has been mentioned above, it should be emphasized that the change in the electronic state in becoming the *N*-oxide compound is very large. It can be stated that the excited wave function of the strong π-π^* band ($^1A_1$) consists mainly of the $^1\chi_{5\to6}$ configuration. The comparison between the ψ_5 and ψ_6 MO's of the VII compound shown in Table II suggests that the charge transfer from the oxygen atom to the conjugated system can be expected when the π-π^* transition from ψ_5 to ψ_6 takes place; this finding is similar to that of heterocyclic *N*-oxides.[15,32] The observed blue shift phenomenon of the π-π^* band always caused by the solvent effect on nitrone compounds[1] may be considered to be due to the decrease in the π-electron density at the oxygen atom of the N→O bond in the excited state, because the hydrogen bonding power at the excited state may decrease in this case.

The Molecular Diagrams of V, VI and VII. —Figures 8a, b, c, show the molecular diagrams calculated on the basis of the results described in the "Theoretical" section. A comparison of the molecular diagram in Fig. 8c with those of heterocyclic *N*-oxide compounds[15] is of much interest from the following standpoints:

32) T. Kubota and M. Yamakawa, ibid., 35, 555 (1962).



(a) (b) (c)

Fig. 8. The molecular diagrams of the compounds shown in Fig. 7.

(i) The double bond character of the N→O bond is decreased;

(ii) The net-charge at the carbon atom 7, which is adjacent to the N→O bond, becomes positive, and

(iii) The electron migration to a benzene ring from the N→O group is comparatively small.

The investigation of the infrared spectra of many nitrones published recently by Shindo[33] shows that the N→O stretching frequency of VII, which was assigned to the very strong band appearing at 1171 cm^{-1}, exists at a longer wavelength than the frequency (1265 cm^{-1}) of pyridine *N*-oxide.[15] This fact is believed to be in agreement with the conclusion obtained from the molecular diagram. The application of Fukui's frontier orbital method,[34] giving a good predictition for the reactivities of heterocyclic *N*-oxides,[15] to the prediction of the reactivities of nitrones is also of interest.

As may easily be understood from the MO's in Table II, the frontier electron density at C_7 (except for the nitrogen and oxygen atoms) is largest in both frontier orbitals, ψ_5 and ψ_6. This fact suggests that the carbon atom, C_7, is very active in both electrophilic and nucleophilic reactions, and that this position may be easily attacked by reagents. In the course of our experiments, as has been stated in the "Experimental" section, we have also established that VII, etc., (i. e., nitrones) are relatively unstable in an acidic medium and show behavior indicating that the carbon atom, C_7, is the reaction center. Thus the spectrum of VII changes into that of benzaldehyde in an acidic aqueous medium and into a composite spectrum of compounds considered to be HCl-addition substances to the C=N bond in the molecule in mixed solvents consisting of absolute alcohol and absolute hydrogen chloride. In the later case, the altered spectra are analogous to those of simple benzene derivatives. These facts support our theoretical predictions.

Summary

The ultraviolet absorption spectra of benzylidene methyl amine, its proton-addition compound and benzylidene methyl amine *N*-oxide have been examined under various conditions. SMO calculations on those compounds have been carried out, and various physicochemical properties have been discussed.

On the basis of these calculations, the spectra of the above compounds have reasonably been assigned by using the spectroscopic exchange integrals $\beta_s(^1A_1)$ and $\beta_s(^1B_1)$, which were evaluated from the spectra and the MO, including C. I., of styrene.

The authors wish to express their deep gratitude to Professor Saburo Nagakura of the Institute for Solid State Physics, The University of Tokyo, for his valuable discussions and for reading the manuscript; to Dr. Ken'ichi Takeda, Director of this Research Laboratory, Dr. Noboru Mataga of Osaka Municipal University, and Professor Yuzuru Ooshika of Kwansei Gakuin University for their valuable discussions; and to Dr. Yutaka Mori of Osaka Gakugei Univerity for supplying samples.

The Hypersensitization of Photoconduction in Microcrystalline Zinc Oxide

By Eiichi INOUE and Takashi YAMAGUCHI

(Received May 9, 1963)

As is well known, microcrystalline zinc oxide exhibits remarkable photoconduction as long as its surface is covered with chemisorbed oxygen, but it becomes a surprisingly poor photoconductor as the oxygen is removed from the surface.[1] In a previous paper,[2] we have reported that the photoconduction characteristics can be further improved if the chemisorbed oxygen is replaced with appropriate electron-affinitive molecules. In the present paper, an enhancement of the photoconductivity of microcrystalline zinc oxide by the adsorption of some electron-affinitive molecules, such as iodine, phthalic anhydride and *p*-chloranil, will be described. The spectral response of the photocurrent and the temperature dependence of dark- and photo-currents have been studied. Rose Bengal, an organic dye which is widely used for the optical sensitization of zinc oxide photoconduction, was added to the above-mentioned systems, to be adsorved together with the electron-affinitive molecules, and the spectral response of the photoconduction has been measured.

It has been found that the electron-affinitive molecules are chemically adsorbed on zinc oxide not only to change the surface barrier height of zinc oxide, but also to co-operate with the dye molecule on the surface and to increase the photoconductive sensitivity of zinc oxide in its proper (ultraviolet) and also in its dye-sensitized (visible) wavelength regions. We shall call such a co-operative optical sensitization in the visible region "the hyper-sensitization of photoconduction."

Experimental

The microcrystalline zinc oxide used was Merck's reagent, 0.3 μ in particle size. It had a purity of 99.95%, containing calcium (0.015 %), lead (0.01 %) and sulfates (0.01%) as impurities. The adsorption of the electron-affinitive molecule onto the zinc oxide was made in the dark from an alcoholic solution. In order to study the hypersensitization, a small amount of Rose Bengal was further adsorbed by the same method onto thus-prepared zinc oxide, which had already adsorbed the electron-affinitive molecule. During these processes, no attempt was made to remove chemisorbed oxygen from the zinc oxide; therefore, the oxygen is considered to remain on the surface, forming a co-adsorbed layer with the electron-affinitive molecule or with the dye and the electron-affinitive molecule. The prepared samples of zinc oxide were coated in the dark on glass plates to a thickness of 40 to 50 μ. Two aluminum strips used as electrodes were placed 0.5 cm. apart on each of the specimens to accomplish a surface-type arrangement. In order to eliminate any pre-irradiation history of the zinc oxide employed, every specimen was kept in the dark for 50 hr. or more before its electric current was measured with a vibrating-reed electrometer. The contact between the electrode and the specimen was known to be ohmic from the linear relationship observed between the applied voltage (ranging from 5 to 100 V./cm.) and the current. A photographic tungsten lamp was used as the light source for measurement, while white light and a xenon arc were combined with a double monochromator for spectral study.

Results

The Sensitization of the Photoconduction.— When zinc oxide which had chemisorbed oxygen further adsorbed 0.03 mol.% of iodine,

phthalic anhydride or *p*-chloranil, the photocurrent was found to increase markedly, while the dark current scarcely changed at all or even decreased. Figure 1 shows the photocurrents of zinc oxide-oxygen-electron affinitive molecule systems measured with a white light with an intensity 1.3×10^{-2} W/cm^2.

When the above specimens were dyed with Rose Bengal of 0.0052 mol.%, the photocurrents, upon irradiation with the same light, increased further, as Fig. 2 shows. All the

specimens hereto used were prepared by coating the zinc oxide samples with silicone resin (7% by volume) as a binder for convenience. It was assumed that the influence of the resin on the photoconduction in each specimen is similar and that it, therefore, can be disregarded. From these measurements, it has been made clear that the electron-affinitive molecule adsorbed on the zinc oxide surface has a distinct effect on the photoconduction of zinc oxide.

Figure 3 illustrates the spectral response of photoconduction in the zinc oxide-oxygen-electron-affinitive molecule systems. The sensitization of the photoconductivity occurs only in the ultraviolet region, not in the visible region, except in the case of *p*-chloranil. In the case of phthalic anhydride, which was found to be the most effective, a double peak was found in the action spectrum. The cause of the double peak has not yet been determined. The system with *p*-chloranil showed a slight

response in the visible region which was too small to be shown in Fig. 3. The wavelength where the small response appears coincides with that of light absorption by *p*-chloranil. The results in Fig. 3 indicate a process whereby the electron-affinitive molecule is chemisorbed on the zinc oxide surface and there draws an electron from the crystal, making a depletion layer which decreases the dark conductivity of zinc oxide. When the system is irradiated with the light which zinc oxide absorbs, the chemisorbed molecule may get physisorbed or desorbed into the atmosphere. This process will lead to an increase in the photocurrent, as is the case in the zinc oxide-oxygen system mentioned at the beginning of this paper.[1] Therefore, the sensitization of the photoconduction under investigation should be considered to be caused by the chemisorption of the electron-affinitive molecule and, therefore, not by the optical sensitization effect. Here, the optical sensitization refers to a type of sensitization caused by light absorption by the sensitizer itself, as has been found in dye-sensitized silver halide in the photographic process.

The spectral response of photoconduction in the zinc oxide-oxygen-electron affinitive molecule-Rose Bengal systems is shown in Fig. 4. A remarkable optical sensitization is found in the visible region, where the light is strongly absorbed by Rose Bengal (420~600 mμ); *p*-chloranil, is an exceptional case, for it shows

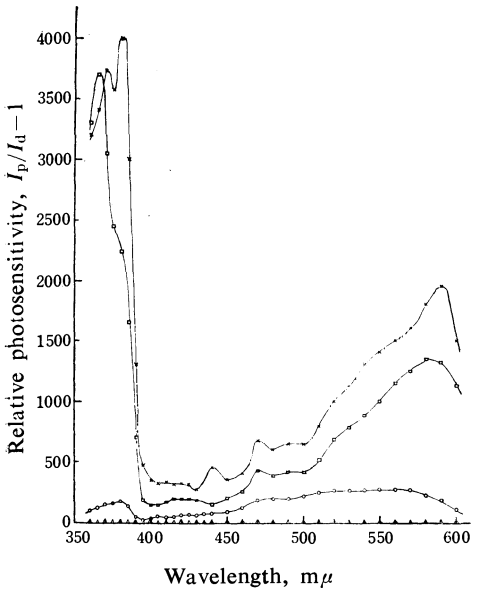

Fig. 4. Spectral response of photoconduction in zinc oxide-oxygen-electron affinitive molecule-dye systems.

○ ZnO-O_2-Rose Bengal (1)
× (1)+Phthalic anhydride
□ (1)+Iodine
△ (1)+*p*-Chloranil

very little effect. The efficiency of sensitization, however, varies from one electron-affinitive molecuce to another. It should be noticed here that the photoconductivity in the ultraviolet region is also much increased by the presence of Rose Bengal. Since Rose Bengal does not absorb light of this wavelength region, the increase can not be caused by optical sensitization. It is most likely that the sensitizing effect by the electron-affinitive molecule is intensified by the co-adsorption of Rose Bengal.

With the zinc oxide co-adsorbed *p*-chloranil and Rose Bengal, this effect has not been observed (see Fig. 4), though quite a large effect of sensitization was observed upon irradiation with the intense white light (see Fig. 2). The discrepancy between the two results can probably be explained by the difference between the incident light—white light and monochromatic light. A superposing effect of the photocurrent, which seems to be responsible for this discrepancy, will be described in the next paragraph.

The photocurrents in the zinc oxide-oxygen-Rose Bengal system and in the zinc oxide-oxygen-*p*-chloranil-Rose Bengal system were measured with ultraviolet (365 mμ), visible (577 mμ) and combined (365 mμ+577 mμ) lights. Here the intensities of the ultraviolet light and the visible light were held constant at 3.24×10^{-6} W/cm². As may be seen in Fig. 5, the photocurrents under co-irradiation were considerably larger than the sum of the photocurrents under separate irradiation. Evidently, there is a co-operative process for the sensitization of the photoconduction in the system,

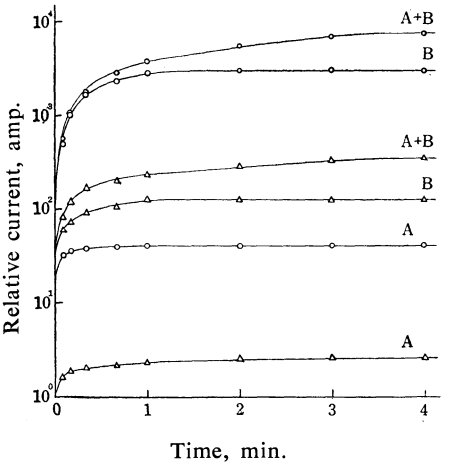

Fig. 5. Rise of photocurrent in dyed zinc oxide irradiated with light of 365 mμ (A), 577 mμ (B) or 365 mμ+577 mμ (A+B).

which takes place when the system is irradiated simultaneously with ultraviolet and visible lights. We shall call such an effect "the superposing effect of the photocurrent."

The Temperature Dependence of the Electric Current. — The change in photoconductivity upon the adsorption of an electron-affinitive molecule can be caused by the change in the electron density of the zinc oxide crystal and also by the change in surface barrier height. The latter can be roughly estimated from a measurement of the thermal activation energy of the dark-current, which is determined from the temperature dependence of the dark-current.

Figure 6 illustrates the temperature dependence of dark- and photo-currents from 20°C to 90°C in each system without Rose Bengal. The thermal activation energy of the zinc oxide-oxygen system in the dark (~0.9 eV.) is maintained in the zinc oxide-oxygen-iodine system too, but those of other systems are smaller. The photoconduction requires less activation energy than the dark conduction in each of the systems investigated. It is certain that the adsorption of the electron-affinitive molecule causes a change in the activation energy of conduction which corresponds to a change in the barrier height or surface level.

Discussion

The sensitization of the photoconduction in the ultraviolet region in microcrystalline zinc oxide is considered to be due to the chemisorption and not to the optical effect. This is evident from Fig. 3, where the enhancement of the photoconductivity is not found in the visible region in spite of the fact that the adsorbed molecules more or less absorb light of this region. The chemisorption of the electron-affinitive molecule would increase the dark resistivity of the system by decreasing the electron density in the zinc oxide crystal as well as by changing the surface barrier height, while the chemisorbed molecule may get desorbed or physisorbed when the system is irradiated with the light which is absorbed by zinc oxide, leading to the marked decrease in resistivity. This change in resistivity upon irradiation may depend upon the electron affinity of the chemisorbed molecule and also on the concentration of chemisorbed molecules on the surface. When the electron-affinitive molecule is adsorbed on zinc oxide, the surface level may become more shallow than when only oxygen is present, and at the same time the surface level density may increase.

When both the electron-affinitive molecule and Rose Bengal are adsorbed on zinc oxide, the hypersensitization of the photoconduction takes place (cf. the visible region of Fig. 4). Here, supposedly the electron-affinitive molecule co-operates with Rose Bengal in the optical sensitization process. In other words, the optical sensitization of the photoconduction is intensified by the chemisorbed molecule. Such a process may be understood by adopting Weigl's postulate[4] on the dye-sensitization mechanism. When the system is irradiated with visible light, the Rose Bengal molecule absorbs the light and injects an electron into the conduction band of zinc oxide. The positively-charged dye ion thus formed captures an electron from a chemisorbed negative molecular ion, e. g., iodine ion or phthalic anhydride ion, returns to the original neutral molecule, and absorbs light again. By repeating this, the chemisorbed molecular ion density on the surface gradually decreases and the surface barrier of zinc oxide is finally eliminated. Therefore, the photosensitivity depends upon the nature and on the surface density of both the dye and the electron-affinitive molecule. However, another possible process, in which an exciton produced by light in dye aggregates elevates an electron from the chemisorbed negative ion directly up to the conduction band of zinc oxide, can not be excluded. One of the present authors (E. I.) and Maki have reported that the photodesorption of oxygen from dye-sensitized zinc oxide occurs upon irradiation with light absorbed by the dye.[5] This fact supports the processes hypothesized above.

The co-operative effect of the electron-affinitive molecule and dye in the ultraviolet region (Fig. 4) may differ from the above-discussed effect in the visible region. In this case, the fact that Rose Bengal does not absorb ultraviolet light of 350~400 mμ eliminates the possibility of the optical sensitization. This co-operative effect is probably to be attributed to the change in the surface level of zinc oxide upon the chemisorption of the electron-affinitive molecule.

The superposing effect of the photocurrent in the zinc oxide-oxygen-dye system upon irradiation with the mixed light of the ultraviolet and visible regions (Fig. 5) can be explained as follows. When the dye-sensitized zinc oxide is irradiated with ultraviolet[6] or visible[5] light separately, the photodesorption of the oxygen occurs and photocurrent increases,

in different processes. The rate of photocurrent increase should depend on the rate of photodesorption. Under ultraviolet light irradiation, the chemisorbed atomic oxygen ion combines with a hole photo-produced in the valence band of zinc oxide and becomes an neutral atom. Then two oxygen atoms recombine on the surface to form a molecule which gets desorbed into the ambient. On the other hand, under visible light irradiation, oxygen atoms produced by the process mentioned in the discussion of the hypersensitization recombine to form molecules which leave the surface. In both processes, the rate-determining step would be the recombination of the oxygen atoms, a step which is proportional to the square of the oxygen atom concentration on the surface. The rate of the photo-desorption oxygen by co-irradiation with ultraviolet and visible lights will thus become larger than the sum of the rates by separate irradiation. This is considered to be the best possible explanation for the superposing effect of the photo-conduction.

The above findings on the sensitization of the photoconduction in microcrystalline zinc oxide can well be employed in order to raise the photosensitivity of the electrophotographic layer in which zinc oxide powder is dispersed in dielectric resin.

The authors wish to thank Mr. Isamu Maki, Mr. Fumio Kawamura and Mr. Yoshimitsu Tsuchiya for their earnest assistance during this investigation.

The Spectrophotometric Determination of Titanium with Xylenol Orange[1]

By Makoto Otomo

(Received May 31, 1963)

Titanium(IV), in a slightly acidic solution buffered with acetic acid and sodium acetate, reacts with xylenol orange to give red or reddish-violet complexes, each consisting of one molecule of the reagent to one atom of titanium. The red complex formed by adding an excess of xylenol orange to a titanium solution is applicable to the spectrophotometric determination of titanium. The present paper will describe the conditions which permit the spectrophotometric determination of titanium at microgram levels and the results of a study of complex formation.

Experimental

Stock Solution of Titanium.—Titanium dioxide, prepared by igniting the precipitates which result from the hydrolysis of titanium tetrachloride (E. Merck Co., Ltd.), was fused with about five times as large a mixture of ammonium sulfate and sulfuric acid. The fused mass, after cooling, was dissolved in 6 N sulfuric acid and then diluted with distilled water to make the solution about 0.1 M in titanium sulfate. The resultant solution was standardized by the volumetric method described by Ishimaru.[2] A working standard solution was prepared by diluting the above solution with distilled water.

Perchloric Acid and Sodium Perchlorate.—In a study of complex formation, perchloric acid and sodium perchlorate solutions were used to maintain constant the hydrogen ion concentration and the ionic strength. The latter was prepared from reagent grade perchloric acid and sodium carbonate.

The other reagents and apparatus used were the same as those reported previously.[3] All experiments were carried out at 25±0.5°C.

Standard Procedure.—To a solution in a 25 ml. volumetric flask, which contained up to 40 μg. of titanium, were added 10 ml. of an acetate buffer (pH 3 to 4.5) and 4 ml. of a 1×10^{-3} M solution of xylenol organge. The solution was diluted to the mark with water and then mixed. After about 30 min., the absorbance of the solution was measured at the desired wave length (502 or 532 mμ), using a reagent blank as the reference.

Results and Discussion

Preliminary experiments showed that the variation in pH value had no significant effect on the absorption spectra of the solution,

3) M. Otomo, This Bulletin, **36**, 137 (1963).

provided the pH of the solution was maintained below 5 and a sufficient excess of xylenol orange was used.

Absorption Spectra.—Figure 1 gives the absorption spectra of solutions containing 35 μg. of titanium and xylenol orange added in various amounts, 3.5×10^{-5} to 1.44×10^{-4} M. There are two absorption bands; the intense absorption band with its maximum at about 440 mμ is due to the xylenol orange, which increases in intensity with the addition of the reagent, while the absorption found at the longer wavelengths seems to be due to the overlap of the titanium-xylenol orange complex band with that of the xylenol orange. It is found that the latter band at about 555 mμ slightly shifts toward shorter wavelengths with the increasing amounts of xylenol orange and that, at the same time, the intensity of the absorbance at this wavelength decreases gradually; for example, when the concentrations of xylenol orange are kept at 3.2×10^{-5}, 4.0×10^{-5}, and 4.8×10^{-5} M, the absorption maxima are found at 555, 552 and 550 mμ respectively. The further addition of xylenol orange causes disappearance of the absorption maximum, giving small shoulders. Further, an isosbestic point can be observed at 532 mμ, where the absorption curves for different solutions with a fixed amount of titanium cross each other, suggesting that titanium reacts with xylenol orange to form at least two absorbing entities which are in equilibrium with each other and also with the free xylenol orange. Similar phenomena have also been observed in the xylenol orange complexes of aluminum,[4] gallium[5] and thallium.[5]

5) M. Otomo, unpublished work.

When, however, more than 3.5 ml. of a 1×10^{-3} M solution of xylenol orange is added and the same amount of this solution is used as the reference, the maximum absorption was always found at about 502 mμ (see Fig. 2), strongly suggesting the existence of only one form of the complex under the conditions so far studied.

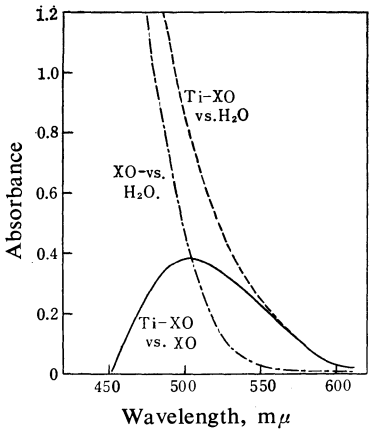

Fig. 1. Absorption spectra of XO and its Ti complex at pH 3.0.
Ti: 35 μg., XO: 1.6×10^{-4} M

The Effect of pH Value.—The effect of pH value on the color development was examined by measuring, at 502 mμ, the absorbance of a colored solution containing 25 μg. of titanium and 4 ml. of a 1×10^{-3} M solution of xylenol orange, the pH being adjusted to the desired value by means of an acetate buffer solution. From the curve shown in Fig. 3, it is found that the maximum and constant absorbance is obtained over the pH range 3 to 4.5. At a pH of less than 1.5, the complex does not

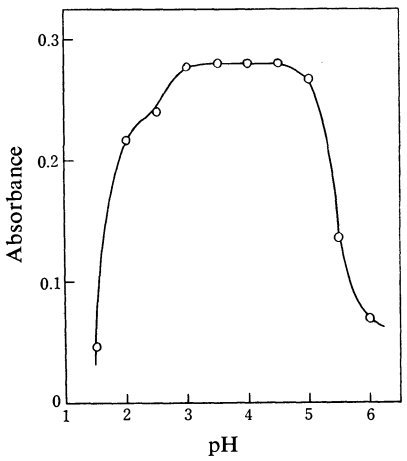

Fig. 3. Effect of pH on color development.
Ti: 25 μg., XO: 1.65×10^{-4} M

give any red coloration. At a pH above 4.5, the absorbance at 502 mμ decreases sharply with the increasing pH value, probably because of hydrolysis of the titanium. A constant absorbance was also obtained at 532 mμ (isosbestic point) provided the pH of the solution was kept between 3 and 4.5.

The Effect of the Addition of the Reagent.—The effect of reagent concentration on the color development was studied with solutions containing 25 μg. of titanium and varying amounts of a 1×10^{-3} M solution of xylenol orange. The absorbance measurement was made at three wavelengths, 502, 532 and 552 mμ. The results are shown in Fig. 4. When more than 3.5 ml. of the reagent solution is added, the absorbance at neither 502 mμ nor 532 mμ is affected by the further addition of the reagent. On the other hand, the absorbance at 552 mμ decreases sharply with the additional reagent unless a large amount of the reagent is used.

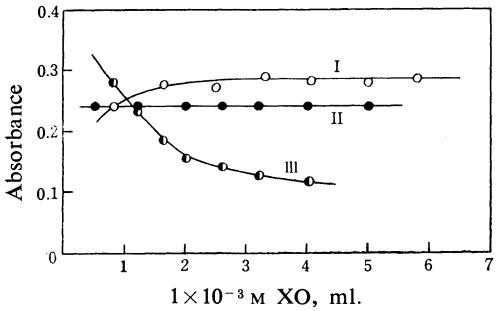

Fig. 4. Effect of addition of reagent (at pH 4.0).
Ti: 25 μg., I: 502 mμ, II: 532 mμ, III: 552 mμ

The Effect of the Standing Time.—The red color of the titanium-xylenol orange complex is stable for at least several hours.

Calibration.—Figure 5 shows that the plots of the absorbance-titanium concentration obey Beer's law over the ranges up to 25 μg. of titanium at 502 mμ and up to 40 μg. of titanium at 532 mμ. The absorbance measurements were made with solutions in which the pH value was adjusted (1) to 4.0 for the measurements at 502 mμ, and (2) to 3.0 for the measurements at 532 mμ. The latter pH value was chosen to minimize the interferences from other cations, which formed complexes with xylenol orange at the higher pH values to give positive errors. The apparent molar extinction coefficients were calculated as 18000 at 502 mμ and 11700 at 532 mμ, respectively.

The Effect of Diverse Ions. — Such anions as chloride, nitrate and sulfate do not interfere, even when present in large amounts. Large amounts of oxalate and tartrate give erroneous results, because they reduced the absorbance of the solution, probably by forming complexes with titanium. Since fluoride, phosphate and EDTA ions can form some stable complexes with titanium, they give large negative errors, even when added in small amounts.

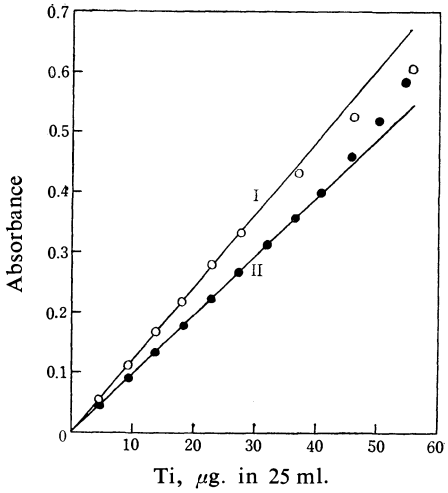

Fig. 5. Calibration curves.
XO: 1.6×10^{-4} M, I: 502 mμ, II: 532 mμ

Of the 26 cations tested, aluminum, iron(III), tin(II), thorium, yttrium vanadium(IV) interfere with the titanium determination by forming colored solutions.

Complex Formation.—The appearance of an isosbestic point, which has already been shown in Fig. 1, suggests that two complexes, one a red complex with its absorption maximum at 502 mμ and the other a reddish-violet one with its absorption maximum at about 555 mμ, are in equilibrium with each other. On the basis of the above suggestion, a study was made to determine the composition of the two complexes and to calculate the formation constants. In order to calculate the formation constants, however, it must be considered that xylenol orange is a polybasic acid* and that, therefore, the stability of the complexes is greatly dependent on the pH value under investigation. In all the solutions used in this study, therefore, the perchloric acid concentration was maintained constant at 0.020 M and the ionic strength was kept constant at 0.50.

* The stepwise acid dissociation constants of xylenol orange have been determined by Řehák and Körbl[6] as $pk_1=2.58$, $pk_2=3.23$, $pk_3=6.37$, $Pk_4=10.46$, and $pk_5=12.28$.

6) B. Řehák and J. Körbl, *Collection Czechoslov. Chem. Communs.*, **25**, 797 (1960).

The Red Complex with its Absorption Maximum at 502 mμ. — This complex is formed when xylenol orange is added in excess to a titanium solution. Although numerous methods have been developed for interpreting spectrophotometric data as they are presented in various cases, none is directly applicable to this particular system. Consequently, a method has been developed which is a modification of that of McConnell and Davidson.[7]

Assuming that the formation of the red complex is in accordance with the following equation:

$$TiO^{2+} + nXO \rightleftharpoons TiO(XO)_n + npH^+$$

the equilibrium constant, K, may be given by:

$$K = [TiO(XO)_n][H^+]^{np}/[TiO^{2+}][XO]^n \quad (1)$$

where XO is the total unbound xylenol orange, $TiO(XO)_n$ is the total titanium-xylenol orange complex, and p is the number of hydrogen ions liberated from one molecule of xylenol orange by the chelation. Unknown charges are omitted. The species of titanium(IV) present at the acidity and concentration level used is TiO^{2+} according to the notations of Musha and Ogawa[8] and of Sone and Tanaka.[9] The apparant formation constant, K', may be expressed as:

$$K' = K/[H^+]^{np} = x/(a-x)(b-nx)^n \quad (2)$$

where x is the molar concentration of the complex, and a and b are the initial molar concentrations of titanium and xylenol orange respectively. If a large excess of xylenol orange is present, the value of $b-nx$ will essentially equal the initial concentration of xylenol orange, b. The formation constant may then be written:

$$K' = x/(a-x)b^n \quad (3)$$

If the molar extinction coefficient of xylenol orange is represented as ε_{XO} and that of the complex, as ε_C, the absorbance of the solution, D, at any wavelength may be written:

$$D = (\varepsilon_C - n\varepsilon_{XO})x + \varepsilon_{XO}b \quad (4)$$

If the absorbance is measured against the solution containing the same amount of xylenol orange as b, D may be reduced to:

$$D = (\varepsilon_C - n_{XO})x \quad (5)$$

Solving for x and substituting it into Eq. 3 yields:

$$D = (\varepsilon_C - n\varepsilon_{XO})a - D/K'b^n \quad (6)$$

The values of D obtained at various concentrations of xylenol orange are plotted against D/b^n. With the correct choice of n, this should give a straight line, the slope of which is $-1/K'$, and the intercept, $(\varepsilon_C - n\varepsilon_{XO})a$. Values of n equal to one-half and two were tried unsuccessfully. Only a choice of n equal to one made the data interpretable. Thus, the only complex present is a 1 to 1 complex. Some of the results are shown in Fig. 6.

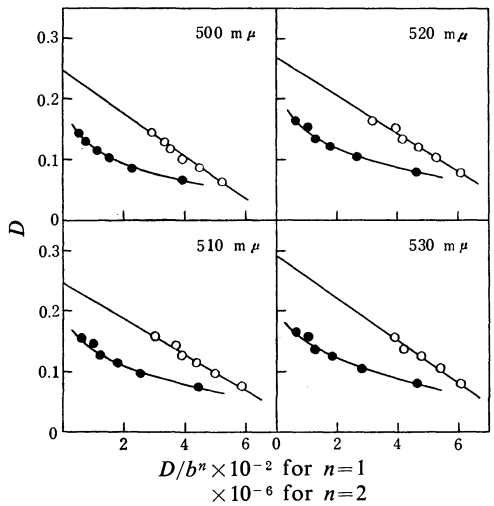

Fig. 6. Plots of D vs. D/b^n.
$HClO_4$: 0.020 M, μ: 0.50 M $NaClO_4$, a: 1.935 $\times 10^{-5}$ M
-○-: $n=1$, -●-: $n=2$

This graphical technique for evaluating the formation constant, K', was applied to data obtained at eight wavelengths, at 10 mμ intervals from 500 to 570 mμ. These eight values of K' were averaged to give a mean value of $K' = 2.9 \times 10^3$, with a standard deviation of 0.3×10^3.

Further, two other methods, one of which has been described by Andrews and Keefer[10] and the other of which has been reported previously by the present author,[11] were applied for the calculation of the formation constant. Both methods showed that a 1 to 1 complex is also formed in the presence of excess xylenol orange. As the mean values for K', 3.1×10^3 and 2.9×10^3 were obtained respectively; these are in good agreement with the value obtained above.

The Reddish-Violet Complex with Its Absorption Maximum at 555 mμ.—This complex is formed by adding titanium in excess to a solution of xylenol orange. The method of

11) M. Otomo, This Bulletin, **36**, 889 (1963).

Frank and Oswalt[12] was applied here: if a 1 to 1 complex is formed, the following equilibrium may exist:

$$TiO^{2+} + XO \rightleftarrows TiO(XO) + qH^+$$

$$K' = [TiO(XO)]\,[H^+]^q / [TiO^{2+}]\,[XO] \qquad (7)$$

where q is the number of hydrogen ions liberated from one molecule of xylenol orange by the chelation. At a constant acidity, the following relation may finally be derived:

$$ab/(D-\varepsilon_{XO}b) = (a+b)/(\varepsilon_C-\varepsilon_{XO}) + 1/K'(\varepsilon_C-\varepsilon_{XO}) \qquad (8)$$

where a and b are the initial molar concentrations of titanium and xylenol orange respectively. D is the absorbance of the solution, ε_{XO} and ε_C are the molar extinction coefficients of xylenol orange and the complex respectively, and K' is the apparant formation constant. If the first assumption is correct, on plotting the values of $ab/(D-\varepsilon_{XO}b)$ at various concentrations of titanium against the values of $a+b$, a straight line with slope $1/(\varepsilon_C-\varepsilon_{XO})$ and intercept $1/K'(\varepsilon_C-\varepsilon_{XO})$ should be obtained. Some of the results obtained are summarized in Fig. 7. From this figure, it is clear that a straight-line relationship is completely satisfied between $ab/(D-\varepsilon_{XO}b)$ and $a+b$, showing that a 1 to 1 complex is also formed. The formation constant, as a mean value of the values found at ten wavelengths between 520 and 610 mμ, was found to be 1.9×10^4, with a standard deviation of 0.5×10^4.

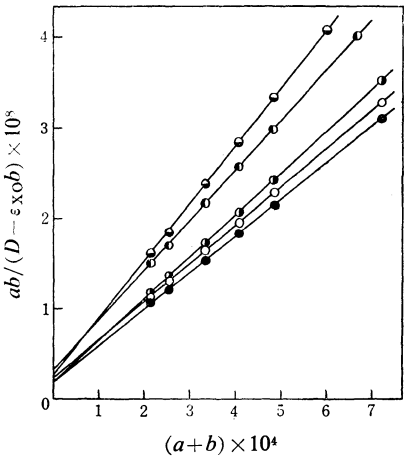

Fig. 7. Plots of $ab/(D-\varepsilon_{XO}b)$ vs. $(a+b)$.
$HClO_4$: 0.020 M, μ: 0.50 M $NaClO_4$
XO: 2×10^{-5} M, -◒-: 520 mμ
-◑-: 530 mμ, -●-: 550 mμ
-○-: 560 mμ, -◐-: 580 mμ

From the foregoing results, it may be concluded that, depending on the amount of the reagent, titanium forms either of two 1 to 1 complexes, a red complex with its absorption maximum at 502 mμ and a reddish-violet one with its absorption maximum at 555 mμ, the latter being more stable than the former. It was also found that the experimental data are satisfied only by assuming the existence of mononuclear 1 to 1 complexes. Although two interesting models of the position of the chelation ring in the xylenol orange complexes of niobium(V) and thallium(III) have been described by Cheng et al.[13] and by Busev et al.[14] respectively*, it is not possible to obtain definite information on the structure of these titanium-xylenol orange complexes on the basis of the experimental results described in the present paper and of the unpublished result. The present author is also, therefore, investigating the structural configuration of these complexes; the results will be presented elsewhere.

Summary

A new method for the spectrophotometric determination of titanium has been described. This method is based on the formation of the colored complex between titanium and xylenol orange in a slightly acidic solution. The effects of pH and the reagent concentration on the color development of the complex have been thoroughly investigated, and experimental conditions which make possible the determination of titanium at microgram levels have been devised. The compositions of the two 1 to 1 complexes have been determined from the data of spectrophotometric measurements. The apparant formation constants of these complexes have also been calculated.

The author wishes to express his hearty thanks to Professor Kôichi Tonosaki for his kind guidance and encouragement throughout this study, and to Dr. Katsumi Yamamoto of the Faculty of Science, Tohoku University, for this valuable advice.

*Hydroxyl Radicals in the γ-Radiolysis of Aqueous Benzene Solutions**

By Minoru TSUDA

(Received June 1, 1963)

The results of studies of the γ-irradiation of aqueous gelatin solutions[1,2] suggest that hydroxyl radicals play an important role in the radiation induced crosslinking of high polymers in aqueous solutions.[3] With dilute aqueous solutions it is ordinarily true that only water absorbs the incident energy. The dissociation of the water leads to the production of hydroxyl radicals, which then attack the solute. The hydroxyl radical can abstract hydrogen atoms from solutes such as organic polymers to produce polymer radicals. This process can be considered an oxidation of the polymer solute. In an oxygen-free solution, hydrogen atoms may also abstract hydrogen from the polymer solute. The polymer radicals produced may then combine with each other to produce crosslinks. However, experiments in this laboratory suggest that hydrogen atoms*1

$$RH + OH^{\cdot} \rightarrow R^{\cdot} + H_2O$$
$$RH + H^{\cdot} \rightarrow R^{\cdot} + H_2$$
$$R^{\cdot} + R^{\cdot} \rightarrow R - R$$

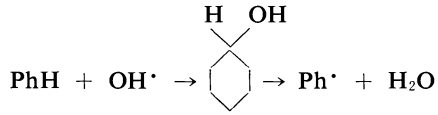
are quite ineffective, although hydroxyl radicals promote crosslinking considerably.[2,3] Hydrogen atoms apparently preferably combine to produce hydrogen molecules. If hydrogen atoms can be changed to hydroxyl radicals, an increase in the extent of crosslinking is to expected.

Dainton et al. have shown that nitrous oxide is capable of reacting with the 'basic form' of the hydrogen atom produced by the γ-radiolysis of water to produce hydroxyl radicals and nitrogen.[4,5] The occurrence of such a reaction should increase the yield of crosslinking. The present author has, accordingly, studied the effect of nitrous oxide on

$$N_2O + H^{\cdot} \rightarrow OH^{\cdot} + N_2$$

the γ-radiolysis of an aqueous benzene solution. Benzene was used instead of a polymeric substance in order to simplify the analysis of the experimental results.

Previous studies[7-10] of the oxidation of benzene in oxygen-free aqueous solutions by γ-irradiation have been interpreted in terms of the following sequence of reactions:



$$PhH + H^{\cdot} \rightarrow PhH_2 \rightarrow \text{Polymer}$$
$$Ph^{\cdot} + Ph^{\cdot} \rightarrow Ph_2$$
$$Ph^{\cdot} + OH^{\cdot} \rightarrow PhOH$$

In aerated solutions the following reaction also occurs:

$$Ph^{\cdot} + O_2 + H_2O \rightarrow PhOH + H_2O_2$$

This schema shows that the oxidation of benzene is effected by hydroxyl radicals, but not by hydrogen atoms. Therefore, the yield of hydroxyl radicals is estimated from the yield of the oxidized products, namely, phenol and biphenyl, from benzene. The production of a small amount of oxygen by the primary action of γ-rays on water and nitrous oxide merely results in an increase in the yield of phenol. The total yields of biphenyl and phenol from benzene in the presence of nitrous oxide should equal the radical yields of water upon radiolysis, provided that nitrous oxide does in fact change all the hydrogen atoms into hydroxyl radicals. According to Allen,[11] the radical yields (G_H and G_{OH} for ^{60}Co-gamma rays) for irradiated water are 2.85± 0.15 and 2.4 respectively in neutral solutions.

Hydrogen peroxide also reacts with hydrogen atoms to give hydroxyl radicals.[9] Therefore, hydrogen peroxide can also be used to study the effect of hydroxyl radicals in the oxidation of

organic compounds. However, in this case it is also necessary to consider the possibility

$$H_2O_2 + H^\cdot \rightarrow OH^\cdot + H_2O$$

of the consumption of hydroxyl radicals by hydrogen peroxide (reaction 1), which will compete with reaction 2. However, it is known

$$OH^\cdot + H_2O_2 \rightarrow H_2O + HO_2 \quad (1)$$

$$PhH + OH^\cdot \rightarrow PH^\cdot + H_2O \quad (2)$$

that, at a high concentration of hydrogen peroxide, the decomposition of the peroxide proceeds through a chain-reaction mechanism,[12] and that hence, the production of oxygen does not result in the consumption of any hydroxyl radicals at all.

Experimental

A 3000 curie ^{60}Co source was used for all irradiations. The dose rate, which was measured with a Fricke Dosimeter, was 1.98×10^5 rads/hr.

Fifty grams of water were weighed into a 100 ml. ampoule, and oxygen was completely removed by passing nitrogen gas through the water for 30 min. After the addition of 2 ml. of benzene, the ampoule was sealed. In the case of the nitrous oxide solutions, flushing with nitrogen for 30 min. was followed by passing nitrous oxide through the water for 30 min. at 3~5°C, prior to the addition of the 2 ml. of benzene. Hydrogen peroxide solutions were prepared by the addition of 10 ml. of an 8.91 mol./l. aqueous hydrogen peroxide solution which had been acidified with sulfuric acid to give the final solution, with a pH of 3, in order to prevent the spontaneous decomposition of the hydrogen peroxide.[13] The ampoules were vigorously agitated for 10 min. immediately before γ-irradiation in order to ensure the saturation of the solution with benzene. All irradiations were carried out at 25°C by a time scale.

Biphenyl was analyzed according to the method of Phung and Burton.[9] Phenol was analyzed by the method of Baxendale et al.[8,14,15] Phenol was extracted from the sample with ether after biphenyl and benzene had first been removed by extraction with *n*-hexane, and it was determined spectrometrically using an absorption at 273.5 mμ. A correction was applied for the distribution of phenol between water and *n*-hexane. With samples containing hydrogen peroxide, correction must be made for the absorption by hydrogen peroxide at 273.5 mμ. The contribution by hydrogen peroxide to the absorption at 273.5 mμ was calculated from the absorption at 247 mμ. (Biphenyl, which also absorbs at 247 mμ, was removed by extraction with *n*-hexane prior to the spectrometric analysis.)

TABLE I. CONDITIONS AND *G* VALUES

Condition	$G(Ph_2)$	$G(PhOH)$
Nitrogen	0.45	0.35
Nitrous oxide	2.15	0.90
Hydrogen peroxide	0.55	4.11

TABLE II

	$G(Ph_2)$	$G_1(PhOH)$	$G_2(PhOH)$	$G(PhOH)$[a]	$G((OH)PhH\cdot)$[b]
N_2	0.45	0.23	0.12	0.35	1.48
N_2O	2.15	0.78	0.12	0.90	5.98
H_2O_2	0.55	0.28	3.83	4.11	5.49

a) $G(PhOH)=G_1(PhOH)+G_2(PhOH)$
b) $G((OH)PhH\cdot)=2G(Ph_2)+2G_1(PhOH)+G_2(PhOH)$

The yield of biphenyl for oxygen-free (N_2-saturated) benzene solutions agrees with the value obtained by Baxendale and Smithies[8], but it is smaller than that reported by Phung and Burton.[9] The yield of phenol reported for oxygen-free benzene solutions is substantially in accordance with other reports.[8,9]

Discussion

The 'basic form' of the hydrogen atom produced by the dissociation of irradiated water seems to be a solvated electron, e_{aq}^-, and it preferably reacts with nitrous oxide[16] and hydrogen peroxide.[17-21]

$$e_{aq}^- + N_2O \rightarrow N_2 + H_2O_2^- \rightarrow N_2 + OH\cdot + OH^-$$

$$e_{aq}^- + H_2O_2 \rightarrow H_2O_2^- \rightarrow OH\cdot + OH^-$$

Under the present experimental conditions, the concentration ratio $[H_2O_2]/[H^+]$ was about 10^3 (pH ~3), and the ratio of the rate constants for the $H_2O_2+e_{aq}^-$ and $H^++e_{aq}^-$ reactions is about 1/2.[20] Therefore, the production of the acidic form of the hydrogen atom, H, should be negligible in the present case.

In nitrous oxide solutions the yield of hydroxyl radicals should be $2(G(Ph_2)+G(PhOH))=6.10$, which is larger than the expected value of 5.25 ± 0.15 (the sum of G_H and G_{OH}).[11] The discrepancy may be partly due to the oxygen produced by the decomposition of water and nitrous oxide.

In hydrogen peroxide solutions the yield of hydroxyl radicals should be $2G(Ph_2)+G(PhOH)=5.21$ because of the presence of the large amount of oxygen produced by the radiolysis of hydrogen peroxide.

Recently, Dorfman et al. reported the production of hydroxycyclohexadienyl radicals in the process of the radiolysis of an aqueous benzene solution.[22] The discussion of our data in terms of their mechanism may be necessary. They proposed the following sequence of reactions:

$$PhH + OH\cdot \rightarrow (OH) \leftarrow PhH\cdot$$

$$2(OH)PhH\cdot \rightarrow ((OH)PhH)_2 \rightarrow Ph_2$$

$$2(OH)PhH\cdot \rightarrow PhOH + (OH)PhH_2 \quad (3)$$

$$(OH)PhH\cdot + O_2 \rightarrow (OH)PhHO_2\cdot \rightarrow PhOH + HO_2\cdot$$
$$\downarrow$$
$$\text{Peroxide (a small part)} \quad (4)$$

$(OH)PhH_2$ may change to $PhH+H_2O$. In deaerated solutions,[22] $G(Ph_2)$ ~0.5 and $G(PhOH)$ ~0.23. The distribution of hydroxycyclohexadienyl radicals between biphenyl and phenol seems to be about 2:1. This ratio of distribution was applied to our data (Table II). $G_1(PhOH)$ is the yield of phenol produced by reaction 3, $G_2(PhOH)$ is that by reaction 4, and $G(PhOH)$ is the experimental result. $G((OH)PhH\cdot)$ should equal the radical yield of water, (G_H+G_{OH}).

In oxygen-free solutions our result for $G((OH)PhH\cdot)$ agrees with that obtained by Dorfman et al.[22]

According to Allen,[11] G_H in an atmosphere with a high concentration of oxygen is larger by 0.1 in G value than the ordinary value. Therefore, $G((OH)PhH\cdot)$ should be 5.35 ± 0.15 in hydrogen peroxide solutions; the experimental result agrees with this expected value.

In nitrous oxide solutions the same value of $G_2(PhOH)$ as in deaerated solutions was applied. The value of $G((OH)PhH\cdot)$ is 10% larger than the expected value.

Summary

Some experiments have been made in order to prove the hypothesis that the hydroxyl radical plays an important role in the oxidation of organic compounds by γ-radiolysis in aqueous solutions. Nitrous oxide and hydrogen peroxide have been found to be capable of converting radiation-induced hydrogen atoms (or their stoichiometrically-equivalent

The Absorption Spectra of Oil-soluble Dyes Solubilized by a Polysoap and a Monosoap

By Fumikatsu TOKIWA

(Received June 3, 1963)

Polysoaps constitute a very special class of soap. In a certain sense the micelles are already formed, because each molecule of polysoap may be regarded as the equivalent of a micelle, each molecule acting as a prefabricated soap micelle.[1] The phenomena associated with the critical concentration and the micelle equilibrium should, accordingly, be absent from polysoap solutions. From this point of view the polysoap is entirely different from ordinary soaps. Strauss and his co-workers[1-5] have extensively studied the solubilization effects of cationic polysoap, formed by adding dodecyl bromide to polyvinylpyridine, and have found that polysoap molecules undergo a considerable change in their structure upon solubilization. They have also pointed out that the solubilization mechanism depends on the nature of the solubilizates.[3,5]

However, no systematic study has as yet been reported either of the solubilization of oil-soluble dyes by polysoap or of the differences between polysoap and monosoap in the solubilization mechanisms of the dyes. The results of such a study, dealing with 1-benzeneazo-2-naphthol and three 1-nitrobenzeneazo-2-naphthols, are presented in this paper and in a subsequent paper. These three 1-nitrobenzeneazo-2-naphthols are equivalent in molecular weight, differing only in the position of the nitro group in the benzene ring.

Spectral measurement furnishes a simple means of obtaining information on the states of solubilized dyes in polysoap and monosoap solutions, although such a measurement is qualitative. In this experiment the absorption spectra of the dyes were measured in polysoap and monosoap solutions, and also in some hydrocarbons for purposes of comparison. The polysoap used was an *n*-dodecyl bromide addition compound of poly-2-vinylpyridine, while the monosoap was *n*-dodecyl-α-picolinium bromide, which seems to be closely related in its chemical structure to the polymeric unit of the above polysoap.

The present paper is a study of absorption spectra, leading to an understanding of the states of solubilized dyes in polysoap and monosoap solutions and of the way in which they are solubilized.

Experimental

Polysoap (*n*-Dodecyl Bromide Addition Compound of Poly-2-vinylpyridine).—Poly-2-vinylpyridine was prepared by polymerizing freshly-distilled 2-vinylpyridine (b. p. 57°C at 17 mmHg) in ligroin (purified by sulfuric acid) in the presence of benzoyl peroxide at 40°C for 3 days, followed by the purification procedure described by Strauss et al.[6] The nitrogen content of the purified polymer was 13.29%; calcd. 13.33%. (All the nitrogen analyses reported in this paper were performed by the Elementary Analysis Center, Kyoto University.) The intrinsic viscosity, $[\eta]$, in 92 weight per cent ethanol was 0.636 at 25°C; this value corresponds to a molecular weight of 1.27×10^5 and a degree of polymerization of 1.2×10^3, assuming that the values of K and α in a viscosity equation, $[\eta]=KM^{\alpha}$, are equal to those of poly-4-vinylpyridine.[7]

The polymer was then quaternized with *n*-dodecyl

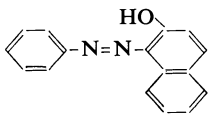
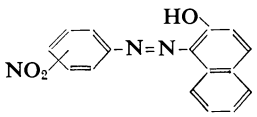
bromide (b. p. 112°C at 3.0 mmHg, prepared from dodecyl alcohol of a high purity) in nitroethane at 80°C for 13 days. Purification was accomplished as reported by Strauss et al.,[6] using petroleum ether instead of isoöctane and ligroin. The polysoap finally purified contained 6.72% nitrogen and 16.70% bromine. The polysoap gave a slightly acidic pH in water (the 0.10% solution had a pH of 3.48). Titration with sodium hydroxide gave an average value of 4.82×10^{-3} equivalent of hydrogen ions per gram of polysoap. From these analytical data, it follows that 33.5% of the nitrogen is quaternized with *n*-dodecyl bromide, while 10.0% carries hydrogen bromide. Only one-third of the nitrogen reacted with *n*-dodecyl bromide in spite of the high temperature and the long time of reaction.

Monosoap (*n*-Dodecyl-*α*-picolinium Bromide).—Monosoap was prepared by the quaternization of *α*-picoline with *n*-dodecyl bromide according to the ordinary method. The soap was then purified by repeated recrystallization from acetone. The nitrogen was 4.08% (calcd. 4.09%); Br, 23.16% (calcd. 23.35%).

Oil-soluble Dyes.—The four dyes, 1-benzeneazo-2-naphthol (abbreviated to BAN) and 1-(*ortho*-, *meta*- and *para*-)nitrobenzeneazo-2-naphthol (abbreviated to *o*-nitro-BAN, *m*-nitro-BAN and *p*-nitro-BAN respectively), were synthesized by coupling diazotized aniline or nitroaniline with *β*-naphthol in alkaline solutions. The starting materials—aniline, (*ortho*-, *meta*- and *para*-)nitroaniline, and *β*-naphthol—were purchased from the Wako Pure Chemicals Co. The crude dyes were thoroughly washed with water and dried in vacuo. The purification of the dyes was carried out by repeated recrystallization from benzene or a benzene-methanol mixture. The dyes were finally obtained as fine crystalline powders.



BAN



(*o*-, *m*-, *p*-)Nitro-BAN

The wavelengths of the absorption maxima (λ_{max}) of these dyes in ethanol and the molar extinction coefficients (ε_{max}) at the maxima are listed in Table I.

TABLE I. THE λ_{max} AND ε_{max} OF OIL-SOLUBLE DYES

Dyes	λ_{max}, mμ	ε_{max}, $\times10^{-4}$
BAN	485	1.46
o-Nitro-BAN	495	2.11
m-Nitro-BAN	478	1.65
p-Nitro-BAN	491	2.52

The Preparation of Polysoap Solutions.—Polysoap solutions were prepared according to the method of Strauss et al.[4,8] The residual HBr was removed from the polysoap by ion-exchange as follows: an anion-exchange resin, Amberlite IRA-410, in the hydroxide form, contained in a bag made of Visking's dialysis casing, was immersed briefiy in an aqueous solution of the polysoap to raise the pH to around 6.

Solubilization.—The solubilization was run in a water bath at 30±0.1°C for 55 hr. to attain equilibrium. The method used was the same as that used in a previous investigation.[9] In the present experiment, appropriate concentrations of polysoap and monosoap were chosen for the solubilization of dyes on the basis of the results of a preliminary experiment, for the reason described under "Results and Discussion."

Absorption Spectra. — Spectral measurements were performed with a Shimadzu Model RS-27 automatic spectrophotometer at room temperature (about 30°C) immediately after the solubilization.

Results and Discussion

Figures 1 and 2 show the absorption spectra of solubilized dyes in polysoap and in monosoap solutions respectively. Since the solubilizing power of polysoap and monosoap is highly dependent on the structure of the dyes (this will be reported on in more detail in a subsequent paper), it is difficult to compare the spectra of the dyes solubilized by equal concentrations of polysoap and monosoap. It is, therefore, necessary to choose appropriate concentrations of soaps in order to obtain the maximum absorbance of solubilized dyes ranging from 0.6 to 0.8, a convenient range for the comparison of the spectra Unfortunately, the polysoap solution itself exhibits a slight yellow color depending on the

concentration, although its spectrum has no absorption maximum, as Fig. 5 shows. This makes the spectrum of the dye somewhat obscure because of the overlap of dye and polysoap spectra. Therefore, to show the spectrum of the dye alone, without the contribution from polysoap, each spectrum shown in Fig. 1 has been obtained by substracting the absorbance of polysoap from the observed absorbance.

p-Nitro-BAN	523, 582	495	495	493

It is generally accepted that, in most aqueous solutions of ordinary soaps, the solubilization of oil-soluble dyes occurs in the interior of the micelles.[10] Therefore, if the dyes studied are solubilized in the interior of the soap micelle, which consists of a dense hydrocarbon region, then some similarities are to be expected between the spectra of the dyes solubilized in soap solutions and those of the dyes dissolved in hydrocarbons.[11] Figures 3 and 4 illustrate the spectra of four dyes in benzene and in hexane respectively. Aside from the shapes of the spectra, one notes that the wavelength of the absorption maximum of each dye in a monosoap solution corresponds closely to that in hydrocarbons (Table II). The wavelength difference is between 0 and 4 mμ; in benzene the difference is much less.

10) M. E. L. McBain and E. Hutchinson, "Solubilization," Academic Press, New York (1955), pp. 45, 147.
11) L. Michaelis and S. Granick, *J. Am. Chem. Soc.*, **67**, 1212 (1945).

This may indicate that the dyes studied are solubilized in the hydrocarbon region of monosoap micelles. In the case of BAN, furthermore, its spectra in both polysoap and monosoap solutions show a good similarity, as may be seen in Figs. 1 and 2. The similarity suggests that the way of the solubilization of BAN by both soaps is nearly the same. This suggestion is supported by the fact that the amounts of BAN solubilized by the two soaps are nearly equal, as will be shown in a following paper.

When one compares Fig. 1 with Figs. 2, 3 and 4, on the other hand, one notes that the spectra of nitro-BAN in polysoap solutions are not similar either to those in monosoap solutions or to those in hydrocarbons. These differences in spectra may be considered to arise from the fact that the state of nitro-BAN solubilized by the polysoap is not similar to that of nitro-BAN solubilized by the monosoap; they also suggest that nitro-BAN molecules are solubilized in different ways by the two soaps. It has been proposed that benzene and heptanol are solubilized between the polar heads of the side-chains of polysoap, in a manner similar to the micelle penetration which occurs with such polar materials as alcohols in ordinary soap solutions.[3,5] By analogy, whatever the detailed mechanism may be, the difference in spectra could be explained as follows: The loci of the solubilization of dyes in the polysoap molecule are not only the dense hydrocarbon region of the interior but also the polar region near the polymer backbone. In this case, the nitro group of the dye molecule seems to play an important role in the solubilization. Among the three nitro-BAN's, *p*-nitro-BAN exhibits a behavior totally different from that observed for the other dyes; that is, its two absorption maxima appear in the longer wavelength region. In view of the fact that the structures of these nitro-BAN molecules differ only in the position of the nitro group on the benzene ring, the solubilization of nitro-BAN molecules may depend upon their molecular volumes as well as on their polarities.

When the polysoap solution containing solubilized *p*-nitro-BAN was diluted with a large amount of ethanol (about 5 times by volume), the two peaks of its spectrum, at 523 and 582 mμ, disappeared and, simultaneously, a new absorption maximum arose, the wavelength of which is approximately equal to that of the maximum observed in hydrocarbons or in a monosoap solution. Any change in the spectrum of the dye molecule may be attributed to the redistribution of the electrons in the molecule.[11,12] Therefore, this means that dilution by ethanol changes the electron distribution in the *p*-nitro-BAN molecule; it also suggests that the electron distribution in this molecule is strongly affected by the polar region of the polysoap molecule as a result of the solubilization. In the case of the solubilization of *p*-nitro-BAN, especially, the polar region of the polysoap appears to act as a strong solubilizing locus.

Summary

The absorption spectra of several oil-soluble dyes, 1-benzeneazo-2-naphthol and three 1-nitrobenzeneazo-2-naphthols, have been measured in aqueous solutions of polysoap and monosoap and in hydrocarbons. The spectra of the above dyes in monosoap solutions are similar to those in hydrocarbons, while the spectra of dyes with a nitro group in polysoap solutions, especially the spectrum of *p*-nitro-BAN, are different. The differences in the solubilization behavior of the dyes in polysoap and in monosoap solutions and the ways in which the dyes are solubilized have been discussed. It has also been proposed that the loci of the solubilization in the polysoap molecule are not only the dense hydrocarbon region in the interior but also the polar region near the polymer backbone. In this case, the nitro group of the dye molecule seems to play an important role in the solubilization.

The Solubilization of Oil-soluble Dyes by a Polysoap and a Monosoap

By Fumikatsu TOKIWA

(Received June 3, 1963)

In the preceding paper[1] the solubilization of oil-soluble dyes by polysoap was discussed by comparing the dye spectra in polysoap solutions with those in monosoap solutions and in hydrocarbons. In order better to understand the difference in solubilization between polysoap and monosoap, as well as the effect of solubilizate structure on the amounts solubilized, studies have now been made of the solubilizing power, viscosity and electrical conductivity of both polysoap and monosoap solutions.

The results of such studies are presented in this paper. As solubilizates, 1-benzeneazo-2-naphthol and three different 1-nitrobenzeneazo-2-naphthols were used, the same dyes as were employed in the preceding paper. The polysoap was obtained by the quaternization of poly-2-vinylpyridine with *n*-dodecyl bromide; the monosoap was *n*-dodecyl-*α*-picolinium bromide.

Experimental

Materials. — The materials used were polysoap (a *n*-dodecyl bromide addition compound of poly-2-vinylpyridine), monosoap (*n*-dodecyl-*α*-picolinium bromide) and four oil-soluble dyes; 1-benzeneazo-2-naphthol and three forms of 1-nitrobenzeneazo-2-naphthols (*ortho*, *meta* and *para*), which are abbreviated to BAN, *o*-nitro-BAN, *m*-nitro-BAN and *p*-nitro-BAN respectively. These materials were also used in the preceding investigation.[1]

A polyelectrolyte, poly-2-vinyl-*N*-ethylpyridinium bromide, was prepared from ethyl bromide and the poly-2-vinylpyridine described in the preceding paper. The method of Strauss et al.[2,3] was employed for preparing poly-4-vinyl-*N*-ethylpyridinium bromide. Analysis gave nitrogen 7.57%, bromine 32.3%.

Procedures.—Solubilizations were run in a water bath for 55 hr. to attain equilibrium, the method described in a previous paper[4] being employed. The amounts of solubilized dyes were determined by optical density measurements using a spectrophotometer, Hitachi Model EPU-2A.

Electrical conductivities were measured with a conductance bridge, Yanagimoto Model MY-7; the platinium electrodes were slightly platinized, and the cell constant was 0.482. The water used in preparing the solutions had a specific conductance of $1.0 \sim 1.5 \times 10^{-6}$ ohm^{-1} cm^{-1}.

The viscosities were measured with Ostwald-type viscometers, the flow times for pure water at 30°C being 67.7 and 140.5 sec.

Results and Discussion

The relationship between the solubilizing power of polysoap and the structure of oil-soluble dyes is shown in Fig. 1, where the extent of the solubilization of dyes is plotted against the concentration of polysoap. Figure 2 illustrates this relationship for monosoap. BAN, which contains no nitro group, is, in both soap solutions, more solubilized than the other dyes at any given soap concentration. This indicates that the introduction of a nitro group on the BAN molecule causes a lowering of the solubilization, probably because of the increase in its molecular volume[5] and the change in its polarity. The polysoap has greater solubilizing power, especially for dyes with a nitro group, than the monosoap. As for the dyes with a nitro group, it can be seen from Figs. 1 and 2 that in polysoap solutions the order of the amount solubilized is *m*-nitro-BAN>*p*-nitro-BAN>*o*-nitro-BAN, while in

monosoap solutions it is *m*-nitro-BAN>*o*-nitro-BAN>*p*-nitro-BAN. These results suggest that the solubilization depends not only on the volumes of the dye molecule, which may not considerably differ from one another in this case, but also on its structure.

The solubilizing powers of polysoap and monosoap at concentrations of 10.0 and 20.0 g./l. for each of the four dyes are compared in Table I, where the symbols C and S denote the concentration of soaps (g./l.) and the amount of solubilized dyes (mol./l.) respectively. The value of S/C represents the number of dye molecules solubilized by a gram of solubilizer. Comparing the values of S/C for polysoap and for monosoap, we find that the polysoap is a better solubilizer of the dyes with a nitro group than the monosoap. It is also of interest to calculate the value of T, the number of dye molecules which are solubilized per dodecyl group, since the presence of the dodecyl groups plays an important role in the solubilization.[3] These values are also given in Table I. From Table I, furthermore, we can calculate the ratio of the S/C-value of polysoap to that of monosoap (A) and the ratio of the T-value of polysoap to that of monosoap (B) at a given soap concentration. These values, which are listed in Table II, show more clearly the characteristics of the solubilization by polysoap and monosoap.

The significant feature of these results is the relatively high solubilization of the dyes with a nitro group in polysoap solutions. These results are most likely due to the greater number of soap molecules contained in a polysoap molecule; probably, also, the soap molecules form larger and hence more efficient micelles when they are attached to a polymer chain than when they are free. The hydrocarbon chain of the polymer, too, may contribute to the solubilization. The fact that the structure of polysoap molecules is less compact and more disordered than that of monosoap micelles[7,8] may also play a role. However, the way in which the solubilizing efficiency depends on the position of the nitro group in the dye molecule is not clear.

In order to learn more about the polysoap and monosoap molecules when they are saturated with the dyes, the viscosities of the solutions were measured. The effects of saturation with dyes on the viscosities of polysoap and monosoap solutions, in which the dyes reached their respective solubilization limits, are shown in Figs. 3 and 4, where the reduced viscosity, η_{sp}/C, is given as a function of the concentration of soaps. For comparison, the viscometric behavior of polyelectrolyte without a dodecyl side-chain is also illustrated in Fig. 3.

The curve of the polyelectrolyte is a familiar pattern: the reduced viscosity, which is very

large at a high dilution because of the highly extended configuration of the flexible polyions, decreases with an increasing polymer concentration as the electrostatic repulsion between ionized groups is diminished. Since reduced viscosity can be interpreted as a measure of the effective specific volume of a polymer molecule,[3,9] the structure of the polysoap

9) U. P. Strauss, N. L. Gershfeld and E. H. Crook, *J. Phys. Chem.*, **60**, 577 (1956).

molecule in water is considerably more compact than that of the polyelectrolyte molecule. The effect of attaching dodecyl chains to a flexible polymer chain is to pull the polymer molecule together.

Now, let us consider the state of monosoap micelles and polysoap molecules after the solubilization of the dyes. In the case of the monosoap, the very small change in viscosity may be explained as being due to the swelling of the micelles as a result of the dye solubilization.[10] On the other hand, the addition of the dyes to a polysoap solution decreases the viscosity, except for that of *p*-nitro-BAN at low concentrations of polysoap. The observed decrease in viscosity can be ascribed to the contraction of polysoap molecules as a result of the dye solubilization. However, the difference in the effect of the structure of dyes on the viscometric behavior of polysoap is small, with the one exception described below.

Among the dyes studied, *p*-nitro-BAN produced an extra-ordinary increase in the viscosity of the polysoap solution upon its solubilization. The reason for this experimental finding is not clear. However, the steep rise of curve 5 in Fig. 3 in the low concentration region of polysoap may be an indication of either an anomalous extension of polysoap molecules or of an anomalous interaction among different polysoap molecules. According to Strauss et al.[3] the following mechanism also seems possible. The dye molecules are predominantly solubilized, with their polar nitro groups located in the polar region near the polymer backbone and with their hydrophobic portions extending into the hydrocarbon region of the polysoap molecule. This will contract the polar region, which, therefore, will be less able to shield the hydrocarbon region from the aqueous medium. The hydrocarbon which is thus exposed at the surface of the polysoap molecule will be attracted by the van der Waals force to similarly-exposed hydrocarbon of other polysoap molecules, with the resul that the polysoap molecules will tend to stick to one another. However, the reason why such an anomalous increase in viscosity occurs exclusively in the case of the solubilization of *p*-nitro-BAN and why it appears in the low concentration region of polysoap is not explainable by the above mechanism.

(1) None (2) BAN
(3) *p*-Nitro-BAN: *o*-nitro-BAN and *m*-nitro-BAN are similar to curve 3.

To find out more about the nature of these effects, a study was also made of the electrical conductance of polysoap solutions containing solubilized dyes. Figure 5 illustrates the effect of saturation with dyes on the equivalent conductance, Λ, as a function of the polysoap concentration, where the values of Λ are based on the bromide-ion content of the polysoap. A similar figure for the monosoap is given in Fig. 6.

With the monosoap, the conductance is affected very little by solubilized dyes. With

10) A. F. H. Ward and A. G. Chitale, *Proc. 2nd Int. Cong. Surface Activity*, Vol. 1, 319 (1956).

the polysoap, contrary to expectation, each solubilized dye produces a small increase in conductance, but no significant difference among them could be found. This suggests that the locus of the solubilization of the dyes inside the polysoap molecule does not strongly affect the conductance. The finding also eliminates the possibility that the anomalous increase in viscosity with *p*-nitro-BAN is caused directly by the electrical charge effect.

Summary

The solubilization of several oil-soluble dyes, 1-benzeneazo-2-naphthol (BAN) and three 1-nitrobenzeneazo-2-naphthols (nitro-BAN), by a polysoap and a monosoap has been studied by measuring the solubilizing power, the viscosity and the electrical conductance of the solutions of both soaps.

The polysoap is a better solubilizer than the monosoap. BAN was more solubilized than nitro-BAN at any given concentration of soap. The amount of nitro-BAN solubilized by the polysoap was increased in the order *m*-nitro-BAN > *p*-nitro-BAN > *o*-nitro-BAN, while the solubilization by the monosoap was in the order *m*-nitro-BAN > *o*-nitro-BAN > *p*-nitro-BAN. However, there appears to be no simple interpretation of the effect of the structure of dyes upon the solubilization. The addition of the dyes to the polysoap solutions decreased the viscosity, except for that of *p*-nitro-BAN at low concentrations of polysoap. *p*-Nitro-BAN produced an anomalous increase in the viscosity, the reason for this being not certain. In the case of polysoap, every solubilized dye produced a small increase in electrical conductance, but no significant difference among them could be found.

The author wishes to express his deep thanks to Professor Toshizo Isemura of Osaka University for his kind advice. He also wishes to express his appreciation to Mr. Zenichi Miyagawa, Director of these Research Laboratories, for the permission to publish this paper, to Dr. Iwao Maruta for his advice, and to Miss Nobuko Kusui for her help in this work.

*The Synthesis of Chelating Agents. II. The Synthesis of Aminoacetone-N,N-diacetic Acid and Its Chelating Behavior with Metal Ions**

By Takeshi ANDO

(Received June 7, 1963)

A great deal of work has been done in the preparation of iminodiacetic acid (IDA) derivatives. However, very little has been reported in the literature on the synthesis of derivatives which have a carbonyl group as an additional coordinating site. The only such compound related to the carbonyl derivative is *N*-acetoamidoiminodiacetic acid (*N*-AIDA), which has been reported on by Schwarzenbach and his co-workers.[1)]

This paper will report on the synthesis as well as on the chelating behavior of a new chelating agent, aminoacetone-*N*, *N*-diacetic acid (AADA), or 1-amino-2-propanone-*N*, *N*-diacetic acid, which is the first iminodiacetic acid derivative to have a keto group as an additional coordinating site. This compound was prepared by the condensation of monobromoacetone with an iminodiacetic acid dimethyl ester, followed by the hydrolysis of the resulting ester.

By comparing the chelating behavior of AADA with that of similar ligands which do not have an additional coordinating group, we have been able to obtain information on whether or not the aliphatic keto carbonyl group can coordinate to the metal ions of the first transition group or the alkaline earth group.

Schwarzenbach and his co-workers investigated the chelation behavior of various iminodiacetic acid derivatives which have different

1) G. Schwarzenbach, G. Anderegg, W. Schneider and H. Senn, *Helv. Chim. Acta*, **38**, 1147 (1955).

additional coordinating groups, they suggested that the coordinating site of the acetoamido group of *N*-AIDA was not the amino group but the carbonyl group.[1] In this connection, it is also of interest to compare the chelating behavior of AADA with that of *N*-AIDA in order to make certain whether or not the coordination of the acetoamido group of *N*-AIDA occurs exclusively of the carbonyl group.

The chelate stability measurements were therefore carried out, by the pH titration method, on solutions with 1 : 1 and 1 : 2 metal ligand ratios in order to determine the first and second stability constants. The metal ions chosen in this study were copper(II). nickel(II) lead(II), zinc(II), cadmium(II), cobalt(II), calcium(II), strontium(II) and magnesium(II).

The results of the stability constant measurements indicate that the chelating behavior of AADA is very similar to that of *N*-AIDA; it is proved that the coordination of the carbonyl group of AADA to metal ions is appreciable, and that the coordination site of the acetoamido group of *N*-AIDA is also the carbonyl group, as has previously been suggested by Schwarzenbach and his co-workers.[1]

Experimental

The Synthesis of AADA.—A solution of 30 g. (1.86 mol.) of an iminodiacetic acid dimethyl ester[2] in 30 ml. of ethylacetate was added dropwise with stirring to a solution of 13.1 g. (0.95 mol.) of monobromoacetone[3] in 90 ml. of ethylacetate, and the mixture was then kept at 60~70°C under reflux for 4hr. After the mixture had cooled, the resulting white crystals of iminodiacetic acid dimethyl ester hydrobromide were filtered off and repeatedly washed with 100 ml. of ethylacetate. About 21 g. of the hydrobromide was recovered.

The mixture of the filtrate and the washing reagent was concentrated to evaporate ethyl acetate under reduced pressure, the temperature of the solution being kept below 50°C. The residue, a pale yellow oil (24 g.), was a crude aminoacetonediacetic acid dimethyl ester containing a small amount of unreacted monobromoacetone. To a solution of this ester in 30 ml. of ethanol, 80 ml. of water and 33 g. of solid $Ba(OH)_2.8H_2O$ were added; the mixture was then refluxed on a boiling water bath for 2 hr. with occasional shaking. After the mixture had cooled, barium sulfate was precipitated by adding a theoretical amount of sulfuric acid. The precipitate was then filtered off with the aid of Celite and repeatedly washed with hot water.

The mixture of the filtrate and the washing reagent was concentrated to 30~40 ml. under reduced pressure, the temperature being kept below 60°C. To the concentrated solution, 200 ml. of ethanol was added, and the mixture was stored in a refrigerator overnight to complete the precipitation of the free acid of AADA; the crude product was then filtered off and recrystallized from 80% methanol five times. Yield, 12.5 g. (70%). Pure AADA consists of white, bulky crystals which decompose at 190~191°C.

Found: C, 44.44; H, 5.86; N, 7.37, 7.29. Calcd. for $C_7H_{11}NO_5$: C, 44.25; H,6.05; N, 7.41%.

AADA is very soluble in water, soluble in boiling methanol and acetone, very slightly soluble in boiling ethanol, and insoluble in benzene and ether. The solid sample is sensitive to acid or alkaline vapor, and it must be stored in a tightly closed container. The aqueous solution gradually decomposes and rapidly turns yellow at a high temperature. The decomposition is also accerelated by an acid or base.

Measurement.—The experimental method and the conditions in this study are similar to those described in a previous paper.[4] A Hitachi-Horiba Model P pH meter equipped with extension glass and calomel electrodes was used to measure the hydrogen ion concentration. The temperature of the titration solutions was kept at 25.0±0.1°C, while the ionic strength was maintained at approximately 0.10 M with potassium nitrate.

The concentration of the ligand for the determination of the acid dissociation constants was about 0.001~0.002 M. For the titration of solutions of 1 : 1 metal ligand ratio, the initial concentrations were about 0.001M of each component. For the 1 : 2 solutions, the concentrations of metal ions and ligand were about 0.001 M and 0.002 M respectively.

Calculations

The equilibrium constants described in this paper may be summarized as follows:

$$pk_1 = -\log\frac{(HA^-)(H^+)}{(H_2A)}$$

$$pk_2 = -\log\frac{(A^{2-})(H^+)}{(HA^-)}$$

$$K_{MA} = \frac{(MA)}{(M^{2+})(A^{2-})}$$

$$K_{MA_2} = \frac{(MA_2{}^{2-})}{(MA)(A^{2-})}$$

The acid dissociation constants were obtained by a direct algebraic method described previously,[4] and the results were checked by a modified Bjerrum method.[5]

The 1 : 1 metal chelate titration curves were used for the calculation of the first stability constants by means of the algebraic method reported on in a previous paper.[4]

2) J. V. Dubsky, *Ber.*, **50**, 1694 (1917).
3) P. A. Levene, "Organic Syntheses," Coll. Vol. II, 88 (1948).
4) T. Ando, This Bulletin, **35**, 1395 (1962).
5) S. Chaberek, Jr., and A. E. Martell, *J. Am. Chem. Soc.*, **74**, 5052 (1952).

The data obtained from the 1 : 2 curves for heavy metals were utilized as a basis for the calculation of their first and second chelate stability constants according to the modified Bjerrum method which has been described in detail by Chaberek and Martell.[5] The final equation which was employed in this paper is:

$$\bar{n}=\frac{1}{C_M}\left[C_A-\left(\frac{(H^+)^2}{k_1\cdot k_2}+\frac{(H^+)}{k_2}+1\right)(A^{2-})\right]$$

where

$$(A^{2-})=\frac{(2-a)C_A-(H^+)+(OH^-)}{2(H^+)^2/k_1\cdot k_2+(H^+)/k_2}$$

where C_A and C_M are the total concentrations of ligand and metal ion species respectively, and where a is the number of moles of sodium hydroxide added per mole of ligand.

However, the exact values of the constants were obtained by the successive approximation procedure developed by Carlson, McReynolds and Verhoek.[6]

Results and Discussion

Titration Curves. — The corrected potentiometric titration curves for AADA with or without an equivalent amount of metal ions are given in Fig. 1. The curve for the free acid is similar in shape to those of IDA and its homologues, but the inflection at one equivalent of the base which corresponds to the formation of the monosodium salt is considerably weaker than those of IDA and its homologues.

During the titration of the solutions with a 1 : 1 metal ligand ratio, a little pH fluctuation was found in the vicinity of $a=1.8$ for cadmium and cobalt, and in the vicinity of $a=2.0$ for copper, nickel and lead, but no fluctuation was observed in the case of zinc and other metal ions. It is interesting to note on these curves that zinc and cadmium form more stable chelates with AADA than does cobalt in the low pH region. This chelating behavior is rather similar to that of 2-hydroxyethyliminodiacetic acid (2-HIDA) and *N*-AIDA, but it is different from that of IDA and *N*-methyliminodiacetic acid (MIDA).

The titration curves for the solutions with a 1 : 2 metal ligand ratio are illustrated in Fig. 2. The curves for alkaline earth metals were not observed, because it is not likely that they form any stable 1 : 2 chelate with this ligand. A similar chelating tendency for zinc and for cadmium was also observed in this case, and a fluctuation of pH was experienced in the case of cadmium and cobalt in the pH region above 7. The curve for zinc apparently shows a considerably strong inflection at three moles of base per mole of metal ion. This indicates that the formation of 1 : 1 and of 1 : 2 chelates occurs in separate pH regions. This two-step reaction may be expressed as follows:

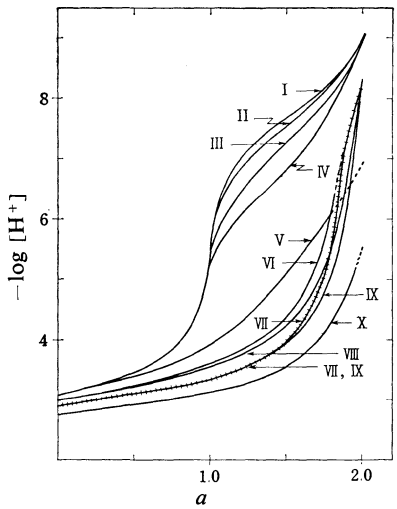

Fig. 1. Titration curves for 1 : 1 solution with 0.1 N NaOH. Concentration of ligand and metal ions……1×10^{-3} M. I, ligand; II, Mg(II); III, Sr(II); IV, Ca(II); V, Co(II); VI, Cd(II); VII, Pb(II); VIII, Zn(II), IX, Ni(II); X, Cu(II). a denotes moles of base added per mole of ligand.

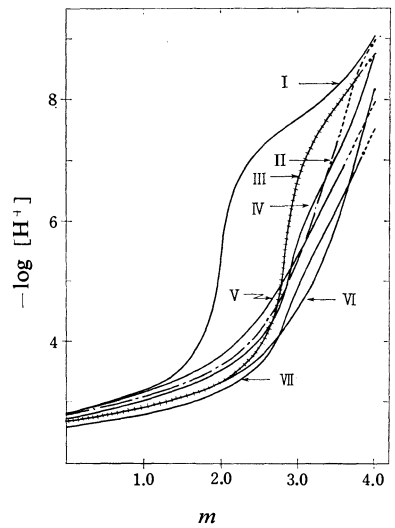

Fig. 2. Titration curves for 1 : 2 solution with 0.1 N NaOH. Concentration of ligand……2×10^{-3} M, metal ion……1×10^{-3} M. I, ligand; II, Cd(II); III, Pb(II); IV, Zn(II); V, Co(II); VI, Ni(II); VII, Cu(II). m denotes moles of base added per mole of metal ion.

6) G. A. Carlson, J. P. McReynolds and F. H. Verhoek, ibid., **67**, 1334 (1945).

the formation of 1:1 chelate in the lower pH region:

$$H_2A + M^{2+} + 2OH^- \rightarrow MA + 2H_2O$$

$$H_2A + OH^- \rightarrow HA^- + H_2O$$

the formation of 1:2 chelate in the higher pH region:

$$MA + HA^- + OH^- \rightarrow MA_2^{2-} + H_2O$$

A similar inflection was also observed on the curves for copper and cobalt, although it is much weaker.

The curve for lead is so unusual that no decisive interpretation can be made. However, the curve indicates that AADA forms a considerably stable 1:1 chelate with lead in the low pH region, and that the chelate changes into a hydroxo-complex or a polynuclear complex in the higher pH region.

Formation Functions.—The Bjerrum formation functions for certain metal chelates of AADA are given in Fig. 3. In the case of

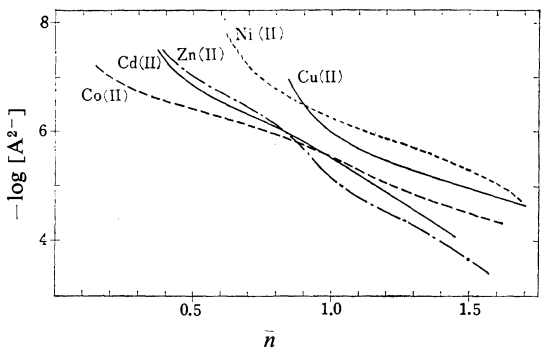

Fig. 3. Formation functions of some divalent metal chelates of AADA. Concentration of ligand……2×10^{-3}, metal ion……1×10^{-3} M; $t=25°C$; $\mu=0.1$ (KNO_3).

copper and nickel, the Bjerrum method could not be employed for the determination of K_{MA} because the values for $-\log(A^{2-})$ were not available at $\bar{n}=0.5$. It was also impossible to determine directly the K_{MA_2} for cadmium from the $-\log(A^{2-})$ value at $\bar{n}=1.5$, for some precipitation occurred in this region. However, K_{MA} at $\bar{n}=0.5$ for nickel was conveniently calculated from the known values of $K_{MA}\cdot K_{MA_2}$ at $\bar{n}=1.0$ and K_{MA_2} at $\bar{n}=1.5$, and the value of K_{MA_2} at $\bar{n}=1.5$ for cadmium, were similarly derived from the values of $K_{MA}\cdot K_{MA_2}$ at $\bar{n}=1.0$ and K_{MA} at $\bar{n}=0.5$.

The formation curve for lead was found to be so unusual that the chelating behavior of AADA for lead was thought to be quite different from that of the other IDA derivatives.

Equilibrium Constants.—The acid dissociation and chelate stability constants of AADA are listed in Table I, along with the corresponding values of some IDA derivatives.

The values of the acid dissociation constants determined by the algebraic method agree reasonably well with those obtained by the modified Bjerrum method. The pk_2 value of AADA indicates that the substitution for a methyl group or hydrogen by a acetyl group apparently results in a marked decrease in the basicity of the imino nitrogen. The same effect was also observed with *N*-AIDA.

The chelate stability constants calculated by these two methods agree well within the range of experimental error for nickel, zinc and cadmium. However, in the case of cobalt, the K_{MA} value obtained by the algebraic method may be erroneous, for the overlapping of 1:1 and 1:2 chelate formation in the 1:1 titration curve is disregarded in the derivation of the stability constant. Therefore, the agreement of the two values for cobalt is not very good.

The K_{MA} values for lead which were calculated from the data of the titration curve in the range of $a=1.1\sim1.7$ did not agree well. Only if the data from the narrower range of $a=0.8\sim1.1$ were chosen were fairly consistent values obtained; their mean values are listed in the table for lead chelate. Therefore, this value may not be accurate enough. The determination of K_{MA_2} for lead by the Bjerrum method was unsuccessful, as has been described before. Above a pH of about 3.5, the reaction of AADA with lead seems to be very complicated; a further investigation will be necessary to analyse the titration curves.

The errors of these stability constants are ±0.1 of log unit. Therefore, the value of two decimal places in the constant means nothing for the below discussion.

The Effect of the Carbonyl Group on the Chelate Stability.—If the carbonyl group is involved in the coordination of AADA to metal ions, it will behave as a quadridentate ligand. Thus, for the metal ions with the coordination number of 4, AADA will form a stable 1:1 chelate; the formation of 1:2 chelate will be more difficult than in the case of such tridentate ligands as IDA or MIDA. This will result in a larger difference between $\log K_{MA}$ and $\log K_{MA_2}$. For the metal ions with the coordination number of 6, the situation will also be the same, although the difference between $\log K_{MA}$ and $\log K_{MA_2}$ is smaller than in the former case. The values of the difference for some metal chelates are also shown in Table I. It may be seen from the table that the tendency of AADA to form a 1:2 chelate from a 1:1 chelate is less marked for zinc and cadmium than for nickel and cobalt. This

8) H. Senn and G. Schwarzenbach, unpublished results (cited from; S. Chaberek and A. E. Martell, "Sequestering Agents," John Wiley & Sons, Inc., New York, (1959) p. 552).

can be understood if one remembers that zinc and cadmium have a coordination number of 4 of tetrahedral configuration, while nickel and cobalt have a coordination number of 6 for a octahedral configuration. A somewhat similar tendency is observed in *N*-AIDA, which is also believed to be a quadridentate ligand for the above-mentioned metal ions, while tridentate ligands such as IDA and MIDA show an ease of 1 : 2 chelate formation.

As has been discussed above, it is quite probable that the carbonyl group is involved in the coordination of AADA to metal ions. If this is the case, this will result in an increase of 1 : 1 chelate stability in comparison with those similar ligands which have no additional coordinating group. In order to examine such an additional stability for the various *N*-substituted IDA derivatives, Schwarzenbach and his co-workers have employed the linear correlation method.[1] According to this method, an increase in the stability which is due to the additional coordinating group is estimated as a difference between the stabilities of the new ligand and of a hypothetical ligand which has no additional coordinating group but which does have the same basicity of imino nitrogen as the new ligand. This comparison can be made by drawing a correlation line of $\log K_{MA}$ versus pk_2 for a series of *N*-alkyl substituted iminodiacetic acids, such correlation lines for selected metal ions are shown in Fig. 4. These lines were drawn using the data from the Schwarzenbach's paper.[1] If the stability of the new ligand increases upon the introduction of an additional coordinating group, the plot of $\log K_{MA}$ versus pK_2 for such a ligand must be above the correlation line; the degree of deviation from the line is a measure of the additional stability due to the additional coordinating group. The increased stabilities of AADA measured by this method, which is expressed as $\Delta \log K_T$, are graphically shown in Fig. 5, along with those of some related IDA derivatives.

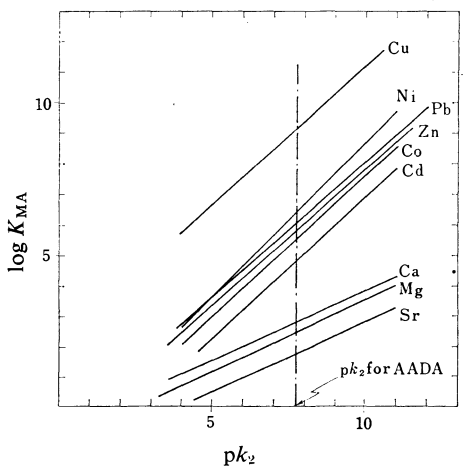

Fig. 4. Correlation lines for the selected metal ions.

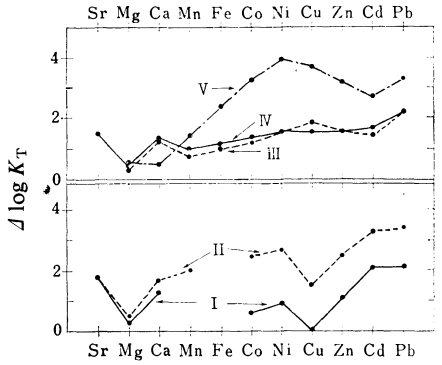

Fig. 5. Increased stability ($\Delta \log K_T$) due to an additional coordinating site.

Ligand : $R-\overset{+}{N}H\begin{cases}CH_2COOH\\CH_2COO^-\end{cases}$

	R
I,	$CH_3-CO-CH_2-$

IV,	$HO-CH_2CH_2-$
V,	$H_2N-CH_2CH_2-$

As is clear from curve I of Fig. 5, the contribution of the carbonyl coordination in AADA is appreciable, with the exceptions of magnesium and copper. The chelating tendency of AADA is also found to be very similar to that of *N*-AIDA (curve II); such a resemblance would indicate that the coordination of the acetoamido group of *N*-AIDA occurs exclusively through the carbonyl oxygen, as has previously been suggested by Schwarzenbach. It is interesting to note that, with the exception of copper, the chelating tendencies of AADA and *N*-AIDA are somewhat similar to those of the *N*-hydroxyethyl and *N*-methoxyethyl derivatives of IDA (curves IV and III respectively), both of which have coordinating oxygen. However, they are quite different from that of aminoethyliminodiacetic acid (curve V), which has amino nitrogen as an additional coordinating site.

In the case of copper, no increase in stability is observed at all, probably because the square planar configuration of copper ion is not favorable for the coordination of the carbonyl oxygen of AADA.

It may also be seen from Fig. 4 that the degree of contribution of the carbonyl coordination to the 1 : 1 chelate stability is greater

in *N*-AIDA than in AADA. This indicates that the basicity of the carbonyl oxygen in the acid amide group is stronger than in the aliphatic keto group, this situation being consistent with the result from the electronic theory of organic molecules.

Summary

1) Aminoacetone-*N*, *N*-diacetic acid or 1-amino-2-propanone-*N*, *N*-diacetic acid has been synthesized. This is the first iminodiacetic acid derivative to have a keto group as an additional coordinating site.

2) The acid dissociation constant and the chelate stability constants of this ligand have been determined by the pH titration method, at 25°C and 0.10 M ionic strength, for such metal ions as copper(II), lead(II), nickel(II), zinc(II), cadmium(II), cobalt(II), calcium(II), strontium(II) and magnesium(II).

3) It has been proved that the coordination of the carbonyl oxygen of this ligand to metal ions is appreciable, and the increase in the chelate stability has been explained by the contribution of the carbonyl coordination.

The author is grateful to Professor Keihei Ueno for his guidance during the course of this investigation. He also wishes to thank Mr. M. Shido, Mrs. S. Shido and Miss T. Tahara for performing the elemental analysis. Finally, this work was supported in part by a scientific research grant of the Ministry of Education, to which the author's thanks are due.

Amperometric Determinations of Metals with Chloramine T

By G. S. DESHMUKH and M. C. ESHWAR*

(Received June 12, 1963)

Erdey and co-workers[1] reported the application of ascorbic acid for direct and indirect determination of vanadium(V) using variamine blue as indicator. An ascorbimetric method[2] was also investigated by Erdey for the determination of cerium(IV) and chromium(VI). Various workers[3-5] found the reduction of pentavalent vanadium by arsenous oxide as too slow, and the reaction was therefore catalysed by iodide :[5] Analytical determination of Ce^{4+} was carried out with arsenous oxide using osmium tetroxide or iodine monochloride as catalyst and ferroin as indicator. Lang[8] studied the reduction of chromic acid with H_3AsO_3. Various workers[9-11] investigated the reduction of vanadium(V) to vanadium(IV) by hydrazine in sulfuric acid. Bray[11] and Cuy discarded the reaction for analytical determination, due to the occurrence of a partial side reaction resulting in the formation of ammonia and hydrazoic acid. Kolthoff[12] inferred that the oxidation of hydrazine proceeds smoothly to nitrogen and water in presence of sufficient concentration of hydrochloric acid. Benrath and Ruland[13] studied the oxidation of hydrazine by ceric sulfate. A review of the literature however, revealed that the reduction of Cr^{6+} with hydrazine has not been attempted.

Earlier results from these laboratories reported the utility of chloramine T in the oxidation of ascorbic acid,[14] arsenious oxide[16] and hydrazine sulfate[15] amperometrically at the rotating platinum wire micro-electrode. Following this, an investigation on the possibility of reducing V^{5+}, Ce^{4+} and Cr^{6+} by the

above reductants, and titrating the excess reductant with chloramine T was taken up.

Experimental

Reagents and Apparatus. — Stock solution of vanadium(V) was prepared by dissolving an accurately weighed amount of vanadium pentoxide (E. Merck) in sodium carbonate (AnalaR) and the solution was made slightly acidic with hydrochloric acid. The vanadium content of this solution was checked by the method of Willard and Young.[17] Ceric sulfate solution was obtained by the usual method and the strength of this solution was determined with a standard solution of ferrous ammonium sulfate. A decinormal solution of potassium dichromate was prepared from a pure E. Merck (G. R.) sample. Approximately decinormal solutions of ascorbic acid and hydrazine sulfate were obtained from pure samples, while that of arsenious oxide was prepared as suggested by Pierce and Haenisch[18] and standardised amperometrically with chloramine T.[14-16]

A solution of chloramine T, approximately N/10, was prepared from a pure sample and standardised iodometrically with sodium thiosulfate. Iodine monochloride solution was 0.005 M. A sodium citrate-citric acid buffer (pH ~5.8), prepared by mixing 3 vol. of 0.5 M sodium citrate, 1 vol. of 0.5 M citric acid and 1 vol. of water, was used to control the pH of the reaction mixture. A simple form of amperometric unit, with an impressed potential of +0.3 volt vs. S. C. E., was used.

Determination of Vanadium

The reduction of V^{5+} to V^{4+} with hydrazine sulfate was found to be smooth, resulting in the formation of nitrogen and water. The possibility of the side reaction reported[10,11] was overcome by using hydrochloric acid instead of sulfuric acid, for acidifying the vanadium solution. Ascorbic acid also was found to reduce V^{5+} to V^{4+} quantitatively, with the formation of dehydroascorbic acid and water. In strongly acidic solutions, the reduction of vanadium(V) by arsenous oxide required more than 24 hr. for completion. However, iodine monochloride was found to catalyse the reaction, and it was also observed that the reaction was accelerated with an increase in the concentration of the catalyst. It was seen that the reaction required 10~15 min. for completion, when 1.0 ml. of iodine monochloride (0.005 M) was added. Accordingly, all the experiments with arsenous oxide were carried out using 1.0 ml. iodine monochloride as catalyst. For titration of excess hydrazine sulfate, 0.25 ml. of iodine monochloride was added as catalyst. The amount of iodine monochloride added to catalyse the reduction of vanadate by arsenous oxide, also served for titration of excess arsenous oxide. The reduction is found to be quantitative with each reductant under the above operating conditions according to:

$$2VO_3^- + C_6H_8O_6 + 6H^+ \rightarrow 2VO^{2+} + C_6H_6O_6 + 4H_2O \quad (1)$$

$$4VO_3^- + As_2O_3 + 12H^+ \rightarrow 4VO^{2+} + As_2O_5 + 6H_2O \quad (2)$$

$$4VO_3^- + N_2H_4 + 12H^+ \rightarrow 4VO^{2+} + N_2 + 8H_2O \quad (3)$$

Hence, 1.0 ml. of $NC_6H_8O_6$, or NAs_2O_3, or $NN_2H_4 \cdot H_2SO_4$ $\equiv$ 0.05094 g. of vanadium

Determination of Cerium

Tetravalent cerium was reduced quantitatively to trivalent state by ascorbic acid with the formation of dehydroascorbic acid and water, whereas the reduction with arsenous oxide was rather slow. The latter reaction was found to be accelerated by the addition of 0.25 ml. (5 drops) of iodine monochloride (0.005 M), which also served for titration of excess arsenous oxide with chloramine T. The procedure with hydrazine under similar conditions presented certain difficulties, detrimental to its utility as an analytical tool and could not therefore be pursued at the present stage. Ascorbic acid and arsenious oxide were, however, suitable for the quantitative determination of cerium.

$$2Ce(SO_4)_2 + C_6H_8O_6 \rightarrow Ce_2(SO_4)_3 + C_6H_6O_6 + H_2SO_4 \quad (4)$$

$$4Ce(SO_4)_2 + As_2O_3 + 2H_2O \rightarrow 2Ce_2(SO_4)_3 + As_2O_5 + H_2SO_4 \quad (5)$$

Hence, 1.0 ml. of $NC_6H_8O_6$, or NAs_2O_3 $\equiv$ 0.1401 g. of cerium

Determination of Chromium

Reduction of Cr^{6+} to Cr^{3+} was complete with all the three reductants viz., ascorbic acid, arsenous oxide and hydrazine sulfate. The reaction products presumably are dehydroascorbic acid, arsenic pentoxide and nitrogen respectively. Whereas the titration of excess ascorbic acid was carried out in presence of citrate buffer only, that of excess arsenite and

hydrazine required iodine monochloride to catalyse the oxidation. The quantitative reduction proceeds as follows:

$$K_2Cr_2O_7 + 3C_6H_8O_6 \rightarrow 2KCrO_2 + 3C_6H_6O_6 + 3H_2O \quad (6)$$

$$2K_2Cr_2O_7 + 3As_2O_3 \rightarrow 4KCrO_2 + 3As_2O_5 \quad (7)$$

$$2K_2Cr_2O_7 + 3N_2H_4 \rightarrow 4KCrO_2 + 3N_2 + 6H_2O \quad (8)$$

Hence, 1.0 ml. of $NC_6H_8O_6$, or NAs_2O_3, or $NN_2H_4 \cdot H_2SO_4$ $\equiv$ 0.01734 g. of chromium

Procedure.—An aliquot of VO_3^-, Ce^{4+} or $Cr_2O_7^{2-}$ solution was taken in a 150 ml. Pyrex beaker, to which an appropriate quantity of the reductant viz., ascorbic acid, arsenous oxide and hydrazine sulfate was added. One milliliter of iodine monochloride (0.005 M) was added for accelerating vanadium(V)-arsenic(III) reaction, and 0.25 ml. for that of cerium(IV)-arsenic(III) reaction. For titration of excess arsenous oxide in $Cr_2O_7^{2-}$ determination and of excess hydrazine sulfate (in VO_3^-, $Cr_2O_7^{2-}$ determinations), 0.25 ml. (5 drops) of iodine monochloride was added as catalyst. In each case, 10~15 ml. of sodium citrate-citric acid buffer (pH ~5.8) was introduced to maintain an overall pH of 4.3~4.9. The contents were diluted approximately to 50 ml. and titrated amperometrically with chloramine T at a potential of +0.3 volt vs. S. C. E.

Observations are returned in 3 short tables.

Summary

An indirect procedure for the determination of V^{5+}, Ce^{4+} and Cr^{6+} is given. Three reductants, viz., ascorbic acid, arsenous oxide and hydrazine have been employed for reduction of each oxidant. Iodine monochloride

has been used as catalyst in the reduction of V^{5+} and Ce^{4+} by arsenous oxide. Reduction of Ce^{4+} with hydrazine presented certain difficulties and is not pursued at the present stage. The excess reductant in each case is determined amperometrically with chloramine T at the rotating platinum wire micro-electrode, and an impressed potential of +0.3 volt vs. S.C.E. The titrations are performed at a pH of 4.3~4.9, using citrate-citric acid buffer. For titration of excess arsenous oxide and $N_2H_4 \cdot H_2SO_4$, 0.25 ml. of iodine monochloride (0.005 M) has been employed as catalyst. The procedure, which is rapid and accurate, has been employed for determination of amounts up to 1.05 mg. vanadium, 5 mg. cerium and 0.86 mg. chromium.

*Studies on Mixture Dyeing. II. The Kinetics of a Mixture of Chrysophenine G and Sirius Red 4B**

By Minoru SEKIDO and Zenzo MORITA

(Received June 14, 1963)

In the previous paper,[1] the mixture dyeing whose dyebath contained an equimolar mixture solution of Benzopurpurine 4B and Sky Blue 6B was kinetically investigated. There was a great difference in surface concentration between the two dyes owing to the great difference in affinity between them. Therefore, because of the sharp gradient of the concentration of Benzopurpurine 4B the interaction between the two dyes in the substrate, especially the effect of the blue dye on the diffusion of the red dye, could not be estimated quantitatively.

In this paper, the mixture dyeing of Chrysophenine G (C. I. Direct Yellow 12) and Sirius Red 4B (C. I. Direct Red 81), which are very similar to each other in dyeing property, has been studied; the single dyeings of these dyes have also been carried out in order to discuss quantitatively their behavior in the mixture dyeing.

First, the equilibrium adsorption from the single and mixture dyebath was investigated. Then, on the basis of the obtained results, the dyeing conditions for kinetic study were determined.

In order to estimate the effect of the yellow dye on the diffusion of the red dye, the surface concentration of the former dye was gradually increased at a constant surface concentration of the latter dye, and vice versa; diffusion experiments were then carried out. When both dyes had equal surface concentrations, the kinetics of mixture dyeing has been investigated. The temperature effect of mixture dyeing has also been studied.

Experimental

Materials.—A cellophane sheet made by the Tokyo Cellophane Co., Ltd., was used as the dyeing substrate. It was scoured with distilled water and conditioned in a desiccator with 50% sulfuric acid.

Purified dyes were used throughout. They were prepared from commercial dyes (Kayaku Chrysophenine GX (KYK) and Suprazo Red 4B (MDW)) by the method of Robinson and Mills.[2] The absence of colored impurities was verified by paper chromatography.

Equilibrium Dyeing.—The dyeings were carried out following the method of Horiki et al.[3] Pieces of the sample, weighing from 25 to 35 mg., were dyed in 200 ml. of dyeing liquor at 90, 85 and 80°C. The dyeing duration was one day (90°C) or two days (85 and 80°C). In the case of the single dyeing, the dye concentrations of the equilibrium dyebath were as shown in Figs. 1 and 2. Those of the mixture dyeing shown in Tables III, IV and V, were determined by a large number of preliminary experiments. After dyeing, the pieces of the sample

—○— 90°C, —△— 85°C, —□— 80°C

were quickly rinsed in a dilute sodium chloride aqueous solution, dried, and stripped in 25% aqueous pyridine. The strippings were analyzed by determining the optical densities at the wavelength of maximum absorption for each component by the use of a Hitachi EPB-V type spectrophotometer (405 and 520 mμ). The absorption spectra of the mixture dye in an aqueous pyridine solution were found to be additive. The concentration of sodium chloride was 0.03 mol./l. for every dyebath.

Diffusion.—The experimental methods were similar to those reported before.[1] The dyeing times were 500 min. (90°C), 750 min. (85°C) or 1000 min. (80°C). The dyeing condition, namely, the concentrations in the mixture dyeing, were determined by the results of the equilibrium adsorption.

Theoretical*

Dyeing Equilibrium.—The adsorption isotherms are obtained from the equilibrium dyeing measurements. According to Vickerstaff,[4] the isotherms are also derived from the theoretical considerations for any particular dyebath and substrate system. The standard affinity of direct dye anions for the substrate, $\Delta\mu^0$ (kcal./mol.), can be calculated by

$$-\Delta\mu^0 = RT\ln\frac{[D]_\phi [Na]_\phi{}^z}{V^{z+1}} - RT\ln[D]_\sigma [Na]_\sigma{}^z \quad (1)$$

$$[Na]_\phi = [D]_\phi\left\{\frac{z}{2}+\left(\frac{z^2}{4}+\frac{V^2[Na]_\sigma[Cl]_\sigma}{[D]_\phi{}^2}\right)^{1/2}\right\} \quad (2)$$

where $[D]_\phi$ (mol./kg.) denotes the concentration of adsorbed dye anions in the substrate at equilibrium; $[Na]_\phi$ (mol./kg.), the concentration of the sodium ions in the substrate at equilibrium; $[Na]_\sigma$ and $[Cl]_\sigma$ (mol./l.), the concentrations of the sodium and the chloride ions in the dyebath at equilibrium; z, the valency of the dye anions; R, the gas constant; T, the absolute temperature, and V (l./kg.), the internal volume of the substrate. In this case, the volume term was taken to be 0.45.

Kinetics.—The theory of diffusion has been reported on before.[1] The distribution of Chrysophenine G and Sirius Red 4B in the substrate in the mixture dyeing, as shown in Results and Discussion, is similar in shape to that in the single dyeing. The diffusion equation of mixture dyeing, therefore, may be given by

$$\frac{\partial C_1}{\partial t} = D_{11}\frac{\partial^2 C_1}{\partial x^2} + D_{12}\frac{\partial^2 C_2}{\partial x^2} \approx D_1'\frac{\partial^2 C_1}{\partial x^2} \quad (3)$$

$$\frac{\partial C_2}{\partial t} = D_{21}\frac{\partial^2 C_2}{\partial x^2} + D_{22}\frac{\partial^2 C_2}{\partial x^2} \approx D_2'\frac{\partial^2 C_2}{\partial x_2} \quad (4)$$

where D_1' and D_2' (cm^2/min.) denote the apparent diffusion coefficient of each dye in the mixture dyeing. The other symbols are as given before.[1] These six diffusion coefficients have been calculated by the same methods as in the previous paper.[1]

Results and Discussion

Single Dyeing.—The adsorption isotherms of the two dyes at 90, 85 and 80°C are shown in Figs. 1 and 2, and the standard affinity, calculated by Eqs. 1 and 2, in Table I. The

* Chrysophenine G denotes dye 1 and Sirius Red 4B, dye 2; they are shown by subscripts such as D_{11} $[D_2]_\phi$.

TABLE I. STANDARD AFFINITY OF DIRECT DYES

Temp., °C	Chrysophenine G	Sirius Red 4B
90	$-(3.40\pm0.06)$	$-(3.73\pm0.06)$
85	$-(3.51\pm0.07)$	$-(3.90\pm0.07)$
80	$-(3.62\pm0.06)$	$-(3.94\pm0.07)$

diffusion coefficients at various surface concentrations are shown in Tables III, IV and V. The surface concentration, C_i^0, in diffusion experiments are assumed to be equal to the equilibrium adsorption, $[D_i]_\phi$, obtained from Figs. 1 and 2 for the same concentration in a dyebath. These results show that the two dyes have similar dyeing properties, although Chrysophenine G has a little larger diffusion coefficient and a little lower affinity than Sirius Red 4B.

The activation energies of diffusion at a constant surface concentration are given in Table II. They decrease with an increase in the surface concentration.

TABLE II. APPARENT ACTIVATION ENERGY OF DIFFUSION

	$C_0\times10^3$	E
Chrysophenine G	2.5	9.89

Sirius Red 4B	2.5	16.9
	3.0	16.3
	3.5	14.7
	4.0	12.9

Mixture Dyeing.—The equilibrium adsorptions in mixture dyeing, which correspond to the expected dyeing condition described before, are as shown in Tables III, IV and V. In the kinetic study, three kinds of dyeing conditions and three dyeing temperatures are employed.

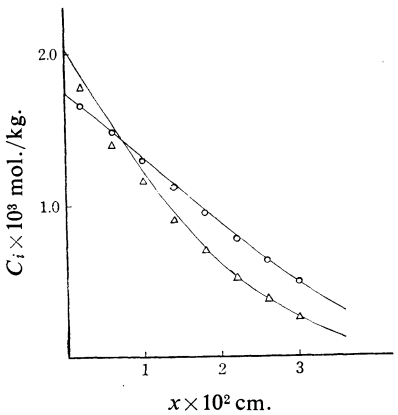

Fig. 3. Dye distribution in mixture dyeing.
○ Chryrophenine G, △ Sirius Red 4B
—— Theoretical curve; $[D_1]_\sigma=9.40\times10^{-5}$, $[D_2]_\sigma=6.35\times10^{-5}$,
NaCl: 3.0×10^{-2} mol./l.; 90°C; 500 min.
(Cf. Table III, Exp. No. 1)

The surface concentration, C_i^0, in diffusion experiments was assumed, as in single dyeing, to be equal to the equilibrium adsorption from the same concentration in the dyebath. As shown in Fig. 3, the surface concentration in diffusion experiments is a little different from the equilibrium adsorption under the same conditions, but this difference does not affect the calculation of the cross-term diffusion coefficients.

When the surface concentration of yellow dye at 90°C is maintained constant and that of red dye is gradually increased, the apparent diffusion coefficient of yellow dye, D_1', increases gradually. In this case, because of the concentration dependence of the diffusion coefficient, D_{22} (the diffusion coefficient of the red dye) increases with an increase in the surface concentration. D_{11} (that of the yellow dye) may not increase for the same reason. However, D_1' increases gradually with an increase in $[D_2]_\phi(=C_2^0)$. This, therefore, may be due to the effect of red dye on the diffusion of yellow dye. The diffusion of red dye may also be affected by yellow dye. As the surface concentration of the yellow dyes, however, is maintained constant, the yellow dyes may be almost identical in their effect on the diffusion of red dye, as Table III shows.

When the surface concentration of red dye is maintained constant, the reverse phenomenon is observed; namely, D_2' increases gradually. The effect of yellow dye on the diffusion of red dye seems to be smaller than in the reverse case. Such a situation is also observed when the surface concentrations of the two dyes are equal; these phenomena may be interpreted by means of the combination effect of the two dyeing conditions mentioned above.

D_{11}, D_{12}, D_{21} and D_{22} should be estimated simultaneously. As has been stated before, D_{11} and D_{22} determined by the single dyeing. Because of the activity of the dye and other factors, D_{11} and D_{22} may vary with the concentration of the two respective dyes. Although the concentration dependence of these diffusion coefficients has been investigated by O'Donnell and Gosting,[5] it can not be estimated from these experimental results with adequate experimental accuracy. As the absolute values of D_{12} are larger than those of D_{21}, and as D_{21} approximates to zero, it is considered, as has been stated before, that the effect of yellow dye on the diffusion of red dye is smaller than in the reverse case.

The distributions of these dyes in the substrate are very different from those in the mixture of Benzopurpurine 4B and Sky Blue 6B. This may be explained as follows. Chrysophenine G and Sirius Red 4B are similar to each other in distribution, while Benzopurpurine 4B and Sky Blue 6B are not. It follows that the effect of the two dyes on the diffusion of each dye is smaller in the former case than in the latter and that the dye distributions in

the present experiments, as shown in Fig. 3, may be Fickian. However, as Fig. 3 shows, the distribution of two dyes in the substrate agrees well with the theoretical curves in the previous paper.[1] Therefore, the unusual distribution of Sky Blue 6B may not be a particular one, and the shape of the dye distribution in the mixture dyeing may be determined by the value of the diffusion coefficients of the dye and the ratio of the surface concentrations; i.e., the dye distribution in the mixture dyeing may be Fickian only when the two dyes are similar to each other in dyeing property.

At 85°C, the dyeing condition of the constant surface concentration of yellow dye and the equal surface concentration of the two dyes are employed. The results are shown in Table IV. At 80°C, the dyeing condition of the constant surface concentration of red dye and the equal surface concentration of the two dyes are employed; the results are shown in Table V. Similar phenomena such as those at 90°C, are observed. As the results exhibit a little scatter, the cross-term diffusion coefficients have not been calculated.

Judging from the difference between D_1' and D_{11} or D_2' and D_{22}, the temperature effect on mixture dyeing seems to decrease with a decrease in the temperature. This is inconsistent with the cases of Benzopurpurine 4B and Sky Blue 6B. This temperature effect is considered to be caused by various complicated factors, such as the activity and the affinity of dye, which vary with the temperature. Therefore, it may not be possible to discuss it simply. The absorption spectra of the dye mixture in the substrate were additive, even in the case of a mixture of Chrysophenine G and Sky Blue 6B, in contrast with those in an aqueous solution.[6] Therefore, in the substrate, there may not be such a strong interaction to vary the absorption spectra as in a solution, and so the same complex between two dyes as in a solution may not result. The main factor influencing the diffusion in mixture dyeing may be a competition of available surfaces in the substrate. Then the dye with the smaller diffusion coefficient or with the larger affinity has a more profound effect on the diffusion of the dye with a larger diffusion coefficient or with a smaller affinity than in the reverse case. The results of these experiments confirm these hypotheses.

Summary

1) The single and mixture dyeing of Chrysophenine G (C. I. Direct Yellow 12) and Sirius Red 4B (C. I. Direct Red 81) have been examined kinetically.

2) The affinity and the diffusion coefficient of each dye at 90, 85 and 80°C have been evaluated. The apparent activation energy of diffusion at a constant surface concentration has been calculated.

3) In the mixture dyeing, although the apparent diffusion coefficient of each dye became larger than that in the single dyeing, whose surface concentration was similar to that in the mixture dyeing, the dye with the smaller diffusion coefficient had a more profound effect on the diffusion of the dye with the larger diffusion coefficient than in the reverse case.

The Electronic Spectra and Electronic Structures of Amino-substituted Benzenes

By Noboru MATAGA

(Received June 1, 1963)

Theoretical studies of the electronic structures and spectra of complex aromatic molecules seem to be of increasing importance from various viewpoints. The electronic spectra and electronic structures of substituted aromatic hydrocarbons for instance, have been the subject of a number of theoretical investigations.[1-12]

Baba and Suzuki[12] have made a comparative study of the electronic spectra of phenol and aniline and also of those of naphthols and naphthylamines. These calculations, as well as those by some of the other investigators,[5,9] employed molecular orbitals delocalized over all the cores of the molecules, in contrast to the method of the composite system, where a molecule is regarded as being made up of several fragments and where the interactions among the wave functions of these fragments are calculated to give the wave functions for the whole molecule.[7,8] The latter method is quite suitable for determining the correlation between the spectrum of a molecule and the spectra of fragments of which the molecule is composed and also for ascertaining the extent of charge transfer (CT) interaction among these fragments in the molecule.

Of course, these two methods are not essentially independent of each other. Recently, Fischer-Hjalmars[13] has developed an elegant method for transforming the wave functions calculated by the former method into those obtained by the latter method using natural spin orbital of Löwdin;[14] she has applied that method to toluene and aniline. In the case of aniline, the result of this transformation was rather close to the wave functions calculated by Murrell[7] with the method of the composite system.

As has been said above, the electronic spectrum and the electronic structure of aniline, among other amino-substituted benzenes, have been studied in detail. However, the electronic structures and spectra of poly-substituted amino-benzenes have not been studied in detail.

Because of the strong conjugation of the amino group with the π-electron system of the aromatic ring, perturbation methods* seem to be poor approximations for systematically interpreting the electronic spectra of amino-substituted aromatics; therefore, a variational method should be employed for this study.

Because of this strong conjugation power of the amino group, the electronic structure of the aromatic hydrocarbon will be considerably affected by this substitution. Actually, Köhler and Scheibe[15] have demonstrated that *s*-triaminobenzene is easily protonated on the ring carbon in an almost neutral aqueous solution, whereas aniline, as well as *m*-phenylenediamine, is protonated on the amino-nitrogen. This is a remarkable example of substitution effecting a large change in the physico-chemical property of a molecule.

We have studied this very interesting phenomenon by means of molecular orbital calculations and have shown that the calculated electronic spectrum of the protonated *s*-triaminobenzene agrees satisfactorily with the observed spectrum, and also that the quite large proton affinity of this molecule is in accordance with the results of the calculations.[16]

In view of the circumstances described above, it seems to be desirable to study the electronic spectra and electronic structures of amino-substituted aromatics in a more systematic way.

Accordingly, we have taken up several amino-benzenes, such as aniline, isomeric phenylene-diamines (PDA) and *s*-triaminobenzene (TAB), and also several amino-substituted nitrogen heterocycles, such as 4-amino-pyridine, 1, 4-di-aminotetrazine and melamine.

In the present report, mainly the results for amino-substituted benzenes will be described.

Method of Calculation

Although our method of calculation in this report is based on the semiempirical ASMO method[12,17,18] with a zero differential overlap, we have tried various approaches including the VESCF[19,20] calculation on *p*-PDA, because the electronic structures of amino-derivatives appear to be much more complicated than those of parent hydrocarbons and simple *n*-heterocycles, where the -CH= groups of the parent hydrocarbon are replaced by -N=.

One of the difficulties with calculation using the MO's delocalized over all the cores of the molecule is the assessment of the core potential at amino nitrogen, which can contribute two electrons to the π-system, in contrast to the case of aromatic hydrocarbons or *n*-heterocycles, where the core potentials for π-electrons are fairly uniform. A similar difficulty arises in the case of pyrrole, for which Brown and Heffernan used the VESCF method.[20]

The outline of our procedure of calculation is as follows:

i) The calculation of Hückel MO's, assuming appropriate values of Coulomb and resonance parameters ($\alpha_N=\alpha+1.2\beta$, $\beta_{CN}=\beta$[12]).

ii) The antisymmetrization of Hückel MO's.

iii) The calculation of electronic spectra invoking configuration interaction (CI) or SCF calculation using Hückel MO's as the starting wave functions, and then the calculation of the electronic spectra by the CI method.

Although the necessary formulas for the ASMO CI calculation have been given elsewhere,[17,18] they will now be described briefly.

The Hückel MO's (ϕ_i's) are expressed by linear combinations of $2p\pi$ AO's ($\phi_1 \cdots\cdots \phi_{2n}$) of carbon and nitrogen:

$$\psi_1=\sum_{\mu}^{2n} c_{i\mu}\phi_\mu \tag{1}$$

The Hamiltonian for $2m$ π-electrons can be written as:

$$\mathscr{H}=\sum_{i}^{2m}\mathscr{H}_i^{\text{core}}+\sum_{i<j}^{2m} e^2/r_{ij} \tag{2}$$

where $\mathscr{H}_i^{\text{core}}$ is the core Hamiltonian for the ith electron and r_{ij} is the interelectronic distance.

By means of the Fock Hamiltonian, $F=\mathscr{H}^{\text{core}}+G$, the apparent orbital energies are expressed by:

$$\varepsilon_i=\langle\psi_i|F|\psi_i\rangle=\sum_{\mu,\nu} c_{i\mu}c_{i\nu}\cdot\langle\phi_\mu|F|\phi_\nu\rangle=\sum_{\mu,\nu} c_{i\mu}c_{i\nu}F_{\mu\nu} \tag{3}$$

Putting $\langle\phi_\mu(i)|\mathscr{H}_i^{\text{core}}|\phi_\nu(i)\rangle=\beta_{\mu\nu}$, the matrix elements of Fock Hamiltonian in terms of AO's are written as:

$$\left.\begin{aligned} F_{\mu\mu}&=-I_\mu+(1/2)P_{\mu\mu}\gamma_{\mu\mu}+\sum_{\kappa\neq\mu}(P_{\kappa\kappa}-Z_\kappa)\gamma_{\kappa\mu}\\ F_{\mu\nu}&=\beta_{\mu\nu}-(1/2)P_{\mu\nu}\gamma_{\mu\nu}\end{aligned}\right\} \tag{4}$$

The excitation energies for the $i\rightarrow k$ transition, $E(^{1,3}\chi_{ik})=\langle^{1,3}\chi_{ik}|\mathscr{H}|^{1,3}\chi_{ik}\rangle-\langle\psi_0|\mathscr{H}|\chi_0\rangle$, where χ_0 is the ground electronic configuration, and the interconfigurational matrix elements, $\langle^{1,3}\chi_{ik}|\mathscr{H}|\cdot{}^{1,3}\chi_{jl}\rangle$, are calculated by the following equations:

$$E(^{1,3}\chi_{ik})=(\varepsilon_k-\varepsilon_i)-(\langle ik|G|ik\rangle-\langle ik|G|ki\rangle)\pm\langle ik|G|ik\rangle \tag{5}$$

$$\langle^{1,3}\chi_{ik}|\mathscr{H}|^{1,3}\chi_{il}\rangle=\varepsilon_{kl}-(\langle ik|G|il\rangle-\langle ik|G|li\rangle)\pm\langle ik|G|li\rangle,\quad k\neq l \tag{6}$$

$$\langle^{1,3}\chi_{ik}|\mathscr{H}|^{1,3}\chi_{jk}\rangle=-\varepsilon_{ji}-(\langle kj|G|ki\rangle-\langle kj|G|ik\rangle)\pm\langle kj|G|ik\rangle,\quad j\neq i \tag{7}$$

$$\langle^{1,3}\chi_{ik}|\mathscr{H}|^{1,3}\chi_{jl}\rangle=-(\langle jk|G|il\rangle-\langle jk|G|li\rangle)\pm\langle jk|G|li\rangle,\quad i\neq j,\ k\neq l \tag{8}$$

$$\langle^1\chi_{ik}|\mathscr{H}|\chi_0\rangle=\sqrt{2}\,\varepsilon_{ki} \tag{9}$$

In these equations, $\varepsilon_{ki}=\langle\psi_k|F|\psi_i\rangle$, $\langle jk|G|li\rangle=\langle\psi_j(i)\psi_k(j)|e^2/r_{ij}|\psi_l(i)\psi_i(j)\rangle$, the + signs before the last terms in the right hand side are for singlets, and the − signs are for triplets. Thus, only the singly-excited configurations and the ground configuration are taken into account.

In the case of the SCF calculation, the secular equation:[21]

$$\sum_{\nu}F_{\mu\nu}c_{i\nu}=\varepsilon_i c_{i\mu} \tag{10}$$

must be solved by an iterative procedure.

In the VESCF method of Brown and Heffernan,[19,20] the SCF procedure involves the dependence of all the integrals except $\beta_{\mu\nu}$ on the charge distribution, $P_{\mu\mu}$.

The wave function, Ψ, for an electronic state is given by a linear combination of χ's. The oscillator strength, f, is calculated by the following equation:

$$f=0.08754\times\nu_{oa}\sum_{r=x,y,z}[m^r_{oa}]^2 \tag{11}$$

where ν_{oa} is the excitation energy in units of eV. of the transition from the ground state, Ψ_0, to an excited state, Ψ_a. The necessary formulas for the calculation of the transition moment, m^r_{oa}, have been given elsewhere.[17b]

Let us now consider the evaluation of integrals. They have been evaluated by semiempirical procedures. $Z_\kappa=1$ for the carbon core and $Z_\kappa=2$ for the core of amino nitrogen, which contributes two electrons to the π-system. The I_μ values for carbon were taken to be 11.42 eV., and that for the amino nitrogen, 28.85 eV.[22]

$\gamma_{\mu\nu}$'s were evaluated by the same procedure as before.[18,23,24] For the evaluation of m^r and $\gamma_{\mu\nu}$, all nearest neighbor C–C bond distances are assumed to be 1.39Å, and those of C–N bonds, 1.36Å.[5] The core resonance integral, $\beta_{\mu\nu}$, was taken into account only for the nearest neighbors and was neglected for more distant neighbors; the same value as before[18,23,24] was used for β_{CC}, namely, $\beta_{CC}=-2.388$ eV. However, the most suitable value for β_{CN} in the present approximation is not yet known. We have calculated the electronic spectrum of *p*-PDA assuming various values for β_{CN} in order to find out the β_{CN} value which fits the observed excitation energy. In this way, the best value of β_{CN} for reproducing the excitation energies to the first and the second excited singlet states has been found to be -3.6 eV.

We have calculated the electronic spectra of some amino-substituted benzenes and nitrogen heterocycles, such as aniline, *p*-PDA, TAB, 4-aminopyridine, 4,4'-diaminotetrazine and melamine, with this β_{CN} value. However, the agreement between the calculated and observed spectra is not very satisfactory with this β_{CN} value.

One of the main causes for this unsatisfactory agreement seems to be as follows. The value of I_μ for the amino-nitrogen (28.85 eV.) used in the above calculation (Approximation A) is the ionization potential of the $2p\pi$ electron of N^+ in the trigonal hybrid state. This value appears to be too large; the real value is probably smaller than this value and a little larger than that for neutral nitrogen because the actual core for a π-electron at amino-nitrogen is not N^{2+} but is partially shielded because of the existence of another π-electron. Moreover, this value of β_{CN} seems to be too large because the overlap between the $2p\pi$ AO's on the amino-nitrogen and the substituted carbon respectively may not be larger than the corresponding overlap between the nearest neighbor carbons.

In view of these circumstances, we should examine other semiempirical procedures more appropriate to the present case. One of the possible procedures is to regard I_μ or $F_{\mu\mu}$ for amino nitrogen as an adjustable parameter and to select the most suitable value for reproducing the observed spectra satisfactorily. For this purpose, we have used a simplified procedure which gives appropriate values for the $F_{\mu\mu}$'s of amino-nitrogen, That is,

$$\langle F_{NN}\rangle=\langle F_{CC}\rangle_{AV}+\delta_N\cdot\langle F_{12}\rangle_{AV} \qquad (12)$$

where $\langle F_{CC}\rangle_{AV}$ is the simple arithmetic mean of $F_{\mu\mu}$'s for carbon, $\langle F_{12}\rangle_{AV}$ is the same quantity of $F_{\mu\nu}$'s for the nearest neighbor carbon-carbon bonds, and δ_N is the Hückel MO parameter for the Coulomb integral of nitrogen, 1.2.

When $\langle F_{\mu\mu}\rangle$ of Eq. 12 instead of $F_{\mu\mu}$ of Eq. 4 is used for amino-nitrogen, the most suitable value of the core resonance integral β_{CN} appears to be -2.399 eV., the β_{CC} value being the same as before. Therefore, in this approximation, $\beta_{CN}\approx\beta_{CC}$; this result seems to be physically reasonable.

For a more refined calculation, the VESCF method of Brown and Heffernan[19,20] may be used. An analogous idea of "differential ionization" has been proposed by I'Haya.[25]

In the VESCF method, it is assumed that Slater's rule for the effective charges of atoms is applicable to a continuous variation in electron density. Accordingly, the effective charge, Z_μ, of the μ atom is expressed as a function of $P_{\mu\mu}$:

$$Z_\mu=N_\mu-\lambda_\mu-0.35(\sigma_\mu+P_{\mu\mu}) \qquad (13)$$

where N_μ is the atomic number and σ_μ is the number of σ-electrons associated with the μ atom in the molecular framework, e. g., 3 for carbon and the amino-nitrogen. λ_μ is the contribution from the inner shell electrons, and $\lambda_\mu=1.35$ for carbon and nitrogen in the present case.

If the I_μ's are plotted against the Z_μ's for the (sp^3, V_4) valence state of the iso-electronic series, C, N^+ and O^{2+}, and for the (sp^4, V_3) valence state of the iso-electronic series, C^-, N and O^+ respectively, the curves are accurately parabolic. In this way, the form of the relationship between the valence state ionization potential, I_μ, and Z_μ has been established.[26] Therefore, $\gamma_{\mu\nu}$'s can be calculated easily from the relations:

$$\gamma_{\mu\mu}(sp^3, V_4)=I_\mu(sp^3, V_4)-A_\mu(sp^3, V_4)$$
$$=I_\mu(sp^3, V_4)-I_\mu(sp^4, V_3)$$
$$a_{\mu\mu}=14.3949/\gamma_{\mu\mu}$$

and

$$a_{\mu\nu}=2a_{\mu\mu}a_{\nu\nu}/(a_{\mu\mu}+a_{\nu\nu})$$

Thus, in this SCF procedure, the I_μ's and $\gamma_{\mu\nu}$'s become functions of $P_{\mu\mu}$'s from their dependence on Z_μ's. We have applied this method to *p*-PDA.

Results and Discussion

The Hückel MO's and MO energies of aniline and isomeric PDA's are given in Appendix I. The numberings of the atoms in these molecules are given in Fig. 1. The MO's and MO energies of TAB are given elsewhere.[16] C_{2v} symmetry is assumed for aniline, *o*- and *m*-PDA, while D_{2h} symmetry is assumed for *p*-PDA.

Using these Hückel MO's, the electronic spectrum of *p*-PDA was calculated, assuming various β_{CN} values as described in the Method-of-Calculation section. The results are indicated in Fig. 2. The observed excitation energy to the lowest excited singlet state of *p*-PDA is nearly 4 eV. This value can be repoduced by taking either $\beta_{CN}=-1.2$ eV. or $\beta_{CN}=-3.6$ eV. However, with $\beta_{CN}=-1.2$ eV. the disagreement between the calculated and observed values of the excitation energy to the second excited singlet state is considerable (observed value

$\sim$5 eV.). Accordingly, $\beta_{CN}=-3.6$ eV. has been chosen in this approximation.

A Comparison of the Calculated with the Observed Spectra. — Using this β_{CN} value, the electronic spectrum of aniline has been calculated and a more extensive CI calculation of *p*-PDA than that given in Fig. 2 has been carried out. The calculated results are shown in Table I, together with the observed values.

The calculated excitation energies are a little larger than the observed values. The calculated relative spacing among $^1A_g^+$, $^1B_{3u}^-$ and $^1B_{2u}^+$ states of *p*-PDA is especially unsatisfactory. That is, the calculated energy difference, $E(^1B_{2u}^+)-E(^1B_{3u}^-)$, is ca. 0.5 eV. larger than the observed value. Even if we use other values for β_{CN} between -2 eV.$\sim$ -3.6 eV., this unsatisfactory result is not very much improved, and with β_{CN} values other than -3.6 eV., the agreement between the observed and calculated excitation energies to the $^1B_{3u}^-$ state become worse, as can be seen from Fig. 2. Thus, the present approximation seems to give rather unsatisfactory results. The reason for this may be the use of too large a value for I_n or F_{NN}, as has already been discussed in the Method-of-Calculation Section. Accordingly, we have tried the next approximation, i. e., the use of Eq. 18. The electronic spectra of aniline and *p*-PDA as

* The observed values are taken from Ref. c of Table I.

well as those of *o*- and *m*-PDA have been calculated with this approximation.

The calculated results are shown in Table II, where the observed results for *o*- and *m*-PDA are given for purposes of comparison.

One can see from Tables I and II that the agreement between the calculated and the observed excitation energies is more satisfactory in Approximation B than in Approximation A, although less extensive configuration interactions are invoked to obtain the results given in Table II.

The calculation predicts that the excitation energies to the lowest excited singlet states of *o*- and *m*-PDA will be larger than that of *p*-PDA; this is in accordance with the observed results. Furthermore, the values of the excitation energies themselves, as well as the relative spacings among the excited states, are given correctly.* These results appear to support the agreements described in Sec. II against Approximation A. However, the procedure of Approximation B seems to be rather arbitrary. Therefore, we have examined a more "theoretical" procedure, i. e., the VESCF method, in the case of *p*-PDA.

The calculated spectrum and the VESCF MO's are given in Table III and Appendix II respectively. The β_{CN} value used in this calculation was the same as that in Approximation B.

As one can see from Table III, the calculated excitation energies are a little smaller than the observed values, although the energy difference between the $^1B_{2u}{}^+$ and $^1B_{3u}{}^-$ states is correctly given. It seems to be possible that one can fit the observed spectrum if one selects a somewhat different β_{CN} value and repeats the SCF calculation. However, we shall not attempt such a calculation here, for this is quite a laborious procedure.

* Quite recently, the electronic spectrum of aniline has been examined in detail up to the vacuum ultraviolet region (K. Kimura, H. Tsubomura and S. Nagakura, presented at the 16th Annual Meeting of the Chemical Society of Japan, April, Tokyo, 1963). According to this measurement, the energy difference between $\Psi(^1B_1)_{II}$ and $\Psi(^1A_1)_{II}$ amounts to 0.33 eV. In our present study, it is calculated to be 0.26 eV. in Approximation A and 0.16 eV. in Approximation B.

The Relation between the Simple Hückel MO Calculation and the Present One. — In the present method, the electronic repulsions are explicity taken into consideration in the calculation of the electronic spectra. However, because of the zero differential overlap approximation, the present method appears to be essentially similar to the simple Hückel MO method. Among the matrix elements of the Fock Hamiltonian, the diagonal element, $F_{\mu\mu}$, and the non-diagonal element, $F_{\mu\nu}$, between the nearest neighbor AO's have appreciable values, whereas the $F_{\mu\nu}$ between the more distant neighbors has a very small value. This circumstance corresponds quite well to the fact that, in the simple Hückel MO method, only the Coulomb integral, α, and the resonance integral, β, between the nearest neighbor AO's are taken into account. Furthermore, the $F_{\mu\mu}$ values for the ring carbons are not very different from each other throughout the mono-, di- and tri-substituted aminobenzenes. The $F_{\mu\mu}$ values for the ring carbons of these compounds are in the range -5.5 eV.~ -6 eV.; the average value is ~ -5.8 eV. This value is rather close to that of the alternant hydrocarbon, -6 eV.

$F_{\mu\mu}$ in Eq. 4 can be rewritten as:

$$F_{\mu\mu} = -(I_\mu + A_\mu)/2 + (P_{\mu\mu}-1)\cdot\gamma_{\mu\mu}/2 + \sum_{\kappa\neq\mu}(\delta Q_\kappa)\gamma_{\mu\kappa} \qquad (14)$$

where $\delta Q_\kappa = (P_{\kappa\kappa} - Z_\kappa)$. When the μth atom is one of the ring carbons, this equation can be further rewritten as:

$$F_{\mu\mu}(\mathrm{C}) = -(I_\mu + A_\mu)/2 - (\delta Q_\mu)\cdot\gamma_{\mu\mu}/2 + \sum_{\kappa}^{\mathrm{all}}(\delta Q_\kappa)\cdot\gamma_{\mu\kappa} \qquad (15)$$

If the electron distribution of the parent hydrocarbon is not very much disturbed by the substitution, the $F_{\mu\mu}(\mathrm{C})$ value may be close to $-(I_\mu + A_\mu)/2$, the $F_{\mu\mu}(\mathrm{C})$ value of the parent hydrocarbon, because the δQ values are small in this case.

As has been described above, this circumstance seems to hold approximately, even in the case of amino-substituted benzenes, in spite of the great conjugation power of the amino group. We can expect that $F_{\mu\mu}(\mathrm{C})$ will become smaller when the Hückel MO parameter, δ_N, becomes smaller. Actually, if we assume $\delta_N \sim 0.8$ in the case of TAB, $F_{\mu\mu}(\mathrm{C})$ becomes ca. -5.0 eV.

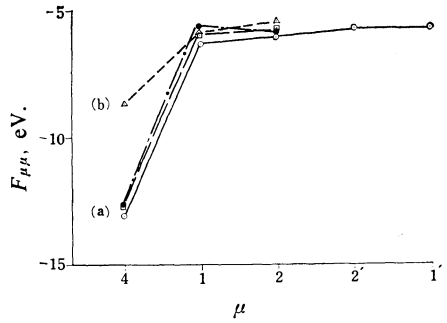

Fig. 3. $F_{\mu\mu}$ values of some aminobenzenes.
(a) Approximation A. —— Aniline
— — *p*-PDA —·— TAB
(b) VESCF approximation for *p*-PDA.
$\mu=7$ is for the amino group of TAB.

Some examples of the $F_{\mu\mu}$ values in aminobenzenes are shown in Fig. 3.

As has been described at the beginning of this article, we have calculated the electronic spectra and electronic structures of some aminobenzenes protonated on the ring carbon, employing the localization model.[16] In this case, for example in the benzenium ion, four electrons move in the field of five positive carbon cores. Therefore, the core field is much stronger in this case than in the case of neutral aminobenzene molecules, although, again in this case, we can observe that the $F_{\mu\mu}$(C) values are fairly uniform. Namely, $F_{\mu\mu}(C) \approx -10\pm0.5$ eV., throughout aniline protonated on para-carbon, *m*-PDA protonated on the carbon atom at the ortho-position to both amino groups and $TABH^+$. This $F_{\mu\mu}$(C) value is rather close to the average $F_{\mu\mu}$(C) value of the benzenium ion, -10.5 eV.

The non-diagonal matrix element, $F_{\mu\nu}$(C), between the nearest neighbor carbon AO's may be rewritten as:

$$F_{12}(C) = \beta_{12} - \frac{1}{2}(P^0_{12} + \Delta P_{12})\gamma_{12}$$

$$= F^0_{12} - \frac{1}{2}(\Delta P_{12})\cdot\gamma_{12} \qquad (16)$$

where F^0_{12} is the matrix element of the parent hydrocarbon because, in the present approximations except for the VESCF method, the β_{12} and γ_{12} are the same as those of the parent hydrocarbon.

We can observe that the F_{12}(C) values are not very different from each other throughout the aminobenzene molecules. The average value for these molecules is -4.063 eV.; this is close to the F_{12}(C) value for benzene, -4.1538 eV. However, as Fig. 4 shows, we can observe a definite linear relation between the F_{12}(C) value averaged over all the nearest neighbor pairs of an aminobenzene and the

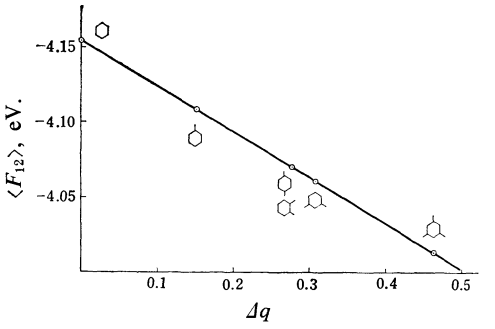

Fig. 4. $\langle F_{12}\rangle_{AV}$ versus Δq relation for aminobenzenes.

Δq value, the total of the charge which has migrated to the ring from the substituents.

Because the F_{12}(C) value in the present approximation is essentially determined by the P_{12} value, this fact indicates the linear relation between Δq and P_{12} averaged over all the nearest neighbor μ-ν pairs ($\langle P_{12}\rangle$), as is shown in Fig. 5.

Remarks on the Relations among the Charge Migrations, Bond Orders and the Extra Delocalization Energies. — As Fig. 5 shows, the linear relation between $\langle P_{12}\rangle$ and Δq seems to

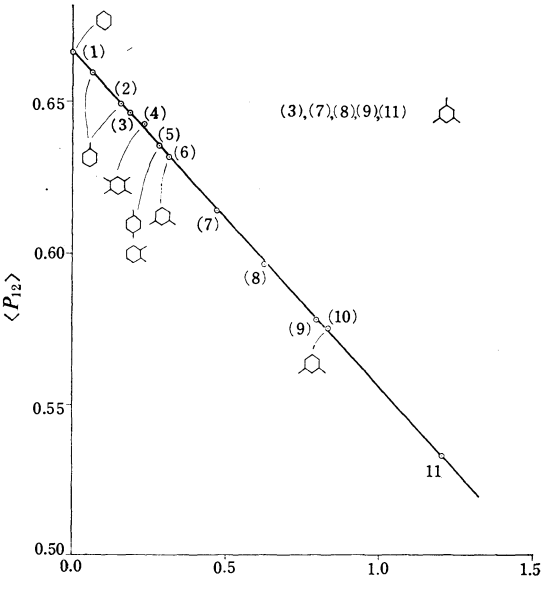

Fig. 5. $\langle P_{12}\rangle$ versus Δq relation for some substituted benzenes.
(1), (3), (4): $\delta_X=1.5$, $\beta_{CX}=0.7\beta$
(2), (5), (6), (7): $\delta_X=1.2$, $\beta_{CX}=\beta$
(8): $\delta_X=0.8$, $\beta_{CX}=\beta$
(9): $\delta_X=0.5$, $\beta_{CX}=\beta$
(10), (11): $\delta_X=0$, $\beta_{CX}=\beta$
The values for the case of $\delta_X=1.5$ and $\beta_{CX}=0.7\beta$ are taken from Ref. 27 and others are calculated by the present author.

hold almost exactly, at least in the case of the benzene derivatives, because the number of the substituents and the Coulomb parameter δ_X are varied from 1 to 4 and from 0 to 1.5 respectively, and the parameters for the resonance integral, β_{CX}, are of two kinds, 0.7 and 1.0.

Thus, the linear relation in this case can be expressed as;

$$\langle P_{12}\rangle = \langle P_{12}\rangle_0 - (0.11)\cdot \Delta q \qquad (17)$$

where $\langle P_{12}\rangle_0 = 2/3$, the bond order of benzene.

Furthermore, we can see an almost complete linear relation between the extra-delocalization energy (vertical), $\Delta\varepsilon$ and Δq, as can be seen from Fig. 6. The $\Delta\varepsilon$ versus Δq relation in Fig. 6 involves various amino-substituted nitrogen heterocycles in addition to the amino-substituted benzenes. The Hückel MO parameters for the amino group of the former compounds are the same as those of aminobenzenes, and the parameters for the ring nitrogen are the same as were used before,[18] i. e., $\delta_N = 0.5$ and $\beta_{CN} = \beta$. The analogous linear relation between $\Delta\varepsilon$ and Δq has already been demonstrated for hydroxy derivatives of benzene and naphthalene, assuming $\delta_O = 1.5$ and $\beta_{CO} = 0.7\beta$.[27]

Qualitatively speaking, we can expect a larger Δq value, the greater the $\Delta\varepsilon$ value, in accordance with the concept of the intra-

$\Delta\varepsilon$ is in unit of $-\beta$.

molecular charge transfer interaction.[7,8,11,28] Furthermore, we can anticipate a smaller $\langle P_{12}\rangle$ value, the larger the Δq value, because the charge is transferred from the substituents to the antibonding orbitals of benzene or *N*-heterobenzenes.

As we can see from Appendix I and Figs. 5 and 6, the $\Delta\varepsilon$, Δq and $\langle P_{12}\rangle$ values of substituted benzenes are approximately proportional to the number of the substituents when the same parameter value is used for the substituents. This fact suggests that we may be able to derive such a proportionality relation by the perturbation method. However, this proportionality and the linear relations seem to be rather peculiar, especially in view of the strong conjugation power of the amino group, which probably invalidates perturbation calculation. Nevertheless, we will examine here whether such a perturbation calculation is possible or not in the case of amino-substituted alternant hydrocarbons.

Now, the energy matrix for the secular determinant may be written as follows according to the LCMO approximation:

$$\begin{pmatrix}
\varepsilon_1^b & & & & \eta_{11}^b \cdots & \eta_{1\sigma}^b \cdots & \eta_{1n}^b \\
& \ddots & & & \vdots & \vdots & \vdots \\
& & \varepsilon_j^b & & \eta_{j1}^b \cdots & \eta_{j\sigma}^b \cdots & \eta_{jn}^b \\
& & & \ddots & \vdots & \vdots & \vdots \\
& & & \varepsilon_m^b & \eta_{m1}^b \cdots & \eta_{m\sigma}^b \cdots & \eta_{mn}^b \\
& & & & \eta_{11}^a \cdots & \eta_{1\sigma}^a \cdots & \eta_{1n}^a \\
& & & & \vdots & \vdots & \vdots \\
& & & & \eta_{j1}^a \cdots & \eta_{j\sigma}^a \cdots & \eta_{jn}^a \\
& & & & \vdots & \vdots & \vdots \\
& & & & \eta_{m1}^a \cdots & \eta_{m\sigma}^a \cdots & \eta_{mn}^a \\
& & & & \lambda_1 & & 0 \\
& & & & & \ddots & \\
& & & & & \lambda_\sigma & \\
& & & & 0 & & \ddots
\end{pmatrix} \qquad (18)$$

In Eq. 18, the ε^a's and ε^b's are the orbital energies of the antibonding and bonding orbitals of the hydrocarbon respectively, and the λ_σ's are those of the lone pair orbitals of the substituents. $\eta_{j\sigma}$ is the matrix element between the jth MO ψ_j of the hydrocarbon and the lone pair orbital, θ_σ, of the σth substituent; that is,

$$\eta_{j\sigma}^a = \int \psi_j^a \mathscr{H}_{\text{eff}} \theta_\sigma \mathrm{d}\tau$$

$$\eta_j^b = \int \psi_j^b \mathscr{H}_{\text{eff}} \theta_\sigma \mathrm{d}\tau$$

If $(\varepsilon_1^b)'$, $\cdots$, $(\varepsilon_m^b)'$, $(\varepsilon_1^a)'$, $\cdots$, $(\varepsilon_m^a)'$, $\cdots$, and $(\lambda_1)'\cdots(\lambda_n)'$ are the exact solutions of the secular equation, then, because of the invariance of trace,

27) K. Nishimoto, This Bulletin, **32**, 445, 699 (1959).

28) S. Nagakura, *Mol. Phys.*, **3**, 105 (1960).

$$\sum_j^m[(\varepsilon_j^a)'+(\varepsilon_j^b)']+\sum_\sigma^n(\lambda_\sigma)'$$

$$=\sum_j^m[\varepsilon_j^a+\varepsilon_j^b]+\sum_\sigma^n\lambda_\sigma \quad (19)$$

Accordingly,

$$\Delta\varepsilon=2\sum_j^m[\varepsilon_j^b-(\varepsilon_j^b)']+\sum_\sigma^n[\lambda_\sigma-(\lambda_\sigma)']$$

$$=2\sum_j^m[(\varepsilon_j^a)'-\varepsilon_j^a] \quad (20)$$

If we approximate $(\varepsilon_j^a)'$ by the second order perturbed energy, then, from Eq. 18,

$$(\varepsilon_j^a)'\cong\varepsilon_j^a+\sum_\sigma^n(\eta_{j\sigma}^a)^2/(\varepsilon_j^a-\lambda_\sigma) \quad (21)$$

From 20 and 21,

$$\Delta\varepsilon\cong2\sum_j^m\sum_\sigma^n(\eta_{j\sigma}^a)^2/(\varepsilon_j^a-\lambda_\sigma)$$

$$=2\sum_j^m\sum_\sigma^n(c_{js}^a\beta_{s\sigma})^2/(\varepsilon_j^a-\lambda_\sigma) \quad (22)$$

In deriving Eq. 22, we have used the ordinary approximation,

$$\eta_j^a=\int\psi_j^a\mathscr{H}_{\text{eff}}\theta_\sigma d\tau$$

$$=\sum_\mu c_{j\mu}^a\int\phi_\mu\mathscr{H}_{\text{eff}}\theta_\sigma d\tau\cong c_{js}^a\beta_{s\sigma} \quad (23)$$

where σth substituent is attached to the sth carbon.

In the case of aminobenzenes, Eq. 22 can be further simplified as follows:

$$\Delta\varepsilon=2\beta^2[\sum_s(c_{1s}^a)^2/(\varepsilon_1^a-\lambda)$$

$$+\sum_s(c_{2s}^a)^2/(\varepsilon_2^a-\lambda)+\sum_s(c_{3s}^a)^2/(e_3^a-\lambda)]$$

$$=(0.407)\cdot n_s\cdot(-\beta) \quad (24)$$

where n_s is the number of the substituents; this equation holds almost exactly.

The approximate MO corresponding to 21 may be written as:

$$(\psi_j^a)'\cong\psi_j^a+\sum_\sigma^n(\eta_{j\sigma}^a)\theta_\sigma/(\varepsilon_j^a-\lambda_\sigma)$$

and the normalized form of $(\psi_j^a)'$ is:

$$(\psi_j^a)'\cong[\psi_j^a+\sum_\sigma^n(\eta_{j\sigma}^a)\theta_\sigma/(\varepsilon_j^a-\lambda_\sigma)]/$$

$$[1+\sum_\sigma^n\{\eta_{j\sigma}^a/(\varepsilon_j^a-\lambda_\sigma)\}^2]^{1/2} \quad (25)$$

If (ψ_j)''s are the exact solutions of the secular equation, there exists the following relation for the coefficients, $c_{j\sigma}$'s, of θ_σ:

$$\sum_j^{m+n}(c_{j\sigma}^b)^2+\sum_j^m(c_{j\sigma}^a)^2=1$$

Accordingly,

$$\Delta q=2[n_s-\sum_j^{m+n}\sum_\sigma^n(c_{j\sigma}^b)^2]=2\sum_j^m\sum_\sigma^n(c_{j\sigma}^a)^2 \quad (26)$$

From 23, 25 and 26, the expression for Δq may be written as:

$$\Delta q\cong2\sum_j\left[\frac{\sum_s(c_{js}^a)^2}{(\varepsilon_j^a-\lambda)^2}\cdot\left\{1+\frac{\sum_s(c_{js}^a)^2}{(\varepsilon_j^a-\lambda)^2}\right\}^{-1}\right] \quad (27)$$

where $\lambda_\sigma=\lambda=1.2$.

If we neglect the second term in the curled bracket compared to 1, then Eq. 27 can be rewritten in the following form:

$$\Delta q\cong(0.170)\cdot n_s \quad (28)$$

However, because the exact value of Δq for aniline is 0.155, Eq. 34 is not a very good approximation.

If we use Eq. 27, the Δq values are calculated to be 0.160, 0.317 and 0.467 for aniline, *m*-PDA and TAB respectively. These values are fairly close to the exact values and are approximately proportional to the number of substituents.

Thus the linear relation between $\Delta\varepsilon$ and Δq and the proportionality of these quantities to n_s in the case of aminobenzenes can be accounted for approximately by the perturbation method.** However, when smaller δ_X values are used, the perturbation method becomes quite a poor approximation.

The calculation of $\langle P_{12}\rangle$ by the perturbation method gives quite poor results. In any way, we cannot explain the linear relation between $\langle P_{12}\rangle$ and Δq for the wide range of parameter values shown in Fig. 5.

The MO of a substituted benzene can be written in the LCMO form as follows:

$$\psi_i=\sum_{j=1}^6c_{ij}\psi_j^B+\sum c_{i\sigma}\theta_\sigma \quad (29)$$

where $\psi_1^B\cdots\psi_6^B$ are the MO's of benzene from the lowest bonding to the highest anti-bonding orbitals.

From Eq. 29, we can derive the following equation;

$$6\cdot\langle P_{12}\rangle=\sum_i^v(2c_{i6}^2+c_{i4}^2+c_{i5}^2)$$

$$-\sum_i^v(2c_{i1}^2+c_{i2}^2+c_{i3}^2) \quad (30)$$

where $\sum_i^v$ means the summation over the vacant orbitals of the substituted benzene.

** The following points should be noted here. In several parts of this paper, we have insisted that the perturbation method in the sense of the expansion of the secular determinant in a series seems to be a poor approximation for amino-substituted aromatics. The calculation of the orbital energies and MO's themselves for the occupied orbitals of these compounds by the perturbation method is certainly a very poor approximation. Therefore, we cannot use the perturbation method for the calculation of the electronic spectra. However, we can use this method to calculate some ground state quantities, such as $\Delta\varepsilon$ and Δq, expanding only the unoccupied orbitals which are affected only slightly by the substitution.

On the other hand, the expression for Δq can be written as:

$$\Delta q = 2\sum_{i}^{v}\sum_{\sigma} c_{i\sigma}^2 = 2\sum_{i}^{v}(1-\sum_{j=1}^{6} c_{ij}^2)$$
$$= 6 - 2\sum_{i}^{v}(2c_{i1}^2 + c_{i2}^2 + c_{i3}^2)$$
$$- 2\sum_{i}^{v}(2c_{i6}^2 + c_{i4}^2 + c_{i5}^2) + 2\sum_{i}^{v}(c_{i1}^2 + c_{i6}^2) \quad (31)$$

From 30 and 31 we can derive the following relation between $\langle P_{12}\rangle$ and Δq:

$$\langle P_{12}\rangle = 0.5 + \sum_{i}^{v}(c_{i1}^2 + c_{i6}^2)/6$$
$$- \sum_{i}^{v}(2c_{i1}^2 + c_{i2}^2 + c_{i3}^2)/3 - \Delta q/12 \quad (32)$$

When the ionization potential of the lone pair orbital of the substituent becomes infinitely large, Δq, $\sum_{i}^{v} c_{i1}^2$ and $\sum_{i}^{v}(2c_{i1}^2 + c_{i2}^2 + c_{i3}^2)$ approach zero, and $\sum_{i}^{v} c_{i6}^2$ approaches 1. Thus $\langle P_{12}\rangle$ becomes the bond order of benzene, 2/3.

Even in the case of amino-substituted benzene, $\sum_{i}^{v}(c_{i1}^2 + c_{i6}^2)$ may perhaps be close to unity and $\sum_{i}^{v}(2c_{i1}^2 + c_{i2}^2 + c_{i3}^2)$, to zero. For example, in the case of aniline, $\sum_{i}^{v}(c_{i1}^2 + c_{i6}^2) = 0.986$, $\sum_{i}^{v}(2c_{i1}^2 + c_{i2}^2 + c_{i3}^2) = 0.007$, and $\sum_{i}^{v}(c_{i1}^2 + c_{i6}^2) = 0.971$, while $\sum_{i}^{v}(2c_{i1}^2 + c_{i2}^2 + c_{i3}^2) = 0.014$ for *m*-PDA. Thus, the sum of the first two terms in the right-hand side of Eq. 32 is approximately equal to the bond order of benzene, and the sum of the 3rd and the fourth terms may be close to $(0.1)\cdot\Delta q$.

In this way, we can "*understand*" to some extent the linear relation between $\langle P_{12}\rangle$ and Δq, although this is not a "*proof*" of the relation in Eq. 17, which holds for a wide range of Hückel MO parameters.

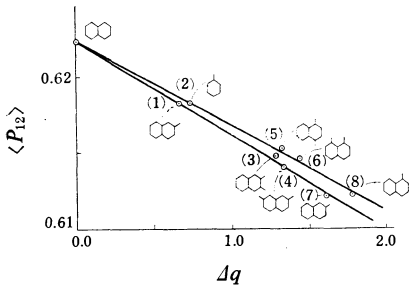

Fig. 7. $\langle P_{12}\rangle$ versus Δq relation for some substituted naphthalenes.
(1)—(6): $\delta_X = 1.5$, $\beta_{CX} = 0.7\beta$ (Taken from K. Nishimoto and R. Fujishiro, This Bulletin, **35**, 390 (1962) and Ref. 27)
(7), (8): $\delta_X = 1.2$, $\beta_{CX} = \beta$ (Taken from Ref. 9)

This sort of approximate linear relation between $\langle P_{12}\rangle$ and Δq holds not only for the benzene derivatives but also for the naphthalene derivatives, as Fig. 7 shows, although there is a slight difference between the α- and β-derivatives in this case.

A Comparison of the Calculated Dipole Moments of Aniline in the Ground State, as Well as in the Excited State, with the Experimental Values. — Using the wave functions given in Tables I and II, we have calculated the π-moment of aniline and compared it with the observed values.

The theoretical expression for the dipole moment in terms of the state function, Ψ, is given by:

$$\vec{\mu} = \langle \Psi | \boldsymbol{M} | \Psi \rangle \quad (33)$$

where $\boldsymbol{M} = \sum_{\tau} e_\tau \boldsymbol{r}_\tau$

e_τ and $\boldsymbol{r}_\tau$ are the charge and the position vector of τth particle respectively. In the π-electron approximation, $\boldsymbol{M}$ can be separated into two parts:

$$\boldsymbol{M} = e\sum \boldsymbol{r}_\lambda + \sum e_\kappa \boldsymbol{r}_\kappa$$

The first summation is over π-electrons, and the second, over the cores.

The necessary formulas for the expansion of 33 have been given elsewhere.[17a,29]

The ground state dipole moment of aniline has been calculated to be:

2.20 D. (Approximation A)

and 1.72 D. (Approximation B)

On the other hand, from the experimental value Smith[30] has estimated the π-moment of aniline to be $\sim$1.67 D., which is very close to the value calculated with Approximation B.

In addition to this study of the ground state dipole moment, we have calculated the π-moment in the lowest-excited singlet state.

On the other hand, we can use the difference between the solvent shifts of the absorption and fluorescence spectra in order to get experimental information on the electronic structure of the excited molecule.[29,31,33]

We have measured the absorption and fluorescence spectra of aniline in several solvents. The light source for the fluorescence measurement was a 300 W. Xenon discharge

29) N. Mataga, This Bulletin, **36**, 654 (1963).
30) J. W. Smith, *J. Chem. Soc.*, **1961**, 81.
31) N. Mataga et al., This Bulletin, **28**, 690 (1955); **29**, 465 (1956).

33) E. G. McRae, *J. Phys. Chem.*, **61**, 562 (1957).

tube with a stabilizer. The fluorescence was excited at 285 mμ, the monochromatic exciting light from the Xenon discharge tube being taken out by a quartz prism monochromator. Aniline, which had been purified[34] by the standard method and stored in a vacuum and in a dark place, was distilled in a vacuum before use. The other details of the experimental procedures have been described elsewhere.[29,35]

Using the experimental results given in Table IV and by means of the following equation,[31,32] we can estimate the difference between the dipole moment in the excited state ($\vec{\mu}_e$) and that in the ground state ($\vec{\mu}_g$); i. e., $\vec{\Delta\mu}=(\vec{\mu}_e-\vec{\mu}_g)$, where the excited state is the fluorescence state.

$$hc(\sigma_a^m-\sigma_f^m)\simeq\text{Const.}+2\left[\frac{D-1}{2D+1}-\frac{n^2-1}{2n^2+1}\right]\frac{(\vec{\Delta\mu})^2}{a^3} \quad (34)$$

In Eq. 34, σ_a^m and σ_f^m are the wave numbers of a peak of the fluorescence band and that of the corresponding absorption band respectively. D and n are the dielectric constant and the refractive index of the solvent respectively, and a is the cavity radius in Onsager's theory of the reaction field.

TABLE IV. THE WAVE NUMBERS OF THE BAND MAXIMA OF ANILINE IN SEVERAL SOLVENTS (in unit of $10^4\,cm^{-1}$)

Solvent	σ_a^m	σ_f^m	$\sigma_a^m-\sigma_f^m$
Cyclohexane	3.48	3.14	0.34
Dichloroethane	3.47	3.07	0.40
n-Butylacetate	3.44	3.00	0.44
Acetonitrile	3.46	2.99	0.47

There are some ambiguities concerning the magnitude of a, although perhaps $a\simeq 2\sim 2.5$ Å. For these a values, $\vec{\Delta\mu}$ values are estimated to be 2~2.5 D. because $(\vec{\Delta\mu})^2/a^3\sim 2000\,cm^{-1}$.

It should be noted here that, if the change in the π-electronic structure induced by the electronic excitation is small, the observed $\vec{\Delta\mu}$ value represents approximately the difference between the π-moment in the excited state and that in the ground state. The theoretical $\vec{\Delta\mu}$ values are calculated as follows:

$\vec{\Delta\mu}=4.82$ D. (Approximation A)

and $\vec{\Delta\mu}=4.12$ D. (Approximation B)

Although the theoretical values are a little larger than the experimental values, their order of magnitudes is the same.

In our previous work[29] on the experimental and theoretical estimation of the $\vec{\Delta\mu}$ values of naphthylamines, it has been argued that the MO calculation may overestimate the $\vec{\Delta\mu}$ values.

If the calculated $\vec{\Delta\mu}$ value in the present case is reduced by multiplying by the same factor as before, i. e., 1/4, then the theoretical value becomes smaller than the experimental value, as was the case in the previous work.

In the case of naphthylamines, it has been suggested that the structure of the amino group changes a little during the life time of the excited state and that this is the cause of the observed value of $\vec{\Delta\mu}$ being larger than the theoretical value.

However, it is not quite certain whether or not the same factor to reduce the calculated $\vec{\Delta\mu}$ value as for naphthylamines is appropriate in the present case. Therefore, we cannot discuss in detail the structural change of the amino group during the life time of the excited state.

Summary

The electronic spectra and electronic structures of amino substituted benzenes have been studied by the semiempirical MO method, with the explicit inclusion of the electron repulsion.

According to the calculated results, we can interpret the difference between the spectra of various poly-substituted aminobenzenes; also, the calculated excitation energies and oscillator strengths are in satisfactory agreement with the observed values.

The relation between the present calculation and the simple Hückel MO calculation has been analyzed. Moreover, several interesting relations between the Hückel MO quantities of substituted benzenes and naphthalenes have been demonstrated and discussed.

The calculated π-moment of aniline in the ground state is in satisfactory agreement with the experimental value. Furthermore, the π-moment of aniline in the lowest excited singlet state has been calculated and compared with the experimental value obtained from the measurement of the solvent shifts of the absorption and fluorescence spectra.

The present author wishes to express his hearty thanks to Dr. Kichisuke Nishimoto and Dr. Shizuyo Mataga for their helpful discussions.

The Quenching Action of Pyridine and Quinoline on the Fluorescence of Naphthalene Derivatives

By Takuji MIWA and Masao KOIZUMI

(Received June 19, 1963)

The influence of the hydrogen bond on the fluorescent properties of aromatic compounds has been studied by seveval authors, including Mataga and Koizumi,[1] Kasha[5] and Weller.[6] Mataga particularly has performed some systematic studies using various combinations of acceptor and donor.[1-4] One of his most interesting findings is that an aromatic fluorescer is strongly quenched when it is hydrogen-bonded directly with another π-electronic system. Thus, for example, the fluorescence of naphthol and acridine is largely quenched by, respectively, pyridine and phenol. He has proposed, as a mechanism for such a quenching process, that the charge transfer from quencher to fluorescer or from fluorescer to quencher via the hydrogen bond occurs, followed by the vibronic energy dissipation. In connection with this hypothesis, it seemed interesting to extend the study to systems in which the possibility of an electronic energy transfer via the hydrogen bond is conceivable. In such cases there is also a possibility that the quenching efficiency depends on the wavelength of the exciting light. Very few examples of such systems have ever been studied, perhaps because the complicated character of such systems is supposed to make the analysis of the results very troublesome.

We have sttempted such an experiment using naphthol and naphthylamine as hydrogen-donating fluorescers and quinoline, as a hydrogen-accepting quencher; for the sake of comparison, we have also studied the effect of quinoline on the fluorescence of 2-naphthylmethylether and *N, N*-dimethyl-2-naphthylamine, both of which are unable to form hydrogen bonds. We have found appreciable quenching, even in the latter cases. In connection with these rather unexpected results, therefore, some experiments have been made with the use of pyridine as a quencher, and, further, the solvent effect has been studied to some extent.

Experimental

Materials.—*2-Naphthylamine.* — A G. R. sample was dissolved in dilute hydrochloric acid, filtered, and neutralized by soduim hydroxide. The precipitate obtained, after being filtered and dried, was submitted to repeated crystallization from a water-ethanol mixture and to sublimation in vacuo.

N, N-Dimethyl-2-naphthylamine. — The mixture of methyl iodide and 2-naphthylamine, with sodium hydroxide added, was heated for ten hours at 120°C in a sealed vessel. The product was extracted by chloroform, and the raw crystal was obtained by evaporating the solvent. For further purification, recrystallization from methanol and sublimation under reduced pressure were repeated several times (m. p. 43.2°C).

2-Naphthol.—A G. R. sample was recrystallized from a water-ethanol mixture and sublimed in vacuo.

2-Naphthylmethylether. — A concentrated sulfuric acid solution of 2-naphthol and methyl alcohol was refluxed for four hours at 125°C. The product was extracted by benzene and washed with an aqueous alkaline solution until no existence of a phenolic hydroxy group was detected by a Millon test. The crystal obtained by evaporating the solvent, after several recrystallizations from ethanol, was dried in a calcium chloride desiccator (m. p. 72.1°C).

Quinoline. — Synthesized quinoline manufactured by Tokyo Kasei was dried over barium oxide for more than a week and was twice distilled in vacuo.

Pyridine.—A G. R. reagent of Wako-Junyaku was dehydrated by making the azeotrope with benzene. Ordinary distillation, fractional distillation with a packed column and vacuum distillation were performed in succession.

n-Hexane.—After being shaken for a long time with fuming sulfuric acid diluted with concentrated sulfuric acid, this was washed with water, neutralized with an aqueous alkaline solution, treated with alkaline potassium permanganate, washed again with water, and then dried over calcium chloride. It was further distilled from over sodium metal or phosphorous pentoxide. The fraction (67.5~68.5°C) was used.

Benzene.—A G. R. sample of Wako-Junyaku was shaken with concentrated sulfuric acid, treated with an aqueous alkaline solution, washed with water, and then dried over calcium chloride. Three recrystallizations in a ice bath and fractional distillation through a packed column were performed.

Ethanol.—A G. R. sample of Wako-Junyaku was fractionally distilled through a column packed with stainless spirals.

Anthracene.—A sample of a high purity was kindly supplied by Professor Shimpachiro Kato of the University of Tokyo.

The purity of 2-naphthylmethylether and of *N*, *N*-dimethyl-2-naphthylamine was checked by I. R., while that of pyridine and quinoline was checked by gas chromatography.

Apparatus.—A block diagram of fluorometer is shown in Fig. 1.

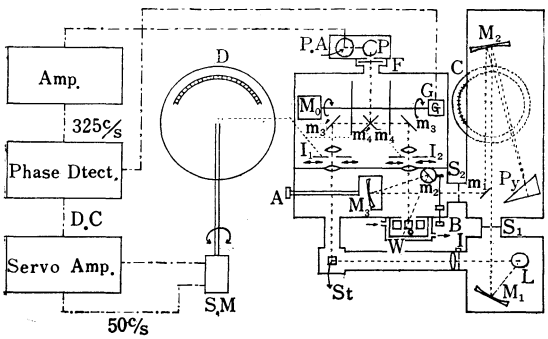

Fig. 1. Fluorometer.

A: priamplifier, Py: prism. S_1, S_2: slit, S. M: reversible motor, St: standard material, W: water jacket

This apparatus is constructed in such a way that the solution is illuminated obliquely from the front, the exciting light being focused close to the cell. The fluorescent light coming out from the same front is compared with a standard beam taken through another path from the same light source; by mechanically balancing the intensity of the two beams, the ratio of the two can be read directly on a scale-disk. The apparatus is suitable for systems with a large optical density. The exciting light from a 500W Xenon lamp of Ushio Kogyo was made monochromatic by a prism monochromator. A RCA 1P28 photomultiplier was used. The absorption spectra were measured by means of a Hitachi spectrophotometer, and the fluorescence spectra, by the same apparatus with its fluorescence attachments.

The Procedure, the Calibration of the Apparatus and an Outline of the Analysis.—The measurement was made in the following way. The relative intensity against the standard light beam was measured with a solution containing only a fluorescer and with a solution containg the same concentration of fluorescer and various amounts of quencher at the same time. From these measurements the ratio of the former, F_0, to the latter, F, was calculated. The measurement was made at constant temperatures and at various wavelengths in the region from 260 to 350 mμ. The concentration was 10^{-3} M for 2-naphthylamine and *N*, *N*-dimethyl-2-naphthylamine, and 2.5×10^{-3} M for 2-naphthol and 2-naphthylmethylether. The concentration of quencher was varied over a suitable range according to the situations.

After the scale of the intensity ratios and of the wavelengths had been calibrated in a suitable way, the depth effect or the effect of the optical density of the system on the measured fluorescence intensity was examined. This effect is, of course, mainly due to the quantity of the absorption of light, but it is expected that the effect partially depends on the geometric condition characteristic of the apparatus. Thus, the emitting position varies according to the optical density of the solution, thereby affecting the measured intensity. This effect is expected to be especially large when the optical density is rather small and when the exciting beam penetrates into the inner part of the solution. This is the reason why the experimental calibration is desirable.

To examine this effect quantitatively, the solution of anthracene in *n*-hexane was used as a sample for calibration, since it has been well established by many investigations[7-9,10] that its fluorescence

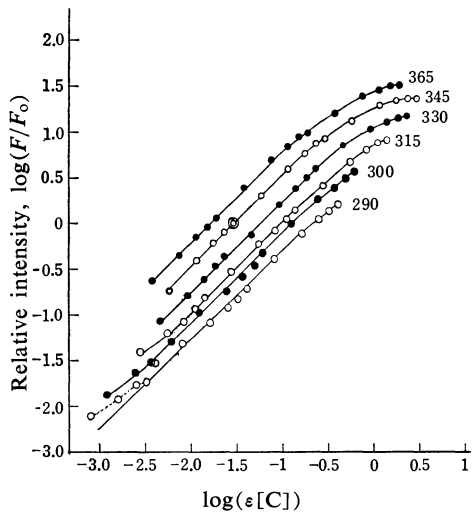

Fig. 2. Relation between fluorescence intensity and optical density for the solution of anthracene in *n*-hexane. All the (F/F_0) values are the relative ones, the value for 10^{-5} M anthracene solution at 345 mμ being taken as a standard (denoted by ◎ in the figure). The number is exciting wavelength (mμ).

quantum yield is independent of the wavelength[8] and that, further, its concentration quenching is practically of no importance up to about 10^{-3} M.[9] Moreover, the experimental conditions quite similar to those for the systems to be studied can be chosen. Actually the concentration of anthracene in *n*-hexane was varied from 2×10^{-6} M to 10^{-3} M. The relations obtained between the optical density of the solution and the measured fluorescence intensity are shown in Fig. 2.

The dependence of the position of the curves on the frequency is no doubt due to the intensity distribution of the exciting light. In the region of low optical density, all the curves have the same unit slope, while they tend to constant values characteristic for each frequency. The latter phenomena are mainly due to the situations approaching the complete absorption of exciting light. In fact, the plot of $\log(F/F_0)$ against $\log(1-e^{-2.303\varepsilon[C]})$ gives a straight line, with a unit slope for each frequency. From the results in Fig. 2 one can estimate the intensity distribution of the exciting light. In most of the experiments the optical density was so high that the intensity of the fluorescence was believed to be independent of it, but in a few cases where the optical density was lower, the correction factor for the incomplete absorption of light was estimated from Fig. 2.

To interpret the relation between F_0/F and the concentration of the quencher, it is necessary in general to take into account the inner filter effect of the absorption of the quencher, the effect of hydrogen bond formation in the ground state, and lastly, the genuine quenching effect. As has been shown by Mataga[4] and by one of the present authors[11] (M. K.), the quenching effect via the hydrogen bond formation must be treated in just the same way as in the case of dynamical quenching, in contradistinction to the case of the enhancement of fluorescence intensity. The prerequisite for the method of analysis, that is, the complete suppression of fluorescence by hydrogen bonding, is supported by the fact that the fluorescence spectra of naphthylamine and naphthol are not affected by the addition of enough pyridine or quinoline to effect an appreciable change in the absorption spectra of the fluorescer. This fact enables us further to disregard the possibility of the reabsorption of the fluorescence by a quencher due to the slight overlapping of the fluorescence spectra and the absorption spectra of the quencher. In addition, the fluorescence intensity of quinoline is so weak that it can be disregarded in comparison with the fluorescence of 2-naphthylamine and 2-naphthol. Thus, it is most plausible to analyze the experimental results on the basis of the assumption that only free fluorescer molecules can emit fluorescence and that the pyridine or quinoline molecules which attack the excited fluorescer molecules cause the quenching phenomenon. In some cases, however, the influence on the fluorescence due to the inner filter effect of the quencher and the influence of the existence of a hydrogen-bonded complex are so great that it is very difficult to obtain the exact value of the quenching constant. It is desirable that any particular device is, if possible, used case by case.

Results

Absorption Spectra and Fluorescence Spectra.—The absorption spectra of some fluorescers and quenchers and the fluorescence spectra for the former are shown in Fig. 3, a, b, c and d.

The Equilibrium Constant of the Hydrogen Bond Formation in the Ground State.—This was obtained spectroscopically by the usual method. Changes in the absorption spectra in the case of 2-naphthol—pyridine and in the case of 2-naphthol—quinoline, both in *n*-hexane, are shown in Fig. 4, a and b.

The equilibrium constant was evaluated by using the following equation:

$$\frac{d^{\lambda}-d_{o}^{\lambda}}{[A]}=\varepsilon'^{\lambda}K[D_o]-Kd^{\lambda} \qquad (1a)$$

$$K=\frac{[A]\,(d_{o}^{\lambda}-d'^{\lambda})+[A']\,(d^{\lambda}-d_{o}^{\lambda})}{[A]\,[A']\,(d'^{\lambda}-d^{\lambda})} \qquad (1b)$$

where [A] or [A'] and [D_o] denote, respectively, the total concentration of quencher and the total concentration of fluorescer, where d^{λ} or d'^{λ} and d_o^{λ} are the optical densities at the wavelength λ in the presence and in the absence of a quencher respectively, and where ε'^{λ} is the molar extinction coefficient of the hydrogen-bonded complex at λ. As Fig. 5 shows, the 1a relation holds quite satisfactorily.

The values obtained from 1a are given in Table I, together with the pertinent data published in the literature. The values from 1a are in good agreement with the average values obtained numerically from 1b.

TABLE I. THE EQUILIBRIUM CONSTANT K OF THE HYDROGEN BOND FORMATION

System	Solvent	Temp. °C	K
2-Naphthol—Pyridine	*n*-Hexane	21	125
		42	61
	Benzene[2]	14	41
2-Naphthol—Quinoline	*n*-Hexane	21	125
2-Naphthylamine—Pyridine	Cyclohexane[4]	15	12
	Benzene[2]	13	0.2

2-Naphthylamine and *N*, *N*-Dimethy-2-naphthylamine in *n*-Hexane.—In the case of *N*, *N*-dimethyl-2-naphthylamine—quinoline which has no ability to act as a hydrogen donor, there are two factors which must be taken into account: (i) the genuine quenching effect and (ii) the inner filter effect due to the absorption of quinoline. On this basis, F_0/F is expressed as follows:

$$F_0/F=\frac{1-e^{-\alpha_D[D]d}}{1-e^{-(\alpha_D[D]+\alpha_A[A])d'}}\left(\frac{\varepsilon_D[D]+\varepsilon_A[A]}{\varepsilon_D[D]}\right)$$
$$\times(1+k[A])=\frac{1-e^{-\alpha_D[D]d}}{1-e^{-(\alpha_D[D]+\alpha_A[A])d'}}$$
$$\times\left\{1+\left(k+\frac{\varepsilon_A}{\varepsilon_D[D]}\right)[A]+k\frac{\varepsilon_A}{\varepsilon_D[D]}[A]^2\right\} \quad (2)$$

where [D] and [A] are the concentrations of fluorescer and of quencher respectively, where α_D, α_A, ε_D and ε_A are, respectively, the molar absorbancy of fluorescer and quencher and the molar extinction coefficient of fluorescer and quencher, and where k is the quenching constant. The first term on the right side concerns the absorption of light, and its denominator can always be well approximated by 1, while for the numerator this is not always possible in the region where α_D is rather small. The value was estimated from the calibration curves of Fig. 2. F_0/F divided by this value will be denoted as $(F_0/F)_{corr.}$. It is to be added that there is no overlapping of the fluorescence spectra and the absorption spectra of quinoline, even in such a high concentration of the latter as 0.388 M. As required by Eq. 2, the plot of $(F_0/F)_{corr.}-1$ against [A] gives a concave curve upward, while the plot of $((F_0/F)_{corr.}-1)/[A]$ against [A] gives a good straight line, as is shown in Fig. 6.

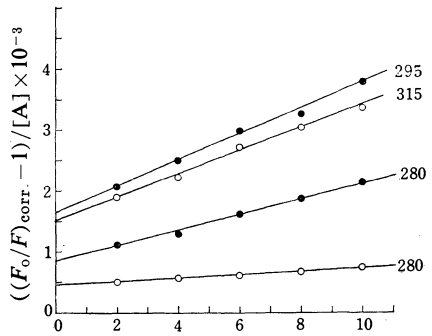

Fig. 6. Plot of $((F_0/F)_{corr.}-1)/[A]$ against the concentration of quinoline [A]. The number is the exciting wavelength (mμ).
● : 2-Naphthylamine (10^{-3} M/l.)—Quinoline in *n*-hexane at 20°C.
○ : *N*, *N*-Dimethyl-2-naphthylamine (10^{-3} M/l.)—Quinoline in *n*-hexane at 20°C.

From the slope and intercept one gets $k\varepsilon_A/\varepsilon_D[D]$ and $k+\varepsilon_A/\varepsilon_D[D]$; k can be evaluated if the values of ε_A and ε_D under the experimental conditions are estimated. In this system, however, the absorption spectra of quinoline do not overlap with those of the fluorescer in the region >335 mμ, and so the correct value of k can be obtained from the linear plot of $(F_0/F)_{corr.}-1$ against [A] at these wavelengths. Thus, in this case,

$$(F_0/F)_{corr.}-1=k[A] \quad (3)$$

The values obtained are $k=90$ (20°C) and $k=100$ (40°C).

This is a result somewhat unexpected, since Mataga[2] found previously that pyridine, the basicity of which is quite similar to quinoline, does not quench the fluorescence of *N*, *N*-dimethyl-2-naphthylamine at all (see Discussion).

In the case of 2-naphthylamine—quinoline, the hydrogen bond is formed with quinoline. However, the equilibrium constant of its formation, as has already been mentioned, is quite small, and under the experimental conditions the change in the absorption spectra due to the hydrogen bond formation is negligible. Therefore, all the effects of hydrogen bond formation such as (i) the increase in the reabsorption of fluorescence, (ii) the decrease in the fluorescence due to the reduced number of free molecules, and (iii) the change in the inner filter effect can be disregarded. Hence Eq. 2 is equally well applicable in this case. In fact, the plot of $(F_0/F)_{corr.}-1$ against [A] gives a concave curve upward, while the plot of $((F_0/F)_{corr.}-1)/[A]\sim[A]$ gives a good straight line (Fig. 6). As in the case of *N*, *N*-dimethyl-2-naphthylamine—quinoline, however, a more exact value of k can be obtained from the results in the $\sim$335 mμ region, where the absorptions of the two substances do not overlap and where Eq. 3 satisfactorily holds. The values obtained are $k=120$ (20°C) and $k=140$ (40°C).

The Frequency Effect on the Quenching Constant in the Cases of 2-Naphthylamine—Quinoline and *N*,*N*-Dimethyl-2-naphthylamine—Quinoline.—Since there is some difficulty in obtaining the correct value of k at various frequencies on the basis of Eq. 2, the dependence of k on the frequency was examined in the following way. From Eq. 2 one can calculate $\varepsilon_D/\varepsilon_A$ if k is assumed to be constant, irrespective of the frequency, and to have the same value as that at 335 mμ, where there is no overlapping of absorptions. If the values of $(\varepsilon_A/\varepsilon_D)$ at various frequencies obtained from the calculation coincide with those from the observed ε_A and ε_D values, one may conclude that there is no frequency effect on k. In the opposite case, one will have to recognize the dependence of k on the frequency. The result is, as Figs. 7 and 8 show, that there is a very good correspondence between the two.

Thus there is no doubt that k is constant, independent of the frequency.

2-Naphthylmethylether and 2-Naphthol in *n*-Hexane.—In the case of 2-naphthylmethylether—quinoline, the absorption spectra of the two substances overlap over the whole wavelength region. Therefore, $\varepsilon_A/\varepsilon_D$ values were estimated from the molar extinction coefficient and k was calculated for various frequencies on the basis of Eq. 2. The value is $k=53$ (21°C), irrespective of the wavelength.

In the case or 2-naphthol—quinoline, there are three kinds of effects which reduce the fluorescence intensity: (i) the genuine quenching action, (ii) the inner filter effect, and

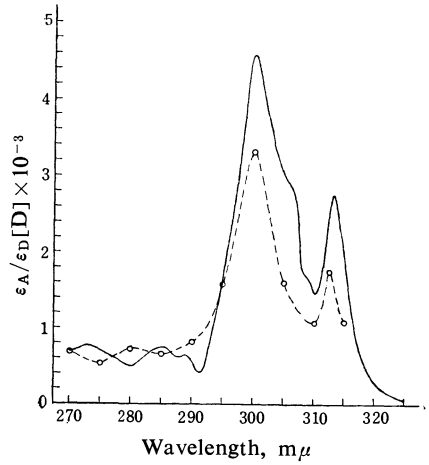

Fig. 7. Inner filter effect for 2-naphthylamine—quinoline in *n*-hexane. Full line and dotted line represent respectively the calculated value $\varepsilon_A/\varepsilon_D[D]$ and the observed value.

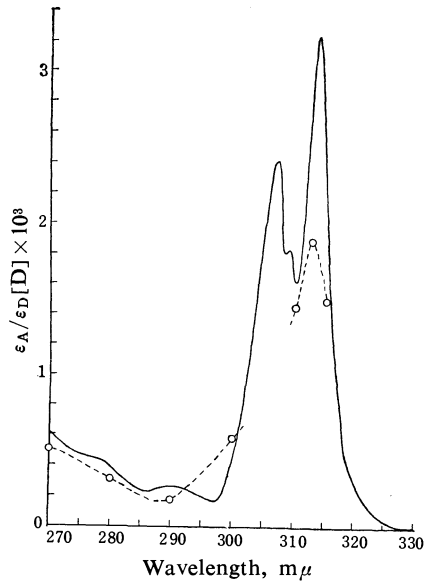

Fig. 8. Inner filter effect for *N*, *N*-dimethyl-2-naphthylamine—quinoline in *n*-hexane. Full line and dotted line represent respectively the calculated value $\varepsilon_A/\varepsilon_D[D]$ and the observed value.

(iii) the formation of the nonfluorescent hydrogen-bond complex in the ground state. Taking these three effects into account, one can derive the following equation:

$$(F_0/F)_{corr.}=(1+k[A])\times\left(1+\frac{\varepsilon_A[A]}{\varepsilon_D[D]}+\frac{\varepsilon_{DA}K}{\varepsilon_D}[A]\right)$$

where K is the equilibrium constant of the

hydrogen bond formation. The above equation is further changed as follows by putting $[D] = [D_o]/(1+K[A])$:

$$(F_o/F)_{corr.}-1=\left(k+\frac{\varepsilon_A+K[D_o]\,\varepsilon_{DA}}{\varepsilon_D[D_o]}\right)[A]+\left(k\frac{\varepsilon_A+K[D_o]\,\varepsilon_{DA}}{\varepsilon_D[D_o]}+\frac{K\varepsilon_A}{\varepsilon_D[D_o]}\right)[A]^2+k\frac{K\varepsilon_A}{\varepsilon_D[D_o]}[A]^3 \quad (4)$$

As Fig. 9 shows,

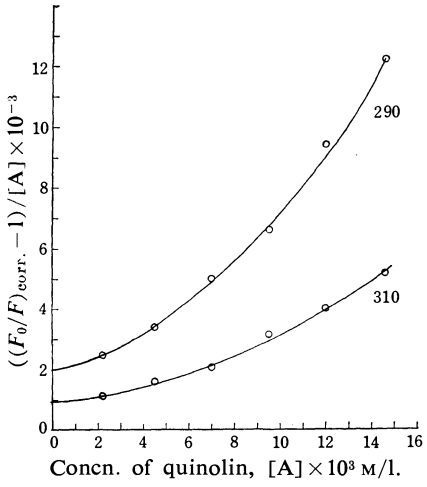

Fig. 9. Plot of $((F_o/F)_{corr.}-1)/[A]$ against the concentration of quinoline [A] for 2-naphthol (10^{-3} M/l.)—quinoline in *n*-hexane at 21°C. The number is exciting wavelength (mμ).

the plot of $((F_o/F)_{corr.}-1)/[A]$ against [A] gives a concave curve upward and so Eq. 4 is considered to fit the experimental results. However, the exact value of k could not be obtained because the other two effects are considerably larger than the genuine quenching action and made the treatment erroneous. It was roughly estimated that $k\approx100$ irrespective of the wavelength.

It is to be added here that in these two cases, quinoline has absorption spectra the long wavelength part of which overlaps slightly with the fluorescence spectra and that, moreover, there is some possibility that the nonfluorescent hydrogen-bonded complex reabsorbs the fluorescence to some extent. Of course, the above treatment does not take any account of these possibilities.

Pyridine as a Quencher. — All the above results, which concern cases where quinoline acts as a quencher, are rather unexpected in view of the results and the proposed mechanism by Mataga,[2] because 2-naphthylmethylether and *N*, *N*-dimethyl-2-naphthylamine, which are both incapable of forming a hydrogen bond, are appreciably quenched by quinoline. Therefore, the quenching action of pyridine was reexamined.

N, N-Dimethyl-2-naphthylamine and 2-Naphthylmethylether.—In the case of these two substances, the effect, if it exists, must be due to the genuine quenching action. The result reconfirmed Mataga's observation[2] that there was not any slight quenching action of pyridine.

2-Naphthylamine and 2-Naphthol. — Taking into account the genuine quenching action and the effect due to the formation of a nonfluorescent hydrogen-bonded complex in the ground state, the following equation can be derived:

$$(F_o/F)_{corr.}-1=\left(k+\frac{\varepsilon'}{\varepsilon}K\right)[A]+k\frac{\varepsilon'}{\varepsilon}K[A]^2 \quad (5)$$

where ε' and ε are, respectively, the molar extinction coefficient of the hydrogen-bonded complex and the free fluorescer, k and K are, respectively, the quenching constant and the equilibrium constant of the hydrogen-bond formation.

In the case of 2-naphthylamine, the plot of $(F_o/F)_{corr.}-1$ against [A] gives a good straight line. This is because the quilibrium constant of the hydrogen-bond formation in the gound state is so small in this case that it can safely be disregarded. From the slope one gets $k=116$ (23°C) and $k=133$ (40°C).

In the case of 2-naphthol, $(F_o/F)_{corr.}-1\sim[A]$ gives a concave curve upward, while $((F_o/F)_{corr.}-1)/[A]\sim[A]$ gives a good straight line and from its slope one gets $kK\varepsilon'/\varepsilon$. At the wavelength where $\varepsilon'\approx\varepsilon$, one gets $k=117$ (21°C) by using the value $K=125$ (21°C).

The Quenching Phenomena in Ethanol and Benzene.—To get a better insight into the mechanism of quenching, analogous experiments for several systems were made in ethanol and benzene. The results for benzene were qualitatively similar to those in *n*-hexane except that the quenching constants in all cases are somewhat less than those in *n*-hexane. In the case of ethanol, however, some extraordinary results were obtained. Thus, pyridine was found slightly to quench the fluorescence of *N,N*-dimethyl-2-naphthylamine.[3] The quenching constant evaluated by applying the Stern-Volmer equation (Eq. 3) is $k=15$ (25°C). However, the fluorescence of 2-naphthylmethylether was not affected at all by the addition of pyridine.* In the case of 2-naphthylamine

* This result contradicts Mataga's remark that this compound shows considerable quenching (see Ref. 3).

—pyridine, the plot of $(F_0/F)_{corr.}-1$ against [A] gives a good straight line and from the slope one gets $k=16$ (25°C). These findings can be comprehended if one considers that both fluorescer and quencher are hydrogen-bonded with ethanol almost completely (see Discussion). When quinoline was used as a quencher, treatment similar to that used in the case of *n*-hexane can be applied, and for 2-naphthylamine and *N*,*N*-dimethyl-2-naphthylamine, quite reliable *k*-values were obtained. No reliable value for 2-naphthylmethylether could be obtained.

The quenching constants so far obtained are tabulated in Table II.

Discussion

In such non-polar solvents as *n*-hexane and benzene, pyridine can be a quencher only when hydrogen bond formation is possible; thus 2-naphthylamine and 2-naphthol are quenched remarkably, while *N*, *N*-dimethyl-2-naphthylamine and 2-naphthylmethylether are not quenched at all. In such cases, therefore, there is no doubt that the hydrogen bond plays an important role in the quenching process. However, the fact that *N*, *N*-dimethyl-2-naphthylamine and 2-naphthylmethylether are quenched to some extent by quinoline indicates that hydrogen bonding is not always necessary for quenching. Particularly, the result that *N*, *N*-dimethyl-2-naphthylamine is quenched by quinoline to almost the same extent as 2-naphthylamine strongly suggests that quite a different molecular process than hydrogen bonding is participating in these quenching phenomena, although it seems natural to consider that hydrogen bond formation plays a role of another type or makes it easy for the afore-mentioned molecular process to occur.

As to the nature of the molecular process which causes quenching in our cases, it seems that all the results are consistent with the mechanism involving a charge transfer from fluorescer to quencher. Thus, firstly, the finding that *N*, *N*-dimethyl-2-naphthylamine is quenched more than 2-naphthylmethylether by quinoline (in *n*-hexane) may be attributed to the larger electron-releasing power of the dimethylamino group than that of the methoxy group and, secondly, the difference between the quenching action of pyridine and quinoline may be due to the difference in their electron-accepting power, though this is not conclusive because of the lack of data on electron affinity. The results obtained in ethanol also favor this view. Thus, in this solvent both pyridine and quinoline, as well as fluorescers, form the hydrogen bond, mainly with ethanol, and the hydrogen bonding between quencher and fluorescer is almost completely suppressed. Now, if one makes the plausible assumption that the effect of the hydrogen bonding between fluorescer and ethanol is of less significance than that of the hydrogen bonding between quencher and ethanol, then, for example, 2-naphthylamine and *N*, *N*-dimethyl-2-naphthylamine may be expected to be affected equally by pyridine and by quinoline. The results are quite consistent with this expectation, since the quenching constants of pyridine and quinoline are about the same for both substances. Further, the fact that *N*, *N*-dimethyl-2-naphthylamine is quenched by pyridine, but not in non-polar solvents, may be interpreted by supposing that pyridine in ethanol gets a larger electron-accepting power because of the hydrogen bond formation with ethanol. Lastly, the finding that 2-naphthylmethylether, unlike *N*, *N*-dimethyl-2-naphthylamine, is not quenched by pyridine in ethanol may again be attributed to the lower electron-releasing power of the methoxy group compared with the dimethylamino group. Thus, it is very tempting to attribute the present quenching phenomena to the charge transfer from fluorescer to quencher. However, it seems somewhat peculiar that quinoline and pyridine act as electron-accepting agents; further studies will be necessary to confirm the above view.

Next, let us discuss the rate-determining step of the quenching process. As Table II shows, the temperature coefficient of the quenching constant is positive in all cases, irrespective of whether hydrogen bonding occurs or not. Besides, in similar systems, such as 2-naphthylamine—pyridine and 2-naphthol—pyridine, or in 2-naphthylamine—quinoline and 2-naphthol—quinoline in non-polar solvents, the quenching constant is of the same order, although the equilibrium constant of the hydrogen bonding in the ground state is quite different.[2,4] From these facts it is very plausible that the rate-determining step in quenching is the process of diffusion. To confirm this view, the quenching constant, k, was calculated by the well-known formula $k_q=4\pi N(D_A+D_B)(r_A+r_B)/1000$; it was then compared with the experimental values. In this equation D_A and D_B are the diffusion coefficients of fluorescer and quencher which were calculated from the experimental formula of Thakar;[12] r_A+r_B was assumed to be 7.5Å,[13] and τ was set as equal to 10^{-8} sec. The results are given in Table III, while the

TABLE III. THE VALUES OF k CALCULATED FROM $k_q=4\pi N(D_A+D_B)(r_A+r_B)/1000$

Quencher / Solvent / Fluorescer	Quinoline			Pyridine		
	n-Hexane	Benzene	Ethanol	*n*-Hexane	Benzene	Ethanol
2-Naphthylamine	234(20°C)[1] 334(40°C)[2]	140(30°C)[7] 191(50°C)	80(30°C)[10] 119(50°C)[11]	266(20°C)]15] 378(40°C)[16]	158(30°C)[21] 216(50°C)	91(30°C) 135(50°C)
N, *N*-Dimethyl-2-naphthylamine	218(20°C)[3] 305(40°C)[4]	131(30°C)[8] 178(50°C)[9]	75(30°C)[12] 111(50°C)[13]	250(20°C)[17] 348(40°C)[18]	149(30°C)[22] 204(50°C)	85(30°C)[24] 127(50°C)
2-Naphthol	238(20°C)[5]	142(30°C)	81(30°C)	268(20°C)[19]	160(30°C)	92(30°C)[25]
2-Naphthyl-methylether	227(20°C)[6]	136(30°C)	78(30°C)[14]	258(20°C)[20]	154(30°C)	89(30°C)[26]

The number [*i*] corresponds to that in Fig. 10.

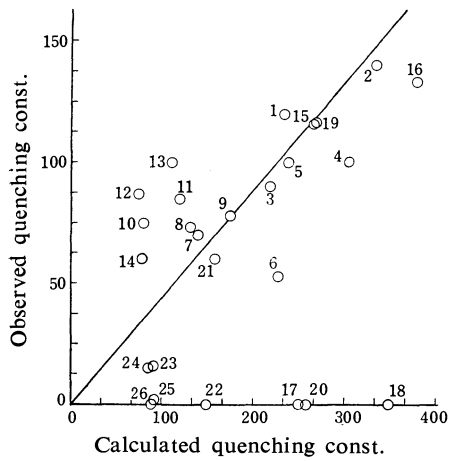

Fig. 10. Plot of the calculated quenching constants against the observed ones. The numbers in the figure correspond to the systems listed in Tables II and III.

comparison between the experimental and calculated values is shown in Fig. 10.

Broadly speaking, the correlation between the experimental and calculated values is rather good.

Thus, 2-naphthylamine—pyridine, 2-naphthol—pyridine, 2-naphthylamine—quinoline and *N*, *N*-dimethyl-2-naphthylamine—quinoline, all in nonpolar solvents, are close to the drawn line. It is clear that the difference between benzene and *n*-hexane is mainly due to the difference in viscosity, which affects the *D*-value. For all cases where the quenching constants are conspicuously small, such as *N*, *N*-dimethyl-2-naphthylamine—pyridine ($k=0$), 2-naphthylmethylether—pyridine ($k=0$) and 2-naphthylmethylether—quinoline, all in nonpolar solvents, there is no question that the genuine quenching process is rate-determining, completely or, at least, partially.

The feature in ethanol is somewhat anomalous. Thus, in the cases of 2-naphthylamine—quinoline and *N*, *N*-dimethyl-2-naphthylamine—quinoline, the observed values are appreciably larger than those which would be expected from the calculated values. Perhaps the calculated values are incorrect because of the improper estimation of τ, D_A, D_B, r_A and r_B. For *N*, *N*-dimethyl-2-naphthylamine—pyridine and 2-naphthylamine—pyridine, the observed k-values are less than the calculated values; this is certainly because the genuine quenching process is rate-determining.

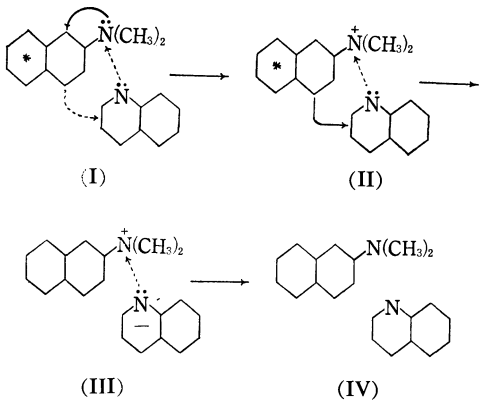
At any rate, it is clear that in nonpolar solvents the quenching process is in many cases so rapid that it is determined by the process of diffusion, irrespective of the molecular mechanism of quenching. Thus, in the case of 2-naphthylamine—pyridine or 2-naphthol—pyridine in nonpolar solvents, k is considered to depend on the rate with which two molecules encounter one another with a mutual

orientation suitable for forming the intermolecular hydrogen bond. It is remarkable that the quenching in *N,N*-dimethyl-2-naphthylamine—quinoline seems to be diffusion rate-determining.

To summarize the above discussion, it is certain that the molecular process essential for quenching in the present systems is something other than hydrogen bonding, although it is clear that the latter plays an impotant role. According to Mataga,[4] charge transfer via the hydrogen bond makes the vibronic energy transfer feasible.

According to the view of the present authors, however, the main cause of the quenching is the charge transfer from fluorescer to quencher; the hydrogen bonding is considered, at least partly, to make it easy for this process to occur by increasing the electron density on the amino or hydroxy groups. The following fact might also have to be taken into account. If charge migration occurs from the electron-releasing group, such as a methoxy or amino group, to a ring in the excited state of the fluorescer, then a lone-pair on the hetero-atom in a quencher molecule will be able to act as a donor to these groups in a somewhat electron-deficient state. This will then make it easier for the charge transfer from fluorescer to quencher through π-π interaction to occur.

To sum up, our model of quenching process may be written schematically as follows:



The essential point for quenching is I→II→III; the mechanism for III→IV is rather indifferent.

To verify the above speculation, the role of the quencher as an electron acceptor and the role of the hetero-atom in the quencher, which possibly acts as a donor, are the key-points which further studies should attack.

In concluding the discussion, brief comment should be made on the frequency effect of the quenching constant and on the experiment for the depth effect using anthracene.

The finding that quenching is independent of the frequency in 2-naphthylamine—quinoline and in *N,N*-dimethyl-2-naphthylamine—quinoline is quite natural and self-evident if one considers the conclusion obtained in the present paper, i.e., the fact that the rate-determining step of quenching is diffusion, since in such a situation the excited fluorescer molecule is sure to attain the equilibrium condition with regard to vibration and rotation and from the standpoint of interaction with the solvent molecules before the quenching process commences.

As to the effect of concentration on the fluorescence of anthracene, some anomalous results have recently been reported by Dammers-de Klerk.[10] According to him, the concentration quenching in *n*-hexane begins in a rather low concentration region, the fluorescence quantum yield at 10^{-3} M being about 1/5 that of the extreme dilute solution. Our present results do not show any such decrease in this concentration but conform quite well with the data of other authors.[9] Although our experiment was made in the presence of oxygen, Damers-de Klerk's results seem to be very doubtful. Förster[14] has also expressed this same opinion recently.

Summary

The quenching constants (k) of quinoline for the fluorescence of several substances in *n*-hexane have been determined. The values obtained are as follows; they are independent of the frequency of the exciting light.

2-Naphthylamine	120 (20°C)	140 (40°C)
N,N-Dimethyl-2-naphthylamine	90 (20°C)	100 (40°C)
2-Naphthol	100 (21°C)	
2-Naphthylmethyl-ether	53 (21°C)	

The results clearly show that the hydrogen bond is not necessary for the quenching to occur, in contradiction to the mechanism proposed by Mataga[4] for the case in which pyridine is used as a quencher.

To elucidate the mechanism, the quenching phenomena in the fluorescence of the above substances have been further studied in benzene and ethanol, using pyridine and quinoline as quenchers. The most notable finding has been that, in ethanol, pyridine can quench the fluorescence of 2-naphthylamine and *N,N*-

14) E. Döller and Th. Förster, *Z. Phys. Chem., N. F.*, **31**, 274 (1962).

dimethyl-2-naphthylamine equally well, the k value for 25°C being, respectively, 16 and 15.

A mechanism has been proposed which involves the charge transfer from fluorescer to quencher. When the quenching is considerable, the rate-determining step is the diffusion process, irrespective of the molecular mechanism for the quenching.

The Photoreduction of Acridine in Deaerated and Aerated Alcohol Solutions.[1] *II.*

By Shigeya NIIZUMA and Masao KOIZUMI

(Received July 24, 1963)

In the preceding paper,[1] Kato, Minagawa and one of the present authors (M. K.) studied the photoreduction of acridine in ethanol and observed the following facts:

i) A solution of aridine, 1×10^{-4} M, in ethanol free from oxygen, when illuminated by 365 mμ, produces acridan, the quantum yield being about 0.13, independent of the temperature.

ii) In an air-saturated solution, the photoreduction goes on at the rate of about one-third of the evacuated solution.

iii) For both cases, the rate is simply proportional to the absorption of light.

iv) When the concentration of oxygen is varied, the reaction proceeds at the same rate as that of the air-saturated solution so long as the oxygen concentration is much larger than that of acridine. However, when the oxygen concentration becomes of the order of the acridine concentration, then the earlier part of the reaction proceeds at a rate approximately equal to that of the air-saturated solution, although at a certain point the rate increases rather suddenly to that of the oxygen-free solution.

The forth finding above was interpreted by assuming that, in the presence of oxygen, the acridan-producing reaction (with no consumption of oxygen) and the oxygen-consuming reaction (with no production of acridan) proceed simultaneously and that, when the existent oxygen is exhausted, only the former reaction survives. On this basis, the rate of oxygen consumption was calculated to be about twice as large as that of the reduction of acridine. A tentative scheme was proposed which can interpret the above results.

Now, in the present paper we will extend the study to the reaction in methanol and isopropanol and discuss all the results so far obtained, including those for ethanol, on the basis of the same scheme.

Experimental

Sample.—Acridine was purified by the method described in the previous paper. The concentration of acridine is always 1×10^{-4} M, while ε at 365 mμ is 1.12×10^{4}, 1.14×10^{4}, 1.19×10^{4} for methanol, ethanol and isopropanol solutions respectively.

Methanol.—Iwai Kasei's methanol (G. R.) was used without further purification.

A large decrease in the optical density of curve 5 is due to the precipitation of the photoproduct (see text).

1) S. Kato, S. Minagawa and M. Koizumi, This Bulletin, **34**, 1026 (1961). This paper shoud be numbered I.

Isopropanol. — Wako Junyaku's isopropanol was twice distilled. (B. p. 81.9~82.1°C) An impurity causing a slight absorption near 240 mμ was eliminated by the purification.

Procedure.—The procedures for degassing and the apparatus are almost the same as in the previous paper. The exciting light was 365 mμ from a high-pressure mercury lamp, and the reaction was followed by the change in the optical density of the sample at 365 mμ in a reaction cell (1×1×4 cm.). The intensity of the exciting light was measured by a potassium ferri-oxalate actinometer and found to be ca. 0.21×10^{-7} and 0.65×10^{-8} M sec^{-1} cm^{-2} for methanol and isopropanol respectively.

Results

The Absorption Spectra of Products. — The absorption spectra of the products in each solvent are shown in Figs. 1, 2 and 3. As can be seen in Figs. 1, 2 and 3 the main product in the case of methanol and ethanol is acridan, irrespective of the presence or absence of oxygen. The differences in the absorbance in the 230~300 mμ region for the aerated and deaerated solutions might be partially due to different by-products or to the small contribution of accompanied side reactions. The latter is plausible in view of the fact that prolonged illumination, after the depression of the optical density down to practically zero in the 350 mμ region, causes a gradual rise in the same region (cf. curve 4 in Fig. 1). When the ethanol solution of the product is kept for a long time, a white precipitate[2] is produced which may be attributed to acridan. In the case of isopropanol, the products in the degassed solution and in the air-saturated solution are different. In the former case, the product is judged to be acridan, while in the latter case the spectra with the peaks at 250, 345, 355 mμ resemble those of diacridan.[3] It is to be added that there is a clear isosbestic point in the change of acridine into acridan.

A Comparison of Aerated and Deaerated Solutions.—When the reaction is proportional to the absorption of light, the relation

$$-\frac{dc}{dt}=\frac{kI_0}{d}(1-e^{-\alpha cd})\times10^3 \qquad (1)$$

must hold, where c, t, I_0, d and α are respectively the concentration of acridine (M), the time of reaction, the quantum yield, the light intensity (M/sec. cm^2), the thickness of the cell (1 cm.), and the absorption coefficient at 365 mμ. The integration of Eq. 1 leads to

$$\ln(e^{\alpha cd}-1)=\ln(e^{\alpha c_0 d}-1)-1000k\alpha I_0 t \qquad (2)$$

Equation 2 can represent very well the results in methanol and isopropanol and for both the air-saturated and oxygen-free solutions. From the linear plot of $\ln(e^{\alpha cd}-1)\sim t$ one gets $1000k\alpha I_0$, and so the value of k (quantum yield) can be calcurated using the values of α and I_0. A few examples of the plots are shown in Fig. 4. The values of k are summarized in Table I.

From Table I we can say that k-values are generally independent of the temperature, and that the ratio of k_d (for an oxygen-free solution) and k_a (for an air-saturated solution) is ca. 4, ca. 3 and ca. 2.8 for methanol, ethanol and isopropanol. It is worth mentioning that, for the degassed solutions, k is practically the same for methanol and for ethanol, while it is much smaller for isopropanol.

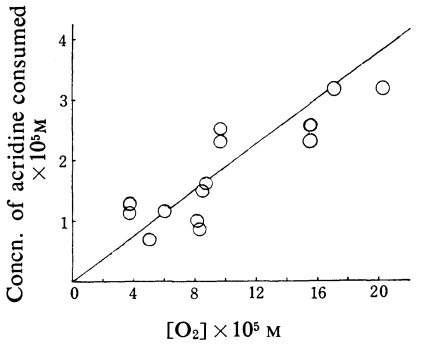

Fig. 6. Plots of the decrease of acridine concentration before the breaking point of the decay curve vs. the initial concentration of dissolved oxygen in isopropanol solution.

The Effect of the Oxygen Concentration.— When the oxygen concentration is of the same order as that of acridine, the rate of the reaction at first is practically the same as that of the air-saturated solution, but after a certain time there appears a sharp break, after which the rate becomes approximately the same as that of the degassed solution. The length before the break is approximately proportional to the concentration of oxygen. This phenomenon is common to both methanol and isopropanol and is quite similar to that already reported in ethanol.[1] There is no doubt that an interpretation similar to that given for ethanol in the previous paper can be applied to methanol and isopropanol. Thus, in such circumstances, the oxygen-consuming reaction (accompanied by the recovery of acridine from some transient intermediate) and the acridan-producing reaction go parallel and that, when the oxygen is exhausted only the latter reaction proceeds by the mechanism prevailing in oxygen-free solution.

The plot of the consumed acridine up to the breaking point against the initial oxygen concentration is given in Figs. 5 and 6. Although the average deviation from the drawn line is rather large especially in the latter case, the ratio between the quantities of acridine and of oxygen consumed before the break is, respectively, about 3 and 5.3 for methanol and isopropanol. The fact that the plot in Fig. 5

cuts the abscissa instead of passing through the origin, might be due to the participation of some other reaction like the following in such a low concentration of oxygen;

$$A^* + RH_2 \rightarrow AH\cdot + RH\cdot$$

$$RH\cdot + O_2 \rightarrow RH\cdots O_2$$

$$AH\cdot + RH\cdots O_2 \rightarrow A + R + H_2O_2$$

A similar tendency, although much less conspicuous, is observed in the case of ethanol described in the preceding paper (see Fig. 5 in Ref. 1). Table II gives a summary of γ and

TABLE II. γ AND k_d/k_a

Solvent	γ	k_d/k_a
Methanol	ca. 3	4
Ethanol	ca. 2	3
Isopropanol	ca. 5.3	2.8

k_d/k_a values. In the case of ethanol, the reaction rate under the air-saturation could be restored when a small quantity of air was dissolved after the break in Fig. 4. Similar experiments were undertaken for isopropanol, but the results proved to be as shown in Fig. 7.

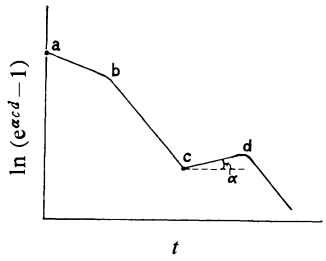

Fig. 7. A typical decay curve for supplementary experiments. At time dissolved oxygen would be exhausted. At c, the cell was shaken and oxygen was introduced into the liquid phase. At d, the oxygen would be exhausted again. The longer the interval bc is, the larger the value of α becomes.

Thus, when 10^{-4} M oxygen is added again after the exhaustion of oxygen (period ab) at c, the optical density does not fall, but rises. It was found that the longer the bc interval (the reaction in the absence of oxygen), the larger the value of α and, so, the larger the increase in the optical density. When bc is extremely short, then the slopes of ab and cd become practically the same. A similar phenomenon was also observed in the case of ethanol, and methanol although to a lesser extent. This is the reason why the phenomenon was overlooked in the preceding paper. At d, oxygen is consumed and the reaction goes on at the rate of the degassed solution.

The rise in the optical density during the cd period seems to be due to the oxidation of acridan to acridine by some unknown process, the extent of this reaction exceeding the usual reduction of acridine to acridan. This view is supported by the following facts. First, as is shown in Fig. 7, the spectra of acridine increase during the cd period while the spectra of the product (280~285 mμ) decrease, and second, this change goes on with an isosbestic point at 325 mμ. The dependence of α on the length of bc strongly suggests that some reaction products during the bc (degassed condition) period play an essential role in the reaction during cd period. To confirm this, the effect of the addition of acridan to various systems was examined. The addition of acridan (0.5×10^{-4} M) to an ethanol solution of acridine (0.5×10^{-4} M) containing 0.7×10^{-4} M of oxygen ($P_{air}=27.5$ mmHg at 18°C) did not have any effect. No effect was observed either when the same amount of acridan was added to an isopropanol solution of acridine (0.5×10^{-4} M) or when 1×10^{-4} M of acridan was added to an ethanol solution of acridine (1×10^{-5} M), both saturated with air.

Thus there is no simple sensitized oxidation of acridan by the excited acridine molecule. This is rather natural in view of the finding that $\ln(e^{\alpha cd}-1)\sim t$ gives a very satisfactory linear plot until more than a half of the acridine is consumed.

Next, the effect of any other conceivable by-product during bc was examined. Of these, acetaldehyde would be most probable in the case of ethanol. The addition of ~1 M acetaldehyde to an air-saturated ethanol solution of acridine (1×10^{-4} M) does not affect the rate, the rate being practically the same as that of an air-saturated solution of acridine. However, the ultraviolet spectra of the product as shown in Fig. 8 resembles that of diacridan. Using the ethanol solution of acridine (0.1×10^{-4} M) and acridan (0.9×10^{-4} M) to which 1.2 M acetal-

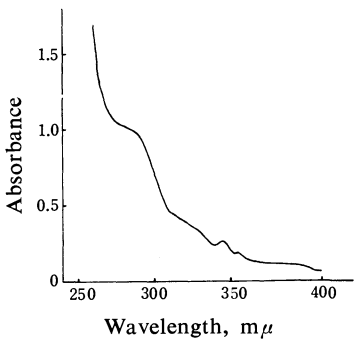

Fig. 8. The Absorption spectrum of photoproduct in air-saturated ethanol solution containing, 0.9×10^{-4} M acridan, 0.1×10^{-4} acridine and ~1 M acetaldehyde.

dehyde had been added, three cases were examined, i.e.; (1) an air-saturated solution; (2) 0.8×10^{-4} M oxygen ($P_{air}=29.0$ mmHg at 17.5°C), and (3) a completely degassed solution. The results was that for 1 the reduction proceeds at a much slower rate, k being approximately 3×10^{-3}, while for 3 the reaction goes on at just the same rate as when no acridan and acetaldehyde are added, (i.e., $k=0.13$); in case of 2, however, the rise in the optical density occurs first and, at a point where oxygen may be expected to be exhausted, a break appears and the optical density then decreases, but at a slower rate than that for the degassed solution of acridine. When oxygen is introduced again, the back reaction becomes apparent. A similar phenomenon, though to a lesser extent, was observed when acetone (1.0 M) and oxygen (1×10^{-4} M) ($P_{air}=36.2$ mmHg at 23.0°C) were added to an isopropanol solution containing acridan (0.9×10^{-4} M) and acridine (0.1×10^{-4} M).

Thus one can conclude that a certain quantity of aldehyde or ketone is necessary in order for acridan to be oxidized by the sensitization of acridine. However, there is rather a great possibility that some other oxidative by-products take part in the cd reaction shown in Fig. 7.

Discussion

The scheme presented in the preceding paper for the reaction under the degassed condition is as follows:

$$\left.\begin{aligned} &A + h\nu \rightarrow A^* \\ &A^* + RH_2 \rightarrow AH + RH \end{aligned}\right\} \quad (0)$$

$$AH\cdot + RH\cdot \rightarrow AH_2 + R \quad (1)$$

$$AH\cdot + RH\cdot \rightarrow A + RH_2 \quad (2)$$

$$AH\cdot + AH\cdot \rightarrow AH_2 + A \quad (3)$$

$$RH\cdot + RH\cdot \rightarrow RH_2 + R \text{ or } HR\text{–}RH \quad (4)$$

where A, RH_2 and R are acridine, ethanol and acetaldehyde respectively. A* is an excited singlet or triplet, but the latter is more plausible since the transient spectra for the degassed solution of acridine observed in our laboratory, perfectly coincides with that reported by Porter[4] and has interpreted to be due to the acridine triplet.

From the above scheme, one can easily derive the following rate formula by means of the steady state method:

$$-\frac{d[A]}{dt}=\frac{d[AH_2]}{dt}=\frac{\phi I_{abs}(k_1+\sqrt{k_3k_4})}{k_1+k_2+2\sqrt{k_3k_4}}$$

$$=\phi\beta I_{abs}$$

$$\beta=\frac{k_1+\sqrt{k_3k_4}}{k_1+k_2+2\sqrt{k_3k_4}}$$

where ϕ is the quantum yield of the formation of AH· and RH·, and k_1, k_2, k_3 and k_4 are the respective rate constants of processes 1, 2, 3 and 4. From the results in Table I, one can discuss the mechanism to some extent. First, the values of k for the degassed solution of methanol, ethanol and isopropanol are not consistent with the well-known fact that the order of ease of α-hydrogen abstraction in an alcohol molecule is isopropanol > ethanol > methanol. This relation was observed to hold[5] in, for instance, the case of the photoreduction of eosine in a degassed alcohol solution, for which the overall quantum yield is very small, of the order of 10^{-4}. Wells[6] also observed the same order for the photoreduction of sodium-anthraquinone-2-sulfonate. Perhaps the tendency of excited acridine to deprive α-hydrogen atom from alcohol is so large that the general ralation does not hold in this case. The small value of isopropanol may perhaps be due to its small number of α-hydrogen atoms (1, while it is 3 or 2 for methanol and ethanol) or to a certain steric factor. The independence of k of the temperature favors the view that the process following (0) goes along a single path, (1) or (3), and not along (1) and (3) both. As to whether (1) or (3) prevails, one cannot give a definite answer at this stage. The separate determination of ϕ and of the quantum yield of the triplet formation is desirable. It is worth mentioning that the triplet is observed in the flash experiment. If the triplet state is very easily reduced by alcohol, as has been mentioned above, then its life-time might be expected to be very small. Perhaps the relative orientation of the alcohol molecule and acridine must be suitable in order for the hydrogen atom transfer to occur, and this will be a chief reason why the life-time of the triplet is not very short.

Next let us consider the reaction in which oxygen takes part. In the preceding paper we tentatively proposed for the case of ethanol that oxygen very efficiently attacks the half-hydrogenated state of acridine on the grounds that the reaction goes on even in the presence of oxygen and that the rate is almost constant as long as the concentration of oxygen is larger than a certain small value ($\sim10^{-4}$ M). Since similar results were obtained for methanol and isopropanol, it can be said that the pro-

4) G. Jackson and G. Porter, *Proc. Roy. Soc.*, **A260**, 13 (1961).

5) M. Imamura and M. Koizumi. This Bulletin, **29**, 899 (1956).

6) C. F. Wells, *Trans. Faraday Soc.*, **57**, 1703 (1961).

posed scheme was largely substantiated. Therefore, we will discuss it on the basis of the analogous mechanism. However, it is to be noted here that the overall reaction will be somewhat different in methanol and isopropanol. In the former case, the final product will be acid, as in the case of ethanol, but for isopropanol, acetone instead of acid is the most plausible product. For methanol the scheme is exactly the same as for ethanol, which runs as follows:

$$AH\cdot + O_2 \rightarrow AH\cdots O_2 \quad (5)$$

$$RH\cdot + O_2 \rightarrow RH\cdots O_2 \quad (5')$$

$$2AH\cdots O_2 \rightarrow AH_2 + A + 2O_2 \quad (6)$$

$$2AH\cdots O_2 \rightarrow 2A + H_2O_2 + O_2 \quad (7)$$

$$2RH\cdots O_2 \rightarrow 2Acid + H_2O_2 \quad (8)$$

$$AH\cdots O_2 + RH\cdots O_2 \rightarrow AH_2 + R + 2O_2 \quad (9)$$

$$AH\cdots O_2 + RH\cdots O_2 \rightarrow A + R + H_2O_2 + O_2 \quad (10)$$

$$AH\cdots O_2 + R\cdots HO_2 \rightarrow A + RH_2 + 2O_2 \quad (11)$$

In the case of isopropanol, the above scheme will be partly altered in the following way; i.e., instead of 6,

$$2AH\cdots O_2 \rightarrow AH\text{–}AH + 2O_2 \quad (6')$$

and instead of 8,

$$2RH\cdots O_2 \rightarrow 2R + H_2O_2 + O_2 \quad (8')$$

6' of course corresponds to the formation of diacridan.

In the above scheme we consider that, in the presence of oxygen, reaction 5 proceeds so fast that 1, 2, and 3 do not occur at all. Of course, the above scheme is too simple and the real situation might involve the participation of $HO_2\cdot$; moreover, some chain reaction might also occur. For example, if the following chain reaction occurs:

$$RH\cdots O_2 \rightarrow R + HO_2\cdot$$

$$HO_2\cdot + RH_2 \rightarrow RH\cdot + H_2O_2$$

$$RH\cdot + O_2 \rightarrow RH\cdots O_2$$

then the oxygen consumption would be much increased. It is to be noted that such a possibility is disregarded in the following discussion because this possibility is very small in view of the consistency of the analysis.

Putting k_d/k_a (the ratio of the rate in the deaerated solution to that in the aerated solution) as n, let us now consider which process, 6, 7 and 8 (case I) or 9, 10 and 11 (case II), is more plausible.

As in the previous paper only two extreme cases will be considered.

Case I.—In this case 6 (or 6' for isopropanol) and 7 occur, and, naturally, 8 (or 8' for isopropanol) accompanies them. The steady state method gives

$$-\frac{d[A]}{dt} = \begin{cases} \dfrac{k_6\phi I_{abs}}{2(k_6+k_7)} & \text{for methanol} \\ \dfrac{k_6\phi I_{abs}}{k_6+k_7} & \text{for isopropanol} \end{cases}$$

$$-\frac{d[O_2]}{dt} = \begin{cases} \dfrac{\phi I_{abs}(2k_6+3k_7)}{2(k_6+k_7)} & \text{for methanol} \\ \dfrac{\phi I_{abs}(k_6+2k_7)}{2(k_6+k_7)} & \text{for isopropanol} \end{cases}$$

Hence,

$$\begin{cases} \dfrac{k_6}{2(k_6+k_7)} = \dfrac{\beta}{n} & \text{for methanol} \\ \dfrac{k_6}{k_6+k_7} = \dfrac{\beta}{n} & \text{for isopropanol} \end{cases}$$

and

$$\gamma = \frac{d[O_2]/dt}{d[A]/dt} = \begin{cases} 2+3\dfrac{k_7}{k_6} & \text{for methanol} \\ \dfrac{1}{2}+\dfrac{k_7}{k_6} & \text{for isopropanol} \end{cases}$$

From these two equations,

$$\gamma = \begin{cases} \dfrac{3n}{2\beta}-1 & \text{for methanol} \\ \dfrac{n}{\beta}-\dfrac{1}{2} & \text{for isopropanol} \end{cases}$$

In the case of methanol, $n=4$ and $\gamma=3$; therefore,

$$\gamma = \frac{6}{\beta}-1$$

For γ to be 3, β must be 1.5. This is nonsense, however, because β should be $\leqq 1$. For ethanol, $n=3$, $\gamma=2$ and, from these values, $\beta=1.5$. In the case of isopropanol, $n=2.8$ and $\gamma=5.3$; therefore, $\beta=0.48$.

Case II. — In this case both methanol and isopropanol can be treated in the same way provided that acridan is a main product in the latter case. When 9, 10 and 11 are the main reactions, the steady state method leads to the following equation:

$$-\frac{d[A]}{dt} = \phi I_{abs} k_9/(k_9+k_{10}+k_{11})$$

$$-\frac{d[O_2]}{dt} = \phi I_{abs} k_{10}/(k_9+k_{10}+k_{11})$$

Hence,

$$k_9/(k_9+k_{10}+k_{11}) = \frac{\beta}{n}$$

and

$$\gamma = \frac{k_{10}}{k_9}$$

From these two equations,

$$\frac{k_{11}}{k_9}=\frac{n}{\beta}-(\gamma+1)$$

In the case of methanol, $n=4$ and $\gamma=3$, and for some values of β, k_{11}/k_9 are calculated as follows:

β	1	0.8	0.6	0.5
k_{11}/k_9	0	1	2.6	4

For ethanol, $n=3$, $\gamma=2$, and, as has been reported already:[1]

β	1	0.8	0.6	0.5	0.4
k_{11}/k_9	0	0.75	2	3	4.5

In the case of isopropanol, $n=2.8$ and $\gamma=5.3$; therefore,

β	1	0.5	0.45
k_{11}/k_9	−3.5	−0.7	0

From the above analysis it can be said that, with ethanol and methanol, only case II fits the experimental results if alcohol is oxidized to acid. If, on the other hand, the oxidation stops at the stage of aldehyde, case I is also conceivable; the calculation requires that $\beta=1$ for both methanol and ethanol.

As for the case of isopropanol, one can not decide from the above analysis whether case I or case II is suitable. However, in this case the product contains a considerable quantity of diacridan, and so case I seems to be more plausible. This would perhaps be because $RH\cdots O_2$ has a great tendency to decompose in the following way:

$$\begin{matrix}CH_3\\CH_3\end{matrix}\!\!>\!\!\begin{matrix}COH\\\vdots\\O_2\end{matrix}\rightarrow CH_3\overset{\displaystyle O}{\overset{\|}{C}}CH_3+HO_2\cdot$$

At any rate, in the case of isopropanol the above analysis requires that $\beta\fallingdotseq 0.5$, whether case I or case II holds. This implies that, in the case of the degassed solution of isopropanol, (3) and (4) prevail instead of (1). On the other hand, in the cases of ethanol and methanol, case I requires that $\beta=1$ (on the condition that the product is aldehyde and not acid); $\beta=1$ holds also in case II if it is assumed that reaction 11 does not occur. Thus, in either case reaction 1 is more favorable.

The above discussion is of itself rather speculative, and we have aimed only at the plausible scheme. For example, the deduction would not hold if the chain reaction participates. However, as to the participation of the chain process, this can be safely denied on the basis of the rather small consumption of oxygen and also from the consistency of the above analysis. Moreover, very recently, it has definitely been established from the pulse radiolysis of ethanol that recombination and disproportionation are the only processes possible for ethanol radicals and that these occur as diffusion rate-determining processes.[7]

This makes our deduction very reasonable. It seems certain that, in the cases of ethanol and methanol, $AH\cdot + RH\cdot \rightarrow AH_2 + R$ occurs, while in the case of isopropanol, $AH\cdot + AH\cdot \rightarrow AH_2 + A$ and $RH\cdot + RH\cdot \rightarrow$ proceed. If such is the case, the existence of different values of k for methanol and ethanol on the one hand and for isopropanol on the other, is at least partly due to the different processes following (0). Wilkinson[8] proposed, for the photoreduction of isopropanol by quinone, the following process:

$$(CH_3)_2\dot{C}OH + Q \rightarrow QH\cdot + (CH_3)_2CO$$

However, such a process is not applicable in our case probably because of a rather small tendency of reduction for acidine. At any rate, the complete analysis of the products is desirable in order to obtain a definite answer. Lastly, it should be added that the experimental evidence for the formation of $AH\cdots O_2$ is lacking, but that the present deduction is not altered if $AH\cdots RH$ is formed and reacts with oxygen in any of three different ways, as has been mentioned in the preceding paper.[1]

As to the sensitized oxidation of acridan into acridine in the presence of aldehyde or acetone and a small quantity of oxygen, the discussion of this will be postponed until much more data have been accumulated.

Summary

The photoreduction of acridine in methanol and isopropanol has been studied and the following results obtained:

1) The quantum yield for the photoreduction in the dagassed solution is, for methanol, 0.13 and, for isopropanol, 0.09. The photoreduction can take place even in an air-saturated solution with quantum yields of 0.032 for methanol) and of 0.032 (for isopropanol).

2) In case of a degassed solution, the product is acridan for both isopropanol and methanol, while in an aerated solution the product is acridan in the case of methanol and mainly diacridan in the case of isopropanol.

3) When the concentration of oxygen is of the order of that of acridine, the reaction proceeds at first at a rate equal to that of an air-saturated solution and then, from the point at which the oxygen is exhausted, the rate

8) F. Wilkinson, *J. Phys. Chem.*, **66**, 2569 (1962).

increases up to the value of a degassed solution.

4) The ratio of the quantities of oxygen and of acridine consumed before the break is, for methanol, about 3 and, for isopropanol, 5.3.

5) By the sensitizing action of acridine, acridan is oxidized to acridine in the presence of aldehyde (or acetone) and a small quantity of oxygen.

6) On the basis of the scheme proposed in the preceding paper and from the reaction product, some tentative discussion of the scheme has been undertaken. It seems plausible that, in the case of ethanol and methanol, $AH\cdot + RH\cdot \rightarrow AH_2 + R$ occurs, while in the case of isopropanol, $AH\cdot + AH\cdot \rightarrow AH_2 + A$ and $RH\cdot + RH\cdot \rightarrow$ take place (for a degassed solution).

The Preparation of Strictly Halide Complexes of Copper(II) and Their EPR Spectra

By Masayasu MORI and Shizuo FUJIWARA

(Received July 17, 1963)

Copper(II) complexes are probably some of the most thoroughly studied of all the metal complexes, and many new findings in the field of EPR study have recently been obtained with these complexes. However, most of the copper complexes so far studied have been those in which ligands are coordinated through oxygen or nitrogen atoms; structurally they form elongated octahedra, with two atoms in the trans positions somewhat far from the central copper ion.

On the other hand, very little information has been obtained with copper complexes in which all the ligands are coordinated through halogen atoms. Bailar and Busch term such a compound "a strictly halide complex";[1] it is indeed in these compounds that various anomalies, both in structure and in spectra, are observed. Thus, in Cs_2CuCl_4 and Cs_2CuBr_4, tetrahalogenocuprate(II) anions form distorted tetrahedra,[2] while in $[Cr(NH_3)_6][CuCl_5]$, pentachlorocuprate(II) anion forms a trigonal bipyramid.[3] Brown compounds, $CsCuCl_3$[4] and $KCuCl_3$[5] of a polymer structure with Cl–Cu–Cl–Cu chains or the like, and a series of mixed valence compounds, $[Cr(NH_3)_6]CuCl_{5-x}$ or $[Cr(NH_3)_6]_4Cu_5Cl_{17+x}$,[6] also belong to this category. Research into these anomalous chlorocuprates seems to be necessary for a more complete understanding of the coordinate linkage in copper complexes.

As a means of studying this subject, the present authors chose to examine electron paramagnetic resonance, since it usually affords useful information, especially in connection with the state of the d electrons, electron delocalization, exchange interaction, and other problems. In particular, the accumulation of such fundamental EPR data as the *g*-values for pure copper halogen linkages can be made possible only by the use of these strictly halide complexes as specimens.

Experimental

Samples.—The chlorocuprates studied in the present research are: (1) hexamminecobalt(III) pentachlorocuprate(II), (2) hexamminecobalt(III) chlorocuprates(I, II), (3) chlorocuprates(II) of chain organic polyamines, (4) chlorocuprate(I, II) and chlorocuprate(I) of a chain organic polyamine, and (5) chlorocuprates(II) of *s*-triazine derivatives. The preparation of 1 and 2 has been described in

1) J. C. Bailer, Jr., and D. H. Busch, "Chemistry of the Coordination Compounds," Reinhold Publishing Corp., New York (1956), p. 5.
2) L. Helmholz and R. F. Kruh, *J. Am. Chem. Soc.*, **74**, 1176 (1952).

4) A. F. Wells, *J. Chem. Soc.*, **1947**, 1662.
5) R. D. Willett, C. Dwiggins, Jr., R. F. Kruh and R. E. Rundle, *J. Chem. Phys.*, **38**, 2429 (1963).
6) M. Mori, This Bulletin, 33, 985 (1960). The series of chlorocuprates(I, II) reported on in this literature may be expressible by either of the above formulae. The former expresses compounnds with a ratio of copper(I) and copper(II) smaller than 1 : 1 and in which x is, therefore, smaller than 0.5. The latter expresses compounds with a low copper(II) content and in which x is, therefore, small. Compounds of the intermediate domain have not yet been thoroughly analyzed to afford an appropriate formula by which they can be expressed.

a previous paper.[6] Most of the compounds of group 3 are those reported by Jonassen et al.[7] In this section the procedure for preparing compounds of groups 4 and 5 will be described.

Diethylenetriammonium Chlorocuprate(I, II).—A cooled mixture of 2.5 g. of diethylenetriamine and 3 ml. of water is slowly acidified with 10 ml. of 12 N hydrochloric acid. To the mixture are added 0.5 g. of copper(I) chloride and 1 g. of copper(II) chloride dihydrate, dissolved together in a mixture of 2.5 ml. of water and 10 ml. of 12 N hydrochloric acid. When the mixture is slowly shaken 2~3 times and allowed to stand for 1 min., small, very dark green, glistening crystals will be deposited. These are separated from the mother liquor by suction, washed with 12 N hydrochloric acid and ethanol, and dried under evacuation. Yield, 1.5 g.

Rubbing the sides of the glassware during the crystallization or allowing the mixture to stand for too long a period should be avoided, as this will cause a crystallization of a colorless copper(I) compound which is very difficult to remove from the substance to be prepared. Once colorless crystals are deposited, preparation should be repeated anew.

Found: Cu, 18.20; Cu(II), 17.85; Cl, 50.77; N, 12.16. Calcd. for $(H_3N\cdot C_2H_4\cdot NH_2\cdot C_2H_4\cdot NH_3)$-$CuCl_{5-x}$, ($x$=0, i. e., for a divalent compound for simplicity's sake): Cu, 18.31; Cl ,51.09; N, 12.11%.

When the analytical value is considered, the copper(I) content is seen to be quite low. Nevertheless, the color (very dark green) is quite different from the yellow color of a pure copper(II) compound; moreover, the copper(II) content and the color are changed when the ratio of mixing in the preparation is changed. Thus, for example, if 0.2 g. of copper(I) chloride is used instead of 0.5 g. in the above procedure, the color of the product is more yellowish but still far deeper than the color of the pure copper(II) compound, while the composition is now almost identical with that of the copper(II) compound. An increase in the quantity of copper(I) chloride used also seems to bring about a color change, but in this case preparation becomes more difficult owing to the readiness with which a colorless copper(I) compound separates out.

Diethylenetriammonium Pentachlorodicuprate(I). The procedure is similar to that for chlorocuprate-(I, II), but 2 g. of copper(I) chloride should be used instead of a mixture of copper(1) chloride and copper(II) chloride. It forms colorless, scaly crystals.

Found: Cu, 30.76; Cl, 43.52; N, 10.64. Calcd. for $(H_3N\cdot C_2H_4\cdot NH_2\cdot C_2H_4\cdot NH_3)Cu_2Cl_5$: Cu, 30.95; Cl, 43.18; N, 10.23%.

Ethylenediammonium Tetrachlorocuprate(II), Diethylenetriammonium Pentachlorocuprate(II) and Triethylenetetrammonium Hexachlorocuprate(II).—These compounds were first reported by Jonassen et al.[7] The present research has revealed, however, that they can be much more easily prepared. For example, diethylenetriammonium pentachlorocuprate(II) can be prepared by a procedure similar to that used in preparing the chlorocuprate-(I, II) described above, except that copper(II) dihydrate is used instead of a mixture of copper(I) chloride and copper(II) chloride. The other cases are analogous.

Chlorocuprates(II) of *s*-Triazine Derivatives.—(*a*) *Dimelammonium Hexachlorocuprate(II)*.—One and three-tenths grams of melamine is dissolved as quickly as possible in 20 ml. of boiling 6 N hydrochloric acid. To this solution is added, without delay, 1.7 g. of copper(II) chloride dihydrate dissolved in 10 ml. of 6 N hydrochloric acid; the mixture is then allowed to cool for several minutes. The yellow crystals that form are collected on a glass filter and washed with 6 N hydrochloric acid and with acetone; after being dried by strong suction, they are immediately sealed in a dry glass tube.

Found: Cu, 11.72; Cl, 39.85; N, 31.62. Calcd. for $\{C_3N_3(NH_2)_3H_2\}_2CuCl_6$: Cu, 11.93; Cl, 39.95; N, 31.56%.

(*b*) *Melammonium Hexachlorodicuprate(II)*.—One gram of melamine is dissolved in 10 ml. of boiling 6 N hydrochloric acid as quickly as possible, and the solution is mixed with 3 g. of copper(II) chloride dihydrate which has previously been dissolved in 20 ml. of 12 N hydrochloric acid. The brown needles thus formed are filtered, washed with 12 N hydrochloric acid and acetone, and kept in a desiccator.

Found: Cu, 26.44; Cl, 44.84; N, 18.21. Calcd. for $\{C_3N_3(NH_2)_3H_2\}Cu_2Cl_6$: Cu, 27.15; Cl, 45.47; N, 17.96%.

(*c*) *Benzoguanammonium Trichlorocuprate(II)*.—Two grams of benzoguanamine are dissolved in 30 ml. of hot glacial acetic acid. Two grams of copper(II) chloride dihydrate dissolved in 5 ml. of 6 N hydrochloric acid are then added, and the yellowish brown needles which precipitate out are washed on a glass filter with a mixture of glacial acetic acid and ether, and dried at about 100°C. Yield, 3.0 g.

Found: Cu, 18.57; Cl, 28.57. Calcd. for $\{C_6H_5\cdot C_3N_3(NH_2)_2H\}CuCl_3$: Cu, 17.74; Cl, 29.70.

The somewhat poorer agreement in the analytical value is probably due to a contamination of the free benzoguanamine or copper(II) chloride; the contaminating to materials are difficult to remove because of their low solubility in a mixture of glacial acetic acid and ether. Washing with such other liquids as hydrochloric acid brings about a decomposition of the preparation.

The Apparatus of EPR Measurement.—The apparatus used in EPR measurements has the same features as a spectroscope working at any other wavelength. The essential components are a source of radiation, an absorption cell, and a detector. In the microwave region the source of radiation is provided by a klystron tube which can be highly stabilized to give a very monochromatic radiation. The absorption cell is a resonant cavity tuned to the klystron frequency, and the specimen can be placed in a region of high r, f. magnetic field strength. The output from the cavity absorption cell is fed to a silicon-tungsten crystal, which detects the microwave radiation and feeds its modulated

7) H. B. Jonassen, T. B. Crumpler and T. D. O'Brien, *J. Am. Chem. Soc.*, 67, 1709 (1945).

envelope on to amplifiers. The resonance condition is

$$h\nu = g\beta H$$

where ν is the microwave frequency; β, the Bohr magneton, and H, the applied magnetic field, and where g is termed the spectroscopic splitting factor and has a value depending on the electronic state of the atom. In the present study, EPR spetra of chlorocomplexes of copper were taken at 9375 Mc., requiring magnetic fields in the 2700~3500 of range. The apparatus used in this experiment is one of Japan Electron Optics Company, of the JES-118, type, using an X-band generated by a Varian X-13 klystron tube. The magnetic field is modulated at 80 c. p. s. The field strength was calibrated by taking the spectra of the DPPH powder of an aqueous solution of manganese(II) sulfate.

The EPR spectra of powdered samples of chlorocuprates are shown in Fig. 1 (a)—(j). In Figs. (a) to (h), the upper curves are the derivatives of the absorption lines observed, and the lower curves, the integrated absorption lines. With the records of (i) and (j), integration could not be performed because of the extreme broadness of the absorption lines.

Results and Discussion

The Composition and the Color of the Chlorocuprates.—All strictly chloride complexes of copper(II) with an atomic ratio of chlorine to copper greater than 4 : 1 are yellow. This is probably due to the fact that the LF bands which impart blue or green colors to aquo or ammine complexes lie in the infrared region in chlorocuprates, while charge transfer bands come into the visible region in chloro complexes and give these compounds their yellowish color.

There is a group of chlorocuprates with the chlorine to copper ratio of 3 : 1. They are crystallized from solutions of high copper(II) concentration or from media of relatively concentrated acetic acid, and they are usually brown in color. Well-known examples are potassium copper(II) trichloride and cesium copper(II) trichloride, both of which have been found to be kinds of coordination polymers.[4,5] Additional examples found in the present research are melammonium hexachlorodicuprate(II) and benzoguanammonium trichlorocuprate(II), although their crystal structures are not yet known. All these compounds show characteristic EPR spectra, as will be discussed later.

The dark green color of diethylenetriammonium chlorocuprate(I, II) is probably due to the interaction of univalent and divalent copper ions.

EPR Absorption Spectra.—Most of the EPR data presented here are those of powdered samples. Kneubühl[8] developed a method to get EPR data from the spectra of powdered samples and applied it to the interpretation of the spectra of anisotropic copper ions. The method seems particularly convenient for the comparison of the EPR spectra of more or less analogous componuds.

Among the chlorocuprates studied in the present research, dimelammonium hexachlorocuprate(II) was the only compound that showed the fine structure of an anisotropic g-tensor. (Fig. 1(h)). By means of the method described by Kneubühl, the components of the g-tensor were evaluated as $g_{//}=2.32$ and $g_{\perp}=2.08$ for this compound.

All the other chlorocuprates studied showed single lines with half-widths ranging from 110 to 220 oe. Generally speaking, a single line can be observed either when three components of a g-tensor coincide with each other or when the superexchange interaction is great enough to smear out the effect of crystal anisotropy. The former can hardly be the case for Cu^{2+} ions in solid samples, as has in many cases been confirmed experimentally and theoretically.[9] The appearance of single lines in some copper compounds is, therefore, to be explained in terms of the latter effect.[10] In order to smear out the fine structure with the components of the g-tensor ranging from 2.08 to 2.32, the interaction energy corresponding to the exchange should be about $10^9\,sec^{-1}$. The fact that only dimelammonium hexachlorocuprate showed the superfine structure of an anisotropic g-tensor may be due to the screening effect of large planar organic molecules present in the crystal lattices of this compound.

There are two ways in which the superexchange of paramagnetic ions influence the line width of the EPR spectra: one is to broaden the width, and the other is to reduce it. The former effect, termed exchange broadening, is observed in a critical case when the exchange frequency is nearly equal to the energy separation between the resonance points divided by Planck's constant. The EPR spectra of the chlorocuprates of chain organic polyamines seem to exemplify such a case; the half width is about 200 oe, and the shape of the curve is of a bell type, with an assymmetric contour (Figs. 1 (d)—(f)).

The latter case (exchange narrowing) is the one in which the exchange frequency is greater than that in the critical case above mentioned; it is characterized by a line shape of the Lorenzian type. The EPR spectra of hexamminecobalt(III), pentachlorocuprate(II) and related

mixed valence chlorocuprates(I, II) seem to fall in this category, since the lines are comparatively narrow (80 oe) and the ratio of the line width at the half-maximum point, $\Delta H_{1/2}$, to that at the points of maximum slopes, ΔH_{msl}, is about 1.7. The symmetric line shape of the EPR absorption spectra may be taken as partly due to the special character of the $CuCl_5^{3-}$ ion, with all the Cu–Cl distance almost identical to one another.[3] Even the line shape of the spectra of a single crystal showed scarcely any angular dependence on the field directions.

The width of the curve is narrower in the chlorocuprates(I, II) than in chlorocuprate(II) in this series when the content of copper(I) is not high. It seems, however, difficult to decide whether this is due to the effect of the dilution of copper(II) or to enhanced exchange interaction caused by the presence of copper(I). When the content of copper(I) becomes overwhelmingly higher than that of copper(II), the width again increases; this is probably due to the increased field anisotropy. The main EPR data of chlorocuprates of various compositions are presented in Table I.

As has been pointed out at the beginning of this discussion, chlorocuprates with a chlorine to copper ratio of 3:1 have a brown color and are considered to have polynuclear structures. The EPR spectra of such compounds have invariably a very broad line width to cover thousands of oersteds, and the *g*-values of these lines can be evaluated only with difficulty (Figs. 1 (i) and (j)). This broadening can perhaps be attributed to the strong exchange and dipolar action and to the great anisotropy of the crystal field, both arising from the linear structure in the crystal lattices.

Summary

Some copper complexes which have only chloride ions in the coordination spheres have been prepared and their EPR spectra examined at the microwave frequency of the X-band. Most of these compounds gave single EPR lines with half-widths ranging from 110 to 220 oe; this seems to indicate the existence of superexchange interaction. Only the yellow plates of dimelammonium hexachlorocuprate-(II) showed the fine structure of an anisotropic *g*-tensor, from which fact the *g*-components were evaluated as $g_{\parallel}=2.32$ and $g_{\perp}=2.08$ for this compound. The dark green color of diethylenetriammonium chlorocuprate(I, II) is probably due to the interaction of Cu^{+} and Cu^{2+} in the crystal lattices. Brown chlorocuprates with a chlorine to copper ratio of 3:1 are probably coordination polymers; the EPR lines of these compounds are so broad as to cover thousands of oersteds.

The authors are very grateful to Dr. Toschitake Iwamoto and Mr. Yasuhito Eguchi for their kind coorperation in the EPR measurements.

On the Jacobsen Reaction. IV.[1] *Character and Reaction Mechanism*

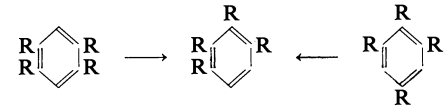
By Hitomi SUZUKI*

(Received July 22, 1963)

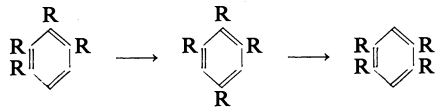
In the electrophilic substitution of highly-substituted aromatic compounds, the migration or replacement of substituents by the attacking groups has often been observed.[2-6] Although these phenomena have long been recognized, however, there have been few systematic studies on the scope of such anomalous substitution. The position at which substitution occurs is determined by the group already present in the aromatic ring and can usually be predicted from the rules governing aromatic substitution. As the compounds become more complex, however, it is difficult to predict the position precisely from the so-called "rules for orientation." This may be because the course of the reaction and the ease with which it takes place become much more influenced by such factors as the number, structure, and type of groups attached to the ring, as well as by the electronic and steric effects of these groups. Thus, the tendency towards an orthodox reaction, in which the replacement of hydrogen by an attacking group is in accordance with the rules of directive influence, is decreased while, at the same time, the reaction leading to the production of anomalous products becomes prominent.

The most typical of these anomalous reactions is the Jacobsen reaction.[7-10] This name has been given to the migration of an alkyl group or halogen atom of polysubstituted benzene derivatives containing only halogen atoms, only alkyl groups or a combination of the two, a migration which occurs when these substances are sulfonated or when their sulfonic acids are allowed to stand in contact with sulfuric acid. One of the most interesting features of this reaction is the migration of an alkyl group or halogen atom to the vicinal position. At first sight, this is in direct contrast to the orienting effects in the Friedel-Crafts reaction and has long been the object of much study.

Jacobsen reaction

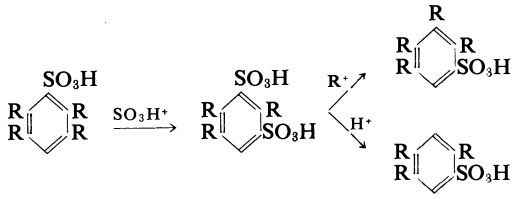


Friedel-Crafts reaction[11]



Although several mechanisms have been proposed for this reaction,[10,12-14] none of these proposals seem to be satisfactory. Some of them will, however, be cited here.

Arnold and Barnes[15] have proposed the following mechanism for the formation of the vicinal compound;



According to this theory, the migrating alkyl group is detached from the sulfonic acid molecule as a cation by the entrance of a second sulfonic acid group; this cation then replaces the more hindered sulfonic acid group

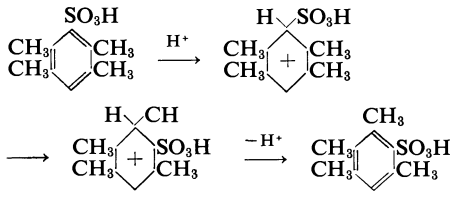
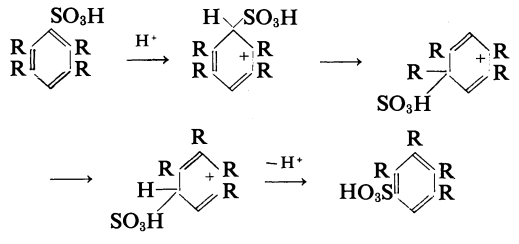
of the di-sulfonic acid. This mechanism is, however, not tenable in view of: (a) the failure to isolate the postulated intermediary di-sulfonic acid; (b) the fact that the migration of an alkyl group occurs, even under the mild conditions under which the formation of di-sulfonic acid is improbable; (c) the failure to explain many reactions involving the migration of halogen atoms, and (d) the fact that the conversion of the sulfonic acid group into amide or ester exerts an inhibitory effect on the reaction.

Dewar[16] has assumed the intramolecular migration of the sulfonic acid group; applied to durene, the reaction can be written as follows:



While a plausible explanation for some reactions of simple compounds, this mechanism fails when attempts are made to apply it to a variety of compounds which undergo the reaction. For example, since the sulfonic acid group always takes the less blocked position, the sulfonation of 5-substituted pseudocumene occurs preferrentially at the 3-position. Thus, one would, according to his theory, expect, 4-substituted hemimellitene to be the sole product from 5-substituted pseudocumene. This is not the case, however, as 5-ethylpseudocumene affords chiefly 3-ethylpseudocumene, whereas 5-isopropylpseudocumene gives no vicinal compound. Moreover, this mechanism is inconsistent with the fact that durene itself undergoes the Jacobsen reaction more readily than isodurene. His mechanism also cannot be applied to the halogen migration.

Fieser and Fieser[17] have explained the reaction on the basis of an allylic-type rearrangement of the substituent groups:



16) M. J. S. Dewar, "The Electronic Theory of Organic Chemistry," Oxford Press, London (1956).
17) L. F. Fieser and M. Fieser, "Advanced Organic Chemistry," D. C. Heath and Company, Boston (1961), p. 665.

In above mechanism the sulfonic acid is first protonated to form the aronium ion, which undergoes the allylic migration of a sulfonic acid group and the reverse migration of a methyl group, followed by the expulsion of a proton, to form prehnitene sulfonic acid. This mechanism is untenable since it cannot be used satisfactorily to explain the formation of vicinal compounds from either *unsym*-tetraalkyl or pentaalkylbenzenes as well as most of the reaction involving the migration of a halogen atom.

Thus no mechanism has yet been found which will satisfactorily explain all the available data. This is probably because several mechanisms are responsible for the Jacobsen reaction. Many of the studies of the mechanism of the reaction so far have been concerned with the reactions involved in the formation of vicinal compounds. In addition to these somewhat peculiar reactions, however, there exist a number of reactions which should be classed as Jacobsen reactions in the sense that they involve the migration of an alkyl group or halogen atom in the course of sulfonation. Therefore, it is apparent that a single mechanism capable of accounting for all the variations of the Jacobsen reaction cannot be postulated on the basis of such simple assumptions as have been mentioned above.

In this paper, the author would like first to summarize all the results of his studies, together with those of some previous workers, of the Jacobsen reactions, and then, classifying them according to their reaction types into three groups, to propose a more reasonable mechanism consistent with all the data.

Experimental Procedure

The details of the experimental procedure and findings have been given in the previous papers of the series, I-III,[1] they will not be repeated here.

The Jacobsen Reaction.—*Polyalkylbenzenes.*—The general procedure was as follows: a mixture of hydrocarbon and sulfuric acid was magnetically stirred and gradually heated on a water bath. The color changed from yellow to red; it then deepened to reddish brown, and finally to black. The complete solution of the hydrocarbon was usually effected at 60~80°C. The mixture was kept at this temperature range for 4~6 hr. and then allowed to stand for a day or two at room temperature. The mixture was diluted somewhat with water, and all solids were removed by filtration. The filtrate was distilled with superheated steam, the distillate was extracted with ether, and the extract was washed with aqueous sodium hydroxide and dried over calcium chloride. Then the solvent was evaporated and the residual oily material was fractionated.

Polyalkylhalogenobenzenes and Polyhalogenobenzenes.—The standard procedure for conducting the experiments with these compounds was divided into two parts, depending upon the solubilities of the reaction products. In procedure I, the whole reaction mixture was poured onto ice and all solids were removed by filtration. The solid was washed, dried and subjected to chromatographic separation on an alumina column. To the acidic filtrate a saturated sodium chloride solution was added to precipitate the sodium sulfonate. The salt was filtered and converted to sulfonamide, which was then fractionally crystallized. Procedure II was the same as I except for the method of handling the filtrate. The sulfonic acid solution was hydrolyzed by passing superheated steam through the filtrate, and the distillate was subjected to fractional distillation.

The Identification of the Reaction Products.—*Polyalkylbenzenes.*—All the specimens obtained from the Jacobsen reactions were inspected by gas-chromatography and infrared spectroscopy and then identified by conversion to known polybromo or polynitro compounds. The structure proof that all the groups attached to the ring were located vicinally, was effected either by the oxidation with diluted nitric acid of a portion of the specimen to benzene polycarboxylic acid, or by the transformation of the specimen into a phenanthrophenazine derivative through the dinitro and diamino compounds, which proved that the two vacant positions were ortho to each other, that is, all four alkyl substituents were in vicinal positions.

Polyalkylhalogenobenzenes and Polyhalogenobenzenes.—The oils obtained from the hydrolysis of sulfonic acids were carefully fractionated, and each fraction was subjected to gas-chromatographic and infrared spectroscopic inspection. The vicinal location of all substituent groups was established by the conversion of a specimen to a phenanthrophenazine derivative by the same method as that used in I. Solid crystalline materials were, after chromatographic separation on an alumina column, recrystallized from ethanol or benzene; they were identified by mixed melting determination with an authentic specimen prepared by other methods.

Results and Discussion

All the Jacobsen reactions may be divided into two general types, intramolecular and intermolecular; in both cases there are transfers of an alkyl group and/or halogen atom.

Polyalkylbenzenes.—The compounds which yield "abnormal products" are limited almost exclusively to tetra or pentaalkylbenzenes containing tetramethylene rings and/or alkyl groups with a short, straight chain, such as methyl, ethyl and *n*-propyl, while those with alkyl groups of a branched structure, such as isopropyl and *t*-butyl, the elimination of these or other alkyl groups are the only reactions taking place. Mono, di and trialkylbenzenes merely yield sulfonic acids, which are quite stable towards sulfuric acid.[18]

The Jacobsen reaction embodies an electrophilic attack upon the ring of polysubstituted benzenes and is dependent upon increased electron density at the position of sulfonation. It is readily apparent that an electron-attracting group, such as the nitro or carboxyl group, would inhibit the reaction. The conversion of sulfonic acid group to sulfonamide or ester exerts an inhibitory influence on the migration of an alkyl group. Reagents also exert a definite effect over the course of the reaction; fuming sulfuric acid usually favors sulfonation, whereas common sulfuric acid often brings about the migration of alkyl groups. These, and other known facts, suggest that the reversibility of sulfonation is the factor of greatest importance in determining whether a Jacobsen reaction will take place or not.

The process of the Jacobsen reaction of polyalkylbenzenes may be divided into two stages; both stages must be gone through before any Jacobsen reaction can be expected to occur in the sulfonation of polyalkylbenzenes.

(a) The elimination of an alkyl group, which occurs during the sulfonation of polyalkylbenzene relatively resistant to sulfonation owing to its highly crowded structure. In most cases the combined effects of steric hindrance and the entrance of a powerful electron-attracting group are necessary to bring about the expulsion of the migrating group.

(b) The alkyl cation thus ejected migrates, according to its stability, intramolecularly (vicinal orientation) or intermolecularly (disproportionation). The formation of the vicinal compound occurs when the migrating alkyl group can readily take the vacant position meta to the entering acid group.

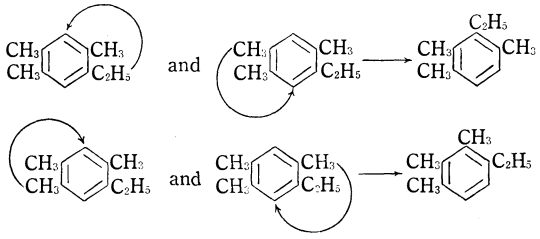
Thus, with polyalkylbenzenes containing isopropyl or a *t*-butyl group, the first stage *a* readily takes place to give a bulky cation, which is, however, incapable of participating in the next stage *b* of the reaction.[19] On the other hand, mono, di and trialkylbenzenes are simply sulfonated to give stable sulfonic acids, from which no alkyl group can be removed at all. Therefore, with these compounds no Jacobsen reaction proceeds. *sym*-Hydrindacene has a structure formally similar to those present in octahydroanthracene and durene, but it does not undergo the reaction when left standing with sulfuric acid. This may possibly be

18) With some di- and trialkylbenzenes containing bulky groups, such as isopropyl or *t*-butyl, the elimination of one of these is observed.

19) Recently, an interesting reaction involving the intramolecular migration of *t*-butyl group has been reported by M. Menard, D. Awang and F. L. Chubb, *Can. J. Chem.*, **40**, 1738 (1962).

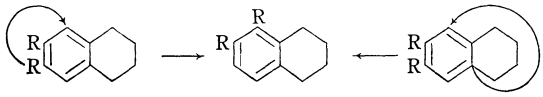
explained by the small hindering effects of five-membered rings.

In the Jacobsen reaction of tetraalkylbenzene, small amounts of trialkylbenzenes and hexaalkylbenzene were always formed. Trialkylbenzene fractions obtained from mixed tetraalkylbenzene were mixtures of several compounds. These facts indicate that there is a possibility of the formation of two or more vicinal isomers, depending on which alkyl group may shift towards the vacant position meta to the sulfonic acid group. For example, 5-ethylpseudocumene afforded two vicinal isomers, together with considerable amounts of prehnitene.[20]



An experiment conducted upon a mixture of durene and *sym*-tetraethylbenzene led to a complex mixture of polyalkylbenzenes, in which the main products were also prehnitene and *vic*-tetraethylbenzene. This fact indicates that the migration of an alkyl group to the vicinal position proceeds intramolecularly. There is apparently an inverse correlation between the ease with which a compound undergoes the Jacobsen reaction and the ease with which the compound can be sulfonated. Thus, when durene and isodurene were subjected to the action of sulfuric acid under the same conditions, it was noted that the time required for the complete migration of the methyl group was much less with durene than with isodurene.

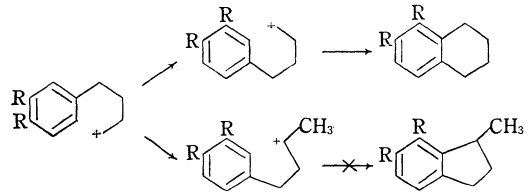
The conversion of 6, 7-dialkyltetralins to vicinal compounds can theoretically proceed by two different routes: the alkyl group may migrate from the 6 (or 7) position to the 8 (or 5), and the tetramethylene ring may open and then close in the ortho position to the alkyl group.



20) The isolation of neither of these isomers was successful. Although all possible isomeric products were undoutedly formed in the reaction of mixed polyalkylbenzene, their presence had been demonstrated or inferred only by a combination of gas-chromatography and infrared spectroscopy because of the experimental difficulties involved in separation.

The evidence that the main reaction takes place through the latter course may be briefly summarized as follows: (a) the reaction products contained only small amounts of monoalkyltetralins; (b) octahydroanthracene, in comparison to *sym*-tetraalkylbenzene, was much more readily converted to the vicinal compound under the same conditions; (c) when 5, 7- and 6, 7-dimethyltetralin were subjected to the same conditions of the Jacobsen reaction, the former gave only a small amount of an oily product which could not be identified, whereas the latter readily converted into the vicinal compound.

Although the opening of a ring, followed by the migration of an intermediate with a cationic terminal carbon atom, would involve the simultaneous isomerization of the group to the more stable secondary carbonium ion, no hydrindene derivative was detected in the reaction products from dialkyltetralins. This may be explained both by the well-known preference for the formation of a six-membered rather than a five-membered ring in cyclization, and by the tendency for a bulky cation to avoid a highly blocked position. Dialkyltetralins containing a isopropyl group were always converted into the compounds in which the isopropyl group was eliminated.



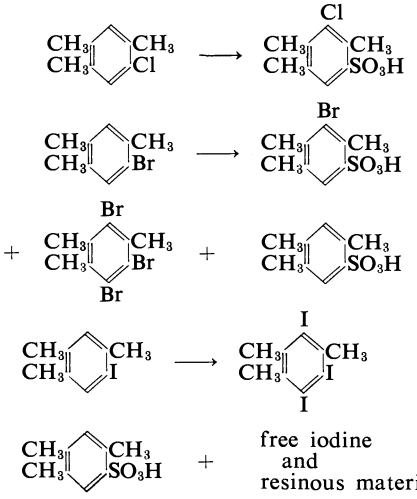
The relatively high yields of *vic*-dialkyltetralins compared to those of *vic*-tetraalkylbenzenes are attributed to the fact that one end of the long chain cation is attached to the ring and so cannot leave the molecule freely. Therefore, although *sym*-tetra-*n*-butylbenzene, with which an analogous process might be expected to occur, has not yet been studied, the formation of a vicinal compound can hardly be expected.

Reaction products from mixed polyalkylbenzenes are usually complex mixtures and require extensive purification. Furthermore, the yields are low, and the probable structure inferred from analogy should be investigated by independent methods. Thus, the Jacobsen reaction cannot be considered as a general synthetic method for *vic*-tetraalkylbenzenes.

Polyalkylhalogenobenzenes and Polyhalogenobenzenes.—An extensive study of the reaction of polyalkylhalogenobenzenes has shown, as can be predicted on theoretical grounds, that increasing the number of alkyl groups attached to the benzene ring favors both the migration

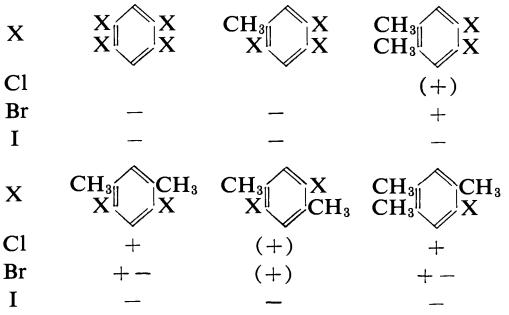
of the halogen atom and the decomposition of the compound to tarry materials. Thus, there exists a certain limited scope within which the reaction can proceed smoothly. For example, monochloroxylenes are merely sulfonated, while monoiodoxylenes afford polyiodoxylenes in high yields; with monochlorotetramethylbenzenes the migration of the methyl group is observed, whereas with monoiodotetramethylbenzenes, the reaction proceeds too readily, yielding intractable resinous materials.

The iodine atom is most readily, and the chlorine atom is least easily, replaced by the sulfonic acid group; therefore, the disproportionation is most prevalent with iodine compounds, whereas the formation of vicinal compounds is found with chlorine compounds. Bromine compounds occupies an intermediate place with respect to ease of replacement; hence, they show both disproportionation and intramolecular migration simultaneously. The three reactions which follow illustrate this statement well:



The iodine cation is unable to re-enter the molecule because of its bulkiness and so is set free as elementary iodine.

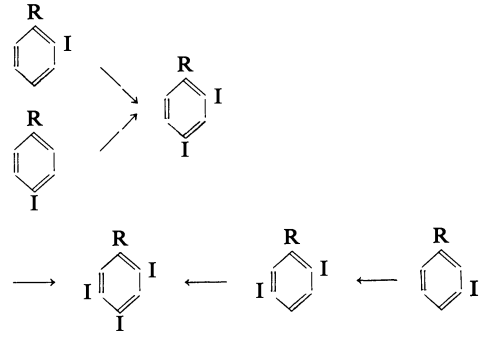
The behavior of a number of *sym*-polyhalogenobenzenes and *sym*-polyalkylhalogenobenzenes towards sulfuric acid is summarized in the following table:



where sign + denotes the formation of the vicinal compound and sign −, disproportionation. The parentheses mean that the reaction occurs only under drastic conditions.

With polyhalogenobenzenes, the Jacobsen reaction is confined almost entirely to polybromo and polyiodobenzenes. A few special cases involving chlorine migration have been found, but for the most part the chlorine atom does not undergo the migration. It appears that the halogen atom always migrates intermolecularly if any reaction occurs at all, and all the available evidence indicates that the ease of migration in these compounds is in the order of I>Br>Cl. As the ring-bonded fluorine atom is unable to form a cation, it, of course, cannot take part in the migration.

In order to determine the effect of various substituents upon the ease, course and limits of the reaction, the action of sulfuric acid upon a number of halogenobenzene derivatives was studied. Electron-attracting groups, such as the nitro, carboxyl and carbonyl, hindered the reaction so greatly that it usually failed to take place when any of these were attached to the ring. On the other hand, an accumulation of electron-releasing groups, such as hydroxy and alkoxy, facilitated the reaction so much that it was often difficult to prevent the compounds from decomposing to tarry materials. The presence of bulky groups, such as isopropyl and *t*-butyl, on the aromatic ring also interfered with the reaction. The importance of the steric factor was revealed by an examination of the products from monoiodoalkylbenzenes; with the methyl and ethyl groups, the migration products were obtained in high yields, whereas with the isopropyl and *t*-butyl groups, the reaction was that leading to the formation of resinous materials, with no definite product.

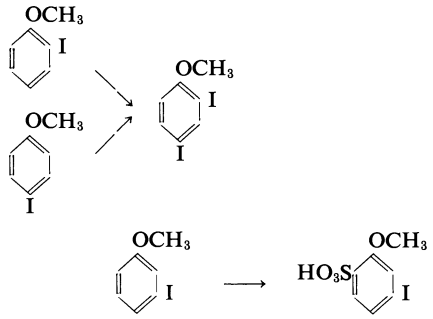


R=Methyl or ethyl

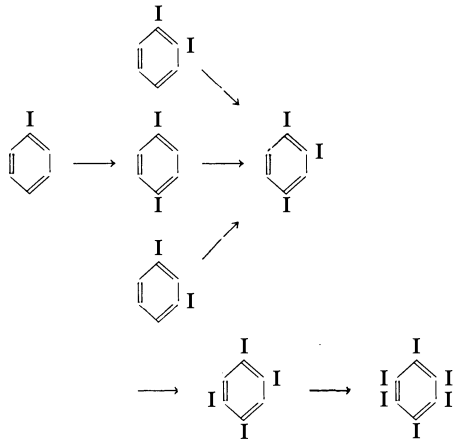
No attack of halogen atom upon the alkyl group was observed.

In some cases, slight changes in the structure of the compound may cause great differences in the ease of the migration of the halogen

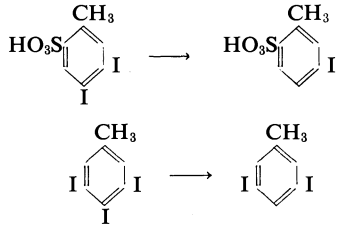
atom. For example, *o*- and *p*-iodoanisol readily gives polyiodo compounds, but *m*-isomer is simply sulfonated to give a stable 6-sulfonic acid.



The reaction usually proceeds as the progressive halogenation of the parent compound, and a certain isomer is always formed in preference to others. For example,



When there exist more than one halogen atom capable of migration, the preferential replacement occurs with those present at the positions that have a higher electron density or a greater steric hindrance.

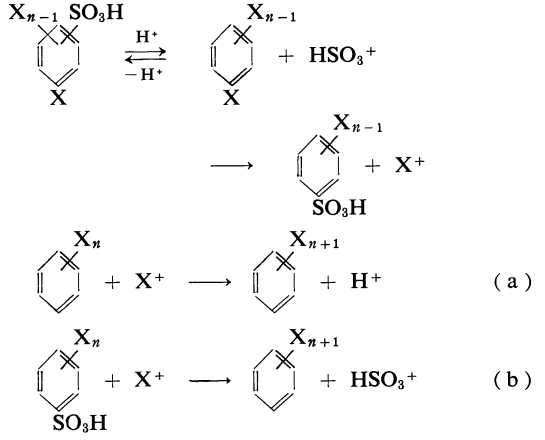


The reaction is considered of much value for the direct synthesis of some polyiodo compounds.[21]

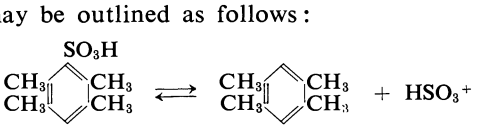
Mechanism.—All the Jacobsen reactions so far observed can be divided into three groups according to their reaction types: *the first*, shown by a compound relatively resistant to sulfonation because of its highly crowded structure, involves an anomalous sulfonation leading to the elimination of an alkyl group or a halogen atom, followed by its migration; *the second*, in which the normal sulfonation of a compound constitutes the initial phase of the reaction, is most often encountered with these compounds which are readily sulfonated to form a stable sulfonic acid (the migration of substituent groups on the ring gradually occurs intra- or intermolecularly, depending on their structures and experimental conditions); *the third* is shown by some polyiodo compounds, in which no sulfonation can be expected at all because of their highly crowded structures and reduced reactivities (the protonation of the compound, followed by the expulsion of the iodine cation, must constitute the initial phase of this reaction).

In the following discussion, for each individual group of reactions the author has attempted to formulate a mechanism with which to explain satisfactorily the experimental findings so far obtained on the Jacobsen reaction.

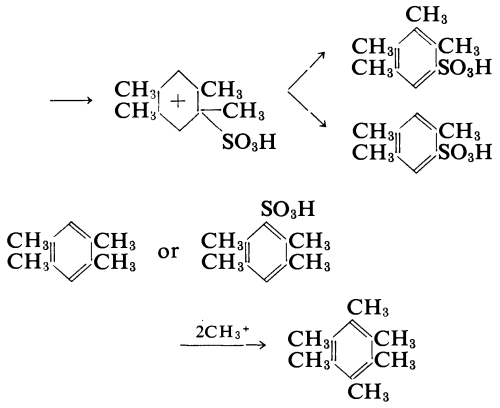
(I) The first group involves compounds relatively difficult to sulfonate and may be represented by the following generalized scheme:



This is a two-stage reaction initiated by the electrophilic attack of a sulfonic acid group, which will, of course, seek a position with high electron density and small steric hindrance. The alkyl group or halogen cation which is eliminated during sulfonation will react with the parent compound according to Eq. a, or with the sulfonic acid according to Eq. b. The most typical reactions of this group are those observed in the sulfonation of *sym*-tetraalkylbenzenes, in which vicinal compounds are formed. Applied to durene, this may be outlined as follows:

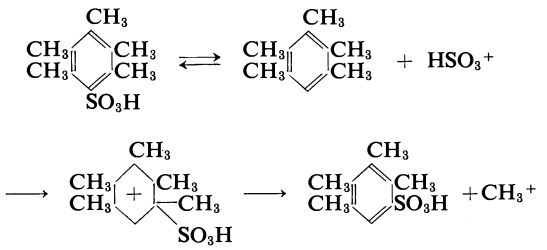


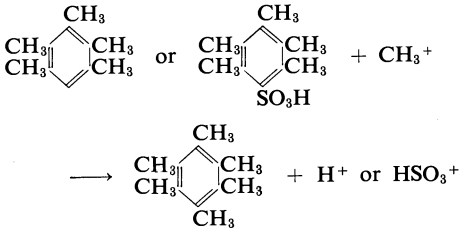
21) H. Suzuki and R. Goto, This Bulletin, **36**, 389 (1963).



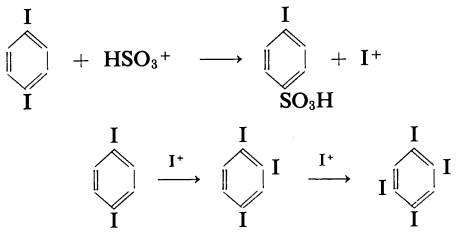
The formation of the vicinal compound may be interpreted as follows: a partially positive methyl group may be ejected from durene by the attack of a sulfonic acid group, but, never becoming completely free, it may form a π-complex with the ring and then pass to the vacant position meta to the sulfonic acid group. The remarkable color changes involved in the initial phase of the reaction support the theory that the reaction proceeds through the intermediary complex described above. The ability of several migrating groups to take this vacant position, giving vicinal compounds, is influenced to a large extent by steric requirements. This can readily be visualized by a series of 5-substituted pseudocumenes: the combined inductive and mesomeric effects of methyl groups give rise to a high electron density at the 5-position of pseudocumene derivatives and hence facilitate the electrophilic attack at this position by a sulfonic acid group, which expels a substituent group there as a cation. When the cationic group ejected is reactive and is sterically small enough, there a vicinal orientation is always observed. This is the case with 5-methyl, 5-ethyl, 5-chloro and 5-bromopseudocumene. If larger groups are involved in the reaction, the elimination of these groups is the only reaction that proceeds. These are found, for example, with 5-isopropyl and 5-iodopseudocumene.

The reactions of dialkyltetralin and pentaalkylbenzene may also be incorporated into this group. For example, with pentamethylbenzene:



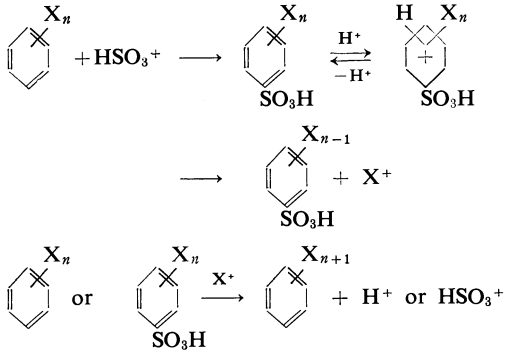


Next, let us consider compounds with only a few substituent groups. It has long been known that the sulfonation of *p*-diiodobenzene is always accompanied by disproportionation, thus giving *p*-iodobenzene sulfonic acid and mixtures of polyiodobenzenes. This process is also represented by an analogous two-stage mechanism, in which the following processes take place:



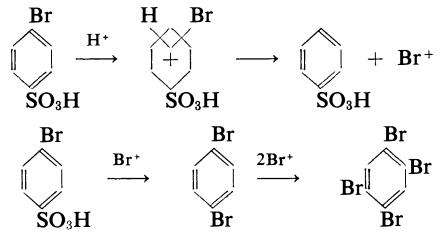
When some polyalkylbenzenes containing *t*-butyl groups are allowed to stand in contact with sulfuric acid, the elimination of the *t*-butyl group is observed to some extent. In these cases, however, the extreme aversion of the *t*-butyl group to the entry in a position ortho to the alkyl groups in the ring inhibits the further alkylation of the parent hydrocarbons; thus, no reaction analogous to the Jacobsen proceeds.

(II) The second group includes the reactions which are most often encountered with compounds readily subject to the action of sulfuric acid. As has been mentioned above, the ease of sulfonation is inversely related to that of migration; hence, the compounds of this group need more time for the completion of the reaction. It is best represented by the following generalized scheme:

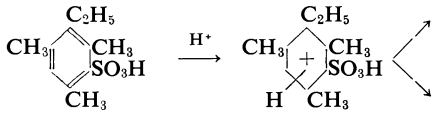


The reaction scheme above is interpreted at follows: sulfonic acid is first protonated to form an intermediate complex, from which the group present at the position of higher electron density and larger steric hindrance is ejected. The alkyl group or halogen atom thus expelled may migrate, according to its stability, intramolecularly to form vicinal compounds or intermolecularly to yield disproportionation products.

The formation of polybromobenzenes from monobromobenzene is one example:

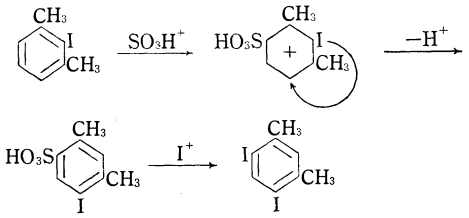


There are two possible routes by which a vicinal compound can be formed from a non-vicinal compound: one is that just described in group I, the other belongs to group II. For example, *unsym*-tetraalkylbenzenes are necessarily sulfonated ortho to both alkyl groups unless one of them is displaced by the entering sulfonic acid group. Thus, there arises a great steric hindrance which forces the migration of one of the alkyl groups so as to reduce the blocking action on the sulfonic acid group. Applied to ethylmesitylene, this may be outlined as follows:



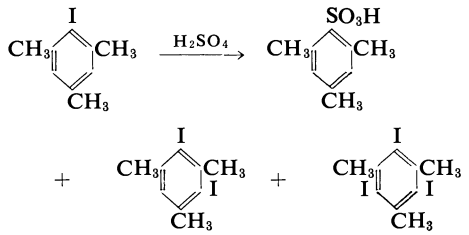
The vicinal orientation found with *unsym*-tetraalkylbenzene sulfonic acid is attributed to the buttressing effect of the alkyl group meta to the sulfonic acid group, because *sym*-trialkylbenzenes in which no buttressing effect of meta alkyl group is present can never show the Jacobsen reaction.

Another interesting example was found in the reaction of 2-iodo-*m*-xylene and 2, 3-diiodotoluene (cf. a future communication), where was formed not the expected 2, 4-diiodo-*m*-xylene nor 2, 3, 6-triiodotoluene, but the symmetrically-substituted 4, 6-diiodo-*m*-xylene and 2, 4, 5-triiodotoluene. These must have been formed as a result of initial sulfonation at the 6-position, followed by the intramolecular shift of the iodine atom from the hindered position 2 to the 4.[22]

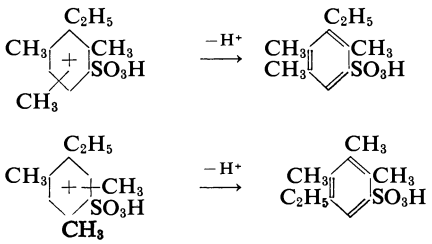


These resuits further support the concept that the entry of a bulky group at the meta position has a great influence on the stability of the substituent group sterically hindered by two ortho substituents.

The sulfonation of iodomesitylene might be another example where no reaction proceeds without accompanying the disproportionation of the iodine atom;[23]



These two types of reaction routes, I and II, however, must be regarded as extremes; a number of the reactions may possibly take place through a course which could be regarded as a combination of the two. Which type



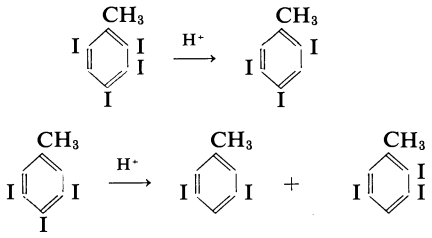
of reaction predominates depends on the steric requirements of the compound subjected to the Jacobsen reaction. With highly crowded compounds, the reaction scheme I, involving direct displacement, seems important, whereas with less crowded compounds the reaction scheme II predominates.

(III) The third group is quite different from the two mentioned above; here sulfuric acid appears to act only as a protic solvent. Some polyiodo compounds with highly crowded structures, with which no sulfonation can be

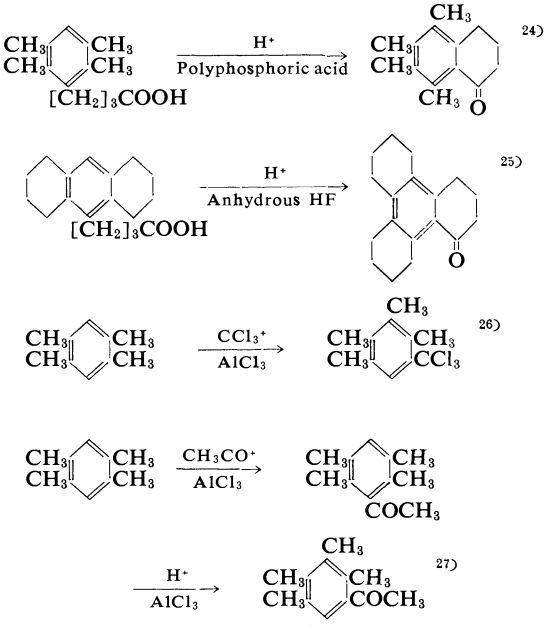
22) As *m*-xylene sulfonic acid and iodine afford no iodinated compound under the same conditions, the intermolecular migration of iodine atom is less probable.

23) A. Tohl and R. Eckel, *Ber.*, **26**, 1099 (1893).

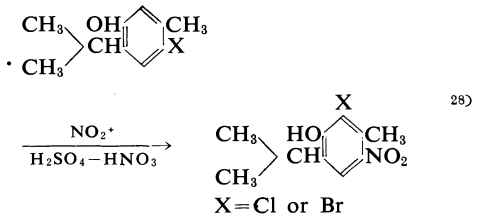
expected to occur, undergo this type of reaction under drastic conditions. For example:



These can not be classed as true Jacobsen reactions, however, because no sulfonation is involved in the above reactions. There are, however, many interesting observations in the literature on the migration of an alkyl group or halogen atom, analogous to the Jacobsen reaction, where neither sulfonation nor a sulfonic acid group is concerned. The following are some examples:



24) W. L. Mosby, *J. Am. Chem. Soc.*, **74**, 2564 (1952); *J. Org. Chem.*, **18**, 483 (1953).
25) G. M. Badger, W. Carruthers and J. W. Cook, *J. Chem. Soc.*, **1949**, 2044.
26) H. Hart and R. W. Fish, *J. Am. Chem. Soc.*, **83**, 4460 (1961).
27) G. Baddeley and A. G. Pendlum, *J. Chem. Soc.*, **1952**, 807.



28) P. W. Robinson and H. V. A. Brisooe, ibid., **101**, 1964 (1912).

All cases contain intra- and/or intermolecular migration in the presence of an acidic medium, of an alkyl group or of a halogen atom, involving the vicinal orientation of these groups. If we consider that the nitro, carbonyl or acetyl group plays the same role as that of the sulfonic acid group in the Jacobsen reaction, then we may suppose that the above reactions are Jacobsen types and may indeed take place by analogous processes.

For the purpose of classifying these anomalous reactions, it seems convenient to give the term "Jacobsen Reaction" a much wider meaning, that is, to extend the definition to the general cases of anomalous electrophilic substitution, in which there is observed an intra- or intermolecular migration of substituent groups expelled by the entry of electrophilic attacking groups under the very influence of acidic solvents. Therefore, the term "Jacobsen Reaction" will no longer mean only abnormal sulfonation in a narrow sense, but a variety of anomalous electrophilic substitutions of a similar nature which are at present not systematized and are included in other categories.

The author wishes to express his gratitude to Professor Ryozo Goto of Kyoto University for his continuous encouragement and helpful discussions throughout this work.

Photoconductive Polymer: Its Preparation and Photoconductive Behavior

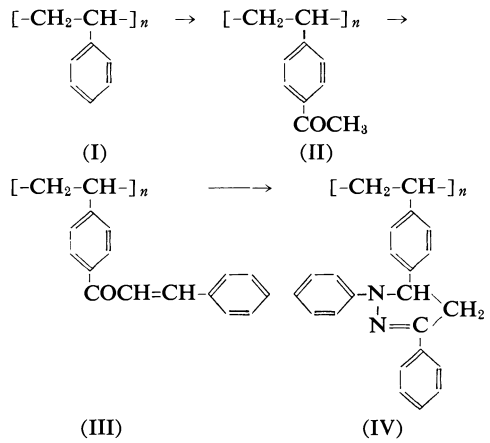
By Kazuhisa MORIMOTO, Yoshiki HAYASHI and Akira INAMI

(Received July 30, 1963)

The photoconductive properties of 1, 3, 4,-triphenyl-2-pyrazoline, its derivatives and homologues have already been established,[1] and the present authors have reported in another paper[2] on their photoconductive and electrophotographic characteristics. A poly-[1, 3-diphenyl-5-(4-vinylphenyl)-2-pyrazoline] is considered to be perhaps the simplest polymer with a triphenyl-2-pyrazoline group to synthesize. Recently several polymers containing heterocyclic group have been reported,[3-5] but because vinyl monomers containing a heterocyclic group are chemically unstable, in most cases only solvent-insoluble high polymers can be obtained. The most successful synthetic route, therefore, is first to prepare polyvinylbenzalacetophenone from polystyrene, and then to let the product react with phenylhydrazine. This sequence produces poly[1, 2-diphenyl-5-(4-vinylphenyl)-2-pyrazoline] of a considerable purity. Under carefully controlled preparative conditions, a high degree of substitution is obtained without the substance's being insoluble in an organic solvent. The photoconductive behavior of this material is then measured.

Experimental

Synthesis of the Polymer. — The polymer was synthesized in three steps as follows:



Polyvinylacetophenone (II) from Acetyl Chloride and Polystyrene (I).[6] — In a stirred flask with a dropping funnel and reflux condenser, 500 ml. of carbon disulfide, 134 g. (1 mol.) of aluminum chloride, and 59 g. (0.5 mol.) of polystyrene ($[\eta]=0.68$, at 25°C in benzene) dissolved in 500 ml. of carbon disulfide were placed in that order. The mixture was refluxed gently for about one hour, and the mass was heated in water to remove the carbon disulfide. The product was broken up and washed in water, then dried to yield about 63 g. of a nearly white powder. The product was soluble in acetophenone, acetone, acetic acid and dioxane.

Found: C, 81.53; H, 6.95. Calcd. for $C_{10}H_{10}O$: C, 82.15; H, 6.90%.

$[\eta]=0.33$, at 25°C in acetone.

Polyvinylbenzalacetophenone (III) from Polyvinylacetophenone with Benzaldehyde.[7]—To a solution of 10.0 g. of polyvinylacetophenone dissolved in 100 ml. of benzaldehyde, 2 g. of concentrated sulfuric acid dissolved in 30 ml. of benzaldehyde were added. After this mixture had stood in the dark for 96 hr., 10 g. of anhydrous sodium acetate was added to decompose the sulfuric catalyst. The solid substance was removed by centrifuging, and the remaining liquid was then poured into methanol. The pale yellow precipitate was twice reprecipitated from a monochlorobenzene solution by pouring it into methanol, and then it was dried in the dark at room temperature. The product was soluble in benzene, monochlorobenzene, ethyl methyl ketone and dioxane.

Found: C, 87.47; H, 6.69. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

$[\eta]=0.73$, at 25°C in dioxane.

Poly[1, 3-diphenyl-5-(4-vinylphenyl)-2-pyrazoline] (IV). — To a solution of 5 g. (0.02 mol.) of polyvinylbenzalacetophenone dissolved in a mixture of 50 ml. of dioxane and 6.5 g. of glacial acetic acid, 2.5 g. of phenylhydrazine were added. After the mixture had been stirred for 90 min. at 90°C, the solution was poured into methanol. The yellow precipitate was twice reprecipitated from dioxane solution by pouring it into methanol; it was then dried to yield about 4.8 g. of yellow powder. The product was soluble in benzene, toluene, monochlorobenzene, dioxane and methylene chloride.

Found: C, 81.67; H, 6.06; N, 8.72. Calcd. for $C_{23}H_{20}N_2$: C, 85.18; H, 6.17; N, 8.64%.

The Infrared Spectra of the Polymers. — The polymers synthesized were identified by comparing the infrared absorption bands of those compounds which do not have a vinyl group, such as acetophenone, benzalacetophenone and 1,3,4-triphenyl-2-pyrazoline. The infrared absorption spectra were measured with a Hitachi double-beam spectrometer. The polymers used were in the form of a thin film.

The Photoconductivity of Polymer, IV. — The conductivity cell used for the polymer was the so-called "sandwich-type photoconductivity cell," a schematic diagram of which is shown in Fig. 1.

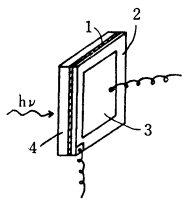

Fig. 1. The sandwich-type cell.
1, NESA coated layer; 2, polymer specimen film; 3, aluminum evaporated layer; 4, glass substratum

The preparation of the cell was carried out by the following technique: a 10% polymer solution of monochlorobenzene was placed uniformly flat onto a NESA conductive glass plate used as a transparent electrode with the aid of a Baker-type film applicator; then the solvent was throughly evaporated in the drying oven. After the solvent had been evaporated, the specimen film was 20 μ thick. The second electrode was formed thereafter by the evaporation of aluminum onto the surface of the specimen film.

The sandwich-type cell thus obtained was then placed in a closed glass chamber (as shown in Fig. 2), which was kept in a vacuo of $<10^{-3}$ mmHg. The

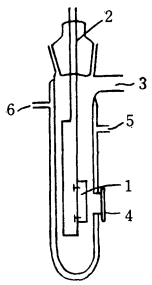

Fig. 2. The schematic diagram of the sandwich type cell placed in glass chamber.

temperature of the specimen was always kept at 25°C. The applied field to the specimen was 1500 V.-cm^{-1} (taken from a 3 V. dry battery source), and the current measurement was carried out with the aid of a vibration-reed electronic micro-micro ammeter (Takeda Riken, type TR-85) and an electronic X-T recorder (Toa-dempa, type EPR-2).

As the resistance of the polymer in both dark and light showed a considerably high value, the glass chamber was completey shielded to avoid all noises. The light source used for measuring the photocurrent of the cell was a 100 W tungsten lamp. When necessary, an interference filter was placed in the path of the light beam to obtain monochromatic light.

The sandwich-type celles tested were stored in a dark desiccator immediately after they had been coated. The cell that had been exposed to light was tested after it had been in the dark at least 24 hr. A diagram of the entire photoconductivity apparatus is shown in Fig. 3.

Results and Discussion

Identification of the Polymers. — *Polyvinylacetophenone.*—The infrared spectrum of polyvinylacetophenone indicates the absorptions of the acetyl group.

Wave number, cm^{-1}	Absorbing structure
1680	Carbonyl
1268	Aromatic ketone
1360	Methyl

Polyvinylbenzalacetophenone. — The absorption bands at 1304 and 975 cm^{-1} may be assigned to disubstituted ethylene, those at 765 and 696 cm^{-1}, to monosubstituted benzene, that at 1576 cm^{-1}, to benzal; that at 1663 cm^{-1}, to carbonyl, and that at 1216 cm^{-1}, to aromatic ketone. As the absorption band at 1360 cm^{-1} resulting from the methyl group is not present, it is considered that the reaction is complete.

Poly[1,3-diphenyl-5-(4-vinylphenyl)-2-pyrazoline].—As is shown in Fig. 4, the absorption bands at 1663 and 1216 cm^{-1}, resulting from the carbonyl group, completely disappear, and the bands at 1304 and 975 cm^{-1} resulting from the disubstituted ethylene group are barely present.

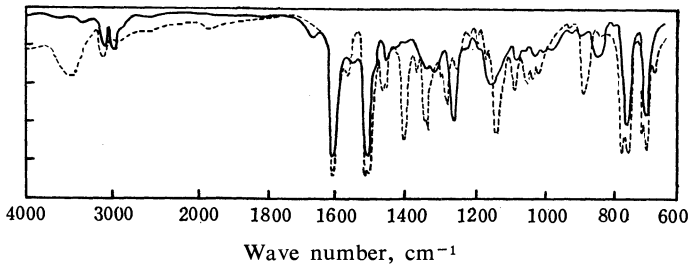

Fig. 4. IR spectra of poly[1,3-diphenyl-5-(4-vinylphenyl)-2-pyrazoline] (solid line) and of 1,3,4-triphenyl-2-pyrazoline (dotted line).

Photoconductivity Behavior. — *V-I Characteristic in the Dark.*—From Fig. 5 it may be seen that the V-I plot in the dark passes through the point of origin, showing that the dark

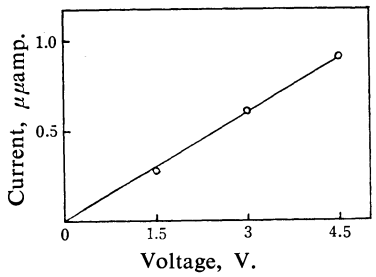

Fig. 5. Relation between voltage applied and photocurrent.

current of the specimen obeys Ohm's law. It may, therefore, be assumed that the contacts between the specimen film and the aluminum layer or NESA conductive surface are perfect.

The Photocurrent in an Incandescent Lamp.— When the cell is illuminated with an intense luminous flux, the photocurrent rises instantly and reaches a maximum value in less than 2 sec. Also, when the light source is switched off, the current decreases to the initial dark value in the same period. When illuminated with a weak light beam or monochromatic light, however, it takes several seconds to attain the peak current. Also, a longer time is required for it to come to equilibrium when the light is switched off to neutralize the space charge to zero.

A large photocurrent value is observed for this type of cell when the illuminated electrode is negative. This behavior suggests that the charge carriers in this polymer are mainly electrons rather than positive holes. The same relation was observed by Northrop and Simpson,[8-10] who used this type of cell for lower molecular weight polyaromatics. The

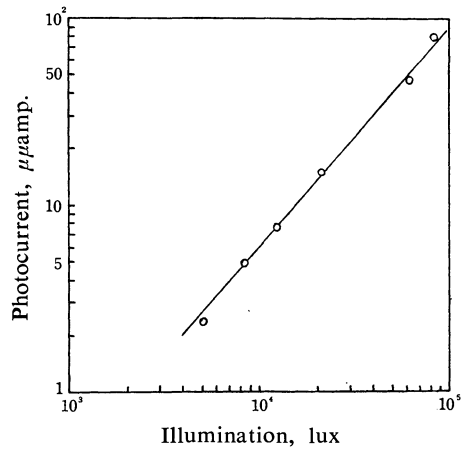

Fig. 6. Photoconductivity curve.

value of I_p(photocurrent)/I_d(dark current) is 34 or 147 depending on whether the illuminated electrode is positive or negative respectively.

When a powerfull incandescence (10^3 to 10^5 luxes) is applied o the cell, as is shown in Fig. 6, the empirical formula

$$I_p = KL^{1.2}$$

can be applied, where K is a constant and L, the illumination.

Monochromatic Photoresponses. — The monochromatic responses of the polymer specimen are shown in Fig. 7. As may be seen from these results, remarkable responses occur in the wavelength of 400 and 425 mμ.

Summary

A photoconductive polymer, poly[1, 3-diphenyl-5-(4-vinylphenyl)-2-pyrazoline], has been synthesized from polystyrene via polyvinylacetophenone and polyvinylbenzalacetophenone. Under carefully controlled preparative conditions, a high degree of substitution has been obtained without its being insoluble. The photoconductive behavior of the polymer has been measured using a sandwich-type cell. The current obeyed Ohm's law, and the value of I_p/I_d was 34 or 147 depending on whether the illuminated electrode was positive or negative respectively.

Studies on Fluorene Derivatives. XXI. The Radical Bromination of Dibiphenyleneethane and Its Derivatives by N-Bromosuccinimide*

By Kazuo SUZUKI and Minoru FUJIMOTO

(Received July 30, 1963)

N-Bromosuccinimide (NBS) has been used as a brominating agent[1] for a wide variety of organic compounds and as an oxidizing agent for some alcohols.

The present investigation is concerned with the reaction of NBS with dibiphenyleneethane and its bromoderivatives in order to introduce, selectively, a bromine atom on a methine group adjacent to an aromatic ring. These compounds were used further to prepare tribiphenylene-propane and its bromo derivatives by a halogen-metal interconversion reaction between 9-fluorenyl lithium and substituted 9-bromodibiphenyleneethane.[2]

The bromination reaction was carried out readily by refluxing the hydrocarbons with equimolar quantites of NBS in absolute benzene for 4 hr. Fluorene,[3] 2-bromofluorene (70%)[4] and 2,7-dibromofluorene (89%) react with NBS in benzene to give fairly good yields of the corresponding 9-bromosubstituted fluorenes. With dibiphenyleneethane it was possible, by selective bromination, to prepare mono or dibromosubstituted ethanes with high yields.

Two isomers were expected in the reaction of NBS with 2-bromodibiphenyleneethane. The structure of one, 2,9'-dibromodibiphenyleneethane (see Table I, Run 6), was confirmed by synthesis from hydrogen bromide and 2-bromo-9'-hydroxydibiphenyleneethane. The reaction of 2,7-dibromodibiphenyleneethane[5] with NBS also yielded two isomers, the structures of which were proved by independent syntheses.

The reaction of the symmetrical compounds, 2,2'-,[6] 3,3'-[7] and 4,4'-dibromodibiphenyleneethanes,[8] with equimolar quantities of NBS gave the corresponding 2,2',9-, 3,3',9- and 4,4',9-tribromodibiphenyleneethanes.

These results are summarized in Table I, which gives data on several preparations made under almost identical conditions.

It is very difficult to introduce a bromine atom on the 9-position of 1,1'-dibromodibiphenyleneethane[9] with NBS. Both of the starting materials were recovered even after having been refluxed for 10 hr. periods, per-

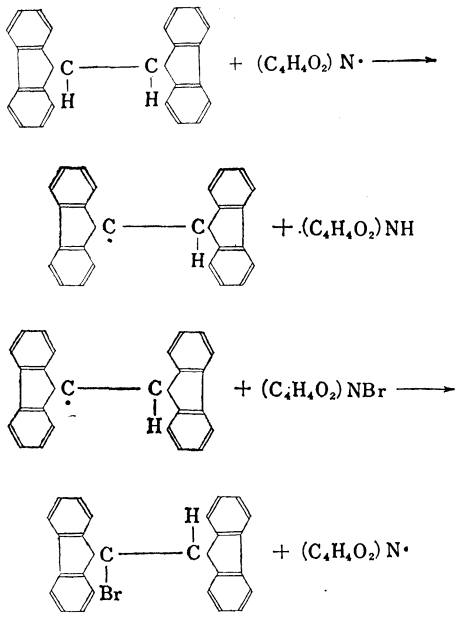
D: Dibiphenyleneethane

(d): Decomposition: These compounds were red colored because of the formation of dibiphenyleneethylenes at their melting points.

Run 5: Three products were separated by chromatography in benzene on alumina.

haps, because of the greater steric hindrance of the bromine atoms at the 1-positions.

These reactions proceed through a thermal, homolytic dissociation of the N–Br bond in NBS, followed by the abstraction of hydrogen from the methine groups by the free radical, and they involve chain termination accompanied by the formation of succinimide. The general mechanism acceptable for the bromination of dibiphenyleneethane derivatives may be visualized as follows:



However, it should be mentioned in connection with these results that, from the direct action of equimolar quantities of bromine on dibiphenyleneethane, small amounts of fluorenone and 10, 10-diphenylen-9-phenanthrone were isolated in carbon tetrachloride. In carbon disulfide, dibiphenylene-ethylene was formed. These compounds result from the formation of 9-bromo-substituted products followed by the evolution of hydrogen bromide. In addition, a small amount of nuclear-substituted 2-bromodibiphenyleneethane was obtained in the reaction carried out in chloroform. From these results, it seems likely, that the reactions with bromine proceed by an ionic mechanism.

Experimental*

The General Reaction Procedure of Dibiphenyleneethanes with *N*-Bromosuccinimide.—To dibiphenyleneethane (1 g., 0.003 mol.) in dry benzene (20 ml.) *N*-bromosuccinimide (0.54 g., 0.003 mol.) was added, and the mixture was refluxed for 4 hr. The orange solution turned red. After this solution had cooled, the succinimide (0.3 g., m. p. 123°C) formed was filtered, and the benzene was removed in vacuo. The crystal mass was digested with water, then recrystallized from cyclohexane after it had been dried. When it had been cooled, a first crop of 0.91 g. of 9-bromodibiphenyleneethane was obtained. The concentration of the mother liquor gave a second crop of 0.12 g. of almost colorless hexagonal crystals. The yield was 84.4%; m. p. 168~170°C. The structure was proved by a mixed melting point determination with an authentic sample of 9-bromodibiphenyleneethane, with had been prepared by the reaction of 9-hydroxydibiphenyleneethane and hydrogen bromide in acetic acid.

The Reaction of 2-Bromofluorene or 2, 7-Dibromofluorene with *N*-Bromosuccinimide.—A mixture of *N*-bromosuccinimide (3.6 g., 0.02 mol. or 5.5 g., 0.03 mol.) and 2-bromofluorene (5.0 g., 0.02 mol.) or 2, 7-dibromofluorene (10.0 g., 0.03 mol.) respectively in dry benzene (20 ml. or 50 ml.) was refluxed for 4 or 5 hr. After the mixture had been cooled, the succinimide was filtered off. Evaporation of the solvent, and recrystallization of the residue from dry cyclohexane or dry benzene, resulted in 4.5 g. (70.3%) of 2, 9-dibromofluorene (m. p. 118~120°C) and 11.0 g. (88.6%) of 2, 7, 9-tribromofluorene (m. p. 190~192°C). These products were identified by a comparison of mixed melting points and infrared absorption spectrum with authentic samples.

The General Reaction Procedure for the Bromination of Dibiphenyleneethane. — To a stirred solution of 1.0 g. (0.003 mol.) of dibiphenyleneethane in 20 ml. of chloroform, there was added very slowly, over an 8 hr. period, 0.5 g. (0.003 mol.) of bromine in 10 ml. of a chloroform solution at 25°C, followed by an additional hour of stirring. Shortly after the addition had begun, hydrogen bromide was evolved. The orange-red reaction mixture was washed with water and dried over anhydrous calcium chloride, and the chloroform was evaporated to a small volume at reduced pressure; when this had been cooled, the deposited material was filtered and recrystallized from benzene to give 9, 9'-dibromodibiphenyleneethane (m. p. 238~242°C (decomp.)) (0.1 g.).

The first chloroform mother liquor was evaporated to one-half its original volume, and the precipitate was digested with hot cyclohexane. 2-Bromodibiphenyleneethane was obtained in the form of colorless needles, which recrystallized from alcohol to give 0.39 g. (m. p. 227~229°C).

The second chloroform mother liquor was evaporated to dryness, and the oily solid was recrystal-

* All the melting points are uncorrected.

lized from benzene, giving 0.05 g. of 9-bromodibiphenyleneethane (m. p. 166~168°C (decomp.)). These three compounds were identified by a comparison of melting points, mixed melting points and infrared absorption spectrum with authentic samples.

Syntheses of 2-Bromo-9'-hydroxydibiphenyleneethane and 2, 9'-Dibromodibiphenyleneethane.—Over a period of 2 hr., in an atmosphere of dry and oxygen-free nitrogen, 40 ml. of an ether solution containing 8.6 g. (0.062 mol.) of *n*-butyl bromide was added to a rapidly stirred mixture of 40 ml. of sodium-dried ether and 0.86 g. (0.12 g. atom) of freshly-cut lithium metal pieces. To this dark, *n*-butyl lithium solution, there was added, drop by drop, over a 45-min. period, a solution of 15.0 g. (0.061 mol.) of 2-bromofluorene in 100 ml. of an anhydrous xylene solution (exothermic reaction). The dark yellow-green color turned orange-red upon being heated. The ether was distilled off until a temperature of 120°C was reached, the solution turned dark-red, and a greenish-yellow solid deposited. Heating was continued for 30 min. at this temperature.

Into this resultant solution there was stirred, drop by drop, a solution of anhydrous xylene containing 11.0 g. (0.061 mol.) of fluorenone. The reaction mixture, which changed brown, was then heated to 100°C over a 90-min. period. The brown precipitate was filtered, hydrolyzed with a dilute ammonium chloride solution, and then recrystallized from cyclohexane to give 11.9 g. (m. p. 123~125°C) of 2-bromo-9'-hydroxydibiphenyleneethane.

Found: Br, 18.26. Calcd. for $C_{26}H_{17}OBr$: Br, 18.79%.

IR: 3270 (ν_{O-H}), 1155 (ν_{C-O}) cm^{-1} (KBr-disk).

The xylene mother liquor was also hydrolyzed with the same solution and dried over anhydrous sodium sulfate. Evaporation in vacuo gave a residual product which was chromatographed in benzene on alumina. 2-Bromo-9'-hydroxydibiphenyleneethane (m. p. 123~125°C) (2.6 g., total 58%) and 2-bromofluorene (0.5 g.) were obtained from the column.

2, 9'-Dibromodibiphenyleneethane.—A solution of 1.0 g. of 2-bromo-9'-hydroxydibiphenyleneethane in 10 ml. of acetic acid was saturated with dry hydrogen bromide. The product was filtered off and recrystallized from cyclohexane to give 2,9'-dibromodibiphenyleneethane (m. p. 146~148°C (decomp.)) (0.6 g.), identical in melting point, mixed melting point and infrared absorption spectrum with the compound obtained by the reaction of 2-bromodibiphenyleneethane and *N*-bromosuccinimide.

Found: Br, 32.51. Calcd. for $C_{26}H_{16}Br_2$: Br, 32.74%.

Syntheses of 2, 7-Dibromo-9'-hydroxydibiphenyleneethane and 2,7,9'-Tribromodibiphenyleneethane.—The former compound was prepared by the same procedure as was 2-bromo-9'-hydroxydibiphenyleneethane. Yield, 20.4% (m. p. 198~200°C).

Found: Br, 31.54. Calcd. for $C_{26}H_{16}OBr_2$: Br, 31.70%.

IR: 3260 (ν_{O-H}), 1154 (ν_{C-O}) cm^{-1} (KBr-disk).

2, 7, 9'-Tribromodibiphenyleneethane.—A solution of 1.0 g. of 2, 7-dibromo-9'-hydroxydibiphenyleneethane in 40 ml. of acetic acid was saturated with dry hydrogen bromide. The solid which was thus formed was recrystallized from benzene to give 2, 7, 9'-tribromodibiphenyleneethane; m. p. 206~207°C (decomp.); 0.8 g. (70%).

Found: Br, 42.10. Calcd. for $C_{26}H_{15}Br_3$: Br, 42.27%.

This product was identical in mixed melting point and infrared absorption spectrum with that obtained by the reaction of 2, 7-dibromodibiphenyleneethane and *N*-bromosuccinimide.

The Syntheses of 2, 7-Dibromo-9-hydroxydibiphenyleneethane and 2, 7, 9-Tribromodibiphenyleneethane.—The former compound was prepared by a method similar to that used for 2, 7-dibromo-9'-hydroxydibiphenyleneethane. Yield, 73%, m. p. 225~226°C.

Found: Br, 31.58. Calcd. for $C_{26}H_{16}OBr_2$: Br, 31.70%.

IR: 3230 (ν_{O-H}), 1155 (ν_{C-O}) cm^{-1} (KBr-disk).

2, 7, 9-Tribromodibiphenyleneethane.—2, 7-Dibromo-9-hydroxydibiphenyleneethane (1.5 g.) was dissolved in 60 ml. of acetic acid, which was then saturated with dry hydrogen bromide. The product deposited was recrystallized from benzene; (1.4 g., 83.3%) m. p. 216~217°C (decomp.). This product was identical in mixed melting point and infrared absorption spectrum with the product obtained by the reaction of 2, 7-dibromodibiphenyleneethane and *N*-bromosuccinimide.

Found: Br, 42.44. Calcd. for $C_{26}H_{15}Br_3$: Br, 42.27%.

The authors wish to express their gratitudes to Drs. John and Elizabeth Weisburger of the National Institutes of Health, U. S. A., for valuable information, and also to Dr. Shôji Kajigaeshi of Kyushû University, for the mixing test of the 2-bromodibiphenyleneethane.

Studies on the Complex Formation between Uranium and Thiomalic Acid

By V. K. MATHUR, H. L. NIGAM and S. C. SRIVASTAVA

(Received July 31, 1963)

Attempts to study the complex formation between thiomalic acid and UO_2(II) has been made using spectrophotometric, potentiometric and magnetic susceptibility measurements. Thiomalic acid gives coloured complexes and has chiefly been used as an analytical reagent.[1-3] Some recent investigations[4-11] on thiomalic acid show it to be a powerful coordinating agent as is expected from the ideal position occupied by the sulphydryl group and two carboxylic groups in the molecule. Thiomalic acid is found to behave as a bidentate ligand with UO_2(II). The complex formed, however, exhibits anamolous magnateic behaviour.

The orangish-yellow coloured complex formed between UO_2(II) and thiomalic acid between pH 3.0~7.0 was studied at a pH 4.5±0.2.

Experimental

Material and Apparatus.—Standard solution of uranyl acetate was prepared from the 'Baker Analysed' $UO_2(C_2H_3O_2)_2 \cdot 2H_2O$ by direct weighing.

Fresh solutions of thiomalic acid were prepared by direct weighing whenever needed. pH of the solutions were fixed by sodium hydroxide and hydrochloric acid.

All the spectrophotometric measurements were carried out by means of a 'Unicam' SP 500 spectrophotometer, connected to a 220 V./50 cycles A. C. mains. Absorbance measurements were observed against distilled water blanks. Two lamps, one tungsten filament and the other hydrogen were used for visible and ultraviolet region respectively.

pH titrations were done with a Leeds and Northrup pH meter supplied with all purpose glass electrode operated at 220 V. mains.

Magnetic susceptibility measurements were done by Gouy's method. The assembly consisted of a semi-micro sartorius balance with a Leybold electromagnet. The field obtained was about 5500 gauss with a 2 cm. pole gap.

Experimental Results

Absorbance Studies.—The absorbance of TMA was zero at the wavelength of maximum absorbance of UO_2-TMA complex. The absorbance of UO_2^{2+} was very little at the wavelength of maximum absorbance of the complex, but this could not be neglected. Hence a few blank sets of observations for uranyl acetate solution were taken at different concentrations. These observations were utilized to introduce necessary corrections in the absorbance values for the complex.

The method of Vosburgh and Cooper[12] was employed to determine the nature of the complex formed in solution. Mixtures containing 1:0.5, 1:1, 1:1.5, 1:2, 1:3, 1:4 ratios of uranium(VI) oxide to TMA were prepared, the total volume was kept 50 ml. in each case. Absorbance readings were recorded between a range of 320 mμ to 600 mμ at suitable intervals. The observations when plotted graphically show that the region of maximum absorbance of the solution lies at 390 mμ. Hence only one stable complex is formed under the conditions of study.

Effect of pH on the Complex.—The absorbances of mixtures containing uranyl acetate and thiomalic acid in the ratio 1:3 (each 1×10^{-2}M) at different pH values were observed. It is seen that λ_{max} (390 mμ) of the yellow coloured complex UO_2(II)-TMA remains the same between pH 3.0~7.0; hence the complex is stable in this range of pH.

variation[13] and mole ratio[14]. A large number of observations were taken, some of the typical results are plotted in Figs. 1—6.

Table I records the resuls obtained from the method of continuous variation (Figs. 1—4) where 'c' denotes the concentration of the metal ion and 'c'' the concentration of the ligand. 'p' is equal to c'/c.

The 1 : 1 composition of the chelate has been confirmed by the mole ratio method (Figs. 5 and 6).

Stability of the Complex. — The formation constant $\log k$ (at fixed pH and ionic strength) has been calculated from the curves of continuous variation (Fig. 7) using the formula $K=x/\{(a-x)(b-x)\}$, where the symbols have their usual meaning.[14] An average value of $\log k=3.0\pm0.1$ has been obtained. The corresponding free energy of formation ΔF° has been calculated as -4.2 ± 0.2 at 25°C.

Potentiometric Study.—Different solutions of ligand, metal ion and the complex were titrated respectively with a standard solution of sodium hydroxide. The plot between pH values and the volume of sodium hydroxide are shown in Fig. 8.

Magnetic Susceptibility Measurements.—Very dilute solutions can not be utilised for magnetic susceptiblity measurements since additivity law does not hold good at low concentrations. As the solubility of uranyl acetate was not very high, uranyl nitrate BDH Analar grade was used for the preparation of the solution.

λ_{max} of the complex being same in both the cases uranyl nitrate and TMA (0.1 M each) were mixed in the ratio 1 : 1. The susceptibility of this mixture was measured. The results are tabulated in Table II.

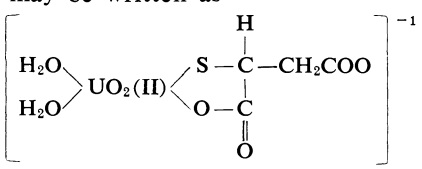
Discussion

Uranyl usually has a coordination number of four, out of which two appear to be satisfied by thiomalic acid in the complex under investigation. The third hydrogen of TMA is not liberated during complexation, is shown by potentiometric studies in which no shift at the inflexion point is observed, i.e., the amount of sodium hydroxide required at the inflexion point for metal and ligand together is equal to the amount required for the complex. From the spectrophotometric curves of continuous variation and mole ratio, it is clear that the complex formed is 1 : 1. The two remaining coordination positions may assumed to be occupied by water molecules. The magnetic moment of hexavalent uranium should have been zero, however, a moment which is slightly less than that expected for one unpaired electron, is observed. There is a lot of uncertainties about the magnetism exhibited by transuranic elements. There are a many complicating factors, e. g., for many uranium(VI) compounds magnetic moment is sufficiently close to the spin only value for two unpaired electrons to suggest $6d^2$ rather than $5f^2$ arrangement. Moreover, it might be showing a temperature independent paramagnetism which can be confirmed if the observations are taken in a wide range of temperature. Thus the formula of the compound on the basis of the above facts may be written as



Summary

Uranyl ion has been found to form an orange-yellow coloured complex with thiomalic acid. Spectrophotometric measurements reveal a composition of 1 : 1 as UO_2(II) : TMA in the complex, where TMA stands for thiomalic acid. Thiomalic acid is found to behave as a bidentate ligand with UO_2(II) in this complex. This has been concluded by potentiometric method. Magnetic susceptibility measurements, however, show an anomolous magnetic behaviour. The formation constant $\log K$, at fixed pH and ionic strength as calculated from the spectrophotometric curves, comes out to be 3.0 ± 0.1 and the corresponding free energy of formation has been calculated as -4.2 ± 0.2 at 25°C.

The authors are thankful to the Council of Scientific and Industrial Research, New Delhi for the award of a fellowship to one of them (V. K. Mathur). Thanks are also due to Dr. A. K. Dey for providing the facilities to work.

The Nature of the Metal-Ligand Bonds in Hexahalostannates(IV) and Ammonium Hexachloroplumbate(IV) Studied by the Pure Quadrupole Resonance of Halogens

By Daiyu NAKAMURA

(Received July 31, 1963)

We have previously observed the pure quadrupole resonance of halogens in various metal halide complexes and discussed the nature of the metal-ligand bonds in these complexes.[1-6] From the investigations of hexahalo complexes, it has been brought to light that the covalent character of the metal-ligand bonds is linearly dependent only on the electronegativity difference between metal and ligand atoms in the case of central metal ions having the same outer electronic configuration. Both tin and lead have the same outer electronic configuration, different from those of selenium, tellurium, palladium and platinum, the hexahalo complexes of which have already been studied. The present investigation of hexahalostannates(IV) and ammonium hexachloroplumbate(IV) has been undertaken in order to confirm the above conclusion and to establish a linear relation between the ionic character of tin-halogen (or lead-halogen) bonds and the electronegativity difference between metal and halogen atoms.

Experimental

Materials. — Potassium hexachlorostannate(IV), ammonium hexachlorostannate(IV) and rubidium hexachlorostannate(IV) were prepared[7] by adding potassium chloride, ammonium chloride and rubidium chloride respectively to a solution of tin(IV) tetrachloride in hydrochloric acid containing a small amount of chlorine. All these compounds were separated as white crystals. Ammonium hexachloroplumbate(IV) was synthesized[8] by adding ammonium chloride to a solution of lead(IV) tetraacetate in concentrated hydrochloric acid. Yellow crystals were obtained. Rubidium hexabromostannate(IV) was prepared[9] from rubidium bromide and tin(IV) tetrabromide. Pale yellow crystals were separated and washed with concentrated hydrobromic acid containing a small quantity of bromine. Rubidium hexaiodostannate(IV) was obtained[10] by adding rubidium iodide to an alcoholic solution of hydrogen iodide. It formed black crytals. For identifying all these compounds, except for ammonium hexachloroplumbate(IV), quantitative analysis was made for halogens. All the samples were treated with an alkaline solution. Subsequently, the volumetric determination of the halogens was carried out by Volhard-Drechel's method. Ammonium hexachloroplumbate(IV) was identified by its X-ray powder patterns[11] as taken with a Norelco X-ray diffractometer.

Calcd. for K_2SnCl_6: Cl, 51.9. Found: Cl, 51.8. Calcd. for $(NH_4)_2SnCl_6$: Cl, 57.9. Found: Cl, 57.8. Calcd. for Rb_2SnCl_6: Cl, 42.3. Found: Cl, 42.0. Calcd. for Rb_2SnBr_6: Br, 62.3. Found: Br, 62.3. Calcd. for Rb_2SnI_6: I, 72.4. Found: I, 72.0.

Apparatus. — Self-quenching super-regenerative spectrometers which have already been described[1] were employed for the determination of the frequencies of the pure quadrupole resonance of halogens. A hexane thermometer was used in the range from −80 to 0°C.

Results and Discussion

Measurements were made at liquid nitrogen, dry ice and room temperatures. Additional measurements were carried out on potassium hexachlorostannate(IV) at 5~10°C intervals between dry ice and room temperatures for the determination of the transition points. The results are shown in Table I, from which data of less abundant isotopes ^{37}Cl and ^{81}Br are omitted because they give correct isotope frequency ratios.

Potassium hexachlorostannate(IV) yielded a single resonance line at room temperature, in

	Liquid N_2	132.57 ±0.10

agreement with its cubic structure of the potassium hexachloroplatinate(IV) type as established by X-ray analysis.[12,13] As the temperature was lowered, the single resonance line was observed to disappear at about −9.5°C. The resonance frequency measured at −6.6°C was 15.068 Mc./sec. The temperature coefficient of the resonance line was about zero in the range from 5 to −8°C. As the temperature was raised, the resonance line appeared abruptly at about −8.5°C. These observations prove the existance of a transition point in the vicinity of −8.5°C. Below this transition point, at least two resonance lines were barely observed. Accordingly, the crystal structure of this compound is less symmetric below the transition point. At the dry ice temperature, three resonance lines were clearly observed. Therefore, another transition point might be expected to exist between the first transition point and the dry ice temperature, as has already been observed in the case of potassium hexabromoselenate(IV). However, above −70°C the intensity of the resonance lines was too weak to permit the determination of another transition point definitely. At the liquid nitrogen temperature, two weak resonance lines were observed, revealing the presence of at least one transition point between dry ice and liquid nitrogen temperatures. In their study of heat capacity,[17] Morfee et al. have reported no transition except for a λ-point, which is in agreement with the first transition point mentioned above.

Ammonim hexachlorostannate(IV) showed a single absorption line at room and dry ice temperatures. This indicates that all the chlorine atoms in the crystal are crystallographically equivalent, a fiinding which is in agreement with the results of X-ray structural analysis.[12] At the liquid nitrogen temperature, two very weak resonance lines were observed. Although Morfee et al. have obtained a normal heat capacity curve[14] between dry ice and liquid nitrogen temperatures, at least one transition point is likely to exist in this temperature range, because doublet absorption lines were observed at the liquid nitrogen temperature.

Rubidium hexachlorostannate(IV), ammonium hexachloroplumbate(IV) and rubidium hexabromostannate(IV) yielded a single absorption line at all the temperatures studied, as was expected from the potassium hexachloroplatinate(IV)-type structure established by X-ray analysis.[15]

Rubidium hexaiodostannate(IV) showed a very weak single resonance line, ν_1, at room and liquid nitrogen temperatures, in agreement with the results of X-ray crystal analysis.[16] At the dry ice temperature, no resonance line could be observed. As the nuclear spin of ^{127}I is 5/2, two resonance lines, ν_1 and ν_2, are expected to be observed. Our attempt to find the ν_2 resonance frequency was, however, unsuccessful, probably because the sensitivity of our spectrometer was low in this frequency range.

Since the crystals of hexahalostannates(IV) and hexachloroplumbates(IV) are known to consist of cations and complex anions with the O_h symmetry,[17] the asymmetry parameter of the electric field gradient about the halogen nucleus vanishes. Therefore, the quadrupole coupling constant, eQq (in Mc./sec.), is equal to twice the resonance frequency for the case of a 3/2 nuclear spin and to 20/3 times the ν_1 resonance frequency for a 5/2 nuclear spin.[18]

From the calculated quadrupole coupling constants (data at liquid nitrogen temperature were used, and the frequencies of the doublet components were averaged), the ionic character, i, of the metal-halogen bonds was evaluated by Townes and Dailey's procedure.[19,20] Fifteen per cent s-hybridization of the halogen σ bond orbitals was assumed in accordance with the data of Dailey and Townes.[20] From the evaluated ionic character, i, of the metal-halogen bonds, the net charge, ρ, on a central metal atom was calculated by

$$\rho = 4 - 6(1 - i)$$

The results are given in Table II, in which the corresponding data for hexahalotellurates(IV)[4] and hexabromostannates(IV)[5] are included for purposes of comparison.

TABLE II, THE QUADRUPOLE COUPLING CONSTANT OF ^{35}Cl, ^{79}Br AND ^{127}I AT LIQUID NITROGEN TEMPERATURE, THE IONIC CHARACTER, i, OF METAL-LIGAND BONDS, AND THE NET CHARGE, ρ, ON A CENTRAL METAL ATOM IN HEXAHALO COMPLEXES

The ionic character of the tin-halogen bonds in hexahalostannates(IV) decreases with the decreasing electronegativity difference between tin(IV) and halogens, as has already been observed for various complexes.[1-6] Judging from the same electronegativity values of the central metal atoms, it is reasonable to assume that the extent of the ionic character of hexachlorostannates(IV) is very close to that of ammonium hexachloroplumbate(IV). The electronegativity values selected by Gordy were used in this paper.[21]

Although tin(IV) and lead(IV) are more electropositive than tellurium (as much as 0.3 in electronegativity units), the extent of the ionic character for hexachlorostannates(IV) and ammonium hexachloroplumbate(IV) is almost equal to that of ammonium hexachlorotellurate(IV). This fact must be attributed to the difference in the electronic structure of the central metal atoms. We have already pointed out, from the results for hexabromostannates(IV),[5] that a tin(IV) atom has one 5s orbital, as well as three 5p orbitals, available for forming bonds with halogen atoms in a $[SnX_6]^{2-}$ ion. On the other hand, tellurium(IV) can use only three 5p orbitals for bond formation.[4] Therefore, tin(IV)-halogen bonds are more covalent in character than tellurium(IV)-halogen bonds, if the electronegativity differences between metal and ligand atoms are the same. This interpretation is also valid for ammonium hexachloroplumbate(IV), because the outer electronic configuration of a lead(IV) atom is equivalent to that of a tin(IV) atom provided that all the principal quantum numbers are increased by one.

In a preceding paper[6] we reported, on the basis of a study of various hexahalo complexes, that the covalent character of the bonds between a central metal atom, M, and ligands, X, is in linear relation to the electronegativity difference $\Delta\chi = \chi_X - \chi_M$. The present investigation adds another series of linear relations, as is illustrated in Fig. 1. The three straight lines in Fig. 1 indicate that the only factor

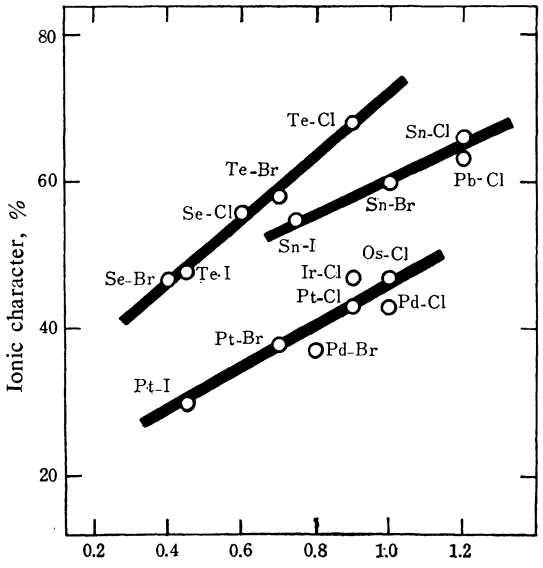

Fig. 1. Dependence of the ionic character of metal-ligand bonds in hexahalo complexes on the difference between the electronegativities of ligands and the central atom.

determining the ionic character of the metal-ligand bonds in a hexahalo complex is the electronegativity difference between ligands and the central metal atom if the central metal atoms belong to the same family of the periodic table. This linear relation offers useful information, because with it one can estimate the extent of ionic character of metal-ligand bonds whenever necessary data are avaialable for hexahalo complexes.

The Electron Spin Resonance and Electronic Spectra of the Anion Radicals of 4-Nitropyridine and 4-Nitropyridine 1-Oxide

By Michiya ITOH, Toshihiko OKAMOTO and Saburo NAGAKURA

(Received August 1, 1963)

Recently, both experimental and theoretical studies of aromatic anion radicals have made remarkable progress. Ward and others[1-3] have made electron spin resonance (ESR) studies of various hetero aromatic anion radicals and have determined the coupling constants from proton and nitrogen hyperfine splittings. Furthermore, theoretical studies of odd electron distribution have been carried out with some anion radicals by the aid of a simple molecular orbital method;[4] the results are considerably consistent with the spin densities estimated from the ESR coupling constants.

Hoijtink et al. observed the electronic spectra of the anion radicals of some aromatic hydrocarbons such as benzene and naphthalene, and discussed their electronic structures by comparing the observed results with the theoretical results.[5]

In these circumstances, the present authors have attempted to study the electronic structures of the anion radicals of 4-nitropyridine and its 1-oxide by combining the experimental results of the electronic spectra and electron spin resonance spectra with the theoretical studies based on the semi-empirical molecular orbital method, including "configuration interaction."

Nitrogen hetero aromatic *N*-oxide compounds such as pyridine 1-oxide are known to have some interesting properties.[6,7] The non-bonding electrons of the oxygen atom are strongly conjugated with the π-electron system of the nitrogen hetero aromatic ring. This conjugation usually exerts a predominant effects upon various substitution reactions in the nitrogen hetero aromatic ring, and also upon various physical properties, such as the ultraviolet[8,9] and infrared spectra[10,11] and the nuclear magnetic resonance absorption.[12,13] One of the principal purposes of the present study is to get some knowledge about the conjugation effect in the anion radical of 4-nitropyridine 1-oxide.

In order to analyze exactly the ESR spectra of 4-nitropyridine and its 1-oxide, the measurements were also carried out with the respective compounds containing ^{15}N instead of ^{14}N in the nitro group. Furthermore, for the purpose of getting experimental data necessary for the present semi-empirical calculations, the electronic spectrum of the 3, 5-lutidine[2] anion radical was measured.

Experimental

Materials. — 4-Nitropyridine and 4-nitropyridine 1-oxide were prepared by the methods given in literatures[14,15] and were purified by repeating recrystallization before use. The melting points of these nitro compounds were in good agreement with those reported in the literatures.[14,15] 4-Nitropyridine 1-oxide with a heavy nitrogen atom (^{15}N) in the nitro group was prepared by the nitration of pyridine 1-oxide with potassium nitrate ($K^{15}NO_3$) containing the heavy nitrogen atom in sulfuric acid.[14] 4-Nitropyridine with the heavy nitrogen atom in the nitro group was obtained by the deoxygenation of 4-nitropyridine 1-oxide (containing $^{15}NO_2$) with phosphorus tribromide.[15] Commercial 3,5-lutidine was purified by repeating distillation:

The Preparation of Anion Radicals and Measurements.—The 4-nitropyridine, 4-nitropyridine 1-oxide and 3,5-lutidine anion radicals were prepared at room temperature by the reduction of the respective parent compounds with potassium metal in 1,2-dimethoxy ethane (abbreviated hereafter to DME). In order to remove reactive impurities, the solvent was kept in contact with sodium metal and the parent compound in vacuo before use. The potassium metal was purified by repeating sublimation in vacuo.

The preparation of the anion radicals and the measurements of electronic absorption spectra and ESR spectra were performed in vacuo by using a vacuum line system similar to that shown in a previous paper.[16] The ESR and electronic spectra were measured by a Hitachi x-band ESR spectrometer Model MPU-2B and a Cary recording spectrophotometer Model-14 M, respectively.

Experimental Results

The 4-Nitropyridine Anion Radical. — The DME solution of the 4-nitropyridine anion radical was colored yellow. The ESR spectrum observed with this solution is shown in Fig. 1a. The ESR spectrum of the 4-nitropyridine anion radical with the heavy nitrogen atom in the nitro group was also measured with the result shown in Fig. 1b. The heavy nitrogen atom leads to a splitting into doublets since ^{15}N has the nuclear spin of 1/2 (the nuclear magnetic moment, $\mu_N=0.404$), while ^{14}N causes a splitting into triplets.

From these spectra, the coupling constants associated with the nitrogen (^{14}N and ^{15}N) and hydrogen atoms were determined to be as shown in Table I. Reconstructions based on these coupling constants are also shown in Figs. 1a and 1b. The reconstructions match well with the observed spectra. Furthermore, the ratio of the nitrogen coupling constants associated with ^{14}N and ^{15}N of the nitro group is in good agreement with that of the nuclear moments of these two nitrogen isotopes. These facts show the high reliability of the coupling constants determined in the presents study.

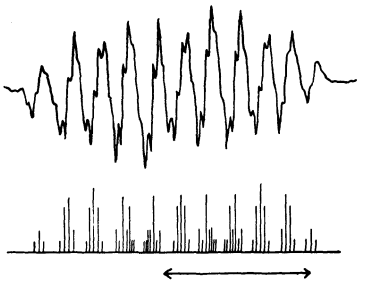

Fig. 1a. The ESR spectrum (first derivative) of 4-nitropyridine anion and the reconstruction based on the coupling constants.

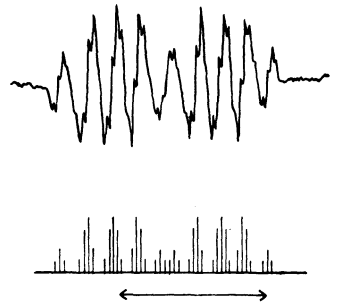

Fig. 1b. The ESR spectrum of the same compound containing ^{15}N in the nitro group and the reconstruction based on the coupling constants.

TABLE I. THE COUPLING CONSTANTS OF THE OBSERVED NITROGEN AND HYDROGEN HYPERFINE SPLITTINGS

Position	4-Nitropyridine anion gauss	4-Nitropyridine 1-oxide anion gauss
$^{14}NO_2$	8.72	7.49
$^{15}NO_2$	12.3	10.32
3-H	0.53*	1.58*
2-H	3.00*	3.58*
Ring N	2.55	4.58

* These assignments were made taking into account spin densities obtained by the molecular orbital calculation.

The electronic absorption spectrum of the DME solution of the 4-nitropyridine anion was measured parallel with the ESR spectrum. The result is shown in Fig. 2. The spectrum consists of three bands at 313, 440 and 640 mμ. It was found that these absorption bands disappeared or decreased remarkably their intensities when the solution was exposed to

15) M. Hamana, ibid., **75**, 135 (1955).
16) A. Ishitani, K. Kuwata, H. Tsubomura and S. Nagakura, This Bulletin, **36**, 1357 (1963).

1) The spectrum of the DME solution of the anion.
2) The spectrum of the solution exposed to air.

air. From this fact, it is inferred that all three bands can be ascribed to the 4-nitropyridine anion. This opinion was also supported by the theoretical consideration based upon molecular orbital calculations which will be described later.

The 4-Nitropyridine 1-Oxide Anion Radical.— When the DME solution of 4-nitropyridine 1-oxide was kept in contact with pure potassium metal in vacuo, the DME solution became yellow after about 2 or 3 days. The ESR spectrum of this colored solution was measured, with the result given in Fig. 3a. The ESR spectrum of the 4-nitropyridine 1-oxide anion containing the heavy nitrogen atom in the nitro group was also measured in order to obtain useful information for the analysis of the hyperfine structure of the ESR spectrum. The result is shown in Fig. 3b. The ESR coupling constants of the 4-nitropyridine 1-oxide anion radical were finally determined to be as shown in Table I. Reconstructions from

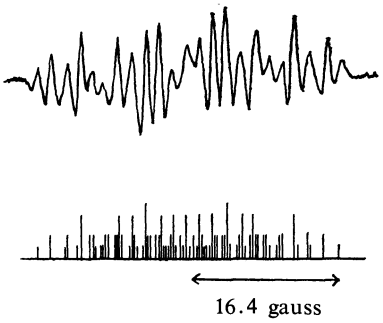

Fig. 3a. The ESR spectrum of 4-nitropyridine 1-oxide anion and the reconstruction based on the coupling constants.

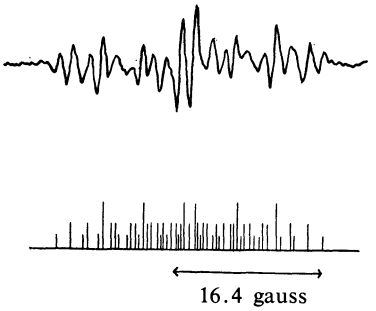

Fig. 3b. The ESR spectrum of the same compound containing ^{15}N in the nitro group and the reconstruction based on the coupling constants.

the coupling constants are also shown in Figs. 3a and 3b for the 4-nitropyridine 1-oxide anion radicals containing ^{14}N and ^{15}N respectively. The reconstructions are well coincident with the observed spectra.

We could not succeed in measuring the electronic absorption spectrum of the DME solution of the 4-nitropyridine 1-oxide anion. This may be because the concentration of the radical is not high enough for the electronic spectrum to be observed.

The Electronic Spectrum of the 3, 5-Lutidine Anion Radical. — The ESR spectrum of the 3, 5-lutidine anion radical was measured by Atherton et al.,[2] but the electronic spectrum has never been observed. Therefore, we measured the electronic spectrum of this anion radical. The DME solution of the 3, 5-lutidine anion shows the electronic absorption band at 355 mμ. This band disappeared parallel with the ESR spectrum by introducing air into the reaction tube.

Theoretical

Molecular orbital calculations were carried out with the π-electron system of the 4-nitropyridine anion in order to ascertain the assignment of the observed electronic spectrum and to obtain some knowledge about the electronic structure of this anion.

In the present calculations, the 4-nitropyridine anion was separated into the two components; the pyridine anion and the nitro group. The interaction between the components was taken into consideration by the aid of the configurational interaction among several π-electron configurations. For accomplishing this theoretical treatment, we need empirical knowledge about the π-electron structure of the pyridine anion radical. Therefore, calculations were first made with the π-electron structure of this anion.

The calculation of the pyridine anion was carried out by taking into account the configurational interaction among the ground and ten excited π-electron configurations which are obtained by putting seven π-electrons into the SCF-molecular orbitals of neutral pyridine.[17] The wave functions and energy values of the electron configurations taken up in the present calculations are shown in Table II. The off-diagonal matrix elements of the total electronic Hamiltonian, H_{ij}'s, are given in Table III. A detailed explanation of the calculation procedure may be omitted since similar calculations have been made for the benzene anion by Hoijtink[5] and by Ishitani et al.[16] In the actual calculation, the approximation of zero-differential overlap was adopted and the one-center Coulomb repulsion integrals of the type of (ii/ii) were calculated from the ionization potentials and electron affinities of the appropriate valence states.[18] The two-center Coulomb repulsion integrals of the type of (ii/jj) were calculated by the aid of quadratic equations* obtained by Pariser and Parr's method.[18]

The finally obtained energy levels and wave functions of the pyridine anion are summarized in Table IV. The transition energy for the transition between the ground and lowest excited states was evaluated to be 3.75 eV. Unfortunately, the electronic absorption of the pyridine anion has never been observed, since it easily converts into the 4, 4'-dipyridyl anion.[1] However, we succeeded in measuring the absorption spectrum of the 3, 5-lutidine anion. Therefore, we compared the calculated transition energy of the pyridine anion with that observed with the 3, 5-lutidine anion.** The calculated transition energy of the former (3.75 eV.) is in good agreement with that of the latter (3.54 eV.).

Table II. The π-electron configurations of the pyridine anion

Wave function	Energy, eV.

$\Phi_{10} = -0.0012\phi_1 - 0.4293\phi_4 - 0.5325\phi_6 + 0.7229\phi_{7a} - 0.0902\phi_{7b} + 0.0364\phi_9$	10.321
$\Phi_{11} = -0.0071\phi_2 - 0.4931\phi_3 + 0.0754\phi_5 + 0.8060\phi_{8a} - 0.3185\phi_{8b}$	11.489

Using the above-mentioned results obtained with the pyridine and 3, 5-lutidine anions, the energy levels and wave functions of the 4-nitropyridine anion were calculated by a method similar to that used for the theoretical consideration of the π-electron structures of the nitromethyl anion,[19] the nitrobenzene anion[16] and other neutral nitro compounds.[20] That is to say, the effect of the nitro group on the energy levels of the pyridine anion was considered by means of the configuration interaction between the ground, locally-excited and charge-transfer configurations. In the actual calculations, the geometrical arrangements of the pyridine ring and the nitro group were assumed to be equal to those of neutral pyridine[21] and the nitro group in nitrobenzene[22] respectively.

The energy of the ground configuration was evaluated by taking electrostatic interaction between the benzene anion and the nitro group into account, since there is a large heterogenity in the π-electron distribution of the nitro group with a large positive charge on the nitrogen atom and a negative charge on the oxygen atoms.

We considered the fourteen locally excited configurations whose wave functions and energy values are shown in Table V, together with those of the other electron configurations. Ten of them are brought about by one-electron excitation within the pyridine ring. Except for the lowest locally excited configuration, the energies of the other nine configurations were calculated by adding the electrostatic interaction energies to the calculated excitation energies of the pyridine anion. The energy of the lowest locally excited configuration was estimated by combining the experimental value which had been determined from the peak wavelength of the 3, 5-lutidine anion with the electrostatic interaction energy. The energy of the locally excited configuration within the nitro group was determined from the experimental value of the $\pi \rightarrow \pi^*$ transition energy of the nitromethane[19] and the electrostatic energy.

In addition to these configurations, a charge-transfer configuration which is caused by one electron transfer from the highest-occupied orbital of the pyridine anion toward the lowest vacant orbital of the nitro group was taken into account. The energy of this configuration, E_{CT}, was evaluated by the following equation:

$$\begin{aligned} E_{CT} &= A_P A_N + \Delta E \\ &= -0.4 - 0.4 + \Delta E \\ &= -0.8 + \Delta E \end{aligned}$$

where A_P and A_N are the electron affinities of pyridine and the nitro group respectively, and ΔE is the electrostatic interaction energy between the neutral pyridine ring and the negatively charged nitro group. ΔE was calculated to be −0.1 eV. A_N was determined to be 0.4 eV. for a series of nitro compounds.[16,20] The electron affinity of pyridine has not been determined. Therefore, assuming that it may be almost equal to or a little larger than the value of benzene (−0.54∼−1.62 eV.[23,24]), the authors adopted the two values, −0.4 and 0.1 eV., as the electron affinity of pyridine. The two calculations gave similar results for the transition energies (see Table VIII).

The off-diagonal matrix elements H_{ij}'s of the total electronic Hamiltonian were evaluated by the aid of the method presented by Pople[25] and by Murrell and Longuet-Higgins.[26] The Coulomb repulsion integrals necessary for the evaluation of the interaction energies between

$\Psi_{13a}=\frac{1}{\sqrt{2}}(\Psi^1_{13}-\Psi^2_{13})$	5.811
$\Psi_{13b}=\frac{1}{\sqrt{6}}(\Psi^1_{13}+\Psi^2_{13}-2\Psi^3_{13})$	5.811
Charge-transfer configuration :	
$\Psi_{14}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\varphi_a\bar{\varphi}_a\varphi_b\bar{\varphi}_b\varphi_c\rvert$	$A_P-A_N+\Delta E$

a) The φ_a, φ_b and φ_c are the molecular orbitals of the nitro group obtained by Tanaka. (*J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zassi)*, **78**, 1643 (1957)).

b) The Ψ^1_{12}, Ψ^2_{12},..... are as follows :

$\Psi^1_{12}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\varphi_5\varphi_a\bar{\varphi}_a\varphi_b\bar{\varphi}_c\rvert$
$\Psi^2_{12}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\varphi_5\varphi_a\bar{\varphi}_a\bar{\varphi}_b\varphi_c\rvert$
$\Psi^3_{12}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\bar{\varphi}_5\varphi_a\bar{\varphi}_a\varphi_b\varphi_c\rvert$
$\Psi^1_{13}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\varphi_4\varphi_a\bar{\varphi}_a\varphi_b\bar{\varphi}_c\rvert$
$\Psi^2_{13}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\varphi_4\varphi_a\bar{\varphi}_a\bar{\varphi}_b\varphi_c\rvert$
$\Psi^3_{13}=\lvert\varphi_1\bar{\varphi}_1\varphi_2\bar{\varphi}_2\varphi_3\bar{\varphi}_3\bar{\varphi}_4\varphi_a\bar{\varphi}_a\varphi_b\varphi_c\rvert$

c) The energy of this configuration was estimated by combining the experimental value which was determined from the peak wavelength of the 3,5-lutidine anion with the electrostatic interaction energy.

locally excited configurations were obtained by the same method as described for the calculation of the pyridine anion. The interaction energies between the charge transfer configuration and the others are calculated through the core resonance integral (β_{CN}) between the carbon atom at the 4-position and the neighboring nitrogen atom of the nitro group. The β_{CN} value was estimated to be −3.0 eV., the same value as that used for the calculation of the nitrobenzene anion.[16] The matrix elements thus evaluated are given in Table VI.

The secular equation composed of the matrix elements given in Table VI was solved by the aid of an electronic computer IBM 7090. The evaluated energy levels and wave functions of the 4-nitropyridine anion are given in Table VII. Oscillator strengths were calculated for the three longer wavelength transitions by the following usual equation : $f=1.085\times10^{-5}Q^2\nu$, where Q and ν are the transition moment (in units of Å) and the peak wave number (in units of cm^{-1}) respectively. The calculated transition energies and oscillator strengths for the transitions between the ground level and the lowest three excited levels are shown in Table VIII, together with the observed transition energies.

Discussion

Karplus and Fraenkel proposed that the hyperfine coupling constants for nuclei such as ^{14}N and ^{13}C in aromatic ring depend not only on the spin densities of the respective atoms, but also on the spin densities of the

* The results calculated by assuming the electron affinity of pyridine to be 0.1 eV.

adjacent aromatic ring atoms via indirect polarization and that the coupling constant for the ring nitrogen atom, A_N, can be represented by the following equation:[27]

$$A_N = Q_N\rho_N + \sum_i Q_{C_i}\rho_{C_i} \quad (1)$$

where ρ_N and ρ_{C_i} are the spin densities of the concerned nitrogen and adjacent carbon atoms, respectively, and Q_N and Q_{C_i} are constants. Carrington and Santos-Veiga, however, suggested that the indirect coupling is apparently less important for ^{14}N in hetero aromatic anion radicals.[3] They proposed the following equation for the relationship between A_N and ρ_N:

$$A_N = Q_N\rho_N \quad (2)$$

and estimated the value of Q_N to be 25.3 gauss.

A similar relation is found also for the coupling constant due to the nitrogen nucleus of the nitro group, but the Q_N value is larger for this case than for the above case.[16] In the present study, the Q_N value was tentatively assumed to be 40 gauss for the nitrogen atom of the nitro group. Furthermore, it is well known that the proton coupling constants, A_H's, are related to the spin densities on carbon atoms, ρ_C's, by the following equation:[28]

$$A_H = Q_H\rho_C \quad (3)$$

where Q_H is a constant and is estimated to be 22.5 gauss.

By combining the observed coupling constants with the relations mentioned above, we have evaluated the spin densities on the nitrogen and carbon atoms of the 4-nitropyridine and 4-nitropyridine 1-oxide anions. The results are shown in Table IX, together with the theoretical values evaluated for the 4-nitropyridine anion by the aid of the wave function, Ψ_{W1}, in Table VII. The spin densities on the nitrogen and carbon atoms of the 4-nitropyridine anion estimated from the observed coupling constants are in good agreement with the calculated values except for the 2-carbon atom.

As is shown in Table IX, the spin densities on the ring nitrogen and carbon atoms are undoubtedly larger in the 4-nitropyridine 1-oxide anion than in the 4-nitropyridine anion, while the spin density on the nitrogen atom of the nitro group of the former decreases compared with that of the latter. This seems to be attributed to the resonance and inductive effects of the *N*-oxide group.***

Now let us turn our attention to the problem of the electronic absorption spectrum of

27) M. Karplus and G. K. Fraenkel, ibid., **35**, 1312 (1961).

* These assignments were made taking into account spin densities obtained by the molecular orbital calculation.

the 4-nitropyridine anion. As is shown in Table VIII, the 313, 440 and 640 mμ bands can safely be ascribed to the $W_1 \rightarrow W_4$, $W_1 \rightarrow W_3$ and $W_1 \rightarrow W_2$ transitions respectively. From the wave functions Ψ_{W_1} and Ψ_{W_3} given in Table VII, it can be seen that the W_1 and W_3 states are in principle brought about by the resonance between the ground and charge-transfer configurations, and that the 440 mμ band corresponding to the $W_1 \rightarrow W_3$ transition may be regarded as the intramolecular charge-transfer band. Since, in the wave function of the W_4 state, the contribution of the locally excited configuration within the pyridine ring amounts to 94%, the 313 mμ band corresponding to the $W_1 \rightarrow W_4$ transition can be interpreted as the shifted band of the 355 mμ band of the 3, 5-lutidine (or pyridine) anion. It is noticeable that the 355 mμ band of the 3, 5-lutidine (or pyridine) anion shows a large blue shift upon the introduction of the nitro group. This is because the charge-transfer configuration is rather close to the ground configuration and therefore the ground configuration is largely stabilized by the resonance interaction with the charge-transfer configuration.

A similar blue shift phenomenon was observed with the nitrobenzene anion.[16] The weak 640 mμ band may conceivably correspond to the $W_1 \rightarrow W_2$ transition with a small transition moment.

Summary

The ESR and electronic spectra of the 4-nitropyridine and 4-nitropyridine 1-oxide anions have been measured. The nitrogen and hydrogen hyperfine splitting constants of these two compounds have been determined. In order to analyze the ESR spectra exactly, the measurements have also been carried out with respective compounds containing ^{15}N instead of ^{14}N in the nitro group. The spin densities on the nitrogen and carbon atoms of these two anions have been estimated from the splitting constants. It has thus been found that the spin densities on the ring nitrogen and carbon atoms are undoubtedly larger in the 4-nitropyridine 1-oxide anion than in the 4-nitropyridine anion.

The electronic spectrum of the 4-nitropyridine anion has been measured and three peaks found at 313, 440 and 640 mμ. According to the molecular orbital calculations carried out with the π-electron system of the 4-nitropyridine anion, it has been concluded that the 440 mμ band may be regarded as the intramolecular charge transfer band, and that the 313 mμ band can be interpreted as the blue shifted band of the pyridine anion.

The authors wish to express their sincere thanks to Mr. Koichi Itoh of the Institute for Solid State Physics for his kind help in measuring the ESR spectra.

The Electronic Structure of the t-Butyl Cation

By Ichiro HANAZAKI, Haruo HOSOYA and Saburo NAGAKURA

(Received August 12, 1963)

There is considerable experimental evidence to show that methyl or other alkyl substituents increase the stability of hydrocarbon molecules.[1-10] The stabilization may be attributed in general to the steric hindrance, inductive effect and hyperconjugation. Although in the case of neutral molecules there is a little doubt about the stabilization effect of hyperconjugation, the effect seems to be vivid and extensive in the case of carbonium ions.[9,10]

In the present paper, we have studied the electronic structure of the *t*-butyl cation, paying special attention to the hyperconjugation effect. One of ourmain purposes is to estimate as accurately as possible the hyperconjugation effect on the electronic structure of the carbonium ion. The fact that the *t*-butyl cation shows a strong absorption band at 290~295 mμ[11,12] in spite of the complete absence of any unsaturated bond may be unexpected from the π-electron theory developed so far and seems to be closely related to the hyperconjugation effect. Another important aim of the present study is to clarify the nature of this band.

The Configuration of the *t*-Butyl Cation

There is a little doubt about the configuration of the *t*-butyl cation.[9,11,12] In the present calculation, however, the ion is reasonably assumed to take a planar configuration, the central carbon atom being in a sp^2 hybrid valence state and a $2p\pi$ AO perpendicular to the molecular plane being vacant. The configuration and the numbering of atoms are shown in Fig. 1.

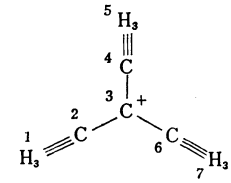

Fig. 1. The structure and numbering of *t*-butyl cation.
The distance between carbon atoms 2 and 3 is assumed to be 1.52Å (same as the distance between the carbon of methyl group and the ring carbon in toluene). The methyl group is assumed to have the same geometrical configuration as methane ($\angle HCH = 109°28'$ and $R_{C-H} = 1.091$Å).

Another possibility is a configuration of the π-complex type:

$$(H_3C)_2C \overset{H^+}{\uparrow\!\!\!\!\!\!\rightleftharpoons} CH_2$$

This possibility, however, may be disregarded because $B(CH_3)_3$, which is isoelectronic with the *t*-butyl cation, has a planar configuration.[12]

According to the usual treatment of hyperconjugation,[13] the following three pseudo AO's can be constructed from the 1s AO's of the hydrogen atoms:

$$\left.\begin{aligned} \chi_1 &= N_1 \cdot [\chi_a - 1/2(\chi_b + \chi_c)] \\ \lambda_2 &= N_2 \cdot (\chi_b - \chi_c) \\ \lambda_3 &= N_3 \cdot (\chi_a + \chi_b + \chi_c) \end{aligned}\right\} \quad (1)$$

where χ_1, λ_2 and λ_3 are three independent and orthonormal pseudo AO's, χ_a, χ_b and χ_c are the hydrogen 1s AO's, and N_i's are normalization constants. Of these, χ_1 can be regarded as a $p\pi$-type pseudo AO antisymmetric with regard to the molecular plane; it can construct a π-type MO together with the $2p\pi$ AO of the carbon atom in the methyl group.[14]

a) The numbers in a given row give the coefficients of the integrals, I's, J's and K's, in the formula representing the energy listed in the first column.

b) $$I_\mu = \int \mu(1) H_h^c(1) \mu(1) \mathrm{d}v$$

where $\mu = \chi_1$, λ_2 or λ_3 and $H_h^c(1) = T(1) - \sum_{p=a,b,c} e^2/R_p(1)$

$T(1)$ and $R_p(1)$ being the kinetic energy operator and the distance between the electron (1) and the hydrogen core p respectively. Coulomb and exchange repulsion integrals are defined by

$$J_{\mu\mu'} = \int \mu(1) \mu(1) e^2/r_{12} \mu'(2) \mu'(2) \mathrm{d}v$$

and

$$K_{\mu\mu'} = \int \mu(1) \mu'(1) e^2/r_{12} \mu(2) \mu'(2) \mathrm{d}v$$

where μ and μ' are χ_1, λ_2 or λ_3.

The Ionization Potential of the H_3 Group

In the present calculation, the *t*-butyl cation was separated into four components; namely, the three methyl groups and the carbon ion with a positive charge. The interaction among them was accounted by the configurational interaction among several electron configurations constructed by putting the electrons into the orbitals of the components. In order to accomplish this kind of calculation, it is necessary to obtain accurate knowledge about the wave functions and energy values of the components. Therefore, we undertook first to evaluate the energy levels and wave functions of the H_3 group necessary for the calculation of the methyl group.

A neutral H_3 group in a methyl group has one electron in each of the pseudo AO's, χ_1, λ_2 and λ_3, so that following wave functions can be constructed as antisymmetrized wave functions:

$$\text{quartet}: \quad {}^4\psi = |\chi_1, \lambda_2, \lambda_3|^{15} \tag{2}$$

$$\text{doublet}: \quad {}^2\psi = (2)^{-1/2}\{|\chi_1, \overline{\lambda_2}, \lambda_3| + |\lambda_2, \overline{\chi_1}, \lambda_3|\} \tag{3}$$

$${}^2\psi' = (6)^{-1/2}\{|\chi_1, \overline{\lambda_2}, \lambda_3| - |\lambda_2, \overline{\chi_1}, \lambda_3| + 2|\chi_1, \overline{\lambda_3}, \lambda_2|\} \tag{4}$$

15) An abbreviated notation of the antisymmetrized wave function. For example,

$$|a, b, \bar{c}| = (3!)^{-1/2} \begin{vmatrix} a(1)\alpha(1), & b(1)\alpha(1), & c(1)\beta(1) \\ a(2)\alpha(2), & b(2)\alpha(2), & c(2)\beta(2) \\ a(3)\alpha(3), & b(3)\alpha(3), & c(3)\beta(3) \end{vmatrix}$$

The energies for the states, ^4E, ^2E and $^2E'$, can be written in terms of integrals over the pseudo AO's, as is summarized in Table I. A valence state energy, E, of the neutral H_3 group can be calculated as an average of them over spin natural abundance;

$$E = (4 \cdot {}^4E + 2 \cdot {}^2E + 2 \cdot {}^2E')/8 \tag{5}$$

Similarly, the H_3^+ ion, in which an electron in χ_1 is removed, has two electronic states, corresponding to the singlet and triplet states, whose energies are represented by $^1E^+$ and $^3E^+$ respectively. An average energy over spin natural abundance is:

$$E^+ = ({}^1E^+ + 3 \cdot {}^3E^+)/4 \tag{6}$$

Therefore, the valence state ionization energy of an electron in χ_1 is:

$$I_p(\chi_1) = E^+ - E \tag{7}$$

Now, taking Slater-type 1s AO's with the effective charge $Z=1$ for χ_a, χ_b and χ_c, the integrals in Table I can be reduced to integrals over AO's;

$$I_{\chi_1} = (\alpha_H - \beta_H)/(1 - S_H) \tag{8}$$

$$\alpha_H = \int \chi_a(1) H_h^c(1) \chi_a(1) \mathrm{d}v^{16} = W_H + 2\langle b \mid aa \rangle \tag{9}$$

$$\beta_H = \int \chi_a(1) H_h^c(1) \chi_b(1) \mathrm{d}v = S_H W_H + \langle b \mid ab \rangle + \langle c \mid ab \rangle \tag{10}$$

16) See the footnote of Table I for the definition of $H_h^c(1)$.

TABLE II. ELECTRONIC REPULSION INTEGRALS IN TERMS OF THE INTEGRALS OVER ATOMIC ORBITALS[a]

$(12\|22)$	—	—	$S/3$	$S/6$	$S/2$	9.3164

a) The first column contains integrals including the pseudo AO's. J_{ij}'s and K_{ij}'s are defined in Table I. For the last nine integrals in the first column, notations 1 or 2 means χ_1 or χ_2 respectively.
For example,

$$(12|\lambda_2\lambda_2) = \int \chi_1(1)\chi_2(1)e^2/r_{12}\lambda_2(2)\lambda_2(2)dv$$

They are reduced into the integrals over AO's by means of Mulliken's approximation. The latters are shown in the first row, for example,

$$(aa|22) = \int \chi_a(1)\chi_a(1)e^2/r_{12}\chi_2(2)\chi_2(2)dv$$

Calculated values for the integrals in the first column are shown in the last column (See also the footnote a of the Table I).

b) Values of $(aa|aa)$, $(aa|bb)$ and $(22|22)$ are taken from the table given by Roothaan.[17]

c) See Appendix for the evaluation of $(aa|22)$ and $(bb|22)$.

d) $x=(2+S_H)^2/12(1+2S_H)(1-S_H)$.

e) $S=\int \chi_1(1)\chi_2(1)dv$.

S_H[d]	0.2805	S_{12}[d]	0.6452

a) Values for basic core integrals are shown in the second row of the first part of this table. See Appendix for the evaluation of these integrals. See also Table I, note a.

b) $S=S_{12}=\int \chi_1(1)\chi_2(1)dv$.

c) W_H and W_2 are experimental ionization energies of hydrogen 1s and carbon 2p AO respectively.

d) Taken from the table given by Mulliken et al.[18]

17) C. C. J. Roothaan, "Special Issue of Technical Report of Laboratory of Molecular Structure and Spectroscopy," The University of Chicago (1955).

18) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

where W_H is the orbital energy of hydrogen 1s AO, S_H is the overlap integral between two hydrogen 1s AO's, and the integrals of the $\langle r \mid pq\rangle$ type are defined by:

$$\langle r \mid pq\rangle = -\int \chi_p(1) e^2/R_r(1) \chi_q(1) \mathrm{d}v \qquad (11)$$

Here $R_r(1)$ is the distance between the electron (1) and the r-th hydrogen core. The electronic repulsion integrals, $J_{\mu\mu'}$ and $K_{\mu\mu'}$ can be reduced to two integrals over atomic orbitals by using Mulliken's approximation,[19] as shown in Table II. Using theoretically calculated values for the integrals over atomic orbitals (Table III), the ionization potential, $I_p(\chi_1)$, is evaluated at 9.2880 eV.

The Ionization Potential of the Methyl Group

The next step in the calculation is to consider the interaction between the pseudo π AO, χ_1, and the 2pπ AO of the carbon atom of the methyl group—in other words, to treat the methyl group as an unsaturated diatomic molecule. The actual calculation was carried out by the aid of the SCF MO method.[20,21]

Denoting carbon 2pπ AO in a methyl group by χ_2, the molecular orbital in question has the form:

$$\varphi = c_1\chi_1 + c_2\chi_2 \qquad (12)$$

The familiar SCF matrix elements in this case are:

$$L_{pq} = I_{pq} + G_{pq} \qquad (13)$$

$$I_{pq} = \int \chi_p(1) H_m^c(1) \chi_q(1) \mathrm{d}v \qquad (14)$$

$$G_{pq} = \int \varphi(1)\varphi(1) e^2/r_{12} \chi_p(2) \chi_q(2) \mathrm{d}v \qquad (15)$$

Here,

$$H_m^c(1) = T(1) + A(1) - e^2/R_2(1)$$

$T(1)$ and $A(1)$ being a kinetic energy operator and a Coulomb potential from the H_3 core (including attractions from three hydrogen cores and repulsions from two electrons in λ_2 and λ_3) respectively.

$$\left.\begin{aligned} I_{11} &= W_1 + \langle 2 \mid 11\rangle \\ I_{22} &= W_2 + (22 \mid \lambda_2\lambda_2) + (22 \mid \lambda_3\lambda_3) \\ &\quad + \langle a \mid 22\rangle + 2\langle b \mid 22\rangle \\ I_{12} &= SW_2 + (12 \mid \lambda_2\lambda_2) + (12 \mid \lambda_3\lambda_3) \\ &\quad + \langle a \mid 12\rangle + 2\langle b \mid 12\rangle \end{aligned}\right\} \qquad (16)$$

Also,

$$\left.\begin{aligned} G_{11} &= c_1^2(11 \mid 11) + 2c_1c_2(12 \mid 11) + c_2^2(22 \mid 11) \\ G_{22} &= c_1^2(11 \mid 22) + 2c_1c_2(12 \mid 22) + c_2^2(22 \mid 22) \\ G_{12} &= c_1^2(11 \mid 12) + 2c_1c_2(12 \mid 12) + c_2^2(22 \mid 12) \end{aligned}\right\} \qquad (17)$$

Here W_1 corresponds to $I_p(\chi_1)$ computed above. W_2 is the 2p atomic orbital energy of carbon and can be taken to be -11.28 eV.[19] (the ionization potential of carbon). The other integrals are given in Tables II and III.

After the usual SCF procedure had been performed, the following secular equation was finally obtained:

$$\begin{vmatrix} 9.6837+\varepsilon, & 10.8957+0.6452\varepsilon \\ 10.8957+0.6452\varepsilon, & 11.6492+\varepsilon \end{vmatrix} = 0 \qquad (18)$$

The resultant orbital energies and molecular orbitals are:

$$\varepsilon_1 = -13.245 \text{ eV.} \quad \varphi_1 = 0.4362\chi_1 + 0.6619\chi_2 \qquad (19)$$

and,

$$\varepsilon_2 = +0.708 \text{ eV.} \quad \varphi_2 = 1.2347\chi_1 - 1.1299\chi_2 \qquad (20)$$

The ionization potential to remove an electron from the orbital φ_1 is the minus of the lower energy:

$$I_p(\text{methyl}) = 13.245 \text{ eV.}$$

The Electronic Structure of the *t*-Butyl Cation

Now let us consider the interaction among the three methyl groups and the central carbon atom. The wave function for the ground configuration is

$$\Phi_G = |A, \overline{A}, B, \overline{B}, C, \overline{C}| \qquad (21)$$

where A, B and C are abbreviated notations of φ_A, φ_B and φ_C, the pseudo π molecular orbitals of the three methyl groups.[22] In the ground configuration, the +1 charge is localized on the central carbon atom.

In addition to the above ground configuration, we must take the three CT (charge-transfer) configurations into account:

$$\left.\begin{aligned} \Phi_1 &= (2)^{-1/2} \cdot \{|A, \overline{3}, B, \overline{B}, C, \overline{C}| \\ &\quad + |3, \overline{A}, B, \overline{B}, C, \overline{C}|\} \\ \Phi_2 &= (2)^{-1/2} \cdot \{|A, \overline{A}, B, \overline{3}, C, \overline{C}| \\ &\quad + |A, \overline{A}, 3, \overline{B}, C, \overline{C}|\} \\ \Phi_3 &= (2)^{-1/2} \cdot \{|A, \overline{A}, B, \overline{B}, C, \overline{3}| \\ &\quad + |A, \overline{A}, B, \overline{B}, 3, \overline{C}|\} \end{aligned}\right\} \qquad (22)$$

19) R. S. Mulliken, *J. chim. phys.*, **46**, 497 (1949).
20) C. C. J. Roothaan, *Rev. Mod. Phys.*, **23**, 69 (1951).
21) R. G. Parr and R. S. Mulliken, *J. Chem. Phys.*, **18**, 1338 (1950).

22) φ is defined by Eq. 19. In this case, however, it is renormalized according to the zero-overlap approximation;

$$\varphi = 0.5505\chi_1 + 0.8348\chi_2$$

Similarly, φ_B and φ_C can be constructed using the AO's (and pseudo AO's) χ_4 and χ_5, and χ_6 and χ_7, respectively.

where number 3 is an abbreviated notation of χ_3, the $2p\pi$ AO of the central carbon atom. Locally excited configurations may be omitted because the excitation energies are considerably high.[23]

The following three new wave functions can be constructed by taking linear combinations of Φ_1, Φ_2 and Φ_3:

$$\left.\begin{aligned}\Phi_{\mathrm{I}} &= (3)^{-1/2}\cdot\{\Phi_1+\Phi_2+\Phi_3\}\\ \Phi_{\mathrm{II}} &= (2)^{-1/2}\cdot\{\Phi_2-\Phi_3\}\\ \Phi_{\mathrm{III}} &= (6)^{-1\ 2}\cdot\{2\cdot\Phi_1-(\Phi_2+\Phi_3)\}\end{aligned}\right\} \quad (23)$$

Among these, only Φ_{I} interacts with Φ_{G}, so that the ground state energy is obtained as the lower root of the secular equation:

$$\begin{vmatrix} -E, & H_{\mathrm{GI}} \\ H_{\mathrm{GI}}, & (H_{\mathrm{II}}-H_{\mathrm{GG}})-E \end{vmatrix}=0 \quad (24)$$

H_{GG} and H_{II} are defined by

$$H_{\mathrm{GG}}=\int \Phi_{\mathrm{G}} H \Phi_{\mathrm{G}} \mathrm{d}v \quad (25)$$

and

$$H_{\mathrm{II}}=\int \Phi_{\mathrm{I}} H \Phi_{\mathrm{I}} \mathrm{d}v \quad (26)$$

where H is the total electronic Hamiltonian of the system. Each element in Eq. 24 can be represented as follows:

$$H_{\mathrm{II}}-H_{\mathrm{GG}}=-I_p(3)+I_p(\mathrm{methyl}) \quad (27)$$

$$H_{\mathrm{GI}}=2.044\cdot\beta \quad (28)$$

where $I_p(3)$ is the ionization potential of an electron in χ_3, $I_p(\mathrm{methyl})$ is the ionization potential of the methyl group computed above, and β is the resonance integral between the carbon $2p\pi$ AO of a methyl group and χ_3.[24]

Φ_{II} and Φ_{III} both correspond to the lower excited state (doubly degenerate) and their energies (taking H_{GG} as the standard of energy) are:

$$\begin{aligned}E_{\mathrm{L}} &= H_{\mathrm{II\ II}}-H_{\mathrm{GG}}\\ &= H_{\mathrm{III\ III}}-H_{\mathrm{GG}}\\ &= -I_p(3)+I_p(\mathrm{methyl})\end{aligned}$$ [25]

Now taking $I_p(3)=11.28$ eV.[19] and $I_p(\mathrm{methyl})=13.245$ eV.;

$$H_{\mathrm{II}}-H_{\mathrm{GG}}=E_{\mathrm{L}}=1.965 \text{ eV}. \quad (29)$$

If we assume $\beta=-1.52$ eV. which is reasonable as will be described later (in Discussion), the roots of Eq. 24 are calculated as follows:

$$E_{\mathrm{G}}=-2.28 \text{ eV}.$$

$$E_{\mathrm{U}}=4.24 \text{ eV}.$$

The first excitation energy is

$$E_{\mathrm{L}}-E_{\mathrm{G}}=4.25 \text{ eV}.$$

which is in good agreement with the empirical value (290~295 mμ=4.27~4.20 eV.) obtained by Symons et al.[11,12] (see Fig. 2).

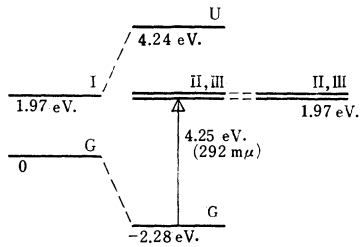

Fig. 2. The energy diagrams of the *t*-butyl cation.

The wave functions for the states are:

$$\left.\begin{aligned}\Psi_{\mathrm{G}} &= 0.8067\Phi_{\mathrm{G}}+0.5909\Phi_{\mathrm{I}}\\ \Psi_{\mathrm{L}_1} &= \Phi_{\mathrm{II}}\\ \Psi_{\mathrm{L}_2} &= \Phi_{\mathrm{III}}\\ \Psi_{\mathrm{U}} &= 0.5909\Phi_{\mathrm{I}}-0.8067\Phi_{\mathrm{G}}\end{aligned}\right\} \begin{matrix}\\ \\ \text{(doubly}\\ \text{degenerate)}\\ \\ \end{matrix} \quad (30)$$

The charge distributions for the ground and first excited states calculated from the above wave functions are shown in Fig. 3. The transition moments for the $\Psi_{\mathrm{G}}\rightarrow\Psi_{\mathrm{L}_1}$ and $\Psi_{\mathrm{G}}\rightarrow\Psi_{\mathrm{L}_2}$ transitions (μ_1 and μ_2 respectively) were evaluated as:

$$|\mu_1|=|\mu_2|=0.681 \text{ Å}$$

by the usual formula

$$\mu_{\mathrm{K}}=\int \Psi_{\mathrm{L_K}} \sum_i \boldsymbol{r}_i \Psi_{\mathrm{G}} \mathrm{d}v$$

The oscillator strength for the first excitation was determined to be 0.346 from the equation:

$$f=(1.085\times10^{-5})\nu G|\mu^2|$$

where ν is the wave number (in cm^{-1} units) for the transition and G is a degeneracy factor (in this case, $G=2$).[26]

23) The local excitation energy in the methyl group is given by

$$\varepsilon_2-\varepsilon_1-J_{\varphi_1\varphi_2}+2K_{\varphi_1\varphi_2}=5.228 \text{ eV}.$$

where ε_1 and ε_2 are the lower and upper roots of Eq. 18 and

$$J_{\varphi_1\varphi_2}=\int \varphi_1(1)\varphi_1(1)\mathrm{e}^2/r_{12}\varphi_2(2)\varphi_2(2)\mathrm{d}v$$

$$K_{\varphi_1\varphi_2}=\int \varphi_1(1)\varphi_2(1)\mathrm{e}^2/r_{12}\varphi_1(2)\varphi_2(2)\mathrm{d}v$$

The values of these integrals can be calculated using the basic integrals in Table II:

$J_{\varphi_1\varphi_2}=13.2592$ eV.

$K_{\varphi_1\varphi_2}=2.2670$ eV.

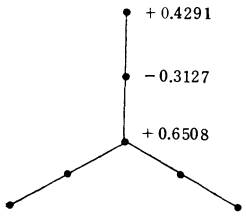
The effect of the locally excited configurations will be discussed below.

24) See Appendix for the reduction of $H_{\mathrm{II}}-H_{\mathrm{GG}}$ and H_{GI}.

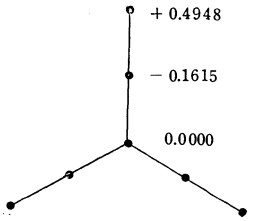
25) Note $H_{\mathrm{II}}=H_{\mathrm{II\ II}}=H_{\mathrm{III\ III}}$ in this approximation.

26) In the evaluation of charge distributions and transition moments, the assumption of zero-differential overlap[27] is invoked. This is in accordance with the fact that overlap integrals are disregarded formally in the above calculation of the interactions between the configurations, G, L_1, L_2 and U.

27) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 466 (1953).



(a) The ground state.



(b) The first excited state.

Fig. 3. The charge distributions of the *t*-butyl cation.

Finally, the hyperconjugation energy, $-E_G$, of the *t*-butyl cation can be obtained as follows:

$$-E_G = 2.28 \text{ eV.}$$
$$= 53.9 \text{ kcal./mol.}$$

Discussion

In the above calculation, the resonance integral, β, was determined to be -1.52 eV. If one plots the resonance integrals against the overlap integrals for this cation,[28] benzene, ethylene and butadiene,[29] all the points fit a straight line well. This seems to mean that the β value assumed for the *t*-butyl cation is reasonable.

From the absorption band of the *t*-butyl cation observed by Symons et al.,[11,12] the oscillator strength can be determined as follows:

$$f_{obs.} = 4.32 \times 10^{-9} \cdot \varepsilon_{max} \cdot \Delta H$$
$$= 0.13 \qquad (31)$$

where ε_{max} and ΔH are the peak molar extinction coefficient and the half-breadth in cm^{-1} units respectively. The theoretical *f* value (0.346) is about two or three times greater than the observed value. A discrepancy of this order of magnitude is usually found between observed and theoretical oscillator strength values. Moreover, the observed value is based on the assumption that the parent molecules (butyl alcohols, isobutene and *t*-butyl halides) can be completely converted into the cation in concentrated sulfuric acid. If they are not converted completely, or if the cation undergoes some futher reactions, the "apparent" extinction coefficient will be lower than the real one. In this connection, a further experimental check may be needed for a more quantitative comparison between the theoretical and observed oscillator strength values.

The calculated hyperconjugation energy (53.9 kcal./mol.) may be said to be unexpectedly large. However, this large stabilization energy due to hyperconjugation is thought to be reasonable from the experimental point of view. Franklin et al.[30] obtained the value 84 kcal./mol. for the stabilization energy of the *t*-butyl cation. Although there is a little question whether or not the observed stabilization energy corresponds to the *t*-butyl cation with the planar structure,[9] the calculated and observed results on the stabilization energy seem to show that the hyperconjugation effect is extraordinarily large in this cation.

As was mentioned in the introductory part of the present paper, the appearance of the absorption band in the 290 mμ region is difficult to be accounted for in molecules without any unsaturated bond. However, it has been established by the present calculations that the absorption can be understood in terms of the electron releasing ability (hyperconjugation effect) of the methyl groups. The excited state of the 290 mμ band is composed of the charge-transfer configurations caused by the electron transfer from the methyl groups towards the central carbon cation. Therefore, the transition corresponding to the 290 mμ band is accompanied by an electron transfer in the same direction. This may easily be seen from the electron distributions in the ground and first excited states shown in Fig. 3. In this interpretation, the band may be regarded as the intramolecular charge-transfer absorption,[31,32] the methyl groups and the carbon cation being the electron donor and the acceptor respectively.

Finally, let us check the effect of locally excited configurations within the methyl groups which were excluded in the above-mentioned calculations. The wave functions for these configurations are:

28) $S_{23} = 0.211$ for the overlap integral between a methyl group and the central carbon atom.
29) R. Pariser and R. G. Parr, *J. Chem. Phys.*, **21**, 767 (1953).
30) L. L. Franklin and H. E. Lumpkin, ibid., **20**, 745 (1952).
31) S. Nagakura and J. Tanaka, ibid., **22**, 236 (1954); S. Nagakura, ibid., **23**, 1441 (1954); *Mol. Phys.*, **3**, 105 (1960).
32) J. N. Murrell, *Quart. Revs.*, **15**, 191 (1960).

$$\left.\begin{aligned}\Phi_1^{\mathrm{L}} &= (2)^{-1/2}\{|A, \overline{A'}, B, \overline{B}, C, \overline{C}| \\ &\quad + |A', \overline{A}, B, \overline{B}, C, \overline{C}|\} \\ \Phi_2^{\mathrm{L}} &= (2)^{-1/2}\{|A, \overline{A}, B, \overline{B'}, C, \overline{C}| \\ &\quad + |A, \overline{A}, B', \overline{B}, C, \overline{C}|\} \\ \Phi_3^{\mathrm{L}} &= (2)^{-1/2}\{|A, \overline{A}, B, \overline{B}, C, \overline{C'}| \\ &\quad + |A, \overline{A}, B, \overline{B}, C', \overline{C}|\}\end{aligned}\right\} \quad (32)$$

where A', B' and C' denote $\varphi_{A'}$, $\varphi_{B'}$ and $\varphi_{C'}$ respectively, the upper MO's in each methyl group. If we take three linear combinations:

$$\left.\begin{aligned}\Phi_{\mathrm{I}}^{\mathrm{L}} &= (3)^{-1/2}(\Phi_1^{\mathrm{L}} + \Phi_2^{\mathrm{L}} + \Phi_3^{\mathrm{L}}) \\ \Phi_{\mathrm{II}}^{\mathrm{L}} &= (2)^{-1/2}(\Phi_2^{\mathrm{L}} - \Phi_3^{\mathrm{L}})\end{aligned}\right\} \quad (33)$$

and

$$\Phi_{\mathrm{III}}^{\mathrm{L}} = (3/2)^{-1/2}\{\Phi_1^{\mathrm{L}} - (1/2)(\Phi_2^{\mathrm{L}} + \Phi_3^{\mathrm{L}})\}$$

$\Phi_{\mathrm{I}}^{\mathrm{L}}$ interacts with Φ_{I} and Φ_{G}; $\Phi_{\mathrm{II}}^{\mathrm{L}}$, with Φ_{II}, and $\Phi_{\mathrm{III}}^{\mathrm{L}}$, with Φ_{III}.

The secular equations are:

$$\begin{vmatrix} -E & 2.04\beta & 1.83 \\ & 1.97-E & -0.551\beta \\ & & 6.23-E \end{vmatrix} = 0 \quad (34)$$

[33]

and

$$\begin{vmatrix} -E & -0.551\beta \\ & 3.72-E \end{vmatrix} \quad (35)$$

Assuming the same value of β (-1.52 eV.) as before, the results are:

Ground state: $E_{\mathrm{G}} = -2.71$ eV. (taking H_{GG} as the standard of energy)

$$\Psi_{\mathrm{G}} = 0.795\Phi_{\mathrm{G}} + 0.566\Phi_{\mathrm{I}} - 0.216\Phi_{\mathrm{I}}^{\mathrm{L}} \quad (36)$$

First excited state: $E_{\mathrm{L}} = 1.79$ eV.

$$\Psi_{\mathrm{L}_1} = 0.977\Phi_{\mathrm{II}} - 0.210\Phi_{\mathrm{II}}^{\mathrm{L}} \quad (37)$$

$$\Psi_{\mathrm{L}_2} = 0.977\Phi_{\mathrm{III}} - 0.210\Phi_{\mathrm{III}}^{\mathrm{L}} \quad (38)$$

The first excitation energy is, then, 4.50 eV., and the corresponding oscillator strength is calculated to be 0.365. From these results, we can see that the inclusion of the locally excited configurations does not bring about any significant change in the transition energy or in the oscillator strength.

Appendix

Electronic Repulsion Integrals.—The integrals $(aa \mid 22)$ and $(bb \mid 22)$ are evaluated as follows: let us denote the direction of the axis of 2p AO, χ_2, as the z-axis, the carbon core C_2 as an origin, and the angle between the z-axis and the direction of hydrogen atom a as θ (see Fig. 1). Similarly, φ is the angle between $-$z and the direction of hydrogen atom b. 2p AO, χ_2, then, can be represented by:[18]

$$\begin{aligned}\chi_2 &= \cos\theta\cdot\chi_{\sigma a} + \sin\theta\cdot\chi_{\pi a} \\ &= -\cos\varphi\cdot\chi_{\sigma b} + \sin\varphi\cdot\chi_{\pi b}\end{aligned} \quad (1A)$$

where $\chi_{\sigma a}$ is the 2p AO of carbon atom 2 directed toward hydrogen atom a, and $\chi_{\pi a}$ is that perpendicular to it. $\chi_{\sigma a}$ and $\chi_{\pi b}$ are defined similarly for b. The integrals $(aa \mid 22)$ and $(bb \mid 22)$ are, then:[34]

$$\begin{aligned}(aa \mid 22) &= \cos^2\theta\cdot(aa \mid \sigma\sigma) + \sin^2\theta\cdot(aa \mid \pi\pi) \\ &= 0.8889(aa \mid \sigma\sigma) + 0.1112(aa \mid \pi\pi)\end{aligned} \quad (2A)$$

and

$$\begin{aligned}(bb \mid 22) &= \cos^2\varphi\cdot(bb \mid \sigma\sigma) + \sin^2\varphi\cdot(bb \mid \pi\pi) \\ &= 0.2221(bb \mid \sigma\sigma) + 0.7778(bb \mid \pi\pi)\end{aligned} \quad (3A)$$

$\cos\theta$, $\sin\theta$, $\cos\varphi$ and $\sin\varphi$ being determined from the assumed bond distance and bond angles. The integrals, $(aa \mid \sigma\sigma)$ etc., are taken from the table given by Roothaan,[17] for the Slater-type 2p AO of the carbon, with $Z=3.18$, and for the 1s AO of the hydrogen, with $Z=1.00$.

Core Attraction Integrals.—The core attraction integrals $\langle a \mid bb\rangle$ and $\langle a \mid ab\rangle$ were calculated non-empirically:

$$\begin{aligned}\langle a \mid bb\rangle &= -\int \chi_b(1)e^2/R_a(1)\chi_b(1)\mathrm{d}v \\ &= -(2/R)\cdot[1-(1+R)e^{-2R}]\end{aligned} \quad (4A)$$

and

$$\begin{aligned}\langle a \mid ab\rangle &= -\int \chi_a(1)e^2/R_a(1)\chi_b(1)\mathrm{d}v \\ &= -2(R+1)e^{-R}\end{aligned} \quad (5A)$$

where R is the distance (in atomic units) between hydrogen cores a and b ($R=3.367$) and χ_a and χ_b are AO's with $Z=1.00$. The three-center integral $\langle a \mid bc\rangle$ is reduced to the form:

$$\begin{aligned}\langle a \mid bc\rangle &= (S_{\mathrm{H}}/2)(\langle a \mid bb\rangle + \langle a \mid cc\rangle) \\ &= S_{\mathrm{H}}\langle a \mid bb\rangle\end{aligned} \quad (6A)$$

using Mulliken's approximation. $\langle 2 \mid aa\rangle$ is obtained from Eq. 4A, putting $R=2.062$, the distance

33) In the evaluation of the off-diagonal element (H_{GL}) between the ground and locally excited configurations, only the inductive effect by the central carbon ion was taken into account; i.e., the off-diagonal element belonging to the field of the methyl group, $H_{\mathrm{GL}}^{\mathrm{Me}}$, was disregarded. This is true when the MO's φ_A and $\varphi_{A'}$ are self-consistent with respect to the methyl group. As has been mentioned above (see footnote 22), however, φ_A and $\varphi_{A'}$ were renormalized in accordance with the zero-overlap approximation, so that we can not put the $H_{\mathrm{GL}}^{\mathrm{Me}}$ value at zero with the same values of α's and β as in the SCF calculation mentioned above (the overlap integral was not disregarded there). However, if we put $\beta=-2.35$ eV., the $H_{\mathrm{GL}}^{\mathrm{Me}}$ value vanishes. This value of β seems to be reasonable in the case of the zero-overlap approximation.

34) Note, $(aa \mid \sigma\pi) = (bb \mid \sigma\pi) = 0$.

between carbon core 2 and hydrogen core a.[35]

$\langle a \mid 22\rangle$ is reduced to the form:

$$\langle a \mid 22\rangle = \cos^2\theta\cdot\langle a \mid \sigma\sigma\rangle + \sin^2\theta\cdot\langle a \mid \pi\pi\rangle \quad (7A)$$

using Eq. 1A. $\langle a \mid \sigma\sigma\rangle$ is evaluated non-empirically, giving the formula:

$$\langle a \mid \sigma\sigma\rangle = -(Z/2)\rho^{-3}\cdot[2(\rho^2+12)-(\rho^5/4 + 3\cdot\rho^4/2+11\cdot\rho^3/2+14\cdot\rho^2+24\cdot\rho+24)e^{-\rho}] \quad (8A)$$

where $\rho=(Z/2)R$, with $Z=3.18$ and $R=2.062$ a. u. The integrals $\langle a \mid \pi\pi\rangle$ and $\langle b \mid 22\rangle$ are calculated by the aid of the "uniformly charged sphere" approximation,[27] in which $\chi_2(1)\chi_2(1)e$ is replaced by a pair of tangent uniformly-charged spheres of the diameter:

$$D=4.597/Z \text{ Å} \quad (9A)$$

where Z is the effective charge of the carbon 2p AO χ_2 ($Z=3.18$).[36]

The Evaluation of Matrix Elements.—The matrix elements necessary for the calculation of the configuration interaction between the ground and charge-transfer configurations of the *t*-butyl cation were evaluated under the approximation of zero-differential overlap:[27]

$$H_{GG}=\int |A, \overline{A}, B, \overline{B}, C, \overline{C}|H|A, \overline{A}, B, \overline{B}, C, \overline{C}|\,dv = 2(I_A+I_B+I_C)+J_{AA}+J_{BB}+J_{CC} + 4(J_{AB}+J_{BC}+J_{CA}) \quad (10A)$$

where

$$I_i=\int \varphi_i H^c \varphi_i dv \quad (11A)$$

$$J_{ij}=\int \varphi_i\varphi_i e^2/r_{12}\varphi_j\varphi_j dv \quad (12A)$$

and

$$H^c = T - \sum_{i=1}^{7}(e^2/R_i) \quad (13A)$$

T and R_i being the kinetic energy operator and the distance of an electron from the i-th core. Similarly,

$$H_{II}=I_A+I_3+2(I_B+I_C)+J_{BB}+J_{CC} + 2(J_{AB}+2J_{BC}+J_{CA})+J_{A3}+2(J_{B3}+J_{C3}) \quad (14A)$$

Accordingly,

$$H_{II}-H_{GG}=I_3-I_A-J_{AA}-2(J_{AB}+J_{CA}) + J_{A3}+2(J_{B3}+J_{C3}) \quad (15A)$$

On the other hand,

$$I_A=\int \varphi_A(T-e^2/R_1-e^2/R_2)\varphi_A dv+\sum_{i=3}^{7}\langle i \mid AA\rangle = I_A^A-2(J_{AB}+J_{CA})-J_{A3} \quad (16A)$$

where the approximate relations

$$\langle 3 \mid AA\rangle \fallingdotseq -J_{A3},\ \langle 4 \mid AA\rangle+\langle 5 \mid AA\rangle \fallingdotseq -2J_{AB} \text{ and } \langle 6 \mid AA\rangle+\langle 7 \mid AA\rangle \fallingdotseq -2J_{CA} \quad (17A)$$

are used. I_A^A is a core integral in the absence of an attraction from the other two methyl groups and from carbon core 3, so that we have a relation:

$$-I_p(\text{methyl}) = I_A^A + J_{AA} \quad (18A)$$

Similarly, we have:

$$I_3 = I_3^3 - 2(J_{A3}+J_{B3}+J_{C3}) \quad (19A)$$

and

$$-I_p(3) = I_3^3 \quad (20A)$$

Putting Eqs. 16A, 18A, 19A and 20A into Eq. 15A, we have

$$H_{II}-H_{GG}=I_p(\text{methyl})-I_p(3) \quad (21A)$$

The off-diagonal element H_{GI} is reduced as follows:

$$H_{GI}=(3)^{-1/2}(H_{G1}+H_{G2}+H_{G3})=(3)^{1/2}H_{G1} \quad (22A)$$

$$H_{G1}=(2)^{1/2}\int \varphi_A H^c \chi_3 dv = (2)^{1/2}\int (0.5525\chi_1+0.8348\chi_2)H^c\chi_3 dv \fallingdotseq (0.8348)(2)^{1/2}\int \chi_2 H^c \chi_3 dv \quad (23A)$$

Denoting $\int \chi_2 H^c \chi_3 dv = \beta$ and putting Eq. 23A into Eq. 22A,

$$H_{GI}=2.044\beta.$$

35) Under the assumption of disregarding a Coulomb penetration integral, the core attraction integral $\langle 2 \mid aa\rangle$, as is well known, can be approximated as equal to the two-center Coulomb integral $-(22 \mid aa)$. This value, -12.256 eV., is rather close to the value, -12.541 eV., obtained by the above-mentioned method.

36) If the "uniformly charged sphere" model is applied directly to $\langle a \mid 22\rangle$, hydrogen core a is "inside" of one of the spheres. Therefore, rigorous computation was carried out for $\langle a \mid \sigma\sigma\rangle$.

*The Electrical Conduction of the p-Phenylenediamine Iodine Complex**

By Shun-ichiro NISHIZAKI and Hideaki KUSAKAWA

(Received August 2, 1963)

Extensive work has by now been carried out on the electronic conduction in molecular complexes of aromatic hydrocarbon with iodine,[1-5] or antimony pentachloride,[6] and amines with quinones,[7-9] but on complexes of amines with iodine, except in solutions, there have been only a few papers.[10]

It seems that iodine is stronger as an electron acceptor[11] than are quinones, therefore, it is to be expected that the complexes constituted of amine and iodine have a lower electrical resistivity than that of amine and quinone.

This paper will report on the electrical conductivity of the complex of paraphenylenediamine with iodine. This complex appeared to have a nonstoichiometrical composition, and its electrical resistivity varied according to the iodine contents. Therefore, it was the objective of the present work to investigate the relation between the magnitude and temperature dependence of the electrical resistivities and the coordination numbers of the iodine.

Experimental

Materials.—The purification of *p*-phenylenediamine (*p*-PDA) and iodine (I_2) was carried out by distillation and sublimation, which were repeated twice.

p-PDA and iodine were dissolved in benzene. When both solutions were mixed, dark-colored complexes of *p*-PDA with iodine precipitated. In order to vary the iodine content in the complexes, the mole ratio of iodine/amine was arranged at 2/4, 3/4, 4/4, 5/4, 6/4 and 7/4. The complexes precipitated were left to stand for 24 hr. in the mixed solution, they were then filtered and dried.

All the complexes gave a rich yield above 90% for the mixed *p*-PDA and iodine, especially in cases of the mixed mole ratios of 2/4 and 3/4, when the yield was approximately 99%.

Electrical Conduction.—The electrical resistivities of the complexes were measured by means of the dc method, using crystalline powder which had been packed into a glass capillary (about 2 mm.) in a dry box and compressed with a pressure of 15 kg. between metal electrodes, the diameters of which were 2.0 mm. (about 500 kg./cm^2). This electrode cell was exposed to an atmosphere of dry air. By applying a dc field of about 50 V./cm. across the electrodes, the current through the specimen was measured with a micro or electronic micro-micro ammeter.

In order to isolate the ionic conduction, for over 15 hr. the d. c. field was applied through the specimen at room temperature (about 30°C). After this treatment, there was no change in the infrared absorption spectra of the specimens, the temperature of the specimen, which was controlled with an electric furnace placed around the cell, was raised to 85°C.

The relation between the electrical resistivities and the temperature for calculating the activation energy was measured during the first cooling.

Apparent Densities.—The apparent densities of the complexes were measured with tablets which had been compressed in a manner similar to that used potassium bromide tablet for the infrared-spectrum. The tablet of the potassium bromide compressed under the same conditions indicated 2.52 g./cm^3 at 30°C, but the density of potassium bromide is 2.7 g./cm^3 at 25°C.

Results and Discussion

The results of this investigation are shown in Fig. 1, as semilogarithmic plots of the resistivity vs. temperature for the complexes. In this case the coordination numbers of iodine (Table I) are noted on the figure. The activation energy for the electrical conduction process, E_c, can be calculated from the slope of the plots, $\rho=\rho_0 \exp(E/\boldsymbol{k}T)$, their values are listed in the last column in Table I.

It may be seen that the electrical conductivities of complexes are remarkably enhanced with a small increase in the iodine content in complexes and that a minimum value for both

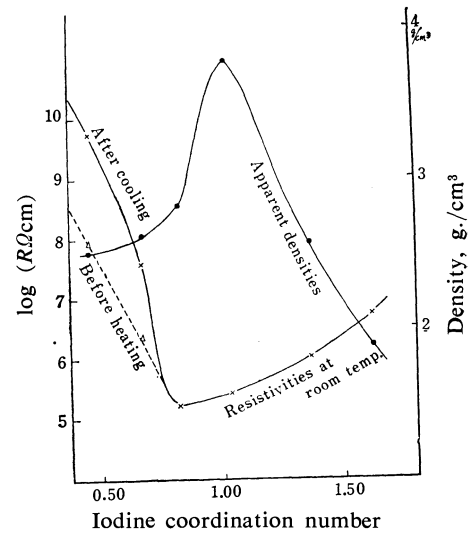

Fig. 2. The relationship between the I_2 coordination number and electrical resitivities, density.

the magnitude and the temperature dependence of the electrical resistivity appears in the complex the coordination number of the iodine of which is around 0.8. Over this range, the magnitude and temperature dependence of the resistivity gradually increase with the iodine content. However, on the other hand, the maximum value of density exists in the vicinity of the coordination number 1.0. These results are shown in Fig. 2.

In view of the fact that the resistivities increased with time when the current was run through the specimens the coordination numbers of which were 0.45 and 0.67, and so did not follow Ohm's law, it seems that ionic conduction formed most of the conduction in these complexes. The different values of resistivities between before heating and after cooling were especially conspicuous in these cases. However, even if these specimens were heated and cooled twice, there was no remarkable change in resistivity.

In the complexes the iodine coordination number of which was above the neighborhood of 0.8, ionic conduction was inferior to electronic conduction, because the current ran in an Ohmic pattern and the resistivity did not change between before heating and after cooling.

As Table II shows, the values for both the magnitude and the temperature dependence of

TABLE II. COMPARISON WITH *p*-PDA-I_2 AND *p*-PDA-CHLORANIL ON THE ELECTRICAL RESISTIVITY AND ACTIVATION ENERGY

	$\rho_{25°C}$ ohm-cm.	ρ_0 ohm-cm.	E_c eV.
p-PDA-I_2	2.1×10^{5}	2.4×10^{-2}	0.41
p-PDA-Chloranil	6×10^{6}	1.9×10^{-5}	0.67

the resistivity of an amine-iodine complex are smaller than those of an amine-chloranil complex[12] when the amine is *p*-PDA. On the other hand, the redox potential of iodine is 0.536 V. and that of chloranil is 0.742 V. From this point of view, chloranil seems to be a

12) R. Sehr, M. M. Labes, M. Bose and H. Ur. F. Wilhelm, "Symposium on Electrical Conductivity in Organic Solid," John Wiley & Sons Inc., New York (1961) p. 309.

stronger oxidative reagent than iodine, although, as an electron-acceptor, iodine is superior to chloranil for *p*-PDA. In the cases of bromine and iodine with benzidine,[10,13] one can see the same results. For this reason it is presumed that the polarization terms in the following equation play an important role[3,14].

$$2E_c \simeq \varepsilon = [I_G(D) - A_G(A)] - [P(D_+) + P(A_-)]$$

where ε is the energy of charge transfer band, $I_G(D)$ is the ionization potential of the donor, $A_G(A)$ is the electron affinity of the acceptor in the gas phase, and the contributions, $P(D_+)$ and $P(A_-)$, from the polarization energy around the positive and negative ion are represented.

The complexes of *p*-PDA with iodine were thermally stable up to the vicinity of 120°C, and their melting points were not lower than those of the two conpenents (*p*-PDA : 140°C iodine : 114°C). Iodine had been freed upon being heated before the complexes were melted therefore, the phase diagram for *p*-PDA-iodine could not be obtained in this atmosphere.

Summary

In the case of a complex of *p*-phenylenediamine with iodine, a nonstoichiometrical composition has been established; the minimum values for both the magnitude and the temperature dependence of resistivity exist on the complex the coordination number of which is around 0.8. On the other hand, the maximum value of the apparent density appears in the vicinity of 1.0.

In comparison with the complex of *p*-phenylenediamine-iodine and that of *p*-phenylenediamine-chloranil, even though the redox potential of chloranil is larger than that of iodine, the resistivity and the activation energy of the *p*-phenylenediamine-iodine system are smaller than those of the chloranil complex.

The Pectic Acid from the Pulp of Jackfruit (Artocarpus Integrifolia). I. Methylation Studies

By U. K. Sen Gupta and C. V. N. Rao

(Received August 27, 1963)

The presence of pectic substances in the pulp of jackfruit has been reported earlier by different workers.[1,2] However, no detailed investigations seem to have been carried out on the structure of these pectic substances. The present paper reports some structural studies of the pectic acid isolated from the soft fleshy pulp of the ripe jackfruit.

The polysaccharide obtained from jackfruit pulp by extraction with hot water gave a blue color with iodine. The product obtained after treatment with diastase to remove starch, on hydrolysis gave L-rhamnose, D-xylose, L-arabinose, D-glucose, D-galactose and D-galacturonic acid.

Ammonium pectate was isolated from the water-extracted residue of the jackfruit pulp with a hot ammonium oxalate solution. The polysaccharide was purified by converting it to insoluble calcium salt, and then to ammonium pectate, and finally by treating the material with diastase to destroy any starch. The hydrolysis of the resulting polysaccharide yielded D-galacturonic acid, D-glucose, and traces of arabinose. The polysaccharide was subjected to further purification by different processes, viz., conversion into sodium salt followed by precipitation as calcium salt, complexing with cetyltrimethylammonium bromide[3,4] and repeated fractional precipitation with acetone from an aqueous solution. However, no pure polygalacturonic acid free from neutral sugar components could be isolated by any of these processes, though xylose, rhamnose and galactose containing moieties were removed after repeated purification. Different

methods of purification yielded polysaccharides with different specific rotation and uronic acid content values. The hydrolyzates of each material gave different amounts of galacturonic acid, together with glucose and traces of arabinose. It was also found that only galacturonic acid residues were released when ammonium pectate was hydrolyzed under mild conditions using 0.1 N sulphuric acid. As the uronic acid content was highest in sample A, this was used in further investigations.

The purified polysaccharide was dissolved in phosphate buffer and subjected to electrophoresis using a potential gradient of 7.0 V. per cm. Two distinct peaks were observed, one of them migrating towards the anode presumably because of the polyuronic acid constituents. A known mixture of quite divergent groups of polysaccharides has been reported[5] to have been separated by this method.

The results of the electrophoretic experiment, together with the earlier findings, viz., the variation of uronic anhydride content in polysaccharides obtained by different methods of purification and the failure to obtain an aldobiouronic acid by mild hydrolysis, indicate that the material under investigation is a mixture of at least two different polysaccharides, one being a polygalacturonan. Another interesting observation is that glucose was detected in the hydrolyzate of the purified polysaccharide even after the treatment with diastase, showing that glucose may be an artifect of a glucan which is different from starch.

Ammonium pectate was methylated first by treatment with methyl sulfate and sodium hydroxide and then by the addition of methyl iodide to the silver salt. The methylated polysaccharide was purified by adding cold ethanolic sodium hydroxide to remove the associated neutral methylated polysaccharide. The methylated sodium pectate so obtained was, as usual, reconverted into methylated methyl pectate, which showed no hydroxyl absorption band in the infrared spectrum.

The methylated product after methanolysis was saponified with aqueous barium hydroxide. The acid portion was separated from the neutral portion by absorbing the former on an anion-exchange resin. On hydrolysis the neutral portion yielded a mixture of methyl sugars which was separated and estimated[6] by paper chromatography to give 2, 3, 4, 6-tetra- (1 mol.), 2, 3, 6-tri- (10.2 mol.), 2, 4, 6-tri- (9.8 mol.) and 2, 3-di-*O*-methyl-D-glucose (1.1 mol.) ; each of these methyl sugars was identified through a suitable crystalline derivative. As no methyl arabinose was found in the hydrolyzate of the neutral polysaccharide, it is assumed that arabinose was eliminated during the methylation and the subsequent purification processes.

The acidic component was displaced from the resin and reduced with lithium aluminum hydride, and the resulting product on hydrolysis gave a mixture of neutral methyl sugars. The mixture was separated on a cellulose column to give 2, 3, 4-tri- and 2, 3-di-*O*-methyl-D-galactose, which were characterised through their crystalline anilides. The relative amounts of sugars were estimated by alkaline hypoiodite. The molar ratio of the tri- and di-methyl galactose was 1 : 91.

From the above results it is possible to assign structures to the pectic acid and to the glucan associated with it. It is clear from these results that the main component, 2, 3-di-*O*-methyl-D-galactose, has arisen from the residues of 2, 3-di-*O*-methyl-D-galacturonic acid, that the jackfruit pectic acid contains chains of 1 : 4 linked D-galacturonic acid residues, and that the 2, 3, 4-tri-*O*-methyl-D-galactose originates from the nonreducing D-galacturonic acid end groups. As no monomethyl galactose could be isolated, the molecule is considered to be unbranched. From the ratio of the amounts of trimethyl and dimethyl galactose, the average length of each molecules is calculated to be 92 hexouronic acid units. Hence, the structure of the pectic acid is as follows:

$$Ga_pU{=}_1{\longrightarrow}_4\ (Ga_pU)_{90}\ {}_1{\longrightarrow}_4\ Ga_pU$$

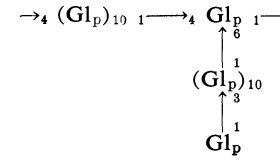
(Ga_pU represents the galactopyranosyl uronic acid residue).

From the methoxyl content of the original polysaccharide, it can be concluded that some of the carboxyl groups are involved in methyl ester linkages. Since the pectic acid and its methylated derivative have high positive rotations, the glycosidic linkages are considered to be of the α-type.

The demonstration of the presence of 2, 3, 4, 6-tetra-*O*-methyl-D-glucose in the tetra-methyl fraction of the neutral hydrolyzate indicates that the non-reducing ends of the glucan are occupied by the glucopyranose residues. The characterization of the two trimethyl sugars, 2, 3, 6-tri- and 2, 4, 6-tri-*O*-methyl-D-glucose, shows the existence of two kinds of linkages, 1→4 and 1→3, in the main a chain. The presence of a considerable amount of 2, 3-di-*O*-methyl-D-glucose suggests that the glucose residues at the branch points are joined through C_1, C_4 and C_6 and that the branches

5) J. R. Colvin, W. H. Cook and G. A. Adams, *Can. J. Chem.*, **30**, 603 (1952).
6) E. L. Hirst, L. Hough and J. K. N. Jones, *J. Chem. Soc.*, **1949**, 928.

originate from certain glucose units linked through the C_1 and C_4 positions and not those through the C_1 and C_3 positions in the chain. On the basis of the above results, one of the possible structures for the repeating unit of the glucan may be given as follow:



(Gl_p represents the glucopyranose unit)

However, it is not possible to stipulate exactly the distribution of 1→3 and 1→4 linked glucopyronose units in the polysaccharide in the light of present knowledge.

Further support for the proposed structure for the pectic acid was obtained from periodic acid oxidation studies of the pectic acid. It was found that one molar proportion of formic acid was liberated for every 30 mol. of anhydrouronic acid residues in 28 hr. and that 0.94 mol. of the oxidant were consumed per anhydrouronic acid residue in 30 hr., the theoretical figure for the consumption of periodate being 0.96 mol. The findings regarding periodate uptake are thus in good agreement with those theoretically expected.

The molecular weight of the methylated pectic acid, as determined by the light-scattering method, is 1.50×10^5.

The pectic acid obtained from the pulp of the jackfruit is similar to those obtained from apple,[7] strawberry,[8] citrus,[9,9a] and sisal.[10] The pectic acid obtained from these sources is generally associated with a neutral polysaccharide such as araban and galactan. In the case of jackfruit pectic acid, the neutral component is a glucan of a rather unusual structure, one which is similar to that isolated from mangifera indica.[11]

Experimental

All specific rotations are equilibrium values. Unless otherwise stated, all evaporations were carried out in vacuo at 30~40°C. Paper partition chromatography was carried out on Whatman No. 1 filter paper with the following solvent systems (v/v): (A) ethyl acetate: pyridine: water (8:2:1); (B) *n*-butanol: acetic acid: water (4:1:5) upper layer; (C) *n*-butanol: ethanol: water (40:11:19); (D) ethyl methyl ketone-water azeotrope; (E) *n*-butanol: ethanol: water (5:1:4) upper layer; (F) ethyl acetate: acetic acid: water (9:2:2). The spray reagents used were: (a) aniline hydrogen oxalate (a saturated aqueous solution), (d) *p*-anisidine hydrochloride (a 3% solution in butanol). Unless otherwise stated, the R_G values of methyl sugars refer to rates of movement relative to 2, 3, 4, 6-tetra-*O*-methyl-D-glucose in solvent E. Methyl sugars were demethylated with hydrobromic acid.[12]

The Isolation and Examination of Water-soluble Polysaccharides.—The pulp of jackfruit was freed from the seed and pericarp, and the soft fleshy material was macerated in a blender in the presence of ethanol. After the product had been kept overnight, the slurry was filtered through a cloth and the residue dried in air. The material (100 g.) so obtained was allowed to swell in water (2 l.); it was then heated, while being stirred, on a boiling-water bath for 4 hr. The slurry was diluted with water (2 l.) and filtered through a cloth. The filtrate was further clarified by passing it through a Cepa supercentrifuge, and the polysaccharide was precipitated as a white gelatinous material by adding thrice its volume of acidified ethanol. The precipitate was filtered, washed with ethanol, triturated and dried. The material isolated gave a blue color when iodine was added, indicating the presence of starch which was removed by the action of diastase. The polysaccharide recovered in the usual way was a white amorphous powder; yield, 18 g.; moisture, 8.8%; ash, 1.02%; OMe,[13] 1.1%; nitrogen, nil; equivalent weight, 388.9; anhydrouronic acid,[14] 46.76%; $[\alpha]_D^{29}+168.7°$ (*c* 1.1, in water). The water-extracted polysaccharide (0.8 g.) was heated with 1 N sulfuric acid (50 ml.) for 10 hr. on a boiling water-bath when the hydrolysis, followed iodometrically,[15] was complete. The cooled solution was neutralized, and the filtrate was concentrated to a sirup. On paper chromatography using solvents A, B and F, the sirup was found to contain rhamnose, xylose, arabinose, glucose, galactose and galacturonic acid. A portion of the sirup (460 mg.) was separated on a cellulose column (60×3.5 cm.), using *n*-butanol half-saturated with water as the eluent, to give five fractions and the sugars L-rhamnose, D-xylose, L-arabinose, D-glucose and D-galactose were identified through their specific rotations and the preparation of suitable crystalline derivatives. The sixth fraction, obtained as barium salt by elution with water, was deionised with Amberlite IR-120 (H) to give D-galacturonic acid, which was characterised through its specific rotation and the preparation of crystalline mucic acid.

The Isolation and Purification of Pectic Acid from Jackfruit Pulp.—The residue left (1.5 kg.) after the water-soluble polysaccharide had been removed from the jackfruit pulp was treated with

a 0.5% ammonium oxalate solution (12 l.) and the polysaccharide was isolated as usual. A calcium chloride solution (5%) was added to a 2% aqueous solution of this material until no further precipitate was formed. The resulting calcium pectate was suspended in water (1 l.) and heated at 90°C for one hour with ammonium oxalate (6 g.). The calcium oxalate was then filtered off, and the polysaccharide was precipitated by adding ethanol. The above process was repeated once more, after which the solution was dialysed aganst distilled water and then treated with diastase. The purified polysaccharide was isolated in the usual way; yield, 85 g. The hydrolysis of the polysaccharide, followed by a chromatographic examination of the resulting sirup, revealed the presence of galacturonic acid and glucose, together with trace amounts of arabinose. D-Galacturonic acid and D-glucose were characterised through their crystalline derivatives. A portion of the ammonium pectate in the aqueous solution was passed through a column of Amberlite IR-120(H); the pectic acid so obtained had $[\alpha]_D^{29}$ +229° (*c* 0.45, in water) [equiv. 221 corresponds to 79.6% of anhydrouronic acid; found: anhydrouronic acid, 81.5%]; OMe, 1.3%.

The Attempted Fractionation of Ammonium Pectate.—(1) A suspension of crude ammonium pectate (40 g.) in ethanol (800 ml.) was treated with a sodium hydroxide solution (40%, 50 ml.) and the mixture kept at 2°C for 48 hr. while occasionally being shaken. After filtration the solid was washed with ethanol-water (1 : 1). An equal volume of ethanol was added to the aqueous solution to precipitate sodium pectate. The product, after extraction with hot ethanol-water (1 : 1), was dissolved in water, precipitated as calcium pectate, and finally converted into ammonium pectate. The above process was repeated once more to yield a polysaccharide (29 g., sample A); $[\alpha]_D^{29}$ +213.4° (*c* 0.6, in water), [equiv. 203 corresponds to 86.7% of anhydrouronic acid; found: anhydrouronic acid, 87.5%]. The hydrolysis of a portion of sample A yielded galacturonic acid, glucose, and a trace of arabinose; the amount of glucose was estimated[16] and found to be 9.5%.

(2) A solution of crude ammonium pectate (15 g.) in water (700 ml.) was treated with an aqueous solution of "Cetavlon" (cetyltrimethylammonium bromide) (10%, 200 ml.); the precipitate was then filtered. 5 N-Acetic acid was stirred into an aqueous suspension of the precipitate to decompose the complex. The polysaccharide was precipitated by ethanol, redispersed in water, shaken for 2 hr. with Amberlite IR-120(H) and filtered. The pectic acid was precipitated as usual and subjected to further purification as above to yield a polysaccharide (9.5 g., sample B); $[\alpha]_D^{29}$ +209.5° (*c* 0.5, in water) [equiv. 217 corresponds to 81.1% of anhydrouronic acid; found: anhydrouronic acid, 84.5%]. The hydrolysis of a portion of sample B gave galacturonic acid, glucose, and arabinose.

(3) An aqueous solution of crude ammonium pectate (2%, 500 ml.) was precipitated with acetone (600 ml.). The process was repeated several times, and the polysaccharide was extracted with hot ethanol-water (1 : 1) and reprecipitated from the aqueous solution by adding ethanol. The polysaccharide (5 g., sample C) had $[\alpha]_D^{29}$ +202° (*c* 0.7, in water) [equiv. 219 corresponds to 80.3% anhydrouronic acid; found: anhydrouronic acid, 81.7%]. The hydrolysis of a sample yielded galacturonic acid, glucose, and arabinose.

Repeated purification by each of these methods did not increase the uronic acid content.

The Electrophoresis of the Polysaccharide.—The purified polysaccharide (116 mg., sample A) was dissolved in a 0.1 M phosphate buffer (10 ml., pH 7.1). The solution was centrifuged on a high speed centrifuge at 20000 G for 15 min. in order to clarify it. The supernatant liquor was dialysed against the same buffer (500 ml.) for 18 hr. at 15°C. The conductivity of the resultant solution was determined, after which electrophoresis was carried out in a Perkin-Elmer electrophoresis apparatus (Model 38A) at 15°C using a potential gradient of 7.0 V./cm. Photographs of the migrating boundaries were taken at the beginning and at regular intervals. The photographs shown above were taken after one hour interval; the boundaries became diffused afterwards.

The Mild Hydrolysis of Ammonium Pectate.—Ammonium pectate (5 g., sample A) was heated with 0.1 N sulfuric acid (200 ml.) for 50 hr. at

16) E. L. Hirst and J. K. N. Jones, *J. Chem. Soc.*, **1949**, 1659.

85~90°C. The solution was then neutralized, filtered, and deionised by passing it through Amberlite IR-120(H). The acid was absorbed on a column of Dowex 1X-4 anion-exchange resin, and the column was freed from neutral sugars by washing it with water. The acid was displaced from the column by sulfuric acid, neutralized, and filtered, and the filtrate was deionized and concentrated to a sirup. The paper chromatographic examination of the sirup using solvent F gave a single spot corresponding to galacturonic acid; [6] $[\alpha]_D^{30}$ +80.5°, equiv. 188. The acid was characterised as D-galacturonic acid by converting it to crystalline D-galactose and to mucic acid.

The Methylation of Ammonium Pectate.—Ammonium pectate (22 g., sample A), was methylated by treatment with methylsulfate and sodium hydroxide[17] and then with methyl iodide and silver oxide,[18] according to the method adopted by Aspinall et al.,[10] to yield a methylated polysaccharide (15.3 g.), $[\alpha]_D^{29}$ +196° (*c* 0.8, in chloroform), OMe 39.8%. The methylated polysaccharide (15 g.) was purified by treating it with cold ethanolic sodium hydroxide according to the method of Aspinall et al.[10] The resulting methylated sodium pectate was converted into methylated methyl pectate (9.7 g.), which showed no hydroxyl absorption band in the infrared spectrum, $[\alpha]_D^{29}$ +208° (*c* 1.1, in chloroform) (Found: OMe, 40.5. Calcd. for $C_8H_{14}O_6$: OMe, 42.6%).

The Molecular Weight Determination of the Methylated Methyl Pectate.—All measurements of the intensities of scattered light for the molecular weight determination of the methyl pectate were carried out with a Brice-Phoenix light-scattering photometer (Model OM 1000A) using a semi-octagonal cell. The concentration used was over a range of $(0.4\sim3.0)\times10^{-3}$ g./ml. The molecular weight was found to be 1.503×10^5 as calculated by the dissymmetry method.[19] The value of *r*, corresponding to the root-mean-square end-to-end distances of the polymer, was calculated to be 1998 Å for the methylated polysaccharide at the wavelength of 5461 Å.

The Methanolysis of the Methylated Methyl Pectate and the Separation of Neutral and Acidic Methyl Sugars.—A solution of methylated methyl pectate (3.5 g.) in methanolic hydrogen chloride (4%, 125 ml.) was heated in a sealed tube at 100°C for 8 hr. Neutralization, filtration and evaporation yielded a sirup which was then heated with a barium hydroxide solution (2%, 50 ml.) at 80°C for 4 hr. The solution, after having been neutralized by passing carbon dioxide gas through it, was filtered and passed through a column of Amberlite IR-120(H) and Dowex 1 X-4 (bicarbonate form). The neutral solution was evaporated to a sirup, and the resulting mixture of methyl glycosides was hydrolysed with 1 N hydrochloric acid at 100°C for 8 hr. The hydrolyzate was neutralised (silver carbonate) and filtered, and the resulting solution after deionization was evaporated to a sirup (346 mg.). On paper partition chromatography using solvents D and E, the sirup gave four spots corresponding to 2, 3, 4, 6-tetra-, 2, 3, 6-tri-, 2, 4, 6-tri-, and 2, 3-di-*O*-methyl-D-glucose.

The mixture of neutral methyl sugars (ca. 335 mg.) was separated on Whatman No. 3MM papers using solvent D. The respective zones were eluted with water and evaporated to sirups.

The Identification of 2, 3, 4, 6-Tetra-O-methyl-D-glucose.—The sirup (15.5 mg.) had $[\alpha]_D^{29}$ +82° (*c* 0.4, in water) and R_G 1.0. Demethylation gave glucose. The sugar was characterised as 2, 3, 4, 6-tetra-*O*-methyl-D-glucose by conversion into the crystalline aniline derivative; m. p. and mixed m. p. 136~137°C; lit.[20] 136~138°C.

The Identification of 2, 3, 6-Tri-O-methyl-D-glucose.—The sirup (150.2 mg.) had $[\alpha]_D^{29}$ +67° (*c* 0.8, in water) and R_G 0.82 (Found: OMe, 41.6. Calcd. for trimethyl hexose: OMe, 41.8%). Demethylation gave glucose. The 2, 3, 6-tri-*O*-methyl-D-glucose was identified by preparing crystalline 2, 3, 6-tri-*O*-methyl-D-glucose-1, 4-di-*p*-nitrobenzoate; m. p. and mixed m. p. 190~191°C; lit.[21] 190~192°C.

The Identification of 2, 4, 6-Tri-O-methyl-D-glucose.—The sirup (148.1 mg.) with $[\alpha]_D^{29}$ +71° (*c* 1.0, in water), R_G 0.76 (Found: OMe, 41.1. Calcd. for trimethyl hexose: OMe, 41.8%.) gave glucose on demethylation. The sugar was identified as 2, 4, 6-tri-*O*-methyl-D-glucose by converting it to the crystalline anilide; m. p. and mixed m. p. 162~163°C; lit.[22] 162~166°C.

The Identification of 2, 3-Di-O-methyl-D-glucose.—The sirup (16 mg.) had $[\alpha]_D^{29}$ +65° (*c* 0.3, in water) and R_G 0.58. The sugar was characterised has 2, 3-di-*O*-methyl-D-glucose by conversion into 2, 3-di-*O*-methyl-D-gluconophenylhydrazide; m. p. and mixed m. p. 160~161°C; lit.[20] 160~162°C.

A portion of the mixture of methyl sugars was quantitatively separated by paper chromatography using solvent E, and each component was estimated by alkaline hypoiodite. The molar ratio of 2, 3, 4, 6-tetra-, to 2, 3, 6-tri- to 2, 4, 6-tri- to 2, 3-di-*O*-methyl-D-glucose was 1.0 : 10.2 : 9.8 : 1.1.

The Examination of the Acidic Component of the Methylated Methyl Pectate.—The Dowex 1 X-4 resin, after a thorough washing with water, was eluted with 1 N sulfuric acid (500 ml.). The eluted acid was neutralized ($BaCO_3$) and filtered, and the resulting solution was, after deionization, evaporated to a light yellowish sirup (2.95 g.).

The sirup (2.9 g.) was refluxed with methanolic hydrogen chloride (4%, 200 ml.) for 8 hr. The solution was neutralised, filtered and evaporated to a sirup. Lithium aluminium hydride (1.5 g.) in dry tetra hydrofuran (100 ml.) was added in portions with occassional shaking to the hot solution of the dry sirup in dry tetrahydrofuran (200 ml.). The mixture was heated for 1 hr., kept at room temperature for 2 hr., and then treated with water. The residue obtained after drying the mixture was extracted with acetone and ethanol;

the combined extract was diluted with water, deionized, and evaporated. Hydrolysis of the resulting product, followed by the usual treatment, gave a sirupy mixture of sugars (2.36 g.).

The mixture of sugars (ca. 2.35 g.) was separated on a cellulose column (60×3.5 cm.) using solvent D, and the total eluate was separated into three fractions.

Fraction I.—The chromatographically-pure sirup (24.5 mg.) had $[\alpha]_D^{30}$ +112° (*c* 0.4, in water) and R_G 0.69 (Found: OMe, 41.6. Calcd. for trimethyl hexose: OMe, 41.8%). Demethylation gave galactose. The sugar was identified as 2, 3, 4-tri-*O*-methyl-D-galactose by conversion into a crystalline aniline derivative; m. p. and mixed m. p., 163~164°C; lit.[10] 163~165°C.

Fraction II.—The sirup (150.3 mg.) having $[\alpha]_D^{30}$ +82° (*c* 0.5, in water) gave galactose on demethylation. Paper partition chromatography using solvent D indicated that the mixture contained 2, 3, 4-tri-, and 2, 3-di-*O*-methyl-D-galactose.

Fraction III. — The sirup (2.05 g.) having $[\alpha]_D^{30}$ +79° (*c* 1.5, in water) and R_G 0.48 (Found: OMe, 29.6. Calcd. for dimethylhexose: OMe, 29.8%) was chromatographically homogenous and gave galactose on demethylation. The 2, 3-di-*O*-methyl-D-galactose was identified as its crystalline aniline derivative; m. p. and mixed m. p. 152~153°C; lit.[10] 152~154°C.

A small quantity of the mixture of methyl sugars was separated quantitatively by paper chromatrography, and the sugars were estimate by alkaline hypoiodite. The molar ratio of 2, 3, 4-tri- to 2, 3-di-*O*-methyl-D-galactose was 1 : 91.

The Periodate Oxidation of Ammonium Pectate.—The polysaccharide (sample A, 100.2 mg.) was dispersed in water (50 ml.) and oxidised by shaking it with 0.2 M periodic acid (50 ml.) in the dark at 15°C. The liberated formic acid and the amount of periodic acid consumed during the reaction were estimated in the usual way[23] at regular intervals. The liberation of formic acid became constant in 28 hr., corresponding to 30 mol. of anhydrouronic acid residues per mole of formic acid, while the periodate uptake became constant after 30 hr., corresponding to 0.94 mol. of the oxidant per anhydrouronic acid residue.

Summary

Water-soluble polysaccharide extracted from the pulp of jackfruit (*Artocarpus Integerifolia*) has been shown to be composed of L-rhamnose, D-xylose, L-arabinose, D-glucose, D-galactose and D-galacturonic acid. The jackfruit pectic acid has subsequently been extracted with ammonium oxalate and purified. The results of electrophoresis, mild hydrolysis and methylation studies indicate the presence of chains of 1 : 4 linked α-D-galacturonic acid residues in the pectic acid, which is physically associated with a neutral polysaccharide, a glucan. Periodate oxidation studies have also been reported.

The authors are grateful to Dr. P. Bagchi, Director of Research, East India Pharmaceutical Works, Ltd., Calcutta, for his valuable advice and his interest in this paper. They also wish to thank Dr. J. J. Ghosh and Dr. P. Sarkar of University College of Science and Technology, Calcutta, for conducting the electrophoresis experiment.

NOTES

A Spectrophotometric Study of the Metal Chelates of Resacetophenone Oxime. III. Nickel Chelate

By K. S. BHATKI,* A. T. RANE and M. B. KABADI**

(Received July, 16, 1963)

The first two parts of the study of resacetophenone oxime (RAPOX) chelates of copper and iron were published in the Proceedings of the Symposium on the Chemistry of Coordination Compounds, Agra, February, 1959. This paper is an extension of the study of RAPOX chelates of the nickel system.

Experimental

The Preparation and Standardisation of the Reagent Solutions.—*Nickel Solution.*—The solution of nickel sulphate was prepared using Merck's G. R. quality reagent. It was standardised using RAPOX.[1] The solution was found to be 7.675×10^{-2} M. Dilute solutions were prepared from the standard solution.

RAPOX.—RAPOX (resacetophenone oxime) was prepared and crystallised in a way which has been described previously.[2] The solutions of the required strength were prepared in freshly-distilled cyclohexanone using the recrystallised reagent.

Cyclohexanone.—Cyclohexanone of a B. D. H. technical quality was treated as described by Vogel[3] and distilled. A fraction distilling between 153°C and 156°C was collected and stored in amber-coloured glass-stoppered bottles.

The other reagents, such as glacial acetic acid, potassium dihydrogen phosphate, and sodium hydroxide, etc. were of either Merck's (G. R.) or B. D. H. (AnalaR) quality.

Besides cyclohexanone, the other organic solvents were used in the solubility study[4] of nickel RAPOXimate. They were chemically-pure reagents supplied by Eastman Organic Chemicals & Co.

Nickel RAPOXimate.—A measured volume of nickel solution was treated with a solution of sodium carbonate to neutralise the mineral acid present. The slight turbidity that developed was eliminated by adding dilute acetic acid. The pH of the resulting solution adjusted to a pH a little higher than 6.2, the required optimum pH for complete precipitation,[2] using sodium acetate. The nickel RAPOXimate was then precipiated by the dropwise addition of a two per cent alcoholic solution of RAPOX. After the precipitate had been digested for some time on a hot water bath, it was filtered using a sintered glass crucible with a porocity of 4 (2G4). It was then washed thoroughly free from impurities with hot distilled water. The precipitate was first dried in a vacuum desiccator to a constant weight. Thereafter the precipitate was dried in an air oven at 110°C. The weight of the precitate even after this treatment was the same, indicating the absence of water molecules in the complex in the solid state. It was preserved over fused calcium chloride in a desiccator.

A weighed quantity of the dried complex was treated in a silica crucible, first with nitric acid and then with perchloric acid. After the organic matter had been completely decomposed, the residue was treated in order to estimate the nickel volumetrically.[5] The nitrogen in the complex was also estimated by Kjeldahl's method.[6] The nickel and nitrogen contents were found to agree with the theory that the composition of the complex is $Ni(C_8H_8O_3N)_2$

The Spectral Study of Nickel RAPOXimate in Cyclohexanone.—A weighed quantity of nickel RAPOXimate was dissolved, and the solution made up to a known volume using freshly distilled cyclohexanone. The spectral examination of the resulting solution was first accomplished on a Beckman DU spectrophotometer, using cyclohexanone as a blank liquid. The detailed study was then carried out using a Lumetron photoelectric colorimeter, model 402-E. The data obtained from these experiments at different wavelengths are given in Fig. 1.

A Standard Curve for Nickel.—Since the point of maximum absorption using the Lumetron was observed at 595 M (monochromatric filter), the obedience of Beer's law by the system was checked using the same filter. Several solutions of the complex in cyclohexanone, possessing different concentrations, were subjected to the Lumetron study. The results are recorded in Fig. 2. It is observed under these conditions that the smallest amount of nickel that can be determined is six parts per million. The molar extinction coefficient was found to be $\varepsilon_{595}=132.5$.

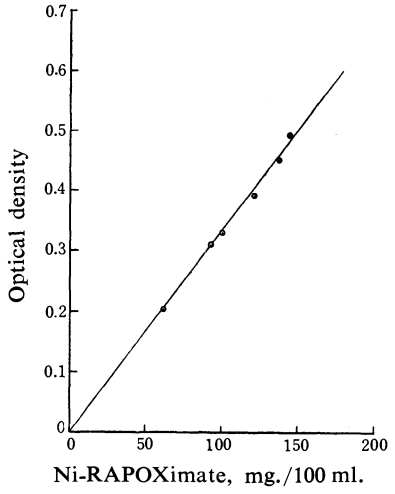

Fig. 2. Standard curve for nickel RAPOXimate in cyclohexanone using 595 M filter.

The Choice of the Solvent for the Extraction Study.—In order to extract nickel from an aqueous solution, it was necessary to choose a suitable water-immiscible solvent. A precise solubility study[4] of nickel RAPOXimate in a few typical water-immiscible solvents was, therefore, undertaken. The different solvents were benzene, nitrobenzene, chloroform, carbon tetrachloride, diisopropyl ether, *n*-butyl ether, amyl acetate, ethyl methyl ketone, methyl isobutyl ketone, diisobutyl ketone and cyclohexanone. In these experiments, the important observation was made that the same amount of nickel RAPOXimate present gave the same optical density, irrespective of the solvent employed, the monochromatic filter being also the same (595 M). Consequently, the standard curve for cyclohexanone can be used as a standard curve for the other solvents also. This observation establishes that the behaviour of nickel RAPOXimate in all the solvents is similar and shows neither association, dissociation nor any complex formation with the solvent itself if no such phenomenon existed in cyclohexanone. It can also be inferred from these findings that in all these solvents the molecular condition of the complex is the same.

Experiments were carried out at a temperature of 30±1°C. From these,[4] it was evident that the solubility of the complex in cyclohexanone was the maximum, 1.710 g. of nickel RAPOXimate per 100 ml. of the solution.

The Partition Study of Nickel RAPOXimate at Various pH Values.—A known and constant volume of the standard nickel solution was pipetted out into several glass-stoppered pyrex centrifuge

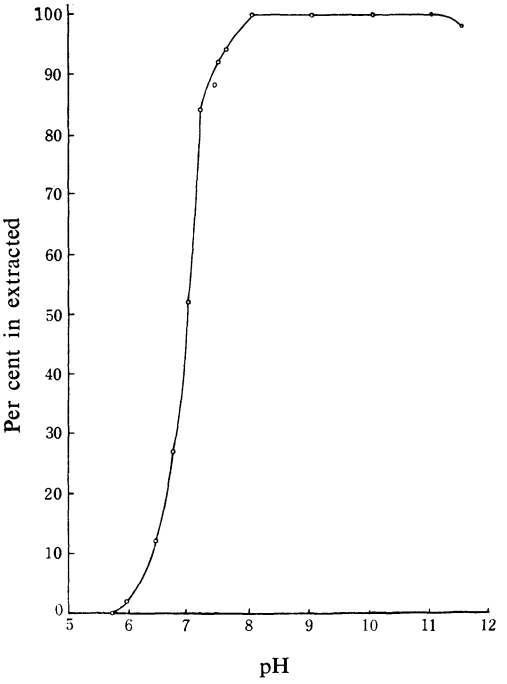

Fig. 3. Extraction of nickel at various pH using RAPOX in cyclohexanone.

tubes. To each of this was added a requisite amount of the buffer solution to fix the pH and then an equal volume of cyclohexanone containing RAPOX. For the sake of maintaining uniformity in the experiment, it was decided to take five times the amount of RAPOX required for the formation of 1 : 2 complex. The tubes were then shaken vigorously on a shaking machine for about eight hours. The phases were separated by centrifuging, and the optical density of the upper organic layer was noted using Lumetron 402-E and 595 M filter. The readings are shown in Fig. 3.

Composition of Nickel RAPOXimate.—The composition of the nickel complex of RAPOX was determined with the help of (i) Job's method[7] of continuous variation as extended to a two-phase system by Irving and Pierce[8] and (ii) the slope ratio method[9,10] modified similarly. These methods, which are generally applicable in case of complexes soluble in an aqueous medium or in an organic medium miscible with water, were employed because they could be so utilised in the present case with the same degree of accuracy. Moreover, the authors experienced no difficulty in extending the slope ratio method to a two-phase system.[11]

(*i*) *Job's Method.*—In this method x ml. of nickel sulphate solution (7.675×10^{-3} M) were mixed with a fixed volume of the buffer solution and diluted to 25 ml. $(10-x)$ ml. of the RAPOX solution of the same molarity in cyclohexanone diluted to 25 ml. was added to the former aqueous solution, and the mixture was shaken vigorously for a few minutes. The upper layer was then separated carefully after centrifuging and examined by Lumetron using a 595 M filter. The results are surveyed in Fig. 4.

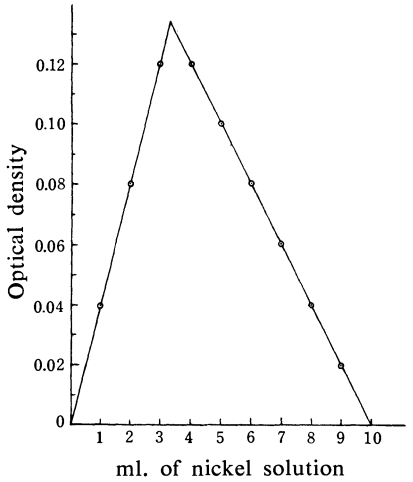

Fig. 4. Job's method in a two phase system.

(*ii*) *The Slope Ratio Method.*—For this purpose two sets of experiments had to be performed. In one, the volume of the nickel solution was kept constant, while that of the reagent was varied. In the other set the volume of the reagent in cyclohexanone was kept constant, whereas that of metal solution was varied. The molarity of the nickel solution and RAPOX in cyclohexanone was the same, namely, 9.225×10^{-3} M.

In the actual experiment different volumes of the standard nickel solution were diluted, each to a fixed volume of 25 ml., after the requisite buffer had been added to bring the pH to 9.0. This mixture was shaken for a few hours with an excess of RAPOX in cyclohexanone, the volume of which was also 25 ml.

In the second set the process was reversed. The volume of the standard RAPOX solution in cyclohexanone was varied and the volume of nickel solution, kept constant. The final volumes of both the aqueous and the organic phase were the same, namely, 25 ml.

The data so collected is surveyed in Fig. 5.

Back Extraction.—Whenever the extraction of a metal chelate is achieved by an organic solvent, it becomes necessary to recover the metal in a pure form from the organic phase. For this purpose a back extraction study was undertaken.

TABLE I. BACK EXTRACTION OF NICKEL FROM ORGANIC PHASE

10 ml. of cyclohexanone containing nickel-RAPOXimate (O. D.=0.59) is shaken for about 4 hr. with equal volume of aqueous solution at various pH.

Filter, 595 M Temp., 30±1°C Cuvette, 0.5 cm.

Nature of the aqueous solution	O. D. of the org. phase after shaking	Per cent of Ni back extrd.	Remarks
Dilute HCl about 1 N	0.00	100	Even hand shaking for a few minutes was sufficient.
Dilute acetic acid about 2N	0.00	100	RAPOX remained in the org. phase whereas nickel got back extrd. quantitatively as seen by dimethylglyoxime test on aq. phase.
Sodium acetate-HCl buffer pH=1.09	0.00	100	
Sodium acetate-HCl buffer pH=2.0	0.00	100	
M/20 K-biphthalate pH=4.05	0.00	100	
Borate Buffer pH=8.0	0.59	0.00	Neither the metal nor the reagent got transferred to the aq. phase.
Borax 0.01 M pH=9.14	0.59	0.00	
Dilute NaOH about 1 N	0.00	100	Reagent too was transferred to the aq. phase with the metal.

△ Phosphate buffer
▣ Borate buffer

A cyclohexanone solution of the nickel complex of a known volume and possessing a known optical density was shaken for about four hours with the same volume of an acidic or alkaline solution. The organic layer was centrifuged and its optical density observed. It diminished with an increase in the acidity and also in the alkalinity. The results are given in Table I.

In another experiment a solution of nickel complex was prepared in cyclohexanone saturated with water. A known volume of this was shaken for about eight hours with an equal volume of a buffer solution previously saturated with cyclohexanone. The results are given in Fig. 6.

Discussion

The foregoing study shows a definite complex formation between nickel and RAPOX in the molecular ratio of 1 : 2. An important observation demanding careful consideration is that the extraction of this complex does not appear feasible below pH 6.0 and above 12.00. Under the former condition the formation of the complex is not quantitative, whereas in the latter circumstance the complex seems to decompose, resulting in the transfer of the reagent, along with the nickel ions, to the aqueous phase.

The plot in Fig. 4 is observed to consist of two intersecting straight lines. The point of intersection shows the presence of the complex in solution and corresponds to the concentrations of nickel and RAPOX given by the ratio 3.3 : 6.7 (i. e., 1 : 2). The inference follows that the composition of the complex must be $Ni(C_8H_8O_3N)_2$, in agreement with that composition determined for the complex in the solid state.

The plot in Fig. 4 is observed to be made up of perfectly straight lines, which suggests that a highly stable single complex is formed.

In the case of the slope ratio method, the ratio of slopes of the straight lines in Fig. 5 is found to be 2.14, confirming the formation of the complex containing nickel and RAPOX in the ratio 1 : 2, an inference drawn from Job's method.

Summary

RAPOX (resacetophenone oxime) in certain water-immiscible organic solvents is found to extract nickel from an aqueous medium as a nickel RAPOXimate complex. Cyclohexanone was found to be the best solvent for this

purpose. The brilliant green-coloured solution of the complex in cyclohexanone gave a maximum absorption at 600 mμ on a Beckman spectrophotometer DU. The coloured solution obeyed Beer's law in the lowest range—six parts per million. The extraction of this complex was quantitative in the pH range from 8 to 11.

The composition of the complex as determined by Job's method and the slope ratio method in a two-phase system was 1 : 2 (nickel to RAPOX). The back extraction study for the metal from the complex in the organic solvent was carried out and quantitative results obtained using an aqueous solution with a pH value below four.

The grateful thanks of the authors are due to Professor B. V. Thosar of the Tata Institute of Fundamental Research for making available the good working facilities of the Institute.

*Some Observations on the Synthesis of 3-Bromofluorenone**

By Kazuo SUZUKI and Masaaki MOMOI

(Received July 30, 1963)

A synthetic pathway leading to 3-bromofluorenone by the following sequence has been investigated and found to result in a better yield than the method starting with 2-(4'-bromobenzoyl)-benzoic acid:[1] 2-Nitrofluorene→ 2-nitrofluorenone → 2-aminofluorenone (I) → 2-amino-3-bromofluorenone (II) → 3-bromofluorenone.

The deamination reaction of II is the crucial step in this route. Fletcher and Pan[2] attemted this reaction, but have not yet reported on the yield.

In the present work the deamination of II was carried out in an 82% yield by diazotization and decomposition in concentrated sulfuric acid. 2-Nitrofluorene, 2-nitrofluorenone[3] and I[4] were obtained in good yields. The bromination of I by the action of 48% aqueous hydrogen bromide in dimethyl sulfoxide[2] resulted in an 80% yield. However, in the present experiments we re-examined[5] the bromination of the same base by the action of an equimolar quantity of bromine in acetic acid; the main product was II (60%), accompanied by a small amount of a new bromoketone, III (6%, m.p. 254°C).

The following experiments proved that the bromine atoms were indeed in the 1, 3-positions of III. The analytical results agreed with a dibromo compound. Reduction and acetylation gave 1, 3-dibromo-2-aminofluorene and its acetyl derivative;[2] deamination gave 1, 3-dibromofluorenone.

The electron-releasing substituent at carbon 2 of I makes carbons 1, 3, 5 and 7 susceptible to an electrophilic attack. This was illustrated by the attack of the second bromine atom at the 1-position of the same ring. The same compound (92%) was obtained by the bromination of II.

Experimental[6]

Bromination of 2-Aminofluorenone (I). — Into a solution of 128 g. of I in 2140 ml. of acetic acid, 32.8 ml. of bromine in 50 ml. of acetic acid were stirred drop by drop over a 1.5 hr. period at about 20°C. The precipitate was filtered and digested with a hot dilute alkali solution; then it was filtered and washed with water. The crude product was extracted several times with hot benzene. The first fraction was a mixture of I, II and III. On being heated with alcohol, it was separated into a soluble (I and II) and an insoluble part (III).

The insoluble part was recrystallized from benzene to give III; 12.3 g. (6%), m. p. 254°C.

2) T. L. Fletcher and H.-L. Pan, *J. Am. Chem. Soc.*, **78**, 4812 (1956). The yield was not good according to a private communication from Dr. M. J. Namkung of the same laboratory.

3) O. Diels, *Ber.*, **34**, 1758 (1901).

4) C. L. Arcus and M. M. Coombs, *J. Chem. Soc.*, **1954**, 3978.

5) T. L. Fletcher, M. J. Namkung and H.-L. Pan, *Chem. & Ind.*, **25**, 660 (1957).

6) All melting points are uncorrected.

Found: C, 44.39; H, 2.20; N, 3.88; Br, 45.55%. Calcd. for $C_{13}H_7ONBr_2$: C, 44.23; H, 2.00; N, 3.97; Br, 45.27%.

IR: 3380, 3280 (ν N-H), 1710 (ν C=O), 1600 cm^{-1} (δ N-H).

III was acetylated, and the product was recrystallized from benzene, melting at 248~249°C.

Found: N, 3.37; Br, 40.46%; Calcd. for $C_{15}H_9O_2NBr_2$: N, 3.55; Br, 40.45%.

IR: 3175 (ν N-H), 1710 cm^{-1} (ν C=O).

The soluble part was evaporated to dryness, and the residue was extracted with hot dilute hydrochloric acid. Crude I (12.4 g.) was recovered by the addition of alkali. II (41 g.) was obtained from the acid-insoluble part.

A small amount of III was isolated from the benzene mother liquor by means of chromatography in benzene on alumina. On the other hand, the second and later benzene extractions contained II almost entirely; this was recrystallized from benzene to give 55.6 g. (total 96.6 g., 60%) (m. p. 215°C).

3-Bromofluorenone. — Finely-powdered sodium nitrite (13 g.) was stirred into a solution of 42.8 g. of II in 234 ml. of concentrated sulfuric acid over a period of 1 hr. at 10~15°C. Stirring was continued for an additional 30 min., and then the brown, diazotized solution was poured into 750 g. of ice, and 310 ml. of 50% hypophosphorous acid was added to the reaction mixture. Upon gradual heating, the vigorous evolution of nitrogen occurred at 60°C; after this stirring was continued at 80°C for 20 min.

The yellow precipitate was filtered and chromatographed in benzene on alumina. The crude product was recrystalized from benzene; weight, 33 g. (82%); m.p. 164~165°C, IR: 1703 cm^{-1} (ν C=O); this compound was identified by melting point and mixed melting point determination and by comparing its infrared absorption spectrum with an authentic sample of 3-bromofluorenone.

Deamination of III, the New Bromoketone (M.p. 254°C).—This deamination was carried out under the same conditions as in the case of II. 1,3-Dibromofluorenone was obtained from the mixture of 3 g. of III, 16.4 ml. of sulfuric acid, 0.87 g. of sodium nitrite and 21.9 ml. of hypophosphorous acid. The crude product was recrystallized from benzene to yield 2.3 g. (80%); m.p. 216~218°C (reported[7] m.p. 225°C), (Found: Br, 46.84%; Calcd. for $C_{13}H_6OBr_2$: Br, 47.28%; IR: 1710 cm^{-1} (ν C=O)).

Reduction of III.—a) A mixture of 0.5 g. of III in 6 ml. diethylene glycol, and 1 ml. of 50% hydrazine hydrate was heated under reflux at 160°C for 1 hr. and at 200°C for 2 hr. The reaction mixture was poured into water, and the product was filtered and recrystallized from cyclohexane to give 1,3-dibromo-2-aminofluoren (0.36 g. (74%), m. p. 183~185°C). (Found: Br, 47.58%; Calcd. for $C_{13}H_9NBr_2$: Br, 47.14%). IR: 3240 cm^{-1} (ν N-H), 1610 cm^{-1} (δ N-H). This was identified with an authentic sample by mixed melting point determination and infrared spectrum comparison.

b) A mixture of 0.5 g. of the same sample, 31 ml. of acetic acid, 3 ml. of hydrogen iodide and 0.1 g. of red phosphorus was refluxed for 7 hr. When poured into cold water, 2-aminofluorene (m.p. 125.5~127.5°C; 0.12 g., 46%) was obtained.

Bromination of II.—A solution of 1.6 g. of bromine in 5 ml. of acetic acid was vigorously stirred into 274 g. of II in 200 ml. of acetic acid over a period of 20 min. at 20°C. The product deposited was filtered, washed with water, and then recrystallized from benzene to give III (m.p. 254°C, 1.6 g.). From the mother liquor, 1.4 g. of II was recovered (balance yield, 92%).

The authors wish to express their gratitude to Drs. John and Elizabeth Weisburger of the National Institutes of Health, U.S.A., for valuable information, and also to Dr. Moses J. Namkung and Dr. Nobuo Ishikawa of the University of Washington, Seattle, for furnishing helpful information on the diazotization of 2-amino-3-bromofluorenone.

Semiconductivity and Color of Pyranthrene

By Mizuka SANO and Hideo AKAMATU

(Received August 22, 1963)

The color of pyranthrene is a reddish brown. However, in the process of purification by a sublimation method, a yellow-colored pyranthrene is often obtained. When pyranthrene is sublimed slowly in the relatively high vacuum of 10^{-4} mmHg, a brown powder is obtained, whereas rapid sublimation in a low vacuum ($10^{-1}\sim10^{-2}$ mmHg) produces a soft yellow powder. The latter is also obtained when a molten sample is vaporized onto a cold glass plate. These two forms of pyranthrene with different colors can be changed to each other by the sublimation procedure; thus, we can obtain the yellow powder from the brown one, and vise versa.

The semiconductivities of these two forms of pyranthrene are of interest in relation to their crystal structures and absorption spectra; this paper will concern itself with these questions.

Pyranthrene was obtained from pyranthrone by zinc-dust fusion.[1] It was purified by a combination of repeated sublimations in vacuo and prolonged boiling in benzene. The two forms of powder were prepared by the procedure described above. A film specimen for each form was also made on a glass plate by a sublimation procedure in the way mentioned above. A single crystal, approximately $5\times0.1\times0.03$ mm^3, was grown in a sealed glass tube by a slow sublimation method. This crystal is brown in color.

The electrical resistivity (ρ) was measured by means of a dc method as a function of the temperature, which ranged from 40 to 200°C for the single crystal, both compressed powders (with the pressure of 116 kg./cm^2) and film specimens in vacuo. The results are summarized in Table I, where the ε-value, the energy gap or twice the activation energy for conduction, can be observed to be definitely lower for the yellow form than for the brown form.

TABLE I. SEMICONDUCTIVE DATA FOR PYRANTHRENE

		ε, eV.	ρ_{15}°, Ω·cm.
Single crystal		1.8	1.4×10^{15}
Powder	Brown	1.6	1.7×10^{16}
	Yellow	1.2	1.3×10^{14}
Film	Brown	1.7	7.3×10^{14}
	Yellow	1.1	3.0×10^{16}

1) E. Clar, *Ber. deut. Chem. Ges.*, **72**, 1648 (1939).

The absorption spectra of pyranthrene in a solid state and in a solution are shown in Fig. 1. Both forms of pyranthrene gave the same absorption spectrum when they were dissolved in benzene. However, film specimens of two forms gave different spectral curves. The brown form exhibited its absorption maxima at 516, 468, 429 and 358 mμ, while the yellow form showed its maxima at 491, 417 and 358 mμ. The absorption at 358 mμ corresponds to the β-band of the molecular spectrum, while the others correspond to the para-band. However, when a KBr-disk technique was employed for the powder specimens, both forms gave the same spectral curve, with absorption maxima at 498, 449 and 425 mμ. Furthermore, both forms exhibited the same fluorescence spectrum.

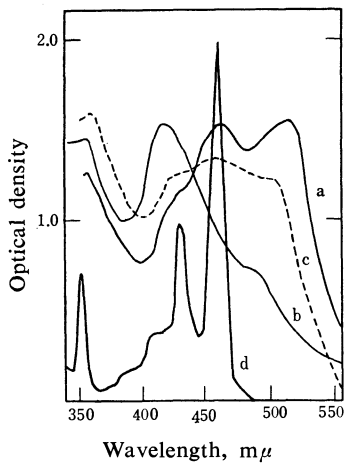

Fig. 1. Absorption spectra of pyranthrene.
(a) Brown film
(b) Yellow film
(c) KBr-disk of powder
(d) Solution in benzene

X-ray diffraction patterns for the powder specimens were obtained with the aid of a diffractometer. The patterns are shown in Fig. 2, which shows that the reflection peaks of the brown form are sharp and distinct, while those of the yellow form are very broad and diffuse. However, the crystal structure may be assumed to be the same for both forms.

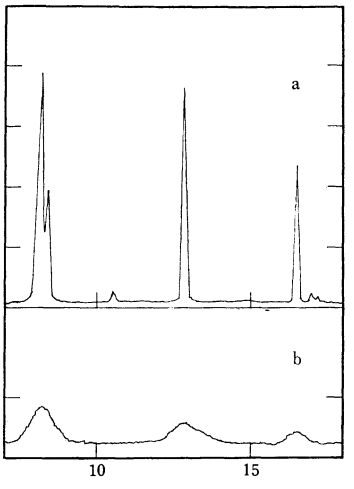

Fig. 2. X-ray diffraction patterns of (a) brown form and (b) yellow form (CuK_α).

An electron microscope revealed that both forms of powder and film specimens consist of flake-like minute crystals. The electron diffraction gave the same powder pattern for both forms of specimen; however, intensive spots could be observed in the reflection rings for the brown form but not for the yellow form.

All of these observations lead to the conclusion that the principal structure is the same for these two forms of pyranthrene, but that they result from different degrees of crystallinity. The yellow form consists of crystallites less perfect than those of the brown form.

The variation in apparent color may be explained mainly by the effect of the light scattering, which varies with the mode of aggregation of crystallites and hence depends on their crystallinity.

It is of interest to see that different semiconductive data were obtained for two forms of pyranthrene. If it can be assumed that the observed value of ε for the brown form corresponds to the intrinsic energy gap for pyranthrene, the lower value of activation energy observed for the yellow form can be related to an extrinsic conduction process which is associated with imperfections in the crystal.

Northrop and Simpson[2] and Parkyns and Ubbelohde[3] have observed the effect of impurities on the semiconductivity of organic crystals. Inokuchi and Ohki[4] have shown that the semiconductive data for pyrene varied according to the purification procedures. Eley and Parfitt[5] and Wihksne and Newkirk[6] have found that the semiconductivity of phthalocyanine changes with the transformation of the crystal structure. The present investigation has found an example of the semiconductivity of an organic crystal which is structure-sensitive and which varies with its crystallinity.

The Polymerization of Trioxane Catalyzed by Rhenium Pentachloride and Molybdenum Pentachloride

By Hajime MIYAMA and Mikiharu KAMACHI

(Received August 24, 1963)

It is well known that the polymerization of trioxane is catalyzed by such Lewis acids as boron fluoride, tin(IV) chloride and antimony-(V) chloride.[1] Also, it has been recently found[2] that rhenium pentachloride and molybdenum pentachloride act as Lewis acids and are effective catalyst for alkylation and carbonylation. Therefore, the present authors have tried to polymerize trioxane by using these catalysts. Three types of polymerization, that is, solid state polymerization by the simultaneous sublimation of monomer and catalyst,[3]

1) S. Okamura, T. Higashimura and M. Fugawa, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **66**, 712 (1962); S. Okamura, T. Higashimura and K. Takeda, *Makromol. Chem.*, **51**, 217 (1962).

2) J. Tsuji and M. Morikawa, Private Communication.

3) H. Miyama and M. Kamachi, *J. Polymer Sci.*, **B 1**, 465 (1963).

solution polymerization, and bulk polymerization, were performed.

In the solid state polymerization by simultaneous sublimation, commercial trioxane (American Celanese Co.) was purified by repeated sublimation at a high vacuum and then introduced, at the pressure $10^{-4}\sim10^{-5}$ mmHg, into an ampoule cooled by liquid nitrogen. At the same time, the desired quantity of rhenium pentachloride or molybdenum pentachloride, which had also been purified by repeated vacuum sublimation, was introduced into the ampoule. After it had been sealed off, the ampoule was placed in a thermostat of a definite temperature for a definite time and then opened. In this reaction, as soon as the polymerization occurred, the color of the reaction system changed from yellow to blue-violet in the case of rhenium pentachloride, and from light yellow to dark yellow in the case of molybdenum pentachloride. The polymer obtained was washed completely with benzene, methyl alcohol, and water to remove any unreacted monomers and catalyst. The inherent viscosity of the polymer was measured in a *p*-chlorophenol solution (0.1 g./100 ml.) containing 2% of α-pinene by using a Ostwald viscometer at 60°C. The results obtained are shown in Table I.

Table I

Catalyst	Concn. of catalst wt. %	Polymn. time min.	Polymn. temp. °C	Yield %	η_{inh}
$ReCl_5$	0.6	60	62	90.5	2.60
			65	84.5	2.81
			43	81.4	2.77
			−10	25.0	3.11
$MoCl_5$	0.6	30	62	93.3	1.36
			50	82.7	0.71
			30	63.1	1.43
			21	64.3	1.47
			0	23.9	2.14
			−10	20.7	1.77
			−20	20.1	1.82

In the solution polymerization, 0.1 g. of the catalyst was dissolved or suspended in 50 cc. of benzene or another solvent. This solution was then mixed with a solution consisting of 20 cc. of benzene and 10 g. of trioxane. The mixture was made to react in the stream of nitrogen. The color of the system changed as soon as the polymerization occurred. For example, when rhenium pentachloride was used in a benzen-ethyl chloroacetate solution, the color changed from green to gray-green. The results are shown in Table II where "solvent" means the reagent used for dissolving of dispersing the catalyst.

In the bulk polymerization, 2 g. of trioxane and 0.01 g. of the catalyst were dispersed into 10 cc. of petroleum ether. After moisture and air had been removed by evacuation at the temperature of liquid nitrogen, the petroleum ether was evaporated; the reaction vessel was then sealed off and kept at 80°C for one hour. Results are shown in Table III.

In the solid state polymerization of trioxane by the simultaneous sublimation of monomer

$MoCl_5$	70	1.4

and iodine,[3] it was once suggested by the present authors that the initiation of radical polymerization takes place in association with the crystal dislocations caused by the simultaneous sublimation and that polymerization occurs in the temperature range between 0°C and 15°C. However, the situation is very different for the present case because the polymerization occurs even at the temperature of −20°C and also in solution and in bulk.

Moreover the color of the polymerization system changes as soon as the polymerization occurs, and the coexistence of a polar solvent increases the polymer yield markedly. On the basis of these findings, it is considered that rhenium pentachloride and molydenum pentachloride catalyze the ionic polymerization of trioxane by forming a complex with trioxane.

The authors wish to express their thanks to Dr. Jiro Tsuji and Mr. Masanobu Morikawa for their advice.

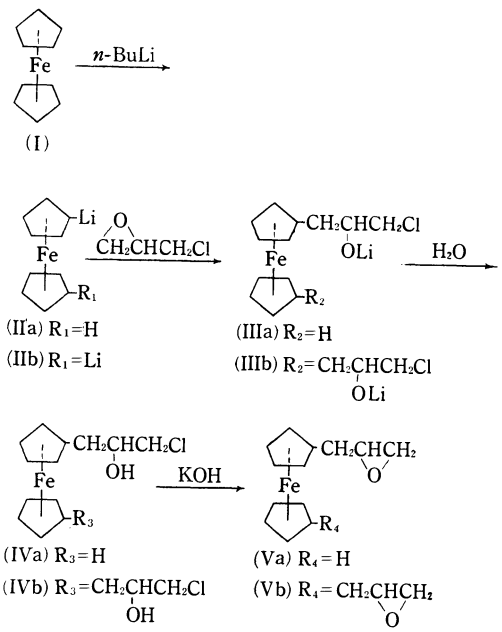
The Synthesis of Glycidylferrocences

By Kazuo HATA, Izumi MOTOYAMA and Hamao WATANABE

(Received October 15, 1963)

Since the discovery of ferrocene, a great number of its derivatives have been synthesized in studies of their chemical properties. However, only a few ferrocence derivatives have been reported which are available as monomers for polymerization to homopolymers in the presence of an adequate initiator.[1] Ketazine derivatives prepared by the present authors from diacetylferrocene and hydrazine have been shown to be novel polymers, the electric resistivities of which are near to those of organic semi-conductors.[2] Now we wish to report the synthesis of a new type of ferrocene derivatives, with one or two glycidyl substituents to provide promising monomers for the formation of a homopolymer. The sequence of the synthesis and the products of the reactions are as follows:



Ferrocene (I) was converted into the lithium derivative (IIa) by treatment with butyllithium

in anhydrous ether under an atmosphere of nitrogen.[3] The suspension was cooled to ca. −50°C. in a dry ice—acetone bath, and the ethereal solution of epichlorohydrin was added slowly.[4] After the reaction was over, the reaction mixture was poured into ice water to hydrolyze the lithium compound IIIa. The ethereal layer was separated and evaporated to remove the ether. On concentration, a large quantity of unreacted ferrocene separated as orange crystals, which were then removed by filtration. The filtrate was further evaporated under reduced pressure to obtain crude chlorohydrin (IVa), which was submitted to vacuum distillation to obtain the pure substance, a very viscous liquid, dark red in color; b.p. 156~158°C/0.8~0.9 mmHg.

Found: C, 56.09; H, 5.33. Calcd. for $C_{13}H_{15}FeClO$: C, 56.05; H, 5.43%.

Glycidylferrocene (Va) was obtained by the epoxidation of the chlorohydrin (IVa) with alkali.[5] An ethanolic solution of the crude chlorohydrin was cooled in an ice water bath, and an aqueous solution of potassium hydroxide was added with vigorous stirring. After the reaction was over, a large quantity of water and ether was added, and the crude epoxide was obtained from the ethereal layer. The crude product was purified by vacuum distillation to a slightly viscous, dark red liquid; b.p. 111~115°C/0.1~0.2 mmHg, n_D^{20} 1.6093. The overall yield of Va was ca. 13% based on ferrocene.

Found: C, 64.41; H, 5.57. Calcd. for $C_{13}H_{14}FeO$: C, 64.50; H, 5.83%. Epoxy equivalent, 0.99 (HCl-dioxane method).

From the residue of the vacuum distillation of Va, a small quantity of diglycidylferrocene (Vb) was obtained. The purification of Vb was unsuccessful by simple vacuum distillation. The distillation residue was treated with a hydrochloric acid dioxane mixture to open the epoxide ring. The products were dissolved in benzene and chromatographed on alumina, followed by elution with the same solvent. The bischlorohydrin (IVb) thus obtained was reconverted into the epoxide (Vb) with potassium hydroxide in the manner described above. The crude epoxide was dissolved in benzene and purified by chromatography on alumina, using a mixture of benzene and ether (1 : 1 by volume) for elution. Pure diglycidylferrocene was obtained as a dark red liquid with a low viscosity. The yield of Vb was ca. 0.3% based on ferrocene.

Found: C, 64.40; H, 6.18. Calcd. for $C_{16}H_{18}FeO_2$: C, 64.45; H, 6.09%.

The chlorohydrins (IVa and IVb) and the epoxides (Va and Vb) were characterized by their infrared absorption spectra (liquid film). The characteristic absorption peaks for the epoxide group in Va and Vb were found at 3050 and 2970 cm^{-1} (ν_{C-H}) and at 1256, 960~900, and 845 cm^{-1} (the epoxy ring). The figures of the two chlorohydrins and of the two epoxides are essentially identical in each pair except for the lack of peaks at 1100 and 1000 cm^{-1} in the disubstituted compounds IVb and Vb, as has been pointed out by Rosenblum in disubstituted ferrocene derivatives.[6]

A. C. Polarography and Reversibility: Behaviour of Methyl Orange

By H. H. BAUER, T. BIEGLER and D. C. S. FOO

(Received November 4, 1963)

The appearance or non-appearance of an a.c. polarographic wave provides information on the mechanism and rate of an electrochemical process. If no wave is observed, the process may be a relatively complex one (reactions preceding or following the electron-transfer step); or a simple one (diffusion and electron transfer only) in which the rate of the electron-transfer is relatively small. If one or other of these factors is involved, it may be that a small a.c. wave is still observed; consequently, preliminary studies by a.c. polarography are usually carried out with comparatively large (~mM) concentrations of depolarizer in order to facilitate the detection of even a small wave. Such a procedure may, however, produce misleading information in the case of processes that are "reversible" at low concentrations but "irreversible" at higher concentrations; the reduction of methyl orange in alkaline solution represents, as far as we are aware, the first system in which such behaviour has actually been observed.

Methyl orange in 1M potassium nitrate and 0.05M sodium hydroxide produces a detectable a.c. polarographic wave at concentrations less than 10^{-6} M; the wave has a maximum height at concentrations of ca. 2×10^{-5} M, and at concentrations above ca. 2×10^{-4} M no a.c. wave is observed (cf. Fig. 1). The d.c. polarographic calibration curve is quite normal in this range of concentrations; but the d.c. step exhibits a maximum at concentrations above ca. 10^{-4} M, and the logarithmic plot changes with concentration (slope = 31 mV. at 10^{-5} M, 38 mV. at 2×10^{-5} M, 44 mV. at 5×10^{-5} M).

Solutions of methyl orange show deviations from Beer's law at concentrations above ca. 10^{-5} M, both in acid and in alkaline media; however, the a.c. polarographic calibration curve is anomalous (in the sense indicated above) only in alkaline solution (cf. Fig. 1) and not in acid (cf. Fig. 2).

Elucidation of the mechanism of the reduction requires additional data; our present purpose, however, is merely to report this new type of effect and to point to the implication that, in the testing of reversibility by a.c. polarography, it is essential to bear in mind the possible effect of concentration of the depolarizer.
