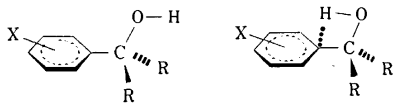
Intramolecular Interaction between Hydroxyl Group and π-Electrons. XVIII[1]. *Proton Magnetic Resonance Spectra of Aryldimethylcarbinols and Related Compounds*

By Michinori Ōki and Hiizu Iwamura

(Received June 26, 1962)

It has been recognized that aryldimethylcarbinols are the examples which have the intramolecular interaction between the hydroxyl group and the π-electrons (II). In a previous paper[2] the effect of the substituents on the equilibrium between I and II was investigated



I II

by infrared spectroscopy. In short, the ratios of the two absorption intensities, A_{II}/A_{I}, which may be regarded to express the equilibrium constant, K, are in linear relation with the Hammett's sigma constants with the negative inclination of $\rho = -0.358$ and the phenomenon has been attributed to the varied π-electron density on the benzene ring as a proton acceptor.

Recent exploitation of NMR spectroscopy as a tool of studying the hydrogen bonding[3] and of detecting the weaker interaction involving hydrogen atom prompted the present authors to study the above system by this newer method.

The chemical shifts of OH proton should differ greatly in I and II. Since the population of the molecular species depends remarkably on the ring substituents, the apparent chemical shifts of OH proton, which will appear singly at the average position between the signals characteristic of I and II, is expected to vary with the substituents.

Owing to the associative nature of the aryldimethylcarbinols, the data obtainable at the most dilute solution (ca. 10^{-2} mol./l.) with use of a nowadays available spectrometer have the contribution of the associated species and cannot reflect directly the status of the aforementioned equilibrium of monomeric nature. In these connections, measurement must be carried out over a range of finite concentration to describe the nature of the association and the data obtained was extrapolated to those at infinite dilution with which the discussion of the equilibrium, I ⇌ II, was attempted.

Experimental

Spectral Measurements.—NMR spectra were obtained by a Varian DP-60 high resolution NMR spectrometer at 60 Mc./sec. The samples were dissolved to a given concentration in carbon tetrachloride and sealed in glass tubes with outside diameter of 5 mm., the chemical shifts in p. p. m. being referred to cyclohexane as an internal standard. The side-band technique was employed to measure the precise chemical shifts[4].

Materials.—Preparation and purity of the compounds have been described in the previous paper[2].

Results and Discussion

The assignments of the NMR signals of the aryldimethylcarbinols which consist of a methyl signal with the intensity of six protons, an OH signal, multiplet signals due to the ring protons, and signals due to the ring substituents, if any, are straightforward. Out of these only the OH proton signal moves significantly with the varying concentration. In Figs. 1 and 2 are illustrated the displacement, due to the change in concentration, of the chemical shift of the OH proton of dimethylphenylcarbinol. It is well known that in a solution of associable solute, there is a definite composition at a given concentration between the several species possible, e.g., monomer, dimer, trimer, and the higher polymers. Although they have different kinds of the hydroxyl group and thus show different ν_{O-H}'s at the same time in the infrared absorption, NMR spectrum of the system shows usually a single OH proton signal, owing to the rapid exchange between, and consequent averaging of, the protons of various kinds. That is, the apparent chemical shift (δ^{a}) of the OH proton at a given concentration can be expressed as follows, where

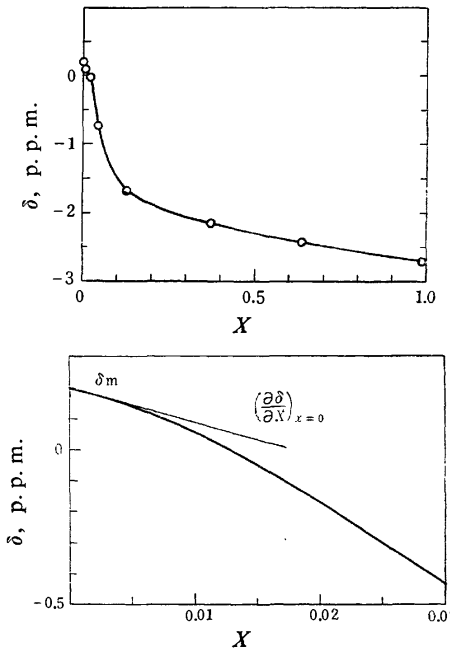

Figs. 1 and 2. Dilution shifts of OH proton signal, δ (in p. p. m. from cyclohexane) versus mole fraction (X) of dimethylphenylcarbinol.

δ_i and x_i represent the chemical shift characteristic of, and the mole fraction of, the i'th

$$\delta^a=\sum_i \delta_i x_i \qquad \sum_i x_i=1 \tag{1}$$

species, respectively, and the summation is made over the whole species present. x_i's are related each other by the respective equilibrium constant, K_{ij}. Since the change in the total concentration (X) accompanies the redistribution between x_i's, δ^a becomes dependent on the concentration.

$$K_{ij}=\frac{(x_j)^n}{(x_i)^m} \tag{2}$$

Although it is almost impossible to analyze the formula 1 over a whole range of concentration, it may be possible to derive Eq. 3 as an approximation in the lower concentration region ($X\leq 0.02$) where the contribution of only the first two terms, that is, monomer and dimer, may be regarded to be major. Here δ_m and δ_d represent the chemical shifts of the OH protons characteristic of monomer and dimer,

$$\delta^a=\delta_m x_m+\delta_d x_d \tag{3}$$ [5]

respectively. K stands for the equilibrium constant of dimerization (Eq. 4). Equation 5 is obtained by differentiating Eq. 3 and taking the limit. Since the left side of Eq. 5 is obtainable from the limiting slope of the δ

$$K=\frac{x_d}{x_m{}^2} \tag{4}$$

$$\left(\frac{\partial\delta^a}{\partial X}\right)_{x=0}=2K(\delta_d-\delta_m) \tag{5}$$

versus X curve in each carbinol (Fig. 2), it is now possible to derive either K or $\delta_d-\delta_m$, if the data of the other are available. It was the authors' choice to determine $\delta_m-\delta_d$ with use the value of K which is available independently from the infrared spectroscopy. To this purpose, the variation of ε at the absorption maximum of the monomeric ν_{O-H}, 3606 cm^{-1}, with concentration, was measured. Supposing that this ε_m represents the apparent absorption coefficient of the band due only to monomer, and that dimer is cyclic, the limiting slope of the ε_m versus concentration curve is found to be related to the equilibrium constant for dimer formation by Eq. 6;

$$\left(\frac{\partial\varepsilon_m}{\partial C}\right)_{c=0}=-2K_c\,\varepsilon_m{}^0 \tag{6}$$ [6]

where $\varepsilon_m{}^0$ stands for ε_m at infinite dilution. The equilibrium constant expressed in terms of mole fraction (K_x) can be related to K_c by $K_x=K_c\times 10$ for the carbon tetrachloride solution.

In Table I are listed the OH proton chemical shift at infinite dilution, δ_m, the limiting slope of the δ versus X curve, $-\left(\frac{\partial\delta^a}{\partial X}\right)_{x=0}$, the equilibrium constant for dimer formation, K, and the difference in the chemical shift between monomer and dimer, $\delta_m-\delta_d$.

As shown in Fig. 3, K and $\delta_m-\delta_d$ are roughly in linear relation with the Hammett's sigma constants. They are also proportional to each other. Strictly speaking, the linearity with a positive slope which reign over the substituents of positive sigma value does not hold true for those of negative sigma constant. It is naturally expected that any ring substitution produces counteracting effect on dimerization. Those substituents which strengthen the proton donor ability of the hydroxyl group are weakening its proton accepting power at the same time. The above finding indicates that, while the electron-withdrawing substituents strengthen the dimerization in effect, the action is just balanced in the case of the electron-donating substituents. Since $\delta_m-\delta_d$ may be regarded to correspond to the strength ($-\Delta E$) of the association[7], the linearity between $\delta_m-\delta_d$ and

K is satisfying the relation, $-RT \ln K = \Delta E - T\Delta S$, where no anomaly in ΔS term is involved. This implies that the dimers of the aryldimethylcarbinols must have a similar structure.

1-Phenylcyclohexanol	0.33	10	5.9	0.85

δ_m obtained by extrapolating δ versus X curve to the infinite dilution is only concerned with the monomeric hydroxyl proton. Since aryldimethylcarbinols have the equilibrium I $\rightleftharpoons$ II at this state, δ_m may be put as follows.

$$\delta_m = \delta_I x_I + \delta_{II} x_{II} \qquad (7)$$

The previous finding by infrared spectroscopy[2] that x_{II}/x_I ranges from 0.85 (for *p*-nitrophenyldimethylcarbinol) to 4.0 (for 1-phenylcyclohexanol) may make one to expect that δ_m would vary considerably with different substituents according to Eq. 7. However, as shown in Fig. 4, it is not the case and δ_m's are almost independent of the substituents.

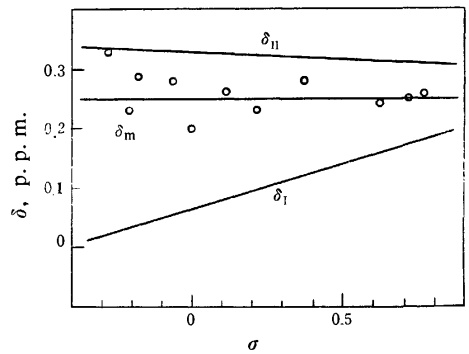

Fig. 4. The effect of the ring substituents on the monomeric OH proton shifts in aryldimethylcarbinols.

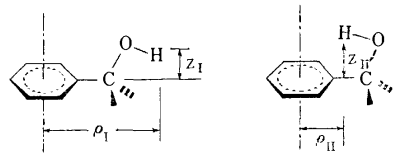
As regards the conformation of isomers, I and II, now assume that the plane made by C_α-O-H group will be situated perpendicularly to that of the benzene ring[8] and that the bonds, Ar-C_α and O-H, will be disposed around the C_α-O bond to be "trans" and "cis", for I and II, respectively. Then through the diamagnetic anisotropy of the benzene ring with the π-current of $J=\frac{3e^2H_o}{2\pi mc}$ [9], the hydroxyl proton in I will be deshielded by 0.234 p. p. m., while that of II will suffer from diamagnetic shift of 0.035 p. p. m., with respect to the hydroxyl proton indifferent to the ring current. A measure of $\delta_{II}-\delta_I=0.27$ p. p. m. has now been obtained.



I' II'

In order to see whether the above postulate on the conformations I and II be valid, δ_I and δ_{II} were actually determined, by solving Eq. 7 and $\delta_{II}-\delta_I=0.27$ simultaneously, for the selected examples listed in Table II in which the π-electron density on the benzene ring may be considered to be equivalent. Fairly

good constancy of the calculated values of δ_I and δ_{II} obtained suggests the adequacy of the above conformations, I and II.

If δ_I and δ_{II} were constant over a whole range of the aryldimethylcarbinols, δ_m should have decreased with the increasing sigma value, because x_{II}/x_I has been shown to decrease in this order. The observed apparent indifference irrespective of the substituents must be ascribed to the change in the π-ring current. The reduced π-current density caused by the substitution with electron-withdrawing substituent will bring about the diminution of the ring current effect for both hydroxyl groups in I and II. However, the degree of this suffering may be seven times (derived from 0.234/0.035) greater in I than in II. That is, the absolute value of the positive slope of δ_I must be seven times greater than that of the negative inclination in δ_{II}, when they are plotted to the sigma constants, as illustrated in Fig. 4. Therefore, δ_m does not necessarily decrease proportionally to the decrease in x_{II}/x_I when the electron-withdrawing substituent is present.

TABLE II. THE COMPUTED OH PROTON SHIFTS IN THE CONFORMATION II

Carbinol	δ_m p. p. m.	x_I*	δ_{II}** p. p. m.

Etude sur l'Équilibre de l'Échange d'Ion des Terres Rares avec la Solution Complexe des Métaux Lourds et des Acides Aminopolycarboxyliques

Par Haruo NATSUME*

(Reçu le 16 Février, 1962)

L'acide éthylènediaminetétraacétique a été, ainsi que d'autres acides complexants, un des premiers éluants essayés pour la séparation de terres rares en microquantité sur résine échangeuse d'ion. Son efficacité s'était révélée bien supérieure à celle d'autres acides, cependant on avait renoncé à l'employer à cause de son insuffisante solubilité dans le domaine utile de pH[1]. Plus tard, Ichikawa a séparé le Ce et le Pm à l'aide de cet acide[2] et Suzuki a constaté une anomalie[3], c'est que lorsque l'on baisse progressivement le pH de la solution éluante pour les mieux séparer, l'élution devient tout d'un coup impossible vers pH 3.2. Nous en concluons que cet acide se trouverait sous forme cationique par les atomes d'azote au dessous d'une certaine valeur de pH, et pourrait être fixé lui-même sur la colonne de résine[4]. Dans ces expériences on n'est jamais arrivé à l'efficacité de séparation que faisaient espérer les constantes de formation des complexes que forment cet acide avec les terres rares.

Pendant ce temps l'utilisation de cet acide, et des acides aminopolycarboxyliques en

4) Ce phénomène a été constaté dans le cas de l'acide hydroxyéthyléthylènediaminetriacétique; communication privée par Z. Hagiwara.

générale, a donné lieu à de remarquables succès dans le cas de séparations et de purifications de terres rares en grande quantité. De ces nombreuses communications nous citons ici la découverte de l'élution du Cd dans les fractions de terres rares pour le cas de l'acide iminodiacétique[5], les interpolations de métaux lourds[6] et l'utilisation de résine cuivrique pour éviter la précipitation de l'acide libre dans le cas de l'acide éthylènediaminetétraacétique[7]. Fuger a publié recemment les résultats de recherches sur les réactions d'équilibre entre l'acide éthylènediaminetétraacétique et les éléments transuraniens en présence de résine échangeuse[8], puis plus tard il a proposé comme solution éluante le complexe entre cet acide et le Zn, la résine étant aussi sous forme zincique pour la séparation de terres rares[9]. Loriers a montré la possibilité d'employer comme la solution complexe de l'acide éthylènediaminetétraacétique et du Cu[10].

L'auteur aussi était déjà arrivé à cette méthode d'employer les solution de complexes de l'acide éthylènediaminetétraacétique avec les métaux lourds[11]. Il a montré une étude sur les réactions d'équilibres qui ont lieu sur le Ce et l'Y sans entraîneur entre la résine sous forme ammonium et les solutions de complexes du Mn^{2+}, du Co^{2+} et du Cu^{2+} avec l'acide éthylènediaminetétraacétique. Il a essayé la séparation de ces deux éléments sur colonne en employant comme la solution éluante le complexe du Co^{2+} avec l'acide éthylènediaminetétraacétique, on a trouvé alors une longue trainée de l'Y après son élution due probablement à l'effet des ions libres du Co^{2+}, le Ce radioactif était cependant resté fixé près du sommet de la colonne après l'élution complète de l'Y. Il semblait que l'on eût obtenu l'efficacité à peu près raisonnable, quoique l'on n'eût pas précisé le facteur de séparation à cause de l'élution impossible à la même condition.

Nous allons maintenant considérer les différentes caractéristiques de l'acide éthylènediaminetétraacétique. Il fait partie des acides aminopolycarboxyliques, parmi lesquels se trouvent les acides nitriletriacétique, cyclohexanediaminetétraacétique etc., à la différence des acides hydroxycarboxyliques tels que les acides lactique, α-hydroxyisobutylique généralement employés pour les séparations de terres rares et d'éléments alcalinoterreux.

L'acide éthylènediaminetétraacétique :

1. Il a la solubilité minimum au pH correspondant au point isoélectrique, vers pH 2.5～3.0, au dessous duquel il pourrait être à l'état cationique.

2. Il n'a pas beaucoup d'action de temponnement.

3. Il est capable de complexer presque complètement les terres rares, et la plupart des métaux lourds. Ce fait n'est pas toujours favorable, en provoquant les changements brusques de conditions à la solution tels que l'abaissement relativement grand de pH, la diminution à la concentration de l'anion.

En remplaçant cet acide par ses complexes avec les métaux lourds, il est possible d'améliorer ces caractéristiques mais par contre un problème se pose, celui de la présence d'ions libres des métaux lourds. Il est plutôt curieux qu'aucune étude poussée n'ait été faite sur ce sujet jusqu'à présent, où l'on a des succès assez remarquables, mais seulement partiels de divers points de vue. Ces expériences sont justement destinées à éclaircir les caractéristiques de ces solutions complexes plus systématiquement. Nous avons cherché à connaître le comportement des coéfficients de répartition et des facteurs de séparation en fonction des diverses variables.

A partir de considérations sur les constantes de formation des complexes et sur les différences d'affinité pour la résine entre les terres rares et les métaux lourds, on aurait trois ions convenables, Co^{2+}, Cd^{2+} et Zn^{2+}. L'auteur a préféré utiliser l'ion Co^{2+} parce qu'il est facile d'en observer le comportement de l'ion libre sur la résine grâce à sa couleur, quoique les deux autres ions, Cd^{2+} et Zn^{2+}, soient très faciles à éliminer par la fixation sur résine anionique en milieu chlorhydrique, s'il est nécessaire. Cependant nous avons expecté qu'il n'y aurait pas très grande différence sur les réactions d'équilibles entre le complexe du Co^{2+} et les deux autres.

Procédéd Experimental

Procédé Général d'Expérience. — Toutes les mesures des coéfficients de répartition ont été effectuées par la méthode qui consiste à mesurer la répartition des activités des deux terres rares, le Sm et l'Eu, entre la résine et la solution éluante, équilibrées en tube à essai.

Une certaine quantité de résine séchée à l'air, équilibrée pour l'humidité atmosphérique, dont le poids correspondra à environ 0.5 g. de résine sous forme de sel d'ammonium séchée en étuve, autrement dit la même capacité d'échange pour les

diverses formes, est introduite dans un tube à essai en lustéroïde général ou en verre si c'est nécessaire. On y ajoute le mélange de deux solutions en proportion variable suivant la composition à obtenir, de façon à avoir la composition prévue dans le volume total de 10 ml. avec la dilution par addition de 2 ml. de la solution de l'activité mélangée de l'Eu et du Sm. Outre un certain nombre de tubes préparés ainsi, on en prépare quelques autres de l'activité mélangée tout à fait de même que les précédants contenant une solution de composition moyenne ou bien des compositions représentatives, en général des deux solution à mélanger, sans résine qui serviront de témoins, et enfin quelques autres contenant un seul radioélément afin de déterminer l'efficacité de comptage et de déceler la présence d'impuretés.

Ces tubes sont agités pendant une vingtaine d'heures de manière discontinue, puis on laisse sédimenter les particules de résine, on prend une partie aliquote de la solution surnageante que l'on verse dans une coupelle en aluminium et on la sèche sous une lampe infrarouge. On en mesure d'abord l'activité qui est au début celle du mélange Sm-Eu, d'une part au moyen d'un spectromètre γ à un canal et/ou d'autre part au compteur G. M, puis plus tard après décroissances suffisamment complète du Sm, on mesure l'activité de l'Eu seule au compteur à scintillateur et/ou au compteur G. M. Ayant comparé l'activité de ces sources à celles du témoin, on peut calculer le coéfficient de répartition. On mesure aussi le pH de la solution restée dans le tube après la décroissance de la plupart du Sm.

La Résine Échangeuse d'Ion.—La résine échangeuse d'ion utilisées pour toutes ces expériences est la Diaïon SK-1 de la classe analytique, spécialement fabriquée par la Section de Réactif Analytique, Institut de Recherche, Société Industrielle de Produits Chimiques Mitsubishi. Elle est essentiellement identique à la Dowex 50W, X-8, c'est-à-dire une résine brune claire copolymérisées de styrène contenant 8% de divinylebenzène, ayant l'acide sulfonique comme groupement fonctionnel mais préparés très soigneusement, particulièrement au point de vue de la polymérisation uniforme et de l'élimination des impuretés. La taille des grains était de 60~80 mesh autant que possible triées par sédimentation dans l'eau.

Dans la plupart des expériences la résine employée est sous forme de sel d'ammonium. La nouvelle résine, on l'a traitée dans un bécher successivement par les solutions suivantes ; NH_4OH 3 N, eau distillée, HCl 3 N et eau distillée, ce traitement est répété 2 fois, puis, on l'a transformée sous forme ammonium sur colonne par la solution NH_4Cl 2 N, finalement la résine est bien lavée, filtrée sur un filtre en verre fritté et séchée à l'air dans un cristallisoir à l'abri des poussières. La résine après avoir fixé les radioéléments peut être décontaminée au moyen d'une solution à peu près neutre d'éthylènediaminetétraacétate d'ammonium, c'est très efficace surtout avec un léger chauffage sur bain-marie pendant plusieurs heures ; on peut ainsi décontaminer parfaitement la résine jusqu'à avoir une activité inférieure à 0.5 coups par minute par gramme de résine au compteur γ, pour une contamination par l'Eu de quelques centaines de milliers de coups.

La résine sous forme de sel cobalteux a été préparée par passage sur colonne d'une solution de chlorure de cobalt 1 N jusqu'à saturation complète. Pour la préparation des résines sous forme de sel de terre rare, on expliquera à l'expérience concernante.

Un certain nombre de parties de résine, dont le poids correspondra à 0.5 g. de résine séchée à l'étuve, sont pesées à l'aide d'une balance Metler B5. La teneur en eau de la résine sous forme ammonium variait de 8.5% à 17% suivant la durée de séchage et l'humidité atmosphérique ; sous forme cobalteuse elle variait entre 18 et 27% ; c'est pourquoi il faut la mesurer chaque fois sur une autre fraction de résine de 0.5 à 2 g. Cette dernière fraction de résine est utilisée aussi pour mesurer la capacité spécifique d'échange et pour contrôler la différence de poids due à la perte en eau de la résine au cours de pesée ; cette perte en effet, mesurée avant et après une vingtaiue de prises au moins pendant une heure, était inférieure à 0.1%, donc négligeable.

La mesure de la capacité spécifique d'échange est nécessaire pour savoir le poids équivalent de résine sous forme cabalteuse et sous forme ammonium. Elle est faite ainsi : après avoir mesuré la teneur en eau de la résine par séchage à poids constant à 110°C, en général pendant 1.5 à 2 heures, on en remplite une petite colonne, sur laquelle on passe environ 30 ml. de HCl 3 N, on lave parfaitement à l'eau distillée jusqu'à ce que la solution éluée ait le même pH, on passe ensuite environ 30 ml. de la solution de NaCl 2 N, on détermine enfin la capacité totale d'échange par titrage de l'acide dans cette dernière solution éluée à l'aide d'une solution de NaOH N/4. On peut de ces données calculer la capacité spécifique connaissant la teneur en eau. La capacité spécifique était de 4.81_5 méq. pour la résine sous forme ammonium, 4.50_3 méq. pour la résine sous forme cobalteuse.

Préparation de Terres Rares Radioactives.—Les terres rarres ont été employées à partir d'oxydes de qualité "Specpure" de la Société Johnson Mathey sans plus de purification. En cas de nécessité de connaître le poids précis, ces échantillons sont calcinés pour éliminer le gaz carbonique contenu.

Eu—10.0 mg. de Eu_2O_3 calciné est irradié pendant 4 semaines sous un flux de neutrons de 1.5×10^{12} n/cm^2/sec. dans le réacteur EL-2, puis laissé plusieurs mois pour faire décroître les activités possibles de période courte provenant des impuretés, dissous dans un petit bécher par 1 ml. de HCl concentré en chauffant légèrement au bain-marie, puis dilué à 10 ml. A partir de cette solution on prépare une deuxiéme solution 25 fois diluée.

Sm—499.2 mg. de Sm_2O_3 calciné est dissous par HCl concentré, l'excès d'acide est chassé doucement, puis la solution est étendue à 25 ml.; en la diluant de 12.5 fois on obtient une solution du Sm à 1.60 mg./ml. On irradie soit 1 ml. de cette solution dans un petit tube en polyéthylène pendant 1 week-end, c'est-à-dire 36 hr. au flux de neutrons

de 1.4×10^{11} n/cm²/sec. dans EL-1, soit 0.35 ml. dans un petit tube en silice pendant 1 semaine par 1.5×10^{2} n/cm²/sec. dans EL-2. Pour ouvrir le tube en polyéthylène, il est convenable d'en couper par une lame de rasoir la partie supérieure sans toucher la solution, pour le tube en silice, on peut le casser de même à l'aide d'un couteau à verre. On transmet la solution dans un petit bécher à l'aide d'une pipette à bout effilé en prenant soin de laver l'intérieur du tube.

On met 2 à 5 ml. de la solution d'Eu radioactif dans un petit bécher, ajoute quelques gouttes de HCl concentré pour assurer l'absence de radiocolloïde, amène presqu'à sec. deux ou trois fois sur bain-marie en reprenant chaque fois par 5 ml. d'eau distillée, puis ajoute 0.1 ml. de HCl 0.1 N et 2 à 3 ml. d'eau, en mouillant soigneusement la paloi intérieure du bécher on laisse refroidir, enfin on dilue à 25 ou 50 ml. dans une fiole jaugée. On en prend une partie aliquote dans un tube à essai pour le controle de l'activité. Parallèlement on traite tout le volume de la solution du Sm irradié. Sauf pour les contrôles, on prend 2 ml. de la solution de l'activité par une seule pipette, après avoir bien mélangé ces deux solutions ci-dessus, afin de rendre plus petite l'erreur de pipetage pour les calcules de facteur de séparation. La solution radioactive a été ajoutée en général après l'addition de solution de complexe.

Les Solutions de Complexe de l'Acide Éthylènediaminetétraacétique avec les Métaux Lourds.—Après une quinzaine d'expériences sur colonne, on est arrivé au choix entre trois sels suivants: le sel acide de l'EDTA*) et du métal, le sel double d'ammonium et du métal avec l'EDTA et le sel contenant plus de métal lourd. La présence des ions étrangers ne sera pas favorable à cause de la diminution du coéfficient de répartition en général sans aucun intérêt, c'est pour cette raison que nous avons préféré les préparer sur colonne. Nous allons examiner d'abord le cas des complexes de l'EDTA et du Co.

A) La Solution Acide. — On dissout 25.000 g. de $Na_2H_2Y\cdot2H_2O$ c'est-à-dire 0.067186 mol. dans environ 800 ml. d'eau distillée, on fait passer la solution successivement sur deux colonnes, l'une de NH_4R (15 mm$\phi\times$32.5 cm. ca. 58 ml. 78 méq. de capacité) l'autre de CoR_2 (15 mm$\times$65 cm. ca. 115 ml. 155 méq.), la première, servant à remplaçer le Na^+ par l'NH_4^+, n'est peut être pas nécessaire. La solution éluée est étendue à 1 l. dans une fiole jaugée que l'on remplit jusqu'à la ligne marquée par la solution de lavage après avoir passé la solution de l'EDTA.

Plus tard le sel disodique a été remplacé par la quantité équivalente d'acide, c'est-à-dire 19.6254 g. de H_4Y plus convenable, car on peut le passer sur la colonne de CoR_2 tout de suite après l'avoir neutralisé par l'ammoniaque concentré jusqu'à pH 5 à 7. Cette neutralisation qualitative est représentée dans Fig. 1.

La solution acide du complexe de l'EDTA avec le Co, obtenue par cette méthode, a un pH de 1.9~2.0, elle ne contient pas d'ion ammonium

* Nous appellerons l'acide éthylènediaminetétraacétique H_4Y ou EDTA, l'acid nitriletriacétique H_3X ou NTA.

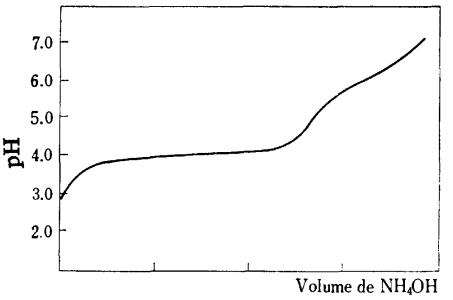

Fig. 1. Courbe de titrage de H_4Y par NH_4OH.

dosable d'après la méthode Kjeldahl, même si elle a été préparés à partir de la solution à pH 7; mais elle contient peut-être un peu d'ions libres Co^{2+}, dont l'élimination a été essayée sans succès.

Elle était stable au moins pendant plusieurs mois sans aucun précipité. Les solutions plus concentrées comme celle à 80 g./l. de Na_2H_2Y 2 aq. ne peuvent pas être préparées par cette méthode à cause de la faible solubilité du complexe. Quoiqu'elle ne corresponde pas exactement à la formule H_2CoY, on la désignera ainsi par la suite.

B) La Solution Neutre Libre du Co^{2+}.—La solution neutre n'est pas convenable à préparer par la méthode sur colonne, car en faisant passer sur colonne une solution non seulement calculée comme $(NH_4)_4Y$ mais encore contenant un excès d'ammoniaque, la solution éluée a au commencement un pH vers 3.5 à 4.5 à cause de l'absorption de l'ammoniaque par le CoR_2. Les composés, $[Co(NH_3)_6]R_2$ et surtout l'état oxydé $[Co(NH_3)_6]R_3$, étant ennuyeux à éliminer à cause de leur forte absorption, on a modifié la méthode de la manière suivante:

On prend la même quantité de H_4Y dans un bécher de 400 ml., on ajoute 200 à 250 ml. d'eau distillée, et la quantité suffisante de résine CoR_2, puis on neutralise jusqu'à pH 7.0 par l'ammoniaque concentré. Pour le cas d'une addition excessive d'ammoniaque, la résine HR peut être employée pour abaisser à 7.0 le pH de la solution. On filtre cette solution sur un filtre en verre fritté, lave complètement à l'eau distillée et dilue jusqu'à 750 à 800 ml. dans une éprouvette graduée, on passe ensuite sur une colonne de NH_4R tout à fait de même manière que précédemment, mais finalement on règle à 7.0 de nouveau le pH.

Cette solution manque un peu de Co^{2+} en comparaison de concentrations équivalentes pour l'H_4Y; nous l'appellerons quand même $(NH_4)_2CoY$.

C) La Solution Neutre Saturée du Co^{2+}.—Au lieu de NH_4R, on emploie CoR_2, à peu près la moitié des ions NH_4^+ sera alors remplacé par des ions Co^{2+}, d'après les observations de la longueur des bandes de NH_4R et de CoR_2, donc notons comme $[(NH_4)_2, Co]CoY$.

D) Les Solutions Complexes de l'EDTA et du Cu^{2+}.—On peut les préparer de la même manière que dans le cas du Co^{2+} sauf quelques légères différences. La première est que par neutralisation en présence de résine CuR_2, on ne peut pas élever le pH à plus de 6.55 à cause de la faible basicité de l'ions Cu^{2+}, on a en effet remarqué un peu de précipité

bleu pâle de $Cu(OH)_2$ après une nuit, ensuite pendant le lavage, tous les deux cas, après l'enlèvement et la saturation du Cu^{2+} la solution passée est colorée longtemps en bleu, peut-être à cause de la faible combinaison de la résine cuivrique et du complexe. Pour la solution acide du complexe il n'y a aucune différence particulière et la solution H_2CuY a pour pH à peu près 1.6.

E) Acide Nitriletriacétique.—Les solutions complexes de l'H_3X et du Co^{2+} sont préparées tout à fait de la même manière que dans le cas de l'EDTA, mais plus facilement encore car cet acide et ses dérivés ont toujours une solubilité plus grande que les composés correspondants de l'EDTA. La solution contient 25.000 gr. de cet acide c'est-à-dire 0.1308 mol./l.

Procédés à Equilibrer.—Dans les tubes à essai, on introduit la résine, on ajoute 8 ml. de solution de complexe mélengée comme expliqué ci-dessous, puis 2 ml. de la solution radioactive, la solution est diluée finalement 1.25 fois, donc 0.05373 mol./l. en EDTA et 0.10463 mol./l. en NTA. Pour une série d'expériences, on prépare d'abord deux des solutions ci-dessus ou des solutions plus ou moins modifiées sans changer la concentration en acide, les mélange progressivement aux taux différents, ainsi on peut réaliser des mélanges de compositions bien définies, ce qui est très important pour cette sorte d'études. En cas de nécessité, on a adapté l'addition sous la forme solide comme NH_4ClO_4 ou bien sous la forme absorbée par la résine comme SmR_3.

Après avoir ainsi préparé les tubes, on les bouche et les agite de temps en temps, une dizaine de fois au cours de la journée, puis encore quelques fois le lendemain. D'après quelques expériences, cette maniére était suffisante pour atteindre à l'équilibre, on les débouche soigneusement à l'aide d'un papier pour ne pas contaminer, laisse sédimenter les particules de résine et prélève une partie aliquote de la solution dans une coupelle en aluminium pour en mesurer l'activité. Cependant du point de vue des vitesses d'échange et de diffusion des ions à l'intérieur de particule, il sera réalisé vraisemblablement en 3 ou 4 hr. par l'agitation continuelle de la machine.

Mesures de l'Activité.—A) Préparation des Sources de Comptage.—Il est très important surtout pour les comptages de préparer des sources dont l'épaisseur de dépôt soit le plus uniforme possible. Une feuille de papier filtre collée au fond de la coupelle peut améliorer ce dépôt. La solution prise a été séchée sous une lampe infrarouge, il est efficace d'éloigner la source de la lampe pendant quelques temps vers la fin du séchage pour avoir un dépôt uniforme. Au cas où la solution contient beaucoup d'électrolyte, on vernit légèrement d'huile Silicone la paroi intérieure de la coupelle pour éviter un dépôt sur le haut de la paroi. Quelques fois 2 ml. solution prise était trop pour avoir une bonne source à cause de la faible solubilité de complexe. Les volumes des pipettes pour le témoin et les échantillons doivent être identiques et il vaut mieux choisir les pipettes les plus semblables possibles.

Les measures de l'activité en solution sont en général plus précises mais dans ces expériences. cette méthode n'était pas adaptée, car les corrections de la décroissance du Sm et de l'évaporation de l'eau seront très compliquées.

B) Comptages.—Toutes les sources sont mesurées au moins 2 fois aux compteurs avant et après la décroissance complète du Sm, c'est-à-dire à peu près 3 à 4 semaines après. L'activité du Sm est prise 10 à 30 fois plus forte au moment de l'addition que l'Eu pour éviter l'erreur de calculer l'activité du Sm. Les efficacités de comptage sont mesurées par l'étalon de l'Eu et aussi du Sm quelque fois, de la solution à la composition moyenne, et toujours surveillées contre la variation légère même pour la condition identique. La correction pour la décroissance du Sm pendant une série de mesures durant 2 à 3 hr. est calculée par la période considérée comme 47.1 hr.

Les caractéristiques des rayonnements de radioéléments employés sont montrées au Tableau I.

B. 1) Comptage β. — Le tube ordinaire G. M. cloche à fenêtre en mica mince est employé. L'activité relativement forte du mélange a été comptée en petite géométrie, au 5^e ou 4^e étage, l'activité de l'Eu seule en grande géométrie comme au 1er ou 2^e étage. Dans certains cas où les coefficients de répartition sont assez grands, l'activité du mélange est aussi mesurée au 1er étage, pour rendre plus petite l'erreur statistique, quoique ce ne soit pas favorable du point de vue de la reproductibilité.

Le plus important, c'est de choisir l'activité du témoin, assez forte, sans cependant donner lieu à de trop fortes pertes de comptage. Il ne faut pas mesurer une activité pour laquelle les pertes de comptage obligent à une correction de plus de 10%. La perte de comptage a été calculée en employant la méthode bien connue qui consiste à mesurer deux sources actives séparément de ^{143}Pr, puis ensemble, et d'en déduire par calcul le temps mort de l'installation de comptage. Les activités dues aux impuretés doivent être prises les précautions puisqu'il n'y a pas moyen de les séparer.

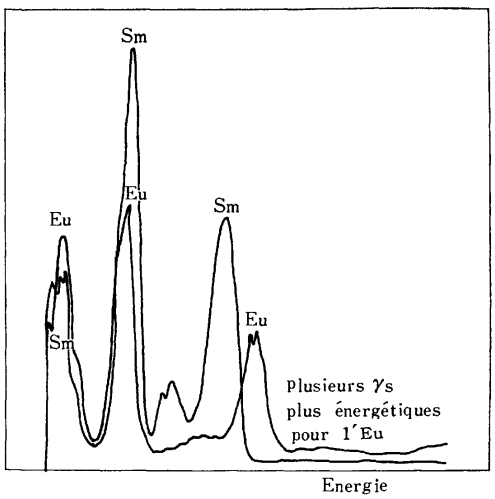

Fig. 2. Spectrographe γ du Sm et de l'Eu irradiés.

* D. Steominger, J. M. Hollander et G. T. Seaborg, UCRL-1928, "Table of Isotopes" (1958).

Cette contribution était également toujours surveillée par la comparaison du reste du Sm seul et des activités des échantillons.

B. 2) Comptage γ.—Deux appareils sont employés pour les comptages γ, l'un le spectromètre γ SGE-2 de l'Intertechnique sous la licence du CEA dans le cas du mélange, l'autre le compteur automatique N-530-P avec le scintillateur du NaI de l'EKCO pour l'Eu seul.

Puisque l'on peut négliger la différence de l'absorption par le dépôt et la perte de comptage, les mesures de γ sont en général plus précises et plus faciles que de β. Cependant les changements possibles de l'efficacité de comptage avec le temps et les mouvements propres doivent être souvent surveillés. En particulier si l'on mesure une faible activité, les mesures successives de mouvements propres sont indispensables, car une légère différence

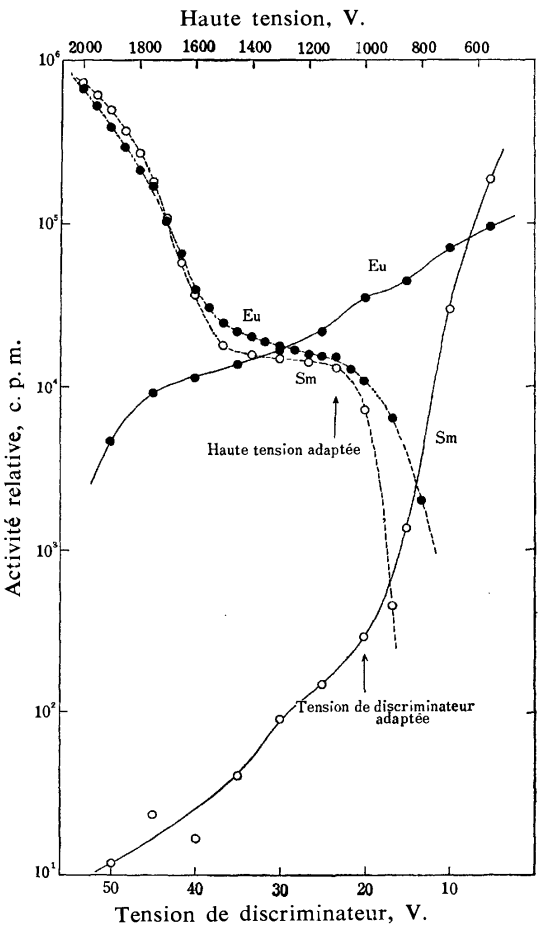

Fig. 3. Détermination des tensions pour le compteur γ.
----- Courbe d'intégration
—— Courbe de discrimination

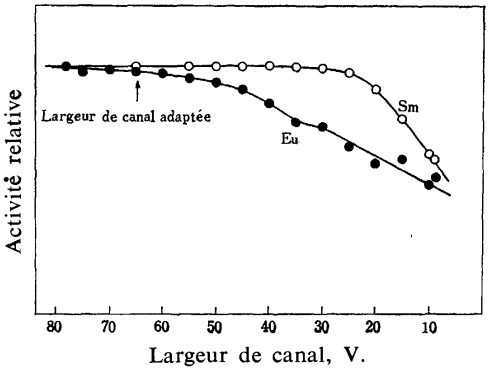

Fig. 4. Détermination de la largeur de canal pour le spectromètre γ.

de tension par température, ou bien le transport ou le déplacement d'une forte source dans les laboratoires voisins peuvent le faire varier.

Pour mesurer l'activité du Sm en présence de l'Eu, il n'y avait pas de condition particulièrement favorable. Les spectrographes γ de ces radioéléments sont montrés dans Fig. 3. Nous avons préféré le 1er pic de Sm 0.103 MeV. avec la largeur du canal qui pourra comprendre le pic 0.122 MeV. tout entier de l'Eu. Ces courbes intégrales sont montrées dans Fig. 4.

Au contraire, l'Eu peut être mesuré au compteur γ, avec une plus grande efficacité que le Sm, et les γs qu'il émet ont des énergies assez différentes de celles du Sm et des impuretés possibles; 90% de l'activité due à aux impuretés se trouve ainsi éliminée. Nous avons mesuré cette activité à la condition H. T. 1100 V., tension de discrimination 20 V.

Mesures de pH.—Comme on le montrera plus tard, le pH ne joue pas un rôle important dans ce système; donc les mesures de pH servent simplement à savoir les comportements de complexe du métal lourd. Après décroissance de la plus grande partie de l'activité due au Sm, on mesure le pH de la solution au moyen d'un pH-mètre Metrohm à électrode en verre dont l'erreur est indiquée comme étant de ± 0.04 unité, cependant on trouve souvent une erreur plus grande surtout au cours d'une série assez longue de mesures.

Causes d'Erreurs sur la Mesure du Coefficient de Répartition et du Facteur de Séparation.—Autant que possible on a essayé de rendre les erreurs inférieures à 0.3%. Les causes importantes d'erreurs sont les pipetages et les mesures des activités. Les premières pourront être diminuées par contrôle du poids de la prise; les deuxièmes comportent plusieurs facteurs: préparation des sources, mesures du témoin, différence des poids de dépôt entre le témoin et les échantillons pour les comptage β, variation des efficacités de comptages, variation du mouvement propre en cas de faibles activités pour le comptage γ.

Des expériences suivantes, on pourrait déduire que la répartition des activités elle-même réalisée par cette méthode expliquée ci-dessus, sera bien établie et cette variation ne dépasse jamais les erreurs expérimentales, et que l'erreur peut être considérée comme inférieure à 2 à 3% pour les coefficients de répartition moyens, c'est-à-dire 0.5 à 100, un peu plus grande pour les coefficients relativement grands c'est-à-dire plus de 100 et très grande pour les coefficients inférieurs à 0.5.

Pour comparer l'efficacité de séparation c'est-à-dire les facteurs de séparation, il faudra faire plus attention, en considérant les conditions de mesures, le degré des erreurs, quelques fois demander les aides de considérations théoriques. Il est presque impossible de comparer les facteurs de séparation d'une série à une autre des expériences sauf les séries effectuées par la même condition.

Resultats des Experiences

Etant donné que l'on peut prévoir d'assez grandes différances entre les caractéristiques de ce système et celles des acides hydroxycarboxyliques, on doit étudier les influences de divers facteurs sur le coéfficient de répartition. Puisque le coéfficent de répartition dans ces expériences dépend du rapport entre le volume de solution et le poids de résine, nous désignons le coéfficient de répartition dans ce système Cr comme

Résine: Diaïon SK-1 sous forme de NH_4R, 60~80 mesh, poids montré calculé comme séché en étuve

Solution: Volume totale 10 ml., 0.05373 mol. en CoY^{2-} aux compositions montrées

Terres rares: Eu 2.2 μg., Sm 57 μg. comme en oxyde

Mesures: Eu par β et γ, Sm par γ

$$Cr = \frac{Act_{témoin} - Act_{échan}}{Act_{échan}}$$

et le facteur de séparation comme

$$\alpha = (Cr)_{Sm}/(Cr)_{Eu}$$

Les poids de résine sont exprimés en résine séchée, ils sont calculés connaissant la teneur en eau de la résine, celle-ci ayant été mesurée une fois sur une autre partie de résine.

1) Le Système NH_4R-[H_2CoY, $(NH_4)_2CoY$].—Une combination possible c'est le cas où l'on emploie NH_4R comme résine et le mélange des solutions de $(NH_4)_2CoY$ et de H_2CoY comme solution, dont, comme il a été dit précédement, la prmière est équiliblée avec NH_4R, mais cette dernière ayant été équiliblée avec CoR_2, donc on ne peut éviter la différence de concentration en ion libre Co^{2+} dans le mélange de ces deux solutions.

Les résultats sont donnés dans Tableau II et dans Fig. 5. La courbe est en convexe en haut, cette diminution du coéfficient de répartition pour les fortes teneurs de la solution en complexe acide est peut-être due à la différence de stabilité des complexes du Co et des terres rares, et pour les fortes teneurs en complexe neutre, elle a nettement pour cause une diminution de la concentration en ion libre Co^{2+}.

Comme facteur de séparation, on obtient la valeur à peu près raisonnable que l'on espére que pouvaient laisser prévoir les valeurs des constantes de formation des complexes, soit $\log Kc_{Eu}/\log Kc_{Sm} = 0.21 \pm 0.09$[12].

2) Le Système CoR_2-[H_2CoY, {$(NH_4)_2$, Co}CoY].— L'autre combinaison possible, c'est le cas où l'on emploie CoR_2 comme résine et la solution mélangée de H_2CoY et de [$(NH_4)_2$, Co]CoY qui sont toutes les deux équiliblées avec la résine CoR_2. Les résultats sont données dans Tableau III et dans Fig. 6.

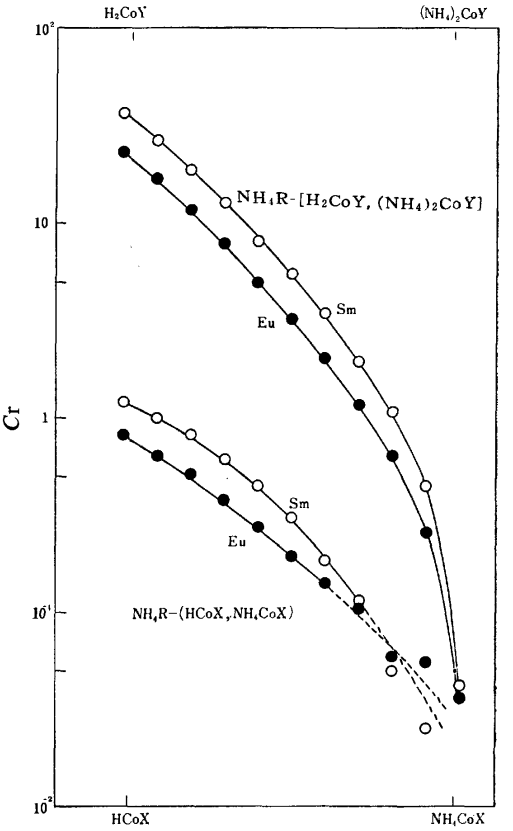

Fig. 5. Exp. 1. NH_4R-[H_2CoY, $(NH_4)_2CoY$] et Exp. 5. NH_4R-[HCoX, NH_4CoX].

Ces résultats indiquent la présence d'ion Co^{2+} en grande quantité n'est pas favorable à la séparation, au moins du Sm et de l'Eu. Il peut y avoir deux raisons possibles à cela, l'une serait l'augmentation de la force ionique, l'autre la formation

Solution: Volume total 10 ml., 0.05373 mol. en CoY^{2-} aux compositions montrées
Terres rares: Eu 2.25 μg., Sm 14.0 μg. comme en oxyde
Mesures: Eu, Sm tous les deux par γ

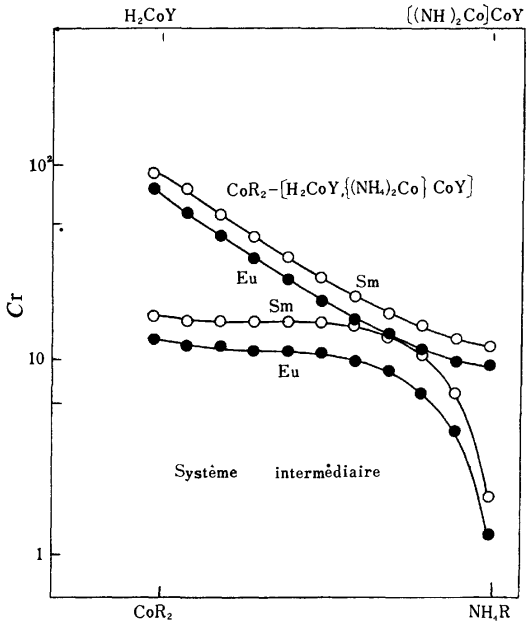

Fig. 6. Exp. 2. CoR_2-[H_2CoY, {$(NH_4)_2$, Co}·CoY] et Exp. 4. système intermédiaire.

d'un complexe polynucléaire où les terres rares sont complexées en état tri- ou tétradentatées au lieu de hexadentatées[13]. Dans la phase de résine occupée par le Co^{2+}, qui est bien hydraté, la séléctivité d'absorption des terres rares sera probablement aussi affaiblie.

3) Solution des Complexes entre l'EDTA et le Cu^{2+}.—Dans le cas de l'expérience 1, la solution $(NH_4)_2CoY$ ne contient que la quantité la moindre du Co^{2+}, c'est-à-dire la quantité qui peut être libérée du complexe en présence d'un grand excès de NH_4R. Les *C*rs dans ce cas sont relativement petits, il est donc difficile d'en constater les variations. Pour les constater, il vaut mieux employer une solution complexe plus stable, on en pourra réaliser une rempaçant le Co^{2+} par le Cu^{2+}.

Les *C*rs des terres rares en présence de NH_4R et des mélanges de solutions H_2CuY et $(NH_4)_2CuY$, sont étudiés, ces résultats figurent dans Tableau IV. Les valeurs de *C*r obtenues étaient très grandes, sauf pour les mélanges constitués presque totalement de $(NH_4)_2CuY$, cependant l'activité due aux impuretés nous a géné et nous n'avons pas pu l'éliminer complètement même en faisant les mesures au compteur γ après supprimé par discrimination la pluspart de l'activité due aux impuretés; on a donc essayé de l'éliminer grâce aux différences dans les efficacité de comtage β, γ, et aussi nous avons assuré par le spectromètre γ ce que l'activité des échantillons était prédominée par le Sm au moins au commencement. Tout de même nous n'avons pas pu obtenir une grade précision satisfaisante, sauf les deux dernières expériences.

De cette série d'expériences, on comprend que la solution $(NH_4)_2CuY$ est très susceptible pour la quantité de l'ion libre de Cu^{2+} à cause de sa teneur moindre, et par la différence dans les constantes de formation de complexe entre le Co et le Cu, on peut déduire que les *C*rs de l'Eu et du Sm pour la solution $(NH_4)_2CoY$ dans l'expérience 1 seraient sûrement presque zéro.

On remarque aussi les facteurs de séparation toujours inférieurs avec la solution complexe du Cu à avec celle du Co, même dans la dernière expérience, où le *C*r est aussi petit que les cas du Co.

4) Les Compositions Intermédiaires des Phases de Résine et de Solution.—Entre les duex systèmes, expériences 1 et 2, on a essayé d'étudier les variations en chageant progressivement la composition des deux phases, c'est-à-dire de la résine et de la solution. Comme les mélanges représentatifs, nous avons choisi 30% de la solution complexe acide toujours, pour le reste de 70%, la solution neutre libre de

Résine : Diaïon SK-1, 60~80 mesh, sous forme mélangée de NH_4R et de CoR_2.
Solution : Volume total 10 ml., 0.05373 mol. en CoY^{2-}
Composition de soln. A: 30% de H_2CoY et 70% de $(NH_4)_2CoY$
Composition de soln. B: 30% de H_2CoY et 70% de $[(NH_4)_2,Co]CoY$
Terres rares : Eu 2.25 μg., Sm 14.0 μg. comme en oxyde
Mesures : Eu, Sm tous les deux par γ

Co^{2+} avec la résine NH_4R, saturée de Co^{2+} avec CoR_2. Les compositions intermédiaires ont été faites par ces deux solutions mélangées et les prises espérées de NH_4R et de CoR_2.

La variation de Cr est représentée dans Tableau V et dans Fig. 6.

5) Le Système du Complexe entre le NTA et le Co.—Si l'on compare les constantes de formation des complexes que forment les acides aminopolycarboxyliques avec les métaux lourds, d'une part, et les terres rares d'autre part, on constate que les métaux lourds ont une plus forte tendance à se complexer que les terres rares pour l'acide plus complexant—de plus les différences entre leurs constantes de formation sont plus grandes, sauf cependant dans quelques cas, tels que les terres rares du groupe gadolinium* avec les acides H_3V et DTPA**.

Dans les cas de séparation de terres rares sans entraîneur, le facteur de séparation doit être proportionnel au rapport entre ces constantes de formation, pourvu que l'on se serve toujours de résine identique ; de ce point de vue l'acide H_4Z** sera plus interressant et l'acide H_3X moins que l'acide H_4Y.

Dans cette série d'expériences nous voulons constater si l'acide H_3X nous donne le facteur de séparation moins grand que l'acide H_4Y comme

* Nous désignons les terres rares à partir du Gd jusqu' au Lu comme groupe gadolinium au lieu d'yttrium, car on peut remarquer certaines différences entre les terres rares et l'Y.

** Nous appellerons l'acide hydroxyéthyléthylènediaminetriacétique H_3V, l'acide diéthylènetriaminepentaacétique DTPA et l'acide cyclohexanediaminetétraacétique H_4Z.

prévu par les considérations ci-dessus, et aussi les Crs plus petits prévu par les rapports des constantes de formation des complexes des terres rares pour des métaux lourds.

Les résultats figurés dans Tableau VI et Fig. 5, montrent exactement comme il était prévu, une efficacité de séparation moins grande et les valeurs de Cr plus petites, quoique ces résultats soient un peu moins précis à cause des valeurs de Cr trop petites à mesurer surtout vers les compositions auprès de NH_4CoX.

6) Effet de la Dilution.—A la suite de ces variations en fonction de la composition, nous voulons connaître les influences de divers facteurs sur les coéfficients de répartition. D'abord nous avons étudié l'effet de la dilution progressive de la solution complexe, car on dit qu'une concentration plus faible donne une séparation moins efficace[14].

Les variations du coéfficient de répartition sont représentées dans Tableau VII et Fig. 7, lorsqu'on a dilué la solution, en maintenant la même composition, c'est-à-dire dilué la solution de complexe mélangée 30% de H_2CoY et 70% de $(NH_4)_2CoY$.

Mesures: Eu par β et γ, Sm par γ

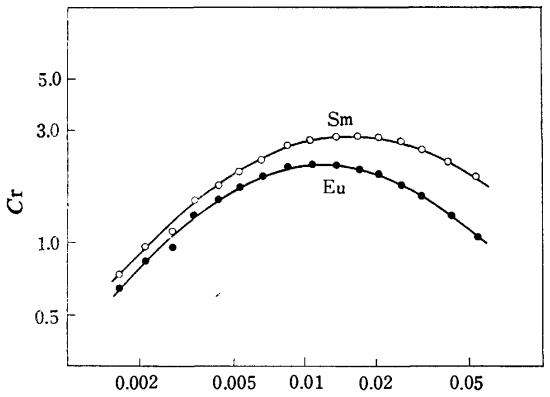

Fig. 7. Effet de la dilution.

On voit d'une part que le coéfficient de répartition augmente d'abord avec la dilution, devient ensuite à peu près constant, puis commence à diminuer, et d'autre part que le facteur de séparation décroît nettement de plus en plus. Il semble que ces variations soient assez difficile à analyser, peut-être on pourra considérer comme suivant. Aux fortes concentrations, l'effet de la diminution en NH_4^+ sera prédominant, tandis que pour les fortes dilution, la résine NH_4R pourra commencer à décomposer le complexe, après avoir fini l'élimiation complète de l'ion libre Co^{2+}, ainsi les terres rares commencent à passer en solution; aux concentration moyennes ces deux effets sont à peu près du même ordre, donc la répartition varie peu.

Cependant la diminution remarquable du facteur de séparation reste plus difficile à expliquer surtout à la comparaison de l'expérience suivante. Il sera possible d'y avoir une certaine quantité du NH_4^+ nécessaire pour tenir l'équilibre du Co^{2+} entre deux phases afin de réaliser l'éfficacité de séparation.

7) Effet de la Dilution pour une Concentration Constante en Ion Ammonium.—Ensuite nous avons étudié l'influence de la dilution en maintenant la concentration en ion NH^{4+} constante. Dans cette série, on a dilué la solution de complexe en remplaçant l'eau distillée, qui était employée dans l'expérience précédante, par une solution de perchlorate d'ammonium 0.09402 mol., soit 1.1048 g. dans 100 ml., qui correspond à la concentration calculée de la composition mélangée 30% H_2CoY et 70% $(NH_4)_2CoY$ 0.05373 mol., c'est pourquoi il est possible qu'elle soit de concentration un peu inférieure à celle de la solution complexe, dans laquelle une légère partie de Co^{2+} a été remplacé par le NH_4^+ au moment de l'élimination de l'excès de l'ion libre Co^{2+} dans la colonne NH_4R.

La légère augmentation de Crs pour les fortes dilutions du complexe viendrait probablement d'une concentration plus faible en ions Co^{2+} dans la phase de résine, et aussi de la dissociation du complexe du Co en ses composants. Cependant cette différence est vraiment légère surtout lorsqu'on compare aux cas des acides hydroxycarboxyliques pour lesquels les coéfficients de répartition varient proportionnellement presqu'au cube de la concentration. Il semble que la dilution provoque une légère diminution de l'efficacité de séparation.

8) Effet de la Concentration en Ion Ammonium.—L'effet de l'augmentation de la concentration en ion NH_4^+ peut être prévus à peu près par les considérations théoriques sur les réactions d'équilibre entre la phase résine et la phase solution. Pour savoir la validité de ces considérations, nous avons fait cette série d'expériences.

Comme solution de départ, on prend le mélenge, 80% de H_2CoY et 20% de $(NH_4)_2CoY$, à cause de sa faible teneur en ion NH_4^+ et des grands coéfficients de répartition qu'il peut obtenir. 50 ml. de cette solution divisée, on en ajoute 9.4367 g. de

Résine : Diaïon SK-1, sous forme NH_4R, 60～80 mesh, poids comme montré
Solution : Volume total 10 ml., 0.05373 mol. en CoY^{2-}, 0.1075 mol. en NH_4^+
Terres rares : Eu 2.92 μg., Sm 13.6 μg. en oxyde
Mesures : Eu, Sm tous les deux par γ
* 1 Goutte de NH_4OH 1 N
** 1 Goutte de NH_4OH N/4
*** 1 Goutte de NH_4OH N/10

NH_4ClO_4 dans une partie, alors on obtient une solution à 0.05373 mol. en CoY^{2-} et à 0.150 mol. en NH_4^+, tandis que l'autre partie reste à 0.0215 mol. en NH_4^+, après addition de la solution de terres rares radioactives. A partir de ces deux solutions on obtient les concentrations différentes en ion NH_4^+, comme dans le tableau suivant.

On voit que le coéfficient de répartition décroît à peu près proportionellement à la concentration en ion NH_4^+ et que l'éfficacité de séparation diminue, comme on prévoyait. Les valeurs obtenues des facteurs de séparation ne sont pas très précises à cause de la difficulté à préparer de bonnes sources, étant donné la quantité relativement grande de perchlorate d'ammonium, qui se dépose d'abord en laissant la solution de complexe, pour cette raison on ne pouvait faire les mesures qu'aux compteurs γ pour quelques sources préparées de solutions concentrées en ion NH_4^+.

9) Effet du pH.—Il est possible de prévoir que le pH aura moins d'influence sur les coéfficients de répartition des terres rares dans le cas où l'on emploie l'EDTA que dans celui où l'on emploie les acides hydroxycarboxyliques, étant donné que la formation du complexe acide non dissocié n'est pas remarquable, et de plus, elle est de même ordre presque tous les métaux, contrairement aux acides hydroxycarboxyliques qui sont sensibles à se dissocier par la différence du pH, donc la concentration d'anion, à qui le coéfficient de répartition sera proportionnel presqu'au cube, varie beaucoup avec le pH.

Pour ces expériences, nous avons préparé les solutions aux pH différents, en partant des solutions du H_2CoY et du $(NH_4)_2CoY$, qui contiennent la quantité équivalente d'ammonium. Les résultats sont dans Tableau X.

La prévision était à peu près constatée, c'est-à-dire. il n'y a pas de différence remarquable dans le domaine des pHs entre 3.5 et 7.0. Notons que dans les cas des acides hydroxycarboxyliques, il est suffisant de changer la valeur de pH d'ordre de 1.0 pour augmenter le coéfficient de répartition 1000 fois plus grand. Cependant dans cette série d'expériences, nous n'avions pas prêté assez d'attention à l'effet de différence par les teneurs en ion libre de Co^{2+} dans les deux solutions de départ. L'augmentation de coéfficients de répartition pour les solutions aux pHs inférieurs à 3.5, sera certainement plutôt à cause de l'augmentation de la concentration de l'ion libre de Co^{2+}. Les coéfficients de répartition pour les pHs supérieurs à 5.0 sont trop petits pour nous permettre de les déterminer avec une grande précision. Il vaudrait mieux préparer les solutions à essayer par mélanger des deux solutions préparées d'une solution de H_2CoY, mais à la manière comme suivante; l'une neutralisée par l'ammoniaque jusqu'à pH 7.0, l'autre ajustée à la concentration en ion ammonium équivalente par l'addition de perchlorate d'ammonium, ainsi on pourrait éviter la différence à la teneur en ion libre du Co^{2+}, et obtenir les coéfficients de répartition convenable, dans ce cas il sera possible de savoir les comportements différents entre les complexes acides non dissociés de terres rares et de Co.

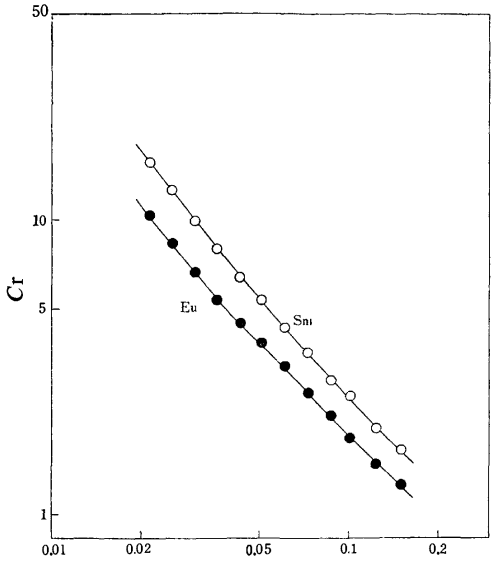

Fig. 8. Effet de concentration en NH_4^+.

10) Effet des Entraineurs Isotopique et non Isotopiques. En ce qui concerne les variations de l'efficacité deséparation en fonction de la différence de la quantité d'une terre rare par rapport à l'autre, il n'y a presque pas d'expérience, bien qu'il soit extrêmement important. Sur ce sujet, l'analyse des résultats de quelques expériences de séparation sur colonne n'a pas permis de préciser le comportement d'une terre rare en présence d'autres en grand quantité; la difficulté était de doser précisément la première. A l'aide de radioélément, on pourrait la determiner facilement. C'est essentiellement nécessaire à savoir surtout pour les préparations de terres rares extrêmement pures ou bien la séparation d'une terre rare sans entraîneur produite partir d'une voisine.

Dans ce but, nous avons choisi parmi les terres rares, le Sm comme entraîneur isotopique, le La, le Nd et l'Y comme non isotopiques mais les deux premières qui doivent être éluées plus tard, le troisième plus avant que l'Eu et le Sm, afin de savoir s'il y a les différences par leurs positions pour l'influence des coéfficients de répartition et de l'efficacité de séparation du Sm et de l'Eu. Plutôt que de partir d'une solution de terres rares nous avons préféré les fixer d'abord sur une petite quantité de résine dans une colonne, pour réaliser des conditions semblables à la séparation sur colonne, et aussi pour ne pas ajouter d'ion inutile.

Une quantité suffisante de résine sous forme d'ammonium séchée dans l'air a été prise par la balance chimique, versée dans une petite colonne avec de l'eau, puis transformée sous forme du sel d'une terre rare, en faisant passer la solution de cette terre rare. La saturation de la résine par terre rare a été verifiée par précipitation des terres rares par l'acide oxalique dans la solution passée. La résine lavée à l'eau distillée est versée sur un petit filtre en verre fritté, lavée une fois par un peu d'alcool puis laissée sécher à l'air. La quantité

de terres rares à ajouter selon la composition espérée peut être calculée par le poids de la résine prise sous forme ammonium et le poids de résine ainsi préparée. La composition de la solution choisie, c'est aussi le mélange de 30% de H_2CoY et de 70% de $(NH_4)_2CoY$, mais dans cette série d'expériences, le poids de résine et le volume total sont tous les deux juste moitié que dans les autres séries.

A la suite de l'agitation après avoir ajouté la solution complexe, on a remarqué le changement de couleur de la solution en rose plus claire assez net dans le dernier tube de chaque série LaR_3, NdR_3 et SmR_3 dans les deux derniers de la série YR_3, ce qui montre la diminution en ion de Co dans la solution et probablement aussi l'abaissement du pH ; à ces trois premiers tubes, on a remarqué les précipités, cependant la durée de ses commencements de l'apparition était différente ; dans le cas de LaR_3, bientôt après l'agitation, un peu plus tard dans le cas de NdR_3, et la quantité de précipité du premier était plus grande que du deuxième ; dans le cas de SmR_3, on n'a pas trouvé de précipité dans la première journée, mais le

Terres rares : Eu 0.96 μg., Sm 4.48 μg. en oxyde
Mesures : Sm, Eu tous les deux par β et γ

lendemain une quantité plus petite de précipité crystallin au lieu de pulvérulent dans les deux cas précédants. Dans les tubes de YR_3, aucun précipité n'était pas remarqué même quelques jours après. Probablement ces précipités seront l'acide libre d'EDTA, mais on n'a pas examiné s'ils ne contenaient aucun métal, soit sous forme de complexe acide d'un ou de deux métaux, soit comme coprécipitation.

Les résultats sont donnés dans Tableau XI et Fig. 9, où nous pouvons citer ces points intéressants.

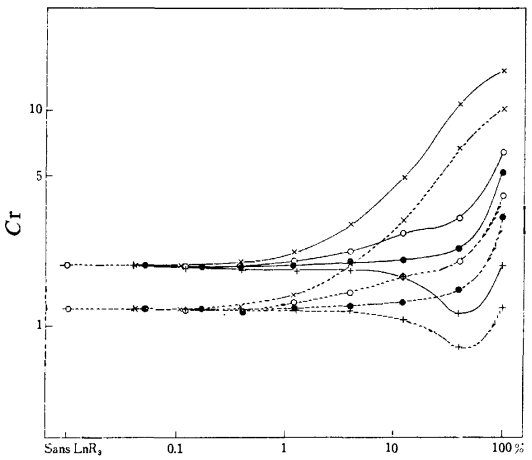

Fig. 9. Effet des entraîneurs isotopique et non isotopiques.

—— Sm × YR_3 ○ SmR_3
---- Eu ● NdR_3 + LaR_3

D'abord selon la quantité de terre rare, dont le complexe est plus fort ou plus faible que celui du Co, les coéfficients de répartition de l'Eu et du Sm sont diminués ou augmentés. Avec l'augmentation d'entraîneur, ces influences sont renforcées, enfin les coefficients de répartition montent plus vite dans tous les quatre cas, lorsque la quantité de terre rare dépasse la quantité équivalente de l'EDTA.

Ensuite il est vraiment remarquable que, dans tous les cas, les comportements de l'Eu et du Sm sont tout à fait identiques, c'est-à-dire le facteur de séparation reste toujours constant, quelle que soit la quantité de l'entaîneur, non seulement non isotopique mais aussi isotopique, soit 0.000895 à 1.20 méq., de plus même s'il y a la décomposition dans la solution à cause de l'excès d'une des terres rares. On doit faire attention ce qu'il y a une grande différence entre les comportements d'une terre rare et d'un métal lourd. Cependant on ne peut pas assurer pour moment si ce fait reste toujours vrai pour une autre couple de terres rares quelconques, car il est possible que ce fait vienne de la différence très petite du facteur de séparation à cause d'une paire des ions la plus semblable, le Sm et l'Eu, même parmis les terres rares.

De la comparaison des comportements du Sm et de l'Eu par les présences du Sm d'un côté et des autres terres rares d'autre, il semble qu'il n'y ait aucune différence entre les entraîneurs isotopiques et non isotopiques, au moins pour ces ions assez samblables.

De la comparaison des comportements de l'Eu à la présence du Sm minimum et maximum, on pourra sûrement appliquer ce facteur de séparation à un cas où il n'y a plus petite quantité de l'Eu que dans ces expérience, même jusqu'à l'état sans entraîneur, car c'est une grande qualité bien constatée géneralement à la séparation par la résine échangeuse d'ion, que le comportement d'un ion au dessous d'une certaine quantité, soit à peu près de l'ordre de quelques milligrammes, est tout à fait identique à celui qu'il est sans entraîneur, pourvu que cet ion reste vraiment à l'état d'ion. Quant à la séparation des terres rares à l'aide de la résine sous forme Zn[15], on a déjà montré jusqu'à la quantité la moindre dosable par la méthode d'absorption; ici c'est étendu jusqu'au cas limite.

Discussion

Etant donné que la solution complexe de l'acide aminopolycarboxylique et du métal lourd peut libérer une quantité plus ou moins grande d'ion libre du métal lourd, qui jouent un rôle important dans l'action de la solution et aussi dans la composition de la phase de résine, le coéfficient de répartition n'est plus indépendant du rapport du volume de solution au poids de résine, tout à fait différent de l'acide hydroxycarboxylique. Le contrôle de cet ion libre sera probablement le grand problème pour la séparation sur colonne, à ce point de vue, le système saturé en métal lourd est moins sensible pour la quantité de l'ion libre, cependant l'excès du métal lourd diminue l'éfficacité de séparation, certainement à cause de la formation des complexes polynucléaires.

Pour cette même raison l'effet de la concentration en ion ammonium aussi a une influence plus faible que dans le cas de l'acide hydroxycarboxylique, ainsi d'ailleur que le pH étant donné la différence entre la tendance à former les complexes acides et à former l'acide hydroxycarboxylique relativement peu dissocié avec l'augmentation de l'ion d'hydrogène. Des effets semblables sont remarqués aussi dans les dilutions de la solution complexe, or la dilution simple nous montre la complexité de cet acide, on doit remarquer aussi qu'il y a de grandes différences dans les facteur de séparation selon qu'on dilue la solution simplement par l'eau ou bien en conservant une concentration constante en ion ammonium;

15) P. Krumholz, K. Bril et al., "Proceedings of the Second United Nations International Conference on the Peaceful Uses of Atomic Energy", p/2491, **28**, 184, Geneva (1958).

dans le premier cas, le facteur de séparation décroît énormément avec la dilution, tandis qu'il décroît légèrement dans le deuxième cas. Nous ne pouvons dire à présent si c'est à cause de l'effet direct des ions ammonium à la concentration nécessaire minimum ou bien des qualités particulières de complexes mais sûrement ces points seront un des motifs pour lesquels on n'a pas pu obtenir une bonne séparation au moyen de l'acide éthylènediaminetétraacétique seule.

Les diminutions du facteur de séparation avec l'augmentation des ions ammonium et aux bas pHs, peuvent être considérés comme probablement dues dans le premier cas à l'augmentation de la force ionique et dans l'autre cas sûrement aux différences moins grandes dans les constantes de formation des complexes acides de ces deux terres rares.

Ces connaissances nous donne la suggestion qu'il vaudra mieux employer la solution de sel presque tétraammoniaque d'acide éthylènediaminetétracétique pour les séparations de terres rares en grande quantité sur colonne pour avoir une concentration plus forte en terres rares dans les solutions éluées et pour éviter la formation des complexes acides dont la solubilité est plus petite. La possibilité de précipitation des hydroxydes de terres rares dans la zone au commencement de la bande absorbée de terres rares où il y a un changement très grand du pH, pourra éviter à l'aide du magnésium par exemple, comme montré par Brunisholtz[16].

D'autre part il est tout à fait remarquable que le facteur de séparation reste toujours constant avec l'augmentation de la quantité d'entaîneurs non seulement non isotopiques mais aussi isotopique, ainsi qu'en présence d'une précipitation provoquée probablement de l'acide libre. Cette constance du facteur de séparation sera réalisée même en l'absence de métal lourd, c'est-à-dire si les terres rares en grande quantité sont séparées sur colonne par élution au moyen de l'éthylènediaminetétraacétate d'ammonium.

De ces connaissance, en bref la solution de complexe a une action remarquable presque tous les variants des études de l'échange d'ion, qui sera favorable à étudier la chimie de complexe surtout de la quantité impondérable de terres rares par la méthode d'équilibre, cependant pour effectuer la séparation sur colonne, il faudra encore beaucoup plus d'attentions pour maintenir la concentration de l'ion libre, de ce point de vue l'acide hydroxycarboxylique sera plus facile à employer.

Résumé

Pour avoir l'efficacité de séparation que peuvent faire espérer les données sur les réactions d'équilibre de l'acide aminopolycarboxylique avec les terres rares, la solution du complexe de ces acides avec les métaux lourds est considérée comme meilleure que l'acide simple, à cause surtout de sa plus grande stabilité et de son comportement à faible concentration et à faible pH.

Les méthodes de préparation de ces solutions de complexes, leurs caractéristiques essentielles vis-à-vis des résines sous forme ammonium et sous forme métal lourd, les comportements des coéfficients de répartition en fonction de la dilution simple et pour une concentration en ion ammonium, en fonction de la concentration en ion ammonium et en fonction du pH sont étudiés. Les motifs qui peuvent diminuer le facteur de séparation sont aussi essayés de discuter, mais il est remarquable qu'ils restent constants en présence d'une grande quantité d'entreîneurs isotopiqus ou non. Les discussions ont été faites sur ces résultats.

L'auteur veut exprimer ses remercients les plus profonds à Monsieur Ch. Fisher, chef de Service de Radioéléments Artificiels, à Monsieur R. Henry, chef de Section de Préparation des Radioéléments du même Service, Département de Chimie, Commissariat à l'Energie Atomique de la France, qui lui permettaient d'étudier ces expériences, à Mademoiselle J. Beydon qui se donnait la peine de discuter les analyses des résultats, et aussi à d'autres ingénieurs de ce Service, au Centre d'Etudes Nucléaires de Saclay qui s'occupaient d'irradier les échantillons, de lui permettre de se servir des diverses appareils de mesure.

Il lui faut remercier profondément à l'Agence Internationale de l'Energie Atomique à Vienne, dont la bourse d'études lui permettait de devenir possible ses séjours à ce Centre au cours de ces expériences.

Asymmetric Hydrogenation with Modified Raney Nickel. I. Studies on Modified Hydrogenation Catalyst. II[1]

By Yoshiharu IZUMI, Masami IMAIDA, Hideaki FUKAWA and Shiro AKABORI

(Received July 25, 1962)

Although a number of methods for asymmetric hydrogenation have been attempted, few reports are available on the asymmetric hydrogenation based on the assymmetric function of catalysts, except enzymatic hydrogenation. Akabori et al.[2-3] reported on asymmetric hydrogenation observed in the experiments using silk-palladium catalyst. However, the efficiency of their asymmetric hydrogenetion was very low and the results were not reproducible. Isoda et al.[4] also reported that asymmetric hydrogenation occurred by the use of silk-palladium catalyst and with R-Ni*, on which optically active amino acid has been adsorbed.

In the previous paper of this series[1] it was reported that the treatment of R-Ni with amino acid solution e. g. Glu* diminished the hydrogenation activity for the carbonyl group without any appreciable effect on the activity toward the C=C double bond.

The present paper deals with the asymmetric hydrogenation of carbonyl compounds carried out with R-Ni modified with optically active amino acid. It has been confirmed that R-Ni treated with L- or D-Glu solution has a definite ability to catalyze the hydrogenation of carbonyl compounds asymmetrically. Ethyl acetoacetate, methyl acetoacetate and acetophenone were asymmetrically hydrogenated with the use of this modified catalyst yielding the corresponding, optically active alcohols. An excellent result was obtained in the hydrogenation of methyl acetoacetate to methyl 2-hydroxybutyrate by the use of R-Ni treated with L- or D-Glu.

$$CH_3\text{-}CO\text{-}CH_2\text{-}CO_2Me \xrightarrow{+H_2} CH_3\text{-}\underset{\displaystyle OH}{\underset{|}{CH}}\text{-}CH_2CO_2Me$$

The treatment of R-Ni with other amino acids showed the same effect to a lesser extent. R-Ni treated with D-tartaric acid also had the capacity to catalyze asymmetric hydrogenation.

The results of experiments described above were reproducible and products of high optical activity were obtained. R-Ni treated with L- and D-Glu respectively gave levo- and dextrorotatory 2-hydroxybutyrate. When R-Ni treated with DL-Glu the product was fully inactive as could naturally be expected. Hydrogenation of benzalazlactone with R-Ni treated with L-Glu gave, however, optically inactive phenylalanine.

The catalyst modified with Glu had no asymmetric activity for the hydrogenation of benzalazlactone. As reported in the previous paper modification of R-Ni with amino acids had no effect on the hydrogenation activity toward the C=C double bond, while it showed a strong inhibition of the activity toward the carbonyl group. On the other hand, the modified catalysts had asymmetric hydrogenation activity toward the carbonyl group above 60°C.

The results described above and that reported in the previous paper suggest that the hydrogenation of the carbonyl group and C=C double bond may take place at different active centers.

Results and Discussion

Effect of the pH of Modifying Solution.— Asymmetric yields of catalytic hydrogenation by R-Ni treated with 2% L-Glu solution of various pH at 0°C were investigated. The pH of the Glu solution was adjusted with 1 N (f=0.833) sodium hydroxide solution according to the titration curve shown in Fig. 1.

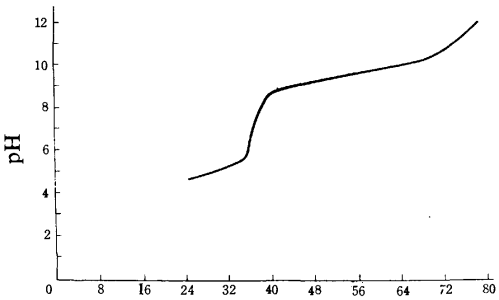

Fig. 1. Titrating curve of 2% L-Glu solution with 1 N NaOH.

* Abbreviation: R-Ni, Raney nickel; Glu, Glutamic acid.

As shown in Fig. 2, the pH of the Glu solution greatly influenced the capacity of the catalyst for asymmetric hydrogenation and adsorbed L-Glu. There was a distinct optimum capacity at pH 5.1 with considerable diminution observed both at higher and lower pH values. It is interesting that the modifying solution turned green on treating R-Ni below pH 5 and blue above pH 5.

Effect of Modifying Temperature.—The relationship between the asymmetric capacity and the temperature of modifying solution was studied using R-Ni immersed in 2% L-Glu at pH 5.0~5.2. The highest asymmetric yield was obtained with R-Ni modified at 0~20°C, and the asymmetric yield was decreased at higher temperatures as shown in Fig. 3. If R-Ni was treated with the same modifying solution at temperatures higher than 80°C the product showed reverse optical rotation. Reaction velocity of hydrogenation decreased as the modifying temperature was increased. However, no relationship between the quantity of adsorbed amino acid and catalytic activity could be established, because exact determination of adsorbed Glu was impossible. The facts mentioned above might sugget that the mode of modification of the catalyst at higher temperature is different from that at lower temperature.

Effect of Concentration of Modifying Solution.—The asymmetric capacity of the modified R-Ni was independent of the concentration of L-Glu within the range of 6 to 0.0625% as can be seen in Fig. 4. This result shows that adsorption of Glu on R-Ni reaches saturation at the lower concentration.

○ Optical rotatory power
● Adsorbed L-Glu on R-Ni

Effect of Immersion Time for Modification.—The effect of immersion time of R-Ni in Glu solution upon the asymmetric hydrogenation is shown in Table I. The adsorption equilibrium appears to be attained within 15 min.

TABLE I. EFFECT OF IMMERSION TIME FOR MODIFICATION

Immertion time	Optical rotation $[\alpha]_D^{20}$	Asymmetric yield P, %
2 min.	−2.56	12.2
10 min.	−3.51	16.8
1.5 hr.	−3.46	16.5
19 hr.	−3.30	15.8
47 hr.	−2.98	14.3

TABLE II. EFFECT OF MIXTURE D- AND L-GLU IN DIFFERENT RATIO UPON THE ASYMMETRIC YIELD

Mixing ratio		Optical rotation $[\alpha]_D^{20}$	Asymmetric yield P, %
L-Glu	D-Glu		
10	0	−2.86	13.7
9	1	−1.90	9.1
6	4	−0.45	2.2
0	10	+2.95	14.1

Effect of Mixing L- and D-Glutamic Acid.— The effect of mixtures D- and L-Glu in different ratios upon the asymmetric yield has been measured and has been compared with the effects of pure D- and L-Glu. A nearly linear relationship between the activity of the reaction products and the mixing ratio was observed as shown in Table II.

TABLE III. EFFECT OF DOUBLE MODIFICATION

Exp. No.	Modifying agent 1st	Modifying agent 2nd	Optical rotation $[\alpha]_D^{20}$
1	L-Glu	L-Glu	−3.14
2	L-Glu	D-Glu	+4.84
3	D-Glu	L-Glu	−3.58
4	D-Glu	D-Glu	+4.89

Effect of Double Modification.—When R-Ni was first treated with L- or D-Glu, and then D- or L-Glu, the capacity of asymmetric hydrogenation was determined by the configuration of the second modifying agents as shown in Table III.

Effect of Relative Amount of Catalyst.—The effect of varying the proportion of catalyst to substrate was investigated. Seventeen grams of methyl acetoacetate were reduced completely to methyl 2-hydroxybutyrate in the presence of modified catalyst which prepared from 1～7 g. of R-Ni alloy and modified with 225 ml. of 2% Glu solution.

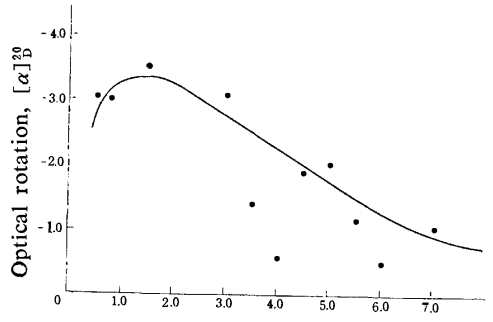

Fig. 5. Effect of the amount of catalyst prepared at 0°C.

When the catalyst was prepared at 0°C, increasing of the amount of catalyst decreased the asymmetric yield (Fig. 5). Catalyst prepared from 1.5 g. of alloy yielded a product with optical rotation $[\alpha]_D^{20}$, of −3.5. A product with the small rotation value, α −0.5, was obtained when a catalyst prepared from 6 g. of alloy was used; however, when the latter catalyst was recovered and one-fourth of it was used, the product showed an optical rotation of α −3.5.

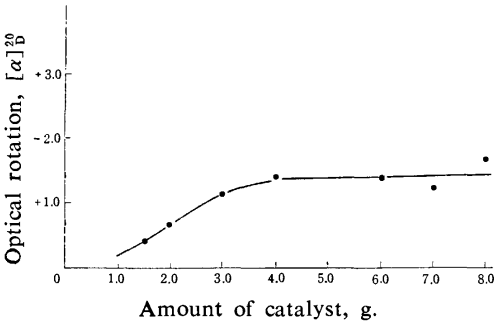

Fig. 6. Effect of the amount of catalyst prepared at 100°C.

The use of increased amounts of catalyst prepared at 100°C increased the asymmetric yield, as shown in Fig. 6. For example a catalyst prepared from 1.5 g. R-Ni alloy yielded a product with an optical rotation, α +0.4, while a catalyst prepared from 6 g. of alloy yielded a product with optical rotation, α +1.65. Recovery of the latter catalyst and the use of about a half and a third of the recovered material for reduction, yield products with rotation, α +0.60 and +0.41, respectively.

These results show that catalyst prepared in small or large amounts have the same activity when used under the same conditions. Therefore the effects shown in Figs. 5 and 6 resulted from the ratio of catalyst to substrate and not from the quantity in which the catalyst was prepared.

Desorption of Glutamic Acid from Asymmetric Catalyst. — The asymmetric catalyst prepared by contact with L-Glu solution of pH 5.2 at 0°C or 100°C was used for study. When this preparation was treated with N sodium hydroxide solution in boiling water for 1 hr., adsorbed Glu on R-Ni was removed from it, and the catalyst lost the adsorbed Glu and the asymmetric activity.

These results show that the presence of glutamic acid absorbed on the R-Ni was necessary for its asymmetric activity.

The results described above suggest that the asymmetric hydrogenation by the modified R-Ni was affected by many factors, particularly by pH and temperature of the modifying solution.

TABLE IV. ASYMMETRIC ACTIVITY OF DIFFERENT LOT OF R-Ni ALLOY

Lot	Optical rotation $[\alpha]_D^{20}$	Asymmetric yield *P*, %
A	−3.02	14.4
B	−3.30	15.8
C	−3.51	16.8

Catalysts were modified with 2% L-Glu solution at 0°C in pH 5.0.

However, so far as the authors experienced with the hydrogenation of methyl acetoacetate by the modified R-Ni prepared from different lots of R-Ni alloy of the same metal composition (Ni : Al = 4 : 6) gave 2-hydroxybutyrate of almost the same optical activity as shown in Table IV.

Further experiments on the asymmetric modification of hydrogenation catalysts are going on in the authors' laboratory.

Experimenal

Preparation of Catalyst.—R-Ni Catalyst used in the present work was prepared by a method similar to that described in the previous paper[4]. One and a half grams of powdered R-Ni alloy (Ni : Al = 40 : 60) was added to 20 ml. of 20% sodium hydroxide solution in small portions during 5 min. and was allowed to stand for 45 min. at 80°C. The nickel catalyst was washed several times with water. All of the hydrogenation experiments were carried out with this quantity of R-Ni catalyst.

Modification of Catalyst. — Two hundred and twenty-five milliliters of 2% L-Glu solution, the pH of which had been adjusted to a specified value, was added to newly prepared R-Ni and was allowed to stand with occasional shaking at 0°C for 1.5 hr. After the modifying solution was removed by decantation the catalyst was washed once with distilled water and twice with methanol, and was then separated by centrifugation.

Hydrogenation of Methyl Acetoacetate.—Commercial methyl acetoacetate was purified by washing with saturated sodium bicarbonate solution and then distilling under reduced pressure. Redistilled methyl acetoacetate (17.0 g.) was hydrogenated in the presence of modified R-Ni which was prepared from 1.5 g. of alloy. The reaction was run at 60°C under initial hydrogen pressure of 90 kg./cm^2 in a shaking autoclave. Hydrogen uptake was almost complete in about 12 hr. Reaction velocity was calculated as per cent hydrogen uptake during the first 3 hr. The reduction product was filtered off from R-Ni and distilled under reduced pressure. The main fraction boiling at 61~62°C/12 mmHg was identified as methyl 2-hydroxybutyrate by an elemental analysis of its hydrazide. The purity of methyl 2-hydroxybutyrate was tested by gas chromatography.

Asymmetric Yield. — Optical rotatory power of the distilled product was measured by a conventional polarimeter at 20°C without dilution in 1 dm. tube and the value was taken as the specific rotation because the density of methyl acetoacetate is nearly 1.0. According to Levene and Haller[5] the optical rotatory power of methyl-L-2-hydroxybutyrate is $[\alpha]_D^{20}$ −20.9, and therefore the percentage asymmetric yield, P, was calculated by the equation $P = ([\alpha]_D^{20}/20.9) \times 100$.

Identification of Methyl 2-Hydroxybutyrate.—Forty five grams of the reduction product ($[\alpha]_D^{20}$ −0.8) was boiled with 40 ml. 6 N hydrochloric acid for about 5 hr. and brought to dryness under reduced pressure. The residue was esterified by reacting it with ethanol (30 ml.) in the presence of benzene (20 ml.) and *p*-toluenesulfonic acid (0.5 g.). After the product was cooled, it was extracted with benzene and washed with water. Removal of the solvent followed by distillation gave ethyl 2-hydroxybutyrate (15.6 g.), b. p. 62°C/12 mmHg, $[\alpha]_D^{20}$ −0.7.

To 3.3 g. of ethyl 2-hydroxybutyrate 4.2 ml. of 80% hydrazine hydrate was added, the mixture was refluxed for 1 hr. and allowed to stand overnight. The crystalline product was stirred with 2 ml. ethanol, filtered and washed with a small quantity of ethanol. The yield was 2.6 g. ; m. p. 124~126°C, $[\alpha]_D^{20} < -0.04$.

Found : C, 40.71 ; H, 8.58 ; N, 23.49. Calcd. for $C_4H_{10}O_2N_2$: C, 40.66 ; H, 8.35 ; N, 23.71%.

This first crop is apparently DL-2-hydroxybutyric hydrazide. A second crop was obtained by adding ethanol to the mother liquor and recrystallizing from a mixture of ethyl acetate and ethanol. Yield 0.5 g. m. p. 123~124°C, $[\alpha]_D^{20}$ −5.67 in water.

Found : C, 40.93 ; H, 8.62 ; N, 23.26. Calcd. for $C_4H_{10}O_2N_2$: C, 40.66 ; H, 8.53 ; N, 23.71%.

Determination of Glutamic Acid Adsorbed on R-Ni Catalyst.—The modified catalysts were washed with water two times and were allowed to stand overnight. Then, the catalyst was filtered after the addition of a few drops of 1% methanol solution of lauric acid and dried in a desiccator. Glutamic acid was eluted with 1 N sodium hydroxide solution by heating for 1 hr. in a boiling water bath. The eluted glutamic acid was determined by the ninhydrin-photometric method of Stein and Moore[6].

Effect of Double Modification of L- and D-Glutamic Acid (Treatment of the R-Ni with D- after L- or L- after D-Glu).—R-Ni catalyst used in this cases was treated with 225 ml. of 2% L- or D-Glu solution adjusted to pH 5.0~5.2 at 0°C and washed once with distilled water. Then the catalyst was treated with 100 ml. of D- or L-Glu solution by the usual method as described above.

Hydrogenation of Ethyl Acetoacetate. — The catalyst was prepared by treating 1.5 g. of R-Ni alloy first with alkali and then with 225 ml. of L-Glu solution adjusted to pH 5.0 at 0°C, as described above. This catalyst was used in the hydrogenation of 16 g. of ethylacetoacetate. The reducing product, ethyl 2-hydroxybutyrate was purified by distillation and its optical rotation was measured, as above mentioned, $[\alpha]_D^{20}$ −2.00.

Hydrogenation of Acetophenone.—Sixteen grams of acetophenone was reduced and its optical rotation was measured by a similar method to the above, $[\alpha]_D^{20}$ +0.90.

Summary

1. Raney nickel catalyst treated with optically active glutamic acid has the property

5) P. A. Levene and H. L. Haller, *J. Biol. Chem.*, **65**, 51 (1925).

6) S. Moore and W. H. Stein *J. Biol. Chem.*, **176**, 367 (1948).

of catalyzing the hydrogenation of carbonyl compounds asymmetrically with high reproducibility and efficiency.

2. Excellent results were obtained in the hydrogenation of methyl acetoacetate to optically active methyl 2-hydroxybutyrate in the presence of Raney nickel catalyst treated with L- or D-glutamic acid.

3. The capacity for asymmetric hydrogenation was strongly dependent upon the pH of the modifying solution. The highest capacity was obtained when modifying solutions were adjusted to pH 4.8~5.5.

4. With elevation of the temperature of the modifying process, the asymmetric capacity of the catalyst decreased markedly, nearly disappearing at 60°C, and yielding products with reverse optical rotation above 80°C.

5. The asymmetric capacity was independent of the concentration of the modifying solution within the range of 6 to 0.0625%.

6. Hydrogenation in the presence of catalyst modified with D-glutamic acid yielded a product with reverse optical rotation to that obtained when L-glutamic acid was used.

7. Asymmetric yield of the reducing product of methyl acetoacetate by the catalyst treated with Glu was varied with the relative amount of the substrate and the catalyst.

The authors with to express their sincere thanks to Dr. Harvey A. Itano of the National Institutes of Health, U. S. A., for his advice on preparing this manuscript and to the Miss Kiku Koike and Miss Masako Kawakita of this Institute for the elemental analysis. This research was made possible through a support of Raney nickel alloy by the Kawakami Institute Ltd. Co., Tokyo. The authors are indebted to the Company for this fellowship.

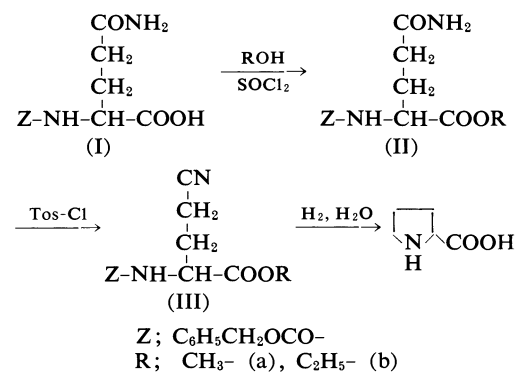
A Synthesis of L-Proline from L-Glutamine

By Tamio Itoh

(Received July 28, 1962)

Since the resolution of racemic proline is difficult, it would be advantageous to develope a practical method for the synthesis of optically active proline. Two successful syntheses of L-proline in which L-glutamic acid was the starting material have been described to date. The method described by Pravda and Rudinger[1], which makes use of the selective reduction of the lactam group of tosyl-L-pyrrolidonecarboxylic acid derivatives by lithium aluminum hydride, resulted in an overall yield of 12% from L-glutamic acid in seven steps. Tanaka et al.[2] obtained L-proline in a 34% yield from methyl L-pyrroglutamate by means of sodium borohydride reduction.

In the course of an investigation of the dehydration products of L-glutamine derivatives, the author developed a novel method for the synthesis of optically active proline. It was found that catalytic hydrogenation of γ-cyano-α-L-carbobenzoxyaminobutyric acid esters in aqueous solvents produced L-proline in high yield under suitable conditions. Thus a single hydrogenation treatment in the presence of water effects pyrrolidine ring formation between the γ-carbon atom and the α-amino nitrogen atom without racemization by successive hydrogenation, hydrolysis and ring closure. The schematic representation of the synthesis of proline from carbobenzoxyglutamine is as follows:



Z; $C_6H_5CH_2OCO-$
R; CH_3- (a), C_2H_5- (b)

The author feels that the method will be of

1) Z. Pravda and J. Rudinger, *Colletion Czech. Chem. Commun.*, **20**, 1 (1955).

practical value for the synthesis of optically active proline because the starting material, L- or D-glutamine, is readily prepared from L- or D-glutamic acid, respectively, by a method previously reported by Akabori and Narita[3].

Results and Discussion

Preparation of Carbobenzoxy-L-glutamine Esters. — The methyl ester IIa was prepared from carbobenzoxy-L-glutamine[4-7] by the action of diazomethane[8], or by esterification with methanol in the presence of thionyl chloride at room temperature. In the latter case, increasing the reaction time or amount of thionyl chloride, or elevating the temperature resulted in increase of alcoholysis of the amide group to produce dimethyl carbobenzoxy-L-glutamate. The ethyl ester IIb was obtained by esterification with ethanol in the presence of thionyl chloride.

Taschner and Wasielewski[9] proposed the use of sulfuryl chloride as catalysts for the esterification of acylated amino acids. In the present work it was found that thionyl chloride is also a useful reagent under suitable conditions.

Dehydration of Carbobenzoxy-L-glutamine Esters.—Procedures for converting carboxamide residues of glutamine or asparagine derivatives to nitrile residue with suitable dehydrating reagents, *p*-toluenesulfonyl chloride, phosphorous oxychloride or *N*,*N'*-dicyclohexylcarbodiimide, were reported recently[10-12].

The author observed that carbobenzoxy-L-glutamine esters in pyridine solution were dehydrated to the corresponding cyano compounds in excellent yield by the action of *p*-toluenesulfonyl chloride, phosphorous oxychloride or thionyl chloride at 50°C for 30 to 50 min. *p*-Toluenesulfonyl chloride was the most suitable dehydrating reagent in these cases. Methyl γ-cyano-α-L-carbobenzoxyaminobutyrate (IIIa) was obtained as long crystalline needles, m. p. 52°C, from ethyl acetate-petroleum benzine mixture. The corresponding ethyl ester IIIb was obtained as crystalline leaflets, m. p. 60°C, from the same solvent system.

The infrared spectra of these cyano compounds showed characteristic nitrile absorption in the 2250 cm^{-1} region.

Hydrogenation of Methyl γ-Cyano-α-L-carbobenzoxyaminobutyrate. — Methyl γ-cyano-α-L-carbobenzoxyaminobutyrate was hydrogenated in a pressure bottle under various conditions as listed in the table.

After the catalyst was removed by filtration, the reaction mixture was hydrolyzed with hydrochloric acid, and the hydrolyzate was analyzed qualitatively by paper chromatography and quantitatively by colorimetry.

The main product was either proline or

ornithine, and the major side product was glutamic acid in all cases. One more ninhydrin positive spot which was believed to be δ-hydroxy-*n*-valine was present in some cases (Exp. no. 1-6, 11).

In order to determine the yield of proline by the ninhydrin method, ammonia formed in the hydrogenation was removed from the hydrolyzates by the addition of aqueous sodium hydroxide and evaporation under diminished pressure. The residue was dissolved in water and evaporated to dryness twice more, and the final residue was dissolved in water and adjusted pH to 7 with hydrochloric acid. The composition of this solution was determined colorimetrically by the ninhydrin method as usual[13]. The yield of proline was calculated from the optical densities at 440 and 570 mμ.

As catalyst for hydrogenation, silk-palladium[14], silk-platinum[15], silk-rhodium[16] and Raney nickel were used.

In aqueous solvent, silk-palladium catalyst produced proline as the main product with some ornithine, glutamic acid and δ-hydroxy-*n*-valine as by-products (Exp. no. 1-7). In acetic acid no hydrogenation occurred and glutamic acid was the only reaction product observed on paper chromatogram (Exp. no. 8). Rather low yield of proline and relatively high yield of ornithine was observed in water or water-methanol system (Exp. no. 1, 2). The pH of the reaction mixture was 9 and the high pH of the reaction media was believed responsible for the increased yield of ornithine. Water-acetic acid system increased the yield of proline (Exp. no. 3—6).

The three other catalysts, silk-platinum, silk-rhodium and Raney nickel, produced ornithine as almost the sole product in water-acetic acid mixture (Exp. no. 9—11). In these cases, only traces of proline were detected on paper chromatogram, and yield of ornithine was estimated to be over 80%.

The schematic representation of the hydrogenation yielding proline, ornithine, glutamic acid and δ-hydroxy-*n*-valine from γ-cyano-α-carbobenzoxyaminobutyric ester is shown in Scheme 1.

Hydrogenation of aldimine (C) to yield ornithine ester (D) is competitive with hydrolysis to yield aldehyde intermediate (E) which forms a pyrroline ring (F) by spontaneous ring closure. The pyrroline ring is hydrogenated to yield a pyrrolidine ring (G). The

aldehyde intermediate (E) is also hydrogenated to form δ-hydroxy-*n*-valine ester (H).

According to this scheme, Raney nickel, silk-platinum and silk-rhodium are highly active catalysts for the reduction of aldimine (C), but silk-palladium has low activity; consequently the hydrolytic reaction of aldimine to produce aldehyde (E) occurs predominantly.

Experimental*

Carbobenzoxy-L-glutamine Methyl Ester (IIa).—Carbobenzoxy-L-glutamine (I), 28 g. (100 mmol.), was dissolved in 200 ml. of methanol containing thionyl chloride, 0.6 g. (5 mmol.), and the mixture was allowed to stand at 15°C for 48 hr. The methanol was distilled off under reduced pressure, and the residual crystalline product was washed thoroughly with cold water and dried. The crude product was recrystallized from methanol-ether. Aggregated colorless needles. Yield 25 g. (85%), m. p. 141~142°C (lit. 140~141°C[8]). $[\alpha]_D^{18}$ −23.6° (*c* 3, MeOH) (lit. $[\alpha]_D^{23}$ −19.4° (*c* 1, MeOH[8])).

Found: N, 9.26. Calcd. for $C_{14}H_{18}O_5N_2$: N, 9.52%.

From the mother liquor of recrystallization a colorless syrup was obtained which became a solid of very low melting point after several days. Elementary analysis and infrared spectra showed that this compound was the alcoholytic product of IIa, dimethyl carbobenzoxy-L-glutamate.

Found: C, 58.27; H, 6.26; N, 4.51. Calcd. for $C_{15}H_{19}O_6N$: C, 58.24; H, 6.19; N, 4.53%.

Carbobenzoxy-L-glutamine Ethyl Ester (IIb).—This compound was prepared from carbobenzoxy-L-glutamine, 14 g. (50 mmol.), and thionyl chloride 0.6 g. (5 mmol.), in 100 ml. of ethanol according to the procedure described for the preparation of the methyl ester IIa. Aggregated needles. Yield 80%, m. p. 125~126°C, $[\alpha]_D^{18}$ −20.6° (*c* 3, MeOH).

Found: C, 58.55; H, 6.53; N, 8.98. Calcd. for $C_{15}H_{20}O_5N_2$: C, 58.43; H, 6.54; N, 9.09%.

Methyl γ-Cyano-α-L-carbobenzoxyaminobutyrate (IIIa).—To a solution of carbobenzoxy-L-glutamine methyl ester (IIa), 18.4 g. (626 mmol.) in pyridine (120 g.), *p*-toluenesulfonyl chloride, 15 g. (788 mmol.) was added, and the mixture kept at 50°C for 30 min. The resulting dark red solution was concentrated under reduced pressure to obtain an oily residue, which was treated with 30 ml. of water and extracted three-times with ethyl acetate. The combined ethyl acetate extracts were washed successively with diluted hydrochloric acid, water, aqueous sodium bicarbonate and water, then decolorized with active charcoal and dried over magnesium sulfate. The concentrated ethyl acetate solution, to which petroleum benzine had been added just to the cloudy point, was stored in a refrigerator overnight. Long featherlike needles were collected and recrystallized from an ethyl acetate-petroleum benzine mixture to yield 14.2 g. (82%) of the ester (IIIa). M. p. 51~52°C, $[\alpha]_D^{21}$ −34.5° (*c* 3, MeOH).

Found: C, 60.82; H, 5.80; N, 10.04. Calcd. for $C_{14}H_{16}O_4N_2$: C, 60.86; H, 5.84; N, 10.14%.

* All melting points are not corrected.

Ethyl γ-Cyano-α-L-carbobenzoxyaminobutyrate (IIIb).—This compound was prepared as described for the methyl ester IIIa from carbobenzoxy-L-glutamine ethyl ester (IIb). Crystalline leaflets. Yield 70%, m. p. 59~60°C, $[\alpha]_D^{18}$ −30.7° (*c* 3, MeOH).

Found: C, 61.85; H, 6.15; N, 9.51. Calcd. for $C_{15}H_{18}O_4N_2$: C, 62.05; H, 6.25; N, 9.65%.

L-Proline.—In a 100 ml. autoclave were placed methyl γ-cyano-α-L-carbobenzoxyaminobutyrate (IIIa), 2.76 g. (10 mmol.), water, 15 ml., acetic acid, 10 ml. and silk-palladium catalyst, 138 mg. An initial pressure of 80 kg./cm² of hydrogen was applied. After 2 hr. of shaking at 120°C, the reaction was stopped, and the catalyst was removed by filtration. The reaction mixture was concentrated under reduced pressure, then hydrolyzed with 60 ml. of 3 N hydrochloric acid for 3 hr. After the hydrolyzate was evaporated in vacuo to remove excess hydrochloric acid, the residue was dissolved in 300 ml. of deionized water and passed through a column (16×400 mm.) of Amberlite CG-45 (OH cycle) then CG-50 (H cycle). The combined effluents and washings were evaporated to dryness. The residue was taken up in absolute ethanol and the proline precipitated by addition of ether. Repeated recrystallization gave 0.75 g. (65%) of non-hygroscopic white crystals of optically and chromatographically pure L-proline. The identity of thus obtained L-proline with authentic L-proline was also confirmed by infrared spectra. M. p. (decomp.) 216~218°C (lit. 226~228°C[1]), $[\alpha]_D^{23}$ −83.0° (*c* 1, H_2O) (lit. $[\alpha]_D^{24}$ −84.6°[1]).

Found: N, 12.02. Calcd. for $C_5H_9O_2N$: N, 12.17%.

D-Ornithine Hydrochloride.—In a 100 ml. autoclave were placed methyl γ-cyano-α-D-carbobenzoxyaminobutyrate (prepared starting from D-glutamic acid) (IIIa), 5.00 g. (18.1 mmol.), acetic acid, 30 ml. and Raney nickel catalyst prepared from 2 g. of the alloy*. High pressure hydrogenation at 90 kg./cm² of initial pressure at 100°C was continued for 2 hr. After removal of the catalyst by filtration and the acetic acid by vacuum evaporation, the residue was hydrolyzed with concentrated hydrochloric acid for 3 hr. under reflux. After excess of hydrochloric acid was removed by vacuum evaporation, the residue was diluted to 100 ml. and adjusted pH to 3 by addition of sodium bicarbonate. Hydrogen sulfide gas was bubbled to precipitate traces of nickel ion, the filtrate was evaporated to dryness. The residue was extracted three times with 95% ethanol. The combined ethanol extract was treated with pyridine to obtain crude crystals of D-ornithine hydrochloride which was recrystallized three times from water-ethanol. Yield 2 g. (63%), m. p. (decomp.) 227~228°C (lit. 236~237°C[10]), $[\alpha]_D^{20}$ −21.7° (*c* 3, 6 N HCl) (lit. −22.5°[10]).

Found: N, 16.48. Calcd. for $C_5H_{13}N_2O_2Cl$: N, 16.61%.

* The alloy was added to 20 ml. of 20% aqueous sodium hydroxide solution, and the mixture was warmed at 80°C for 20 min. The sodium hydroxide solution was decanted, and the catalyst was washed three times with water and twice with acetic acid by decantation.

Summary

1. Novel syntheses of optically active proline and ornithine from optically active glutamine are described.

2. Carbobenzoxy-L-glutamine esters were dehydrated to γ-cyano-α-L-carbobenzoxyaminobutyric acid esters with *p*-toluenesulfonyl chloride, phosphorous oxychloride or thionyl chloride.

3. Hydrogenation of γ-cyano-α-L-carbobenzoxyaminobutyric acid esters in aqueous solvent systems were effected by silk-palladium catalyst to yield mainly L-proline.

4. By hydrogenation in the presence of Raney nickel in non-aqueous solvent, L-ornithine was obtained.

The author wishes to express his hearty thanks to Professor Shiro Akabori and Dr. Yoshiharu Izumi for their cordial guidance and encouragement throughout this work. He is also grateful to Miss Kiku Koike and Miss Masako Kawakita for microanalysis.

Electrochemical Fluorination of 2, 2, 3, 3-Tetrafluoro-1-propanol

By Shunji NAGASE, Hajime BABA and Rimpei KOJIMA

(Received August 27, 1962)

Earlier work[1] of the present authors has shown that the electrochemical fluorination of alcohols gives perfluorocarboxylic acids in a significant yield. The present paper describes work extended further to the fluorination of C3 fluoroalcohol, 2, 2, 3, 3-tetrafluoro-1-propanol. The fluorocarboxylic acid with the corresponding number of carbon atoms, 3*H*-tetrafluoropropionic acid, which is easily obtained by oxidation from the C3 fluoroalcohol, was also fluorinated for the sake of comparison.

It is well known that the effect of enhancing the oil repellency of cotton fabrics treated by derivatives of perfluorocarboxylic acids or fluoroalcohols is markedly lessened if one hydrogen atom is present, instead of fluorine, at the ω-position of these fluorochemicals[2]. The ω-hydrogen of fluoroalcohols is relatively stable to chlorination[3]. From these facts, along with the results obtained from a series of electrochemical fluorinations of esters[4], ketones[5], aldehydes[6] and ethers[7], undertaken in order to prepare perfluorocarboxylic acids, the electrochemical fluorination of fluoroalcohols seemed of interest 2, 2, 3, 3-tetrafluoro-1-propanol was taken up.

No report has been made on the fluorination of fluoroalcohols. As expected, the ω-hydrogen was substituted for by fluorine, and perfluoropropionic acid containing a small amount of trifluoroacetic acid was obtained in quite a good yield from 2, 2, 3, 3-tetrafluoro-1-propanol. The yield was much higher than that obtained from propanol[1]. On the other hand, the amount of perfluorocarboxylic acid obtained from 3*H*-tetrafluoropropionic acid was extremely small.

The mechanism of the formation of perfluorocarboxylic acid fluorides from the fluoroalcohols should be similar to that for common alcohols[1].

Experimental

Materials.—2, 2, 3, 3-Tetrafluoro-1-propanol, given for research purposes by the Osaka Metal Industries Co., was purified by fractional distillation. 3*H*-Tetrafluoropropionic acid was prepared in this laboratory from 2, 2, 3, 3-tetrafluoro-1-propanol by oxidation with potassium permanganate according to Berry's method[8]. Hydrogen fluoride of about 99.4% purity was furnished by the Osaka Metal Industries Co.

Apparatus.—The apparatus used for this work consisted essentially of a nickel electrolytic cell of a 1 l. capacity, provided with a reflux codenser at the top and a drain at the bottom, a sodium fluoride pellet tube, and a pair of polyethylene bottles in which perfluorocarboxylic acid fluorides generated from the cell reacted with water and were converted into perfluorocarboxylic acids. In this system, gaseous products which are inert to water are allowed to escape as gases. Nickel electrodes with an effective surface area of 9.2 dm^2 were used as usual. The details of the apparatus have been fully described previously[1,4].

Standard Procedure.—Hydrogen fluoride (1 l.) was introduced into the cell, and, in order to remove a trace of water, electrolysis was carried out in a nitrogen atmosphere, prior to the addition of the sample, with the anodic current density of 2.7 A./dm^2 and at 5~6°C, until the cell voltage rose to 5.7 V. Then 35 g. (0.265 mol.) of 2, 2, 3, 3-tetrafluoro-1-propanol was introduced into the cell, and electrolysis was carried out with the anodic current density of 2.7 A./dm^2 at about 5.2~5.6 V. and at 5~6°C until the cell voltage rose to 6.0 V. The amount of electricity required for this fluorination reaction was 55.4 A. hr.; the same amout of electricity was supplied for the reaction under other current densities and temperatures.

In the case of 3*H*-tetrafluoropropionic acid, 38.7 g. (0.265 mol.) of the sample was used. The amount of electricity required to raise the cell voltage to 6.0 V. was 44.4 A. hr. at 5~6°C, with the anodic current density of 2.7 A./dm^2.

By the same method as has been reported before, perfluorocarboxylic acids were obtained as their sodium salts; these were analyzed quantitatively by the base-line technique of the infrared absorption spectrum.

Results and Discussion

Electrolysis was carried out under a variety of operating conditions, achieved by changing the current density and the cell temperature, in order to find the conditions which would make the fluorination reaction mild and which would give the products in a good yield. The results are shown in Table I. The calculation of the current efficiencies shown was based on the amount of electricity assumed to be required to form fluorine by discharging the fluoride ion which would substitute for hydrogen in the sample. This means that the amount of electricity corresponding to that needed for the formation of 3 mol. of fluorine would be required to convert 1 mol. of 2, 2, 3, 3-tetrafluoro-1-propanol into 1 mol. of sodium perfluoropropionate.

In general, the yield of perfluoropropionic acid increased with an increase in the anodic current density and in the temperature of fluorination, but the amount of degraded acid, trifluoroacetic acid, formed also increased. Under the reaction conditions used, perfluorocarboxylic acids were obtained in the highest yield with an anodic current density of 1.6 A./dm^2 and at 16°C. Though the ratio of trifluoroacetic acid to perfluoropropionic acid decreased when the reaction was carried out at a lower temperature (which shows the reaction to be milder), the yield of perfluorocarboxylic acids decreased considerably. The least degraded products were obtained by the reaction at −10°C, with an anodic current density of 2.7 or 1.6 A./dm^2. The product obtained at −10°C with an anodic current density of 1.1 A./dm^2 contained rather a higher percentage of trifluoroacetic acid. This might be attributed to the smaller degree of agitation brought about by the evolved gases and to the fact that the reaction was less mild, because the rate of gas evolution should be smaller under this condition.

It is interesting to note that the composition of the perfluorocarboxylic acids obtained

* Anodic current density

** The amout of electricity supplied for this reaction is 41 A. hr., because the cell voltage rose to 6.2 V. at this point.

by the fluorination of 2, 2, 3, 3-tetrafluoro-1-propanol is almost identical with those obtained from propanol[1], propyl propionate[4], diethyl ketone[5], or dipropyl ether[7]. As expected, the composition of the products formed was not affected by the change in the anodic current density.

The mechanism for the formation of perfluorocarboxylic acid fluorides from fluoroalcohols is possibly similar to that for common alcohols[1]. This involves the first attack by fluorine on the α-carbon atom of the fluoroalcohols, and dehydrofluorination followed by exhaustive fluorination of the fluorocarboxylic acid fluorides thus formed into perfluorocarboxylic acid fluorides.

For the sake of comparison, electrochemical fluorination of 3*H*-tetrafluoropropionic acid was carried out with an anodic current density of 2.7 A./dm^2 at 5~6°C, and of 1.6 A./dm^2 at 16°C and at 5~6°C. By these reactions, the sample was degraded and fragmented seriously; only a trace of perfluorocarboxylic acids (0.2, 0.2 and 0.1 g. respectively) was obtained as their sodium salts. The product consisted of trifluoroacetic acid and perfluoropropionic acid in the ratio of 68 : 32, 61 : 39, and 60 : 40 under the respective reaction conditions given above. One reason for this result might be that given by Simons et al.[9] for the electrochemical fluorination of carboxylic acids. 3*H*-Tetrafluorocarboxylic acid is a highly fluorinated acid, strong enough to form the $HC_2F_4CO_2^-$ ion in hydrogen fluoride; the Kolbe-type electrochemical process would then decompose this ion into fluorocarbons and carbon dioxide.

With both samples, a trace of polymeric material (0.2~0.3 g.) was found in the residue in the electrolytic cell.

9) J. H. Simons et al., *J. Electrochem. Soc.*, **95**, 53 (1949).

Summary

Perfluoropropionic acid, accompanied by a small amount of trifluoroacetic acid, was obtained in a good yield by the electrochemical fluorination of 2, 2, 3, 3-tetrafluoro-1-propanol. The yield or current efficiency increased with an increase in the anodic current density and cell temperature. Although the yield decreased at lower temperatures, the reaction became milder, giving a smaller amout of trifluoroacetic acid in the product. The composition of the perfluorocarboxylic acids obtained by this fluorination reaction is very similar to that of those obtained by the fluorination of propanol, propyl propionate, diethyl ketone, and dipropyl ether. Only a trace of perfluorocarboxylic acid was formed by the electrochemical fluorination of 3*H*-tetrafluoropropionic acid.

The authors are much indebted to Professor Ikumi Kagawa of Nagoya University for his invaluable advice and encouragement throughout this work. They wish also to express their thanks to Osaka Metal Industries Co. for supplying the chemicals used in this work.

Sterically-hindered Organosilicon Compounds Containing Cyclohexyl Groups. I. Reactions of Organolithium Compounds with Tricyclohexylfluorosilane

By Michio TAKAKUSA

(Received August 29, 1962)

Since organolithium compounds were reported to be very effective in obtaining highly-substituted organosilicon compounds[1], most studies on steric hindrance have been done with the reactions between silicon tetrachloride and alkyl- or aryl-lithiums. By these reactions tetra(*o*-phenoxyphenyl)silane[2], tetra-*o*-anisylsilane[3] and tetra-*o*-tolylsilane[3,4] were successfully obtained, while, with 1-naphthyl[5],

1) For example, H. Gilman and R. N. Clark, *J. Am. Chem. Soc.*, **68**, 1675 (1946).
2) K. Oita and H. Gilman, *J. Org. Chem.*, **21**, 1009 (1956).
3) H. Gilman and G. N. R. Smart, ibid., **15**, 720 (1950).
4) G. N. R. Smart, H. Gilman and H. W. Otto, *J. Am. Chem. Soc.*, **77**, 5193 (1955).
5) H. Gilman and C. G. Brannen, ibid., **73**, 4640 (1951).

2-biphenylyl[6], cyclohexyl[7] and isopropyl[8] groups, only a trisubstituted silane was obtained even when an excess of the lithium compound was used.

$$R_3SiCl + RLi \not\longrightarrow R_4Si$$

R ; 1-$C_{10}H_7$, *o*-Ph-C_6H_4, C_6H_{11} or *iso*-Pr

An attempt to introduce a third *t*-butyl group was unsuccessful in the reaction of di-*t*-butyldichlorosilane with the lithium compound[9].

These results provide some rough idea about the steric nature of those groups, but more detailed knowledge on the steric hindrance can be obtained by comparing difficulties with which various types of groups are introduced into a fixed radical (for example, R_3Si-).

Advantage of using fluorosilanes in preparation of sterically-hindered organosilicon compounds was shown by Eaborn[10] who paid attention to the smaller atomic size of fluorine. Thus, Grignard reactions with fluorosilanes gave many compounds that had not been obtained through interaction of Grignard reagents and chlorosilanes.

$$(C_6H_{11})_2SiF_2 + C_6H_{11}MgX \rightarrow (C_6H_{11})_3SiF$$

It was proved by Petrov and Chernysheva[11] that the feature was the case also in reactions of organolithium compounds. They reported that the combination of fluorosilanes and the alkyl- or aryl-lithium gave three tetraorgano-substituted silanes, tetra-1-naphthylsilane, tetraisopropylsilane and tetracyclohexylsilane, which had not been obtained by the reactions with chlorosilanes.

At the present stage, an interaction of alkyllithium with alkylfluorosilanes under drastic conditions is thought to be the most effective way of obtaining a highly-substituted organosilicon compound with some bulky groups, and hence, reactions of some organolithium compounds with tricyclohexylfluorosilane were studied in the present work.

$$(C_6H_{11})_3SiF + RLi \rightarrow$$

R ; *n*-Bu, *iso*-Pr, C_6H_{11} or Ph

Prolonged treatment of tricyclohexylfluorosilane with an excess of butyllithium in boiling petroleum ether (90~110°C)[12] yielded 41% of tricyclohexylbutylsilane which melts at 160°C. This compound was identical with tricyclohexylbutylsilane[13] obtained from hydrogenation of triphenylbutylsilane, but not the same as the tricyclohexylbutylsilane[11] that Petrov and Chernysheva obtained from a similar butyllithium reaction[14]. Tricyclohexylphenylsilane was obtained in a pretty high yield from the reaction after 12 hrs' refluxing in petroleum ether. Tricyclohexylfluorosilane did not react with an excess of isopropyllithium nor an excess of cyclohexyllithium even at an elevated temperature. The results obtained here show that the presence of three cyclohexyl groups on a silicon atom allows introduction of only a less bulky group such as *n*-alkyl or phenyl but not that of the *sec*-alkyl group, though[14] tetracyclohexylsilane has been reported by Petrov and Chernysheva[11] to be obtained through a similar route. No evidence was obtained that would indicate any difference in the reactivity between isopropyl and cyclohexyl groups.

Experimental*

Tricyclohexylfluorosilane. — A typical example was shown here. A mixture of 5.2 g. of tricyclohexylsilanol, 350 ml. of ethanol and 50 ml. of 58% hydrofluoric acid solution was kept at about 70~75°C for 2.5 hr., and then poured onto 1 l. of cold water. The product was extracted with petroleum ether (50~70°C), and the extract dried over Drierite. On concentration of the extract, 2.3 g. of tricyclohexylfluorosilane melting at 44.5~46°C was obtained. Recrystallization from ethanol gave 2.1 g. of the fluorosilane, m. p. 45.8~46.5°C (reported[15], 45~46°C).

Isopropyl Bromide. — Reagent grade isopropyl bromide was dried over Drierite and distilled. B. p. 59.2~59.4°C.

Cyclohexyl Bromide.—The bromide was prepared by introducing hydrogen bromide to cyclohexanol. A fraction boiling at 74~76°C/33 mmHg was collected. n_D^{20} 1.4866. A commercial material was also used after distillation.

Petroleum Ether.—High boiling petroleum ether was shaken with concentrated sulfuric acid until it did not give a yellow color, washed with alkali and water repeatedly, dried over calcium chloride and then over sodium, and distilled again. A fraction boiling at about 90~110°C was collected and dried over sodium.

Tricyclohexylbutylsilane.—Butyllithium was prepared from 1.2 g. of lithium and 10.2 g. of butyl

bromide in the usual method[16]. To the butyllithium solution in ethyl ether, 4.1 g. of tricyclohexylfluorosilane in 30 ml. of ethyl ether was added with stirring, the mixture warmed to reflux for 8 hr., ether distilled off, 40 ml. of petroleum ether added, and the content of the flask heated to reflux (oil bath, 120~130°C) for 7 hr. After cooling, some petroleum ether was added, and the mixture was shaken with about 150 ml. of water. The organic layer was washed with water, and dried over anhydrous sodium sulfate. Concentration of the liquid gave 1.5 g. of tricyclohexylbutylsilane melting at 156~159°C. From the mother liquor, on chromatography, was obtained 0.4 g. of crude material with a combined yield of 41%. Duplicated recrystallization from benzene-ethanol gave pure material melting at 159.2~160.0°C. Further recrystallization did not raise the melting point. (Found: C, 78.90; H, 12.08. Calcd. for $C_{22}H_{42}Si$: C, 78.95; H, 12.65%.) The infrared spectrum of this compound was completely identical to that of tricyclohexylbutylsilane obtained by hydrogenation of triphenylbutylsilane, the mixed melting point with the authentic sample did not show any depression.

Tricyclohexylisopropylsilane (Attempted).—Isopropyllithium was prepared in ethyl ether from 0.9 g. of lithium shots and about 10 g. of isopropyl bromide. Preparation in petroleum ether was not successful. To the isopropyllithium solution was added 1.8 g. of tricyclohexylfluorosilane dissolved in 20 ml. of ethyl ether, the mixture was refluxed for 4 hr., the ether was substituted by petroleum ether, and refluxed for 10 hr. The reaction mixture was worked up in the same way as above, but only crude tricyclohexylfluorosilane, m. p. 43~46°C, was recovered.

Tetracyclohexylsilane (Attempted).—Cyclohexyllithium solution was prepared from 17 g. of lithium and 162.3 g. of cyclohexyl bromide in petroleum ether, and 2.5 g. of tricyclohexylfluorosilane dissolved in 20 ml. of petroleum ether was added to it. The mixture was refluxed (oil bath, 150~160°C) for 12 hr., and worked up in the usual way. Tricyclohexylfluorosilane was recovered.

Tricyclohexylphenylsilane. — Phenyllithium was prepared in the usual way[16] from 1.8 g. of lithium and 16.8 g. of phenyl bromide in 140 ml. of ethyl ether. To the stirred phenyllithium solution 3.7 g. of tricyclohexylfluorosilane dissolved in 20 ml. of ethyl ether was added, the mixture refluxed for 3 hr., the solvent substituted by petroleum ether, and then refluxed (oil bath, 100°C) for 12 hr. The reaction mixture was worked up in the usual way, and 4.1 g. of crude material melting at 202~207°C was obtained. Recrystallization from petroleum ether-ethanol gave 3.2 g. (72%) of tricyclohexylphenylsilane melting at 206.8~208.2°C. Further recrystallizations from petroleum ether-ethanol did not change the melting point. Infrared spectrum offered a structural support.

Found: C, 81.21; H, 10.80. Calcd. for $C_{24}H_{38}Si$: C, 81.28; H, 10.80%.

Summary

The reactions of tricyclohexylflurosilane with *n*-butyl-, phenyl-, isopropyl- and cyclohexyllithiums in boiling petroleum ether (90~110°C) were studied, and tricyclohexylbutylsilane and tricyclohexylphenylsilane were prepared (41 and 72%, respectively) for the first time. A secondary alkyl group can not be bonded to the silicon of tricyclohexylsilyl group even under these drastic conditions.

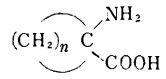
Reactions of Alicyclic Aminonitrile

By Rokuro SUDO and Shigehiro ICHIHARA

(Received September 1, 1962)

α-Aminonitriles are generally unstable and directly hydrolyzed to the corresponding amino acids commonly without their isolation in Strecker's synthesis.



I: $n=5$
I': $n=4$

In an attempted synthesis of alicyclic amino acids I, I', some of which have been known as physiologically interesting substances[1,2], the authors found some characteristic reactions of alicyclic aminonitriles.

1-Aminocyclohexylonitrile (II) could be isolated only as an oily product by ether extraction from the reaction mixture of cyclohexanone, potassium cyanide and ammonium chloride, and this aminonitrile was characterized by the quantitative conversion into its benzoyl-derivative III and by hydrolysis to 1-aminocyclohexanecarboxylic acid (I).

This oily 1-aminocyclohexylonitrile (II) was, however, solidified after being kept at room temperature for a few weeks or heating under reduced pressure for a few hours giving a crystalline substance (m. p. 138°C). This substance was confirmed by elemental analysis and infrared spectrum to be 1, 1'-imino-dicyclohexylonitrile (V) and seemed to be identical with the compound, which Bucherer[3] isolated as a by-products in a rather low yield from the reaction mixture of aminonitrile and carbon dioxide. V was also hydrolyzed with concentrated hydrochloric acid giving I.

While, II was softly hydrolyzed in the presence of sodium hydroxide in the ethanol solution to give the compound of formula $C_{13}H_{22}ON_2$, which melted at 213°C. This compound was confirmed to be 2, 4-dicyclohexyl-iminazolidone-(5) (VI) by elemental analysis and infrared spectrum, which showed strong absorption bands at 3280 cm^{-1} (–NH–) and at 1710 cm^{-1} (ring forming amide), and then no band at 1500~1600 cm^{-1} region (free amide). Analogous to 2, 4-dicyclohexyl-5-thiaiminazolidone which was prepared by Gatewood[4] from α-aminonitrile and hydrogen sulfide, formation of VI was thought to proceed through the intermediate of V by the fact that V was similarly treated giving the same product VI. In addition, the structure VI may be explained by the following equation, because VI gave equimolecular I and ammonium chloride on heating with concentrated hydrochloric acid.

Moreover, V was allowed to stand with concentrated sulfuric acid at room temperature giving 1, 1'-iminodicyclohexanecarboximide sulfate (VII), which was neutralized yielding 1, 1'-iminodicyclohexanecarboximide (VIII). VIII was heated in 10% sodium hydroxide solution to give mono-amide IX, which was cyclized again to imide salt with

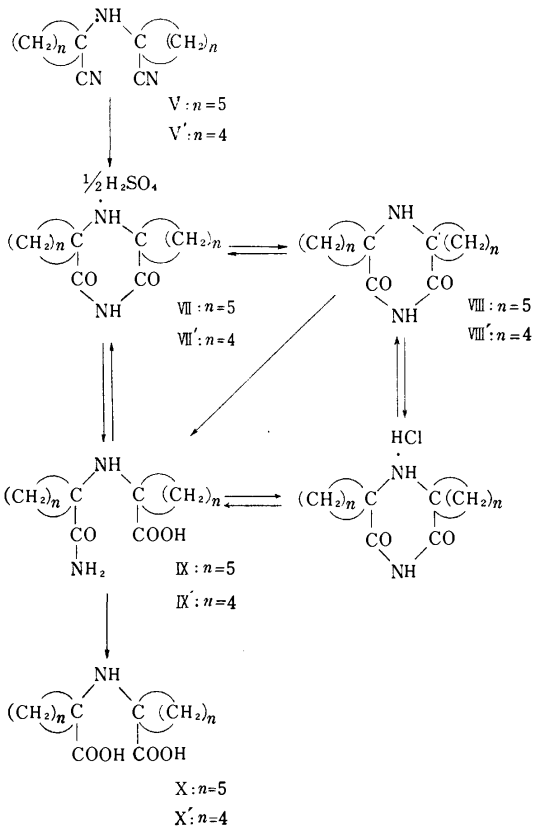
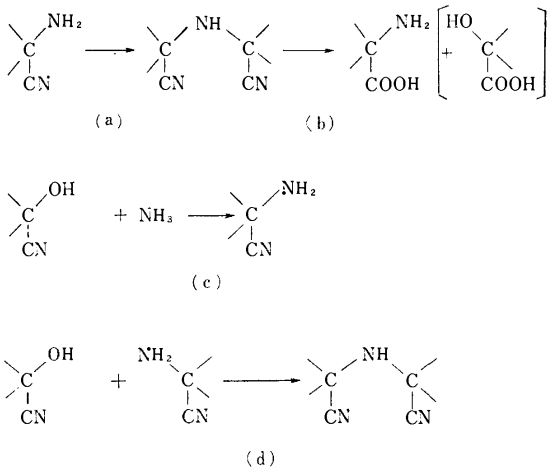
mineral acid, but was heated for a long time (16 hr.), giving 1, 1'-iminodicyclohexanecarboxylic acid (X).

This synthetic schema was also repeated beginning with cyclopentane derivatives, which involved physiologically interesting compounds[2], 1-aminocyclopentanecarboxylic acid (I') and 1, 1'-iminodicyclopentanecarboxylic acid (X'). 1, 1'-Iminodicyclopentylonitrile (V') was similarly prepared from 1-aminocyclopentylonitrile (II') but in a rather low yield.



In view of above results, it is very interesting that imino-dinitrile was synthesized easily from aminonitrile and was hydrolyzed to amino acid as following equations a and b. In addition, aminonitrile can be prepared from hydroxynitrile (Eq. c)[5] and imino-dinitrile from hydroxynitrile and aminonitrile (Eq. d)[6].



In this consideration, it was desirable to investigate the behavior of ammonolysis of iminodinitrile. In fact, it was discovered that 1, 1'-iminodicyclohexylonitrile (V) was heated with aqueous ammonia in a sealed tube giving 2 mol. of 1-aminocyclohexylonitrile (II), which was confirmed by conversion into its benzoyl-derivative.

Further experiments were tried in order to acertain that aliphatic iminodinitrile could be converted into α-aminonitrile. α, α'-Iminodipropionitrile (XII) was similarly treated

with aqueous ammonia giving 2 mol. of α-aminopropionitrile (XI), which was confirmed conversion into benzoyl derivative. In this case, the benzoyl derivative isolated was α-benzaminopropionic amide (XIII) which was hydrolyzed to DL-alanine (XIV) in good yield. XIII was also hydrolyzed with hydrochloric acid giving 1 mol. of XIV (90%) and was treated after ammonolysis giving 2 mol. of XIV (60%).

Experimental

Alicyclic Aminonitrile II, II''. — Aminonitriles were prepared by Strecker's method[7] and extracted with ether. The ether solutions were dried with anhydrous sodium sulfate and gave a syrupy residue after removal of the solvent. These syrups were confirmed to be aminonitrile by conversion into benzoyl derivatives and α-amino acids. Benzoyl derivatives III, III' were prepared by Schotten-Baumann's method. Aminonitriles were suspended in sodium bicarbonate solution and benzoyl chloride added under stirring. Precipitates were filtered off and recrystallized from ethanol-water giving prisms.

Alicyclic Amino Acid I, I'.—Aminonitriles were heated in ten times the volume of concentrated hydrochloric acid for 4 hr. The reaction mixtures were concentrated to half the volume and allowed to stand overnight. The precipitates of their hydrochloride IV, IV' were collected and gave prisms by recrystallization (from water). These hydrochlorides were dissolved in a little water and neutralized with sodium bicarbonate. The precipitates were collected and recrystallized from ethanol-water. Colorless crystals were obtained. These data are summarized in Table I.

Alicyclic 1, 1'-Iminodinitriles (V), (V').—Syrup of II or II' was warmed for 5~6 hr. under reduced pressure and allowed to stand overnight at room temperature. Solidified compounds were collected and recrystallized from ethanol giving prisms. The infrared spectrum of V showed -C≡N band at 2260 cm^{-1} and -NH- band at 3380 cm^{-1}. These data were summarized in Table II.

Hydrolysis of V.—A solution of V (5 g.) in 50 ml. of concentrated hydrochloric acid was heated for 4 hr. The reaction mixture was concentrated to 10 ml. volume and allowed to stand at room temperature. Two grams of precipitates was collected. This product was identical to IV.

2, 4-Dicyclohexyliminazolidon-(5) (VI). — To a solution of II (2 g.) in 10 ml. of ethanol was added 2 ml. of 10% sodium hydroxide solution. The mixture was refluxed on a water-bath for 6 hr. and allowed to stand overnight at room temperature. The precipitates were collected and recrystallized from ethanol giving 1 g. of colorless prisms, melted at 213°C.

Found: C, 70.27; H, 10.11; N, 12.51. Calcd. for $C_{13}H_{22}ON_2$: C, 70.23; H, 9.97; N, 12.60%.

Infrared spectrum of VI showed strong bands at 1710 cm^{-1} (-CONH-) and at 3280 cm^{-1} (-NH-). V was similarly treated to give the same product VI.

1, 1' - Imino - dicyclohexanecarboximide Sulfate (VII).—V (5 g.) was dissolved in 30 ml. of concentrated sulfuric acid under cooling and allowed to stand overnight at room temperature. The mixture was added in ice-water and then gave precipitates. This product was collected and recrystallized from water giving 4 g. of crystals, melted at 273~274°C (decomp.).

7) V. Zelinsky and G. Stadnikoff, ibid., 39, 1728 (1906).

Found: N, 9.40. Calcd. for $C_{14}H_{22}O_2N_2 \cdot 1/2 \cdot H_2SO_4$: N, 9.36%.

1, 1'-Iminodicyclohexanecarboximide (VIII).—VII (2 g.) was dissolved in small water and neutralized with a solution of sodium bicarbonate. The precipitated product was collected and recrystallized from ethanol giving 1 g. of colorless crystals, melted at 164°C.

Found: C, 67.52; H, 8.71; N, 11.30. Calcd. for $C_{14}H_{22}O_2N_2$: C, 67.17; H, 8.86; N, 11.19%.

Hydrochloride of VIII.—A solution of VIII in hydrochloric acid was concentrated to give precipitates. The product was collected and recrystallized from ethanol-water giving colorless crystals, melted at 268°C (decomp.).

Found: N, 9.63. Calcd. for $C_{14}H_{22}O_2N_2 \cdot HCl$: N, 9.67%.

In a similar manner, a solution of VIII in sulfuric acid gave VII.

Mono-amide of 1, 1'-Iminodicyclohexanecarboxylic Acid (IX).—Two grams of VIII was heated for 30 min. in 20 ml. of 10% sodium hydroxide solution. The mixture acidified with acetic acid to give precipitates. The product was collected and recrystallized from ethanol, giving 1.8 g. of colorless crystals, melted at 204°C (decomp.).

Found: C, 62.48; H, 8.84; N, 10.42. Calcd. for $C_{14}H_{24}O_3N_2$: C, 62.66; H, 9.02; N, 10.44%.

1, 1'-Iminodicyclohexanecarboxylic Acid (X).—One gram of IX was heated with 10ml. of 10% sodium hydroxide solution for 10 hr. After cooling, the mixture was acidified with acetic acid to give precipitates. This product was collected and recrystallized from ethanol-water giving 0.4 g. of crystals, melted at 134°C. (decomp.).

Found: C, 62.31; H, 8.63; N, 5.50. Calcd. for $C_{14}H_{23}O_4N$: C, 62.43; H, 8.61; N, 5.20%.

1, 1'-Iminodicyclopentanecarboximide Sulfate (VII').—Four grams of this sulfate from 5 g. of V' was obtained in a manner similar to VII and melted at 274~275°C (decomp.)

Found: N, 10.78. Calcd. for $C_{12}H_{18}O_{12}N_2 \cdot 1/2H_2 \cdot SO_4$: N, 10.33%.

1, 1'-Iminodicyclopentanecarboximide (VIII').—In a manner similar to VIII, 1.3 g. of this imide was obtained from 2 g. of VII' and melted at 146°C.

Found: C, 64.57; H, 8.05; N, 12.49. Calcd. for $C_{12}H_{18}O_2N_2$: C, 64.84; H, 8.39; N, 12.66%.

Mono-amide of 1, 1'-Iminodicyclopentanecarboxylic Acid (IX).—In a manner similar to IX, 1.5 g. of IX' was obtained from 2 g. of VIII' and melted at 188~181°C (decomp.).

Found: N, 11.25. Calcd. for $C_{12}H_{20}O_3N_2$: N, 11.66%.

1, 1'-Iminodicyclopentanecarboxylic Acid (X).—IX' (1 g.) was heated in 10 ml. of 10% sodium hydroxide solution for 16 hr. The mixture was treated in a manner similar to X giving crystals (0.4 g.), which did not show clear melting point and sublimed at high temperature (above 200°C).

Found: C, 60.41; H, 8.36; N, 5.73. Calcd. for $C_{12}H_{19}O_4N$: C, 59.73; H, 7.94; N, 5.81%.

Ammonolysis of 1,1'-Iminodicyclophexylonitrile.—V (1 g.) was heated with 30 ml. of 28% aqueous ammonia in a sealed tube for 6 hr. The reaction mixture was extracted with ether. The ether solution was dried with anhydrous sodium sulfate and afforded syrupy residue after removal of the solvent and the syrup was confirmed by conversion into benzoyl derivative in a manner similar to III. 1.8 g. of crystals was obtained, (m. p. 138°C) and was identical to III. The melting point did not depress by mixing III.

α, α'-Iminodipropionitrile (XII).—This iminodinitrile was prepared from acetaldehyde by Dubsky's method[6], m. p. 66.5°C (reported m. p. 68°C).

Ammonolysis of α, α-Imino-dipropionitrile.—XII (6 g.) was treated with 28% aqeous ammonia in a manner described above. Oily syrup (crude 7 g.) was obtained. This syrup (1 g.) was converted into benzoylderivative (2 g.), which melted at 230~231°C and was confirmed to be α-benzaminopropionic amide (XIII) by elemental analysis.

Found: C, 62.36; H, 6.36; N, 14.42. Calcd. for $C_{10}H_{12}O_2N_2$: C, 62.48; H, 6.29; N, 14.58%.

This amide (4 g.) was heated in 40 ml. of hydrochloric acid. The reaction mixture was concentrated to dryness. After removal of ammonium chloride, the ethanol solution was neutralized with aniline giving crystalline (3 g., m. p. 260°C (decomp.)), which was identical to DL-alanine (XIV).

Hydrolysis of XII with Hydrochloric Acid.—a) XII (5 g.) was heated in 50 ml. hydrochloric acid and treated in a manner described above giving crystals of XIV (3 g., 90% to 1 mol.).

b) XII (5 g.) was treated similarly after ammonolysis giving 4.2 g. of XIV (60% to 2 mol.).

The authors wish to express deep gratitude to Professor Masaki Ohta for his kind and constant guidance throughout this study and to Dr. Tadashi Sato for the measurement of the infrared spectrum.

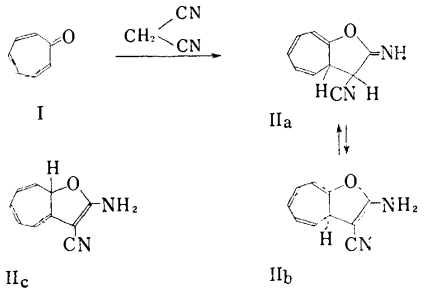
Synthesis of 1-Oxaazulan-2-imine Derivatives from Tropone[1]

By Tetsuo NOZOE, Toshio MUKAI and Tsunao SUZUKI*

(Received September 3, 1962)

The authors have investigated the reaction of tropones with an active methylene compound as a part of their continuing study of the chemistry of the troponoid system. A few years ago[2], it was found that the reaction of tropone (I) with malononitrile, in the presence of piperidine as a catalyst, afforded pale yellow crystals (II), m. p. 149°C, with a formula $C_{10}H_8ON_2$, in about 75% of yield. Since this reaction was considered to proceed by 1,8-addition mechanism[3,4], the authors proposed the structure of IIa or IIb for II[2]. A few months later, Kitahara and Doi[5] suggested that IIc would be more reasonable than IIa or IIb on the basis of its ultraviolet and infrared spectra.



In the present paper, the authors wish to report the results of the reexamination of the structure of II and dehydrogenation of II, which resulted in the formation of derivatives of 1-oxaazulan-2-imine (2*H*-cyclohepta[b]furan-2-imine) in a fairly good yield.

As shown in Fig. 1, the ultraviolet spectrum of II exhibits a maximum around 320 mμ, which can not be explained by IIa or IIb as pointed out by Kitahara and Doi[5]. In infrared spectrum of II (see experimental part), there is a sharp band at 2210 cm^{-1} for the cyano group conjugated with unsaturated bond, besides three bands at 3230~3460 cm^{-1} for amino

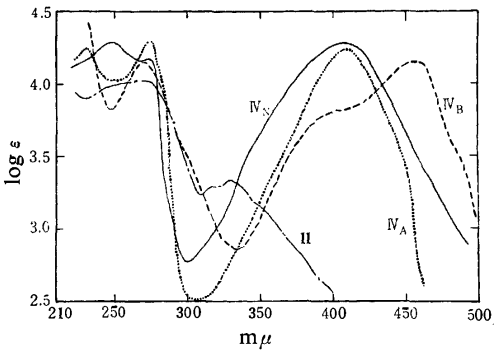


Fig. 1. UV spectra of II in methanol and of 3-cyano-1-oxaazulan-2-imine in methanol (IV_N), in 1 N HCl (IV_A) and in 1 N NaOH (IV_B).

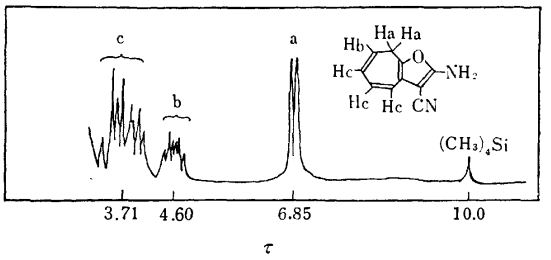

Fig. 2. NMR spectrum of II in pyridine (60 Mc.), with tetramethylsilane as an internal reference.

group. To elucidate the structure more clearly, the nuclear magnetic resonance spectrum of II was measured in a pyridine solution (Fig. 2). The signals appear as three groups, a, b and c with an area appropriate to 2, 1 and 3 protons respectively. The doublet signal a which appears at 6.85 τ with J=6.6 c. p. s. is ascribed to Ha and the multiplet signals b (centred at 4.60 τ) and c (centred at 3.71 τ) are attributed to Hb and Hc, respectively. This result is accommodated much better by the structure of 2-amino-3cyano-8*H*-cyclohepta-[b] furan (IId) than by IIa, II_b or IIc. The observed shift of the Ha peak to the lower field, compared with the NMR spectrum of cycloheptatriene[6], is ascribed to the paramagnetic shielding of the adjacent oxygen atom. 2-Amino-3-cyano-8*H*-cyclohepta [b] furan (IId) is

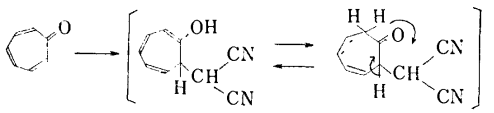
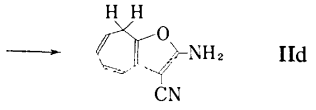
assumed to be formed through the intermediate[7] as depicted below.

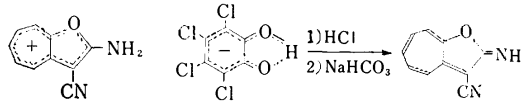


I



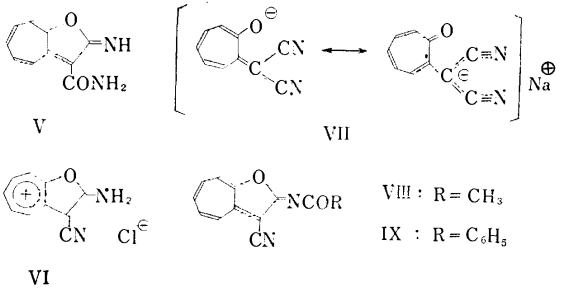
IId

The dehydrogenation of II with tetrachloro-1, 2-benzoquinone in benzene or chloroform afforded dark red complex (III). The treatment of III with dilute hydrochloric acid gave tetrachlorocatechol and 3-cyano-1-oxaazulan-2-imine (IV) in a good yield. When II was treated with selenium dioxide, the dehydrogenation was accompanied by simultaneous hydrolysis of the cyano group at 3-position and 3-carbamoyl-1-oxaazulan-2-imine (V), m. p. 192°C (decomp.), was obtained[8].



III IV

As shown in Figs. 1 and 3, the ultraviolet spectra of IV and V are very similar to that of 1-oxaazulan-2-one (2*H*-cyclohepta[b]furan-2-one)[9]. The infrared spectrum of IV shows an absorption band at 3300 cm^{-1} for the imino group and at 2207 cm^{-1} for the conjugated cyano group. In the infrared spectrum of V, there are bands at 3310 and 3155 cm^{-1} for the imino and amino groups and at 1650 cm^{-1} for the conjugated carbonyl group. IV and V are amphoteric substances, and soluble in both dilute acid and alkali. Passage of hydrogen chloride gas through a solution of IV in chloroform precipitated out the hydrochloride (VI) as pale yellow crystals, from which IV was regenerated by neutralization with sodium hydrogen carbonate. VI is much more stable than IV and it is possible to purify VI by sublimation under reduced pressure. Addition of sodium ethoxide to a solution of IV in chloroform gave the sodium salt VII as yellow crystals. From the fact that infrared spectrum



V VII

VI

VIII : R = CH_3
IX : R = C_6H_5

of VII showed two bands at 2210 and 2170 cm^{-1} for the cyano group, it is clear that the ring is opened as depicted above. The infrared spectrum of VII was similar to that of sodium troponate[10] (experimental part). There are no absorption bands from 2000 to 1600 cm^{-1}, but a band at 1595 cm^{-1}. It is not clear, however, whether this band should be due to the polarized carbonyl group or carbon-carbon double bond vibration as in the case of sodium troponate[10].

The ultraviolet spectra of IV in 1 N hydrochloric acid and 1 N sodium hydroxide solution are shown in Fig. 1. In an alkaline solution, the bathochromic shift ascribed to the formation of VII was observed, whereas in an acidic solution there is no remarkable shift in spite of the formation of VI.

Attempts to obtain 1-hydroxy-8, 8-dicyanoheptafulvene or its derivatives such as 1-methoxy-[11] or 1-acetoxy-8, 8-dicyanoheptafulvene did not succeed. For example, neutralization of VII with dilute acetic acid resulted in the ring closure to give IV. Acylation of

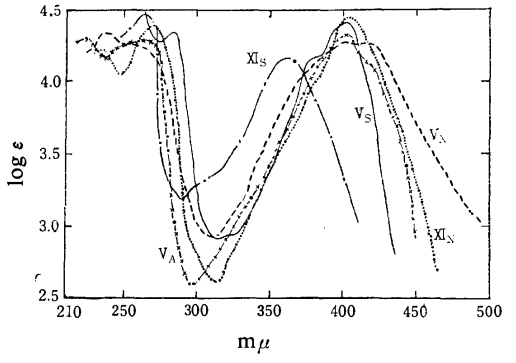


Fig. 3. UV spectra of 3-carbamoyl-1-oxaazulan-2-imine in methanol (V_N) in 1 N HCl (V_A) in conc. H_2SO_4 (V_S) and of 3-carbamoyl-1-oxaazulan-2-one in methanol (XI_N) and in conc. H_2SO_4 (XI_S).

7) In the addition reaction of tropones, the adducts same type as the intermediate have been obtained by. K. Takase and M. Yasunami (unpublished data), cf. Ref. 4.

8) Kitahara and Doi reported that dehydrogenation of II with selenium dioxide afforded 3-cyano-1-oxaazulan-2-imine, m. p. 161°C. Cf. Ref. 5.

9) S. Seto, *Sci. Repts. Tohoku Univ,, Ser. I*, 37, 367 (1954).

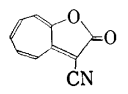
10) Y. Ikegami, *Kagaku-no-Ryoiki*, (*Extra* Vol.) 38, 70, Nankodo, Tokyo (1959).

11) Kitahara and Doi reported that, on using acetic anhydride as condensation reagent, reaction of tropolone methyl ether with malononitrile afforded 1-methoxy-8, 8-dicyanoheptafulvene, m. p. 206°C. Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

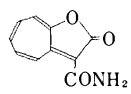
VII with acetyl or benzoyl chloride resulted also in the ring closure giving VIII or IX, which were obtained by acylation of IV. The infrared spectrum of VIII shows a band at 2164 cm^{-1} for the cyano group and at 1666 cm^{-1} for the carbonyl group. The latter supported the presence of the *N*-acetyl group rather than the *O*-acetyl group. The ultraviolet spectrum of VIII is shifted to a longer wavelength region than that of IV, because of the extension of the conjugate system (Fig. 4).

Previously, Nozoe and his coworkers reported that the reaction of tropolone methyl ether with ethyl cyanoacetate in the presence of sodium ethoxide afforded the azulene derivatives in a good yield[12]. However, Matsumura found that, under the same condition as above, the reaction of tropolone methyl ether and malononitrile resulted in the formation of the unknown compound, m. p. > 300°C, instead of the expected azulene derivative[13]. By comparison of the infrared spectra, it was found to be identical with VII. Furthermore, it was confirmed that, in the presence of sodium ethoxide, the reaction of VII with malononitrile did not yield the azulene derivatives, but resulted almost in the recovery of VII.

The heating of 3-cyano-1-oxaazulan-2-imine (IV) with 1 N hydrochloric acid gave 3-cyano-1-oxaazulan-2-one[14] (X) and 3-carbamoyl-1-oxaazulan-2-imine (V). On the other hand, X was not affected by heating with 1 N hydrochloric acid. This fact shows that the presence of imino group in IV assists the hydrolysis of the cyano group.



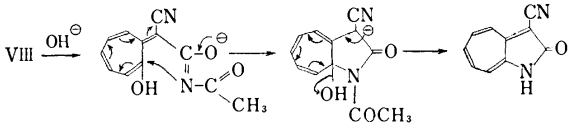
X



XI

The formation of V instead of IV, on dehydrogenation of II with selenium dioxide as mentioned before, may be explained as the result of hydrolysis of the cyano group with selenic acid. Upon treatment of IV with acid, an increase in acid concentration suppressed the hydrolysis of the imino group of 2-position. The same tendency was also observed in the acid-hydrolysis of V. The heating of V with 1 N hydrochloric acid afforded 3-carbamoyl-1-oxaazulan-2-one (XI) in a good yield, whereas heating of V in concentrated sulfuric acid resulted in the recovery of V accompanied with a small amount of XI. These facts indicated that, in an acid solution, IV and V were stabilized by the formation of the corresponding conjugate acid making the hydrolysis of the 2-imino group difficult. It is well known that the carbamoyl group of 1- or 3-position of azulenes is difficult to be hydrolyzed by acid treatment[15]. The heating of 3-carbamoyl-1-oxaazulan-2-one (XI) with concentrated or 50% sulfuric acid or the treatment of XI with sodium nitrite in sulfuric acid resulted almost in recovery of the starting material. The ultraviolet absorption spectra of V and XI are measured in methanol and concentrated sulfuric acid (Fig. 3). There is no distinguishable shift between V and its conjugate acid (in concentrated sulfuric acid), whereas the spectrum of the conjugate acid of XI is shifted to the shorter wavelength region as compared with that of XI in methanol.

The behavior of 3-carbamoyl-1-oxaazulan-2-imine (V) against alkali was studied by Nozoe and his coworkers[16] who discovered that V gave 3-cyano-1-azaazulan-2-one (3-cyano-cyclohepta[b]pyrole-2(1*H*)-one) (XII) in a quantitative yield. To obtain X exclusively, hydrolysis of the acylated compounds VIII or IX was attempted by using acid or alkali. The heating of VIII with dilute acid resulted in the formation of V and XI via IV. The treatment of VIII with dilute alkali, even ice-cooling, afforded unexpected XII in a good yield the formation of which is explained as follows.



XII

By application of the method mentioned above, it is possible to synthesize not only 1-oxaazulan-2-ones but 1-azaazulan-2-ones from the tropone derivatives.

The reaction with malononitrile was extended to other tropone derivatives. Almost in the same way as the case of II, 2-phenyltropone afforded the condensation product XIII as pale yellow crystals, m. p. 150°C, in about 80% of yield. On the basis of its ultraviolet spectrum (Fig. 4), infrared spectrum (experimental part) and analytical value, $C_{16}H_{12}ON_2$, XIII was proved to be the phenyl derivative

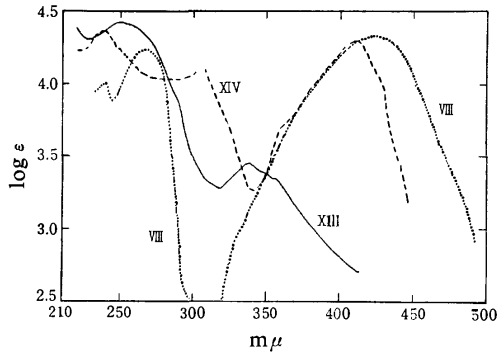

Fig. 4. UV spectra of VIII, XIII and 3-cyano-8-phenyl-1-oxaazulan-2-imine (XIV) in methanol.

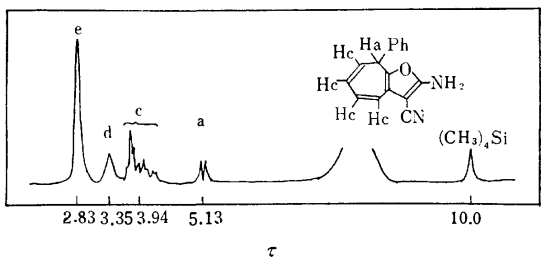

Fig. 5. NMR spectrum of XIII in acetone (60 Mc.). Tetramethylsilane as an internal reference.

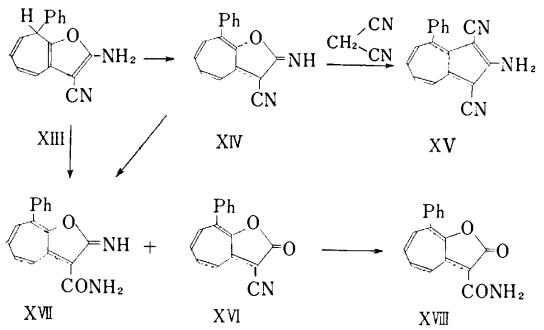
of II, 2-amino-3-cyano-8-phenyl-8*H*-cyclohepta-[b]furan. Especially, the NMR spectrum of XIII, shown in Fig. 5, furnished the additional evidence concerning the protons of XIII. There are four groups of the absorption signal, a, c, d and e with an area appropriate about 1 : 4 : 2 : 5 protons respectively. The signals a (doublet at 5.13τ, J=7.4 c. p. s.) and c (multiplet centred at 3.94τ) are ascribed to Ha and Hc of XIII and correspond to the signals a, and b and c of II (Fig. 2). The peak corresponding to b of II may be shifted to the lower field by the paramagnetic effect of the adjacent phenyl group and included to the signal c. The observed shift of Ha to the low field, compared with that of II, seemed due to the same effect of the phenyl group. The hydrogens of the phenyl group appear at 2.83τ and the signal d at 3.35τ seemed due to the amino group at 2-position of XIII.



The dehydrogenation of XIII with tetrachloro-1, 2-benzoquinone was carried out in two steps and 3-cyano-8-phenyl-1-oxaazulan-2-imine (XIV) was obtained. Application of malononitrile to XIV in the presence of *tert*-butylamine yielded 2-amino-1, 3-dicyano-4-phenylazulene (XV)[17]. The yield of XIV was about 50% and that of XV was about 45% from 2-phenyltropone. The structure of XV was confirmed by the independent synthesis of XV from 2-chloro-7-phenyltropone and malononitrile[18].

The heating of XIV with 4 N hydrochloric acid afforded 3-cyano-8-phenyl-1-oxaazulan-2-one (XVI) and 3-carbamoyl-8-phenyl-1-oxaazulan-2-imine (XVII) with the recovery of considerable amount of XIV. XVII was also obtained by the dehydrogenation of XIII with selenium dioxide. The heating of XVI in concentrated sulfuric acid gave 3-carbamoyl-8-phenyl-1-oxaazulan-2-one (XVIII).

These approaches to the synthesis of the compounds from XIV to XVIII are of considerable significance from the view point of the synthetic tool for derivatives of 1-oxaazulan-2-one and azulene, not only because of the advantage of yield but the simplicity of the method.

Experimental[19,20]

Condensation of Tropone (I) and Malononitrile (Formation of II).—To a solution of 5 g. (0.047 mol.) of I and 3.6 g. (0.052 mol.) of malononitrile in 20 ml. of ethanol was added 0.2 ml. of piperidine. The solution turned to dark red with the heat formation and gave pale yellow prisms immediately. After standing overnight, the filtration gave 6.4 g. (75% of yield) of II as pale yellow prisms, m. p. 141~143°C, which on recrystallization from ethanol showed m. p. 149°C. IR (Nujol): 3460, 3340, 3230, 2210, 1640, 1592, 1422, 1346, 1235, 1160, 1110, 1042, 993, 850, 763, 706 and 687 cm^{-1}.

Found: C, 69.80; H, 4.36; N, 16.18. Calcd. for $C_{10}H_8ON_2$: C, 69.75; H, 4.68; N, 16.27%.

Dehydrogenation of II with Tetrachloro-1, 2-benzoquinone (Formation of IV).—Addition of a solution of 1.5 g. (6.1 mmol.) of tetrachloro-1, 2-benzoquinone dissolved in benzene into a solution of 1 g. (5.8 mmol.) of II in 150 ml. of benzene resulted in immediate precipitation of dark red crystals. After let to stand for 30 min. at room

17) The method for synthesizing azulene derivatives from 1-oxaazulan-2-ones or 1-oxaazulan-2-imines was established by T. Nozoe, K. Takase and N. Shimazaki. Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

temperature, 2.2 g. (90% of yield) of complex (III), m. p. 130°C (decomp.) was filtered off. Three hundred milligrams of III ware also obtained by addition of 0.3 g. of tetrachloro-1,2-benzoquinone to a solution of 0.2 g. of II in 11 ml. of chloroform. IR (Nujol): 3340, 2220, 1672, 1587, 1345, 1270, 958, 805 and 751 cm^{-1}.

Found: C, 45.60; H, 1.83; N, 6.58. Calcd. for $C_{16}H_8O_3N_2Cl_4$: C, 45.96; H, 1.93; N, 6.70%.

To a suspension of 1 g. of III in 20 ml. of chloroform or benzene, 40 ml. of 1 N hydrochloric acid was added and the mixture was shaken. The chloroform or benzene layer, after separation, was extracted again with 20 ml. of 1 N hydrochloric acid, washed with water and dried over sodium sulfate. Evaporation of chloroform gave 240 mg. of tetrachlorocatechol, as yellowish crystals, m. p. 185~190°C. The extract with dilute hydrochloric acid was neutralized by addition of sodium hydrogen carbonate, during which orange red crystals separated out. Filtration afforded 400 mg. (90% of yield) of orange crystals (IV), m. p. 143°C (decomp.), which tended to decompose on recrystallization. Purification of IV was done through its hydrochloride as follow: Passing hydrogen chloride gas through a solution of IV in chloroform gave hydrochloride (VI) as yellow crystals, m. p. over 260°C. The hydrochloride could be sublimed at about 200°C and 3 mmHg. Addition of sodium hydrogen carbonate to an aqueous solution of VI gave 3-cyano-1-oxaazulan-2-imine (IV), m. p. 153°C (decomp.). IR (Nujol): 3300, 2207, 1676, 1598, 1498, 1271, 1106, 976, 958, 924, 875, 772, 756 and 720 cm^{-1}.

Found: C, 70.48; H, 3.34; N, 15.90. Calcd. for $C_{10}H_6ON_2$: C, 70.58; H, 3.55; N, 16.46%.

Dehydrogenation of II with Selenium Dioxide (Formation of V).—A solution of 300 mg. (1.7 mmol.) of II and 225 mg. (2.0 mmol.) of selenium dioxide in 5 ml. of methanol was refluxed for 30 min., during which dark brown precipitate separated out. After evaporation of methanol, the residue was washed well with 20 and 10 ml. of 1 N hydrochloric acid. The combined washing was neutralized by adding solid sodium hydrogen carbonate and extracted with chloroform. The extract was washed with water, dried over sodium sulfate and evaporated giving 130 mg. (60% of yield) of brownish orange crystals, m. p. 182°C (decomp.). Infrared spectrum of the product was completely superposed on that of 3-carbamoyl-1-oxaazulan-2-imine (V) (see below).

Sodium Salt (VII) of 1-Hydroxy-8,8-dicyanoheptafulvene.—*a) From IV.*—To a solution of 100 mg. of IV in 2 ml. of chloroform was added the sodium ethoxide, prepared from 30 mg. of sodium and 2 ml. of absolute ethanol, giving 100 mg. of orange yellow crystals (VII), m. p. over 300°C.

Found: N, 13.98. Calcd. for $C_{10}H_5ON_2Na$: N, 14.58%.

b) From Tropolone Methyl Ether.—To a ethanol solution of the sodium salt of malononitrile, prepared from 40 mg. of sodium, 50 mg. of malononitrile and 2 ml. of absolute ethanol, 100 mg. of tropolone methyl ether was added. After being stirred overnight, crystals separated out. Filtration gave 120 mg. of yellow crystals, m. p. over 300°C, infrared spectrum of which was completely the same as that of VII.

c) Regeneration of IV from VII.—Under the coexistence of a chloroform layer, a solution of 200 mg. of VII in 2 ml. of water was neutralized by adding 2 N acetic acid with vigorous stirring. The chloroform layer was separated, washed with water and dried over sodium sulfate. Evaporation of the chloroform afforded 70 mg. of orange red crystals, m. p. 145°C, (decomp.), which was identical with IV (from infrared spectrum).

VII was dissolved in dilute hydrochloric acid and the resulting solution was neutralized by addition of solid sodium hydrogen carbonate giving IV almost quantitatively.

Acylation of Sodium Salt (VII) and 3-Cyano-1-oxaaulan-2-imine (IV)[21].—*a) Acetylation of VII.*—To a suspension of 100 mg. of VII in 2 ml. of pyridine was added 0.3 ml. of acetyl chloride under ice-cooling. The reaction mixture was allowed to stand for 60 min., poured into water and extracted with chloroform. The chloroform extract was washed with water, dried over magnesium sulfate and evaporated to 75 mg. (68% of yield) of yellow crystals, m. p. 144~146°C. Recrystallization from ethanol gave yellow needles (VIII), m. p. 146°C. IR (Nujol): 2164, 1666, 1575, 1493, 1281, 1236, 1224, 1214, 970 and 763 cm^{-1}.

Found: C, 68.20; H, 4.05; N, 12.80. Calcd. for $C_{12}H_8O_2N_2$: C, 67.92; H, 3.80; N, 13.20%.

b) Acetylation of IV.—To a solution of 59 mg. of IV in 0.8 ml. of pyridine was added 0.3 ml. of acetyl chloride under ice-cooling. The same treatment as a) gave 60 mg. of yellow crystals, m. p.

21) This part of the experiment was carried out by Mr. Haruki Tsuruta.

130~137°C, which on recrystallization from ethanol gave VIII, m. p. 145°C.

c) Benzoylation of VII.—To a mixture of 1 g. of VII and 4 ml. of pyridine, 2 ml. of benzoyl chloride was added with stirring under ice-cooling. After being allowed to stand for 1.5 hr., the reaction mixture was poured into water giving some oil, which crystallized on standing. Filtration afforded 1.3 g. of red crystals, m. p. 110~130°C, which on recrystallization from benzene-alcohol mixture gave brown scales (IX), m. p. 155°C. IR (Nujol): 2214, 1645, 1566, 1473, 1296, 1239, 1217, 1046, 960, 897, 715 and 698 cm^{-1}.

Found: C, 74.41; H, 3.59; N, 9.88. Calcd. for $C_{17}H_{10}O_2N_2$: C, 74.44; H, 3.68; N, 10.21%.

Hydrolysis of 3-Cyano-1-oxaazulan-2-imine (IV) with Acid.—*a) With 1N Hydrochloric Acid.*—A solution of 400 mg. of IV dissolved in 100 ml. of 1 N hydrochloric acid was heated on the boiling water bath for 2 hr. After being cooled, the reaction mixture was extracted with ethyl acetate. The extract was evaporated up to give 80 mg. of yellow crystals, which on recrystallization from ethyl acetate afforded 50 mg. of X, m. p. 240°C. It was shown to be identical with 3-cyano-1-oxaazulan-2-one synthesized by Sato[14] by comparing infrared spectra of them and the mixed melting point determination. The acid layer was neutralized by addition of solid sodium hydrogen bicarbonate giving 160 mg. of reddish brown crystals, m. p. 186°C, (decomp.), which were obtained by filtration. The filtrate was extracted with ethyl acetate. After being dried over sodium sulfate, evaporation of the extract gave 100 mg. of brown crystals, m. p. 182°C (decomp.). The combined crystals were recrystallized from ethyl acetate to give reddish orange needles (V), m. p. 192°C (decomp.). IR (Nujol): 3310, 3155, 1650, 1595, 1500, 1408, 1302, 1271, 1143, 1125, 879, 856, 824, 784, 756, 736 and 684 cm^{-1}.

Found: C, 63.65; H, 4.01; N, 14.38. Calcd. for $C_{10}H_8O_2N_2$: C, 63.82; H, 4.29; N, 14.89%.

b) With Ethanolic 4N Hydrochloric Acid Solution.—A solution of 200 mg. of IV in 6 ml. of concentrated hydrochloric acid and 12 ml. of ethanol was refluxed for 2 hr. on a water bath. After addition of 5 ml. of 6N sodium hydroxide, the reaction mixture was extracted with ethyl acetate. The extract was washed with water, dried over sodium sulfate and evaporated to give 15 mg. of brown crystals, m. p. 180~200°C. The aqueous layer was neutralized by adding sodium hydrogen carbonate and extracted with chloroform. The extract was dried over sodium sulfate and evaporated giving 140 mg. of reddish orange crystals, m. p. 180°C (decomp.), which was found to be V contaminated with a little amount of IV by inspection of the infrared spectrum.

Hydrolysis of 3-Carbamoyl-1-oxaazulan-2-one Imine (V) with Acid.—*a) With 1N Hydrochloric Acid.*—Heating of a solution of 230 mg. of V in 20 ml. of 1 N hydrochloric acid on a water bath afforded 110 mg. of brownish crystals, m. p. 270°C, which were filtered off after being cooled. Further heating of the filtrate on a water bath for 10 hr. gave 50 mg. of brown crystals, m. p. 275°C. The combined crystals were recrystallized from acetic acid giving yellow brown needles (XI), m. p. 275°C. IR (Nujol): 3415, 3135, 1740, 1680, 1611, 1544, 1488, 1309, 1277, 1229, 942, 882 and 795 cm^{-1}.

Found: C, 63.73; H, 3.46; N, 7.47. Calcd. for $C_{10}H_7O_3N$: C, 63.49; H, 3.73; N, 7.41%.

b) With Sulfuric Acid.—A solution of 100 mg. of V dissolved in 0.5 ml. of sulfuric acid was heated in a closed vessel on a boiling water bath for 2 hr. The reaction mixture was poured into 10 ml. of water and extracted with chloroform continuously for 6 hr. Evaporation of the extract yielded 40 mg. of yellow brown crystals, m. p. 270°C, which on recrystallization from acetic acid gave XI, m. p. 275°C. The aqueous solution from the chloroform extraction was neutralized by addition of sodium hydrogen carbonate to give orange crystals, which were extracted with ethyl acetate. Evaporation of the extract gave 60 mg. of orange crystals, m. p. 186°C (decomp.), which was identical with the starting material V (from infrared spectrum).

The same treatment of XI as b) with concentrated sulfuric acid resulted in the recovery of XI.

Hydrolysis of the Acylated Compound (VIII and IX) of 3-Cyano-1-oxaazulan-2-imine[21].—a) A solution of 200 mg. of VIII dissolved in a mixture of 1 ml. of concentrated hydrochloric acid and 10 ml. of methanol was refluxed for 30 min., and the methanol was evaporated under reduced pressure. The residual solution was poured into water and extracted with chloroform. The extract was washed, dried over magnesium sulfate and evaporated to 10 mg. of brown crystals, m. p. 167~242°C, which have not been examined. The acidic solution was neutralized by addition of sodium hydrogen carbonate and extracted with chloroform. The same treatment of the extract afforded 100 mg. of reddish orange crystals, m. p. 144~158°C (decomp.), which was found to be a mixture of IV and V by inspection of its infrared spectrum.

b) A solution of 200 mg. of VIII dissolved in a mixture of each 2 ml. of 2 N potassium hydroxide and methanol was refluxed for 2 hr. After being diluted with water and extracted with chloroform, the reaction mixture was neutralized to pH 3 with 2 N hydrochloric acid giving 135 mg. of yellow crystals, m. p. over 250°C. Recrystallization from dimethylformamide gave XII as yellow crystals, m. p. over 280°C, whose infrared spectrum was superimposed on that of the authentic sample[16].

c) To a suspension of 300 mg. of IX in 6 ml. of methanol was added 2 ml. of 2 N potassium hydroxide and the resulting mixture was shaken with ice-cooling for 15 min. By acidification of the solution to pH 3, 145 mg. of dark orange crystals, m. p. over 280°C, were obtained by filtration. The filtration, after being evaporated and diluted with water, afforded 40 mg. of the same crystals, m. p. over 280°C. The combined crystals were identical with the authentic 3-cyano-1-azaazulan-2-one[16] (from infrared spectum).

Condensation of 2-Phenyltropone and Malononitrile (Formation of XIII).—To a solution of 1 g. (5.5 mmol.) of 2-phenyltropone and 400 mg. (6 mmol.) of malononitrile in 4 ml. of absolute ethnol was added 0.2 ml. of piperidine and the

reaction mixture was allowed to stand overnight at room temperature. Filtration of the crystals deposited gave 1.08 g. (80% of yield) of XIII as pale yellow needles, m. p. 150°C. IR (Nujol): 3520, 3380, 2220, 1639, 1601, 1557, 1494, 1100, 837, 789, 743, 728, 698 and 687 cm^{-1}.

Found: C, 77.38; H, 4.77; N, 11.21. Calcd. for $C_{16}H_{12}ON_2$: C, 77.40; H, 4.87; N, 11.28%.

Dehydrogenation of XIII with Tetrachloro-1,2-benzoquinone (Formation of XIV).—To a solution of 400 mg. (1.6 mmol.) of XIII in 20 ml. of benzene was added 480 mg. (1.9 mmol.) of tetrachloro-1,2-benzoquinone and the reaction mixture was allowed to stand at room temperature for 30 min., during which reddish crystals precipitated out. Filtration afforded 850 mg. of dark orange crystals, m. p. 135°C (decomp.), which were difficult to be recrystallized from the usual solvent. The crystals obtained ware added to a mixture of 20 ml. of 2 N hydrochloric acid and 20 ml. of ethanol and the reaction mixture was shaken for 1 hr. and then poured into water. Some resinous matter with dark red separated out, from which the acidic layer was decanted. After being shaken with benzene to remove tetrachlorocatechol, the acidic solution was neutralized by addition of sodium hydrogen carbonate giving 240 mg. (60% of yield) of XIV as orange red crystals, m. p. 183°C (decomp.). IR (Nujol): 3360, 2220, 1658, 1618, 1587, 1538, 1495, 1321, 1285, 1233, 1115, 979, 912, 790, 781, 756, 717 and 692 cm^{-1}.

Found: C, 77.58; H, 3.90; N, 10.94. Calcd. for $C_{16}H_{10}ON_2$: C, 78.03; H, 4.09; N, 11.38%.

Synthesis of 2-Amino-1,3-dicyano-4-phenylazulene (XV) from 3-Cyano-8-phenyl-1-oxaazulan-2-imine (XIV).—A solution of 50 mg. (0.2 mmol.) of XIV and 30 mg. (0.45 mmol.) of malononitrile in 6 ml. of absolute ethanol was stirred overnight in the presence of 60 mg. of *tert*-butylamine giving yellow crystals. Filtration afforded 50 mg. (90% of yield) of yellow crystals (XV), m. p. 296°C, which showed no depression on admixture with the authentic sample synthesized from 2-chloro-7-phenyltropone and malononitrile[18]. The infrared spectrum of XV was superimposed on that of the authentic sample[18].

Hydrolysis of 3-Cyano-8-phenyl-1-oxaazulan-2-imine (XIV) with Acid.—A solution of 400 mg. of XIV dissolved in 35 ml. of 4 N hydrochloric acid was heated on a water bath for 3 hr. and on being cooled dark yellow needles crystallized out. Filtration afforded 150 mg. of yellow needles, m. p. 255°C, which on recrystallization from dimethylformamide gave needles (XVI), m. p. 265°C. IR (Nujol): 2215, 1755, 1613, 1582, 1488, 1312, 1282, 1230, 961, 930, 905, 795, 768, 732 and 699 cm^{-1}.

λ_{Max}^{MeOH} mμ (log ε): 223 (4.40), 255 (4.26), 310 (4.20) and 414 (4.39).

Found: C, 77.25; H, 3.65; N, 5.80. Calcd. for $C_{16}H_9O_2N$: C, 77.72; H, 3.67; N, 5.67%.

The filtrate of XVI was neutralized by addition of solid sodium hydrogen carbonate giving 200 mg. of orange crystals, m. p. 173°C, which were obtained by filtration. The crystals obtained were dissolved in benzene and chromatographed through a column containing 6 g. of alumina. After evaporation, the elute with ether gave 20 mg. of reddish crystals (XIV), m. p. 172~173°C (decomp.), and the elute with ethyl acetate gave 50 mg. of reddish orange crystals (XVII), m. p. 184~185°C (decomp.). IR (Nujol): 3345, 3165, 1660, 1585, 1497, 1357, 1304, 1282, 1107, 1092, 930, 795, 769, 751, 726, 694 and 674 cm^{-1}. λ_{Max}^{MeOH} mμ (log ε): 238 (4.46), 290 (4.18) and 422 (4.38).

Found: C, 72.79; H, 4.46; N, 10.22. Calcd. for $C_{16}H_{12}O_2N_2$: C, 72.71; H, 4.58; N, 10.60%.

Hydrolysis of 3-Cyano-8-phenyl-1-oxaazulan-2-one (XVI) with Sulfuric Acid.—One hundred milligrams of XVI ware dissolved in 0.5 ml. of concentrated sulfuric acid and the solution was heated in a closed vessel in the boiling water bath for 1 hr. The solution was poured into 3 ml. of water to give brownish crystals. Filtration afforded 110 mg. of crystals, m. p. 233~236°C, which on recrystallization from benzene gave yellow crystals (XVIII), m. p. 258~260°C. IR (Nujol): 3400, 3145, 1724, 1672, 1603, 1580, 1490, 1277, 1259, 1217, 804, 781, 754, 735 and 698 cm^{-1}. λ_{Max}^{MeOH} mμ (log ε): 223 (4.37), 253 (4.23), 304 (4.16) and 415 (4.35).

Found: C, 72.49; H, 4.32; N, 4.92. Calcd. for $C_{16}H_{11}O_3N$: C, 72.44; H, 4.18; N, 5.28%.

The authors express their gratitude to Mr. K. Osaka of the Asahi Chemical Industry Co. for his cooperation during the early stage of this experiment and Mr. H. Tsuruta for carrying out some experiment concerning VIII and IX. They also thank Dr. K. Takase for helpful discussion and Mr. K. Takahashi for measurement of the NMR spectrum, and Sankyo Co. for donation of a research fund which covered a part of the expenses for this work.

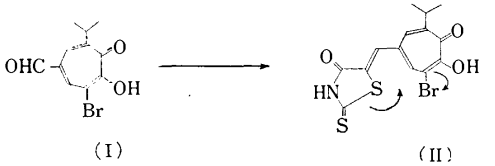
The Mannich Base of Troponoid and its Application. IX. Reaction of 3-Bromo-5-formyl-7-isopropyltropolone

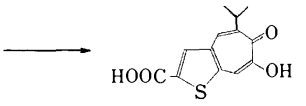
By Kyozo OGURA

(Received September 5, 1962)

It has been found that alkaline treatment of 3-bromo-7-isopropyltropolon-5-ylmethylenerhodanine (II) obtained by the reaction of 3-bromo-5-formyl-7-isopropyltropolone (I) and rhodanine resulted in the abnormal intramolecular attack of sulfide anion at the 4-position of the tropolone ring with the liberation of the bromide ion from the 3-position to give thieno [2, 3-d] tropolone derivative III[1].



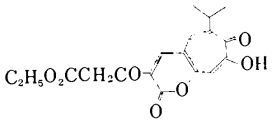
(I) (II)



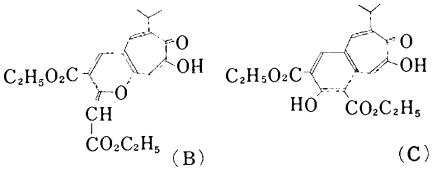
(III)

In order to make further extension of such an abnormal cyclization, some reactions of aldehyde I were studied.

Treatment of I with diethyl acetonedicarboxylate in the presence of piperidine gave colorless needles of m. p. 215°C (IV), corresponding to the molecular formula of $C_{20}H_{22}O_7$. The fact that the bromide ion was liberated in this reaction suggested that IV was not a simple condensation product, but a cyclization product formed by the condensation followed by such an abnormal intramolecular substitution as in the case of thienotropolone derivative III. According to the manner of the intramolecular attack, three structures (A, B and C) are expected for IV, while structure A must be excluded by the analytical values of IV. The ultraviolet absorption spectrum of IV is similar to those of 4, 5-benzotropolone and its derivatives[2], and its infrared spectrum shows absorptions for the hydroxyl group at 3280 cm^{-1} and for the carbonyl group at 1727 and 1680 cm^{-1}. Furthermore it shows absorp-



(A)



(B) (C)

tions at 1638, 1587, 1538 and 1468 cm^{-1} which agree well with absorption bands of 4, 5-benzotropolone reported by Tarbell et al.[3] These facts show that IV is 1', 3'-diethoxycarbonyl-2'-hydroxy-3-isopropyl-4, 5-benzotropolone (C). Treatment of IV with alkali gave dicarboxylic acid V, whose ultraviolet spectrum was shown in Fig. 1.

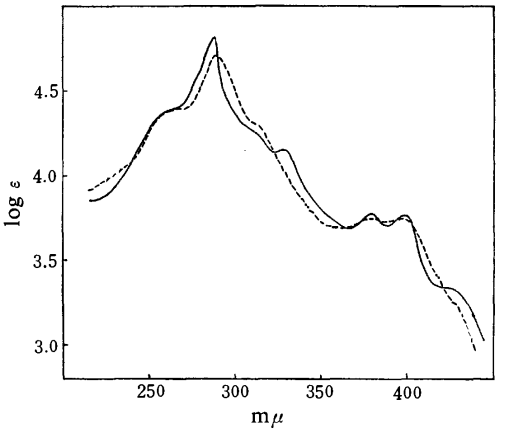


Fig. 1. Ultraviolet spectra of IV (——) and V (·····) in methanol.

Although it was expected that pyrazolotropolone derivative would be obtained by the action of alkali on tosylhydrazone VI, the cyclization did not occur, but 3-bromo-7-isopropyltropolon-5-ylmethyl *p*-tolyl sulfone

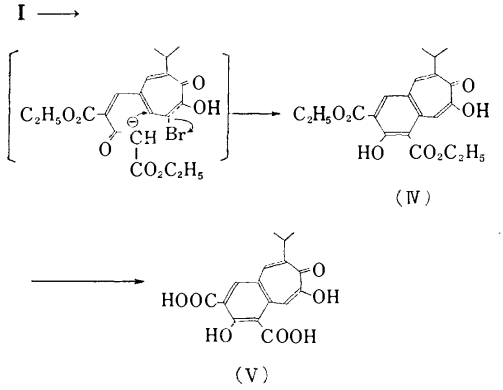
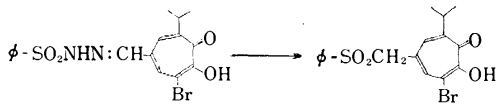
3) D. S. Tarbell, G. P. Scott and A. D. Kemp, *J. Am. Chem. Soc.*, 72, 379 (1950).



(V)

(VII) was obtained. It seems to have been formed in the same manner as known in the case of benzaldehyde tosylhydrazone[4].



(VI) (VII)

$\phi = p$-tolyl

Finally for the synthesis of thiazinotropolone derivative the reaction of I with thiourea in the presence of pyridine was examined, and the product corresponding to the molecular formula of $C_{11}H_{12}O_3$ (VIII) was obtained. Its infrared spectrum shows an absorption at 1688 cm^{-1} due to a carbonyl group, and other absorptions expect those in the finger print region agree well with those of I. The ultraviolet spectrum is also similar to that of I. These facts suggest that VIII should be 3-isopropyl-5-formyltropolone formed by debromination of I. In order to make this problem more clear the reaction of 3, 7-dibromotropolone with thiourea in the presence of pyridine was examined, and it was found that the

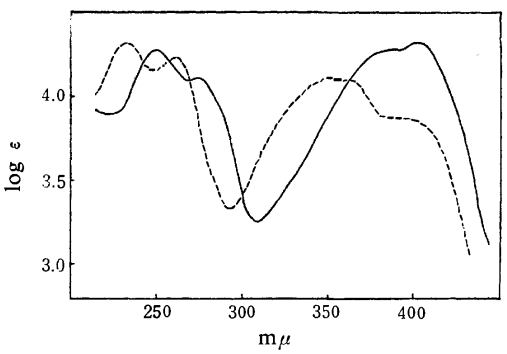


Fig. 2. Ultraviolet spectra of I (——) and VIII (……) in methanol.

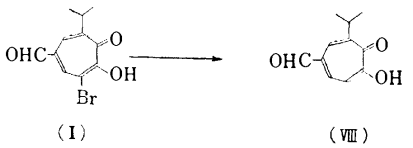
4) W. R. Barmford and T. S. Stevens, *J. Chem. Soc.*, 1952, 4735.



(I) (VIII)

debromination occurred to give 3-bromotropolone in a low yield.

Experimental*

1', 3'-Diethoxycarbonyl-2'-hydroxy-3-isopropyl-4, 5-benzotropolone (IV).—A mixture of I (100 mg.), diethyl acetonedicarboxylate (120 mg.) and piperidine (30 mg.) was refluxed for 7 hr., and then cooled to room temperature. Colorless needles (10 mg.) of IV which precipitated on being cooled were collected. The filtrate was refluxed, with 30 mg. of piperidine further added, for 1 hr., and the solvent was removed to dryness. Addition of a small amount of water and methanol to the resinous residue caused to solidify. The solid thereby formed was collected and recrystallized from ethanol to afford colorless needles of IV (5 mg.), m. p. 213~215°C. λ_{max}^{MeOH} mμ (log ε) : 288 (4.82), 330 (4.16), 380 (3.78), 400 (3.77).

Found : C, 64.15 ; H, 6.19. Calcd. for $C_{20}H_{22}O_7$: C, 64.16 ; H, 5.92%.

1', 3'-Dicarboxy-2'-hydroxy-3-isopropyl-4, 5-benzotropolone (V).—After IV (30 mg.) was heated in aqueous potassium hydroxide solution (potassium hydroxide, 15 mg. ; water, 0.2 ml.) in a water bath for 1 hr., the solution was neutralized with hydrochloric acid (pH, 3~4). The mixture was extracted by ether. The evaporation of the ether from the extract left pale yellow powder, which was collected, washed with water and recrystallized from methanol to afford colorless crystals, m. p. 270~275°C (decomp.). Yield, 10 mg. λ_{max}^{MeOH} mμ (log ε) : 290 (4.72), 380 (3.75), 398 (3.75).

Found : C, 59.39 ; H, 4.71. Calcd. for $C_{16}H_{14}O_7$: C, 60.38 ; H, 4.43%.

3-Bromo-5-formyl-7-isopropyltropolone *p*-Tosylhydrazone (VI).—A solution of I (100 mg.) and *p*-tolylsulfonylhydrazide (60 mg.) in methanol (1 ml.) was refluxed for 15 min., and then cooled to room temperature. Yellow crystals that separated were collected and recrystallized from ethanol to give yellow granular crystals, m. p. 165~166°C. Yield. 120 mg.

Found : C, 47.36 ; H, 4.31 ; N, 6.32. Calcd. for $C_{18}H_{19}O_4N_2$ SBr·H_2O : C, 47.28 ; H, 4.63 ; N, 6.13%.

3-Bromo-7-isopropyltropolon-5-ylmethyl *p*-Tolyl Sulfone (VII).—A solution of VI (100 mg.) and piperidine (30 mg.) in ethanol (1.5 ml.) was refluxed for 4 hr. The evaporation of the ethanol left yellow oily residue, which was solidified by addition of a few drops of 6 N hydrochloric acid and 1 ml. of methanol. The solid was collected and recrystallized from methanol to afford colorless needles,

* All melting points are uncorrected. The microanalyses were carried out by Miss Yoko Endo and Miss Yukiko Endo of this Institute, to whom the present author wishes to express his gratitude.

m. p. 162~164°C. Yield, 20 mg. λ_{max}^{MeOH} mμ (log ε): 277 (4.23), 265 (4.50), 345 (4.00), 413 (3.76).

Found: C, 52.52; H, 4.69. Calcd. for $C_{18}H_{19}O_4SBr$: C, 52.57; H, 4.66%.

3-Isopropyl-5-formyltropolone (VIII).—A mixture of I (130 mg.) and thiourea (40 mg.) in pyridine (1 ml.) was warmed in a water bath for 1.5 hr., by which the whole dissolved to form a black solution. After the removal of pyridine dilute hydrochloric acid was added to the residue and the precipitate was collected, washed with water and recrystallized from benzene to form pale yellow granular crystals, which was further purified by sublimation in reduced pressure, m. p. 107~109°C. Yield, 20 mg. λ_{max}^{MeOH} mμ (log ε): 233 (4.31), 262 (4.23), 351 (4.10), 390 (3.88).

Found: C, 66.55; H, 5.92. Calcd. for $C_{11}H_{12}O_3 \cdot 1/2H_2O$: C, 66.65; H, 6.32%.

Reaction of 3, 7-Dibromotropolone and Thiourea.—A mixture of 3, 7-dibromotropolone (100 mg.) and thiourea (30 mg.) in pyridine (1 ml.) was heated in a water bath for 2 hr., by which the whole dissolved to form a dark red solution. The pyridine was evaporated, 6 N hydrochloric acid (0.5 ml.) was added to the residue, and the brown precipitate so formed was collected. The solid was warmed in benzene and the mixture was filtered. The evaporation of the benzene left pale yellow powder, whose sublimation in reduced pressure afforded a trace of 3-bromotropolone.

The author wishes to express his deep gratitude to Professor Shuichi Seto for his kind guidance and encouragement throughout this work, and to Dr. Yusaku Ikegami and Dr. Shingo Matsumura for their helpful advice. 3-Isopropyltropolone was graciously furnished by the Takasago Perfumery Co., Ltd., and a part of the expenses was defrayed by Sankyo Co., Ltd., to whom the author is deeply indebted.

σ Electronic Structures and Some Physicochemical Properties of Halogenated-conjugated Hydrocarbons

By Keiji MOROKUMA, Kenichi FUKUI, Teijiro YONEZAWA and Hiroshi KATO

(Received September 6, 1962)

Researches of the electronic structures of large organic compounds have been carried out, with the molecular orbital and the valence bond methods, almost exclusively on the electronic states of conjugated molecules; these examinations have dealt with electronic spectra, chemical reactivities, π dipole moments and so on. In these discussions no attention has been paid to the behavior of σ electrons in making an unchangeable framework for π electrons to move on. However, some of the physicochemical properties—σ moments, coupling constants *eqQ* in PQR spectra, proton shifts in NMR spectra, etc.—cannot be interpreted theoretically without an explicit consideration on the σ electronic structures.

Recently, in order to discuss the σ electronic structures of conjugated compounds, the present authors have developed a simple molecular orbital method which had previously been successfully adopted for the computation of the electronic structures of saturated hydrocarbons and their derivatives[1-3]; they have published some results of their calculations on the σ electrons of aromatic and olefinic hydrocarbons[4]. In this paper a numerical calculation is performed on the σ electronic structures of halogenated olefins and benzenes, and on this basis the *eqQ* of halogens and the dipole moments of these compounds are discussed.

It would be interesting to compare this paper's calculated results on conjugated halides with those on saturated halides in Refs. 2 and 3.

Method of the Calculation and Evaluation of Parameters

The method of the theoretical calculation of the σ electronic structures of conjugated systems was explained in detail in Ref. 4. In this paper, therefore, it will be repeated only

briefly. Molecular orbitals are linear combinations of all σ atomic orbitals (LCAO) of all the atoms present—sp^2 hybridized orbitals of carbons, 1s orbitals of hydrogens, and σ atomic orbitals of halogens. Electronic interactions and overlap integrals are completely disregarded. The parameters of the Coulomb and of the resonance integrals employed are given in Table I. Those for carbon atoms and for hydrogen atoms are the same as were given in Ref. 4. The Coulomb integrals for halogen atoms have been chosen so as to fit Mulliken's electronegativity scale and to be consistent with the integrals in saturated compounds, and the resonance integrals between carbon and halogen have been proportionated to the overlap integrals of the bonds.

The effects of the variation of parameters and those of neglecting overlap integrals will be discussed in the following paragraphs.

TABLE I. PARAMETERS OF COULOMB AND RESONANCE INTEGRALS OF σ AO's

Coulomb integral: q_{rr}*		Resonance integral: q_{rs}**	
C_{sp^2}	0	C_{sp^2}–C_{sp^2} (σ bonding)	1
		C_{sp^2}–C_{sp^2} (on the same carbon) m	$\equiv 0.38$

F	0.7	C_{sp^2}–F	0.45
Cl	0.3	C_{sp^2}–Cl	0.6
Br	0.25	C_{sp^2}–Br	0.5
I	0.2	C_{sp^2}–I	0.45

* Coulomb integral α_r is expressed as follows:

$$\alpha_r = \alpha + q_{rr}\beta$$

where α and β are the standard Coulomb and the standard resonance integrals in sp^2 system.

** Resonance integral β_{rs} is expressed as follows:

$$\beta_{rs} = q_{rs}\beta$$

General Properties of the Results of Calculations

A few examples of the results of our calculations are shown in Tables II and III and in Figs. 1, 2, 3 and 4. The general propeties of these results for halogenated conjugated systems may be summarized as follows:

1) As is seen in Tables I and II and Fig. 1, each orbital has a large distribution on two certain atomic orbitals which form a bond. This tendency seems to reflect the localized nature of the σ electrons.

2) The lowest unoccupied σ orbital of halides lies much lower than that of mother hydrocarbons, and it is localized on carbon-halogen bonds with a negative and large (in magnitude) bond order. Moreover, the lowering of the level becomes more and more notable with the increased number of halogen atoms. This result comes from the electronegativity of the halogen atoms and the small overlap (the small absolute value of the resonance integral) between the carbon and the halogen.

3) The electronegativity of the halogen atoms causes them to attract a considerable amount of electron density to the carbon-halogen (C–X) bonds from other near-by bonds, so that the sum of the σ charge density

C–C bonds and is transmitted to farther bonds with, however, a rapid decrement.

Results 3 and 4 seem to correspond to the so-called inductive effect in organic chemistry.

Effects of Parameters.—In order to see the effects of parameters on the results, some calculations on various compounds have been carried out with varied parameters; a few examples are shown in Tables V and VI. For the sake of brevity, only a summary of the calculated results will be given here. A change in the Coulomb integral of chlorine atoms causes a change in their σ electron density; the bond moment of the C–Cl bond is well explained with its value near 0.3 (as has been adopted) or less, though its influence is little on the qualitative results of calculation.

Effects of Overlap Integrals.—In σ electron systems where neighboring atomic orbitals are mutually deeply overlapping, the neglect of

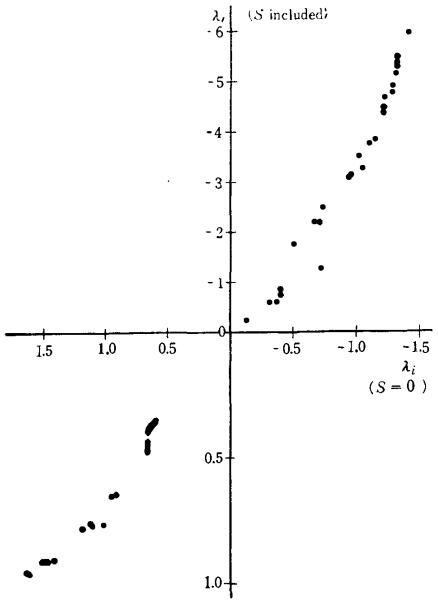

Fig. 5. Energy levels with overlap included and neglected.

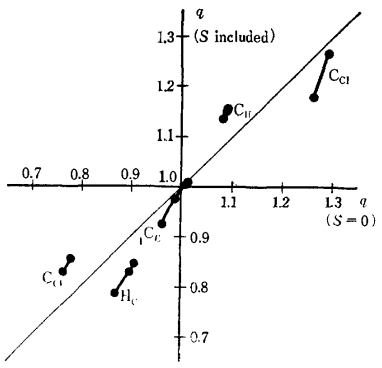

Fig. 6. Total σ electron densities on each kind of AO's with overlap included and neglected (C_H, for example, denotes the carbon AO in a C-H bond.).

the overlap integrals might lead to an erroneous conclusion, even in a qualitative sense. Therefore, some computations have been performed with the inclusion of overlap integrals between adjacent atoms, which have been settled as follows:

$$S_{CH}=0.72$$

$$S_{CC}=0.77$$

$$S_{CCl}=0.46$$

Results with respect to ethylene, 1, 2-dichloroethylene, tetrachloroethylene, benzene and *p*-dichlorobenzene, as shown in Table VII and Figs. 5 and 6, indicate that those energy levels with overlap included are almost completely parallel to those with overlap neglected and that the occupied levels of the former come near to α_σ, while unoccupied levels flee from α_σ. As for the σ electron density, on the basis of Fig. 6, those on similar atomic orbitals on similar bonds (for instance, carbons' AO's on C-Cl bond, as is expressed by C_{Cl} in the figure) very parallel with each other, leading also to an unvaried qualitative conclusion in both calculations.

Dipole Moments

The dipole moment of conjugated compounds is composed of the σ moment and the π moment. Most of the theoretical works have been concerned with only the π moment till now, and in those cases the σ moment was empirically estimated on the basis of bond moments which are assumed to be constant in a series of compounds. In this paragraph, the σ moment of each compound is evaluated by the use of the σ electron distribution given in the tables and the figures. In the evaluation, all the bond angles are assumed to be 120°; the C–Cl bond length, 1.70 Å; C–H, 1.08 Å; C–C (aromatic) 1.40 Å, and C–C (olefinic) 1.34 Å, and the displacement of the center of the charge distribution is taken into

Table IX. Dipole moments of chlorobenzenes

Substituent	Calculated			Observed
	σ Moment	π Moment	Total Moment	
Cl	1.69	0.31	1.39	1.57
o-di-Cl	2.96	0.54	2.41	2.25

account by 0.46 Å in an sp^2 hybridized orbital of carbon and by 0.44 Å in a σ orbital (the s character of 15% is tentatively assumed) of chlorine.

The σ moments obtained are tabulated in Tables VIII and IX, together with the π moments calculated in the simple LCAO MO approximation with parameters $\alpha^{\pi}_{Cl}=\alpha_{\pi}+1.8\beta_{\pi}$, $\alpha^{\pi}_{C'}=\alpha+0.18\beta_{\pi}$ and $\beta_{CCl}=0.8\beta_{\pi}$, where α_{π} and β_{π} are the standard Coulomb and the standard resonance integrals in the π electron systems, and with the calculated total moments compared with the observed dipole moments.

Generally speaking, the calculated moments are larger than observed ones; this may be attributed to the choice of parameters and also to a disregard of the σ overlaps. However, a calculated σ moment does not seem to be a simple vector sum of bond moments. A part of the so-called ortho effects—a deviation from the additivity of bond moments in ortho-disubstituted compounds—may be understood on the basis of this result. However, the extremely small moment of trichloroethylene cannot so be explained, probably due to the roughness on the electronic repulsions between the neighboring polar groups. On these problems a theoretical paper would be published in the near future[5].

The Coupling Constant of Halogen in the PQR Spectra

In chlorides, bromides and iodides the coupling constants, eqQ, of halogen nuclei are observed in pure nuclear quadrupole resonance (PQR) spectroscopy. In conjugated chlorides these constants are connected to the σ electron density, q^{σ}_{Cl}, and to the π electron density, q^{π}_{Cl}, on the chlorine atom by the following equation:

$$eqQ=\left(\frac{q^{\pi}_{Cl}+2}{2}-q^{\sigma}_{Cl}\right)eqQ_{atom} \qquad (1)$$

where the eqQ_{atom} is the coupling constant of an atomic chlorine and is set at 109.7 Mc. In Eq. 1 the orbital of chlorine is assumed to be a pure p orbital. If the s character of the orbital is considered to be s%, eqQ is given by Eq. 2 instead of Eq. 1:

$$eqQ=\left[\frac{q^{\pi}_{Cl}+2}{2}-q^{\sigma}_{Cl}-\frac{s}{100}(2-q^{\sigma}_{Cl})\right]eqQ_{atom} \qquad (2)$$

By adopting the π and the σ electron densities calculated in previous paragraphs in Eq. 1, the values of eqQ shown in Tables X and XI are obtained; their parallelism with the experimental values seems to be sufficient.

The difference in the calculated coupling constants among chlorobenzenes is unexpectedly small. As the coupling constants of these compounds were experimentally determined from the resonance spectra in the solid state, a part of this discrepancy may be attributed to the effects of crystal fields, which in some other cases might change the constant by 0.8 Mc[6]. The difference is also probably due in

part, however, to the crudeness of our approximation in calculating molecular orbitals. On the approximation of this calculation, some discussions will be published in the future[5].

Other Problems

Interesting relations between the electronic structures and the potential of polarographic reduction of conjugated halides have also been found and will be presented in a separate paper[7].

The proton chemical shifts of these halides in NMR spectra will be discussed in connection with σ electron distributions in another paper[8].

Summary

The simple LCAO MO method previously developed by the present authors has been adopted to the calculation of the σ electronic structures—σ molecular orbitals, their energies, separate and total σ electron densities, etc.—of conjugated halides. The general results of the computation—the so-called inductive effects along σ bonds, the unoccupied levels with the very low energy which is characteristic to halides, and so forth—have been described. Sigma dipole moments and the coupling constants in PQR have been calculated with the σ electron densities obtained and discussed in comparison with the experimental values.

The numerical calculations were carried out on the digital computer KDC-I of Kyoto University.

The Concentration of Molecular Hydrogen on the Platinum Cathode

By Shigeo SHIBATA

(Received September 6, 1962)

It has previously been shown[1] that the concentration of hydrogen, ${}_0C_{H_2}$, in the immediate vicinity of the cathode during the passage of a current could be estimated by analyzing the potential-time curve which had been obtained when the cathodic current polarizing the electrode was abruptly reversed into a steady anodic one.

In the present work, ${}_0C_{H_2}$ was determined as a function of the cathodic current density by the following two different methods:

1) If the diffusion of hydrogen is the rate-determining stage in the anodic ionization process of the molecular hydrogen in the solution, ${}_0C_{H_2}$ can be estimated by the use of Sand's equation[2]:

$$ {}_0C_{H_2} = i_a \tau^{1/2} / F\pi^{1/2} D^{1/2} \qquad (1) $$

where τ is the transition time of the horizontal portion of the steady potential appearing at the first stage of that potential-time curve, F is a Faraday, D is the diffusion coefficient of the hydrogen molecule in the solution, and i_a is the anodic polarizing current density.

When, in addition to the diffusion, the spontaneous expellant of hydrogen from the solution as bubbles of gas is also contributable, ${}_0C_{H_2}$ can be written as[1]:

$$ {}_0C_{H_2} = \frac{i_a}{2FD^{1/2}k^{1/2}} \exp(k\tau)\,\mathrm{erf}(k^{1/2}\tau^{1/2}) \qquad (2) $$

where k is a expellant rate constant of the hydrogen from the solution. It is assumed that the rate of expellant is proportional to the supersaturation.

2) The polarization, or departure from the reversible potential, observed during the discharge of hydrogen ions at the electrode is generally considered to be due to the following effects[3,4]: a discharge overpotential of hydrogen ions η_D[5]; a recombination overpotential

of hydrogen atoms, η_R[5-8]; the ohmic fall of resistance between the working electrode and the tip of a fine capillary connecting with the reference electrode, η_Ω[4]; a concentration overpotential of hydrogen ions, η_{H^+}[5,9] and a concentration overpotential of hyrogen molecules, η_{H_2}[5,10]. When the current is cut off, the overpotentials η_D, η_R and η_Ω should disappear at once, while η_{H^+} and η_{H_2} decay only slowly[3,11]. Moreover, in the acidic electrolyte the value of η_{H^+} is so small that it can be disregarded except in the cases of very large electrolytic currents[5,9]. The overpotential which is still contributable after the current of a moderate intensity has been cut off may be η_{H_2} only. Clamroth and Knorr[4] attempted to measure the concentration overpotential ${}_0\eta_{H_2}$ during the passage of current, free from the effect of the other kinds of overpotential, by extrapolating to zero time the decay curve of η_{H_2}, taken after the circuit had been opened. They could also obtain ${}_0\eta_{H_2}$ by means of extrapolating the $m_{H_2}-\eta_{H_2}$ curve to the zero volume of m_{H_2}, where m_{H_2} is the amount of hydrogen gas evolved for the time elapsed since the cut off of the current; it has a linear relation with η_{H_2} observed at the same time. Though their results obtained are reliable for low current experiments, they are not reliable for high current experiments, because the rates of overpotential decay and of H_2 gas evolution are so rapid that their manual potentiometric or microvolumetric technique surely never could follow them. The present author has therefore attempted to obtain a reasonable way of measuring ${}_0\eta_{H_2}$ at high currents, i_k, by means of oscilloscopic observation of the overpotential. The relation of the concentration overpotential, ${}_0\eta_{H_2}$, and the activity, ${}_0a_{H_2}$, of the hydrogen is, according to Nernst's equation, as follows:

$$ {}_0a_{H_2} = a_{H_2}{}^0 \exp\{-(2F/RT)\cdot {}_0\eta_{H_2}\} \qquad (3) $$

where $a_{H_2}{}^0$ is the activity of hydrogen in the solution which is in contact with hydrogen gas at 1 atm. pressure. Since the hydrogen behaves ideally even under high pressure[12,13], the activity can be replaced by the concentration.

Experimental

Measurement of the Potential-time Curve.—The electrical circuit used for reversal of the current through the cell, from cathodic to anodic, is shown in Fig. 1. It is fundamentally the same as that used in the previous work[1], except for modification by the addition of an appropriate switching arrangement. Instead of a mechanical switch, a cyratron was used for the sake of a quick raising of the current following the reversal. The change of the working electrode potential against an S. C. E. was recorded with a cathode-ray oscilloscope (Iwasaki Synchroscope, Model SS-5151) synchronized with the reversal of current direction.

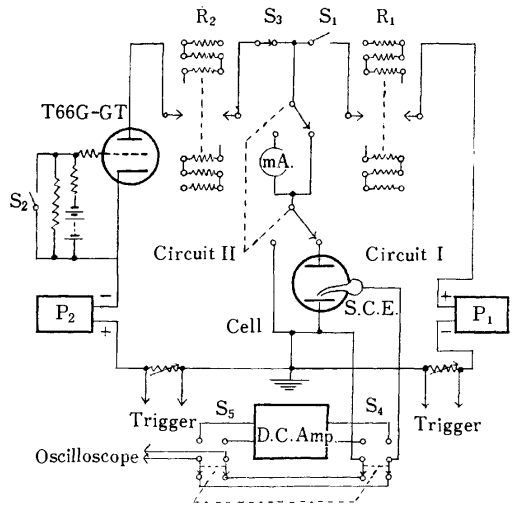

Fig. 1. Circuit diagram.

Measurement of the Decay Curve of η_{H_2}.—In order to measure the decay curves, circuit I was used, circuit II being excluded. A constant cathodic current, i_k, was passed through the cell, sufficient time being allowed for the potential to become constant; the circuit was then opened, and the decay curve was photographed with the cathode-ray oscilloscope synchronized with the cut-off of the current. As the amount of the concentration overpotential was too small for direct oscilloscopic measurement, a d. c. vacuum-tube amplifier was used in order to detect it. The value of ${}_0\eta_{H_2}$ on the cathode was obtained by extrapolating the decay curve to zero time; the constant, k, in Eq. 2 was obtained from the slope of the curve.

The cell used for the experiment is shown in Fig. 2. The working electrode A, bright platinum wire 1 cm. in length and 0.05 cm. in diameter, the end of which had been covered with a small glass ball to prevent edge effect of the discharge, was placed vertically in the solution. B is an auxiliary electrode consisting of a cylindrical platinum foil of a large area, on the center-line of which the working electrode had been fixed in order to ascertain the uniform current density over the surface of the working electrode. A platinized platinum plate C is a hydrogen gas electrode used as a reference electrode immersed in the experimental solution. The difference in potential between A

and C gives the overpotential directly. The solution was saturated with hydrogen passing through two inlets made at the bottom of each chamber. Prior to use, the working electrode was activated by means of anodic and subsequent cathodic polarizations[14]. The sulfuric acid solution (1 N) used as the electrolyte throughout was prepared with G. R. sulfuric acid and with conductivity water which had been carefully redistilled thrice with a silica still.

All experiments were carried out in a thermostat at a temperature of 25±0.1°C.

Results and Discussion

The Hydrogen Concentration Evaluated from the Transition Time.—Provided that Sand's Eq. 1 is applicable to the anodic process after the reversal of the current, the value of $i_a\tau^{1/2}$ for the given i_k should be constant, independent of i_a. As is seen in Fig. 3, however, the value of $i_a\tau^{1/2}$ was affected considerably by the strength of the anodic polarizing current. Thus, the value of $i_a\tau^{1/2}$ for the given i_a value passed through a maximum at a certain i_k value which is larger because of a higher i_a value. Further, the height of this maximum decreased with the increasing value of i_a untill it vanished when i_a exceeded some definite value. The appearance of such a maximum on the curve may be attributed to the removal of the accumulated hydrogen during τ by the agitation of the solution due to the bubbling of the evolved hydrogen gas. At a low i_k value, the effect of this removal would not be very large, so that the accumulation of deposited hydrogen would be increased with an increasing value of i_k. At a large i_k value, however, the amount of the hydrogen ionized during τ may be rather decreased by increasing stirring. The magnitude of $i_a\tau^{1/2}$ at a given i_k value should grow and finally tend to a limiting value according as the i_a value increases, since the transition time, τ, becomes so short that the effect of stirring is very much diminished during that time. Furthermore, as a cause of the reduction of the transition time, τ, we must call attention to the spontaneous expulsion of hydrogen from the solution due to supersaturation. The curves in Fig. 3 are subject to the influence of both the stirring and the expulsion. For the above-mentioned reason, the correct values of ${}_0C_{H_2}$ at a given i_k value must be evaluated from τ_0, the limiting value of the transition time obtained at a sufficiently large i_a value. Figure 4 shows plots of the concentration of hydrogen, calculated with Eq. 1 and Eq. 2, against i_k for various values of i_a. Since in the range of small i_k values under about 10 mamp./cm² and of large i_a values over about 30 mamp./cm² (cf. Fig. 4.), the value of $i_a\tau^{1/2}$ for a given i_k value is constant, independent of the magnitude of the i_a value, the disturbance, by the expulsion of hydrogen and the agitation, of the solution in relation to the transition time obtained in this range of i_k and i_a values is so small that it can be disregarded. The concentrations calculated with Eq. 2, being little affected by the strength of i_a, may be considered to be the true concentrations of ${}_0C_{H_2}$. These values at higher i_k values were evaluated with a τ_0 value obtained at a large anodic polarization current, i_a=634 mamp./cm².

Relation of the Cathodic Current and the Concentration Overpotential of the Hydrogen.— When, after the cut-off of the cathodic current through the working electrode, the solution in the cell was suddenly stirred with bubbles of hydrogen gas, the overpotential decayed rapidly and settled down on the reversible potential, i. e., on $\eta_{H_2}=0$, as is shown in Fig. 5. This fact is an illustration of how the overpotential is caused by the accumulation of hydrogen and of how the rapid decay, following the bubble agitation, is attributable to the almost

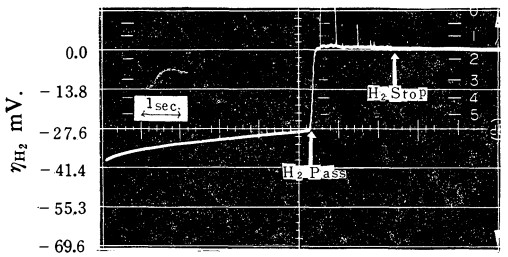

Fig. 5. Oscillogram of the overpotential change when, after the cut off of the cathodic current, $i_k=7.0$ mamp./cm², the solution was stirred with bubbles of hydrogen gas.

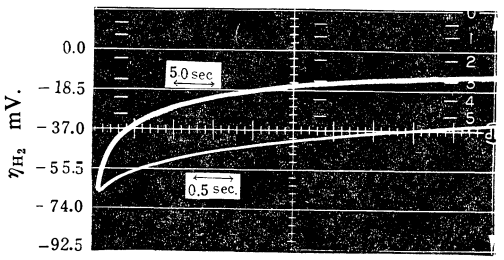

Fig. 6. Oscillograms of the overpotential decaying after the cut off of the cathodic current, $i_k=92.4$ mamp./cm².

complete removal of the accumulated hydrogen. Figures 6 and 7 show oscillograms tracing the decay of η_{H_2} taken after the cut-off of the cathodic current. The potential falls down rapidly at first, but at last tends only slowly to zero. As the initial, short part of the decay curve, as seen in Fig. 7, can be taken to be a straight line, it could be exactly extrapolated to zero time ; ${}_0\eta_{H_2}$ was obtained. As may be seen in Fig. 8, ${}_0\eta_{H_2}$ increases linearly with the logarithm of the cathodic current density, but at last tends to a constant value of 64.5±0.5 mV. as the current density exceeds about 300 mamp./cm².

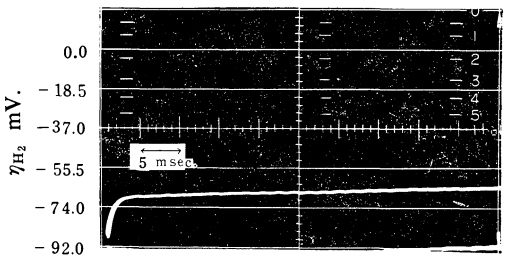

Fig. 7. Oscillogram of the overpotential decaying immediately after the cut off of the cathodic current, $i_k=92.4$ mamp./cm².

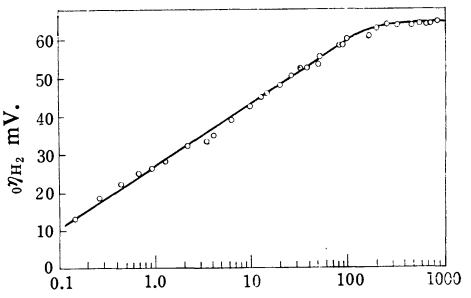

Fig. 8. Relation between the cathodic current density and concentration overpotential of hydrogen.

The concentrations of ${}_0C_{H_2}$ obtained by means of the potential-time curve, together with that obtained from the concentration overpotential, are shown in Fig. 9, the solubility of hydrogen at 1 atm. $C_{H_2}{}^0$ being taken to be 7.24×10^{-4} mol./l.[15] The agreement between the results for ${}_0C_{H_2}$ derived from τ_0 and from ${}_0\eta_{H_2}$ is seen to be satisfactory. The limiting value of ${}_0C_{H_2}$ was 11.6×10^{-2} mol./l. Such a high supersaturation may be ascribed to the fact that the process of the evolution of hydrogen as bubbles of gas may be relatively slow. The rate of the transfer of hydrogen molecules from the solution to the gas phase should be proportional to the product of the

density of the distribution of bubbles and the rate of growth of each bubble. If the rate of the formation of growth nuclei is represented with the equation described by Hook[16] and if the rate of growth is proportional to $_0C_{H_2}-C_{H_2}^0$, the rate of the transfer of hydrogen, V, may be given by the expression:

$$V=K'C_{H_2}^0(\alpha-1)\cdot K''\exp\left[-\frac{16\pi M^2\sigma^3}{3d^2R^3T^3\ln^2\alpha}\right] \quad (4)$$

where α is the supersaturation as a concentration ratio, $_0C_{H_2}/C_{H_2}^0$; K', a rate constant of the growth; K'', a frequency factor; σ, an interfacial energy between the solution and hydrogen gas; d, the density of the nucleus; M, the molecular weight of hydrogen; R, the gas constant, and T, the absolute temperature. This expression demands an almost explosive increase in the rate of nucleation, as α exceeds the denfinite real value. It has been confirmed that a limiting value of the supersaturation calculated with Eq. 4 for water vapor was in good agreement with that one obtained experimentally, i.e., $\alpha=4.2$ at 275.2°K[17]. Since the d of gaseous nucleus is far smaller than that of the liquid or solid nuclei, the supersaturation of the gas in the solution may be much larger than the above value of the water vapor and also than the result obtained in the present work. However, the irregularity of the electrode surface may accelerate the formation of nuclei, and agitation and convection of the solution may prevent the high increase of α near the electrode.

Summary

The concentration of molecular hydrogen in the vicinity of the bright platinum cathode during electrolysis was determined as a function of current density by means of two different methods, the potential-time curve on the reversal of current from cathodic to anodic, and the concentration overpotential obtained by extrapolating the decay curve of the overpotential to zero time, free from other overpotentials. The agreement between the results for the concentration derived from the potential-time curve and from the concentration overpotential was satisfactory. It was found that the concentration of hydrogen increased with the increasing i_k value and approached a limiting value of 11.6×10^{-2} mol./l. for cathodic currents exceeding about $i_k=300$ mamp./cm².

*Oxidative Degradation of Polyethylene in Nitrogen Dioxide**

By Taeko OGIHARA

(Received September 18, 1962)

The oxidative degradation of polyethylene in the presence of oxygen has been studied by several investigators[1,2]. Oxygen has been reported to react with polyethylene to form hydroperoxide in the early stages of the process. However, the degradation of polymers by reagents other than oxygen has scarcely yet been studied. Only Beachell and Nemphos[3] have studied the degradation of polyethylene in ozone and in fuming nitric acid. They have reported that, at low temperatures, the effect of nitric acid is principally the molecular chain scission, as is seen from the appearance of the C=C stretching band at 1645 cm^{-1} in the infrared region, while at high temperatures nitration becomes the principal reaction. However, it is questionable whether or not it is correct to assign 1645 cm^{-1} to the C=C stretching band as they have done.

The present author's experiments were made on the oxidative degradation of polyethylene in nitrogen dioxide. The oxygenated groups which were produced in polyethylene were identified by the use of infrared absorption spectrometry. Oxidation mechanisms will also be discussed.

Experimental

The sample used was high pressure polyethylene, a relatively highly-branched polyethylene called Yukalon which is produced by the Mitsubishi Yuka Co., Ltd. Its molecular weight has been determined by viscosity measurement to be 34000. The sample contained no antioxidant.

Nitrogen dioxide was prepared by heating mixtures of lead nitrate and sand at 300°C; it was then dried by passing it through phosphorous pentoxide.

The infrared spectra were recorded with a Perkin-Elmer Model 13, a Perkin-Elmer Model 112, or a Hitachi EPI-S infrared spectrometer equipped with either a sodium chloride prism or a potassium bromide prism for the 4000~400 cm^{-1} region.

A film specimen, about 0.015 mm. thick and 20×45 mm. in area was prepared by hot moulding, mounted on a glass plate, and placed in a Pyrex cylindrical reaction vessel, 26 mm. in diameter and 22 cm. in length. One-third of the atmospheric nitrogen dioxide gas, free from air, was put into the reaction vessel, and this vessel was heated in a silicone bath controlled at 100±0.05°C. After heating, a thin polyethylene film was peeled off and its spectrum was recorded at room temperature within 3 min. after it had been taken out from the vessel.

Results

The experimental results are summarized in Table I, while the characteristic spectra of the oxidized polyethylenes and their spectral changes in accordance with the time they were left in the atmosphere are shown in Fig. 1. According to the spectral changes, the observed bands of oxidized specimens can be divided into four categories, i. e., A, B, C and D.

The bands at 1730, 1300, 900 and 1681 cm^{-1} belong to group A and disappear within 24 hr. when the oxidized film is left in the atmosphere. The bands at 1640, 778 and 600 cm^{-1} belong to group B and disappear within two months. On the other hand, the bands at 3400 and 1713 cm^{-1}, which belong to group C, gradually increase in intensity. The bands at 1554, 1365, 629, 562, 1635, 1280, 852 and 675 cm^{-1}, which fall into group D, did not change. However, when the oxidized film was heated in nitrogen

** Observed bands in the polyethylene oxidized by nitric dioxide

at 200°C for 20 min., the bands in group A and group B and some of those in group D, namely, 1635, 1280, 852 and 675 cm^{-1}, disappeared. Therefore, group D can be subdivided into group D_1, which did not disappear upon heating, and group D_2, which disappeared upon heating. When polyethylene was aged in nitric acid (more than 60% concentration) at room temperature (Fig. 2), the bands in groups C and D were observed, but those in groups A and B were not.

Assignment

Rigg[4] identified nitroalkanes, alkyl nitrates and alkyl nitrites as reaction products by means of the infrared analysis of an irradiated mixture of *n*-dodecane and nitrogen dioxide. Brand and Stevens[5] also identified nitro alkanes and alkyl nitrates as products in the reactions between nitrogen dioxide and olefins, e. g., cyclohexene and cyclopentene.

As, however, the data obtained above were insufficient for the intended assignment, several compounds were synthesized whose infrared spectra were measured for the assignment. On the basis of these findings, together with changes of observed bands upon various treatments, the assignments of the observed bands were determined as follows:

D_2 Group.—The infrared spectrum of 2-ethylhexyl nitrate, which had been prepared from 2-ethylhexyl alcohol[6], was observed (Fig. 3). The bands other than those due to 2-ethylhexyl alcohol were regarded as bands due to the nitrate group. The locations of the oxygenated groups of polyethylene were compared with those of alkyl nitrate, and it was shown that the bands which belonged to the D_2 group are to be assigned to the nitrate ester group. This assignment is shown in the last column of Table I, with reference to the results on alkyl nitrates given by Brown[7] and by Brand and Cawthon[8].

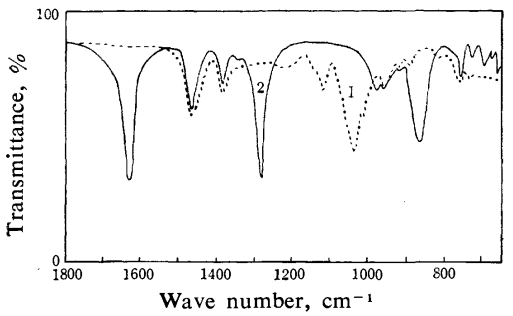

Fig. 3. Infrared spectra of 2-ethylhexyl alcohol (1) and 2-ethylhexyl nitrate (2).

D_1 Group.—By comparison with the data on various types of nitroalkanes reported by Smith et al.[9] and by Pierson et al.[10], the bands in the D_1 group were assigned to the nitro group.

C Group.—The bands at 3400 and 1713 cm^{-1} were also observed when the oxidation of polyethylene was carried out in the presence of oxygen (Fig. 4). The band at 3400 cm^{-1} was assigned to hydrogen-bonded hydroxyl group by reference to the data on low molecular weight compounds[11]. Rugg et al.[1] and Loungo[2] also assigned these bands to the hydroxyl group and carbonyl group respectively.

A and B Groups. — The infrared spectra of low-molecular-weight alkyl nitrites were measured. These compounds had various types of branches, ranging from ethyl nitrite to octyl nitrite. They were prepared by the ordinary synthetic method from alcohols. It was shown that the band at 1681 cm^{-1} in A group and the bands in B group are to be assigned to the nitrite ester group, as may be seen in the last column of Table I, by reference to the data of Tarte[12], Haszeldine and Mattinson[13] and Bellamy et al.[14]

Beachell and Nemphos[3] assigned the band at 1640 cm^{-1} to the C=C stretching band. When the thermal degradation of polyethylene was carried out at 350~370°C for 20 min. in nitrogen, the C=C stretching band was observed at 1640 cm^{-1}. At the same time, four strong bands which were attributable to C–H out of plane vibrations were observed at 900~1000 cm^{-1} (Fig. 4), whereas when the oxidative degradations were carried out in nitrogen dioxide, the bands at 900~1000 cm^{-1} were not observed. Similarly, the bands at 900~1000 cm^{-1} were not observed in the oxidative degradations in fuming nitric acid or in 60% nitric acid at room temperature (Fig. 2). Moreover, when those double bonds of the polyethylene which had been produced by the thermal degradation were brominated, the bands at 1640 cm^{-1} and 900~1000 cm^{-1}

1 Thermal oxidation in the air (at 150°C)
2 Thermal degradation in nitrogen (at 350°C)

disappeared and a new band appeared at 573 cm^{-1}. This new one is attributable to the C–Br stretching band[11]. However, when the polyethylene which had been oxidized in nitrogen dioxide was brominated, the band at 1640 cm^{-1} disappeared, but the new band did not appear. Therefore, it would be erroneous to assign the band at 1640 cm^{-1} to the C=C stretching band, as was proposed by Beachell and Nemphos[3].

In the case of low-molecular-weight alkyl nitrites, the intensities of the trans N=O stretching at 1681 cm^{-1} are stronger than those of the cis N=O stretching at 1620 cm^{-1}, as may be seen in Fig. 5, but the reverse is true of the nitrite ester groups in polyethylene (Fig. 1). By preservation of oxidized products in a vessel cooled by a mixture of dry ice and *n*-heptane, the bands at 1730, 1300, 900 and 1681 cm^{-1} in group A could be preserved for more than a week before they disappeared (Fig. 6). When they were kept in a vacuum desiccator with phosphorous pentoxide, the band at 1681 cm^{-1} did not disappear until after more than a week, but the bands at

4 Left 30 min. in the atmosphere
5 Left 3 days in the atmosphere

1730, 1300 and 900 cm^{-1} went away within 24 hr., as when the samples were left in the atmosphere. The prevention of the disappearance of the band at 1681 cm^{-1} was greater in a cool place.

The intensities of bands in the A group decreased as the reaction gas or the produced gas was removed from the polymer. As for the band at 1681 cm^{-1}, it seemed that the above process was not responsible for its disappearance, because when the oxidized films were left in a desiccator, the band did not

disappear. However, the bands at 1730, 1300 and 900 cm^{-1} could be attributed to the production of nitric acid in view of the location of the absorption bands, their relative intensities[15], and the fact that when the products were placed in a desiccator, the bands at 1730, 1300 and 900 cm^{-1} disappeared. It seems that the rate of disappearance of the band at 1681 cm^{-1} depends on the temperature, but it is not clear why the intensity of the trans N=O is weaker than that of the cis N=O in the polymer. This problem should be investigated in the future.

Discussion

The kinetic studies of polyethylene oxidations in nitrogen dioxide were made on the basis of the identification of the groups which were formed in polyethylene during oxidation and of the rates of formation of groups (Fig. 7). The bands used for the studies were 1554 (nitro group), 778 (nitrite ester group), 852 (nitrate ester group) and 1713 cm^{-1} (carbonyl group). As may be seen in Fig. 7, the nitro group and the nitrite ester group were produced in the early stages; the intensity of the nitro group increased constantly, while that of the nitrite ester group reached its maximum point and even began to level off in five hours. On the other hand, the nitrate ester group and the carbonyl group did not appear in the early stages; they appeared after the nitro group and some of the nitrite ester groups had been formed.

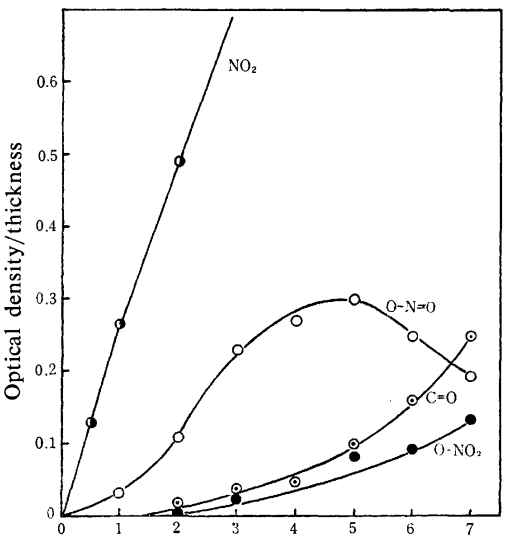

Fig. 7. Rate of formation of oxygenated groups in polyethylene.

15) R. A. Marcus and J. M. Fresco, *J. Chem. Phys.*, **27**, 564 (1957),

As nitrogen dioxide gas has an odd electron structure, it may be expected to combine with radicals easily[4,16]. Therefore, it seems that in the early stages the nitro groups and the nitrite ester groups are produced by the reaction of activated polyethylene with nitrogen dioxide in terms of the $\dot{R} + \dot{N}O_2 \rightarrow RNO_2$ and $\dot{R} + \dot{O}NO \rightarrow RONO$ processes. The carbonyl groups and the nitrate ester groups were produced as decomposition products of the nitro and the nitrite ester groups in the secondary state. Gray et al.[17] have identified aldehyde and ketone as decomposition products of the pyrolyses of alkyl nitro compounds, especially nitroethane, at temperatures between 240 and 800°C. As the intensity of the nitro group did not change when the oxidized products were left in the atmosphere, and as the change in intensity was only a little when the products were heated at 200°C in nitrogen gas, it seems that the nitro group formed in polyethylene is relatively stable. On the other hand, as the intensity of the nitrite ester group decreased when the oxidized products were left in the atmosphere, the nitrite ester group seems to be unstable.

Phillips[18] has identified methyl alcohol, formaldehyde and hydrogen cyanide as the decomposition products of the pyrolysis of methyl nitrite. Levy[19] has identified not only isopropyl alcohol and acetone, but also such chain scission products as acetaldehyde and hydrogen cyanide as the thermal decomposition products of isopropyl nitrite, while for ethyl nitrite he has identified acetaldehyde and ethyl alcohol. Gray and Williams[20] and Pollard et al.[21] have suggested that alkyl nitrate is produced by the pyrolysis of alkyl nitrite in the presence of nitrogen dioxide. From the present analyses of the infrared spectra of the oxidized products, the carbonyl, hydroxyl and nitrate ester groups have been identified and it seems that these are mainly the decomposition products of the nitrite ester group, because the nitrite ester group is unstable, as has been mentioned above.

On the basis of the mechanisms which have been proposed by several investigators for the pyrolyses of alkyl nitrite[18,19,22] and alkyl nitrate[20] and for the photolysis of alkyl

nitrite[23], the following mechanisms may be considered:

$$RH \xrightarrow{\text{activated}} \dot{R} + \dot{H} \quad RH\text{; polyethylene}$$

In early stages:

$$\dot{R} + \dot{N}O_2 \rightarrow RNO_2\text{; nitro group}$$

$$\dot{R} + \dot{O}NO \rightarrow RONO\text{; nitrite ester group}$$

In secondary stages:

$$RONO \rightarrow R\dot{O} + \dot{N}O\text{; O-N fission}$$

$$R\dot{O} + \dot{N}O_2 \rightarrow RONO_2\text{; nitrate ester group}$$

$$\left.\begin{aligned} R'CH_2\dot{O} &\rightarrow R'CHO + \dot{H} \\ R''R'''CH\dot{O} &\rightarrow R''R'''CO + \dot{H} \\ R''R'''CH\dot{O} &\rightarrow R''CHO + \dot{R}''' \end{aligned}\right\} \text{carbonyl group}$$

$$R\dot{O} + \dot{H} \rightarrow ROH\text{; hydroxyl group}$$

$$RONO_2 \rightarrow R\dot{O} + \dot{N}O_2$$

In our study no decision was made whether the nitro group or the nitrite ester group was produced in the greater amount, for the absolute intensity of the nitrite ester group has not yet been obtained.

Conclusion

From analyses of the infrared spectra of polyethylene oxidized in nitrogen dioxide, the formation of the nitro, nitrite ester, nitrate ester, carbonyl and hydroxyl groups have been identified. In early stages, the nitro group and the nitrite ester group were produced by the addition of nitrogen dioxide to the activated position of polyethylene. The nitrate ester, carbonyl and hydroxyl groups were produced as decomposition products of the two aforementioned groups, mainly the nitrite ester group.

A Study of the Sol-Gel Transformation of Gelatin Solutions

By Nobuo TANAKA and Isamu UTSUMI

(Received August 24, 1962)

Gelatin has been universally used in such pharmaceutical preparations as capsules, tablets and injections. The physical properties of gelatin are important in the production of these pharmaceutical preparations. In recent years, the physical properties of gelatin solutions have been extensively investigated in the field of rheology[1,2], but reports of the sol-gel transformation have been limited to its lower concentrations. Since the productions of pharmaceutical preparations is carried out with gelatin solutions of the higher concentrations, data on the lower concentrations are not useful. Therefore, that sol-gel transformation which is considered to determine the physical nature of the pharmaceutical preparations produced was investigated.

In the study of this transformation, Bourgoin[3] has examined the viscosity and the double refraction of gelatin solutions of the lower concentrations. On the other hand, the method of measuring the solution with a 10% concentration has been described in JIS[4]. In the JIS method for measuring the sol-gel transformation, an apparatus (shown in Fig. 1) is used in which 50 cc. of a hot, 10% gelatin solution is put into an inside vessel. Immediately, the sample is gently stirred with a thermometer, and the flowing behavior of gelatin solution is observed with the naked eye; of the phenomena which the solution shows before the appearance of resistance, some rigidity is called the transformation temperature. The JIS method, however, based as it is on the observation of the human eye, is essentially

inaccurate and is not applicable to solutions of the higher concentrations.

A new measuring method with a Macmichael viscometer is proposed for application to the solutions of necessarily higher concentrations in order to determine their transformation points. On the other hand, a co-axially oscillating rheometer is used for studying the behavior of the sol-gel transformation through the transformation temperature.

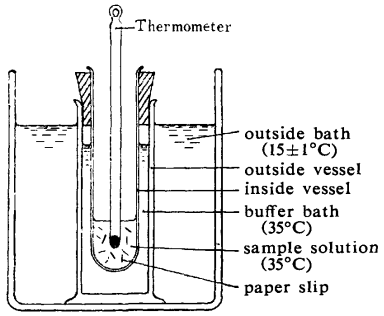

Fig. 1. The apparatus for measuring the transformation temperature. (JIS method).

Experimental

A Macmichael viscometer (I) was used for the observation of viscosity change at the sol-gel transformation, and a co-axially oscillating rheometer (II) was employed to follow the change of viscoelastic behavior through the sol-gel transformation.

Rheometer (I).—The sample was put into the gap between the co-axial internal and external cylinders. The diameters of the internal cylinder, d_1, and of the external cylinder, d_2, were 2.00 and 3.00 cm. respectively. The depth of the immersion of the internal cylinder was 4.00 cm., which was equal to the height of the cylinder. The viscosity is calculated from the following equation:

$$\eta_I = C \cdot (\theta/r) \qquad (1)$$

where η_I is the apparent viscosity, θ is the angle of deflection of the internal cylinder in radian, r is the number of revolutions of the external cylinder (5 r. p. m.), and C is an instrumental constant, which is either 29.0 or 1.79. Both cylinders ware heated previously by circulating water at 52~55°C and by putting the sample into the gap between the cylinders, where it was heated for about five minutes at 52~55°C. Then, the sample was gradually cooled at the rate of 1°C per 5 min. and the viscosity was measured at various temperatures at 5 r. p. m.

Rheometer (II).—A top-drive co-axial rheometer which has previously been described by Nakagawa and Seno[5] was used. The sample was put into the gap between the cylinders. The radius of the internal cylinder, r_1, was 0.6 cm. and that of the external cylinder, r_2, was 0.9 cm. The depth, h, of the immersion of the internal cylinder was about 10 cm. The moment of inertia, I, of the internal cylinder and the wire chuck were 38.07 g. cm. The torsional constants of two wires determined from the period of the free torsional oscillation, $\bar{k}$, were 587.8 and 1313 dyn. cm. To the top of the wire a torsional oscillation was applied, and the oscillation of the internal cylinder was recorded on a paper. A Lissajous figure was obtained by combining perpendicularly the oscillation of the top of the wire and that of the internal cylinder. Since the Lissajous figure thus obtained was an ellipse, the dynamic viscosity, η_{II}, and the dynamic modulus, G, were calculated by the following equations:

$$\eta_{II} = (R/4h) \cdot (1/r_1^2 - 1/r_2^2) \quad \text{(poise)}$$
$$G = (K/4h) \cdot (1/r_1^2 - 1/r_2^2) \quad \text{(dyn./cm}^2\text{)} \qquad (2)$$

where R and K were the quantities to be determined experimentally by using the following equations:

$$R = \bar{k}\ T \sin\phi/2m \text{ and } K = \bar{k} (\cos \phi/m - 1) + (4\pi^2 I/T^2) \qquad (3)$$

Here, the lag angle, ϕ, and the amplitude ratio, m, were obtained by an analysis of the Lissajous' figure, and the period of oscillation, T, was 0.0286 cycl./sec.

Preparation of the Gelatin Solution.—The preparation of the gelatin solution has been generally described in JIS. but here the water content of the gelatin was changed to 16%. The gelatin was then dried for 5 hr. at 105~115°C; after it (X) had been weighed accurately, the amount to be needed was calculated from "$X \times 84/(100-y)$", with y indicating the water concent (%) of gelatin. After water had been added to the gelatin, the solution was kept at room temperature for half an hour in order for the gelatin to be completely swollen and then on a water bath at 55~60°C for 1 hr. for the gelatin to be dissolved. This solution was used for the measurements.

Results and Discussion

The dependnce of the apparent viscosity on the temperature has been shown in Fig. 1. In this figure the sol-gel transformation is shown by a sudden increase in the apparent viscosity. The transformation temperatures obtained by this method are shown in Table I in comparison with the values obtained by the JIS method[4].

The transformation temperature obtained is higher by 1~5°C than that of the JIS method, and the temperature rose with the concentration. The rates of the sol-gel transformation seemed to become slower with the increase in the concentration.

Differences in the behavior of various gelatins could not be observed definitely through the data of the sol-gel transformation. Therefore, the transformation was investigated by rheometer II. From the results of viscoelastic measurement, the dynamic viscosity, η_{II}, and

the dynamic modulus, G, were calculated by Eq. 2; they are show in Figs. 3—6, where the change of η_{II} or G with time is plotted at several temperatures. Both η_{II} and G at the higher concentration rose rapidly in a shorter time than at the lower concentration at the same temperature.

Further, the kinetic procedure was employed in order to investigate what the nature of the transformation was from sol to gel. From the plot of the logarithm of η_{II} or G against time,

two straight lines, AB and BC, crossing at B were obtained as Figs. 3—6 in most cases. The slope, k, of the initial line, AB, $d \ln \eta_{II}/dt$ or $d \ln G/dt$, was calculated as shown in Table II. On the other hand, the slope, k', of the second line, BC, of the appearance at the 30% solution was calculated by the same method at the initial line, AB.

TABLE II. RELATIONSHIP OF THE INITIAL SLOPE, k, OF THE AB PERIOD TO THE TEMPERATURE

RELATIONSHIP OF THE SECOND SLOPE, k', OF THE BC PERIOD TO THE TEMPERATURE

Concn. of sample %	Temp. °C	k'	
		η_{II}	G
30	31.5	0.04204	0.09933
	32.4	0.02062	0.04027
	33.0	0.01151	0.01918
	33.5	0.00768	0.01148

The values of η_{II} or G at the point of B were lower at the higher temperature than at the lower temperature. The values of k', were lower than that of k. These results are probably due to the increased difficulty of the arrangement of the colloidal particles at the BC period than at the AB period.

Besides, log k was plotted against the inverse temperature, as in Fig. 7. The straight line was obtained within a narrow range at the lower temperatures. Its range decreased in a 20% solution and deviated from the straight line. At the 30% concentration, the relationship of k' and the inverse temperature was similarly obtained as a straight line.

From the relation between the activation energies of k and k', $\Delta E_{K'}^{*}$ and $\Delta E_{K'}^{*}$ were calculated by the Arrhenius equation; they are shown in Table III. $\Delta E_{K'}^{*}$ higher than ΔE_{K}^{*} was obtained.

TABLE III. ACTIVATION ENERGY, ΔE^{*}, OF k AND k'

Concn. of sample %	k		k'	
	η_{II}	G	η_{II}	G
20	77.0	97.3	—	—
30	109	139	159	201

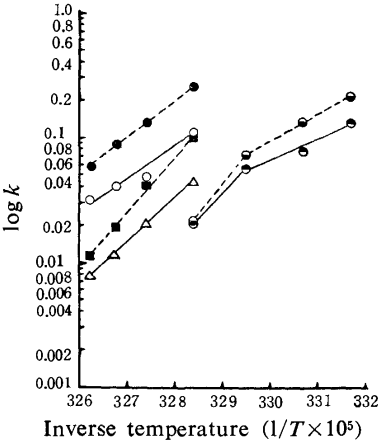

Fig. 7. Relationship of log k of η_{II} or that of G with the inverse temperature.
-◓- η_{II} at the concentration 20% of AB period
-◒- G at the concentration 20% of AB period
-○- η_{II} at the concentration 30% of AB period
-●- G at the concentration 30% of AB period
-△- η_{II} at the concentration 30% of BC period
-■- G at the concentration 30% of BC period

The difference in behavior between the AB and BC periods is probably due to the difference in the interaction of colloidal particles at various temperatures. In other words, the movement of colloidal particles is restricted at the BC period as compared with the AB period.

As has been described above, as the change from sol to gel at the AB period is relatively easy, the aggregation of gelatin particles occurs rapidly in a gelatin solution, but as the gelatin has already started the aggregation at the BC period, it is more difficult for the remaining gelatin particles in sol at the BC period to aggregate than at the AB period, when almost all the gelatin particles are in sol. Accordingly, it is natural that k' should be a smaller quantity than k and that $\Delta E_{K'}^{*}$ should be larger than ΔE_{K}^{*}. The arrangement of colloidal particles at the higher temperature must be more systematical than that at the lower temperature.

The authors wish to express their deep appreciation to Professor M. Nakagaki of Kyoto University and to Dr. M. Fujisawa and Dr. N. Sugimoto of the Tanabe Seiyaku Co., Ltd., for their valuable advice and encouragement, and to Mr. T. Hashimoto for his assistance in this work. Thanks are also due to Nihonhikaku Co., Ltd., which prepared the samples for this work.

The Kinetics of Substitution Reactions Involving Metal Complexes. VI. Reaction between Lead(II) and Ethylenediaminetetraacetatocobaltate(II) Complexes in Aqueous Solutions

By Nobuyuki TANAKA, Hisao OSAWA* and Minoru KAMADA

(Received September 21, 1962)

A series of substitution reactions involving metal-ethylenediaminetetraacetate (EDTA) complexes has been studied[1-7]. The reactions were found to proceed through three simultaneous reaction paths in the case of the substitution reactions of lead(II) and copper(II)-EDTA[3,4], lead(II) and zinc(II)-EDTA[2,6] and copper(II) and zinc(II)-EDTA[5], but through four simultaneous reaction paths in the case of the substitution reaction of copper(II) and cadmium(II)-EDTA[1,7].

In the present paper, the kinetic study of the substitution reaction between lead(II) ions and cobalt(II)-EDTA complexes is presented. From the rate constants of substitution of coordinated water[8,9], it was expected that the rate of dissociation of cobalt(II)-EDTA complexes is considerably slower than those of copper(II)-, zinc(II)- and cadmium(II)-EDTA complexes. This expectation was confirmed in the present study by the fact that the dissociation of cobalt(II)-EDTA complexes acts as a rate-determining reaction.

Derivation of the Rate Equation

Let us consider the acetate buffer solution which contains lead(II) ions and cobalt(II)-EDTA complexes. In the solution containing acetate ions less than 0.2 M in concentration, lead(II) forms mono- and diacetato complexes[10] and cobalt(II), monoacetato complex[11]. As for the EDTA complexes, the equilibria

$$CoY^{2-} + H^+ \rightleftarrows CoHY^-,$$
$$PbY^{2-} + H^+ \rightleftarrows PbHY^-$$

must be taken into consideration when pH of the solution is less than 5, where Y^{4-} means a tetravalent EDTA anion. Consequently, the overall substitution reaction is represented by the equations

$$Pb^{2+} + 2OAc^- \rightleftarrows PbOAc^+ + OAc^- \rightleftarrows Pb(OAc)_2 \quad (1)$$

$$Pb^{2+} + \left\{\begin{matrix} CoY^{2-} \\ \downarrow\uparrow \\ CoHY^- \end{matrix}\right\} \rightleftarrows \left\{\begin{matrix} PbY^{2-} \\ \downarrow\uparrow \\ PbHY^- \end{matrix}\right\} + Co^{2+} \quad (2)$$

$$Co^{2+} + OAc^- \rightleftarrows CoOAc^+ \quad (3)$$

As described in the previous papers[6,10], the concentration of simple lead ions that can be determined polarographically is an apparent concentration $[Pb^{2+}]_{app}$ which, under the present experimental conditions, is given by

$$[Pb^{2+}]_{app} = [Pb^{2+}] + [PbOAc^+] + [Pb(OAc)_2] \quad (4)$$

In the preliminary experiments in which the apparent initial rate of the reaction, $-\Delta[Pb^{2+}]_{0,app}/\Delta t$, was determined, the following facts were recognized, where the subscript 0 means the initial state.

(1) At the given pH and the given concentrations of $[Pb^{2+}]_{0,app}$, $[Co^{2+}]_{0,app}$ and $[OAc^-]$, the apparent initial rate was proportional to the initial concentration of cobalt(II)-EDTA complex, $[Co\text{-}EDTA]_0$, given by

$$[Co\text{-}EDTA]_0 = [CoY^{2-}]_0 + [CoHY^-]_0$$

(2) At the given pH and the given concentrations of $[Co\text{-}EDTA]_0$, $[Co^{2+}]_{0,app}$ and $[OAc^-]$, the apparent initial rate varied with the change of $[Pb^{2+}]_{0,app}$ according to the relation

$$-\frac{\Delta[Pb^{2+}]_{0,app}}{\Delta t} \Big/ [Co\text{-}EDTA]_0 = k'[Pb^{2+}]_{0,app} + k'' \quad (5)$$

(3) The relation given by Eq. 5 held at any pH where the experiments were carried

out. In addition, the values of k' and k'' in Eq. 5 which were obtained at various pH's satisfied the relations

$$k' = k_\xi' [H^+] + k_\eta' \quad (6)$$

and

$$k'' = k_\xi'' [H^+] + k_\eta'' \quad (7)$$

These facts, which were analogous to those found in the preliminary study of the substitution reaction between lead(II) and nickel(II)-EDTA complexes[12], suggested that the overall reaction would proceed, under the experimental conditions, through four simultaneous reaction paths,

$$\text{(i)} \quad Pb^{2+} + CoY^{2-} \underset{k_1^-}{\overset{k_1^+}{\rightleftharpoons}} PbY^{2-} + Co^{2+} \quad (8)$$

$$\text{(ii)} \quad Pb^{2+} + CoHY^- \underset{k_2^-}{\overset{k_2^+}{\rightleftharpoons}} PbHY^- + Co^{2+} \quad (9a)$$

$$PbHY^- \rightleftharpoons PbY^{2-} + H^+ \quad (9b)$$

$$\text{(iii)} \quad CoY^{2-} \underset{k_{3a}^-}{\overset{k_{3a}^+}{\rightleftharpoons}} Co^{2+} + Y^{4-} \quad \text{(rate-determining)} \quad (10a)$$

$$Pb^{2+} + Y^{4-} \underset{k_{3b}^-}{\overset{k_{3b}^+}{\rightleftharpoons}} PbY^{2-} \left(\underset{-H^+}{\overset{+H^+}{\rightleftharpoons}} PbHY^- \right) \quad (10b)$$

$$\text{(iv)} \quad CoHY^- \underset{k_{4a}^-}{\overset{k_{4a}^+}{\rightleftharpoons}} Co^{2+} + HY^{3-} \quad \text{(rate-determining)} \quad (11a)$$

$$Pb^{2+} + HY^{3-} \underset{k_{4b}^-}{\overset{k_{4b}^+}{\rightleftharpoons}} PbHY^- \left(\underset{+H^+}{\overset{-H^+}{\rightleftharpoons}} PbY^{2-} \right) \quad (11b)$$

It is assumed that in these reactions only the hydrated lead(II) ion Pb^{2+} is a reactive species. The apparent initial rate for the forward reaction is, then, derived as,

$$-\frac{\Delta [Pb^{2+}]_{0,app}}{\Delta t} = (k_1^+ [CoY^{2-}]_0 + k_2^+ [CoHY^-]_0)[Pb^{2+}]_0 + k_{3a}^+ [CoY^{2-}]_0 + k_{4a}^+ [CoHY^-]_0 \quad (12)$$

Introducing the formation constants of acetatolead(II) complexes $K_{Pb(OAc)_n}$ and the equilibrium constant K_{CoHY}^H ($= [CoHY^-]/([CoY^{2-}][H^+])$), Eq. 13 is obtained for the apparent initial rate of the reaction.

$$-\frac{\Delta [Pb^{2+}]_{0,app}}{\Delta t} = \left[\{k_1^+ + k_2^+ K_{CoHY}^H [H^+]\} \times \frac{[Pb^{2+}]_{0,app}}{1 + \sum_{n=1}^{2} K_{Pb(OAc)_n} [OAc^-]^n} + k_{3a}^+ + k_{4a}^+ K_{CoHY}^H [H^+] \right] \frac{[Co\text{-}EDTA]_0}{1 + K_{CoHY}^H [H^+]} \quad (13)$$

For the sake of convenience, Eq. 13 is rewritten as

$$-\frac{\Delta [Pb^{2+}]_{0,app}}{\Delta t} \cdot \frac{1}{[Co\text{-}EDTA]_0} = \frac{1}{\alpha\beta} \{k_1^+ + k_2^+ K_{CoHY}^H [H^+]\} [Pb^{2+}]_{0,app} + \frac{1}{\alpha} \{k_{3a}^+ + k_{4a}^+ K_{CoHY}^H [H^+]\} \quad (14)$$

$$\alpha = 1 + K_{Co\ Y} [H^+]$$

$$\beta = 1 + \sum_{n=1}^{2} K_{Pb(OAc)_n} [OAc^-]^n$$

Experimental

Reagents.—The solution of disodium ethylenediaminetetraacetate (EDTA) was standardized against the standard copper(II) solution by amperometric titration using a dropping mercury electrode as an indicator electrode[13]. The standard solution of lead(II) nitrate was prepared from the guaranteed grade reagent, and the concentration of lead(II) was determined amperometrically with the standardized EDTA solution[13]. The standard solution of cobalt(II) nitrate was obtained by dissolving cobalt metal in reagent grade nitric acid and standardized against the standardized EDTA solution amperometrically and also volumetrically with murexide[14]. Although the polarographic analysis showed that the cobalt metal contained 0.2% of nickel as impurity, the metal was used without further purification. It was taken into consideration that the substitution reaction between lead(II) and nickel(II)-EDTA complexes proceeds at much slower rate than the reaction between lead(II) and cobalt(II)-EDTA complexes[12], and consequently a small amount of nickel contained in the cobalt metal would not interfere to an appreciable extent in the present experiments. All other chemicals used were of guaranteed reagent grade.

Apparatus and Procedure. — The initial rate of reaction was determined by measuring the change of the polarographic diffusion current of lead ions at −0.60 V. vs. SCE as a function of time in acetate buffer solutions. The current-time curves were recorded with a Shimadzu RP-2 pen-recording polarograph using a dropping mercury electrode. The dropping mercury electrode used had an m value of 2.93 mg./sec. and a drop time of 3.16 sec./drop, being measured in an air-free 0.2 M potassium

nitrate solution with open circuit at 55 cm. of mercury column at 25°C.

Measurements were made at 5 and 15°C in acetate buffer solutions of pH from 4.75 to 5.66. The ionic strength was adjusted to be 0.2 with potassium nitrate. Gelatin was added as a maximum suppressor by 0.01% in concentration. The pH of the solution was measured with a Hitachi Model EHP-1 pH-meter, within the accuracy of 0.02 pH unit, immediately after the measurement of the current-time curves.

Results

Since α and β in Eq. 14 are constant at the given pH and the given concentration of acetate, a plot of the left-hand side of Eq. 14 versus $[Pb^{2+}]_{0,app}$ should give a straight line with a slope of

$$\frac{1}{\alpha\beta}\{k_1^{+}+k_2^{+}K^{H}_{CoHY}[H^{+}]\} \qquad (15)$$

and the intercept at $[Pb^{2+}]_{0,app}=0$ given by

$$\frac{1}{\alpha}\{k_{3a}^{+}+k_{4a}^{+}K^{H}_{CoHY}[H^{+}]\} \qquad (16)$$

The apparent initial rates were determined at various lead(II) concentrations with the reaction mixtures of the given pH which contained acetate buffer of the given acetate concentration and cobalt(II) ions and cobalt(II)-EDTA complexes in large excess over lead(II) ions. These measurements were carried out at various pH's ranging from 4.75 to 5.66. The plots of the left-hand side of Eq. 14 versus $[Pb^{2+}]_{0,app}$ obtained at 15°C are shown in Fig. 1. The intercepts at $[Pb^{2+}]_{0,app}=0$ and the slopes of these plots were determined by the method of least square. In these measurements at 15°C, the pH of the solutions was varied from 5.04 to 5.66 and consequently the value of α in Eq. 14 changes from 1.00_9 to 1.00_3. In the present calculation α was assumed to be unity, taking into consideration the accuracy of the measurement of the apparent initial rate and the deviations of the plots in Fig. 1. Then, the intercepts at $[Pb^{2+}]_{0,aPp}=0$ in Fig. 1 correspond simply to $\{k_{3a}^{+}+k_{4a}^{+}K^{H}_{CoHY}[H^{+}]\}$ and the slopes to

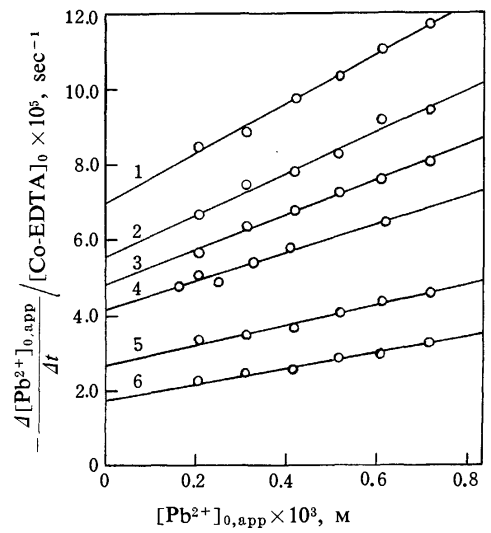

Fig. 1. $(-\Delta[Pb^{2+}]_{0,app}/\Delta t)/[Co\text{-}EDTA]_0$ as a function of the initial concentration of lead(II) ion in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Co^{2+}]_{0,app}=5.14\times10^{-3}$; $[Co\text{-}EDTA]_0=4.91\times10^{-3}$ M. pH: (1), 5.04; (2), 5.11; (3), 5.21; (4), 5.30; (5), 5.47; (6), 5.66. Concentration of free acetate is 0.090 M.

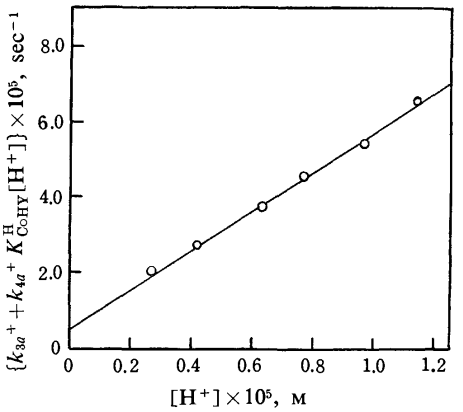

Fig. 2. The observed values for $\{k_{3a}^{+}+k_{4a}^{+}\cdot K^{H}_{CoHY}[H^{+}]\}$ at various hydrogen ion concentrations in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Co^{2+}]_{0,app}=5.14\times10^{-3}$ M; $[Co\text{-}EDTA]_0=4.91\times10^{-3}$ M. Concentration of free acetate is 0.090 M.

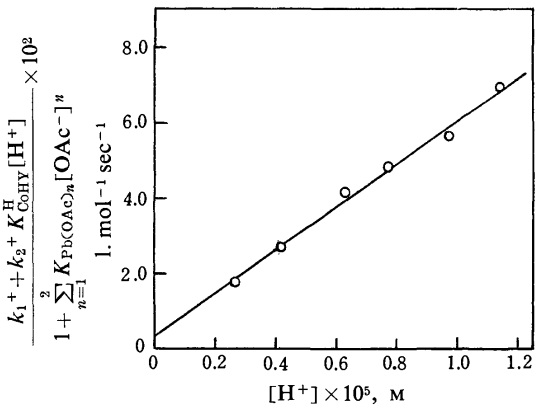

Fig. 3. The observed values for $(k_1^{+}+k_2^{+}\cdot K^{H}_{CoHY}[H^{+}])/(1+\sum_{n=1}^{2}K_{Pb(OAc)_n}[OAc^{-}]^n)$ at various hydrogen ion concentrations. The conditions are the same as Fig. 2.

** The value is less accurate.

$\{k_1^+ + k_2^+ K^{H}_{CoHY}[H^+]\}/\beta$. The values of $\{k_{3a}^+ + k_{4a}^+ K^{H}_{CoHY}[H^+]\}$ and $\{k_1^+ + k_2^+ K^{H}_{CoHY}[H^+]\}/\beta$ obtained are plotted against the hydrogen ion concentration in Figs. 2 and 3. From these plots, the values of k_1^+, k_2^+, k_{3a}^+ and k_{4a}^+ were determined, when K^{H}_{CoHY} at 15°C was estimated from the value given by Schwarzenbach, Gut and Anderegg[15] and β was calculated with the aid of the formation constant $K_{Pb(OAc)_n}$ reported previously[10]. Similar results were also obtained in the experiments carried out at 5°C. The rate constants k_1^+, k_2^+, k_{3a}^+ and k_{4a}^+ at 5 and 15°C are given in Table I.

Discussion

The assumption that reactions 10a and 11a are rate-determining in reaction paths iii and iv, respectively, should be discussed, though it is confirmed by the experimental results. Let us consider reaction path iii, for example. The initial rate of the reaction (v_3), which is measured by the decrease of $[Pb^{2+}]_{app}$, is given as

$$v_3 = k_{3b}^+ [Pb^{2+}]_0 [Y^{4-}]_0 \qquad (17)$$

Applying the steady state treatment, $[Y^{4-}]_0$ is represented as

$$[Y^{4-}]_0 = \frac{k_{3a}^+ [CoY^{2-}]_0}{k_{3a}^- [Co^{2+}]_0 + k_{3b}^+ [Pb^{2+}]_0} \qquad (18)$$

Introducing Eq. 18 into Eq. 17, v_3 is written as

$$v_3 = \frac{k_{3a}^+ k_{3b}^+ [Pb^{2+}]_0 [CoY^{2-}]_0}{k_{3a}^- [Co^{2+}]_0 + k_{3b}^+ [Pb^{2+}]_0} \qquad (19)$$

In Eq. 19, if the condition,

$$k_{3a}^- [Co^{2+}]_0 \ll k_{3b}^+ [Pb^{2+}]_0$$

is satisfied, Eq. 19 is simplified to

$$v_3 = k_{3a}^+ [CoY^{2-}]_0 \qquad (20)$$

Eq. 20 indicates that the rate of the reaction is independent of the concentration of lead(II) ions present in the solution. A similar treatment is applied to reaction path iv, when the same relation that the reaction rate is independent of the concentration of lead(II) ions is obtained. These results agree with the experimental observations. At this point, the substitution reaction between lead(II) and cobalt(II)-EDTA is entirely different from those reported previously[1-7].

In this study, k_1^+ and k_{3a}^+ at 5°C could not be determined, and those at 15°C were less accurate than other rate constants. This was presumably due to the fact that the reactions through paths i and iii make only a small contribution to the whole reaction. The contribution of the each reaction path was calculated under the appropriate conditions, and is given in Table II, which indicates that the reaction through paths i and iii is less than 10% of the whole reaction.

Equation 13 predicts that the reaction rate decreases with increasing concentration of acetate ion. This has been found and confirmed experimentally with several substitution reactions studied previously. Using Eq. 14, the values of $(-\Delta[Pb^{2+}]_{0,app}/\Delta t)/[Co\text{-}EDTA]_0$ were calculated at various concentrations of acetate ion with the rate constants given in

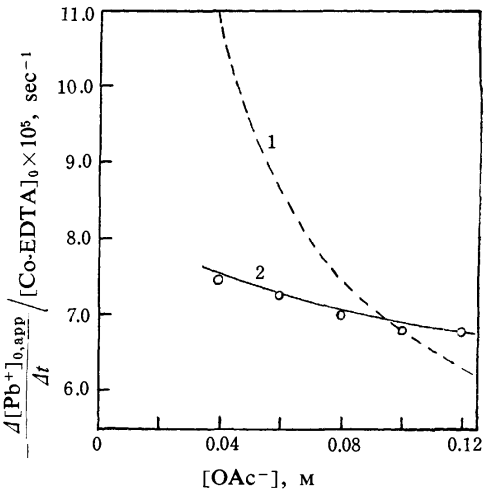

Fig. 4. $(-\Delta[Pb^{2+}]_{0,app}/\Delta t)/[Co\text{-}EDTA]_0$ as a function of the acetate ion concentration in acetate buffer-potassium nitrate solutions of pH 5.22 and ionic strength 0.2 at 15°C. Initial concentrations are: $[Pb^{2+}]_{0,app}=5.00\times10^{-4}$ M; $[Co^{2+}]_{0,app}=5.14\times10^{-3}$ M; $[Co\text{-}EDTA]_0=4.91\times10^{-3}$ M. Curve 1 represents the theoretical values calculated with Eq. 14, while curve 2, that calculated with Eq. 22. ○ indicates the experimental value.

TABLE II. CONTRIBUTION OF EACH REACTION PATH TO OVERALL SUBSTITUTION REACTION AT pH 5.21, 15°C AND 0.2 IONIC STRENGTH*

Reaction path	Expression for reaction rate**	Reaction rate sec^{-1}	Contribution to total reaction rate %
(i)	$k_1^+[Pb^{2+}]_{0,app}/\alpha\beta$	$2.6_5\times10^{-6}$	2.9
(ii)	$k_2^+K^H_{CoHY}[H^+][Pb^{2+}]_{0,app}/\alpha\beta$	$2.0_6\times10^{-5}$	29.1
(iii)	k_{3a}^+/α	4.0×10^{-6}	5.5
(iv)	$k_{4a}^+K^H_{CoHY}[H^+]/\alpha$	4.5×10^{-5}	62.6

* $[Pb^{2+}]_{0,app}=5.18\times10^{-4}$ M, $[Co^{2+}]_{0,app}=5.14_4\times10^{-3}$ M, $[Co\text{-}EDTA]_0=4.90_5\times10^{-3}$ M, $[OAc^-]=0.090$ M

** $\alpha=1+K^H_{CoHY}[H^+]$; $\beta=1+\sum_{n=1}^{2}K_{Pb(OAc)_n}[OAc^-]^n$

Table I. These values are plotted against acetate ion concentration in Fig. 4 (curve 1), where the experimental values for $(-\Delta\cdot[Pb^{2+}]_{0,app}/\Delta t)/[Co\text{-}EDTA]_0$ obtained at various concentrations of acetate ion are also given. Figure 4 indicates that the values of $(-\Delta[Pb^{2+}]_{0,app}/\Delta t)/[Co\text{-}EDTA]_0$ calculated with Eq. 14 fairly deviate from the experimental ones, as has been noticed in the studies on other substitution reactions[4-7]. The discrepancy apparently arises from the assumption that the reaction proceeds through only hydrated ions.

Then, the reaction was assumed as to proceed through both hydrated ion and monoacetato complex. The rate-determining steps in reaction paths i and ii are as follows:

(i) $Pb^{2+}+CoY^{2-}\overset{k_{1h}^+}{\rightleftharpoons}PbY^{2-}+Co^{2+}$ (8')

$PbOAc^++CoY^{2-}\overset{k_{1c}^+}{\rightleftharpoons}PbY^{2-}+CoOAc^+$ (8'')

(ii) $Pb^{2+}+CoHY^-\overset{k_{2h}^+}{\rightleftharpoons}PbHY^-+Co^{2+}$ (9a')

$PbOAc^++CoHY^-\overset{k_{2c}^+}{\rightleftharpoons}PbHY^-+CoOAc^+$ (9a'')

where k_{ih}^+ and k_{ic}^+ mean the rate constants of the reactions which proceed through the hydrated ion and monoacetato complex, respectively. Reaction paths iii and iv are not concerned with this treatment because the rate-determining steps of these paths are the dissociation of cobalt(II)-EDTA complexes and involve no acetato complex.

Since it seemed extremely difficult, however, to determine all of these rate constants, k_{ih}^+ and k_{ic}^+, separately because of insufficient accuracy in the measurement, a procedure similar to that reported previously[7] was taken up as the first approximation.

In reaction paths i and ii, the ratios of k_{ic}^+ and k_{ih}^+ are assumed to be the same and denoted with x.

$$\frac{k_{ic}^+}{k_{ih}^+}=x \tag{21}$$

Introducing the relation of Eq. 21 into Eq. 13 and rearranging, one obtains Eq. 22.

$$\left\{-\frac{\Delta[Pb^{2+}]_{0,app}}{\Delta t}\cdot\frac{\alpha}{[Co\text{-}EDTA]_0}-k_{3a}^+-k_{4a}^+K^H_{CoHY}[H^+]\right\}\frac{\beta}{[Pb^{2+}]_{0,app}}=\{k_{1h}^++k_{2h}^+K^H_{CoHY}[H^+]\}\times\{1+xK_{PbOAc}[OAc^-]\} \tag{22}$$

Equation 22 indicates that the plot of the left-hand side of the equation against the acetate ion concentration should give a straight line with a slope of $xK_{PbOAc}\{k_{1h}^++k_{2h}^+K^H_{CoHY}[H^+]\}$ and an intercept of $\{[k_{1h}^++k_{2h}^+K^H_{CoHY}[H^+]\}$ at zero acetate concentration.

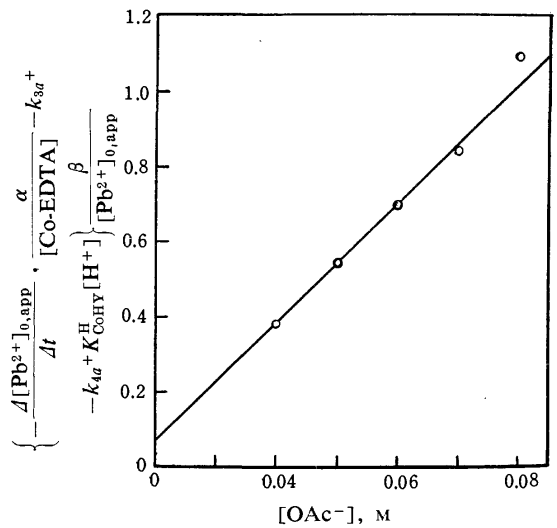

Fig. 5. Left-hand side of Eq. 22 as a function of the acetate ion concentration. The conditions are the same as Fig. 4.

The experimental values obtained at varied acetate concentrations were utilized in a plot given in Fig. 5. A straight line in Fig. 5 shows the validity of the treatment. The values of k_{ih}^{+} and k_{ic}^{+} were calculated with the value of x which was determined from this plot. Using k_{ih}^{+}, k_{ic}^{+}, k_{3a}^{+} and k_{4a}^{+}, $(-\Delta[Pb^{2+}]_{0,app}/\Delta t)/[\text{Co-EDTA}]_0$ was calculated at various concentrations of acetate ion and is given in Fig. 4 (curve 2). It is seen that curve 2 is in satisfactory agreement with the experimental observations. Although this treatment is not strictly rigorous, it proves that the substitution reaction proceeds through both hydrated ions and monoacetato complexes.

Summary

The kinetic study of the substitution reaction of lead(II) and ethylenediaminetetraacetatocobaltate(II) complexes in aqueous solutions has been carried out by a similar method as reported previously[3-7]. The reaction was found to proceed through four simultaneous reaction paths and to be characterized by involving the dissociation of ethylenediaminetetraacetatocobaltate(II) complexes as a rate-determining process. The rate constants of the rate-determining steps of four reaction paths were determined at ionic strength 0.2 at 5 and 15°C. It was confirmed also that this substitution reaction proceeds through both hydrated and monoacetato lead(II) ions.

Decomposition of Peroxybenzoic Acid in Solution. IV. Decomposition in Solvents in the Presence of Radical-Generators

By Katsumi TOKUMARU, Naoki INAMOTO and Osamu SIMAMURA

(Received September 22, 1962)

In previous parts of this series, decompositions of peroxybenzoic acid in alcohols[1], hydrocarbons[2] and ethers[3] have been reported, and a radical chain mechanism has been proposed. In this mechanism, the initial radical-forming decomposition of peroxybenzoic acid and its induced decomposition by radicals are essential features. In order to get further information about the induced decomposition, decomposition of peroxybenzoic acid in solvents has been carried out in the presence of radical-generators such as α, α'-azobisisobutyronitrile and isobutyryl peroxide, and the results are described in this part.

Experimental

Materials.—Peroxybenzoic acid was prepared and purified as described previously[1]. α, α'-Azobisisobutyronitrile was recrystallized from ether, m. p. 105~106°C. Isobutyryl peroxide was synthesized from isobutyryl chloride prepared by the usual method[4] and sodium peroxide according to the procedure of Kharasch et al.[5]

Kinetic Measurements.—The rate of decomposition of peroxybenzoic acid was measured by the same method as described previously[1]. The active oxygen of peroxybenzoic acid was determined by the usual method[6]. This method was found not applicable to the case of isobutyryl peroxide, because this peroxide was not easily reduced with iodide under these experimental conditions. Isobutyryl peroxide therefore was assayed according to Wagner, Smith and Peter's[7] procedure.

Product Study.—*Decomposition of Peroxybenzoic Acid in Benzene in the Presence of α, α'-Azobisisobutyronitrile.*—To a solution of peroxybenzoic acid (5.5 g., 40 mmol.) in benzene (20 ml.) heated on a boiling water bath α, α'-azobisisobutyronitrile (6.6 g., 40 mmol.) was added in small portions over 2 hr., and the mixture was heated for a further

4.5 hr. to complete the reaction. Nitrogen and hydrogen cyanide evolved during the reaction. The reaction mixture, to which sodium hydrogen carbonate was added, was subjected to steam distillation and tetramethylsuccinonitrile was separated from the distillate. On treatment with 2, 4-dinitrophenylhydrazine of the aqueous distillate, 2, 4-dinitrophenylhydrazone of acetone (3.6 mmol.) precipitated. From the residue of the steam distillation benzoic acid (4.3 g., 35 mmol.) was obtained.

In another experiment, peroxybenzoic acid (2.0 g., 14.5 mmol.) and α, α'-azobisisobutyronitrile (2.5 g., 15 mmol.) were similarly allowed to decompose in boiling benzene (20 ml.) for 6.5 hr. The reaction mixture was first distilled on a boiling water bath, chloroform was added to the distilling flask as a carrier to remove low boiling volatile matter completely, and the distillation was continued. The distillate was extracted with water; the aqueous extract, on treatment with 2, 4-dinitrophenylhydrazine, gave 2, 4-dinitrophenylhydrazone of acetone (0.6 mmol.). To the residue from the distillation sodium hydrogen carbonate was added, and the mixture was distilled with steam. The aqueous distillate, on treatment with 2, 4-dinitrophenylhydrazine, gave 2, 4-dinitrophenylhydrazone of acetone (0.6 mmol.).

Decomposition of Benzoyl Peroxide in Benzene in the Presence of α, α'-Azobisisobutyronitrile.—Benzoyl peroxide (5.0 g., 20.6 mmol.) and α, α'-azobisisobutyronitrile (6.6 g., 40 mmol.) were decomposed in boiling benzene (20 ml.) for 7 hr. During the decomposition nitrogen evolved, but hydrogen cyanide was not detected. The reaction mixture was distilled as in the second experiment above, but no acetone was detected in the aqueous extract of the distillate. The residue from the distillation was added with sodium hydrogen carbonate and subjected to steam distillation. Addition of 2, 4-dinitrophenylhydrazine to the aqueous distillate gave 2, 4-dinitrophenylhydrazone of acetone (1.5 mmol.), and the residue from the steam distillation gave benzoic acid (1.5 g., 12.3 mmol.) after the usual working up procedure.

Decomposition of Peroxybenzoic Acid in Benzene in the Presence of Isobntyryl Peroxide.—To a solution of peroxybenzoic acid (4.8 g., 34 mmol.) in benzene (50 ml.) heated at 60°C, a benzene solution of isobutyryl peroxide (17 mmol. in 30 ml.) was added gradually and the heating was continued for a total of 3 hr. The reaction mixture was distilled on a boiling water bath. The distillate was shown to contain isopropyl alcohol and acetone by gas chromatography. It was extracted with water, and the aqueous extract, on treatment with 2, 4-dinitrophenylhydrazine, gave 2, 4-dinitrophenylhydrazone of acetone (4 mmol.). Benzoic acid (3.1 g., 25 mmol.) was obtained from the residue of the distillation.

Decomposition of Peroxybenzoic Acid in Cumene in the Presence of Isobutyryl Peroxide.—A solution of isobutyryl peroxide (4 mmol.) in cumene (20 ml.) was added little by little to a cumene solution (100 ml.) of peroxybenzoic acid (3.0 g., 22 mmol.) heated at 60°C and the heating was continued for a total of 3.5 hr. The reaction mixture was extracted with water, and, on addition of 2, 4-dinitrophenylhydrazine in ethanol to the aqueous extract, 2, 4-dinitrophenylhydrazone of acetone (trace) precipitated. The cumene layer was extracted with aqueous sodium hydrogen carbonate, and the aqueous extract gave benzoic acid (1.7 g., 14 mmol.). Distillation of the cumene solution gave cumyl alcohol (1.2 g., 9 mmol.), m. p. 33°C. The needle shaped crystals (0.2 g.) in the residue from the distillation were filtered off, washed with ethyl alcohol and identified as 2, 3-dimethyl-2, 3-diphenylbutane by m. p. (from ethyl alcohol) and mixed m. p. with an authentic sample, 118~119°C, and by comparing infrared spectra.

Results and Discussion

The results of the analysis of reaction products are summarized in Table I.

The formation of acetone and hydrogen cyanide in the decomposition in the presence of α, α'-azobisisobutyronitrile indicates oxidative attack[8] on the 1-cyano-1-methylethyl radical generated from this azonitrile. The process must be the induced decomposition of peroxybenzoic acid by the 1-cyano-1-methylethyl radical (reaction 1) with formation of the benzoyloxy radical and acetone cyanhydrin, the latter subsequently decomposing to acetone and hydrogen cyanide.

$$PhCO_3H + (CH_3)_2\dot{C}CN \rightarrow PhCO_2\cdot + (CH_3)_2C(OH)CN \quad (1)$$

$$(CH_3)_2C(OH)CN \rightarrow (CH_3)_2CO + HCN \quad (2)$$

Distillation of the reaction mixture gave a distillate containing acetone, and subsequent steam-distillation of the residue after addition of sodium hydrogen carbonate yielded a further crop of acetone in a nearly equal amount (isolated as 2, 4-dinitrophenylhydrazone). The latter acetone must have been produced, in the course of the steam-distillation, from some precursor, probably acetone cyanhydrin benzoate produced by the following reaction:

$$PhCO_2\cdot + (CH_3)_2\dot{C}CN \rightarrow PhCO_2C(CH_3)_2CN \quad (3)$$

A mechanism similar to that suggested by Suehiro[9] for the reaction of peroxybenzoic acid with the triphenylmethyl radical may not be excluded:

$$PhCO_3H + (CH_3)_2\dot{C}CN \rightarrow PhCO_2H + (CH_3)_2C(CN)O\cdot \quad (4)$$

The 1-cyano-1-methylethoxy radical will give rise to acetone and hydrogen cyanide through

TABLE I. PRODUCTS FORMED FROM DECOMPOSITION OF PEROXYBENZOIC ACID IN THE PRESENCE OF RADICAL-GENERATORS

Both the amount of radical-generators and the yields of products are given in percent of the peroxybenzoic acid used.

Radical-Generator	Solvent	Temp. °C	Benzoic acid	Other products
α, α'-Azobisisobutyronitrile 100	Benzene	Under reflux	87	Acetone, 9 Hydrogen cyanide
Isobutyryl peroxide 50	Benzene	60	73	Acetone, 12 Isopropyl alcohol
Isobutyryl peroxide 18	Cumene	60	64	α-Cumyl alcohol, 41 Acetone, trace 2, 3-Dimethyl-2, 3-diphenylbutane, 5

similar paths to those postulated previously in the reaction of α, α'-azobisisobutyronitrile with nitro compounds[8]. If reaction 4 takes place to the complete exclusion of reaction 1, the benzoyloxy radical will not be produced for reaction 3 to occur, and consequently it would be difficult to account for the formation of acetone cyanhydrin benzoate without invoking the improbable reaction 5. It therefore seems that reaction 4 should be only of subordinate importance compared with reaction 1.

The formation of acetone cyanhydrin benzoate would suggest that the following reaction might take place:

$$PhCO_3H + (CH_3)_2\dot{C}CN \rightarrow PhCO_2C(CH_3)_2CN + HO\cdot \quad (5)$$

This possibility, however, seems to be unlikely in view of the evidence discussed previously[2,3], which favours reaction 1 as the more probable one.

In contrast to the case with peroxybenzoic acid, when benzoyl peroxide was decomposed in benzene in the presence of α, α'-azobisisobutyronitrile, no evolution of hydrogen cyanide was detected. Simple distillation of the reaction mixture gave no acetone, but steam-distillation of the residue from the distillation gave acetone, whose source is also attributable to acetone cyanhydrin benzoate.

While peroxybenzoic acid decomposed slowly in *o*-dichlorobenzene at 80°C, addition of α, α'-azobisisobutyronitrile accelerated the decomposition enormously. Thus, while the half life of decomposition of peroxybenzoic acid (the initial concentration, 0.1 mol./l.) was 10.7 hr. in the absence of α, α'-azobisisobutyronitrile, it decreased to 40 min. in its presence (the initial concentration of α, α'-azobisisobutyronitrile, 0.2 mol./l.). On the basis of the rate constant for the unimolecular decomposition of α, α'-azobisisobutyronitrile, 1.53×10^{-4} sec^{-1} at 80°C[10], it is estimated that about 30% of this initiator was decomposed in the course of 40 min., during which 50% of the peroxybenzoic acid originally present had reacted. According to Eqs. 1 and 3, this amount of the acid consumed the 1-cyano-1-methylethyl radical from just an equimolecular quantity of the initiator, that is, 25% of the original amount. This is in rather good agreement with the value of 30% deduced above, indicating that the average efficiency of the 1-cyano-1-methylethyl radical in reaction with peroxybenzoic acid is about 80%. This efficiency of 80% may be too high, because part of peroxybenzoic acid may fairly rapidly be consumed by oxidation of chemical species other than the 1-cyano-1-methylethyl radical, e.g., dimethylketenecyanoisopropylimine produced by dimerization of this radical.

Isobutyryl peroxide decomposes much more rapidly than peroxybenzoic acid in most solvents[11,12]. In the presence of the former, the latter decomposed very rapidly at 60°C. For example, the presence of isobutyryl peroxide (concentration, 0.04 mol./l.) in benzene solution of peroxybenzoic acid (0.1 mol./l.) at 60°C, reduced the half life of peroxybenzoic acid to only 270 sec. Investigation of the products showed the formation of acetone and isopropyl alcohol besides benzoic acid. It therefore was deduced that the isopropyl radical generated thermally from isobutyryl peroxide by way of the isobutyryloxy radical attacks the oxygen atom of peroxybenzoic acid, producing a molecule of isopropyl alcohol and a benzoyloxy radical, and the isopropyl alcohol is further oxidized to acetone (reactions 6 and 7).

$$PhCO_3H + (CH_3)_2HC\cdot \rightarrow (CH_3)_2CHOH + PhCO_2\cdot \quad (6)$$

$$(CH_3)_2CHOH \xrightarrow{\text{oxidation}} (CH_3)_2CO \quad (7)$$

10) F. M. Lewis and M. S. Matheson, *J. Am. Chem. Soc.*, 71, 747 (1949).

11) J. Smid and M. Szwarc, *J. Chem. Phys.*, 29, 432 (1958).

12) K. Tokumaru and O. Simamura, unpublished results.

Obviously, the oxidation of isopropyl alcohol to acetone in accordance with the findings described previously[1] contributes to consumption of peroxybenzoic acid at a rate larger than that corresponding to the straightforward decomposition of isobutyryl peroxide followed by reaction 6 alone.

It was expected that if the reaction was carried out in cumene, which has a hydrogen atom reactive towards radicals, the isopropyl radical generated as well as the benzoyloxy radical from reaction 6 would abstract the hydrogen atom from cumene giving an α-cumyl radical (reactions 8 and 9). This radical then would attack peroxybenzoic acid producing α-cumyl alcohol and a benzoyloxy radical, the latter undergoing reaction 9 leading to the induced decomposition of peroxybenzoic acid as was shown previously[2].

$$(CH_3)_2HC\cdot + PhCH(CH_3)_2 \rightarrow C_3H_8 + Ph(CH_3)_2C\cdot \quad (8)$$

$$PhCO_2\cdot + PhCH(CH_3)_2 \rightarrow PhCO_2H + Ph(CH_3)_2C\cdot \quad (9)$$

$$Ph(CH_3)_2C\cdot + PhCO_3H \rightarrow PhC(CH_3)_2OH + PhCO_2\cdot \quad (10)$$

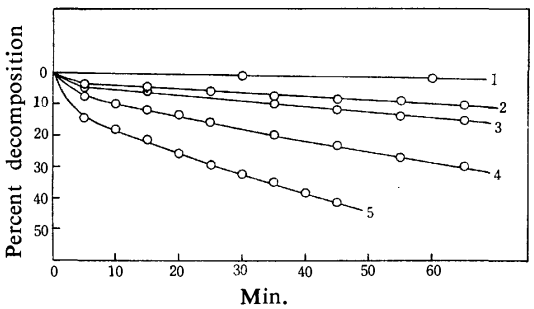

Fig. 1. Decomposition of peroxybenzoic acid in cumene in the presence of isobutyryl peroxide at 40°C. The initial concentration of peroxybenzoic acid, 0.1 mol./l. The initial concentration of isobutyryl peroxide relative to peroxybenzoic acid (in mol. %) : 1, 0%; 2, 5.6%; 3, 13.8%; 4, 22.6%; 5, 46.0%.

In fact, addition of isobutyryl peroxide to a cumene solution of peroxybenzoic acid caused a rapid decomposition of the latter as depicted in Fig. 1, and α-cumyl alcohol and 2, 3-dimethyl-2, 3-diphenylbutane were found among the products. Evidently 2, 3-dimethyl-2, 3-diphenylbutane, which was not detected in the decomposition in cumene in the absence of isobutyryl peroxide[2], was produced by dimerization of the α-cumyl radical, whose stationary concentration was higher owing to rapid supply of radicals by the decomposition of isobutyryl peroxide than that otherwise prevailing.

The rate of decomposition of peroxybenzoic acid became larger according as the initial concentration of isobutyryl peroxide was increased, but further kinetic study was not made, since this reaction was complicated.

Acetyl peroxide, which is known to decompose more slowly than isobutyryl peroxide, was added to a cumene solution of peroxybenzoic acid at 60°C, but the apparent decomposition rate of peroxybenzoic acid was not so much accelerated as when isobutyryl peroxide was added.

The present results indicate that in the presence of an efficient radical-generator a very rapid decomposition of peroxybenzoic acid takes place, and that this is due to the enhanced induced decomposition of the latter by radicals derived from the former.

Summary

The decomposition of peroxybenzoic acid in solvents was accelerated in the presence of radical-generators such as α, α'-azobisisobutyronitrile and isobutyryl peroxide. This acceleration was ascribed to the induced decomposition of peroxybenzoic acid by radicals formed directly or indirectly from these radical-generators.

Decomposition of Peroxybenzoic Acid in Solution. V. Decomposition of Peroxybenzoic Acid and of Benzoyl Peroxide in Binary Mixtures of Carbon Tetrachloride with Cyclohexane, Toluene, or Diethyl Ether

By Katsumi TOKUMARU and Osamu SIMAMURA

(Received September 22, 1962)

In the course of investigation of the decomposition of peroxybenzoic acid in various organic solvents[1-4], it has become evident that peroxybenzoic acid suffers induced decomposition on the oxygen to oxygen bond by radicals derived from hydrocarbons, alcohols and ethers with great ease. Although a similar induced decomposition also takes place with benzoyl peroxide, the reactivity towards benzoyl peroxide differs widely from radical to radical, decreasing in the order: 1-hydroxyalkyl, 1-alkoxyalkyl>alkyl>chloroalkyl radical[5]. It therefore has seemed of interest to examine the behaviour of chloroalkyl radicals towards peroxybenzoic acid. An account is given in this paper of results of the decomposition of peroxybenzoic acid and of benzoyl peroxide in a binary mixture of carbon tetrachloride with a solvent containing hydrogen, in which the trichloromethyl radical is supposed to be produced by abstraction of a chlorine atom from carbon tetrachloride by radicals.

Experimental

Materials. — Peroxybenzoic acid was prepared according to the procedure described previously[1]. Benzoyl peroxide was purified by precipitation from a solution in chloroform by addition of methyl alcohol. The solvents used were purified as described previously[1-3].

Decomposition of Peroxybenzoic Acid in a Mixture of Cyclohexane and Carbon Tetrachloride. — Peroxybenzoic acid (2.8 g., 20 mmol.) was decomposed in a mixture of cyclohexane (50 ml.) and carbon tetrachloride (25 ml.) at 80°C under an atmosphere of nitrogen. The reaction mixture was extracted with aqueous sodium hydrogen carbonate, and the aqueous extract gave benzoic acid (1.8 g., 15 mmol.) on acidification. Distillation of the organic layer afforded a mixture of carbon tetrachloride and cyclohexane, crude cyclohexyl chloride (ca. 3 g., 25 mmol.) and cyclohexanol (0.2 g., 2 mmol.). Benzene and chloroform were detected in the recovered solvent by gas chromatography. Presence of small amount of chlorobenzene in the crude cyclohexyl chloride was confirmed by infrared spectrum and gas chromatography. Cyclohexanol was identified as 3,5-dinitrobenzoate, m. p. and mixed m. p. with an authentic sample, 112°C. In the residue from the distillation, ε-caprolactone (0.3 g., 3 mmol.) was found and identified as ε-hydroxycaproic acid hydrazide, m. p. 112°C.

Decomposition of Peroxybenzoic Acid in a Mixture of Toluene and Carbon Tetrachloride.—Peroxybenzoic acid (2.8 g., 20 mmol.) was decomposed in a mixture of toluene (50 ml.) and carbon tetrachloride (25 ml.) at 80°C in a stream of nitrogen. The reaction mixture was distilled; after the solvent was recovered, benzyl alcohol distilled over (trace, identified by infrared absorption measurement). Extraction of the residue from the distillation with aqueous sodium hydrogen carbonate gave benzoic acid (2.1 g., 17 mmol.). In the distillate benzene, chlorobenzene and chloroform were detected, but no benzyl chloride was detected by gas chromatography.

Decomposition of Peroxybenzoic Acid in a Mixture of Diethyl Ether and Carbon Tetrachloride.—Peroxybenzoic acid (2.8 g., 20 mmol.) was decomposed in a mixture of diethyl ether (50 ml.) and carbon tetrachloride (25 ml.) at 37°C under an atmosphere of nitrogen. After 30 hr. the reaction mixture was distilled. Acetaldehyde (5 mmol.) was detected in the distillate and characterized as the 2,4-dinitrophenylhydrazone, m. p. 168°C. Chloroform and ethyl alcohol were found by gas chromatography. However, no chloroether was detected in the distillate. Benzoic acid (2.1 g., 17 mmol.) was isolated from the residue from the distillation.

Decomposition of Benzoyl Peroxide in a Mixture of Cyclohexane and Carbon Tetrachloride.—Benzoyl peroxide (3.0 g., 12.4 mmol.) was decomposed in a mixture of cyclohexane (100 ml.) and carbon tetrachloride (50 ml.) at 80°C under an atmosphere of nitrogen until the peroxide was completely decomposed. Distillation of the reaction mixture gave a mixture of carbon tetrachloride and cyclohexane, crude cyclohexyl chloride (ca. 34.4 g., 290 mmol.) and a liquid boiling at higher temperatures (trace). The crude cyclohexyl chloride was shown to contain small amount of chlorobenzene by the infrared spectrum and by gas chromatography, and in the recovered solvent chloroform and benzene were detected by gas chromatography. Extraction

of the residue from the distillation with aqueous sodium hydrogen carbonate gave benzoic acid (1.1 g., 9 mmol.). The cyclohexyl chloride was hydrolysed to cyclohexanol and characterized as 3,5-dinitrobenzoate, m. p. 112°C.

Decomposition of Benzoyl Peroxide in a Mixture of Toluene and Carbon Tetrachloride.—Benzoyl peroxide (5.0 g., 20.6 mmol.) was decomposed in a mixture of toluene (100 ml.) and carbon tetrachloride (50 ml.) at 80°C under an atmosphere of nitrogen until the peroxide was completely decomposed. The reaction mixture was distilled, giving carbon tetrachloride, toluene, chlorobenzene (0.9 g., 8 mmol.), b. p. ca. 35°C at 20 mmHg, and benzyl chloride (0.5 g., 4 mmol.), b. p. ca. 72°C at 20 mmHg. Both chlorides were identified by infrared absorption measurement and by gas chromatography, and the benzyl chloride, on treatment with *N*, *N*-dimethylaniline, afforded benzyldimethylanilinium chloride, m. p. 110°C. In the recovered solvent, benzene and chloroform were detected by gas chromatography. The remaining mixture from the distillation was extracted with aqueous sodium hydrogen carbonate, and the aqueous layer gave benzoic acid (0.8 g., 6.5 mmol.) on acidification. Further distillation of the organic mixture gave a distillate (1.8 g.), b. p. 90~120°C at 2 mmHg, which on cooling, gave bibenzyl as needle shaped crystals (0.5 g.), melting point (from ethyl alcohol) and mixed m. p. with an authentic sample, 52°C.

Decomposition of Benzoyl Peroxide in a Mixture of Diethyl Ether and Carbon Tetrachloride.—Benzoyl peroxide (10.0 g., 41.2 mmol.) was allowed to decompose in a mixture of diethyl ether (200 ml.) and carbon tetrachloride (100 ml.) at 37°C for four weeks in a stream of nitrogen. During the reaction volatile product was collected in a trap cooled with dry ice and ethyl alcohol. After the reaction was over, the reaction mixture was distilled below 40°C on a water bath under reduced pressure of a water-jet aspirator. The distillate was subjected to redistillation, giving, after ether and carbon tetrachloride, a fraction (ca. 15 g.), b. p. ca. 25°C at 60 mmHg. This turned out to be 1-chloroethyl ethyl ether, since it afforded, on being allowed to stand in the air, hydrogen chloride and acetaldehyde, which was identified by conversion into the 2,4-dinitrophenylhydrazone, m. p. 168°C. The recovered solvent and the condensate in the trap were combined and extracted with water, and the aqueous extract, on treatment with 2,4-dinitrophenylhydrazine, gave 2,4-dinitrophenylhydrazone of acetaldehyde. The residue from the first distillation was extracted with aqueous sodium hydrogen carbonate, and the aqueous layer yielded benzoic acid (2.2 g., 18 mmol.) on acidification. Addition of methyl alcohol to the organic layer caused precipitation of benzoyl peroxide (0.8 g., 3 mmol.). After it was filtered off, methyl alcohol was removed and the liquid residue was shown to contain chlorobenzene by infrared measurements.

Results and Discussion

The results of the analysis of reaction products are shown in Table I.

The formation of all the products containing no chlorine atom is readily understood on the basis of the free radical mechanism previously postulated for the decomposition of peroxybenzoic acid in solution[1-4], which involves the initial homolysis of the oxygen to oxygen bond:

$$PhCO_3H \rightarrow PhCO_2\cdot + HO\cdot$$

In a mixture of carbon tetrachloride and cyclohexane, the radicals thus generated abstract a hydrogen atom from cyclohexane giving a cyclohexyl radical and benzoic acid or water. The cyclohexyl radical causes the

Table I. Products from decomposition of peroxybenzoic acid or benzoyl peroxide in a mixture of carbon tetrachloride and a solvent (SH) (1 : 2 by volume)

Solvent	Peroxide*	Temp. °C	Product and yield (in % based on peroxide) Benzoic acid	Product of S-Cl type	Products formed by oxidation of solvent	Other products detected

	BPO	37	47	1-Chloroethyl ethyl ether, approximately 330		Benzoyl peroxide recovered (7), acetaldehyde, chlorobenzene

* PBA and BPO stand for peroxybenzoic acid and benzoyl peroxide, respectively.

induced decomposition of peroxybenzoic acid giving a benzoyloxy radical and cyclohexanol, the latter subsequently giving ε-caprolactone as has previously been discussed in detail[2]. For the other solvent mixtures formation of the products containing no chlorine is accounted for in a similar way.

In the presence of carbon tetrachloride besides cyclohexane, the cyclohexyl radical would abstract a chlorine atom from the former yielding cyclohexyl chloride and a trichloromethyl radical. This radical gives chloroform on abstraction of a hydrogen atom from cyclohexane. Chlorobenzene is thought to be formed by attack on carbon tetrachloride by the phenyl radical generated by decomposition of the benzoyloxy radical.

Similarly, benzyl chloride and 1-chloroethyl ethyl ether found in the products from the decomposition of benzoyl peroxide in binary mixtures of carbon tetrachloride with toluene and diethyl ether are formed by abstraction of a chlorine atom from carbon tetrachloride by solvent radicals, namely, the benzyl and the 1-ethoxyethyl radical.

In the decomposition of peroxybenzoic acid in a mixture of cyclohexane and carbon tetrachloride, both cyclohexyl chloride and cyclohexanol were formed, indicating that the two following reactions took place side by side:

$$C_6H_{11}\cdot + PhCO_3H \rightarrow C_6H_{11}OH + PhCO_2\cdot \quad (1)$$

$$C_6H_{11}\cdot + CCl_4 \rightarrow C_6H_{11}Cl + CCl_3\cdot \quad (2)$$

However, in this solvent mixture the yield of cyclohexyl chloride was much higher in the decomposition of benzoyl peroxide than in the case of peroxybenzoic acid. The yield of as much as 23 mol. of cyclohexyl chloride for one mole of the benzoyl peroxide decomposed shows that the chain reaction that produces cyclohexyl chloride is sustained for a considerable number of cycles:

$$C_6H_{11}\cdot + CCl_4 \rightarrow C_6H_{11}Cl + CCl_3\cdot$$
$$CCl_3\cdot + C_6H_{12} \rightarrow CHCl_3 + C_6H_{11}\cdot$$

The difference between the two peroxides undoubtedly lies in greater tendency of peroxybenzoic acid to be attacked by the cyclohexyl radical.

In the decomposition of peroxybenzoic acid in a mixture of toluene and carbon tetrachloride and of diethyl ether and carbon tetrachloride no chlorides derived from the solvents, that is, benzyl chloride and 1-chloroethyl ethyl ether, were found, showing that the reactions corresponding to reaction 2 could not successfully compete with those corresponding to reaction 1 in these cases. The benzyl and the 1-ethoxyethyl radical are accepted as stabilized owing to resonance and therefore rather sluggish in reaction, so that they would abstract a chlorine atom from carbon tetrachloride only slowly, but it is quite remarkable that they attacked peroxybenzoic acid with ease.

On the other hand, the decomposition of benzoyl peroxide in these solvent mixtures gave benzyl chloride and 1-chloroethyl ethyl ether, indicating that the benzyl and the 1-ethoxyethyl radical abstracted a chlorine atom from carbon tetrachloride rather than react exclusively with benzoyl peroxide. Thus it is concluded that peroxybenzoic acid reacts with the cyclohexyl, benzyl and 1-ethoxyethyl radical much more readily than benzoyl peroxide does.

In a mixture of diethyl ether and carbon tetrachloride the decomposition of benzoyl peroxide was not finished in four weeks, whereas it was shown complete in ten days at 37°C in a separate experiment in pure diethyl ether; indeed, the 1-ethoxyethyl radical is known to be highly reactive towards benzoyl peroxide[6]. It is concluded from these findings that the induced decomposition of benzoyl peroxide by the 1-ethoxyethyl radical is suppressed in the presence of carbon tetrachloride, the 1-ethoxyethyl radical readily reacting with carbon tetrachloride instead of reacting with benzoyl peroxide. The change in polarity of the solvent, that is, from pure ether to a mixture of ether and carbon tetrachloride might be another contributing factor.

The formation of bibenzyl in the decomposition of benzoyl peroxide in a mixture of toluene and carbon tetrachloride is accounted for by the comparative inefficiency of the benzyl radical in attacking benzoyl peroxide; thus its stationary concentration would be increased to such an extent that the dimerization giving bibenzyl would become noticeable. The comparative inertness of the benzyl radical towards carbon tetrachloride should be partly responsible for the increased stationary concentration.

The trichloromethyl radical formed from carbon tetrachloride would abstract a hydrogen atom from a molecule of solvent (SH) giving chloroform (reaction 3), and it could attack peroxybenzoic acid, producing phosgene and hydrogen chloride (reactions 4 and 4').

$$CCl_3\cdot + SH \rightarrow CHCl_3 + S\cdot \quad (3)$$

$$CCl_3\cdot + PhCO_3H \rightarrow CCl_3OH + PhCO_2\cdot \quad (4)$$

$$CCl_3OH \rightarrow COCl_2 + HCl \quad (4')$$

Reaction 3 is a well known reaction, and in fact extensive formation of chloroform was

6) W. E. Cass, *J. Am. Chem. Soc.*, **69**, 500 (1947).

observed in all cases examined. Reaction 4, however, does not seem important, since formation of only negligible traces of phosgene and hydrogen chloride was observed. Thus the trichloromethyl radical, in contrast with the other radicals so far examined, appears to be extremely reluctant to attack peroxybenzoic acid. The cause should be ascribed to the electron-accepting property of the trichloromethyl, as will subsequently be discussed.

Summary

Decompositions of peroxybenzoic acid and of benzoyl peroxide were carried out in binary mixtures of carbon tetrachloride with cyclohexane, toluene or diethyl ether. The results of the product study strongly support the radical mechanism established previously and show that the oxygen to oxygen bond of peroxybenzoic acid is attacked by radicals more readily than that of benzoyl peroxide, but even peroxybenzoic acid is hardly attacked by the trichloromethyl radical.

The Crystal Structure of Phenazine 5, 10-Dioxide

By Yoshiyuki NAMBA, Tsutomu ODA and Tokunosuké WATANABÉ

(Received September 15, 1962)

This paper describes part of an investigation of the structure of the *N*-oxides of heterocyclic compounds. Here we present the results of an analysis of the crystal and molecular structure of phenazine 5, 10-dioxide. In the course of the present investigation, a paper on the structure of the same substance was published[1]. Though the space group and the general scheme of the structure remain the same, the unit cell dimensions, and hence the interatomic distances, are different.

Experimental

Sample.—Phenazine 5, 10-dioxide was synthesized by the oxidation of phenazine 5-oxide using hydrogen peroxide and a acetic acid mixture. Single crystals were obtained from acetic acid solutions. Ethanol solutions of these crystals did not show any trace of absorption lines due to phenazine 5-oxide. Single crystals are elongated needle-like in the direction of the b-axis, are red in color and have predominant faces at {100} and $\{10\bar{2}\}$.

Crystal Data.—The unit cell dimensions were determined from oscillation photographs by recording the same reflections on both sides of the film, while the radius of the camera used was calibrated by superimposing a powder pattern of pure sodium chloride.

The density was measured by the pycnometer method using water as the medium.

Phenazine 5, 10-dioxide, $C_{12}H_8N_2O_2$, M. wt. = 212. D. p. = 190°C

Monoclinic;

$a = 7.83 \pm 0.02$ $\quad b = 3.95 \pm 0.02$

$c = 15.50 \pm 0.05$ Å $\quad \beta = 104°48' \pm 10'$

Volume of the unit cell: 463.47 Å^3

Density: Obs. 1.52 g. cm^{-3}, calcd. (with $z=2$) 1.519 g. cm^{-3}

Linear absorption coefficient for X-ray ($\lambda =$ 1.542 Å): $\mu = 10.1$ cm^{-1}

Total number of electrons per unit cell: $F(000) = 220$

The extinction rules were found to be $(h0l)$ for l odd and $(0kl)$ for k odd. Accordingly, the space group was determined as $P\,2_1/c - C^5_{2h}$.

It may be added here that on extremely long-exposured films there appeared several weak reflections which did not agree with the extinctions mentioned above. However, the shape of these reflections differ from the rest, and their indices (101), (201), $(20\bar{1})$ and (203) can be interpreted as due to double reflections arising from the following combinations of indices whose intensities are all very strong:

$(101) : (0\bar{1}3)$; $(1\bar{1}\bar{2})$ $\quad (201) : (311)$; $(\bar{1}\bar{1}0)$

$(20\bar{1}) : (\bar{1}13)$; $(3\bar{1}\bar{4})$ $\quad (203) : (310)$; $(\bar{1}\bar{1}3)$

It is to be noted that similar double reflections have also been reported in the cases of anthraquinone[2] and other crystals[3] consisting of planar molecule.

Intensity Data.—The intensity data were obtained from equi-inclination Weissenberg photographs

1) R. Curti and V. Riganti, *Rend. it. Lombardo Sci., Pt. I. Classe Sci. mat e nat.*, **94A**, 117 (1960).

2) B. V. Murty, *Acta Cryst.*, **8**, 113 (1955).

3) H. Watase, K. Osaki and I. Nitta, This Bulletin, **30**, 532 (1957).

(*h*0*l*) and (0*kl*) taken by means of CuK_α radiation filtered through nickel foil.

The multiple-film technique was used, and the intensities were estimated visually by comparison with a calibrated scale prepared with the same crystal. The range of intensities measured was 1~6000 for the two zones, and the number of reflections observed were 107 for (*h*0*l*) and 48 for (0*kl*). These figures correspond to 75% and 70% of the total number of reciprocal lattice points included within the sphere of reflection.

The intensities were corrected for Lorentz and polarization factors to obtain the relative values of $|F|^2$.

No absorption corrections were applied, as the cross-sections of the crystals used were 0.2 mm.× 0.2 mm. for *h*0*l* (μr=0.2) and 0.5 mm.×0.5 mm. for 0*kl* (μr=0.5) respectively.

Structure Determination

Since the space group is $P\ 2_1/c$ and since the unit cell contains two molecules, it follows that the center of gravity of the molecules should be placed at one of the following four sets of equivalent positions:

(a) 0, 0, 0; 0, 1/2, 1/2

(b) 1/2, 0, 0; 1/2, 1/2, 1/2

(c) 0, 0, 1/2; 0, 1/2, 0

(d) 1/2, 0, 1/2; 1/2, 1/2, 0

It is immaterial which set is chosen; hence, case (a) was chosen.

The fact that the length of the b-axis of the unit cell is comparable to the van der Waals' contact between condensed rings (3.5Å) suggests that the molecular planes have to be almost parallel to the (010)-plane. Therefore, if we designate the molecular axes by L and M, where L is the longest axis joining the centers of the three hexagons of the phenazine ring and M is the one along the N–O bonds, it is anticipated that the orientations of these molecular axes with respect to the a- and c-axes may be found easily by an optical Fourier transform of a single molecule.

The b-Axis Projection.—With a model of a planar molecule having the bond lengths 1.4 Å, 1.4 Å, 1.3 Å for C–C, C–N and N–O respectively and a bond angles of 120° for all, Fraunhofer diffraction patterns for various inclinations of the molecular axes to the b-plane were prepared. Comparing these Fraunhofer diffraction patterns with the (*h*0*l*) weighted reciprocal lattice, it was found that the molecular axis L points in the [102] direction. Furthermore, using the superposition method proposed by Otsuka and Watanabe[4], signs of the structure factors for several reflections

C	0.341	0.001	0.277	0.005	0.0526	0.0005	6.2
C	0.173	0.001	0.136	0.004	0.0244	0.0005	5.4

with strong intensities, as are shown in the following table were obtained.

Signs of the structure factors not determined by the above method were obtained by calculations of structure factors based on the atomic coordinates derived from the molecular orientation found by the optical method.

The first Fourier map $\rho(xz)$ was prepared, by using about 70 terms whose calculated structure factors showed a fairly good agreement with the observed F values. All the atoms were well resolved in this projection. The refinement was made successively by Fourier syntheses and by difference syntheses, which gave a disagreement index R 18 %.

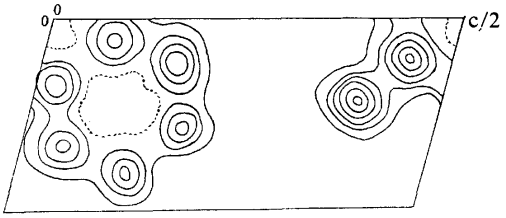

Fig. 3. Electron-density projection along [010].

***y*-Coordinates.**—There remained two possible sets of y-coordinates of all the atoms to be determined. Calculations of the structure factors, $(0kl)$, were carried out for the two structures. It was possible to eliminate one of the two structures from the disagreements between F_c and F_o, even for lower order reflections.

The successive refinement of the y-coordinates was accomplished by the trial and error method with the aid of the structure factor maps[5], while keeping the z-coordinates unchanged from the positions already obtained from the analyses of the (010) projection.

In the calculation of structure factors, the atomic scattering factors given by Berghuis et al.[6] were used throughout.

Final refinements of the positional- and isotropic temperature- parameters of individual atoms were made by least squares calculations[7] for $(h0l)$ and $(0kl)$ zones respectively, the contributions of hydrogen atoms being, however, omitted.

The final positional- and isotropic temperature-parameters with standard deviations, are listed in Table I.

TABLE II. BOND LENGTHS AND BOND ANGLES

Bond length, Å		Bond angle	
O—N	1.34	∠ONC$_1$	121°
N—C$_1$	1.34	∠NC$_1$C$_2$	120°
C$_1$—C$_2$	1.44	∠C$_1$C$_2$C$_3$	120°
C$_2$—C$_3$	1.36	∠C$_2$C$_3$C$_4$	121°
C$_3$—C$_4$	1.44	∠C$_3$C$_4$C$_5$	119°
C$_4$—C$_5$	1.39	∠C$_4$C$_5$C$_6$	119°
C$_5$—C$_6$	1.37	∠C$_5$C$_6$C$_1$	119°
C$_6$—C$_1$	1.45	∠C$_6$C$_1$C$_2$	118°
C$_6$—N	1.39	∠C$_6$C$_1$N	121°
		∠C$_1$N C$_6$′	122°
		∠ONC$_6$′	117°
		∠C$_1$C$_6$N′	117°
		∠C$_5$C$_6$N′	122°

The disagreement index, R, for the final coordinates was 16% for $(h0l)$ and 15% for $(0kl)$. The comparison of the observed structure factors with the calculated ones is shown in Table III.

Discussion of the Structure

Molecular Structure.—The phenazine-ring skeleton found in this investigation is practically the same as those for α-phenazine[8] and phenazine 5-oxide[9]. The bond distances and valency angles found in these three compounds are shown in Table IV.

The value 1.33 Å for the N–O bond indicates that it has some double bond character. In Table V, several N–O bond distances previously

reported are given. The value of 1.42Å found for trimethylamine *N*-oxide hydrochloride[15] can be taken as the standard single bond distance. The N–O bond distances in *N*-heteroconjugate ring compounds are shorter than that of trimethylamine *N*-oxide; this indicates that there exists a resonance between lone-pair electrons in the oxygen atom and the π-electron system in conjugate rings. If we assume 1.16 and 1.43 Å for the single and double bonds for N–O, the total bond order N[10] for the N–O bond in phenazine 5, 10-dioxide is

calculated to be 1.3, which can be compared to the value $N=1.17$ assigned for the N–O bond in pyridine *N*-oxide hydrochloride[11,12]. The distance, 1.37 Å, found for the N–O bond in pyridine *N*-oxide hydrochloride, which is somewhat longer than that of any other pyridine derivatives, would indicate that the n-π resonance here is weakened by the addition of a proton to oxygen*.

Arrangement of the Molecules.—The arrangement of the molecules and the packing between nearest neighbors are shown in Figs. 4 and 5, which are the b- and c-axes projections of the structure respectively. The packing of the molecules is found to be quite similar to those for α-phenazine[8], phenazine 5-oxide[9] and anthraquinone[16]. It can be said that these are iso-structural.

The shortest intermolecular distance between

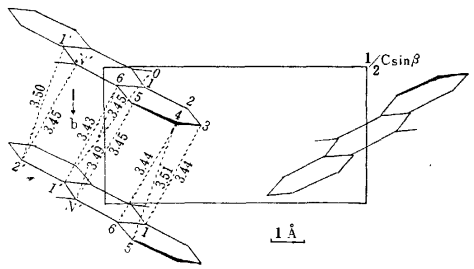

Fig. 5. Projection of the half unit-cell contents down [100].

TABLE V. N–O BOND LENGTHS IN RELATED COMPOUNDS

	N-Oxides	N–O Bond length, Å
	Pyridine *N*-oxide hydrochloride	1.37[11,12]
A	4, 4-*trans*-Azopyridine *N*-oxide	1.28[13]
	4-Nitropyridine *N*-oxide	1.26[14]
	Phenazine 5-oxide	1.24[9]
B	Trimethylaminoxide hydrochloride	1.42[15]

* The crystal structure of pyridine *N*-oxide has not yet been determined. As the result of an infrared absorption study, it was reported by Dr. Kubota et at. of Shionogi Research Laboratory at the 5 th Meeting for Infrared and Raman Spectra that the distance of the N-O bond in it was 1.27~1.29 Å.

neighboring molecules related by the translation parallel to the a-axis is 4.04 Å ($C_5\cdots C_{5'}$), while that between molecules related by the glide plane is 3.99 Å ($C_2\cdots C_2$), and that along a diagonal direction, 3.76 Å ($C_3\cdots C_4$).

These intermolecular distances are found to be very close to the corresponding intermolecular distances reported for α-phenazine, as is shown in Table VI.

TABLE VI. THE INTERMOLECULAR DISTANCES OF NEAREST NEIGHBORING MOLECULES

	$C_5\cdots C_{5'}$	$C_2\cdots C_2$	$C_3\cdots C_4$
This crystal	4.04 Å	3.99 Å	3.72 Å
α-Phenazine	4.07 Å	3.88 Å	4.02 Å

It is very interesting to see that in the structures of 5-oxide and 5, 10-dioxide the oxygen atoms can be said to lie in the holes resulting from the packing of the phenazine rings. Such holes, though small in size, can also be found in the structure of α-phenazine. The ratio of the number of oxygen atoms to the number of holes is 1 for 5, 10-dioxide crystal, whereas it is 1/2 for the 5-oxide crystal.

The angle of inclination of the molecule to the (010)-plane is about 30° for the longest molecular axis, L, and about 5° for the shorter one, M.

Let us now compare the structure of the 5, 10-dioxide crystal with those of related crystals. We notice that the unit cell dimensions of these crystals change by degrees with an increase in the number of oxygen atoms in a molecule, as is shown in Table VII.

TABLE VII. UNIT CELL DIMENSIONS OF RELATED CRYSTALS

	a, Å	b, Å	c, Å	β
α-Phenazine	7.088	5.061	13.22	109°13′
5-Oxide	7.37	4.60	14.34	108°59′
5, 10-Dioxide	7.85	3.95	15.50	104°48′
Anthraquinone	7.92	3.98	15.85	102°42′

The differences in the lengths of these b-axes correspond to the different inclinations of the molecular plane to the (010)-plane. However, it is to be emphasized that the interplanar distances between the neighboring molecular planes remain practically the same, about 3.5 Å, for all the compounds listed. The inclination of the molecular plane mentioned above is related to the mutual displacement of the molecular planes in the same stack. These features can well be seen in Fig. 6, where the structures projected onto their molecular planes are shown for α-phenazine and phenazine 5, 10-dioxide. We are now trying to elucidate the different inclinations of the molecular planes in these related structures, taking into account various interactions between molecules.

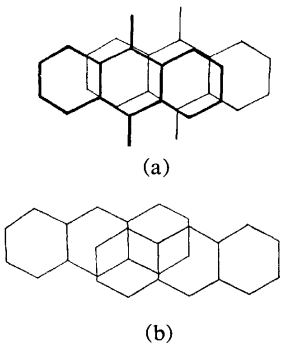

Fig. 6. Normal projection of two molecules in the same stack separated by unit translation along [0/0].

Syntheses of Aliphatic Dibasic Acids from Paraffinic Hydrocarbons by Way of Auto-oxidation in Systems Containing Water[*1]

By Masaru KOBAYASHI[*2], Shiro KUDO[*3] and Kunio SHIMOMURA[*3]

(Received February 5, 1962)

Several attempts have been made to obtain dibasic fatty acids by the direct oxidation of paraffinic hydrocarbons with molecular oxygen; for instance, Zellner and Lister[1] obtained a distillate fraction of succinic acid to sebacic acid in a yield of 20~25% against the amount of reactant consumed in the oxidation of the scale waxes. In this investigation, the oxidation by air or oxygen was carried out at 150°C, employing a catalyst composed mainly of manganese salt; Zellner and Lister have stated that the reaction was inhibited during the course of oxidation due to the lactone-like polymers produced secondarily, leading to the cessation of the reaction at an early stage of oxidation. In order to attain a deep oxidation without a decrease in the reaction velocity in the later stage, many counterplans have been proposed, such as strict control[2] of the reaction temperature and of the depth of oxidation, and employment of effective cocatalysts[3]. However, the yield of the object materials, crystalline dibasic acids (C_4-C_{10}), has been low so far. Recently, however, Tsyskovskii et al.[4] repeated the investigation of Zellner and Lister in an attempt to improve the yield of crystalline dibasic acids; they obtained a fraction of succinic acid—sebacic acid in a yield of 40% against the charged starting material by oxidizing liquid paraffin of a high boiling point and by then hydrolyzing the reaction products at 160°C and 15 atm.

One of the present authors has reported[5] that dibasic acids can be obtained by the auto-oxidation of long chain aliphatic monobasic acids or aliphatic hydrocarbons in the presence also of water. For this paper, this method of reaction has been extended to the oxidation of *n*-decane and solid paraffin; the results obtained are compared with those for the oxidation of anhydrous decane and other former studies, and the effect of water is discussed.

Experimental

Apparatus, Procedure and Materials.—The apparatus used for the oxidation reaction is a vertical autoclave (made of SUS-32) 355 cc. in capacity and with a magnetic stirrer. The reaction temperature was maintained constant within ±0.5°C.

Hydrocarbons and water were charged into the autoclave and, while being stirred, were heated to a desired temperature. Then, after the total pressure had been read, oxygen was introduced until a desired pressure was reached; the depression of the pressure with time was followed at the constant temperature. The rate of the revolution of the stirrer was kept at about 600 r. p. m. to prevent the dissolution of oxygen from becoming a limiting factor for the overall reaction velocity. The total pressure (gauge reading) was kept in a range of 20~80 kg./cm^2 during the reaction.

After the reaction had been stopped by cooling the autoclave, the residual gas, collected in a trap in a dry ice-methanol bath, was subjected to gas analysis. In this experiment, only a trace of condensate was found in the cold trap. The liquid products were taken out, treated according to a method described later, and subjected to analysis.

The *n*-decane used was prepared[6] from commercial *n*-decanol-1; it showed a b. p. of 174~175°C and a purity of 99.5~99.7% (in analysis by gas chromatography). Commercial solid paraffin (m. p., 60°C) and oxygen gas in a cylinder (purity, 99.6~99.7%) were used without further purification.

After-treatment and Method of Analysis.—The carbon dioxide, oxygen, carbon monoxide and unsaturated as well as saturated hydrocarbons in the gaseous product were immediately analyzed according to the usual method employing Hempel's apparatus; in some cases, analysis by gas chromatography was also applied. In order to estimate quantitatively each of the acidic constituents in the liquid product, the reaction product was after-treated according to the scheme summarized in Fig. 1, and gas chromatagraphic analysis[*4] was applied to each fraction.

A liquid reaction product was filtered through a wet filter paper, rinsed with water, and divided

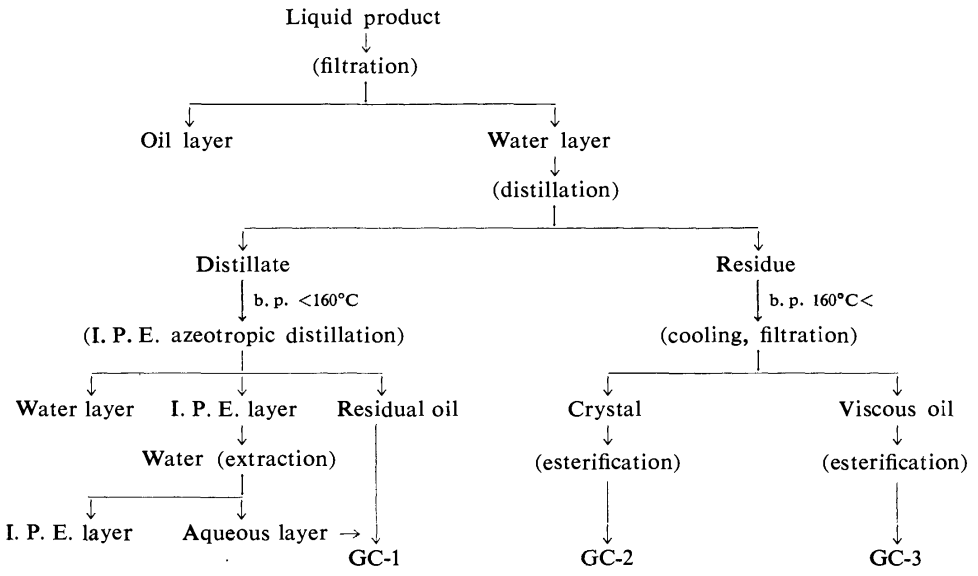

Fig. 1. After-treatment of the liquid product.

into an oily layer and an aqueous layer. While this oily layer consisted of unchanged hydrocarbons containing a few non-acidic oxidation products, the aqueous layer contained, as main ingredients, monobasic fatty acids in addition to the desired dibasic fatty acids, and the existence of a minute amount of carbonyl compound was detected. This aqueous layer was separated by distillation into two fractions, that is, a fraction distilling below 160°C (water and C_1-C_6 monobasic acids) and a residual fraction with a boiling point higher than 160°C (monobasic acids higher than C_7, dibasic acids and other polymerized compounds).

The former fraction was subjected to azeotropic distillation with isopropyl ether (abbreviated as I. P. E. in Fig. 1) and was separated into three portions: water layer, I. P. E. layer, and residual oil. The I. P. E. layer was further extracted with water; a small amount of the acidic ingredients was recovered, added to the residual oil, and subjected directly to gas chromatographic analysis.

The latter high-boiling residue gave crystals of dibasic acids (C_4-C_6) immediately after cooling. These crystals and the highly viscous filtrate were both esterified with *n*-butanol by the aid of sulfuric acid in the usual procedure, using benzene as an accompanying agent for the water formed. Finely powdered sodium carbonate was added to the esterified product to neutralize the acidic contaminant; the solution was then filtered and vacuum distilled; colorless and clear or slightly yellow *n*-butyl esters were used, respectively, as samples for the gas chromatographic analysis.

The GC noted in Fig. 1 indicates the quantitative analysis by gas chromatography.

After-treatment was conducted in the order shown in Fig. 1; the absolute amounts of samples GC-1-GC-3 were calculated from the acid value obtained in the usual way, while the relative amount of each acidic constituent was determined by gas chromatography. The conditions for the gas chromatographic analysis were as follows: for GC-1, column OS 2 m. (dioctyl sebacate+sebacic acid)[7], 150°C, helium as the carrier gas, rate of flow, 47 cc./min.; for GC-2 and GC-3, column O 2 m. (silicon grease), 260°C, helium as the carrier gas, rate of flow, 17 cc./min.

Results

Absorption of Oxygen.—In Fig. 2 are shown examples of the time course of oxygen absoption by *n*-decane (Exp. DX-8, reaction temperature 160°C) and solid paraffin (Exp. DX-14, 150°C). Oxygen is absorbed almost linearly with time after some lapse of the induction period. These curves represent apparent pressure decreases. The true oxygen absoption curves could be almost straight lines if necessary corrections are made for carbon dioxide, carbon monoxide and other gases formed secondarily during the reaction; thus the over-all oxidation reaction may be considered to proceed in a steady state.

With the object of finding the partial pressure of oxygen necessary for maintaining the steady rate in this reaction, the reaction was allowed to proceed without any replenishment of oxygen after the start of the reaction; a gas aliquot was sampled for analysis at the point where the reaction velocity began to decrease, and the partial pressure of oxygen in the gas phase of the reaction system was calculated. The results are shown in Table I. ρ_{max} (maximum rate of oxygen absorption) and θ (induction period) in the table indicate,

respectively $-d[O_2]/dt$ at the linear portion of the oxygen absorption curve and the time reading at the cross point of this straight line with the abscissa, as is shown in Fig. 2.

It can be infered from the results shown in Table I that ρ_{max} becomes independent of the oxygen pressure when the effective partial pressure of oxygen is higher than 5~6 kg./cm^2 and that $P_{O_2}=5\sim6$ kg./cm^2 may be taken practically as a critical value.

Oxidation Products from *n*-Decane.—*Water-soluble Products and Gaseous Products.*— In Table II are presented the experimental conditions and reaction products in the oxidation of *n*-decane under a pressure at 160°C in the presence also of water. In this table, instances for various depths of oxidation in the case of the oxidation of *n*-decane are given; from these a relation between the amount of oxygen absorbed and the amount of *n*-decane consumed was sought, resulting in a straight line, as shown in Fig. 3. The amount of *n*-decane consumed was calculated by subtracting the amount of the water-insoluble oil layer remaining after the reaction from the amount charged originally. The recovered oil layer consisted mainly of *n*-decane, besides about 10% of *n*-decanone and a small amount of lower fatty acids, as will be described later. Therefore, the oily layer was regarded as the same as the starting material, *n*-decane.

Furthermore, the linear relation between the amount of water-soluble products and that of oxygen absorbed is also illustrated in Fig. 3. From the fact that linear relations were obtained between the depth of oxidation and the consumption of *n*-decane or the amount of water-soluble products respectively, the oxidation reaction in this system containing water may be considered as directly producing water-soluble fatty acid fractions, but not as proceeding step by step via water-insoluble neutral oxidation products.

The water layer separated from the oil layer was clear but slightly yellow, and was subjected to quantitative analysis for each fatty acid in the way cited in Fig. 1; the results are shown in Table II. When the water-soluble products were treated in order of Fig. 1, and the residue of higher boiling point than 160°C was esterified and then vacuum destilled, there

remained only a small amount (0.2～0.5%) of the residue of distillation (probably polymers of the lactone series) in each experiment listed in Table II. Thus, it can be said that the formation of products which look like polymers of the lactone series is not remarkable in this oxidation procedure.

Furthermore, the gas chromatograms of the samples GC-1-GC-3 obtained by the treatment shown in Fig. 1 were compared precisely, with respect to the retention time, with each standard specimen of the fatty acids, but no peak other than that of the fatty acids was noticed. Thus, the main reaction products in this oxidation reaction can be concluded to be a mixture of fatty acids.

Immediately after the reaction was stopped, both oil and water layers were examined for hydroperoxide (expressed as HPO hereafter), but only a trace was found in each experiment cited in Table II.

As aqueous products, the monobasic fatty acids C_1—C_9 and the dibasic fatty acids C_4—C_7 were obtained; the dibasic acids C_8—C_9 were found only in traces, as is shown in Table II. In order to realized the relation between the depth of oxidation and the formation of each fatty acid, the sum of the monobasic acids C_7—C_9 (cited as higher monobasic acids), the sum of the dibasic acids and the amount of acetic acid formed are plotted against the depth of oxidation in Fig. 4.

The ratio of the amount of dibasic acids consisting mainly of succinic acid to the total acidic ingredients was 22～27%, which can be regarded as nearly constant irrespective of the depth of oxidation. On the other hand, the content of higher monobasic acids decreased, while that of acetic acid increased with the depth of oxidation. Finally it seemed that the aqueous constituents became succinic acid and acetic acid; for instance, in Exp. DX-8

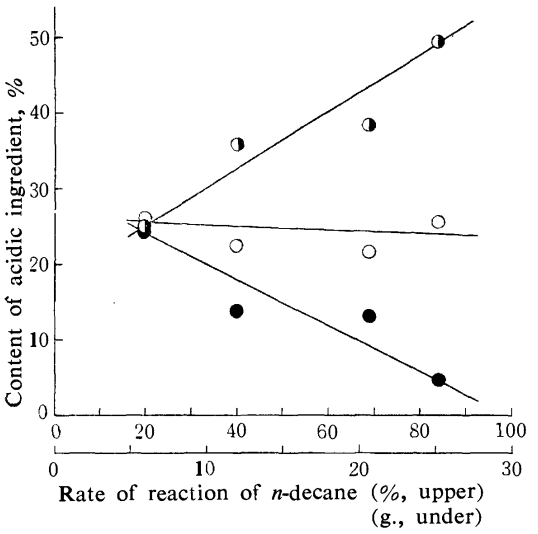

Fig. 4. Depth of oxidation—acidic ingredients.
○ Dibasic acid ◑ Acetic acid
● Higher monobasic acid

of Table II, acetic acid was found to form 49%, succinic acid, 19%, and their sum, 68% at a 85.6% consumption of *n*-decane.

As is shown in Table II, gaseous products consisted mainly of carbon dioxide, together with a small amount of carbon monoxide and a trace of lower olefinic hydrocarbons (shown as C=C in Table II and hereafter).

In order to investigate the other gaseous ingredients, gas chromatographic analysis was conducted on the residual gas in Exp. DX-10 of Table II as an example; the results showed a composition: H_2, 42; CH_4, 4; H_2, 54%. It was also found that hydrogen formed more than 40%. It has not yet been elucidated how this hydrogen is produced, but perhaps it did so in a reaction which can be formulated by the following equation:

$$RCH_2OOH \rightarrow RCOOH + H_2$$

in which prim-HPO is thermally decomposed directly into fatty acids and hydrogen[8]; a mechanism analogous to this may also be interpreted to be operating.

Cleavage of Carbon Chains.—In view of the fact that acetic acid, carbon dioxide and carbon monoxide increase rapidly with the progress of oxidation, as may be seen from the experimental results in Table II, the relation between acetic acid and these gaseous constituents was investigated. As is seen in Fig. 4 and as has been described above, the ratio of the rate forming dibasic acids to the total rates forming all products appears constant, irrespective of the depth of oxidation, whereas the increase in the amount of acetic acid in the range of deep oxidation, contrary to the decrease in the amount of higher monobasic acids, suggests that acetic acid may be formed by a cleavage of the carbon chain of higher monobasic acids. Therefore, the competitive occurrence of the following three elementary steps, A, B_1 and B_2, were assumed to contribute to the overall oxidation reaction:

$$n\text{-Decane} \rightarrow \text{acetic acid} + \text{dibasic acid} + CO_2, CO \quad (A)$$

$$n\text{-Decane} \rightarrow \text{acetic acid} + \text{higher monobasic acid} + CO_2, CO \quad (B_1)$$

$$\text{Higher monobasic acid} \rightarrow \text{acetic acid} + CO_2, CO \quad (B_2)$$

In addition to these steps, other processes, such as the formation of HPO, keto-acid, alcohol and hydroxy-acid as intermediate products, the formation of dibasic acids from higher monobasic acids (perhaps Reaction A proceeds via higher monobasic acids intermediately), and the oxidative decomposition of higher dibasic acids to lower dibasic acids, are also conceivable, but Reactions A, B_1 and B_2 were taken as representative.

Assuming that Reaction A is a normal reaction yielding dibasic acids, and that B_1 and and B_2 represent reactions to shorten carbon chains, it seems probable that B_1 contributes in the early stage of oxidation and that B_2 becomes important in the range of deep oxidation. Thus, if Reaction A actually competes with Reaction B_1, as above, the amount of acetic acid and gaseous constituents found should maintain a constant ratio to the amount of dibasic acids, and the rapid increase of the former in the range of the deeper degree of oxidation is wholly due to reaction B_2. It was established by the experimental results in Table II that this was the case. Experiment DX-9 of shallow oxidation (conversion of *n*-decane, 20.0%) was thought to proceed by way of Reaction A, without any contribution of Reaction B_1 or B_2, until this extent of reaction. Thus, the ratio of each amount of acetic acid (35 mmol.), carbon dioxide (34 mmol.) and carbon monoxide (5.5 mmol.) to the amount of dibasic acids (18 mmol.) obtained in this experiment was assumed to be the normal ratio of production by Reaction A. The increase in the amount of acetic acic and gaseous constituents in experiments of deeper oxidation than this was ascribed to the reaction to shorten the carbon chain and was estimated by calculation. The method of calculation and the results are given in Table III. In

a) Sum of carbon dioxide+formic acid

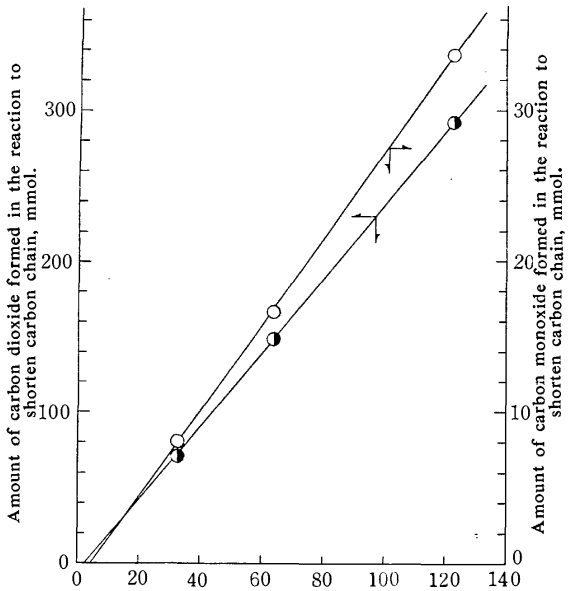

Fig. 5. Formation of acetic acid, carbon dioxide and carbon monoxide in reaction to shorten carbon chain.

the calculations of Table III, formic acid appearing in water-soluble products was regarded as a precursor to carbon dioxide and was so added to the latter.

The amounts of carbon dioxide and carbon monoxide which are thought to have been formed in the reaction to shorten the carbon chain were plotted respectively against the amount of acetic acid, resulting in straight lines, as is shown in Fig. 5. Thus, it is probable that Reactions A and B proceed together, as was presumed afore, and, at least in the reaction of carbon chain shortening, acetic acid and carbon dioxide, together with carbon monoxide, would be formed concurrently.

Ingredients in the Oil Layer.—The oil layer obtained after oxidation constitutes mainly of unchanged *n*-decane, but it also contains a small number of products from shallow oxidation (C_{10} ketone and C_{10} alcohol) and a minute amount of lower fatty acid. These products are estimated, to be from the amount of oxygen absorbed, negligible as compared with products from deep oxidation (water-soluble constituent and gaseous constituent); as no quantitative analysis was conducted, the composition was only roughly examined.

Ten grams of the oil layer from the experiment DX-7 in Table II (carbonyl content, 14.8% as C_{10} ketone, carboxyl content, 15.0% as C_{10} acid) were washed with dilute alkali and water. This sample was applied to the gas chromatography, in a method which has been reported previously[7], and also to the chemical analysis. The results are given in Table IV.

In view of the range of relative retention time,

TABLE IV. COMPOSITION OF OILY MATERIAL

Ingredient	Gas chromatography		Chemical analysis
n-Decane	79.2		
n-Decanone-2	3.3	10.6	10.7
n-Decanone-3	2.1		
n-Decanone-4 + *n*-Decanone-5	5.2		
Others (C_2-C_4 monobasic acid + C_{10} alcohol)	10.2		
	100		

the fraction of C_{10} alcohol seems to be a mixture of isomers having the functional group at different positions, like the *n*-decanone fraction, but the amount was so small that characterization of the constituents was impossible.

On the other hand, the oil layer obtained in the series of experiments in Table II was directly analyzed chemically; the carbonyl content estimated as C_{10} ketone was 9.1% (DX-9), 14.3% (DX-7), 11.4% (DX-10) and 2.8% (DX-8), in the order of degree of oxidation. They were usually about 10% except for the last experiment of the deepest oxidation (the consumption of *n*-decane was 85.6% in DX-8). On the basis of these results, this oxidation reaction is thought to take a course through HPO to ketone and alcohol as the primary process in the same manner as in the oxidation of the system without water; moreover, the composition of the ketone (*n*-decanone) regarded as an intermediate is also identical with that in the thermal auto-oxidation of the system without water. Therefore, the course of this oxidation is thought to be that, initially, *n*-decanone (or *n*-decanol) is formed from *n*-decane, and that it is then subjected continuously to successive oxidation, without accumulating in the oil layer, to give acidic constituents and is then transferred into the aqueous layer.

Oxidation of Solid Paraffin.—Solid paraffin was oxidized in the same way as *n*-decane. The oxygen absorption curve, an example of which is shown in Fig. 2, assumes a straight line after a certain induction period, as does *n*-decane. The experimental results obtained at 150 and 160°C are tabulated in Table V, and an example of an experiment, in which oxidation was continued until the unchanged oil layer disappeared completely at a reaction temperature of 160°C, is presented in Table VI.

In Tables V and VI are shown analytical values for all the acidic ingredients in the aqueous layer, which was treated according to the after-treatment precedure illustrated for *n*-decane in Fig. 1. The unchanged oil layer and the aqueous layer were both distilled, and the residual fraction (b. p. 160°C<) of the latter was esterified in the same way as in Fig. 1. The residue (about 0.3~0.5 g.) remaining after vacuum distillation of esters was not examined in further detail.

As for acidic ingredients, C_1—C_9 monobasic acids and C_4—C_9 dibasic acids were found over the whole range of oxidation, as in the case for *n*-decane. In gas chromatograms of samples GC-2 and GC-3 obtained by the method of treatment in Fig. 1, no peak corresponding to an unidentified substance was found in the range of a lower fraction than that of C_9 monobasic acid, and capric acid could not be detected, even by careful examination while changing the operating conditions for chromatography.

Table V. Oxidation of solid paraffin

Experimental No.	DX-14	DX-17

matter obtained in the treatment of the aqueous layer (of Fig. 1) were joined together and oxidized in experiment DX-20 until the oil layer had completely disappeared. The results reveal that it is possible to convert starting hydrocarbons almost completely into water-soluble products. By comparing these results with those of experiment DX-17, it can be realized that perfectly deep oxidation converts monobasic acids to acetic acid, and dibasic acids to succinic acid. This finding agrees well with that of *n*-decane illustrated in Table II.

In order to compare the results for solid paraffin with those for *n*-decane, Table VII presents the amount of each acidic constituent produced per 1 kg. of hydrocarbon consumed in experiments of roughly the same depth of oxidation (extent of reaction: 85~92%). In summary, the yield of dibasic acids against consumed hydrocarbon is 29% for *n*-decane, poorer than the value of 40% for solid paraffin.

TABLE VII. AMOUNT OF DIBASIC ACID FORMED PER 1 kg. HYDROCARBON CONSUMED

Experimental No.	DX-8	DX-14	DX-17

Monobasic acid			
Acetic acid	560	239	393
C_1, C_3—C_9 acid	283	216	288
Total	843	455	671

The amount of such lower fatty acids as acetic acid and propionic acid is large in the case of *n*-decane, but small, in the case of solid paraffin. It may therefore be concluded that in the case of *n*-decane the yield of dibasic acids is small, while that of lower monobasic acids is large. The discrepancy is probably due to the difference in the carbon chain length of the original hydrocarbons. It seems probable that *n*-decane, owing to its comparatively short carbon chain, has an extremely poor chance to form two moles of dibasic acids of C_4—C_5 by the random attack of a molecular oxygen, but that it has a large possibility to form one mole of dibasic acid and residual fragments of carbon chain, which will then turn into lower monobasic acids. On the contrary, in the case of solid paraffin composed mainly of *n*-paraffins of mean carbon number 26—27, no such restriction is imposed since its yield in dibasic acids is higher.

Comparison with Reactions in the Absence of Water.—In comparing the present oxidation reaction with the reaction without water added in advance[9], some consideration must be given

9) Hereafter we shall call this system the "anhydrous system". A small amount of water is certainly produced in the oxidation reaction, but it is usually carried away from the system together with exhaust gas, by virtue of some suitable apparatus in the works of Zellner[1], Buckmann[2] and Tsyskovskii[4]. Thus the system can be regarded as "anhydrous".

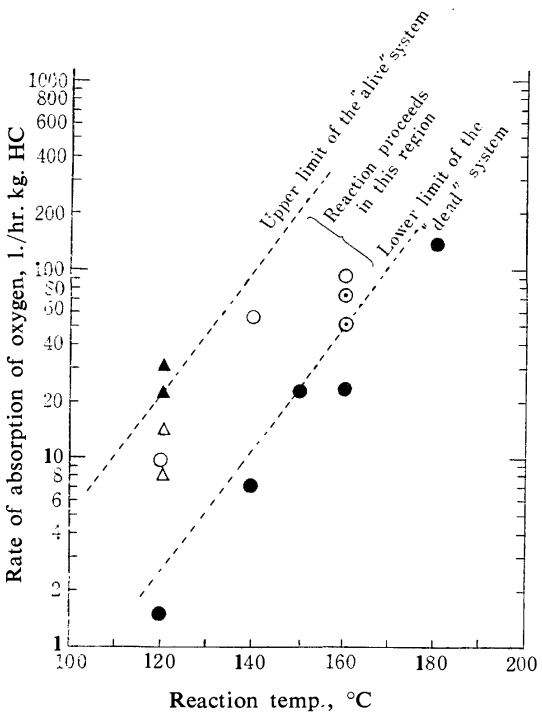

Fig. 6. Rate of oxygen absorption plotted against the reaction temperature.
▲ Instance of dead[2] △ Instance of alive[2]
● Instance of dead[9] ○ Instance of alive[9]
⊙ Instance of this experiment

to the characteristics of the present system, especially the role of water.

In the methods of both Zellner et al.[1] and Buckmann[2], solid paraffin in oxidized under strict control of the reaction temperature as well as of the amount of oxygen absorbed; too large[2] or too small[10] aeration is thought to inhibit the absorption of oxygen on account of the polymerization of reaction products.

For instance, Zellner assumed that the appropriate depth for the oxidation of products would correspond to a saponification value above 400[10], a recent patent has claimed a value of 600[3], and Buckmann considered it to be represented by an acid value above 490[2]; in every case, the main object of study was to realize a rapid and smooth arrival at this line before the reaction was retarded by these polymers. The relation between the reaction temperature and the rate of oxygen absorption observed in these studies, together with data from the present work, are shown in unified units in Fig. 6. (The rate of oxygen absorption is shown in liters of gas absorbed per 1 kg. of original hydrocarbon per hour and is denoted as l./hr. kg. HC). In our experiments, the rates of the oxygen absorption calculated are 56.1 and 78.3 l./hr. kg. HC respectively for DX-8 in Table II (the *n*-decane charged was 30 g., reaction temperature, 160°C; ρ_{max}, 9.1 kg. cm^{-2} hr^{-1}) and for DX-17 in Table V (the solid paraffin charged was 20 g.; reaction temp., 160°C; ρ_{max}, 9.2 kg. cm^{-2} hr^{-1}).

Zellner[10] called a state a "dead system" in which oxidation has been interrupted during the reaction and in which the replenishment of oxygen through aeration does not provoke further oxidation. Figure 6 gives examples of "alive" and "dead" reaction systems. In regions above and below the two dotted lines in the figure, the progress of reaction is stopped owing to the formation of polymers and other retarders.

In 1960 Tsyskovskii et al.[4], improving on the method of Zellner and Lister, oxidized *n*-paraffin with a b. p. of 240~350°C, a by-product of diesel fuel, with oxygen using manganese naphthenate as a catalyst at 135~155°C under ordinary pressure; the reaction product was then hydrolyzed at 160°C under about 15 atm., giving dibasic acids in an yield of 40% against the starting material. The composition of these dibasic acids, including succinic acid through sebacic acid, is almost identical with our results for solid paraffin listed in Table V. The reaction mechanism of hydrolysis at a high temperature in their method has not yet been elucidated, but it seems probable that hydrolysis[11] of a lactone-type compound at a high temperature and pressure was applied to the case of the recovery of fatty acids from oxidized oil.

When the present results of oxidation in systems containing water are compared with the data of previous literature, our method interestingly produces almost no polymers in spite of the small rate of oxidation. Namely, as may be seen from Fig. 6, the rate of oxygen absorption in this experiment lies in the region of "death", if the system were anhydrous, where reaction should cease owing to the formation of polymers. The reason why the reaction is not interrupted in the present system may be attributable to the inhibition of polymerization due to the ring rupture by water (hydrolysis) of lactonic substances during the reaction.

Examinations of the reaction velocity and the distribution of products in comparison with those in the anhydrous system[6] have been perfomed; they are tabulated in Tables VIII-1, 2 and 3,

In these tables are listed, for the sake of comparison, the results of oxidation at the same depth (1 mol. oxygen absorbed per 1

mol. decane) in systems both with and without water. The rate of maximum oxygen absorption, ρ_{max}, is shown with a calculated value per 1 kg. of decane in the same way as in Fig. 6, and the amounts of gas produced, C_{10} ketone + C_{10} alcohol and water, and other data listed in Table VIII-3 are all given in terms of weight calculated on the basis of 100 g. of *n*-decane charged. "Other" cited in Table VIII-3 means polymers other than dibasic acids in DX-9, and the sum of lower neutral compounds containing oxygen in EX-16 and EX-12.

As to the effect of water on the reactivity of *n*-decane, a comparison between the data from experiments DX-9 and EX-16 shown in Table VIII-1 indicates that, in the presence of water, the induction period, θ, increases a little, while the maximum rate of oxygen absorption, ρ_{max}, is diminished to about one-third of that in the anhydrous system. That is to say, oxidation is greatly retarded by the addition of water.

As is shown in Table VIII-2, the extent of reaction is equal in these experiments on the basis of the oxygen absorbed, but the extent differs appreciably from experiment to experiment in terms of the *n*-decane consumed; the *n*-decane consumption is twice as much in the anhydrous system as that in water-containing system. Furthermore, the product distribution is also greatly different in these two reaction systems. In the system containing water, the amounts of the fractions of C_{10} ketone and C_{10} alcohol, which are regarded as primary intermediate products in the oxidation, are small, while the amount of acetic acid formed is large. In the case of the anhydrous system, no dibasic acids fraction comes out, whereas oxygen-containing neutral products of a low boiling point (shown as "others" in Table VIII-3) are abundant. Besides, it is interesting to note that caprylic acid is not formed in the system containing water. Monobasic acids of the C_3—C_7 range are continuously richly present in anhydrous systems, while in systems containing water C_3 acid and C_7 are richly present, but C_5 shows only a minimum.

As for gaseous products, carbon dioxide is richly present in the system containing water, while there is far less carbon monoxide than in the anhydrous system.

Thus, the product distribution shown in Tables VIII-2 and VIII-3 suggests that the following two reactions:

n-decane → HPO → C_{10} ketone, C_{10} alcohol

C_{10} ketone, C_{10} alcohol → succeeding oxidation products

proceed with nearly the same velocity in the anhydrous system, whereas in the system containing water, the rate of the succeeding oxidation is so extremely that the C_{10} neutral

fraction of intermediate products (ketone, alcohol) seems not to accumulate in the reaction system.

A comparison of both reactions has also been made from the standpoint of the dependency of the reaction velocity, $-d[O_2]/dt$, on the oxygen pressure. In the system containing water, ρ_{max} becomes independent of the partial pressure of oxygen above $P_{O_2}=6$ kg./cm^2, as has already been shown in Table I, while in the anhydrous system it becomes independent even under ordinary pressure at the same temperature (160°C). The mechanism of this oxidation (including the oxidation of *n*-decane or that of the succeeding C_{10} neutral fractions) seems substantially analogous to the reaction type proposed by Bolland-Gee[12]; hence, the reaction rate may be represented by the well-known equation, (1)[12], where R_i is the rate of chain initiation. The propagation steps are expressed by $R\cdot+O_2 \xrightarrow{k_2} RO_2\cdot$, $RO_2\cdot+RH \xrightarrow{k_3} RO_2H+R\cdot$, and the termination by $2R\cdot \xrightarrow{k_4}$, $R\cdot+RO_2\cdot \xrightarrow{k_5}$, $2RO_2\cdot \xrightarrow{k_6}$, where $k_5^2=k_4k_6$.

$$-d[O_2]/dt = R_i^{1/2}\left(\frac{k_3}{k_6^{1/2}}\right)[RH]\times\left\{\frac{k_2/k_6^{1/2}[O_2]}{k_3/k_4^{1/2}[RH]+k_2/k_6^{1/2}[O_2]}\right\} \quad (1)$$

Assuming that in Eq. 1 the critical values of oxygen pressure, above which the value within the large bracket could be approximated to 1, are $[O_2]=6$ kg./cm^2 (in the system containing water) and $[O_2]=1$ kg./cm^2 (in the anhydrous system), as has been described before, the values of the ratio in the denominator $k_3/k_4^{1/2}$: $k_2/k_6^{1/2}$ are surmised to be fairly different between the two systems.

As the value of [RH] seems equal in both systems, the condition of the oxygen pressure independency can be expressed approximately by Eq. 2, where A_n, B_n (anhydrous system) and A_h, B_h (system containing water) represent $k_2/k_6^{1/2}$ and $k_3/k_4^{1/2}$ respectively.

$$\frac{A_n[1]}{B_n+A_n[1]}=\frac{A_h[6]}{B_h+A_h[6]}=1 \quad (2)$$

In the system containing water, the condition $k_2[R\cdot] \gg k_3[ROO\cdot]$, which makes the content in large bracket 1, can not be established at O_2 pressure below 6 kg./cm^2; that is to say, the applicability of Eq. 1 has been enlarged, namely into the region where ρ_{max} depends upon the oxygen pressure, since the reactivity of RH with molecular oxygen is enhanced as compared with that in anhydrous systems. If RH is presumed to be a C_{10} neutral substance produced during reaction, it is highly probable that these neutral ingredients are attacked preferentially by oxygen to form dibasic acids in the system containing water.

Pyrolysis of Acid Amides. III. Pyrolysis of Cyanoacetamides and 2-Phenylacetamides

By Teruaki MUKAIYAMA, Hisashi TAKEI and Yasuo KOMA

(Received September 13, 1962)

The pyrolyses of acetoacetamides and 2-haloacetamides to give isocyanates and acetone, and nitriles, isocyanates and hydrogen chloride, respectively, have been reported in preceding papers[1,2]. It has been shown there that carboxylic acid amides containing atomic groups which are stable as anion in their acyl groups can produce isocyanates or nitriles by vapor phase decomposition. For the present study, the pyrolyses of cyanoacetamides, 2-phenylacetanilide, 2, 2-diphenylacetanilide and 2, 2, 2-triphenylacetanilide were carried out in order to confirm this finding.

The pyrolysis of cyanoacetamides, which have

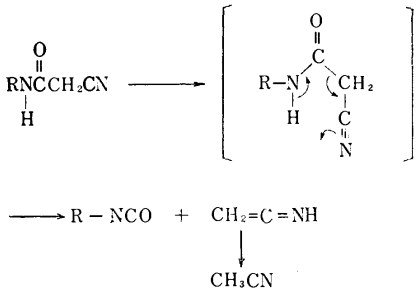
e) Found: C, 52.88; H, 3.50; N, 20.25. Calcd. for $C_9H_7O_3N_3$: C, 52.68; H, 3.44; N, 20.48%.

a structural possibility of forming $NCCH_2^-$ and $RNHCO^+$ ions at an elevated temperature, was tried first by using a quartz column packed with quartz chips; isocyanates and acetonitrile were obtained, as had been expected. The results of the experiments are summarized in Table I.

$$R\text{-}NHCCH_2CN \xrightarrow{\Delta} R\text{-}NCO + CH_3CN$$

The amounts of isocyanate and acetonitrile increase as the temperature rises, but they decrease markedly above 700°C, probably because of side reactions. The amount of undesirable char deposited in the reaction tube was larger than that found in the case of acetoacetamides. In addition, it was shown that the pyrolysis of cyanoacetamides has poor reproducibility, unlike the results obtained in the case of acetoacetamides (see Table I). In the case of 4'-nitrocyanoacetanilide, the char deposit in the reaction tube was much larger and *p*-nitrophenyl isocyanate could not be obtained, although it can be pyrolyzed at a relatively low temperature (550°C).

The results listed in Table I show that the temperature required for the pyrolysis of cyanoacetamides is about 100°C higher than that needed for the pyrolysis of acetoacetamides. This may be attributed to the relative stabilities of the anions[3], $NCCH_2^-$ and $CH_3COCH_2^-$, which determine the ease of the carbon-carbon bond breaking of the acid-amide linkage. Assuming six-membered cyclic intermediates for the pyrolysis, as has been mentioned in the case of acetoacetamides, the result can be explained by the linear nature of the nitrile group, because of which the formation of the cyclic intermediate is more difficult.



Pyrolyses of 2-phenylacetanilide and 2,2-diphenylacetanilide were next attempted on the assumption that carbon-carbon bond breaking may also be facilitated by the introduction of phenyl groups which stabilize $C_6H_5CH_2^-$ or $(C_6H_5)_2CH^-$ ions by the resonance effect. These amides were expected to produce phenyl isocyanate and toluene, and phenyl isocyanate

3) The pK_a values of acetone and acetonitrile are about 20 and 25 respectively.

f) Gas chromatographic analysis showed that crude toluene was 15% benzene.
g) Gas chromatographic analysis showed that crude toluene was 11% benzene.

and diphenylmethane, respectively. The reactions, however, were complicated, and the isocyanate and toluene or diphenylmethane formed was accompanied with a considerable amount of by-products. Since the reaction pathway is markedly influenced by even a minor change in the reaction conditions, the pyrolytic reactions also have poor reproducibility in both cases. The results of several runs are listed in Table II.

In the case of 2-phenylacetanilide, generalizations may be made as follows. Below 600°C, most of the starting material was recovered. In temperature range from 600 to 650°C, phenyl isocyanate was obtained along with toluene, benzene and *sym*-diphenylurea. However, it was shown that there was another reaction, the formation of aniline instead of phenyl isocyanate, under nearly the same conditions. At a more elevated temperature (670~680°C), the reaction became more complicated and the char deposit in the reaction tube was much larger. Phenyl isocyanate could not be obtained from the pyrolyzate, although aniline, toluene, benzene and *sym*-diphenylurea were obtained, along with various unidentified by-products.

$$C_6H_5\underset{\underset{H}{|}}{N}\overset{\overset{O}{\|}}{C}CH_2C_6H_5 \xrightarrow{\Delta} C_6H_5NCO + C_6H_5CH_3 + C_6H_6 + C_6H_5NHCONHC_6H_5$$

$$\xrightarrow{\Delta} C_6H_5NH_2 + C_6H_5CH_3 + C_6H_6 + C_6H_5NHCONHC_6H_5$$

When 2, 2-diphenylacetanilide was pyrolyzed with the temperature range from 490 to 650°C, phenyl isocyanate, diphenylmethane and *sym*-diphenylurea were obtained.

$$C_6H_5\underset{\underset{H}{|}}{\overset{\overset{O}{\|}}{N}}CCH(C_6H_5)_2 \xrightarrow{\Delta} C_6H_5NCO + (C_6H_5)_2CH_2$$

$$+ C_6H_5NHCONHC_6H_5$$

As was mentioned in a previous report[2], the percentage of conversion in the pyrolysis of 2-haloacetamides increases in proportion to the number of halogen atoms, with a large electronegativity value being attached to the α-carbon of acid amides. Similarly, the finding that 2, 2-diphenylacetanilide decomposed more easily than 2-phenylacetanilide indicates that the number of phenyl groups attached to the α-carbon of acid amides plays an important role in this type of pyrolysis.

Unexpectedly, phenyl isocyanate could not be obtained by the pyrolysis of 2, 2, 2-triphenylacetanilide, only a large amount of tarry product resulted, although it decomposed at a relatively low temperature (450°C). From the tarry pyrolyzate, traces of aniline, triphenylmethane and *sym*-diphenylurea were obtained. The reason why phenyl isocyanate could not be obtained by the pyrolysis of 2, 2, 2-triphenylacetanilide remains unexplained.

$$C_6H_5\underset{\underset{H}{|}}{\overset{\overset{O}{\|}}{N}}CC(C_6H_5)_3 \xrightarrow{\Delta} C_6H_5NH_2 + (C_6H_5)_3CH$$

$$+ C_6H_5NHCONHC_6H_5$$

Contrary to the cases of the pyrolyses of acetoacetamides and cyanoacetamides, which yield only isocyanates through the cyclic intermediate, the pyrolyses of 2-phenylacetamides gave various products. These results indicate that the pyrolyses of 2-phenylacetamides does not involve cyclic intermediates, but rather proceeds through radical intermediates, benzyl-type radicals, formed by the homolytic breaking of the carbon-carbon bond or the carbon-hydrogen bond.

In conclusion, it can be said of the pyrolysis of acid amides that: 1) The reactivity of amides toward the pyrolytic decomposition depends on the easiness of the carbon-carbon bond breaking of the amide linkage. This suggests that amides containing atomic groups which are stable as anion or free radical in their acyl groups decompose readily.

2) Since acetoacetamides and cyanoacetamides can form the cyclic intermediates, the pyrolytic decomposition takes place in the direction of forming isocyanate. However, such amides as 2-haloacetamides and 2-phenylacetamides, which form the cyclic intermediate only with difficulty, gave a small amount of isocyanate along with various by-products probably through radical intermediates. These results show that the greater the chance of forming cyclic intermediates, the greater the proportion of isocyanate.

Experimental

Materials.—Cyanoacetamides were prepared from corresponding amines and ethyl cyanoacetate. Their melting points are listed in Table I.

2-Phenylacetanilide, 2,2-diphenylacetanilide and 2,2,2-triphenylacetanilide were prepared from aniline and corresponding acid chlorides, and their melting points are listed in Table II.

Pyrolysis of Cyanoacetanilide.—The apparatus used consisted of a vertical quartz tube, 18 mm. in diameter and 120 cm. in length, equipped with a standard taper joint and a side-inlet tube near the top for the replacement of air with nitrogen. This tube was packed with quartz chips and externally heated with an electric furnace. The temperature was measured by a pyrometer with a thermocouple attached to the outside of the pyrolysis tube. During the pyrolysis, a slow stream of dry nitrogen was introduced through the capillary under reduced pressure. By the use of this apparatus, 5.0 g. (0.031 mol.) of cyanoacetanilide was pyrolyzed at 645~650°C over a period of 55 min. under the reduced pressure of 5.0 mm. The pyrolyzate was collected in a flask cooled in a dry ice-ethanol bath, and a 71% (0.70 g.) yield of acetonitrile and a 65% (1.84 g.) yield of phenyl isocyanate were obtained by fractional distillation. From the residue, 1.17 g. (23%) of cyanoacetanilide was recovered; m. p., 196°C.

Pyrolyses of cyanoacetanilide under various conditions and of other derivatives of cyanoacetamides are listed in Table I.

Pyrolysis of 2, 2-Diphenylacetanilide.—With the same apparatus as was employed in the case of cyanoacetamides, 5.0 g. (0.017 mol.) of 2, 2-diphenylacetanilide was pyrolyzed at 550~570° under the reduced pressure of 5.0~7.0 mmHg. The precipitate was collected from the dark brown pyrolyzate and washed with benzene. After recrystallization from ethanol, *sym*-diphenylurea (0.34 g.; m. p., 237°C) was obtained. When the filtrate was distilled, a 42% (1.23 g.) yield of diphenylmethane and a 15% (0.31 g.) yield of phenyl isocyanate were obtained, along with considerable amounts of unidentified by-products.

The results of the pyrolyses of 2,2-diphenylacetanilide under other conditions and of 2-phenylacetanilide and 2,2,2-triphenylacetanilide are listed in Table II.

Summary

The pyrolyses of cyanoacetamides, 2-phenylacetanilide, 2, 2-diphenylacetanilide and 2, 2, 2-triphenylacetanilide have been studied. The pyrolysis of cyanoacetamides gave the corresponding isocyanates and acetonitrile. On the other hand, the pyrolysis of 2-phenylacetanilide and 2, 2-diphenylacetanilide gave a small amount

of phenyl isocyanate, along with various by-products. The pyrolysis of 2, 2, 2-triphenylacetanilide, however, against expectation, did not give isocyanate; only a tarry product resulted.

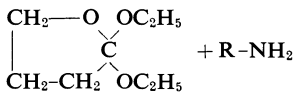
The Synthesis and Ring-opening Polymerization of N-Substituted 2-Iminotetrahydrofurans

By Teruaki MUKAIYAMA and Kenichiro SATO

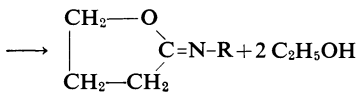
(Received September 13, 1962)

A new type of ring-opening polymerization of *N*-substituted iminocarbonates, cyclic ketene acetals and iminooxazolidines, producing polyurethans, polyesters and polyureas respectively, has been shown in previous papers[1,2]. In the present investigation, for the purpose of obtaining polyamides, the synthesis of *N*-substituted 2-iminotetrahydrofurans and their ring-opening polymerization have been studied.

A successful method for the preparation of *N*-substituted iminotetrahydrofurans (II) from 2, 2-diethoxytetrahydrofuran (I) and various amines in the presence of a catalytic amount of acetic acid has been discovered (see Table I).



(I)

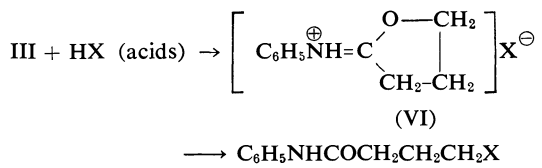


(II)

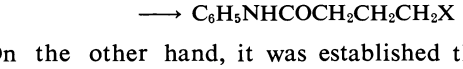
The highest yield (85%) of 2-phenyliminotetrahydrofuran (V) was obtained when compound I was treated with one equivalent of aniline for 30 min. at 120°C in the presence of a catalytic amount of acetic acid (run 2, Table II). The yield of 2-phenyliminotetrahydrofuran decreased upon prolonged heating because of the polymerization of the tetrahydrofuran produced (run 3, Table II).

It was shown that these tetrahydrofurans were quite sensitive to acidic substances and reacted with hydrogen chloride and benzoic acid to give γ-chlorobutyranilide (IV) and γ-benzoxybutyranilide (V) respectively in good yields.

These reactions seem to proceed through an initial formation of intermediates VI, which in turn decompose to give anilides by ring opening.



(VI)



On the other hand, it was established that III was very stable to bases and that III did not react with aniline, even when they were heated for 3 hr. at 120°C and the starting materials were recovered quantitatively.

These behaviors of the tetrahydrofurans toword acids or bases were similar to those of ethylene *N*-phenyliminocarbonate reported in a previons paper[1].

Next, the ring-opening polymerization of *N*-substituted 2-iminotetrahydrofurans was attempted in the presence of a catalytic amount of boron trifluoride etherate. This catalyst

9	*n*-Hexyl-	7	90～100	5	—	—

was chosen because it was most effective for the ring-opening polymerization of 2-iminocyclic carbonates, which resemble *N*-substituted 2-iminotetrahydrofurans in structure. The results are listed in Table III.

It is also noted that the polymerization of *N*-substituted 2-iminotetrahydrofurans was promoted by heating, even in the absence of a catalyst.

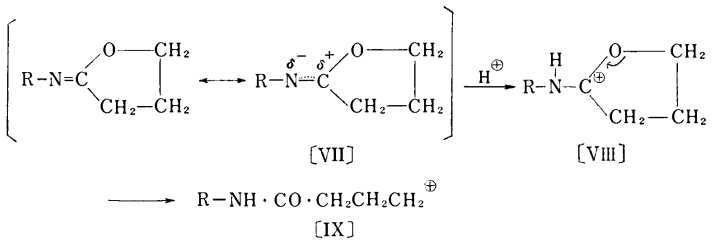
The polymeric substances obtained by this experiment show a weak N-H absorption at 3350～3450 cm^{-1} and a strong carbonyl absorption at 1650 cm^{-1} but no cyclic ether absorption band at 1170～1180 cm^{-1}, which is present in all the monomers.

A reasonable path by which *N*-substituted 2-iminotetrahydrofurans are converted into polyamides can be the cationic polymerization mechanism proposed in the case of cyclic iminocarbonates[2].

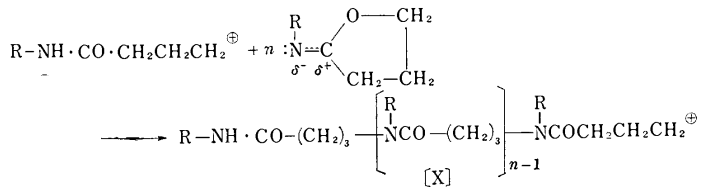
An interesting feature regarding ring-opening polymerization in general is the relationship between ring strain and polymerizability. The successful result for the ring-opening polymerization of tetrahydrofuran suggests that the ring strain considered in tetrahydrofuran facilitates the polymerization[3]. However, no polymerization of γ-butyrolactone has ever

3) E. L. Muetterties, U. S. Pat. 2856370 (Oct. 14, 1958).

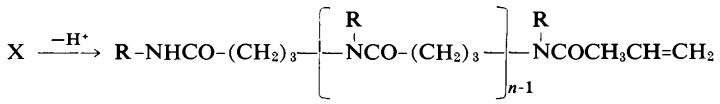
Initiation



Propagation



Termination



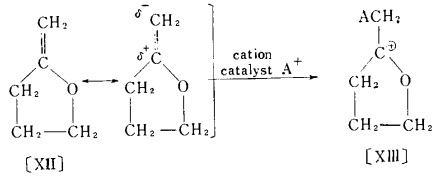
been discovered because the strain is relieved by the introduction of the exo double bond[4].

The fact that *N*-substituted 2-iminotetrahydrofurans which also possess an exo double bond stabilizing the tetrahydrofuran ring are readily polymerized in the presence of cationic catalysts may be because of the basic nature of the imino group, which easily forms a reactive intermediate VIII with the catalyst.

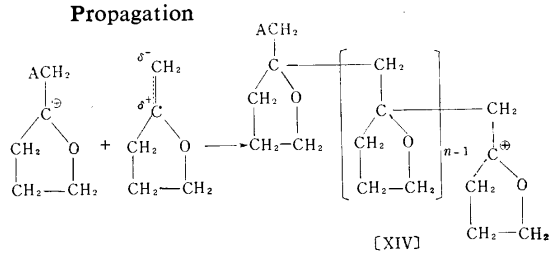
Although *N*-aromatic substituted compounds were readily converted into corresponding polymers, as is indicated in Table III, even under more vigorous conditions, the polymerization of *N*-aliphatic substituted compounds took a long time and their yields were poor. This leads to the conclusion that the step of ring-opening in forming IX from VIII plays a predominant role in this polymerization because the C–O bond fission is facilitated by the introduction of electron-withdrawing aromatic groups.

This type of polymerization was extended further to 2-methylene tetrahydrofuran XII, which also possesses the structural possibility of ring-opening polymerization. When the polymer obtained from the polymerization of XII in the presence of boron trifluoride etherate was examined by means of its infrared spectrum, a strong absorption band attributable to ether linkage (1030 cm^{-1}) was observed. The expected carbonyl band (1700 cm^{-1}) and C=C band (1640 cm^{-1}) were also observed, but they were so weak that the structure of the polymer is assumed to consist of poly cyclic ether, not of poly ketone. This indicates that the polymerization occurs mainly by means of vinyl type ones and that the following mechanism can be suggested:

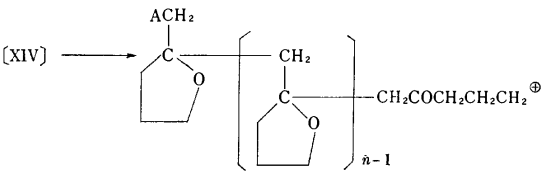
Initiation



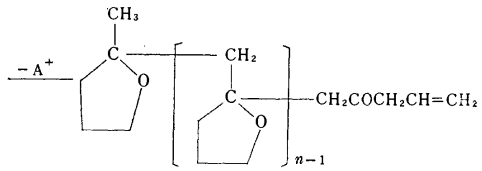
Propagation



Termination



4) H. C. Brown, J. H. Brewstead and H. Shechter, *J. Am. Chem. Soc.*, **76**, 467 (1954).



From the results obtained by the polymerizations of those tetrahydrofurans possessing a C=N or C=C exo double bond, it can be said that the ring strain of these tetrahydrofurans is not so large that the compound possessing the structural possibility of vinyl type polymerization does not give raise to ring opening.

In conclusion, ring opening polymerization took place when *N*-substituted 2-iminotetrahydrofurans were treated with acidic catalysts, but this type of ring-opening polymerization was scarcely observed in the case of 2-methylenetetrahydrofuran.

Experimental

2, 2-Diethoxytetrahydrofuran. — This compound was prepared according to the method of Meerwein[5].

Preparation of 2-Phenyliminotetrahydrofuran.— A mixture of 8.0 g. of 2, 2-diethoxytetrahydrofuran, 4.7 g. of aniline, and 2 drops of glacial acetic acid was heated at 120°C for 30 min. After the removal of the alcohol under reduced pressure, 2-phenyliminotetrahydrofuran was distilled as quickly as possible; yield, 6.8 g. (85%); b. p., 128°C/2 mmHg.

In a similar way, 2-(3,4-dichlorophenyl)-, 2-(*p*-chlorophenyl)-, 2-(*o*-chlorophenyl)-, 2-(*p*-methylphenyl)-, 2-(*o*-methylphenyl)-, 2-(*p*-methoxyphenyl)-, 2-(*o*-methoxyphenyl)-, 2-cyclohexyl-, 2-benzyl-, and 2-*n*-hexyliminotetrahydrofuran were prepared from 2, 2-diethoxytetrahydrofuran and corresponding amines.

2-(3,4-Dichlorophenyl)-iminotetrahydrofuran
Found: N, 6.01. Calcd. for $C_{10}H_9ONCl_2$: N, 6.09%.

2-(*p*-Chlorophenyl)-iminotetrahydrofuran
Found: N, 7.32. Calcd. for $C_{10}H_{10}ONCl$: N, 7.19%.

2-(*o*-Chlorophenyl)-iminotetrahydrofuran
Found: N, 7.42. Calcd. for $C_{10}H_{10}ONCl$: N, 7.19%.

2-Phenyliminotetrahydrofuran
Found: N, 8.42. Calcd. for $C_{10}H_{11}ON$: N, 8.69%.

2-(*p*-Methoxyphenyl)-iminotetrahydrofuran
Found: N, 7.21. Calcd. for $C_{11}H_{13}ON$: N, 7.33%.

2-Cyclohexyliminotetrahydrofuran
Found: N, 8.14. Calcd. for $C_{10}H_{16}ON$: N, 8.38%.

2-Benzyliminotetrahydrofuran
Found: N, 7.76. Calcd. for $C_{11}H_{13}ON$: N, 7.99%.

Bulk Polymerization of *N*-Substituted 2-Iminotetrahydrofurans.—About 1.0~2.0 g. of *N*-substituted 2-iminotetrahydrofurans were kept under the condition shown in Table III in the presence of a catalytic amount of boron trifluoride etherate. Polymer obtained were reprecipitated from chloroform-petroleum benzin (boiling range 50~90°C).

Reaction of 2-Phenyliminotetrahydrofuran with Hydrogen Chloride.—Dry hydrogen chloride was passed into a solution of 1.4 g. of 2-phenyliminotetrahydrofuran in 5 ml. of dry benzene at 60~70°C for 15 min. On evaporation of the benzene, crude γ-chlorobutyranilide was obtained and recrystallized from ether-ligloin; yield, 1.2 g. (70%); m. p., 69~70°C. This compound was identical in all respects with the authentic sample.

Reaction of 2-Phenyliminotetrahydrofuran with Benzoic Acid.—A solution of 1.4 g. of 2-phenyliminotetrahydrofuran and 1.0 g. of benzoic acid in 5 ml. of dry benzene was refluxed for 1 hr., and then the benzene was removed. γ-Benzoxybutyranilide was obtained and recrystallized from ether; yield, 60%; m. p., 132~134°C. Found: N, 4.78. Calcd. for $C_{17}H_{17}O_3N$: N, 4.91%.

Preparation of 2-Methylenetetrahydrofuran.— This was prepared according to the method of Paul and Tchelitcheff[6].

Bulk Polymerization of 2-Methylenetetrahydrofuran.—2.0 g. of 2-methylenetetrahydrofuran was kept at 100~110°C for 1 hr. in the presence of a catalytic amount of boron trifluoride etherate. The polymer obtained was reprecipitated from ether-acetone; yield, 40%. Softening point, 62°C (m. p., 62~67°C). $[\eta]^{30°}_{\text{chloroform}}$ 0.1.

Summary

Various *N*-substituted 2-iminotetrahydrofurans are prepared from 2, 2-diethoxytetrahydrofuran and corresponding amines.

N-Substituted 2-iminotetrahydrofurans give *N*-substituted polyamides by ring-opening polymerization when treated with a catalytic amount of boron trifluoride etherate.

On the other hand, 2-methylenetetrahydrofuran undergoes mainly a vinyl-type polymerization.

The authors wish to express their hearty thanks to Mr. Hiroyuki Nohira for his kind advice and to Miss Toshiko Aoyagi for her microanalyses.

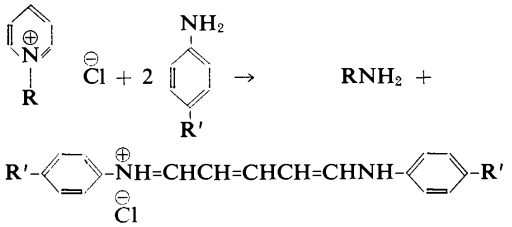
Kinetics of the Reaction of N-Arylpyridinium Chloride with Anilines

By Ryohei ODA and Shinji MITA

(Received September 22, 1962)

It is known that some *N*-arylpyridinium salts react with aniline to give glutacondialdehydedianil hydrochloride (I)[1,2]:



(Here R stands for 2, 4-dinitrophenyl or other electron-withdrawal groups.) Since the mechanism of the reaction had scarcely been studied, for the present paper the rates of the reaction with various R′ and R were measured by the estimation of the dianil produced in order to obtain some information on the mechanism.

Results and Discussion

The rate of the reaction is expressed in terms of the third-order equation:

$$dx/dt = k(a-2x)^2(b-x)$$

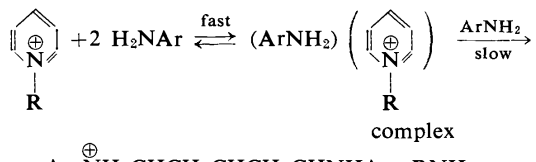
or

$$k = \frac{2.30}{t(a-2b)^2}\log\frac{b(a-2x)}{a(b-x)} + \frac{1}{t(a-2b)}\cdot\left\{\frac{1}{a-2x}-\frac{1}{a}\right\}$$

Here, a is the initial concentration of aniline, b, that of pyridinium salts, and x, the concentration of dianil at time t. As an example, a typical run with aniline is shown in Table I. The second-order equation does not agree with the results.

The third-order constants for substituted anilines are listed in Table II, which shows the effect of substituents in aniline.

The Hammett plot of σ: $\log(k/k_0)$ gives a straight line (Fig. 1) which affords the ρ-value of -4.50. This fact suggest a mechanism involving a nucleophilic attack of aniline on the pyridine-aniline complex and a transition state consisting of two molecules of aniline and a molecule of the pyridinium ion:



complex

R : 2, 4-dinitrophenyl

The equilibrium for the formation of complex as well as the rate of the nucleophilic attack of aniline should be suppressed by the decreased electrophilicity of the pyridinium salt, i. e., by the smaller electron-withdrawal group. This expectation is supported by the fact that *p*-nitrophenylpyridinium salt (lower electrophilicity) failed to react with aniline.

TABLE I. TYPICAL THIRD-ORDER RATE CONSTANTS FOR THE REACTION OF ANILINE WITH 2, 4-DINITROPHENYLPYRIDINIUM CHLORIDE

Time min.	Conversion %	$k\times10^{-2}$ l. mol^{-2} sec^{-2}

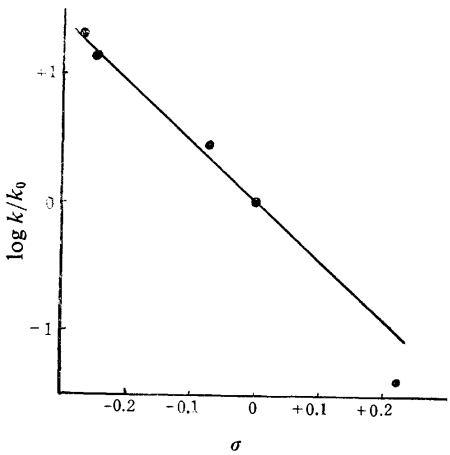

Fig. 1. Hammett's plot of the reaction of pyridinium salt with anilines.

2, 4, 6-Trinitrophenylpyridinium salt reacted very rapidly with aniline, yielding a considerable amount of picrylphenylamine (II) as well as a smaller amount of dianil I.

Experimental

Materials.—2, 4-Dinitrophenylpyridinium chloride was prepared by the reaction of 2, 4-dinitrochlorobenzene and pyridine[1]. *p*-Nitrophenylpyridinium chloride was prepared by the reaction of *p*-nitroaniline, pyridine and cyanogen bromide[2]. 2, 4, 6-Trinitrophenylpyridinium chloride was prepared by the reaction of picryl chloride[2]. The melting points of all these materials agree with those in the literature.

The Rate Measurements.—2, 4-Dinitrophenylpyridinium chloride (2.50 g.) was dissolved in methanol (90 ml.) and 9 ml. of the solution was introduced into test tubes dipped in a thermostat maintained at 30°C. Ten milliliters of a methanolic solution of aniline (2.48 g.) was kept at the same temperature until the temperature equilibrium was reached. One milliliter of the aniline solution was then pipetted out and poured into the pyridinium solution to start the reaction. At appropriate time intervals, the contents of the test tubes were poured into an ice-cooled mixture of acetone (15 ml.) and concentrated hydrochloric acid (15 ml.) to stop the reaction, and the mixture was allowed to stand for about 30 min. while being shaken. The red precipitate, glutacondialdehyde-dianil, was filtered with a glass filter, washed with a small amount of acetone and water, dried at 80~100°C, and weighed. From the amount of the dried product, the third-order rate constant was calculated. Another product, 2, 4-dinitraniline, is soluble in acetone, but is only with difficulty soluble in water, while the dianil is soluble in water, but far less soluble in acetone. From blank tests under the kinetic conditions, the ratios of the produced amount of dianil after a long reaction time vs. the calculated amount were found to be as follows: *p*-anisidine, 1.00; aniline, 1.02; *p*-phenetidine, 1.04; *p*-chloraniline, 1.10; *p*-toluidine, 1.02 and *p*-nitraniline, no reaction. The amount of the obtained precipitate was corrected by the above ratio.

The Reaction of 2, 4, 6-Trinitrophenylpyridinium Chloride.—In a methanolic solution, 2, 4, 6-trinitrophenylpyridinium chloride (0.29 g.) was reacted with aniline (0.248 g.) at 30°C for 5 min. The solution immediately turned red. After filtration of the precipitate of 2, 4, 6-trinitrodiphenylamine (m. p. and mixed m. p. 178°C), diluted aqueous hydrochloric acid was added to the solution. The resulting precipitate, after being filtered and washed with boiling acetone, gave the dianil; 0.011 g. (4.3%); m. p. and mixed m. p., 143°C. 2, 4, 6-Trinitrodiphenylamine was recovered from the acetone solution. The combined yield of this product was 0.213 g. (81%).

Summary

The rates of the reaction of 2, 4-dinitrophenylpyridinium chloride with ring-substituted anilines in methanol have been estimated by the gravimetry of the produced glutacondialdehyde dianil. The rates have been found to be second-order with aniline and first-order with pyridinium salt. The electron-withdrawal groups in pyridine accelerate the reaction. These facts suggest a mechanism involving a nucleophilic attack of the molecules of aniline on a complex consisting of 2 molecules of aniline and a pyridinium ion. The products of the reaction of 2, 4, 6-trinitrophenylpyridinium chloride with aniline were 2, 4, 6-trinitrodiphenylamine and the dianil.

Charge Carriers in Pyrene Crystals

By Hiroo INOKUCHI and Kenji OHKI

(Received September 25, 1962)

The experimental studies on the electrical behaviours of the organic semiconductors have been carried out by a number of investigators[1]. The work on the determination of signs of charge carriers in molecular crystals have already been reported with association of a several methods. For anthracene, Chynoweth and Schneider[2] found it to be positive by the rectifying behaviour of photoconduction and also Schneider and Waddington[3] found the identical result by means of a charge carrier generation in the crystal by absorption of gases.

Applying the rectifying effect of the photoconduction, on the other hand, the predominant charge carrier in violanthrene ($C_{34}H_{18}$) was found to be negative by the present author[1]. Further, the charge carrier in pentacene, hexacene, ovalene or violanthrene was negative one and in anthracene, pyrene, chrysene, naphthacene or anthanthrene was found to be positive by Northrop and Simpson[4]. Recently, Kepler[5] and LeBlanc[6] reported that positive charge carriers are more mobile than negative ones in anthracene single crystals from an observation of the drift mobility.

As is described above, there are some discrepancies among the different investigators concerning the signs of charge carriers. One of the reasons for such discrepancies may be related to the purity of specimen. In this paper, the authors are presenting the effect of impurities on the sign of the charge carriers in pyrene single crystal and in pyrene thin film.

Experimental

Crude pyrene (A) was provided by Rütgerswerke-Aktiengesellschaft A. G., Germany. Among the methods of purifying pyrene crystals, the techniques of recrystallization from xylene or toluene, sublimation in vacuo and chromatography with benzene or benzene-petroleum ether were effectively applied to make specimens for measuring the electronic

properties with combination and repeat of the above purification methods six sorts of specimens, single crystals and evaporated thin films, were prepared as shown in the chart, Fig. 1.

The other hydrocarbons applied in this work, violanthrene, dibenzpentacene and quaterrylene, were also purified through the above techniques.

The cell applied in this experiment was prepared by evaporating an organic film on a Pyrex glass which has been coated in advance with a metal film to provide an electrode. For a single crystal specimen, an electrode of metal film was prepared on the crystal directly by means of a vacuum evaporation. The second electrode was formed thereafter by evaporation of a metal onto the surface of the specimen film or single crystal. In order to determine the sign of the predominant charge carrier, the rectifying effects of the photocurrent of the sandwhich-type cells were observed with association of a Cary vibrating-reed electrometer, model-32.

Results and Discussion

It is known that the charge carriers are generated predominately at the thin surface layer closed to the illuminated electrode. Therefore, when the illuminated electrode is charged in negative, the negative charge carriers, electrons, traverse the crystal to reach the other electrode and when the electrode is positive, the positive carriers, holes, will traverse. (It is denoted that the former current is forward one, I_f, and the latter is reverse, I_r.) Therefore, when there is a difference in the mobilities of both signs of charge carriers, the rectifying effects are found.

The variation of the photocurrent (I_p) of the crystal, pyrene, with the applied voltage obeyed the following equation:

$$I_p \propto V^{1.2} \qquad (1)$$

As an example, this variation for specimen No. 1 is illustrated in Fig. 2. When two light sources*, 1000 W tungsten lamp and monochromatic mercury one (3650 Å) were applied no significant difference of the voltage-photocurrent curve was found as shown in the figure. It is suggested that photocarriers are generated only at the surface, even for wavelengths at which it would expect volume generation. For the convenience of understanding, the relation between the photocurrent and the applied voltage is illustrated with logarithmic scale in Fig. 3. Two curves, forward photocurrent and reverse one, are nearly linear except for the highest field applied in the work and are parallel with each other, that is to say, no change of the ratio of these forward and reverse currents, I_f/I_r, is found within the applied electric field.

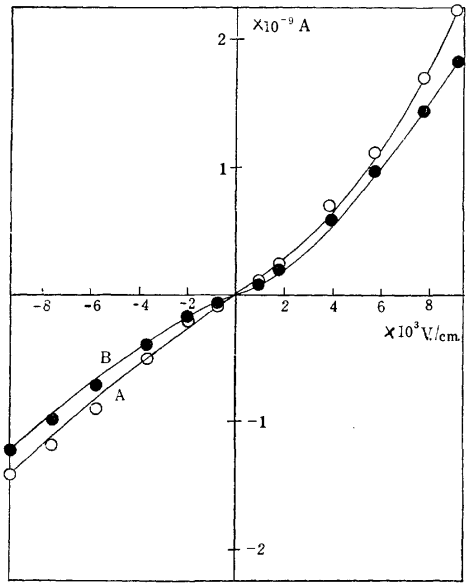

Fig. 2. The variation of the photocurrent with the applied voltage for the pyrene crystal; -●- illuminated with mercury lamp, 3650 Å, and -○- with tungsten lamp.

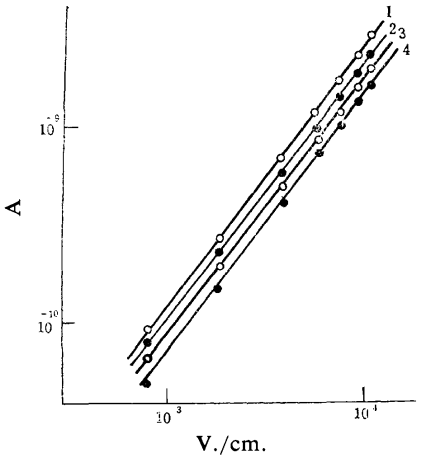

Fig. 3. The photocurrent-voltage curves for pyrene No. 1 with logarithmic scale; -●- illuminated with mercury lamp and -○- with tungsten lamp. Curves 1 and 2 are the reverse photocurrent, 3 and 4 are the forward one.

Following the consideration of transient photoconductivity in ionic crystals, I_f/I_r is described as[7],

* The intensities of these sources were approximately 10^{15}~10^{16} photons/cm² sec.

7) R. S. Van Heyningen and F. C. Brown, *Phys. Rev.*, **111**, 462 (1958).

$$\frac{I_f}{I_r}=\left[\omega_e\left\{1-\frac{e^{-Kl}}{1-K\omega_e}+\frac{K\omega_e}{1-K\omega_e}e^{-l/\omega_e}\right\}+\omega_h\left\{\frac{1}{1+K\omega_h}+\frac{K\omega_h}{1+K\omega_h}e^{-(K+(1/\omega_h))l}-e^{-Kl}\right\}\right]\Big/\left[\omega_e\left\{\frac{1}{1+K\omega_e}+\frac{K\omega_e}{1+K\omega_e}e^{-(K+(1/\omega_e))l}-e^{-Kl}\right\}+\omega_h\left\{1-\frac{e^{-Kl}}{1-K\omega_h}+\frac{K\omega_h}{1-K\omega_h}e^{-l/\omega_h}\right\}\right] \quad (2)$$

where K is an absorption constant ($10^4\,cm^{-1}$ at 365 mμ for pyrene), l is a thickness of crystal, $\omega_e=\mu_e E\tau_e$, $\omega_h=\mu_h E\tau_h$. Furthermore, μ_e and μ_h are the mobilities of electron and hole respectively, τ_e and τ_h are the meantimes for trapping of electron and hole. $E=V/l$, where V is an applied field.

In rough approximation*, this ratio, I_f/I_r, reduces as follows:

$$\frac{I_f}{I_r}\propto\frac{1+K\omega_e}{1+K\omega_h} \quad (3)$$

The ratios for pyrene specimens are summarized in Table I. These results suggests that the ratio reaches over a unity with repeating the purification, that is, the predominant charge carrier is changed from hole to electron with increasing the purity of the crystals. It is expected that the impurities, which may be compounds comprised oxygen**, provide trapping centres for electrons or catch the negative charge carriers. Thereby, it is observed the positive charge carriers in impure crystal are more mobile than the negative one. Recently, Hoesterey has reported the impurity in anthracene acts as an additional dissociation centre capable of trapping the electron component of the exciton[8]. These ratios, I_f/I_r, for violanthrene, dibenzpentacene and quaterrylene were 5~10, 4 and 1.0, respectively. The ratio of pyranthrene ($C_{30}H_{16}$) was found to be 1.5 by Sano[9].

TABLE I. THE RATIOS FOR A NUMBER OF PYRENE CRYSTALS

Sample No.	Form	I_f/I_r
1	Single crystal	0.8
2	Evaporated film	0.9
3	Single crystal	0.6
4	Single crystal	1.3
5	Evaporated film	2.4
6	Single crystal	1.2

To avoid the effect of electrodes and also to estimate the charge mobility in organic crystals, the observation of transient photoconductivity of the organic single crystal sandwiched with two blocking layers is in due course. Further, in comparison with the experimental results, the calculation of overlap integrals between the molecular orbitals of different pyrene molecules in the crystal lattice will be appeared elsewhere.

Summary

From the rectifying behaviour of photoconduction, the sign of charge carriers in molecular crystals is estimated; the ratio of forward photocurrent and reverse one corresponds to the ratio of mobilities μ_e/μ_h, where μ_e is the mobility of electron and μ_h is that of hole. The ratio for pyrene crystal reaches over a unity with repeating the purification, that is, the predominant charge carrier changed from hole to electron with increasing the purity of the crystals. For violanthrene or dibenzpentacene, the ratio is larger than 4 and for quaterrylene, that is almost a unity.

Proton Magnetic Resonance Spectra of Some Thenyl Derivatives[1]

By Kensuke TAKAHASHI, Tyo SONE, Yasuo MATSUKI and Genjiro HAZATO

(Received May 29, 1962)

In the previous works[2,3], we investigated the proton magnetic resonance spectra of some thiophene derivatives. In these studies, the coupling constants and the chemical shifts were measured and discussed in connection with their structures. In the present case we have extended our investigation to some thenyl derivatives.

Experimental

The procedure and apparatus were similar to those described previously[2]. All spectra were observed with a Varian high resolution NMR spectrometer at 40 Mc. The chemical shifts were read directly from the spectra recorded with a Sanborn model 127 recorder. Sweep rate of the magnetic field was calibrated frequently by measuring the displacement between the two peaks for benzene-cyclohexane mixture (1 : 1 by volume). The value assumed for this displacement in the present work is 227 c.p.s. at 40 Mc.[4], although more recent measurements indicate that this value is about 230 c.p.s. at 40 Mc.[5] The small sweep rate was calibrated by running acetaldehyde, with its known splitting of 2.85 c.p.s. The spectra of most of the compounds were measured in cyclohexane solutions and chemical shifts referred to cyclohexane were read in c.p.s., carbon tetrachloride, carbon disulfide, trichloroethylene and acetone were used as solvents in some cases.

All thenyl derivatives and some of the corresponding benzyl derivatives used in the present observations were prepared by the usual method with exception of the commercially available products. The measured conditions and the boiling points or the melting points of the compounds studied are given in Table I.

Results and Discussion

Tables II, III and IV list the results of the chemical shifts and the coupling constants

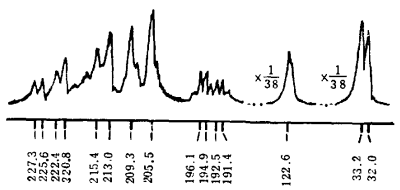

Fig. 1. The proton magnetic resonance spectrum of a mixture of 2-methyl-5-bromothiophene and 2-thenyl bromide at 40 Mc./sec. Applied magnetic field increases from left to right.

which we have obtained. Figure 1 shows the spectrum of a mixture of 2-methyl-5-bromothiophene and 2-thenyl bromide which was obtained by bromination of 2-methylthiophene with *N*-bromosuccinimide in the presence of benzoyl peroxide[6] and cannot be separated easily by distillation. At the highest field, $32._5$ c.p.s. referred to cyclohexane, there is the methyl proton peak of 2-methyl-5-bromothiophene which has the doublet structure with the coupling constant of 1.1_5 c.p.s. The next ill-resolved broad peak at $122._5$ c.p.s. corresponds to the methylene protons of 2-thenyl bromide. The peaks of the ring protons are rather complicated because of the overlapped signals of the two isomers. But it can be partially assigned as follows; two overlapped quartets at the highest field in the ring proton spectrum come from the 3-positioned proton in 2-methyl-5-bromothiophene and four peaks at the lowest field come from the 5-positioned proton in 2-thenyl bromide. The methylene proton peaks in these compounds are distinguished very clearly even with the measurements in the mixture. Chemical shifts of methylene protons in 2-thenyl, 3-thenyl and the corresponding benzyl derivatives are given in Table II. In the course of these studies, we have observed the thermal isomerization of 2-thenyl thiocyanate which easily occurs even at about 150°C[7,8]. But in the case of 3-thenyl thiocyanate, the thermal isomerization could not be observed under the same conditions so that it seems to be sure that 3-thenyl thiocyanate is more stable than 2-thenyl thiocyanate. The chemical shifts of methylene protons given for thenyl and benzyl isothiocyanate in Table II are those obtained from the thermal isomerization of the corresponding thiocyanates. It is seen from Table II that the methylene proton resonance peaks of 2-thenyl derivatives are observed usually at lower field than those of the corresponding 3-thenyl ones. The mean

difference between them is about 6 c.p.s. A similar magnitude of the chemical shifts is also observed in thiophene where 3-protons are more shielded than 2-ones by about 6 c.p.s.[9,10,11] From Table II, the methylene protons of benzyl derivatives are more shielded than those of the corresponding 2-thenyl and 3-thenyl derivatives by about 9 and 3 c.p.s. as the mean value, respectively. It is very interesting to note that the ring protons of thiophene are more shielded than those of benzene, while, the methylene protons of thenyl derivatives are less shielded than those of the corresponding benzyl derivatives. This may arise from the difference between the circulating currents of π-electrons in benzene and the thiophene ring. Ring proton spectra of thenyl derivatives studied are rather complex for analyses. But the weighted mean chemical shift for three ring protons in each compound can be estimated from the observed spectrum, the results of which are given in Table III. The ring proton spectrum of each thenyl derivative spreads more widely as compared with the corresponding benzyl derivative. It means that the five ring protons in each benzyl derivative are rather magnetically equivalent, but it is not the case with the three

ring protons in each thenyl derivative. Of the two series of thenyl derivatives, as shown in Table III, the mean chemical shift of the ring protons is mainly affected by the position of the substituent in the ring to which the CH_2X group attached, and in this case, the substituent effect of X in the CH_2X group is unimportant. The Shoolery's method[12] for calculating the alkyl proton frequencies in acyclic systems is highly successful for systems of the type $Y-CH_2-X$[13]. His additivity rule is also applicable to the methylene protons of some benzyl derivatives[13] and the same will be the case with thenyl derivatives. In Table II, acetoxy group, which causes the methylene protons to shift to the lowest field side, is a very distinct one, such a case being not found in Shoolery's or Jackman's table[12,13]. Some of the substituted thenyl derivatives are also investigated and the results are summarized in Table IV. In the case where the signal is split by the indirect spin-spin interaction, the chemical shift given in Table IV is that for the center of the resonance pattern. The observed coupling constants between two ring protons, J_{34}, fall into the range of 3.7~4.2 c.p.s., which are consistent with our previous assumption, $J_{34} \simeq 4.0$

c.p.s.[2], and also with the others[14]. The coupling constants observed between methylene protons and the 3-positioned ring proton in 2-thenyl derivatives fall into the range of 0.6 ~1.0 c.p.s. This kind of interaction between the ring proton and the methylene protons in thenyl derivative gives us some useful information for the assignments of the spectra, especially in the cases of small internal chemical shifts. For example, in 5-chloro-2-thenyl chloride, the assignment of the two ring protons was made by the observed multiplet structure, but the chemical shift between them is small, then the assignment was also ascertained by taking the spectrum at 56.4 Mc.[15] In all 5-substituted 2-thenyl derivatives tabulated in Table IV, except 5-chloro-2-thenyl chloride, the 3-positioned proton is more shieled than the 4-positioned one, respectively.

TABLE V. DISPLACEMENTS OF THE METHYLENE PROTON PEAKS WHEN THE SAMPLES ARE DILUTED WITH CYCLOHEXANE, CARBON TETRACHLORIDE AND ACETONE, IN c.p.s. AT 40 Mc./sec., REFERRED TO THE VALUES DILUTED WITH CYCLOHEXANE, MINUS SIGN SHOWING THE DISPLACEMENT TOWARD HIGHER FIELD

Compound	Solvent		
	Pure*	CCl_4	Acetone
Benzyl cyanide	−1.0	5.0	16.0

3-Thienylacetonitrile	1.0	5.0	16.0
Benzyl thiocyanate	−3.5	4.5	15.5
2-Thenyl thiocyanate	−3.5	4.0	15.5
3-Thenyl thiocyanate	−2.5	3.0	13.5
5-Chloro-2-thenyl chloride	1.0	4.5	15.0
Benzyl methyl ether	−1.0	1.5	3.5
2-Thenyl methyl ether	−0.5	1.5	3.5
3-Thenyl methyl ether	0.0	0.5	3.5
Benzyl acetate	1.5	1.0	4.5
2-Thenyl acetate	2.5	1.0	5.0

* The values are estimated from Table II.

The observation of the solvent effects on the chemical shifts for methylene protons of several compounds was also made. Three typical solvents were used. The experiment was carried out with definite dilute solutions of the compounds in each solvent; those are 13.5 wt.% solutions in cyclohexane, 7.5 wt.% solutions in carbon tetrachloride containing 1.5 wt.% cyclohexane and 14 wt.% solutions in acetone containing 14 wt.% cyclohexane. The results are summarized in Table V. The values in pure liquid state in Table V are estimated from the values in Table II. It is seen from Table V that the displacements in question are much affected by the difference of X of the CH_2X groups and not so much by the difference between the corresponding benzyl, 2-thenyl and 3-thenyl derivatives.

Distribution of Inorganic Impurities in Graphite Electrodes

By Michio INAGAKI and Tokiti NODA

(Received August 10, 1962)

In most domestic graphite electrodes, the ash content is usually less than 0.2%. However, some Acheson 18'' electrodes have been found to contain larger quantities of ash. Moreover, the main component of the ash in the Acheson 18'' electrode was found to be iron. It would be very interesting to know the distribution pattern of inorganic impurities in graphite electrodes. However, the usual method of determining ash content[1] does not serve here.

In the present work, the distribution of inorganic impurities in many graphite electrodes was investigated by means of radiography, ash pattern technique and sulfur print technique.

Experimental and Results

Radiograph. — The arrangement for radiography is illustrated in Fig. 1. Flat specimens

1) JIS (Japan Industrial Standards) R 7202·3·3 (1952).

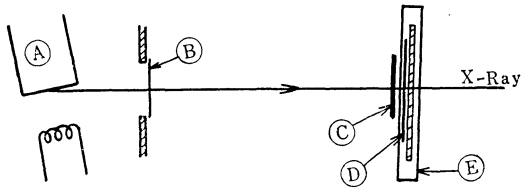

Fig. 1. Arrangement for radiography.
A: Anticathode B: Ni-filter
C: Specimen D: Ni-foil
E: Film cassette

1.0 or 1.5 mm. thick were made from Acheson 14", 18" and 30" graphite electrodes and from six kinds (A—F) of domestic 14" and 18" graphite electrodes. The surface of the specimen was polished with fine sand-paper, although the degree of polishing was found to have no remarkable effect on the radiograph. The distribution of a small amount of iron compound in the graphite product is detectable because the mass absorption coefficient of iron ($\mu/\rho=320$) is far greater than that of carbon ($\mu/\rho=5.50$), while a small amount of sulfur ($\mu/\rho=91.3$) or silicon ($\mu/\rho=60.3$) is very difficult to detect.

The texture of the graphite product, such as the shape and distribution of both grain and pore, can be revealed by a radiograph.

The radiographs of the Acheson electrodes and of some domestic electrodes are represented in Fig. 2a and Fig. 3 respectively. The radiographs for the domestic electrodes were taken from both central and peripheral parts, which are designated as C and P in Fig. 3.

Ash Pattern.—If the specimen was slowly burned out at 750°C on a porcelain plate, an ash pattern consisting of non-volatile impurities was obtained. The ash pattern was very fragile and had to be handled with great caution.

The ash patterns of the Acheson electrodes are shown in Fig. 2b. The ash patterns of these electrodes were found to correspond very closely to the patterns of their radiographs.

Sulfur Print.—The sulfur print technique, which is often used to detect sulfide in steel, was applied to the graphite electrode. The sulfur print of the Acheson 18" electrode is shown in Fig. 4. The pattern of the sulfur print of the electrode does not necessarily correspond to the pattern of the radiograph or to the ash pattern of the same electrode, because the sulfur print only reveals the sulfide distribution on the surface of the specimen plate. As for the Acheson 14" and the domestic electrodes, no sulfur print was obtained of them.

Discussion

The ash pattern of the Acheson 14" electrode consisted of a small amount of white and light ash which was distributed relatively uniformly. Some of the minute black particles in the ash pattern correspond to those on the radiograph, and these particles seem to consist of iron. An appreciable amount of impurities was found in the Acheson 18" and 30" electrodes. The ash content of the Acheson 18" electrode ranged from 0.2 to 2%, varying from place to place even in a single electrode. The main component of the ash was iron oxide (Fe_2O_3), which was identified by the X-ray diffraction method. From both the radiograph and ash pattern, impurities in the Acheson 18" electrode were found to exist in a fibrous

Fig. 3. Radiographs of domestic electrodes (×1).

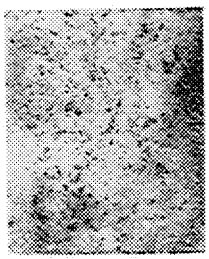

Fig. 4. Sulfur print of Acheson 18″ electrode (×1).

texture intermingled with fine coke powder or with coke derived from binder pitch in the interstices between the coke grains. The fibrous texture of the impurities suggests that they might have condensed from the vapor phase.

The average sulfur content of the Acheson 18″ electrode, which was determined by Eschka's method, was 0.55%, and the average iron content was 1.13%. The impurities in the electrode were gradually dissolved out by dilute sulfuric acid evolving hydrogen sulfide. The mole ratio of sulfur to iron in the electrode, the evolution of hydrogen sulfide, and the development of the sulfur print suggest that the main component of inorganic impurities in the Acheson 18″ electrode is iron sulfide.

In most domestic graphite electrodes, such as E–18″–C and F–14″–P, small black particles of impurities are distributed fairly uniformly all over the electrodes in a way similar to that in the Acheson 14″ electrode. In radiographs of some domestic electrodes such as A–18″–C, however, small clusters of impurities were found to exist in the interstices of the coke grains.

From radiographs of graphite electrodes, one can estimate the shape and the size distribution of coke grains and pores. On the radiographs of A–18″–C and E–18″–C, large coke grains and fairly large pores may be clearly observed. The central part of an eighteen-inch electrode was found to have a less compact texture than the peripheral part of the same electrode. This finding corresponds to the other experimental finding that the bulk density of the peripheral part of graphite electrode is larger than that of its central part[2]. Particularly, the central part of the electrode of D–18″ has an extremely loose texture, as is shown in the radiograph of D–18″–C. Eighteen-inch or larger-sized electrodes contain larger grains and have a less compact texture than 14″ electrodes.

Summary

The distribution of inorganic impurities in graphite electrodes was investigated by means of radiography, ash pattern technique and sulfur print technique. The pattern of the radiograph of an electrode corresponded closely with its ash pattern.

Radiography of graphite electrode was proved to be useful in showing not only the distribution of inorganic impurities in the electrode, but also the texture of the electrode, such as the shape and distribution of both coke grains and pores.

*Radiation-Induced Addition of Acetaldehyde to Ethylene**

By Kozo HIROTA, Shinji IIZUKA, Hiroshi OCHI and Motoyoshi HATADA

(Received August 13, 1962)

It was found by two of the present authors[1] that several ketones of the type, $CH_3CO\cdot(C_3H_6)_nH$ ($n=1, 2, 3, \cdots\cdots$), can be synthetized by radiation-induced addition of acetaldehyde to propylene at room temperature with a maximum $G(-C_3H_6)$ value of 150. The mechanism could be ascribed to a following chain reaction, where acetyl radical which plays a role of the initiator is produced not only by irradiation but also by a result of chain transfer.

$$CH_3CHO \rightsquigarrow CH_3\dot{C}O + \dot{H} \quad (1)$$

$$CH_3\dot{C}O + C_2H_3R \rightarrow CH_3COCH - \dot{C}HR \quad (2)$$

$$CH_3COCH_2-\dot{C}HR + CH_3CHO \rightarrow CH_3COCH_2CH_2R + CH_3\dot{C}O \quad (3)$$

$$CH_3COCH_2-\dot{C}HR + CH_2=CH_2 \rightarrow CH_3COCH_2CHRCH_2\dot{C}HR \quad (4)$$

etc., where R denotes CH_3.

Such a kind of telomerization was later reported by Stoops and Furrow[2], who investigated the effect of methyl substitution of both telogen and taxogen, but detailed experimental conditions were not described. Radiation-induced telomerizations of similar type have been reported by several authors, who used different telogen (mercaptan[3], carbontetrachloride[4,5], alcohol[6], etc.), though their taxogen were the same and mostly ethylene. Nevertheless, the details of the research have not been described so extensively, except the recent of Takehisa et al.[5]

It was found since then by the present authors that G values of such telomer formation, G(telomer), depend evidently on the temperature and pressure of the irradiated samples and also on the natures of telogens and taxogens. Especially such a dependency was shown when ethylene was adopted as the taxogen instead of higher olefins, and acetaldehyde as the telogen; moreover, G value of ethyl methyl ketone produced, 1 : 1 telomer of ethylene, reached more than 1000 even at room temperature, as reported in the preliminary paper[7]. Therefore, it will be interesting to report the results of this telomerization, the experimental condition of which was varied over the ranges of pressure and temperature up to 50 kg./cm^2 and 110°C, respectively.

Experimental

Materials.—Acetaldehyde was prepared by heating commercial paraaldehyde, which had been purified by distillation at 70°C, with a small amount of concentrated sulfuric acid. The final product was again distilled under vacuum. Ethylene was obtained from the Takachiho Chemicals Co., and was purified by vacuum distillation. Impurities of ethylene thus treated were found to be within 0.5% by mass-spectrometric and gas chromatographic measurements.

Procedure.—Two different procedures were adopted according as the experiments were carried out at low or high pressure. In the first experiment, glass tubes were used as in the former reports. The pressure of ethylene in the tubes could not be determined absolutely. Therefore, a bomb equipped with a pressure gage was used in the second experiment. Both procedures and also the results will be described separately.

Experiment at Lower Pressure.—All the samples were carefully deaerated, and then enclosed in the glass tube, shown in Fig. 1. The following procedure was adopted in order to avoid polymerization of acetaldehyde when it was cooled with liquid nitrogen: 1) A measured amount (0.05 mol.) of acetaldehyde was introduced into A of the glass tube by cooling it at −78°C; 2) the tube was sealed off at B, and connected to the vacuum system at C; 3) a measured amount (0.027$_4$ mol.) of ethylene was introduced into D through C; 4) the tube was sealed off at E; 5) both liquid samples were mixed by opening the break-off tip.

The glass tube was put to irradiation of gamma-rays from the Co-60 source (1000 c.) of our laboratory. If not otherwise described, the irradiation was carried out at 7~15°C. After irradiation, samples were taken out from the tube and their

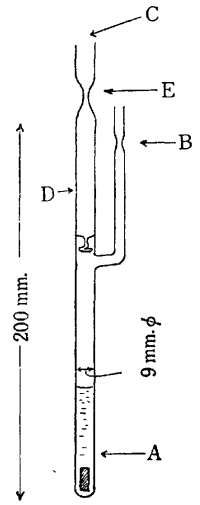

Fig. 1. Irradiation tube for experiments at lower pressure.

liquid part was analyzed by gas chromatography on a Shimadzu G-C 1A instrument by the use of a 3-m. column of dioctyl phthate at the flow rate of 120 ml./min. of helium. For analysis of 1 : 3 telomer, a 5.25-m. column of high vacuum oil was used at an operating temperature of 150°C and at the flow rate of 120 ml./min. of helium.

Experiment at Higher Pressure.—According to the preliminary run, it was found that acetaldehyde reacted with the inner surface of the autoclave made of stainless steel. Therefore, samples were introduced by the following procedures so as to prevent the direct contact of acetaldehyde with the wall:—Acetaldehyde was enclosed under vacuum in a glass ampoule which was then charged in another glass tube which has a small hole A at its side-wall. After the glass ampoule and tube were set up in the autoclave as shown in Fig. 2, an ethylene tank was connected via valves. Ethylene was introduced up to the desired pressure which was measured by a Bourdon gage. The autoclave was rocked and the upper end of the ampoule B was broken by shaking the autoclave upside down. After the time sufficient to reach the dissolution equilibrium of ethylene into acetaldehyde, the sample was irradiated through the wall of the autoclave with Co-60 γ-rays.

After cooling the autoclave down at 5°C and ventilating the unrecacted gas, the liquid product was taken out and put to the gas chromatographic analysis by making methylamyl ketone an internal standard. Operating condition of the gas chromatograph was similar to that of the first experiment.

Gelled part of the product was filtered, dissolved in carbon tetrachloride, and purified by the column chromatography using aluminum oxide as an adsorbent. The result of the elementary analysis is the purified gell was as follows:

Found: C, 81.2; H, 13.47. Calcd. for $C_{21}H_{42}O$: C, 81.21; H, 13.63%.

Mean molecular weight determined by the freezing-point method was found to be 410, though

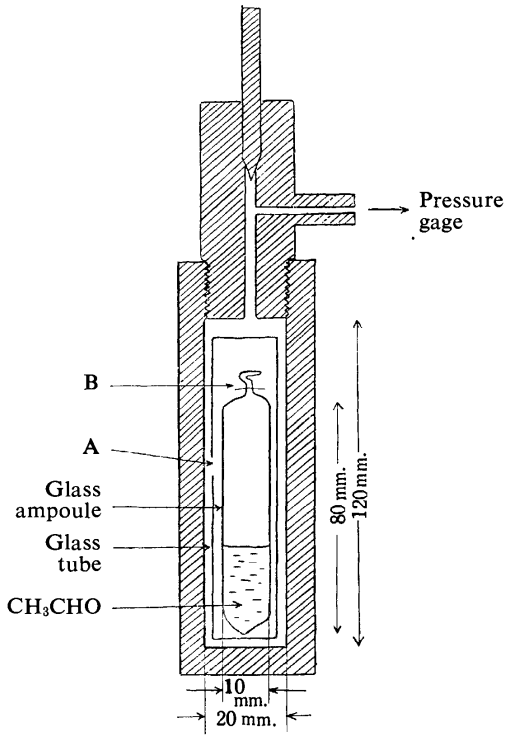

Fig. 2. Irradiation apparatus for experiments at higher pressure.

calculated value was given to be 310 from $C_{21}H_{42}O$.

Results and Discussions of the Experiment at Lower Pressures.—*Identification of the Products.*—Ethyl methyl ketone (EMK) and methyl-*n*-butyl ketone were found to be produced in the irradiated samples. They correspond to

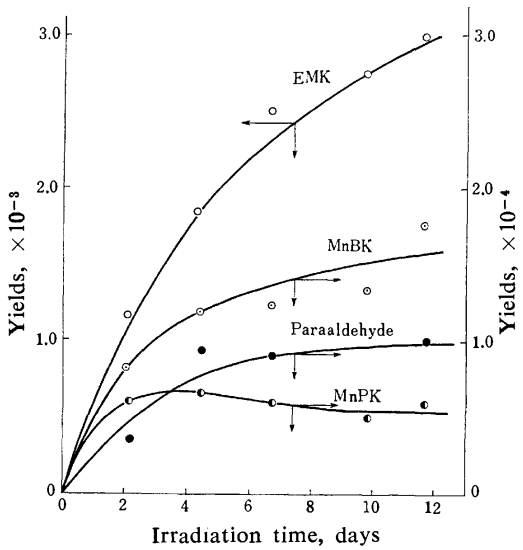

Fig. 3. The yields of EMK, MnBK vs. irradiation time.
Irradiation dose rate 1.3×10^4 r/h.
Ethylene 0.00411 mol.

1 : 1 telomer and 1 : 2 telomer, respectively, of acetaldehyde and ethylene. Both yields increase with irradiation time as shown in Fig. 3*. However, 1 : 3 telomer could not be identified. Besides a small amount of methyl-*n*-propyl ketone was found, which was probably produced by the termination of the following type:

$$CH_3COCH_2-\dot{C}H_2 + \dot{C}H_3 \rightarrow CH_3COCH_2-CH_2-CH_3 \quad (5)$$

The methyl radical in Eq. 5 might be produced by thermal decomposition of acetyl radical, i. e.

$$CH_3\dot{C}O \rightarrow \dot{C}H_3 + CO \quad (6)$$

or directly from acetaldehyde by irradiation, i. e.,

$$CH_3CHO \xrightarrow{h\nu} \dot{C}H_3 + \dot{C}HO \quad (7)$$

Such reactions are very probable from the data of both photochemical and thermal decompositions of acetaldehyde[8].

Effect of Dose Rate on G(Ethyl Methyl Ketone).—The effects of dose rate I on the yield are shown in Figs. 4a and b. The G values were estimated from the initial inclination of the curves in Fig. 4a and logarithms of the G(EMK) are plotted against $\log I$ in Fig. 4b. From this plot, it is clearly shown that EMK is produced in proportion to -0.59 powers of I. This value is slightly smaller than -0.50 which will be derived under the assumption of a bimolecular termination of all the propagating radicals in Eqs. 3 and 4.

Effect of Irradiation Temperature on G(Ethyl Methyl Ketone). — Effect of irradiation temperature on the G(EMK) is shown in Fig. 5. The G values increase gradually with irradiation temperature. From their Arrehnius plots

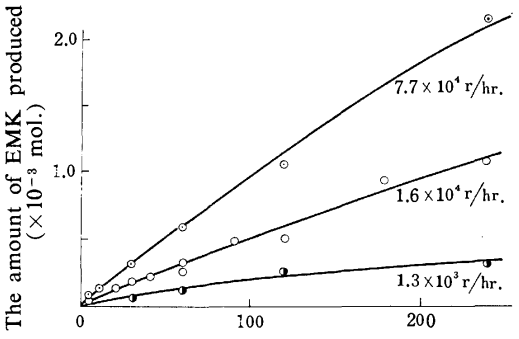

Fig. 4a. The amount of EMK produced vs. irradiation time.

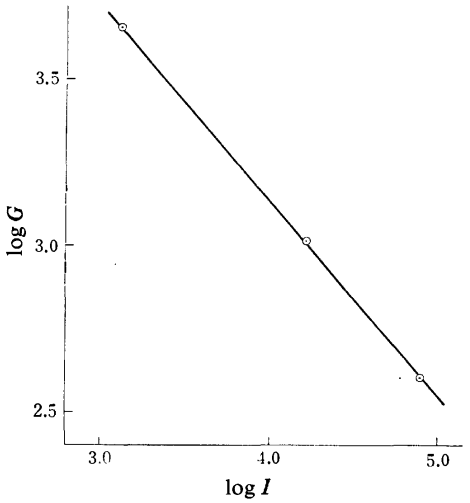

Fig. 4b. Log G vs. log I.

a relatively good straight line was obtained, and an apparent activation energy was determined to be 5.0 kcal./mol. from the inclination of this line. It will be interesting to compare this value with that of the system of ethylene and isopropanol (7.0 kcal./mol.)[7]. Such a smaller value may denote that hydrogen abstraction from acetaldehyde is easier than from isopropanol.

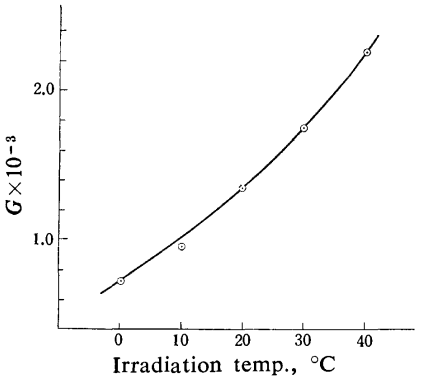

Fig. 5. G(EMK) vs. irradiation temperature.

Because if a bimolecular termination of the propagating radicals is assumed, the apparent activation energy of such a chain polymerization will be given generally by

$$E_a' = E_p - 1/2E_t \quad (8)$$

where E_p and E_t denote the propagating and the terminating steps, respectively. In the present case E_t may be equated practically to zero. The above two values (5.0 and 7.0 kcal./mol.) however do not correspond exactly to E_p of Eq. 8 due to the change of solubility of ethylene into acetaldehyde with the reaction temperature. Nevertheless, since

8) Cf. E. W. R. Steacie, "Atomic and Free Radical Reactions", 2nd ed., Reinhold Publishing Corp., New York (1954), pp. 215—219. pp. 286—294.

* Since the amount of paraaldehyde is not reproducible, it may not be produced by irradiation. The data will therefore be omitted hereafter.

the temperature dependency on solubility of ethylene will be similar in both alcohol and aldehyde, the above conclusion on the difference of activation energy may be drawn.

Effect of Molar Percent of Ethylene in the Feed on G(Ethyl Methyl Ketone).—It is shown in Fig. 6 that the G(EMK) increases with increasing pressure of ethylene, the inclination of the curve decreases gradually. It will be interesting to study the behavior of G values at higher molar per cent. The investigation will be carried out in the higher pressure experiment.

Effect of Additives. — Presence of the air scarcely affected the yield of telomers but rather increased slightly. A small amount of DPPH inhibited the production of telomers perfectly, except that of paraaldehyde. Addition of water reduced the yield markedly; e. g. 20% decrease was found in the telomer formation by the addition of 2% water. Such a reducing effect of water may be ascribed to the hydration of acetaldehyde.

Dose rate 1.6×10^4 r/hr.
Irradiation time 1 hr.

Results and Discussion of the Experiments at Higher Pressure*.— *Effects of Irradiation Time on Telomer Yields.*—In addition to the 1 : 1 and 1 : 2 telomers described in the previous section, methyl-*n*-hexyl ketone (1 : 3 telomer) was found to be produced in the experiments at higher pressures. The effects of irradiation time on the yield of each telomer were shown in Figs. 7—9, where ethylene was charged at the initial pressures of 10, 20 and 50 kg./cm², respectively, to 0.05 mol. of acetaldehyde. The yields of 1−1 and 1−2 telomers increase approximately linearly with increasing dose, while tendency of the yield of 1−3 telomer is not so clear, as the value is too small.

Effect of Irradiation Temperature.—As can be shown by the data in Figs. 7—9, it may be clear that the effect of temperature is very small, especially at the pressure range higher than 20 kg./cm², if it ever exist. Such a result

* According to a Germa Pat. 1077662 (Jan. 30, 1957), such telomers are produced without irradiation under the pressures higher than 35 atm. This effect was found to be negligibly small in the present experimental conditions.

is quite different not only from the low pressure experiment but also from the system of isopropanol and ethylene where G(telomers) increases with temperature up to 250°C[9]. These differences may be brought about by the less stability of acetyl radical than that of isopropyl radical, $(CH_3)_2\dot{C}OH$, as already mentioned[8].

Effects of Initial Pressure of Ethylene.—In order to investigate the effect of the initial pressure of ethylene on the yield of telomers, their G values at room temperature and 75°C are plotted against the initial pressure in Fig. 10. It is evident that the total $G(-C_2H_4)$ increases with increasing pressure up to 4000 at 50 kg./cm². However the G(1 : 1 telomer) has an optimum value and decreases above ca. 30 kg./cm² of the initial pressure. This optimum value seems to shift to the region of lower pressure when the irradiation temperature is 75°C. On the other hand, the G(1 : 2 telomer) increases in proportion to the ethylene pressure, and the G(1 : 3 telomer) to its second power. Such results ought to be expected from the reaction mechanism proposed above.

High Molecular Weight Products. — At the highest pressure, a small amount of white gelled product was obtained. This substance is soluble in carbon tetrachloride, benzene, toluene and hot ethanol, and has a melting point of 65～66°C. The infrared spectrum of this substance is shown in Fig. 11. Strong absorption at 1710 cm^{-1} indicates the presence of carbonyl group. Besides, taking the data of elementary analysis of this substance into account, it is considered to be a mixture of telomers differing in n; e.g.

$$CH_3C(-CH_2CH_2-)_nH$$
$$\quad\quad\quad

Molar fractions of $1:i$ telomer, F_i, are plotted against the ratio of acetaldehyde/ethylene(R) as the abscissa in Fig. 12, making both total dose and dose rate constant. In evaluating R, the absorption coefficient of Ostwald was assumed to be five irrespective of pressures. The lines in the figure indicate the calculated curves from the following equation,

$$F_i = \frac{C_i R}{(C_i R + 1)} \qquad (9)$$

where C_i's, chain transfer constants, are assumed to be 1.0, 1.1 and 4.6, respectively as the most probable values. These numerals resemble to those obtained in the system of acetaldehyde and propylene, but are quite different from those obtained in the system of isopropanol and ethylene (cf. Fig. 13). In the latter system, the change of C_i's against i is small as well as their magnitude. This difference, therefore, is a result to be characterized by the nature of the taxogens.

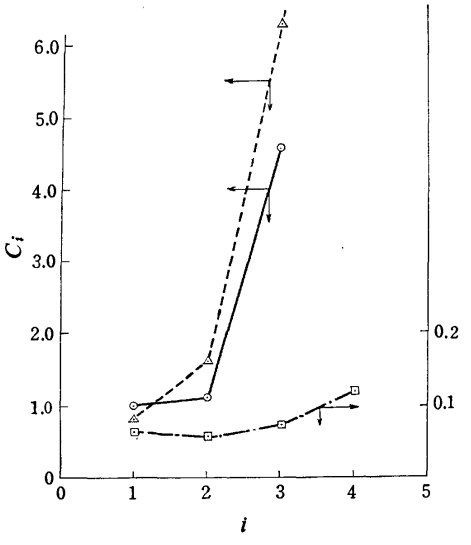

Fig. 13. Chain transfer constant C_i vs. i of the various systems.
⊙ $C_2H_4+CH_3CHO$ △ $C_3H_6+CH_3CHO$
◙ $C_2H_4+(CH_3)_2CHOH$

As mentioned already, the apparent activation energy, 5.0 kcal./mol., obtained between 0 and 40°C seems to correspond approximately to that of the abstraction reaction of hydrogen atom from CHO group of acetaldehyde. However, in the experiment at higher temperature and pressure a smaller temperature dependency or rather independency of temperature was observed on G(telomers). This may probably be ascribed to the increasing occurrence of thermal decomposition of acetyl and/or $CH_3\cdot COCH_2\cdots\cdots\dot{C}H_2$ radicals at higher temperature. Because though telomers of the type as mentioned in Eq. 5 may be produced, the decomposition of acetyl radical, followed by stabilization into CH_4+CO, will contribute to decrease the yield of telomers.

It must be pointed out finally that by the present experiment the acetyl radical seems to be not so unstable as assumed in the photochemical decomposition of acetaldehyde[10]. This conclusion is in agreement with the finding that the activation energy of the decomposition 7 is 9.6 kcal.[11]; i.e., acetyl radical would react with ethylene more easily from the standpoint of the activation energy.

Summary and Conclusions

(1) It has been found that radiation-induced addition of acetaldehyde to ethylene occurs at room temperature with a relatively high $G(-C_2H_4)$, e.g., 4000 at the initial pressure of 50 kg./cm² of ethylene, and that the production of 1:2 telomer is more favorable than that of 1:1 telomer at higher pressure of ethylene. In order to obtain higher G values of 1:1 telomer, it has been shown to be unnecessary to make the initial pressure of ethylene higher than 10 kg./cm², and also to elevate the irradiation temperature much higher than room temperature.

(2) It has been confirmed that a major part of the telomerization proceeds by a chain mechanism, which accompanies a chain-transfer process simultaneously, acetyl radical playing a role of the chain-carrying radical as well as role of initiator. Moreover it has been pointed out that the acetyl radical reacts with ethylene more easily than decomposes, though the decomposition is assumed to occur dominantly in the photochemical and thermal decomposition of acetaldehyde alone[8].

The present research was partly supported by a financial grant from the Ministry of Science and Technology, to which the authors' thanks are due.

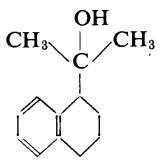
Studies of the Photochemical Reactions. V. The Synthesis of Dimethyldioxanylcarbinol and Dimethyl-α-tetrahydrofurylcarbinol[1]

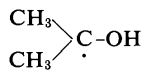
By Kensuke SHIMA and Shigeru TSUTSUMI

(Received September 28, 1962)

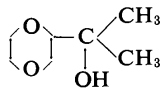
In a previous paper[2], it was reported that dimethyl-α-tetralylcarbinol (I) was easily produced by the reaction of photoactivated acetone in tetralin. In order to use the intermediate radical (II) formed from photoactivated acetone for synthetic purposes, dioxane and tetrahydrofuran were chosen as the hydrogen donor solvents in this experiment. New substances, dimethyldioxanylcarbinol (III) and dimethyl-α-tetrahydrofurylcarbinol (IV), were synthesized in fairly high yields.



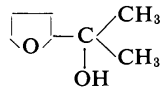
(I)



(II)



(III)

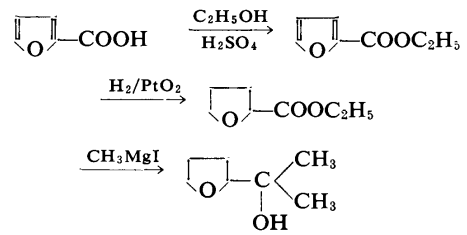


(IV)

A mixture of acetone and dioxane or tetrahydrofuran (mole ratio: 1:4) was irradiated in an atmosphere of nitrogen at room temperature for 10 hr. using a high pressure mercury lamp. The reaction products were then fractionated and analyzed by gas chromatography.

In the photochemical reaction of acetone in dioxane, isopropyl alcohol, dioxanyldioxane and dimethyldioxanylcarbinol (III) were obtained as the reaction products. The new substance, dimethyldioxanylcarbinol (III), which can only with difficulty be prepared by other methods, was easily synthesized.

When acetone was irradiated in tetrahydrofuran, isopropyl alcohol, dimethyl-α-tetrahydrofurylcarbinol (IV) and di-α-tetrahydrofuryl were isolated as the reaction products. The new substance, dimethyl-α-tetrahydrofurylcarbinol (IV), was also easily obtainable by this method. Dimethyl-α-tetrahydrofurylcarbinol was identified by comparison with an authentic sample which had been prepared by the following procedure:



(IV)

The reaction conditions and yields of the products are summarized in Table I.

TABLE I. THE REACTION CONDITIONS AND THE YIELDS OF PRODUCTS

Hydrogen donor solvent	Dioxane	Tetrahydrofuran

Experimental[3]

Materials.—Dioxane was purified by the following method. The mixture of 900 cc. of commercial dioxane, 11.7 cc. of 37% hydrochloric acid, and 90 cc. of water was refluxed for 10 hr. while nitrogen was bubbled. After the mixture had been cooled, solid potassium hydroxide was added and the separated dioxane layer was fractionated over metallic sodium: b. p., 100~101°C, n_D^{20} 1.4222. Tetrahydrofuran was purified by the fractional distillation over sodium: b. p., 66~67°C, n_D^{20} 1.4052. Acetone was purified by the ordinary method[4]: b. p., 56.5~57°C, n_D^{20} 1.3598.

The Photochemical Reaction of Acetone in Dioxane.—The reaction apparatus used was described in the previous paper[2]. A mixture of

acetone (39.1 g., 0.675 mol.) and dioxane (237.2 g., 2.69 mol.) was placed in a 300 cc. reaction vessel and irradiated at 11°C in a nitrogen atmosphere for 10 hr. After the irradiation, the reaction product was fractionally distilled to give the following fractions:

b. p., °C	Weight, g.	n_D^{20}
(1) 56～ 63	5.8	1.3572
(2) 63～ 82	4.7	1.3681
(3) 82～ 95	3.4	1.3807
(4) 95～101	13.2	1.4143
(5) 101～103	195.2	1.4199
Residue	53.0	

The presence of isopropyl alcohol was assumed by gas chromatography. 3, 5-Dinitrobenzoate was synthesized from fraction 3 and was identified as the 3, 5-dinitrobenzoate of isopropyl alcohol by the mixed-melting point test. The amounts of acetone, dioxane and isopropyl alcohol were estimated by gas chromatography: column, D. N. P. 3 m.; carrier gas, H_2, 0.32 kg./cm²; bridge current, 160 m amp.; column temp. 50°C; retention time, acetone: 4 min., isopropyl alcohol: 7 min., dioxane: 9.5 min. After the residue had been cooled, the crystalline substance precipitated was filtered and washed with a small amount of cold methanol to give 4.8 g. of dioxanyldioxane, m. p. 155～155.5°C (recrystallized from methanol) (lit[5]. m. p. 157°C). (Found: C, 55.16; H, 7.95. Calcd. for $C_8H_{14}O_4$: C, 55.16; H, 8.10%.)

The filtrate was distilled under reduced pressure to give the following fractions:

b. p., °C/11 mmHg.	Weight, g.	n_D^{20}
(1) ～ 72	1.3	1.4312
(2) 72～ 81	15.1	1.4445
(3) 81～ 87	4.1	1.4497
(4) 87～100	2.2	1.4521
Residue	22.3	

Fractions 2 and 3 were shown by gas chromatography to consist of almost only one component and were purified by using preparative gas chromatography: column, Si D. C. 550; column temp., 150°C; carrier gas, N_2; gas pressure, 1 kg./cm²; b. p. 86～87°C/11 mmHg, n_D^{20} 1.4533. The Denigés test[6] gave a positive result for this fraction. The infrared spectrum is shown in Fig. 1.

Found: C, 57.34; H, 9.42. Calcd. for $C_7H_{14}O_3$: C, 57.51; H, 9.65%.

3, 5-Dinitrobenzoate was synthesized and recrystallized from ethanol; m. p., 158.5～159.4°C.

Found: C, 49.34; H, 4.67. Calcd. for $C_{14}H_{16}O_8N_2$: C, 49.41; H, 4.74%.

From the above results, this fraction was confirmed to be dimethyldioxanylcarbinol.

The Photochemical Reaction of Acetone in Tetrahydrofuran.—A mixture of acetone (40.8 g.,

5) G. Leuschner and K. Pfordt, *Ann.*, **625**, 30 (1959).

6) G. Denigés, *Compt. rend.*, **126**, 1048, 1277 (1898).

0.705 mol.) and tetrahydrofuran (203.0 g., 2.82 mol.) was irradiated at 10~15°C for 10 hr., and the reaction product was fractionally distilled under atmospheric and reduced pressure to give the following fractions:

	b. p., °C	Weight, g.	n_D^{20}
(1)	58~62	11.0	1.3859
(2)	62~66	34.3	1.3980
(3)	66~75	171.6	1.4051
(4)	~30/15 mmHg	5.1	1.3863
(5)	30~57/15 mmHg	2.1	1.4374
(6)	57~78/15 mmHg	21.6	1.4468
(7)	78~85/15 mmHg	9.0	1.4502
	Residue	12.6	

Fraction 4 was assumed to be isopropyl alcohol, and the amounts of acetone, tetrahydrofuran and isopropyl alcohol were estimated by gas chromatography: column, D. N. P. 3 m.; carrier gas, H_2, 0.5 kg./cm²; bridge current, 160 m amp.; column temp. 46°C; retention time, acetone: 3 min., tetrahydrofuran: 7 min.

It was established that fractions 5, 6 and 7 were mainly composed of two components and were separated by preparative gas chromatography.

(A) B. p. 57~59.5°C/10 mmHg, n_D^{20} 1.4468.

Found: C, 64.64; H, 10.83. Calcd. for $C_7H_{14}O_2$: C, 64.58; H, 10.84%.

The infrared spectrum is shown in Fig. 2. 3, 5-Dinitrobenzoate was synthesized and recrystallized from ethanol (m. p., 81~82°C), and no depression was observed in the mixed-melting point test with an authentic sample.

Found: C, 51.95; H, 5.03. Calcd. for $C_{14}H_{16}O_8N_2$: C, 51.85; H, 4.97%.

From the above results, fraction (A) was identified as dimethyl-α-tetrahydrofurylcarbinol.

(B) B. p. 71°C/10 mmHg, n_D^{20} 1.4594

Fraction B was confirmed to be di-α-tetrahydrofuryl from the infrared spectrum and from the elementary analysis described below. Infrared absorption spectrum data: 1070 cm^{-1} (tetrahydrofuran ring), no hydroxy absorption.

Found: C, 67.33, H, 9.66. Calcd. for $C_8H_{14}O_2$: C, 67.57; H, 9.93%.

Synthesis of Dimethyl-α-tetrahydrofurylcarbinol. —Ethyl furan-2-carboxylate[7] was prepared by the reaction of furan-2-carboxlic acid with ethanol in the presence of concentrated sulfuric acid under reflux conditions. B. p. 193~195°C; m. p., 35~36°C (lit[7]. m. p. 34~35°C). Ethyl tetrahydrofuran-2-carboxylate[8] was prepared by the hydrogenation of ethyl furan-2-carboxylate in the presence of an Adams catalyst[9]; b. p., 76~86°C/10 mmHg, n_D^{20} 1.4484 (lit[8]. 82°C/11 mmHg, n_D^{18} 1.4455). Dimethyl-α-tetrahydrofurylcarbinol was prepared by the reaction of methylmagnesium iodide with ethyl tetrahydrofuran-2-carboxylate; b. p., 66~73°C/15 mmHg, n_D^{22} 1.4455, 3,5-dinitrobenzoate; m. p., 82~83°C (from ethanol).

Summary

The photochemical reaction of acetone in dioxane or tetrahydrofuran has been studied, and two new compounds, dimethyldioxanylcarbinol (III) and dimethyl-α-tetrahydrofurylcarbinol (IV), were easily produced by this photoreaction.

NOTES

2, 2'-Binaphthoxazoline

By Eisuke ISHIDA and Kyoji TÔEI

(Received May 17, 1962)

The reaction between *o*-aminophenol and glyoxal was studied by Bayer[1] and Murase[2]. The condensation product, 2, 2'-bibenzoxazoline, was found to be an organic reagent for various cations and especially selective and specific for calcium. It was used as a metal indicator for calcium in chelatometry[3] and as a colorimetric reagent by extraction[4].

The condensation product of 2-amino-1-naphthol with glyoxal, 2, 2'-binaphthoxazoline, also reacts with calcium to form a deep blue chelate which can be extracted by chloroform;

1) E. Bayer, *Chem. Ber.*, **90**, 2325 (1957).
2) I. Murase, This Bulletin, **32**, 827 (1959); **33**, 59, 607 (1960).
3) D. Goldstein, *Anal. Chim. Acta*, **21**, 339 (1959).
4) K. T. Williams and J. R. Wilson, *Anal. Chem.*, **33**, 244 (1961).

the absorption curve has a maximum at 638 mμ. The chelate is, however, unstable, and the color fades gradually. Therefore, it is usable for the detection but not for the determination of calcium.

Synthesis of 2, 2'-Binaphthoxazoline.—2-Amino-1-naphthol was prepared by the reduction of 2-nitroso-1-naphthol made from α-naphthol. It is very unstable in air, and so its hydrochloride is used for the preparation. Five grams of 2-amino-1-naphthol hydrochloride are dissolved in 1 l. of boiling water containing 10 ml. hydrochloric acid. The solution turns red upon oxidation with air. To reduce the solution, 0.5 g. of tin powder is added and the solution is boiled until it is almost colorless. After cooling quickly, it is filtered. At about 20°C, 3.8 ml. of a 40% glyoxal solution are stirred into it, and then sodium acetate is added until a large volume of a red precipitate is formed (about 20 g. of sodium acetate are needed, and the pH value is 3~4). Three more grams of sodium acetate are added with agitation. The stirring is continued for 1~2 hr. The solution is then allowed to stand for 12 hr., is filtered, and is washed with dilute hydrochloric acid and water. The precipitate is dissolved in 400 ml. of alcohol and decolorized with active carbon. The filtrate is condensed by a rotary evaporator to deposit crystals. They are recrystallized two or three times, affording 100 mg. of pale blue needles which melt at 223°C. The preparation shown above should preferably be done in a dark room, because the compound tends to decompose in daylight.

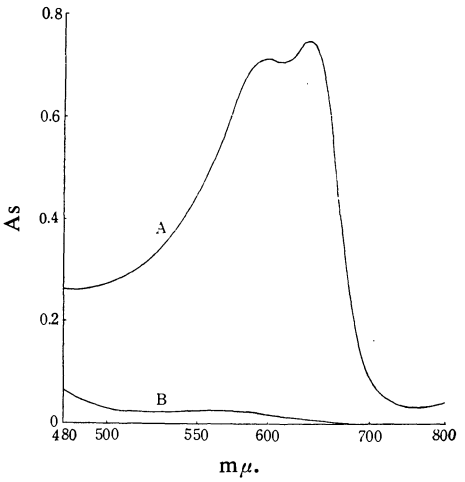

Fig. 1. Absorption curves.
A: 2, 2'-Binaphthoxazoline-Ca complex in chloroform.
B: 2, 2'-Binaphthoxazoline in chloroform (masked a minute amount of Ca in alkaline solution with EDTA).

Found; C, 77.33; H, 4.980; N, 8.280. Calcd. for $C_{22}H_{16}N_2O_2$: C, 77.63; H, 4.74; N, 8.23.

The condensation of 1-amino-2-naphthol with glyoxal was not successful.

Detection of Calcium.—One milliliter of the reagent solution (20 mg. in 100 ml. ethanol), 0.4 ml. of an alkaline solution (10 g. sodium hydroxide and 0.5 g. sodium carbonate in 100 ml. water) and 4 ml. of a calcium solution are mixed together in a 15 ml. stoppered tube and then extracted with 5 ml. of chloroform by vigorous shaking. The absorption curve in chloroform (Fig. 1) has a maximum at 638 mμ. The color change and the extractability are very excellent, and so a micro amount of calcium can be detected. However, the color is not very stable and fades gradually. Therefore, the reproducibility is not so good that the quantitative determination cannot be carried out by this method, though the calibration curve can be roughly drawn.

The authors wish to express their deep gratitude to Dr. Ichiro Murase for his kind suggestion in the course of the preparation of 2, 2'-binaphthoxazoline.

Products of the Radiolysis of Water Containing Benzene and Nitric Acid

By Ken'ichi SUGIMOTO, Wataru ANDO and Shigeru OAE

(Received August 27, 1962)

Radiolysis of water saturated with benzene and containing dissolved air has been studied by many workers[1-6]. Stein and Weiss[1] reported that phenol and hydrogen peroxide are formed until oxygen is depleted, then, the formation of phenol begins to slow down, while diphenyl starts to appear in increasing yield. The effect of pH on the phenol yield

1) G. Stein and J. Weiss, *J. Chem. Soc.*, **1949**, 3245.
2) T. J. Sworski, *J. Chem. Phys.*, **20**, 1817 (1952).
3) T. J. Sworski, *Radiation Research*, **1**, 231 (1954).
4) J. H. Baxendale and D. Smithies, *J. Chem. Soc.*, **1959**, 779.
5) P. V. Phung and M. Burton, *Radiation Research*, **7**, 199 (1957).
6) E. Collinson and A. J. Swallow, *Chem. Revs.*, **56**, 505 (1956).

is only slight, as might be expected if the mechanism were a free radical one[1,4]. On the other hand, the yield of diphenyl is significantly lower at high pH[4], and this result is difficult to understand. All their experiments were carried out either in aqueous sulfuric acid or in phosphoric acid. No specific influence was observed at the same pH with the two different anions in their experiments. Meanwhile, we found in the irradiation of benzene in nitric acid solution that nitrophenol formed and diphenyl did not appear. The present paper provides data on the radiation induced reaction of water containing benzene and nitric acid at various concentrations.

Experimental

Irradiations.—The γ-radiation was provided by either a 1000 or a 3800 curie cobalt-60 source. The rate of energy absorption in solution was determined with the Fricke ferrous sulfate dosimeter taking G as 15.6[7]. All the irradiations were carried out at ambient temperature between 15 to 25°C.

Preparation of Solutions.—Benzene was purified by an ordinary method. Distilled water and reagent grade nitric acid were used. Actually water shaken with benzene at room temperature is found to dissolve 0.022 mol. per liter. Stock solution of irradiated sample was prepared by mixing standard benzene solution and nitric acid solution to the final desired concentration for both benzene and nitric acid. Solutions used for irradiation were made containing dissolved air.

Determination of *p*-Nitrophenol.—The determination of *p*-nitrophenol was carried out by colorimetry. After adjusting the pH of the irradiation solution, which, if necessary, was filtered off, the absorbance of *p*-nitrophenolate ion was measured spectrophotometrically at 400 mμ, and also determined by pentacyanoammineferroate.

Determination of *o*-Nitrophenol.—The formation of cobalt-chelate compound was used to the determination of *o*-nitrophenol. The *o*-nitrophenol was nitrosated by reduction with calcium chloride and zinc powder and the isolated nitroso compound was treated with a cobalt salt in an acetate buffer solution.

Results and Discussion

Nitric acid solutions of benzene were irradiated with Co-60 gamma rays by a varying dose rate from 2.9×10^3 to 5.6×10^4 r/hr. The yield of *p*-nitrophenol produced is shown in Table I. As is shown in Table I, the yield of *p*-nitrophenol decreases with increasing dose rate. The observed decrease of yield with dose rate may be ascribed to the increased probability of the recombination between generated radicals at the higher dose rate, although its exact nature is not yet clear.

Table I. The yield of *p*-nitrophenol from the irradiated solutions

Dose rate r/hr. $\times10^{-3}$	G-Value
56	0.47
28.2	0.57
16.4	0.71
11.5	0.79
8.1	0.84
5.9	0.86
5.2	0.85
3.8	0.92
2.9	0.96

0.8N HNO_3 saturated benzene solution, 0.022 mol./l. Irradiation time, 18 hr.

Nitric acid concentration dependence for the yield of *p*-nitrophenol at the fixed dose of 3×10^6 r is shown in Table II. The yield of *p*-nitrophenol decreases with increasing nitric acid concentration.

The quantitative results indicate the preferential formation of *p*-nitrophenol to that of *o*-nitrophenol. The formation of *p*-nitrophenol is proportional to the energy absorbed, and the yield depends on dose rate and nitric acid concentration.

Table II. Dependence of nitric acid concentration

Nitric acid concentration	Formation of *p*-nitrophenol	
N	mol./l. $\times10^4$	G-Value
1.7	7.95	0.28
0.86	10.7	0.37
0.43	15.9	0.55
0.23	18.2	0.63

Irradiation time, 6 hr. Dose rate, 5×10^5 r/hr. Benzene concentration, 0.016 mol./l.

The action of ionizing radiations on dilute aqueous solutions results in formation of free radicals according to

$$H_2O \rightsquigarrow H+OH \qquad (1)$$

On the other hand, the gamma radiolysis of nitric acid solutions indicates that nitric acid is decomposed by radical mechanism as given by the following equation[8].

$$HNO_3 \rightsquigarrow HNO^*_3 \rightarrow OH+NO_2 \qquad (2)$$

The radical process is, as direct action effects are generally considered to be, directly proportional to the concentration. The qualitative results are best explained by assuming that the primary reaction 1 and reaction 2, resulting in the formation of hydroxyl radical, which attacks on a benzene molecule.

7) C. J. Hochanadel and J. A. Ghormley, *J. Chem. Phys.*, 21, 880 (1953).

8) H. A. Mahlman, *J. Chem. Phys.*, 35, 936 (1961).

$$C_6H_6+OH\rightarrow C_6H_5+H_2O \quad (3)$$

The phenyl radical formed can reacts with hydroxyl radical, yielding phenol

$$C_6H_5+OH\rightarrow C_6H_5OH \quad (4)$$

or with NO_2 radical, giving nitrobenzene.

$$C_6H_5+NO_2\rightarrow C_6H_5NO_2 \quad (5)$$

In fact, it was found by gas chromatography that the ether extraction from the irradiated solutions contained nitrobenzene. But no phenol was observed in the irradiated solutions. Consequently, the phenol furthermore reacts with hydroxyl radical to forms phenol radical,

$$C_6H_5OH+OH\rightarrow C_6H_4OH+H_2O \quad (6)$$

which is readily scavenged by NO_2 radical.

$$C_6H_4OH+NO_2\rightarrow C_6H_4(OH)NO_2 \quad (7)$$

The phenol is effectively converted to *p*-nitrophenol. While, irradiation of nitrobenzene in nitric acid solution did not give *p*-nitrophenol.

The decrease of *G*-value at higher acid concentration is probably due to the formation of nitrobenzene, which is increases with increasing NO_2 radicals from nitric acid irradiation. This becomes important at higher concentration of nitric acid, and leads to the formation of *p*-nitrophenol in a lower yield.

A Handy Method of Determining Relative Amounts of DL-*Threonine and* DL-*Allothreonine with the Aid of Infrared Absorption Spectroscopy*

By Toshiyuki FURUYAMA and Saburo SENOH

(Received October 2, 1962)

In the preparation of threonine, mixtures of the diastereoisomers, DL-threonine (I) and DL-allothreonine (II), are produced and the selective preparation of one isomer is considered to be difficult. Thus, it is very important to be able to determine the relative amounts of I and II by a simple method.

The authors have found a simplified method to determine the relative amounts of I and II with the aid of infrared absorption spectra in the potassium bromide region. Many quantitative analytical methods for I and II have previously been reported, e. g., paper chromatography[1], ion exchage resin chromatography[2], 2, 4-dinitrophenyl derivative chromatography[3], and microbial assay[4]. Of these, the last one is probably the most reliable[5], but the procedure is still limited in scope.

Concerning the infrared absorption spectra of threonine, there have been some communications[6-8], but they show only the rock salt region.

In the present communication, the infrared absorption spectra of the potassium bromide region are dealt with; also, a simplified calculation method with absorption spectra at 702 cm^{-1} and 619 cm^{-1} by the potassium bromide tablet method is described[9]. The method was found experimentally and was not so much affected by the sizes of the sample granules[10]. Measurements were carried out as usual for qualitative analysis as absorptions appeared in the range between 20 and 80 per cent in transmission[11]. The calculation was

8) K. Kodera, the 7th Infrared and Raman Spectra Conference, Osaka (1960), p. 173; T. Yamazaki and T. Takenishi, ibid. (1960), p. 176. In the above communications, quantitative analytical methods of allo/threo are given with absorption spectra at 14.26μ and 14.83μ, and at 870 cm^{-1} and 835 cm^{-1} respectively. However, the calculation is rather complicated.
9) A double-beam Hitachi infrared spectrophotometer Type EPI-2 was used.
10) S. Tanaka and M. Ogawa, *Japan Analyst*, **6**, 285 (1957). In this paper, Tanaka and Ogawa reported that the size of the sample granules had an effect on the optical density.
11) D. Z. Robinson, *Anal. Chem.*, **23**, 273 (1951).

as follows: In Fig. 1, the base line AB is drawn, and then CD lines are drawn vertically to the zero line at 702 cm^{-1} and 619 cm^{-1}. The CD lines at 702 cm^{-1} and at 619 cm^{-1} are measured with a rule ($\overline{CD}$(702 cm^{-1}) and $\overline{CD}$ (619 cm^{-1}) respectively) and the ratio is calculated.

Thus, the percentages of threonine and allothreonine are obtained:

$$\text{Percentage of threonine} = \frac{\overline{CD}(702\ cm^{-1})}{\overline{CD}(702\ cm^{-1}) + \overline{CD}(619\ cm^{-1})}$$

$$\text{Percentage of allothreonine} = \frac{\overline{CD}(619\ cm^{-1})}{\overline{CD}(702\ cm^{-1}) + \overline{CD}(619\ cm^{-1})}$$

The results obtained for authetic mixtures are presented in Table I. Authentic mixtures of threonine and allothreonine were prepared, using pure DL-threonine and DL-allothreonine. The purity of each substance was examined with infrared absorption spectra in the rock salt region[6], elementary analysis[12], paper chromatography[1] and melting point. From Table I, more favorable results were obtained when the content of DL-allothreonine in relation to DL-threonine was smaller. This method was applied to the synthesized sample. The synthesis was carried out according to the procedure reported by Sato et al.[13] The molar percentages of the threonine and allothreonine synthesized[14] were determined by this method; values of 77.6% of threo and of 22.4% of allo were obtained. The microbial assay method gave values of 78.9% of threo and of 21.1% of allo[15].

TABLE I. RESULTS OBTAINED FOR AUTHENTIC MIXTURES

NO.	A		B	
	threo-	allo-	threo-	allo-
1	95.0	5.0	95.2	4.8
2	93.7	6.3	93.8	6.2
3	84.3	15.7	84.7	15.3

9	11.5	88.5	12.3	87.7

A: Percentages of DL-threonine and DL-allothreonine in authentic mixtures.
B: Percentages determined by infrared absorption spectroscopy.

The bands which appear at 702 cm^{-1} and 619 cm^{-1} also abide by Beer's law in authentic mixtures, so the present authors are also investigating quantitative analysis on the basis of this fact. Details will be presented hereafter.

The authors wish to express their appreciation to Mr. Hideaki Kai for his measurements of infrared spectra.

SHORT COMMUNICATION

*Synthesis of o-Phosphonobenzeneazochromotropic Acid as a New Reagent and its Thorium Complex**

By Haruo MIYATA

(Received November 15, 1962)

The present paper describes the preparation of *o*-phosphonobenzeneazochromotropic acid, and the spectrochemical properties of the reagent and its thorium complex.

Synthesis of the Reagent.—*o*-Bromobenzenephosphonic acid**,[1] was prepared by the reaction of *o*-bromobenzenediazonium fluoborate with phosphorus trichloride in ethyl acetate, m. p. 198°C.

* Presented in part at the Symposium of the Analytical Chemistry, Tokushima, October, 1962.

** Identification of these samples were made by Doak.

1) G. O. Doak and L. D. Freedman, *J. Am. Chem. Soc.*, **73**, 5658 (1951); **74**, 754 (1952); **75**, 685 (1953).

o-Aminobenzenephosphonic acid** was prepared by the amination of *o*-bromobenzenephosphonic acid with ammonia by the procedure described by Doak and Freedman[2] and by Doak[3] who presented subsequently the following modified methods: Twelve grams of *o*-bromobenzenephosphonic acid, 9 g. of freshly prepared cuprous oxide and 200 ml. of ammonium hydroxide were heated for 18 hr. Nitrogen gas was then passed through the solution in order to remove free ammonia. It is not possible to remove all of the ammonia at this stage. Hydrogen sulfide was then passed into the solution. The precipitated copper sulfide was removed and the pH value of the filtrate was adjusted to 2.1 with concentrated hydrochloric acid. Pure *o*-aminobenzenephosphonic acid (1.1 g.), m.. 185~189°C, precipitated in a crystalline form, free from chloride ion. The mother liquors were evaporated to about 100 ml. and a second crop of 2.8 g. was obtained. This contained a trace of chloride ion.

o - Phsophonobenzeneazochromotropic acid was obtained from the corresponding diazonium salt by coupling with chromotropic acid. *o*-Phosphonobenzeneazochromotropic acid thus obtained was recrystallized from concentrated hydrochloric acid to give reddish brown needles. The reagent being very hygroscopic, it was stored in a phosphrus pentoxide desiccator.

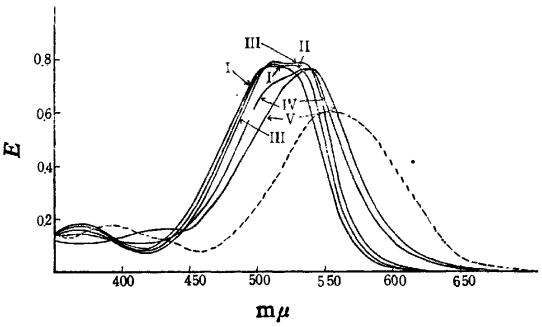

Fig. 1. Absorption curves of *o*-phosphonobenzeneazochromotropic acid (I—V) and its thorium complex (broken line pH 3.3).
I 2.8×10^{-5} mol./l., pH 1.1
II pH 6.3
III pH 8.0
IV pH 6.5
V pH 11.2

Spectrochemical Properties of the Reagent and its Thorium Complex.—Absorption spectra of the reagent solution (2.8×10^{-5} mol./l.) as well as its thorium complex (concentration of the reagent : thorium = 1 : 2) are shown in Fig. 1 over various pH values.

On addition of thorium to the reagent solution, the absorption maxima shifted towards the longer wavelengths. The curve shows an absorption maximum at 555mμ.

Mole ratio of thorium to the reagent was confirmed by the mole ratio method (Fig. 2) and the result obtained indicates the formation of a 1 : 1 complex.

The Chromatographic Separation of Polyoxyethylene Nonylphenyl Ether

By Takashi ISHIWATA, Masuzo NAGAYAMA and Hiroshi ISA*

(Received February 8, 1962)

Studies of the properties of polyoxyethylene derivatives, prepared by the addition of ethylene oxide to molecules already containing active hydrogen, have long been confused by the fact that such preparations have always resulted in mixtures. Mayhew and Hyatt[1] obtained a narrow range of molecular species by distillation in a centrifugal molecular distillation still. Several other workers[2] have studied fractionation by means of molecular distillation. Also, chromatographic separation has been applied by Kelly[3].

In these studies, it has been found that the distribution of molecular weight was close to the theoretical distribution curve proposed by Flory[4]. He assumed that all steps in the reaction of the ethylene oxide sequence are kinetically identical, and his results showed a Poisson's distribution. On the other hand, the products of relatively low molecular weight polyoxyethylene derivatives have been shown by means of vacuum fractional distillation not to agree with Flory's distribution[5].

Regarding the assumption of the kinetic identity of all steps as an oversimplification, Weibull and Nycander[6] have suggested a compromissed treatment for the reaction of an alcohol with ethylene oxide. They have proposed that all hydroxyl groups bound to an oxyethyl group have an equal ability to add ethylene oxide, this ability differing, however, from that of the parent alcohol. This has led to the following equations:

$$v = c \ln\frac{n_{00}}{n_0} - (c-1)\left(1-\frac{n_0}{n_{00}}\right) \qquad (1)$$

$$\frac{n_i}{n_{00}} = \frac{c^{i-1}}{(c-1)^i}\left\{\frac{n_0}{n_{00}} - \left(\frac{n_0}{n_{00}}\right)^c \times \sum_{j=0}^{i-1}\frac{1}{j!}\left[(c-1)\ln\frac{n_{00}}{n_0}\right]^j\right\} \qquad (2)$$

where

N_i=molecule with i added ethylene oxide molecules

m=number of moles of ethylene oxide consumed

n_{00}=number of moles of the starting material

n_0=number of moles of the surviving starting material

n_i=number of moles of N_i in reaction product

k_i=rate constant for the reaction of N_i with ethylene oxide

k_0=rate constant for the reaction of the starting material with ethylene oxide

$c=k_i/k_0$=distribution constant

$v=m/n_{00}$=average number of moles of ethylene oxide per mole of the starting material.

Since the polyoxyethylene derivatives are not thermostable, fractional distillation is not suitable for separation of the products; also, complete separation by distillation is not possible in the presence of many components.

For fractionation of this type, there are several attractive features of column chromatography. This method was used in the present preparation of polyoxyethylene nonylphenyl ether in order to provide data on the distribution of products for comparison with the theoretical equations mentioned above.

Experimental

Materials.—The nonylphenol (produced by the General Aniline and Film Co., Ltd.) was purified by distilling it with a Widmer column at 138~139°C/2.5 mmHg (hydroxyl value 249.8).

Ethylene oxide with a quoted minium purity of 99% was used.

The polyoxyethylene derivatives of nonylphenol were prepared by blowing ethylene oxide gas into nonylphenol in presence of metallic sodium as a catalyst; the amount of sodium was 0.1% by weight of the nonylphenol.

The reaction temperatures of 190, 140 and 100°C (±2°C), were selected. The products were neutralized with sulfuric acid, freed of water under vacuum, and then filtered through filter paper.

The properties of the polymers obtained by the reaction are shown in Table I.

TABLE I. PROPERTIES OF THE POLYOXYETHYLENE DERIVATIVES OF NONYLPHENOL

Reaction temp., °C	Hydroxyl value	Refractive index n_D^{25}
100	182.5	1.5057
140	179.9	1.5050
190	177.8	1.5050

Apparatus.—The diameter and the length of the column were 3.5 and 75 cm. respectively. The column was packed with silicic acid up to a height of 50 cm. Silicic acid (Mallinckrodt A. R., 100 mesh powder, suitable for chromatographic analysis) was used as supplied. A spectrophotometer (Hitachi Model EPU-2) was used for the spectrophotometric measurements.

Procedure. — The gel ratio was 160 : 1. The development was carried out by applying the mixture of chloroform and acetone (95 : 5, 85 : 15 volume ratio). A solvent system of benzene and methanol was examined for this purpose, but the results were not satisfactory. In each case, 1.000 g. of the sample was used. The flow rate was adjusted to 20 cc. per 13 min., and portions were collected with a volumetric fraction collector. An aliquot of 3 cc. was taken from every 20 cc. fraction, and the solvent was evaporated in a vacuum desiccator. The absorbance of the chloroform solution was measured at the wavelength of 277 mμ by a spectrophotometer.

Results and Discussion

A typical elution curve is plotted in Fig. 1. The figure shows that the chromatographic separation of polyoxyethylene nonylphenyl ether was satisfactory. A very small peak was observed in the fraction, at 26~32 of Fig. 1; this seems to come from a trace of impurity. This will be evident from the following tests.

a) The OCH_2CH_2OH group was not detected.

Following the procedure indicated by Feigl[7], the sample was treated with periodic acid, but no aldehyde was detected.

b) No phenolic OH was detected.

No coloration was observed when a diazonium sulfanilic acid solution was sprayed on filter paper spotted with the samples. The evidence described above suggests that the trace of impurity was not nonylphenol derivatives, but no further investigation was made. The amount of the impurity was at any rate, less than 1%.

The materials eluted from each peak were collected and weighed by microbalance. The molar absorptivities of each peak were calculated from the absorbance of the 0.01% chloroform solution at 277 mμ and were assumed the molecular weight.

If this assumption is right, each molar absorptivity should agree well with that of nonylphenol, because the absorption at 277 mμ originates from the phenyl radical. The numbers of the polymerized oxyethylene radicals for each peak were thereby determined. These results showed no nonylphenol survived in the reaction.

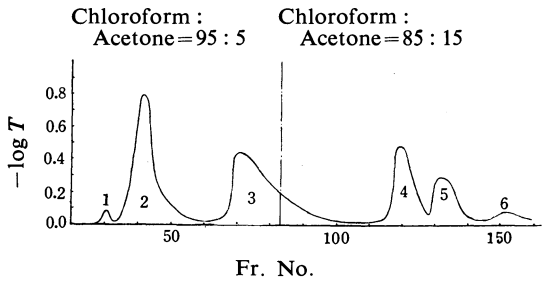

Fig. 1. Chromatogram (reaction temp. 190°C).

This fact shows that the ethylene oxide addition of nonylphenol was selective and that ethylene oxide reacted with nonylphenol completely in the first step.

The weights of all the peaks are shown in Table II. These results show that a high rate

of recovery should be obtained by adding the fraction eluted with acetone to the separate sample.

The weight percentages of all the peaks are shown in Table III. In this Table, C was calculated by applying Weibull's equation (1). "The number of the starting material" was calculated on the basis of nonylphenyloxyethanol.

TABLE III. DISTRIBUTIONS OF THE WEIGHT PERCENTAGE

Reaction temp.		190°C	140°C	100°C
Oxyethylene, $\bar{P}$		2.04	2.00	1.85
Peak No.	No. of oxyethylene			
2	1	25.5	25.6	32.1
3	2	39.5	43.0	45.8
4	3	20.5	20.1	15.4
5	4	7.1	6.7	4.2
6	5	3.1	1.7	0.9
Acetone elute		3.4	2.3	1.0
Peak No. 1		0.9	0.6	0.6
C		0.66	0.61	0.58

The results of these experiments may be compared with Poisson's and Weibull's distributions.

Poisson's distribution as proposed by Flory[4] (weight):

$$W_x = \frac{M_x}{M+44v} e^{-v} \frac{v^i}{i!} \qquad (3)$$

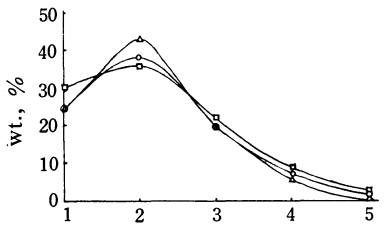

Fig. 2. Weight distribution (reaction temp. 190°C).
-○- Experimental
-△- Weibull's distribution
-□- Poisson's distribution

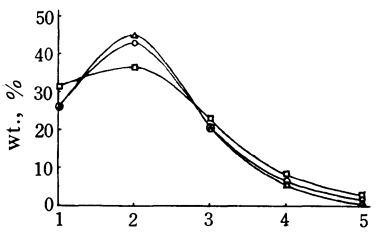

Fig. 3. Weight distribution (reaction temp. 140°C).

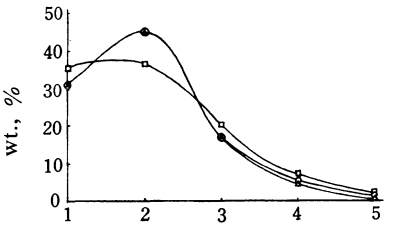

Fig. 4. Weight distribution (reaction temp. 100°C).

Distribution (weight) based on Weibull's formula.

$$W_x = \frac{M_x}{M+44v} \cdot \frac{c^{i-1}}{(c-1)^i} \left\{ \frac{n_0}{n_{00}} - \left(\frac{n_0}{n_{00}}\right)^c \times \sum_{j=0}^{i-1} \frac{1}{j!} \left[(c-1) \ln \frac{n_{00}}{n_0} \right]^j \right\} \qquad (4)$$

where

M=molecular weight of the starting material

M_x=molecular weight of the product of chain length x units.

W_x=weight fraction of the product of chain length x units

The results indicated in Figs. 2, 3 and 4 show that distribution in these cases agreed better with Weibull's distribution than with Poisson's.

With the increase of the reaction temperature, however, a considerable difference was observed.

Also, these figures show that the lower the reaction temperature, the narrower the distribution of molecular weights.

Summary

Polyoxethylene nonylphenyl ether can be separated with respect to the unit of the oxyethylene radical by applying the chromatographic method, using silicic acid as the adsorbent and a chloroform-acetone mixture as the eluent. Nonylphenol was allowed to react with ethylene oxide in the mole ratio of 1:2 in the presence of metallic sodium as a catalyst at the three different temperatures of 190, 140 and 100°C.

The chromatographic method was applied to the reaction products, and it was shown that the distribution became somewhat narrower at the lower reaction temperature.

A comparison of these results with the theoretical distributions proposed by Flory and by Weibull indicated significant agreement with the latter but a discrepancy with the former. However, when the temperature was rather high, the agreement with the Weibull formula was not good.

Similarly, polyoxyethylene nonylphenyl ether having more than two oxyethylene units could be separated by this method. When $\bar{P}=10.3$, 14 peaks was obtained from a chromatogram.

The separation and recovery by this method were considerably better than the distillation method, and a better understanding of the distribution of molecular weights was obtained.

Determination of Sodium, Arsenic, Antimony and Copper in Carbon by Neutron-Activation Analysis

By Yuichiro KAMEMOTO and Shigeru YAMAGISHI

(Received July 17, 1962)

The neutron activation analysis of graphite with or without the chemical separation of impurities after irradiation has been reported by several workers[1-3]. In general, the method with such chemical separation has been more satisfactory than that without in terms of sensitivity and precision of analysis. However, the method involving the chemical processing of the irradiated sample has some problems in the process of the leaching-out of impurities from the irradiated graphite. They are: (1) The burning method for the destruction of graphite has the possibility of the evaporation of a portion of the impurities. (2) The leaching method with concentrated nitric acid has the possibility of the incomplete leaching-out of the impurities from graphite. (3) The destruction of graphite with a nitric acid-perchloric acid mixture is difficult.

The purpose of this investigation was to decide the most desirable method for the separation of impurities from the irradiated graphite. On the basis of the results, the burning method, combined with the treatment of a burning boat (quartz) with a hydrofluoric acid-nitric acid mixture, was found to be the most desirable. This method was applied to the determination of sodium, arsenic, antimony and copper in carbon. The analytical values obtained were compared with those obtained by the non-destructive method.

Experimental

Sample.—About 1 g. of the amorphous carbon prepared by the Nihon Carbon Co., Ltd., was weighed into a polyethylene pouch.

Standards.—One-tenth of a milliliter of each standard solution, prepared as follows, was infiltrated into a filter paper 2 cm. in diameter and sealed in a polyethylene pouch.

Sodium.—The reagent-grade sodium carbonate was dissolved in water and diluted to 270 μg. of sodium per ml. of solution.

Arsenic.—The reagent-grade arsenious acid was dissolved in hydrochloric acid and diluted to 499.7 μg. of arsenic per ml. of solution.

Antimony.—The 99.998% antimony metal was dissolved in aqua regia and diluted to 210.6 μg. of antimony per ml. of solution.

Copper.—The 99.99% copper metal was dissolved in dilute nitric acid and diluted to 266 μg. of copper per ml. of solution.

Irradiation Conditions.—For the irradiation, the sample and standards were placed side by side in a polyethylene capsule. All irradiations were made in the No. 16 Hole (pneumatic tube) of the JRR-1 reactor. The neutron flux was approximately 10^{11} n/cm^2/sec. Each irradiation was continued for 2 hr.

Radiochemical Separation.—The irradiated sample was placed in a quartz boat and burned for 30 min. at 700°C in an oxygen atmosphere. The apparatus used is outlined in Fig. 1. The sample was completely burned. The boat was then treated twice with a hydrofluoric acid-nitric acid (1 : 1) mixture solution on a hot plate, and the apparatus used was washed with hot nitric acid. The resulting solutions were added to the catching solution. After the addition of 1 ml. each of carrier solutions for sodium, arsenic, antimony and copper (sodium 27.0 mg.; the other cation, 10 mg.), the whole solution was evaporated repeatedly with hydrochloric acid and adjusted to agree with the dilute hydrochloric acid solution.

From this solution, each element mentioned above was isolated as follows. (The flow system of the separation is shown in Fig. 2.)

Arsenic, antimony and copper were precipitated as sulfides with hydrogen sulfide and then separated from the sodium. The filtrate was concentrated to about 3 ml. and then poured into a polyethylene tube, which was mounted on a 3×3 inches sodium iodide scintillator. The sodium content was determined by γ-ray spectrometry.

The precipitate of sulfide was treated with an ammonium polysulfide solution, arsenic and antimony being dissolved in this solution and separated from the copper precipitate. This residual precipitate was then dissolved in aqua regia and reprecipitated as thiocyanate from the dilute sulfuric acid solution. The cuprous thiocyanate was filtered off, washed, dried and weighed to determine the chemical yield, and it was then put in a polyethylene tube; the copper content was determined by γ-ray spectrometry.

The ammonium polysulfide solution of the precipitate sulfide was evaporated with nitric acid and adjusted to agree with the concentrated hydrochloric acid solution. Arsenic was precipitated as sulfide with hydrogen sulfide from the concentrated hydrochloric acid solution and separated from antimony. The precipitate was digested with aqua regia. After the addition of an antimony solution to this solution as the hold-back carrier, the arsenic was reprecipitated as sulfide. The precipitate was filtered off, washed, dried and weighed to determine the chemical yield, and it was then put in a polyethylene tube. The arsenic content was determined by γ-ray spectrometry.

The concentrated hydrochloric acid solution, from which arsenic had been separated, was adjusted to agree with an about 2 N hydrochloric acid solution. Antimony was precipitated as sulfide from this solution. The precipitate was digested with aqua regia. After the addition of an arsenic-carrier solution to this solution, the separation of antimony from arsenic was repeated. The antimony sulfide formed was filtered off, washed, dried and weighed to determine the chemical yield, and it was then put in a polyethylene tube. The antimony content was determined by γ-ray spectrometry.

Counting.—Each isolated element was mounted on 3×3 inch sodium iodide scintillator attached to an RCL-256 channel pulse-height analyzer, and the γ-ray spectrum was measured. The content of each element was determined by comparing the peak height of the photopeak (i. e., at 1.37 MeV. for sodium-24, at 0.56 MeV. for arsenic-76, at 0.57 MeV. for antimony-122, and at 0.51 MeV. for copper-64) with that for the respective standard.

Results

Radiochemical Purity.—From the results of the γ-ray spectra and the decay curves of the photopeaks, it was found that the arsenic, antimony and copper isolated by this method were radiochemically pure.

Although two photopeaks, at 0.82 MeV. and 0.56 MeV., appeared in the γ-ray spectrum of the sodium fraction, the interference of these activities could be disregarded in the determination of sodium by analyzing the decay curve of the sodium-24 photopeak at 1.37 MeV.

Results.—The results obtained are given in Table I.

TABLE I. RESULTS

Element	Content, p. p. m.	Standard deviation
Sodium	170	±11
Copper	35	± 1.3
Arsenic	0.2	± 0.01
Antimony	0.30	± 0.018

Discussion

Leaching-out Methods of Impurities from Irradiated Carbon.—*The Burning Method.*—Irradiated carbon was burned in an oxygen atmosphere at 700°C in the apparatus shown in Fig. 1. After this burning, much activity was found on the quartz-burning boat. This activity could not be completely leached out from the boat by treating it four times with hot aqua regia. It was found, however, that complete leaching is possible when the boat is treated twice with a hydrofluoric acid-nitric acid (1 : 1) mixture solution. The results are shown in Fig. 3.

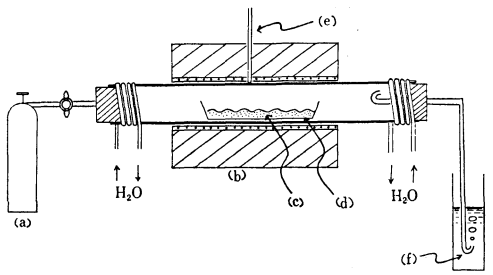

Fig. 1. Apparatus.
(a) O_2 bomb
(b) Heater
(c) Carbon sample
(d) Burning boat
(e) Thermocouple
(f) Catching solution, dil. HNO_3

This solution obtained from the leaching of the quartz boat and from the nitric-acid washing of the apparatus, and the catching solution, together, contained 98~100% of the impurities in carbon.

When a porcelain boat was used, however, the adherring activity could not be leached out from the boat.

The Leaching Method with Concentrated Nitric Acid.—The leaching-out method of impurities from carbon with concentrated nitric acid has

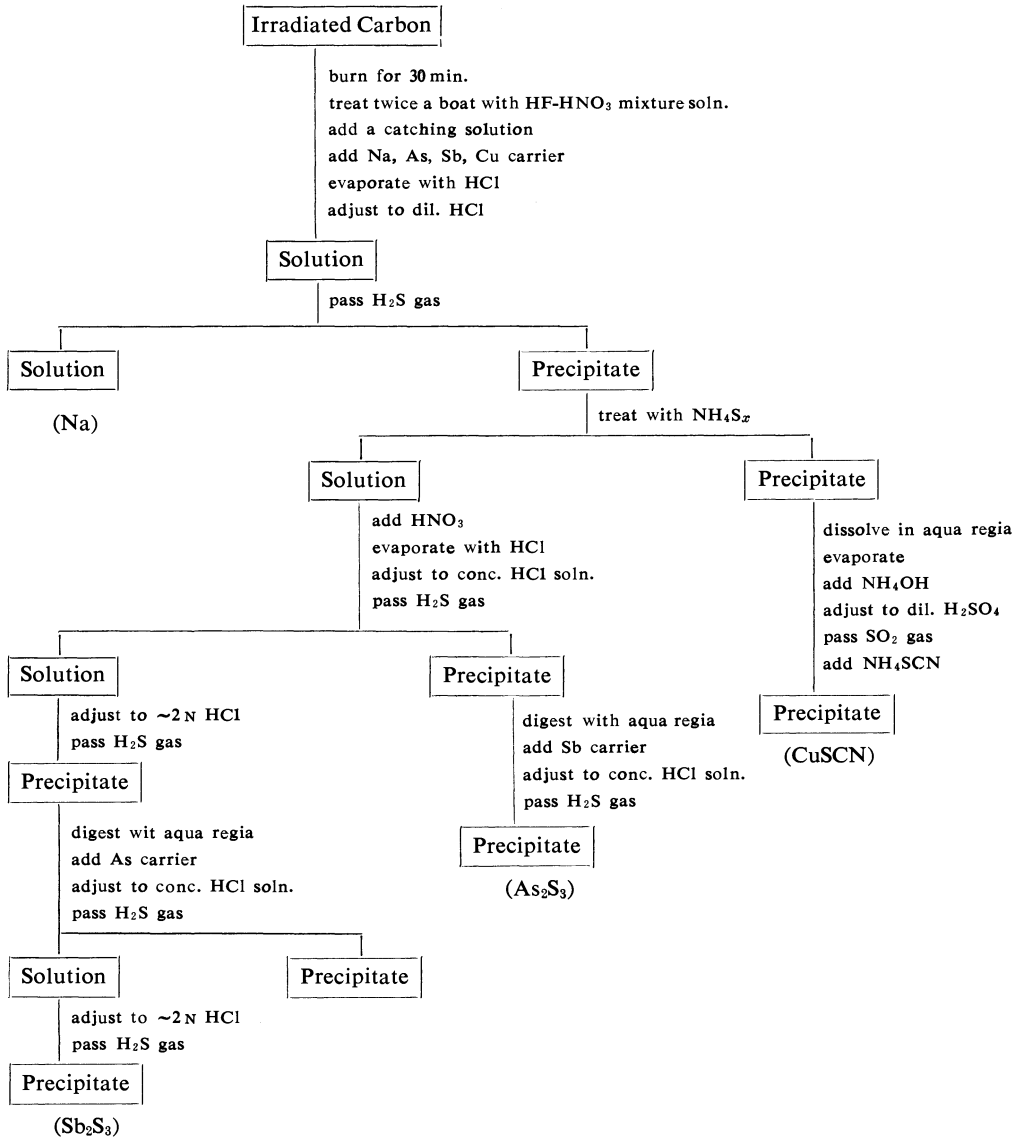

Fig. 2. Flow system of separation.

been reported by several workers[4,5]. However, as it was doubtful that they can be leached out completely by this method, an experiment was made.

About 1 g. of irradiated carbon was treated in a beaker on a hot plate with about 50 ml. of concentrated nitric acid, adding a small volume of nitric acid at some intervals. The γ-ray spectrum of the carbon treated was measured after having been heated for some hours; the results are shown in Fig. 4. The leaching-out of impurities by this method was not complete, however, even when the sample was heated for 7.5 hr. with concentrated nitric acid.

The Carbon-Destruction Method with a Nitric Acid-Perchloric Acid (1:1) Mixture Solution.— The destruction method using a mineral acid-oxidizing agent mixture solution has been reported by some workers[6]; however, the destruction of carbon by this method was not complete. Fifty milliliters of a nitric acid-perchloric acid (1 : 1) mixture solution was added to about 1 g. of the irradiated carbon; the resultant solution was heated on a hot

plate for some hours, with a small volume of the same mixture solution being added at some intervals. The γ-ray spectrum of the treated carbon was measured and is shown in Fig. 5. It may be seen from Fig. 5 that some portion of the impurities remained in the carbon even when it had been treated for 5 hr., so this method is not desirable.

TABLE II. COMPARISON OF THE RESULTS OF THE DESTRUCTIVE AND NON-DESTRUCTIVE METHODS

Element	Destructive method		Non-destructive method	
	Content p. p. m.	Standard deviation	Content p. p. m.	Standard deviation
Sodium	170	±11	230, 220, 180	—
Copper	35	± 1.3	46, 47	—
Arsenic	0.20	± 0.01	2, 3	—
Antimony	0.30	± 0.018	0.4	—
Manganese	—	—	2.2	—

The Sodium Hydroxide-Fusion Method.— About 0.5 g. of irradiated carbon was added to about 3 g. of sodium hydroxide in a nickel crucible. After they had been fused for one or two hours, the melt was leached with water and dilute hydrochloric acid and the carbon which remained undissolved was filtered off.

The activity of the residual carbon was measured with a γ-ray scintillator. The results obtained, which are shown in Fig. 6, indicate that the fusing method did not provide a complete leaching-out of impurities from carbon, even when the fusing lasted for two hours.

Consequently, it was found that the burning method is most satisfactory.

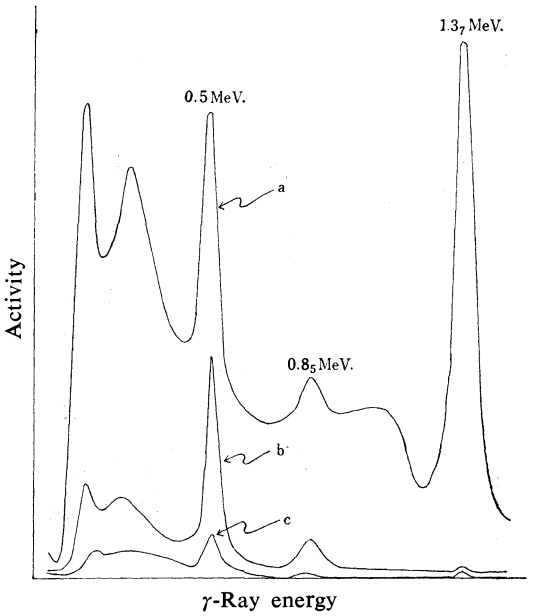

Fig. 6. γ-Ray spectra of carbon after fusing for some hours with NaOH.
(a) Non-treatment
(b) Fusing for 1 hr.
(c) Fusing for 2 hr.

Comparison of the Proposed Method with the Non-destructive One.—Table II compares the results of the destructive and non-destructive methods, which have previously been reported on[7,8].

Not much difference was observed between the results of the two methods, except in the case of arsenic; however, the analytical value of each element in the former was smaller than in the latter. This might be due to the fact that some photopeaks were apparently higher in the latter case, affected by the other peaks near them; this was pointed out in our previous report[9], "Determination of Chlorine and Manganese in Bismuth Metal by Neutron Activation."

The difference between the analytical values of arsenic in the two methods was too large to explain by the effect just mentioned. This large difference may be due to the fact that, in the non-destructive method, the analysis of the decay curve of the photopeak at about 0.5 MeV. into the decay curves of copper-64 (half life: 12.8 hr.), arsenic-76 (half life; 26.8 hr.), and antimony-122 (half life: 2.8 days) was not correct.

The identification of the decay curve for arsenic was difficult in the non-destructive method because its activity was much lower than those of copper and antimony.

The authors wish to thank Dr. Toshio Nakai for the advice he has given during this investigation.

The Spectrophotometric Determination of Vanadium(IV) with Xylenol Orange

By Makoto Otomo

(Received August 22, 1962)

Xylenol orange, in a slightly acidic medium, reacts with vanadyl ion to ~~give a~~ reddish violet complex, and it has widely been used as a metal indicator for vanadium in EDTA titration. Recently this laboratory needed a sensitive method for determining trace amounts of vanadium in uranium compounds. This paper describes the results of a spectrophotometric study of the vanadium-xylenol orange complex and of the application of this reagent to the determination of trace amounts of vanadium. The composition of the colored complex and methods for the elimination of some interfering substances are also discussed.

Experimental

Apparatus.—All absorbance measurements were made with a Hitachi Model EPU-2A spectrophotometer, using 1-cm. cells.

Reagents.—*Vanadyl Chloride Stock Solution.*—Pure vanadium pentoxide was treated with concentrated hydrochloric acid and redistilled ethyl alcohol[2]. The solution was standardized against a standard EDTA solution, using EBT as an indicator[3].

Xylenol Orange Solution.—The same as that used in a previous work[1].

Procedure.—Transfer a sample aliquot, containing 10 to 40 μg. of vanadium, to a 25 ml. Erlenmeyer flask. Add 1 ml. of 5% ascorbic acid and 2 ml. of a xylenol orange solution. Adjust the pH value to 2.8±0.1 with an acetate buffer solution. Mix, and heat the solution on a boiling water bath for 2 to 3 min. Cool the solution, transfer it to a 25 ml. volumetric flask, and dilute it to the mark with small amounts of distilled water. Measure the absorbance of the solution at 562 mμ vs. a reagent blank.

Results and Discussion

Absorption Spectra.—The spectra of xylenol orange and its vanadium(IV) complex are shown in Fig. 1. The maximum absorption of the complex is found at 562 mμ.

Effect of the pH Value. — Figure 2 shows that the optimum pH value range for the color formation of the vanadium-xylenol orange complex is 2.8±0.1.

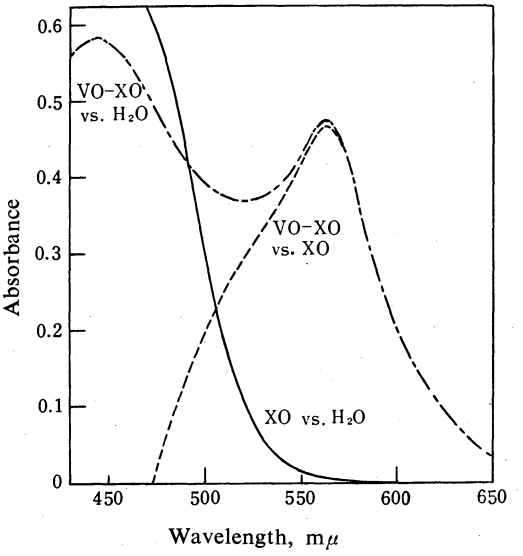

Fig. 1. Absorption spectra of xylenol orange and its vanadium complex.
V: 2×10^{-5} M XO: 9×10^{-5} M

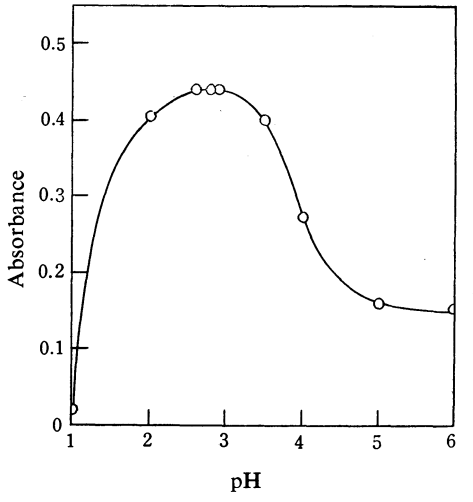

Fig. 2. Effect of pH on color development.
V: 24 μg.

Effect of the Addition of Xylenol Orange.—As is shown in Fig. 3, the absorbance gradually

3) K. Ueno, "KiretoTekitei (Chelatometric Titration)" (In Japanese), Nankodo, Tokyo (1960), p. 323.

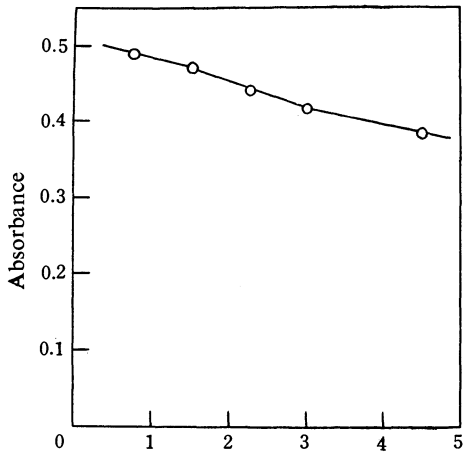

Fig. 3. Effect of addition of xylenol orange.
V: 24 μg.

decreases with the presence of increasing amounts of xylenol orange. However, the use of 1.5ml. of a 1×10^{-3} M xylenol orange solution is recommended for further experiments.

Effect of the Amount of Ascorbic Acid. — Ascorbic acid was used to prevent oxidation of the vanadyl ions to a vanadic state. It is suitable to add 0.2 to 1.5 ml. of a 5% ascorbic acid solution for less than 50 μg. of vanadium.

Effect of the Time of Standing.—Figure 4 shows the curves for the heated and the unheated solutions of the vanadium-xylenol orange complex. Curve I indicates that, for the unheated solution, it requires about 2 hr. for the complete color developement. However, the color formation is greatly accerelated by heating a mixture of vanadium and a xylenol orange solution on a boiling water bath for only 2 to 3 min. The color produced is stable for at least 24 hr.

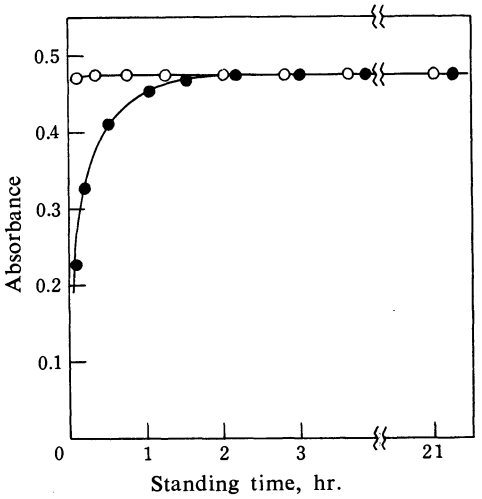

Fig. 4. Effect of time of standing.
V : 24 μg.
-●- : Unheated solution (I)
-○- : Solution heated on a water-bath (II)

Calibration Curve.—A linear concentration-absorbance relationship is obtained in the range between 10 to 40 μg. of vanadium (curve I in Fig. 5). The molar extinction coefficient of the vanadium xylenol orange complex is found to be 24000 at 562 mμ.

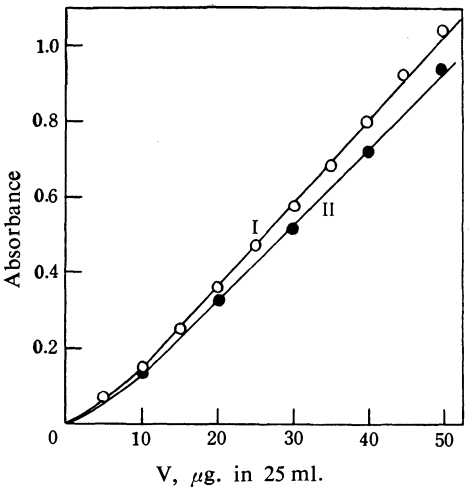

Fig. 5. Calibration curve.
I: In the absence of fluoride
II: In the presence of 50 μmol. of fluoride

Effect of Anions.—No interference is caused by chloride, nitrate, sulfate, thiosulfate, phosphate or tartrate under the conditions studied. As might be expected, such anion as oxalate, citrate, NTA (nitrilotriacetate) and EDTA (ethylenediaminetetraacetate), especially the last two, inhibit the color for mation of the vanadium-xylenol orange complex. A large amount of fluoride also decreases the absorbance moderately. If 1 ml. of a 0.4% fluoride solution is used for masking some interfering cations, the same amount of fluoride must be added in preparing the calibration curve (curve II in Fig. 5).

Effect of Cations.—The effect of foreign elements was studied by preparing solutions containing 0.5 μmol. of vanadium and the same amount of various cations. The results of these tests are presented in Table I. The cations, aluminum(III), bismuth(III), chromium-(III), tin(II), thorium(IV), titanium(IV), yttrium(III) and zirconium(IV), form a colored complexes with xylenol orange to give a positive error in the determination of vanadium. Some of these cations, however, can be completely or partially masked by adding 1 ml. of a 0.4% fluoride solution (Table II). Interference from

bismuth can also be eliminated by adding thiosulfate. Interference from tin(II) can be avoided by oxidizing it to a stannic state and by adding fluoride before treatment by the recommended procedure*.

Complex Formation.—The mole ratio and the formation constant of the vanadium-xylenol orange complex was determined spectrophotometrically by the same method as that previously reported for the rare earth complex of xylenol orange[1] (Figs. 6 and 7). It is evident that vanadium(IV), like cerium(III) and other rare earths, forms a 1:1 complex with xylenol orange. The formation constant for the

* As the tin(IV)-fluoride complex is very stable, it is not reduced by zinc or aluminum[4].

4) K. Sone and M. Tanaka "Teisei Bunsekikagaku" Transttd., Charlot, "L'Analyse Qualitative et lesRéaction en Solution" (In Japanese), Kyoritsu Shuppan, Tokyo (1958), p. 333.

complex at a pH value of 2.9 was calculated, from the curves shown in Fig. 7, as 2.8×10^6. It is expected that this dye will find many applications where a highly sensitive reaction for vanadium is desired.

Summary

The reddish-violet complex of vanadium with xylenol orange has been studied spectrophotometrically, and the conditions for using xylenol orange as a reagent for the determination of trace amounts of vanadium have been established. The complex shows a maximum absorption at 562 mμ, and the molar extinction coefficient of the complex is found to be 24000. It is a 1 : 1 complex and has a formation constant of 2.8×10^6 under the conditions studied. Such anions as oxalate, citrate and EDTA inhibit the color formation of the complex. Some of the interfering cations can, however, be completely or partially masked by adding a fluoride solution.

The author wishes to express his deep thanks to Professor Kôichi Tonosaki for his kind guidance and encouragement throughout this work. Thanks are also due to Mr. Tomizô Yamada for his help in the optical measurements.

The Spectrophotometric Determination of Uranium with Xylenol Orange[1]

By Makoto Otomo

(Received August 27, 1962)

The uranyl ion forms a weak, red chelate with xylenol orange in a slightly acid solution buffered with sodium acetate and acetic acid. The uranium(IV) ion, however, reacts sensitively with this reagent to form a stable, intensely reddish-violet complex, while uranium(VI) is reduced to uranium(IV) by ascorbic acid in an acetate buffer solution in the presence of xylenol orange.

Budĕšínský[2] has recently proposed a method for determining uranium with xylenol orange, using uranium(IV) sulfate as a starting material. He has also indicated that the optimum pH value range for color development is 1.2 to 1.6 and that a complex of 1 to 1 is formed between xylenol orange and uranium.

The present results, however, differ appreciably from those reported by Budĕšínský; the complex has its maximum absorption at 568 mμ, the maximum absorption develops over the pH value range 3.5 to 3.7, and the results of the mole ratio method and the continuous variation method show a complex consisting of two molecules of xylenol orange to one uranium(IV) ion.

1) Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

2) B. Budĕšínský, *Collection Czechoslov. Chem. Commun.*, **27**, 226 (1962).

3) K. Ueno, "Kireto Tekitei (Chelatometric Titration)" (In Japanese), Nankodo, Tokyo (1960), p. 320.

Experimental

Reagents.—An approximate 10^{-4} M uranyl nitrate solution was prepared by the dilution of a 10^{-2} M uranyl nitrate solution previously standardized against EDTA by using xylenol orange as an indicator[3].

A pH value 3.6 buffer solution was prepared in the usual manner with sodium acetate and acetic acid.

All the other reagents and apparatus used were the same as those reported previously[4].

Procedure.—Into a 25 ml. Erlenmeyer flask an aliquot of the solution containing up to 120 μg. of uranium was pipetted, after which 10 ml. of the acetate buffer solution and 1 ml. of 5% ascorbic acid were added. The volume was made to about 20 ml. with distilled water, and the flask was covered with a watch-glass. After being boiled gently for about 20 min., the solution was cooled with water to room temperature and transferred to a 25 ml. volumetric flask, and the volume was made up to the mark with distilled water. Within the following 30 min., the absorbance of the solution was then measured at 568 mμ, with reference to a blank solution.

Results and Discussion

Absorption Spectra.—The absorption spectra of xylenol orange and its uranium(IV) chelate are presented in Fig. 1. Inspection of the

4) M. Otomo, This Bulletin, **36**, 137 (1963).

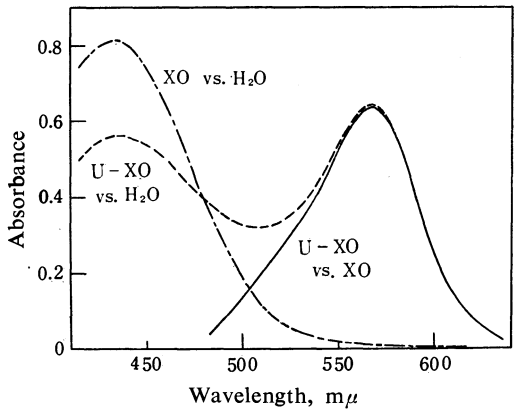

Fig. 1. Absorption spectra of xylenol orange and its uranium complex.
U: 71 μg. XO: 6×10^{-5} M

curves shows that the maximum absorption of red uranium-xylenol orange chelate lies at 568 mμ, at which point the reagent does not absorb appreciably. The spectrum is very similar to that shown by thorium-xylenol orange chelate[5]. The maximum color development was observed over the pH value range from 3.5 to 3.7, the values of which are considerably higher than those reported by Budĕšínský.

Effect of Heating Time.—As in the case of the complexometric titration of uranium with EDTA[3], the chelating reaction of xylenol orange with uranium is made to take place only by boiling a uranium(VI) solution in the presence of ascorbic acid and xylenol orange. The maximum absorbance is attained after about 20 minutes' boiling (Fig. 2). About 1 ml. of 5% ascorbic acid is a sufficient amount to reduce the uranyl ions quantitatively.

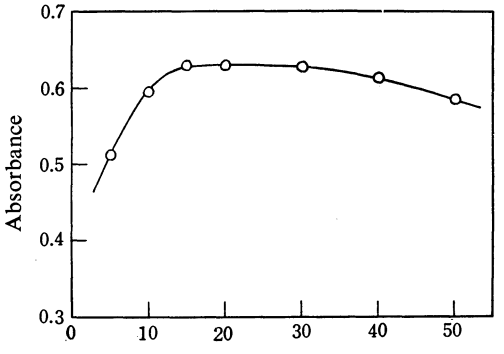

Fig. 2. Effect of heating time.
U: 71 μg. XO: 6×10^{-5} M

5) M. Otomo, unpublished. (Presented at the Tōhoku Branch Meeting of the Chemical Society of Japan, Yonezawa, October, 1961.)

Effect of Excess Reagent.—For 20 to 100 μg. of uranium, 1 to 1.5 ml. of a 1×10^{-3} M xylenol orange solution is required. Much as in the previous cases of the color development of xylenol orange complexes of zirconium[6] and iron[7], large amounts of xylenol orange tend to decrease the absorbance.

Stability of Color. — Figure 3 shows the stability of the color produced with uranium and xylenol orange. The absorbance began to be recorded as soon as the solution was transferred to the volumetric flask. The intensity of the color decreases slowly with time. However, during the first 10 to 30 min. the absorbance remains practically constant.

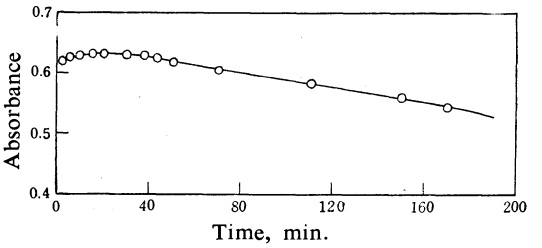

Fig. 3. Stability of color.
U: 71 μg. XO: 6×10^{-5} M

Beer's Law. — Beer's law is obeyed in the range from 20 to 100 μg. (0.8 to 4 p. p. m.) of uranium at 568 mμ. Under the conditions of the spectrophotometric determination, the molar extinction coefficient was found to be 51000.

Effect of Anions. — Chloride, nitrate, sulfate and borate do not interfere. Large amounts of phosphate, fluoride, tartrate and citrate reduce the absorbance considerably. Oxalate, NTA and EDTA interfere with the color reaction because they form more stable complexes with uranium than xylenol orange does.

Effect of Cations.—Of the 26 cations tested, aluminum(III), bismuth(III), chromium(III), copper(II), iron(III), palladium(II), thorium(IV), titanium(IV), vanadium(IV) and zirconium(IV) interfere with the uranium determination. Among the above cations, copper, iron and palladium give large negative errors.

Complex Formation.—Xylenol orange forms 1 to 1 complexes with some bi-, ter- and quadri-valent metals, including zinc(II)[8], iron(III)[7], bismuth(III)[9], rare earths[10], vanadium(IV)[4] and zirconium(IV)[6]. Budĕšínský reported that uranium(IV) and thorium(IV) also form 1 to 1 complexes with this reagent in a slightly acid medium.

10) K. Tonosaki and M. Otomo, ibid., 35, 1683 (1962).

In this work, the mole ratio of xylenol orange and uranium was studied by the continuous variation method and by the mole ratio method. As is shown in Figs. 4 and 5, both methods indicate clearly that, as with thorium[5], a complex of 1 to 2 between uranium and this reagent is formed under the conditions so far studied.

II: $[U]+[XO]=3\times10^{-5}$ M

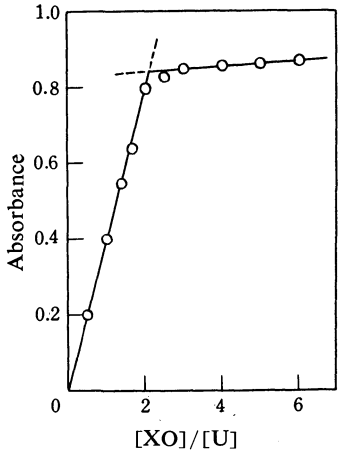

Fig. 5. Mole ratio method.
[U]: 8×10^{-6} M

In the course of spectrophotometric studies of the metal complexes of xylenol orange, it was recently found that such cations as gallium(III)[11], thallium(III)[11] and also iron(III)[12] form 1 to 2 complexes with xylenol orange in a slightly acid or a neutral medium, while they give 1 to 1 complexes in a more acid solution. This is an interesting fact; details of the results will be shown eleswhere. In addition, Leonard and West[13] have suggested that a 1 to 2 complex can be formed between thorium(IV) and alizarin complexan, since thorium adopts an eight co-ordinate configuration. Being capable of adopting a configuration similar to that of thorium, uranium(IV) seems to be considered to form a 1 to 2 complex with alizarin complexan and also with xylenol orange. It seems, therefore, that some differences between the results shown by Budensinsky and those obtained here may be attributed to the differences in the experimental conditions used.

The formation constant, K, was then calculated from the curves shown in Fig. 4, on the basis of the following relationships[14]:

$$K=C(1-\alpha)/(\alpha C)(2\alpha C)^2 \quad (1)$$

$$\alpha=(E_m-E_s)/E_m \quad (2)$$

where C is the total concentration of the complex in moles per liter, assuming no dissociation, α is the degree of dissociation, E_m (PR or PR') is the maximum absorbance obtained from the horizontal portion of the curves, and E_s(PQ or PQ') is the absorbance at the stoichiometric molar ratio of xylenol orange to uranium in the complex. This ratio was found to be 2.9×10^{11}.

Summary

A new spectrophotometric method for determining trace amounts of uranium has been developed. This method is based on the coloration of xylenol orange with uranium(IV) formed by the reduction of uranium(VI) in the presence of ascorbic acid. The effects of the pH value, reagent and boiling time have been thoroughly investigated, and experimental conditions which make possible the determination of 20 to 100 μg. of uranium have been devised. The mole ratio of the complex between uranium and this reagent has also been discussed.

The author gratefully acknowledges the kind guidance and encouragement given him by Professor Kôichi Tonosaki. He thanks also Dr. Shôzô Shibata of the Nagoya Industrial Research Institute for his interest.

Synthesis of Cyclic Peptide. I.[1] *Preparation of Cyclo-di-β-alanyl from 1,4-Cyclohexanedione*

By Hiroshi WATANABE, Shigeru KUWATA and Sugao KOYAMA*

(Received August 2, 1962)

Since the discovery of such naturally occurring cyclic polypeptides as gramicidines and tyrocidine having strong biological activities, synthetic methods of cyclic polypeptides have been studied. A method used for this purpose is that of cyclizing the corresponding linear peptide in dilute conditions. By this method some of the cyclic peptides having several amino acid residues were prepared successfully, though in some peptides, e.g. tri-α-peptide, cyclization was found difficult.

An alternative method to approach these peptides may be the expansion of a compound already having a cyclic structure. It is well known that cyclic ketone oxime rearranges to lactam by the Beckmann reaction in a good yield. Applying this principle to cyclic diketone compound, Tokura et al.[2] rearranged cyclododecane-1,6-dione dioxime with sulfur trioxide in liquid sulfur dioxide and obtained 1,7-diaza-6,12-dioxocyclododecane. In the same way, from 1,4-cyclohexanedione dioxime, a cyclic dipeptide of β-alanine should be produced. By heating di-*p*-tosylate of 1,4-cyclohexanedione dioxime and hydrolyzing the product, Knunyants and Fabrichnyi[3] obtained β-alanine, succinic acid and ethylenediamine. This result suggests the production of cyclo-di-β-alanyl as well as ethylenesuccinamide as the rearrangement products, and in fact Hall[4] has isolated the former from the rearrangement mixture. On the other hand, Mamlock[5] tried the same reaction using 1,4-cyclohexanedionedioxime monohydrochloride and polyphosphoric acid, but he only isolated 2-chloro-*p*-phenylenediamine as reaction product. Recently, Rothe[6] reported that 1,4-cyclohexanedione dioxime, treated with 8% oleum in a Beckmann rearrangement, gives only cyclo-di-β-alanyl, instead of the mixture of two cyclic amides.

We intended to re-examine these reactions in order to establish a route to obtain cyclo-di-β-alanyl. In the first place, a direct rearrangement was studied. According to Mamlock, 1,4-cyclohexanedione dioxime was treated with polyphosphoric acid at about 120°C for a short time, though the starting material was dioxime itself in order to avoid the complexity caused by chloride ion. The hydrolyzate of the reaction product was studied by paper-chromatography, but the spot corresponding to β-alanine or ethylenediamine could not be found, though the presence of a spot of lower R_f-value was recognized, which was proved to be due to *p*-phenylenediamine by paperchromatography. When such an acid as perchloric acid, sulfuric acid or trifluoroacetic acid, was used under similar conditions (50~100°C), similar results were also obtained. Treatment of the dioxime with polyphosphoric acid in the cold resulted in the mere recovery of the starting material.

Then the indirect method according to Knunyants and Fabrichnyi was examined secondly. Di-*p*-tosylate of the dioxime was heated in methanol at 100°C for 90 min. in an autoclave. In the hydrolyzate of reaction product, the presence of β-alanine and ethylenediamine was confirmed by paperchromatography, as they had observed, though no crystals corresponding to cyclo-di-β-alanyl were isolated after treatment of the syrup with Amberlite IRA-400 and CG-120.

Another reaction which will give the same results with the Beckmann rearrangement is the Schmidt reaction, as has been suggested by Rothe[7]. The latter will be more useful for our purpose, because milder conditions can be chosen. Thus, dry hydrogen chloride was passed into chloroform solution of 1,4-cyclohexanedione and hydrazoic acid at 0~5°C for about 2 hr. From the reaction mixture after removal of hydrogen chloride, a viscous syrup was obtained, containing many fine crystals, from which fine hexagonal plates or granules were isolated, which, after recrystallization

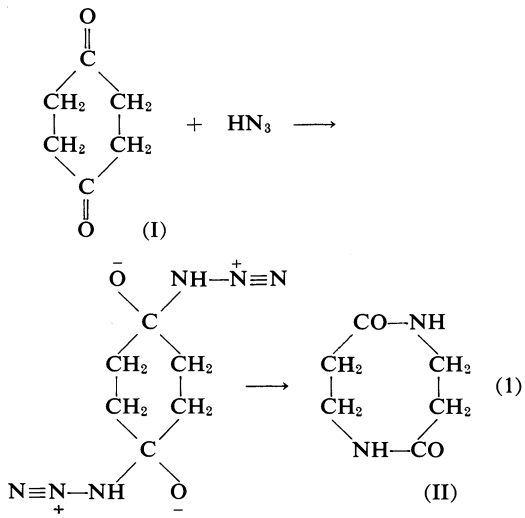
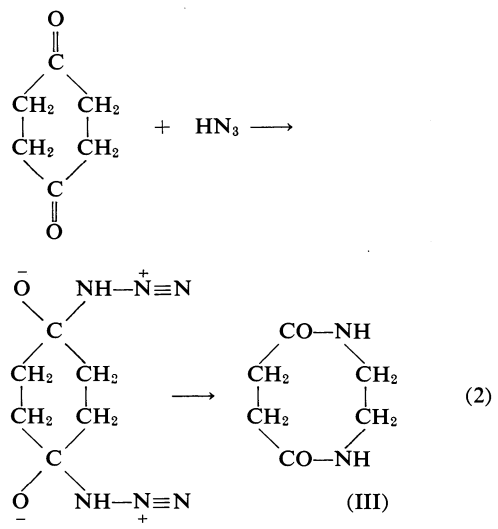
from ethanol, showed m. p. of 295~300°C. The elementary analyses and the molecular weight of this substance showed agreement with theoretical values for cyclo-di-β-alanyl. In Fig. 1 its infrared spectrum is shown. It was also confirmed that the paper-chromatogram of the hydrolyzate of this compound shows only one spot, which coincides completely with that of β-alanine itself. From these evidences, it is clear that the compound obtained here is the expected cyclo-di-β-alanyl, formed by the scheme:



But, the paper-chromatogram of the hydrolyzate of the crude syrupy reaction product shows in addition a different spot which was proved to be due to ethylenediamine, from that of the expected β-alanine. This shows that the reaction by the scheme 2 also occurs simultaneously, though the intermediate cyclic product III could not be isolated.



Experimental

Diethyl Succinate (IV).—Succinic acid was esterified with ethanol and sulfuric acid: b. p. 84~85°C/6 mmHg; b. p. 210~214°C.

Diethyl Succinosuccinate (V).—According to the method of Upenski[8], IV was condensed to V by sodium sand: m. p. 126~128°C (lit.[8] 126~127°C).

1, 4-Cyclohexanedione (I).—V was converted to I by the method of Vincent et al.[9]: b. p. 130~131°C/20 mmHg (lit.[9] b. p. 132°C/20 mmHg).

1, 4-Cyclohexanedione Dioxime (VI).—This was derived from I by usual method: m. p. 190~192°C (lit.[10] 192°C).

Attempted Beckmann Rearrangement of VI with Trifluoroacetic Acid.—A mixture of dioxime VI (1 g.) and trifluoroacetic acid (3 g.) was heated in a boiling water-bath for 30 min. After the reaction product was concentrated to dryness, the residue was boiled with 6 N hydrochloric acid for 8 hr. and paper-chromatogrammed. (Method: circular paper-chromatography; developer: *n*-BuOH: AcOH: H_2O=5 : 1 : 4; coloring agent: ninhydrin). Several spots were obtained but no one corresponding to β-alanine could be found. In this chromatogram, a spot having R_f value of ca. 0.29 was identified as that of *p*-phenylenediamine by comparison, after isolation, with an authentic specimen

The same reaction was tried by using polyphosphoric acid, perchloric acid or sulfuric acid, with similar results.

Indirect Beckmann Rearrangement Using Di-*p*-tosylate of VI as an Intermediate.—Dioxime VI in pyridine was added to *p*-tosylchloride in pyridine at −8°C and the mixture was allowed to stand at 0°C overnight[3]. The di-*p*-tosylate was obtained as precipitate by diluting the solution with water. A solution of ditosylate in methanol was heated in an autoclave at 100°C for 90 min. After removal of the solvent, the residue was dissolved in water and passed through Amberlite IRA-400 and CG-120. Viscous syrup was obtained by concentrating the eluate. Crystallization from ethanol did not succeed. From the paper-chromatogram of the hydrolyzate of this syrup, spots corresponding to β-alanine and ethylenediamine were confirmed by the comparison with authentic specimens.

Schmidt Reaction of I.—To a chloroform solution of I (2 g.) and hydrazoic acid (0.6 N chloroform solution, 60 ml.), dry hydrogen chloride was bubbled at 0~5°C for about 2 hr., when a syrupy material containg fine needles was formed. After removal of chloroform, the residual syrup was dissolved in water and treated with silver acetate to remove chloride ion and then hydrogen sulfide to remove excess silver ion. Resulting aqueous solution was concentrated to dryness in vacuo. Syrupy material containing fine crystals was obtained. Paper-chromatogram of the hydrolyzate of this syrup showed the presence of spots corresponding to β-alanine and ethylenediamine. The

Infrared Absorption Spectrum. — The spectrum was recorded with a Perkin-Elmer Infracord, model 137. Phase: KBr disk. The result was shown in Fig. 1.

Summary

1) By the direct Beckmann rearrangement of 1,4-cyclohexanedione dioxime by polyphosphoric acid, trifluoroacetic acid, perchloric acid or sulfuric acid at about 100°C, no expected cyclo-di-β-alanyl but *p*-phenylenediamine was obtained.

2) By indirect Beckmann rearrangement using di-*p*-tosylate of 1,4-cyclohexanedione dioxime as an intermediate, the rearrangement occurs certainly though the isolation of the cyclic dipeptide was not successful.

3) By the Schmidt reaction of 1,4-cyclohexanedione, the expected rearrangement proceeded smoothly and from the reaction products cyclo-di-β-alanyl was easily isolated.

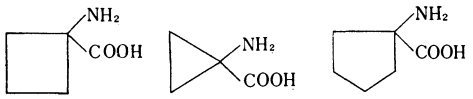
Synthesis of 1-Aminocyclobutanecarboxylic Acid

By Rokuro SUDO and Shigehiro ICHIHARA

(Received September 25, 1962)

Some alicyclic amino acids have been known as physiologically interesting compounds. 1-Aminocyclopropanecarboxylic acid (II) was prepared by Ingold and his coworkers[1] and



I II III

was recently isolated by Burroughs[2] from apple cider and perry pear juices, and 1-aminocyclopentanecarboxylic acid (III) was reported to show anticancerous action[3,4].

The authors wish to report the synthesis of an additional alicyclic amino acid, 1-aminocyclobutanecarboxylic acid (I) by two methods, the first of which involves reaction of methyl 1-bromocyclobutanecarboxylate (IV) with ammonia and the second involves hydrolysis of 5-cyclobutane-spiro-hydantoin (IX).

The first attempted method did not afford I, but an isomeric unsaturated amino acid, which was produced by a rupture of the cyclobutane-ring. Although IV[5] was easily converted by ammonium hydroxide into 1-bromocyclobutanecarboxamide (V), amination of V by using potassium phthalimide or hexamethylenetetramine was unsuccessful. When V was heated with aqueous ammonia in a sealed tube, a substance of m. p. 163~164°C was obtained and its analytical values corresponded to the molecular formula of $C_5H_{11}ON_2Br$ (VI). Hydrolysis of VI with a solution of barium hydroxide gave a very hygroscopic amino acid (VII). This amino acid was characterized by conversion into its benzoyl derivative VIII

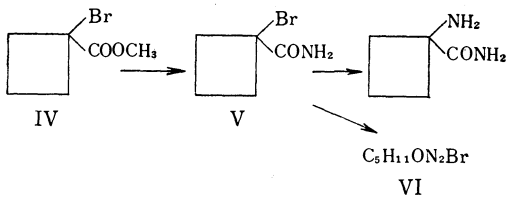
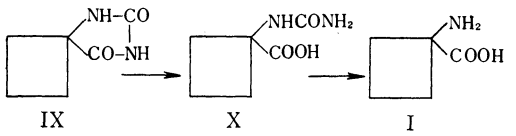
4) T. A. Connors and W. C. J. Ross, *J. Chem. Soc.*, **1960**, 2119.
5) A. Campbell and H. N. Rydon, ibid., **1953**, 3002.



which had the same molecular formula as that of benzoyl derivative of I, but absorbed bromine, indicating the presence of a double-bond.

In the second procedure, partial hydrolysis of 5-cyclobutane-spiro-hydantoin (IX), which was prepared by the method of Ingold[1] et al., afforded 1-uramidocyclobutanecarboxylic acid (X). IX or X was heated with a solution of



barium hydroxide for 24 hr., affording an amino acid, whose paperchromatograph showed a spot of R_f value 0.5 in *n*-butanol/acetic acid/water; (4 : 1 : 1). This amino acid was confirmed to be 1-aminocyclobutanecarboxylic acid (I) by elementary analysis and conversion into its benzoyl derivative (XII), which saturated against bromine.

Although the structure of VII was thought to be γ-amino-α-methylcrotonic acid from chemical behavior and infrared spectrum of its benzoyl derivative, it could not be confirmed. In addition, paperchromatograph of VII showed a spot of R_f value 0.50 as main-product, whose benzoyl derivative was isolated and some other two spots of R_f value, 0.30 and 0.10 in *n*-butanol/acetic acid/water; (4 : 1 : 1), (Fig. 1). They also seemed to be produced by a rupture of the cyclobutane-ring, but were not isolated.

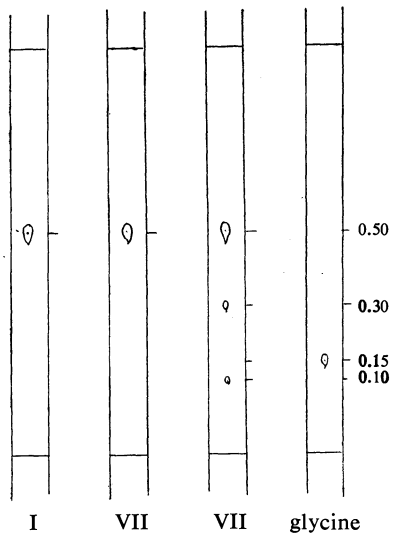


Fig. 1

Experimental

Methyl 1-Bromocyclobutanecarboxylate (IV).—The procedure of Campbell and Rydon[5] was used. Twenty two grams of cyclobutanecarboxylic acid was heated under reflux at 100°C for 1 hr. with 29 g. of thionyl chloride. Red phosphorus (0.25 g.) and 40 g. of bromine were added and heating was continued at 110~120°C for further 3 hr. The reaction mixture was poured into 30 cc. of absolute methanol, and then diluted with water and extracted with ether. After removal of ether, the distillation of the residue gave 30 g. of oil, b. p. 70~75°C/23 mmHg, in a 70% yield.

Found: C, 37.33; H, 4.87; Br, 42.04. Calcd. for $C_6H_9O_2Br$: C, 37.33; H, 4.67; Br, 41.40%.

1-Bromocyclobutanecarboxamide (V).—Twenty six grams of IV was added to 100 cc. of concentrated aqueous ammonia and was continued, stirring for 2 hr. The precipitate was collected and recrystallized from ethanol affording 20 g. of needles, melted at 153~154°C.

Found: C, 33.85; H, 4.64; N, 7.81. Calcd. for C_5H_8ONBr: C, 33.72; H, 4.49; N, 7.87%.

Ammonolysis of V.—Three grams of V was suspended in 30 cc. of concentrated aqueous ammonia and was heated for 6 hr. in a sealed tube. Removal of the solvent from the reaction mixture gave a syrupy residue. When the residue was allowed to stand in an ice bath, a precipitate was formed. After recrystallization from ethanol, 1.5 g. of colorless prisms, m. p. 163~164°C (VI), were obtained.

Found: C, 30.92; H, 5.49; N, 14.11. Calcd. for $C_5H_{11}ON_2Br$: C, 30.77; H, 5.64: N, 14.36%.

Hydrolysis of VI with Barium Hydroxide Solution.—Two grams of VI and 5 g. of barium hydroxide were added to 50 cc. of water and refluxed for 2 hr. The reaction mixture was filtered and to the filtrate was added carbon dioxide gas. After removal of barium carbonate, the solution was concentrated in vacuo resulting a syrupy residue. This syrup was solidified by addition of 30 cc. of absolute ethanol affording a crystalline substance, which was so hygroscopic that its melting point was not determined. The syrup was positive in the ninhydrin-test and its paperchromatograph showed 3 spots of R_f values 0.50, 0.30 and 0.10 in *n*-butanol/acetic acid/water; (4 : 1 : 1). (Fig. 1). The syrup, however, was characterized by conversion into its benzoyl derivative VIII, which melted at 183~185°C and absorbed bromine.

Found: C, 65.19; H, 5.77; N, 6.30. Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; N, 6.39%.

The infrared spectrum showed strong bands at 3400, 1615, 1545 (-NH-CO-), 1695 (-COOH) and 1425 cm^{-1}.

The carboxyl band, shifting toward a lower wave

number, indicates the presence of C=C bond adjacent to the carboxyl group[6]. The band at 1425 cm^{-1}, seemed to be attributed to the CH_2 deformation frequency of the group of $-C=C-CH_2-$[7].

VIII was hydrolyzed by hydrochloric acid giving an amino acid whose paperchromatograph showed only one spot of R_f value 0.50.

5-Cyclobutane-spiro-hydantoin (IX). — The procedure of Ingold et al.[1] was used. This hydantoin melted at 222~225°C (reported m. p. 225°C).

1-Uramidocyclobutanecarboxylic Acid (X).—Two grams of IV and 4 g. of barium hydroxide were added to 50 cc. of water and refluxed for 2 hr. The reaction mixture was filtered and to the filtrate was added carbon dioxide gas. After removal of barium carbonate, the solution was concentrated in vacuo resulting a residue. The residue was recrystallized from ethanol affording 1 g. of colorless m. p. 200~202°C.

Found; N, 17.25. Calcd. for $C_6H_{10}O_3N_2$: N, 17.71%.

1-Aminocyclobutanecarboxylic Acid (I). — Two grams of IV and 5 g. of barium hydroxide ware added to 50 cc. of water and refluxed for 24 hr. The reaction mixture was filtered and to the filtrate was added carbon dioxide gas. After removal of barium carbonate, the solution was concentrated in vacuo resulting a residue. The residue was recrystallized from ethanol-water affording 1 g. of colorless prisms, m. p. 222~225°C (sublime). Paperchromatograph showed a spot of R_f value 0.50 in *n*-butanol/acetic acid/water; (4:1:1). (Fig. 1). The infrared spectrum showed amino acid bands (2930, 1630, 1520 cm^{-1}).

Found: C, 51.67; H, 7.90; N, 12.15. Calcd. for $C_5H_9O_2N$: C, 52.16; H, 7.88; N, 12.17%.

Benzoyl Derivative of I.—I was converted into a benzoyl derivative by the general method and gave colorless prisms, which melted at 205~206°C and saturated towards bromine. The infrared spectrum showed strong bands at 3280, 1630, 1530 (-CONH-) and 1710 cm^{-1} (-COOH).

Found: C, 65.87; H, 6.18; N, 6.35. Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; N, 6.39%.

The authors wish to express their deep gratitude to Professor Masaki Ohta for his kind and constant guidance throughout this study and to Dr. Tadashi Sato for the measurement of infrared spectra.

*Syntheses and Structures of Acetylformoin and its Related Compounds. I**

By Ryozo GOTO, Yo MIYAGI and Hiromi INOKAWA

(Received May 15, 1962)

Acetylformoin (AF) and benzoylformoin (BF) are synthesized by the acyloin condensation of methyl- and phenyl-glyoxal respectively:

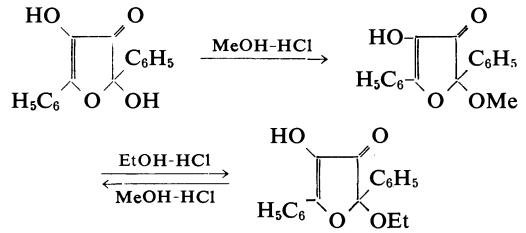
$$2\,RCOCHO \xrightarrow{KCN} RCOCH(OH)COCOR$$

$R=CH_3$: AF

$R=C_6H_5$: BF

The probable structures for these formoins are indicated by I—V in Fig. 1.

The structure of benzoylformoin has been investigated by earlier workers[1,2]. Benzoylformoin has two different kinds of hydroxyl groups, one of which is alkylated with an alcoholic solution of a mineral acid to give an *O*-alkyl derivative. *O*-Methyl derivative (methyl benzoylformoin) is converted to *O*-ethyl derivative (ethyl benzoylformoin) with ethanolic hydrogen chloride and vice versa with methanolic hydrogen chloride.



Blatt[2] stated that this type of etherification is characteristic of the glycosidic linkage and has suggested the cyclic structure VI for the

* Partly presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1959.

1) P. W. Abenius, *Ber.*, 25, 706 (1894).

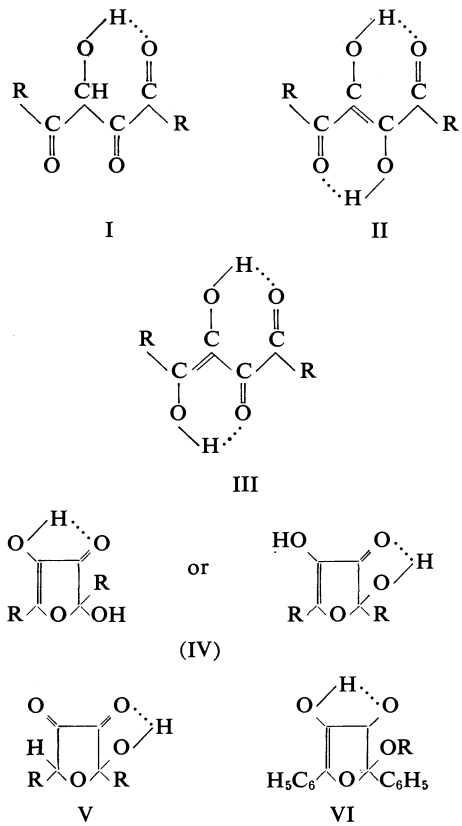

Fig. 1.

O-alkyl derivative. On this basis, he also proposed structure IV for benzoylformoin itself. On the other hand, it has been reported that the reaction with *o*-phenylenediamine and some other chemical behavior supported structure III. Blatt was of opinion that an equilibrium between III and IV occurred in solution. If this is the case, the formation of VI by the etherification can not be considered as an unequivocal evidence for the straightforward structure IV of benzoylformoin, since the equilibrium between the two tautomers could have been shifted due to the removal of IV by the etherification.

Acetylformoin was first synthesized by Nodzu and Kunichika[3] in our laboratory. More recently Steinbauer and Waldmann[4] studied the structure of acetylformoin. The reaction with *o*-phenylenediamine and methanolysis suggest an equilibrium between IV and III or II in solution.

3) R. Nodzu and S. Kunichika, This Bulletin, **15**, 211 (1940).

4) E. Steinbauer and E. Waldmann, *Monat.*, **89**, 570 (1958).

The authors have tried to determine the structure of benzoyl- and acetyl-formoin by the spectrophotometric method.

Results and Discussion

The spectral data obtained by the authors are listed in Tables I and II.

The Structure of Acetylformoin. — Acetylformoin was examined as a solid state in Nujol and as a solution in chloroform. The spectrum of acetylformoin in Nujol is very similar to that of the chloroform solution immediately after dissolving, except that in solution there appears another absorption band of weak intensity, at 1710 cm^{-1}. In both cases, there is an intense absorption at 1620 cm^{-1}. In the chloroform solution, immediately after dissolving a very weak broad absorption band, extending from 2800 cm^{-1} to beyond 3600 cm^{-1}, is observed. In Nujol, acetylformoin shows no distinct absorption over 3000 cm^{-1}, but a weak, broad absorption on both sides of the sides of the strong absorption of Nujol at 2800~3000 cm^{-1}.*

A part of structure II, $-C(OH)=\underset{|}{C}-CO-$, is the enol form of a β-diketone and constitutes the so-called "conjugate chelation". In enolic β-diketones, the C=O stretching absorption band is found to be widely shifted close to 1600 cm^{-1}, with a great enhancement of its intensity, and the OH stretching absorption band becomes very weak and broad. This phenomenon was first reported by Rasmussen, Tunnicliff and Brattain[5], who attributed the anomalies to resonance structures:

This chelation has been termed "conjugate chelation" to distinguish it from the normal hydrogen bonding. Similar observations have been reported for acetylacetone[5,6], benzoylacetone[6], dibenzoylmethane[5,6], α-acetyltetronic acid[7] and many other compounds[8].

Exactly the same type of anomalies was observed with the spectra of acetylformoin: there arise a C=O stretching absorption band at a very low wave number, 1620 cm^{-1}, and a

* The spectum of acetylformoin in hexachlorobutadiene mull also shows this broad absorption band. In this case, however, there arises an additional absorption at 1710 cm^{-1}, as in the chloroform solution. It might be considered that acetylformoin partly dissolves in hexachlorobutadiene. On this point more details are under investigation.

6) S. Batos, D. Hadži and G. Rossmy, *Trans. Faraday Soc.*, **52**, 464 (1956).

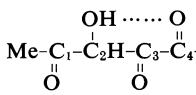
7) L. A. Duncanson, *J. Chem. Soc.*, **1953** 1207.

8) L. J. Bellamy, "Infrared Spectra of Complex Molecules", Methuen, London (1958), pp. 104, 142.

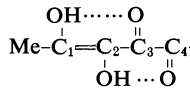
weak, broad band of the OH stretching absorption. In structure II, enediol -C(OH)=C(OH)- serves to form conjugate chelation on both sides of the carbonyl group; therefore a stronger chelation may be expected.

In enolic β-diketones, the C=C stretching absorption can not be observed. Rasmussen[5] stated that this is to be accounted for by its being hidden by the very strong C=O band or by its being shifted out of the double-bond region because of its loss of a double-bond character. Furthermore, it is not too difficult to comprehend the disappearance of the C=C stretching absorption band of acetylformoin when due attention is paid to the fact that C=C is fully and symmetrically substituted.

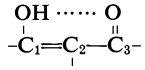
The other structures, I, III, IV and V, are excluded for the following reasons.



As for structure I, there are three kinds of carbonyl groups: C_1=O is a normal carbonyl group; C_3=O is a carbonyl group in α-diketone, and C_4=O is a hydrogen-bonded carbonyl group. Therefore, their absorption may be expected to split. Among them, the absorption band of C_4=O is expected to arise at the lowest wave number because of the hydrogen bonding, but the so wide shift over to 1620 cm^{-1} as observed can not be expected with the simple hydrogn bonding, which would produce somewhat sharper bands of the OH stretching absorption.

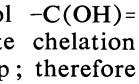


As for structure III, the band at 1620 cm^{-1} is attributable to C_3=O because a part of the structure,



constitutes the conjugate chelation and can result in a large shift, as been observed. C_4=O, however, is simply* a hydrogen-bonded carbonyl group, and its absorption band will arise at a higher wave number, probably close to 1700 cm^{-1}. Since the hydroxyl group attatched to C_2 forms only a simple* hydrogen bonding on C_1=O, there should appear some distinct bands of the OH stretching absorption.

As for structure IV, the value, 1620 cm^{-1}, is too low for the carbonyl group of IV, which is the enol form of α-diketone.



In such enolic α-diketones as phenylbenzylglyoxal $C_6H_5COCOCH_2C_6H_5$, no anomalies arising in enolic β-diketones are observed, and the C=O stretching absorption arises at the position of normal conjugated ketones, around 1670 cm^{-1} [9]. Moreover, in structure IV, the bands of the C=C and C=O stretching absorption may be expected to separate, and weak, broad band of OH stretching absorption can not be explained with structure IV.

As for structure V, the C=O stretching absorption may be expected to arise at a much higher wave number because the α-diketones in 5-membered ring system absorb at 1760~1776 cm^{-1} [10]. In structure V, some distinct bands of OH stretching absorption may be expected to arise.

The absorption band at 1710 cm^{-1}, which is observed in the chloroform solution immediately after dissolving, becomes stronger when the solution is left standing; at the same time there arise very weak but distinct absorption bands at 3600, 3340, 2970, 2880 and 1763 cm^{-1}. Therefore, in the chloroform solution acetylformoin seems to change to another structure than II, but the identity of this new structure has not yet been determined.

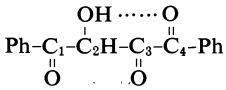
The Structure of Benzoylformoin.—Benzoylformoin absorbs at 3500, 3210, 1685, 1608 and 1595 cm^{-1}. An *O*-alkyl derivative, ethyl benzoylformoin (EBF), absorbs at 3270, 1688, 1605 and 1595 cm^{-1}. Structure IV seems to be most compatible with these observations. The reasons are as follows: first of all, in the region of C=O and C=C stretching absorption, the spectrum of benzoylformoin is very similar to that of ethyl benzoylformoin, the structure of which was established to be VI, as mentioned above. The band at 1685 cm^{-1} may be assigned to the carbonyl group, and those at 1608 and 1595 cm^{-1}, to the phenyl and olefin groups. These assignments seem to be appropriate, since enolic α-diketones absorb at around 1670 cm^{-1} [9], as mentioned above in the discussion of acetylformoin. When one of the hydroxyl groups of benzoylformoin is ethylated there occurs an accompanying change in the spectrum: benzoylformoin shows two bands of OH stretching absorption, while ethyl benzoylformoin shows one of OH stretching absorption.

Structures I, II, III and V are excluded for the following reasons.

* Here "simple" or "simply" means hydrogen bondinigs without any involvement in the conjugate chelation.

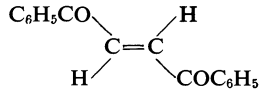
9) R. P. Barnes and G. E. Pinkney, *J. Am. Chem. Soc.*, 75, 479 (1953).

10) K. Alder, H. K. Schäfer, H. Esser, H. Krieger and R. Reubke, *Ann.*, 593, 23 (1955).



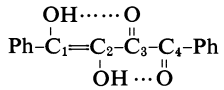
As for structure I, the C=O stretching absorption bands will probably split, because C_4=O is conjugated and hydrogen-bonded, C_3=O is the carbonyl group in α-diketone, and C_1=O is conjugated but not hydrogen-bonded. Above all, the absorption band of C_3=O will arise at around 1710 cm^{-1} [5].

As for structure II, a model compound of II, *trans*-dibenzoylethylene VII, absorbs at 1635 cm^{-1}. The C=O stretching absorption band of structure II may be shifted to a lower wave number than 1635 cm^{-1} by its conjugate chelation*. Furthermore, two distinct bands of OH stretching absorption can not be explained with structure II.



VII

As for structure III, there are two kinds of carbonyl groups: C_4=O is conjugated and simply hydrogen-bonded, while C_3=O is a carbonyl group involved in the conjugate chelation*. Hence, the following assignment



is possible: the absorption band at 1685 cm^{-1} is attributed to C_4=O, and the bands at 1605 and 1595 cm^{-1} are attributed to the overlapping bands of C_3=O and C=C stretching absorptions. If this be the case, the bands at 1605 and 1595 cm^{-1} would have been stronger than the bands at 1685 cm^{-1}, because the band of C_3=O is that of the conjugate chelation, which should have a much stronger intensity and because, moreover, this band of C_3=O is overlapped with the C=C stretching absorption band to enhance the intensity. The intensities of the band at 1685 cm^{-1} and the bands at 1605 and 1595 cm^{-1}, however, are almost equal. Furthermore, the hydroxyl group attatched to C_1 constitutes a conjugate chelation, but the absorption bands of benzoylformoin in the region of the OH stretching absorption are not so weak and broad as that of the conjugate chelation.

As for structure V, structure V is expected to show its C=O stretching absorption bands at a higher wave number, over 1760 cm^{-1}, as mentioned above in the discussion of acetylformoin.

Benzoylformoin is so scarcely soluble in carbon tetrachloride or other desirable solvents for the spectrophotometric measurement that the spectrum of benzoylformoin in solution could not be observed.

More details are under investigation.

* As for the conjugate chelation, see the discussion for acetylformoin.

Experimental

Synthesis of Acetylformoin[3,4].—The freshly distilled monomer of methylglyoxal was dissolved in cold water (pH value: 2.4) and the solution was stored in a refrigerator overnight. The condensation was effectd according to Steinbauer's method[4], i.e., under a nitrogen stream, a pH-meter being used. An aqueous solution of sodium cyanide (molar ratio to methyl glyoxal: 0.08), previously cooled to 0°C, was added through a dropping funnel to the aqueous methylglyoxal solution; then the pH value rose to 9.5. The temperature of the reaction mixture did not rise above 2°C under cooling with ice-water, though Steinbauer and Waldman stated that it rose up to 5°C under cooling. Sodium bicarbonate was added to keep the pH value of the solution between 7～8. When the aqueous methylglyoxal solution was used soon after dissolving, the pH value did not decrease below 8 even though considerable amount of sodium bicarbonate was added. After 30 min., condensation was stopped by adding phosphoric acid (pH: 5.0). The procedure thereafter was as usual. The solution was concentrated to a syrup, and alcohol was added to it. Inorganic salt was filtered off. The filtrate was concentrated to a syrup which was dissolved in ether, and the inorganic salt was filtered off again. The filtrate was dried over sodium sulfate. The syrup obtained by concentrating the ethereal solution was distilled under a vacuum. The yield was about 10%. The purification was effected by vacuum sublimation at 30～35°C, resulting in yellow crystals, m. p., 82～83°C.

Synthesis of Benzoylformoin. — Phenylglyoxal hydrate (1 g., m. p. 81°C) was dissolved in 35 cc. of water, with slight warming if it was necessary. To this solution was added a solution of 0.04 g. of potasium cyanide (molar ratio to phenylglyoxal hydrate: 0.08) in 10 cc. of water. Immediately the mixture of solution was colored yellow, and crystalline benzoylformoin began to precipitate. After 3 hr, the solution was neutralized with hydrochloric acid. Benzoylformoin was collected by filtration. The yield was about 85%. The recrystallisation was effected from aqueous ethanol. Yellow crystals, m. p., 186~188°C.

Synthesis of Ethyl Benzoylformoin[2].—Benzoylformoin was dissolved in a minimum amount of about 10% ethanolic hydrogen chloride. Ethyl benzoylformoin was deposited when the solution was left standing at room temperature overnight. It was decanted off from the mother liquor, dried in vacuo over potassium hydroxide, and recrystallized from ethanol. The yield was about 90%. Yellow crystals; m. p., 214°C.

Synthesis of *trans*-Dibenzoylethylene. — This was prepared from fumaryl chloride and benzene by the method of Conant and Lutz[11]. Yellow crystals; m. p., 109~110°C.

Spectra. — The infrared spectra were recorded with a Koken model DS-301 spectrophotometer (double-beam type).

The Colorimetric Determination of Traces of Selenium with Dithizone

By Hisao MABUCHI and Hiromichi NAKAHARA*

(Received September 5, 1962)

The composition of selenium is generally determined by reduction to reddish elemental selenium with such reducing agents as sulfur dioxide. This method is, however, not only insensitive but also subject to interference from other elements. Recently, Cheng reported a useful new method of determining traces of selenium colorimetrically by using 3-diaminobenzidine as an organic reagent[1]. Although Cheng's method is more sensitive and simpler than the former one, it still has some difficulties in the color development and involves complicated procedures.

The present authors have recently found that selenium(IV) can be extracted almost quantitatively by dithizone from an acid solution of a fairly high concentration. In carbon tetrachloride the dithizone complex of selenium is yellow in color and shows a maximum absorption at 420 mμ (Fig. 1).

The fact that selenium can be extracted by dithizone from a highly acidic solution, especially a hydrochloric acid solution of as high as 6N, may be regarded as very favorable for the colorimetric determination of selenium, because the high concentration of hydrochloric acid prevents other metals from complexing with dithizone. Taking these points into consideration, the authors studied the colorimetric determination of selenium with dithizone.

Experimental

Apparatus and Reagents.—*Spectrophotometer.*—A Beckman model DU spectrophotometer.

Standard Selenium Solution.—Purified metal selenium was first dissolved into a small amount of concentrated nitric acid, and the solution was evaporated to dryness in order to remove any excess nitric acid. Hydrochloric acid was then added to dissolve the residue, and the resulting selenous acid solution was diluted with redistilled water so as to be 0.5~4 μg. selenium per milliliter.

Dithizone Solution.—The concentration of the dithizone-carbon tetrachloride solution was adjusted to be 40~60 μmol./l. As for the purification of dithizone, Iwantscheff's method was employed[2].

Other Reagents.—Redistilled water and distilled ammonium hydroxide were used. The other reagents used were of analytical reagent grade.

Proposed Procedure for Determining Selenium.—Preliminary experiments indicated that selenium can be extracted most favorably from a 6 N hydrochloric acid solution. In general, two ways of colorimetric determination by dithizone are applicable to such metals as can be extracted from acidic media: the so-called mono-color method and the mixed-color method. For the present studies, both methods were examined. The proposed procedures for the mono-color and mixed-color methods will be described separately below. The extraction is carried out from a 6 N hydrochloric acid solution in both cases.

Mono-color Method.—Acidify 5 ml. of a sample solution with the same volume of concentrated hydrochloric acid and shake it thoroughly for two minutes with 5 ml. of a dithizone-carbon tetrachloride solution (60 μmol./l.) in a small separatory funnel. Allow the two phases to separate, and draw off the carbon tetrachloride layer into a 10-ml. measuring flask. Repeat the same extraction procedure with small portions of dithizone until selenium is completely extracted. Finally, wash the aqueous solution with one milliliter of carbon tetrachloride, drawing off the latter into the flask. Dilute the combined extracts in the measuring flask to a definite volume (10 ml.) with carbon tetrachloride, and transfer the solution into a separatory funnel. Wash it with 10 ml. of redistilled water, shaking the funnel for thirty seconds. Draw off the carbon tetrachloride layer into another separatory funnel, and add 10 ml. of dilute ammonium hydroxide (1 : 100) to remove the excess dithizone. Repeat the washing with another portion of ammonium hydroxide, and then determine the extinction of the solution at 420 mμ.

Mixed-color Method.—Acidify 2.5 ml. of a sample solution with the same volume of concentrated hydrochloric acid, and shake it thoroughly in a small separatory funnel for two minutes with 5 ml. of a dithizone solution (45 mol./l.). Allow the two phases to separate, draw off the carbon tetrachloride layer into an absorption cell, and determine the extinction at 410 mμ.

Results and Discussion

Absorption Spectra.—The absorption curve of the reagent and the dithizone complex of selenium(IV) in carbon tetrachloride are given in Fig. 1. As may be seen in the figure, the reagent has maximum absorptions at 620 and 450 mμ, while the dithizone complex of selenium has its maximum at 420 mμ. Therefore, extinction measurement may be made at 420 mμ in the mono-color method. As for the mixed-color method, however, it is preferable to measure at 410 mμ, where the absorption by dithizone is rather weak. In fact, in the case of the mixed-color method, it was almost impossible to carry out colorimetric determination at 420 mμ, while good results were obtained at 410 mμ.

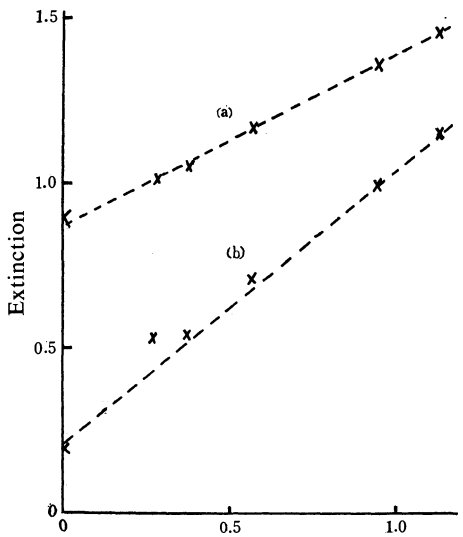

Fig. 2. Calibration curves (referred to carbon tetrachloride)
(a) Mixed-color method (dithizone concentration ~60 μmol./l)
(b) Mono-color method

In the mono-color method, the calibration curve does not cross the origin. This is likely due to some contamination of other metals or decomposition of dithizone during elimination process of excess dithizone.

0.56_3	Te(IV)	0.53_1	0.55_9
0.56_3	Hg(II)	0.68_3	0.53_3
0.56_3	Bi(III)	0.63_7	0.56_9
0.56_3	Cu(II)	0.56_1	—
Preliminary treatment was carried out at pH 7.			
0.56_3	Cu(II), Ag, Te(IV), Hg(II), Bi(III)	0.57_5	—
Preliminary treatment was carried out at pH 2.			

The Calibration Curve and Precision of the Methods.—The calibration curves are given in Fig. 2 for both mono-color and mixed-color methods. Extinction measurements were made at 420 mμ in the mono-color method and at 410 mμ in the mixed-color method. The linearities are good in both cases. The spectrophotometric sensitivity* of the color reaction is, in the mono-color method, 0.001 μg. of selenium in carbon tetrachloride per square centimeters, while it is 0.002 μg. in the mixed-color method.

The experimental errors of the mixed-color method are shown in Table I. From these experimental results, it may safely be said that the proposed mono- and mixed-color methods are both applicable to determining traces of selenium.

Interfering Substances.—The reaction of selenium with dithizone in 6 N hydrochloric acid media is very specific. The substances which would interfere with the determination of selenium with dithizone would include, in the first place, those which oxidize dithizone itself, such

·—· Absorption curve of dithizone extract when copper(II) is present in the aqueous solution in a tenfold amount of selenium.

* Here, spectrophotometric sensitivity is defined as follows: the number of micrograms of the element, converted to the colored product, which, in a column of solution with a cross section of 1 cm^2, shows an extinction of 0.001. For details, see E. B. Sandell, "Colorimetric Determination of Traces of Metals," Interscience Publishers, New York (1959), p. 83.

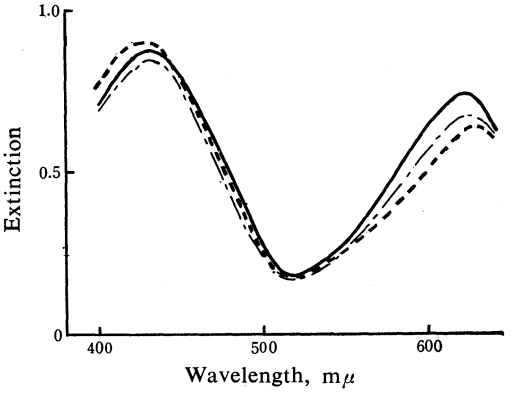

Fig. 4. Changes of absorption curve effected by the presence of mercury(II).

—— Absorption curve of dithizone extract of selenium in CCl_4.
- - - Absorption curve of dithizone extract when mercury(II) is present in the aqueous solution in a comparable amount with selenium.
·—· Absorption curve of dithizone extract when mercury(II) is present in the aqueous solution in a tenfold amount of selenium.

as ferric ion, halogens, nitrous acid, permanganate and so forth. These should be removed, of course, from the reaction system. Some metals which react with dithizone in acidic media, such as copper(II), palladium, silver, tellurium(IV), gold, mercury(II) and bismuth-(III) may possibly be interfering substances (TableII). The interfering action of these metals was investigated expeimentally and is shown in Table III. We paid no attention to palladium and gold, since they are not so abundant in nature.

From Table III we can conclude that tellurium(IV), silver, and bismuth do not essentially interfere with our method even if any of the three exist in amounts of ten times as much as selenium in the sample solution. This seems to be due to the high acidity and/or the high concentration of chloride ions (which may cause the masking effect) in the extraction system. Copper(II) interferes, and mercury(II) may also be considered to interfere. Changes in the absorption curves of the selenium dithizone complex and of dithizone due to the existence of copper(II) or mercury (II) are shown in Figs. 3 and 4.

Separation of Selenium from the Interfering Metals.—We made several tests of selenium extraction with a dithizone solution, using the radioactive isotope ^{75}Se as a tracer, and observed that, for pH values higher than 2, only less than 1.5% of the total amount of selenium is extracted by a 10^{-3} mol./l. dithizone solution. However, a considerable amount of copper(II) is extracted under the same conditions, so it seems probable that we can exclude the interference of copper by extracting it preliminarily from the sample solution. The procedure of selenium determination including such preliminary treatment is as follows:

First, extract copper from the sample solution with dithizone under neutral or slightly acidic media, and then make the aqueous layer approximately 6 N in hydrochloric acid. An example of determining the selenium content in the sample solution, which contains a comparable amount of copper, by such a procedure is shown in Table III. Table III also gives the results obtained from a similar experiment in which the five kinds of interfering metals described above are contained in the sample solution, each in an amount comparable with that of selenium. Both of these examples give good results, and, as we expected, the extraction from 6 N hydrochloric acid solution is found to be really favorable, since even such interfering metals such as copper(II) and mercury(II) can be separated by a simple preliminary treatment.

Molar Extinction Coefficient.—The extinction coefficient of the selenium dithizone complex in carbon tetrachloride was estimated to be about 70×10^3 per mole-centimeter.

Stability of Color.—The stability of color was carefully examined. The experimental results are given in Fig. 5. It may be observed in Fig. 5 that the color of the dithizone extract of selenium is nearly stable when the extract is separated from the aqueous layer (6 N in hydrochloric acid) immediately after shaking, while the color fades away gradually when the organic layer remains in contact with the aqueous one.

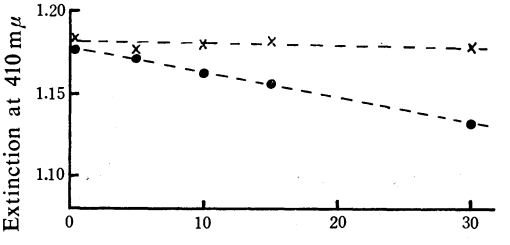

Fig. 5. Stability of color of selenium-dithizone complex in carbon tetrachloride.

×--× Extinction of organic layer which was separated from aqueous layer immediately after shaking.
-•-•-• Extinction of organic layer which has been in contact with aqueous layer after shaking.

Summary

A colorimetric method of determining traces of selenium with dithizone has been studied. Selenium is extracted from a 6 N hydrochloric acid solution with a carbon tetrachloride solution of dithizone almost quantitatively, and the dithizone complex of selenium in carbon tetrachloride has a maximum absorption at the wavelength of 420 mμ. One p. p. m. of selenium can be determined spectrophotometrically, by measuring the extinction at 420 mμ in the mono-color method and at 410 mμ in the mixed-color method.

The errors of these two methods are estimated to be within 3%. Copper(II) and mercury(II) were found to be interfering metals. However, they are easily removed by a preliminary extraction. Finally, attention should be paid to the fact that the color of the dithizone complex of seleium is apt to fade away rapidly when it is left in contact with a 6 N hydrochloric acid solution for some time.

The authors wish to thank Professor Nobufusa Saito, Dr. Yuji Yokoyama and Dr. Hirotoshi Sano for their invaluable advice and comments.

Asymmetric Hydrogenation with Modified Raney Nickel. II. Studies on Modified Hydrogenation Catalyst. III

By Yoshiharu IZUMI, Masami IMAIDA, Hideaki FUKAWA and Shiro AKABORI

(Received September 24, 1962)

In the previous paper[1], it was reported that R-Ni catalyst treated with L-Glu solution had asymmetric activity on the hydrogenation of some carbonyl compounds to alcohols, and that the activity was much influenced by pH and temperature of Glu solution.

In the present work, asymmetric activity of R-Ni catalyst treated with other sorts of amino acids, that is, *N*-substituted amino acids, hydroxy acids, and L-Glu dissolved in acetate buffer was studied in order to elucidate the mechanism of these asymmetric hydrogenations.

The asymmetric activity of catalyst modified with various amino acids $RCH(NH_2)COOH$ was tested in order to know the effect of substituent (R) on the asymmetric activity of a catalyst. In order to find out the role of the amino residue on the asymmetric activity of a catalyst modified with amino acid, *N*-substituted L-Asp and L-Glu derivatives were used as modifying reagents of the R-Ni catalyst. Since homocysteinic acid is structually analogous to Glu, the asymmetric activity of a catalyst modified with this amino acid was studied for the purpose of elucidating the effect of the structure of a molecule.

In order to elucidate the effect of the carbonyl group on the asymmetric activity of a catalyst modified with Glu, the modification was carried out in the presence of acetic acid. Because, if the asymmetric activity of the catalyst modified with Glu depends on the adsorption of the carbonyl group of Glu, some influence will occur in the presence of the carboxyl group of other acids.

The hydroxy acids were used as a homologue of amino acid used as modifying reagents. Experiments were carried out for the elucidation of the relationship between the absolute configuration of the modifying reagent and that of the hydrogenation product.

Result

In the case of Glu[1], the pH of the modifying solution influenced the asymmetric activity of the catalyst and the great asymmetric activity of the catalyst was obtained near the lower limit of the pH jump of neutralization curve of Glu. The neutralization curve of acidic substances, *N*-substituted L-Asp and L-Glu, D-tartaric acid, L-malic acid et al., were measured with sodium hydroxide solution. The lower and the upper limits of the pH jump of the neutralization curve of these substances

1) H. Fukawa, Y. Izumi, S. Komatsu and S. Akabori, This Bulletin, 35, 1703 (1962); Y. Izumi, M. Imaida, H. Fukawa and S. Akabori, ibid., 36, 21 (1963).

are shown in Table I. Thus the R-Ni catalyst was modified near the neutralization point of each substance and its asymmetric activity was tested.

Treatment with Several Amino Acids.—One and a half unit* of the R-Ni catalyst was treated with solutions of several amino acids as shown in Table II for 1.5 hr.

The asymmetric activity of the catalyst was tested in the hydrogenation of 17.0 g. of methyl acetoacetate to methyl 2-hydroxybutyrate at 60°C. The relationship between the asymmetric activity of the catalyst and modifying temperature is shown in Fig. 1.

From these results, amino acids could be divided into the following two groups.

The catalyst treated with L-Ala, L-Ser, L-Cystine, L-Thr and L-Pro at 0°C produced predominantly methyl D-2-hydroxybutyrate and the L-form contents of the reduced products increased according to the increase of the temperature of treatment. These amino acids

belong to the amino acids of which the L-form has a sweet taste. Modification by amino acids other than the amino acids mentioned above resulted in giving the catalyst which produces predominantly methyl L-2-hydroxybutyrate at 0°C. Some of the catalysts modified at higher temperature increased the content of the D-form of reduced products as in the case of modification by L-Glu.

L-Met and L-Cys are probably desulfurized by R-Ni during the treatment, so it was omitted from consideration.

The asymemtric activity of the catalyst modified by L-Tyr, L-Lys and L-His are shown in Table III. When the hydrochlorides of L-Lys and L-His were used as the modifying reagents at higher temperature, the chloride anion brought about a remarkable depression of hydrogenation activity of the catalyst; therefore, the asymmetric activity of the catalyst could not be measured.

TABLE III. EFFECT OF THE MODIFYING TEMPERATURE

Modifying reagent	Modifying temp., °C	$[\alpha]_D^{20}$ of Me 2-hydroxybutyrate
L-Tyr	100	−0.50
L-Lys (HCl)	0	−1.45
L-Lys (HCl)	40	−1.42
L-His (HCl)	0	−0.04

(Catalyst modified with amino acid)

Because of the lower solubility of L-Tyr, the effect of temperature on the asymmetric activity could not be measured at a lower modifying temperature.

***N*-Substituted L-Asp and L-Glu Derivatives.**— One and a half unit of the R-Ni catalysts were modified in the neighborhood of the pH jumps of the modifying reagents under the conditions shown in Table IV and the results are shown in this table.

1) Effect of these conditions is discussed in the other.
2) Ethanol, pH was not measured.
3) pH was adjusted with 1 N NaOH exactly, so total volume of the modifying solution varied with the amount of the modifying reagent.
4) R-Ni was treated under reflux.

These results show that asymmetric activity of the catalyst has no close correlation with basicity of the nitrogen of the modifying reagent, but is much influenced by the steric effect of the substituent.

Homocysteinic Acid $HOOCCH_2CH_2CH(NH_2)\cdot SO_3H$.—The conditions for the preparation of the catalyst and the results are shown in Table IV. Asymmetric activity of this catalyst is much less than that prepared with Glu. But other characteristics of these catalysts resemble each other.

Effect of Acetic Acid on the Modification with Glu.—When the catalyst was prepared by the treatment with Glu in acetate buffer, the asymmetric activity of the catalyst was less, as compared with that treated without acetic acid, as shown in Table V.

Hydroxy-carboxylic Acid.—The modification of the catalsyt with hydroxy carboxylic acid was carried out with the solution shown in Table VI.

1) D-Tartaric Acid. — *Effect of pH (Table VI-No. 1, 2).*—The relation between the pH of the modifying solution and the asymmetric activity of catalyst at 0°C is shown by curve 1 in Fig. 2 and the neutral point is shown in Table I.

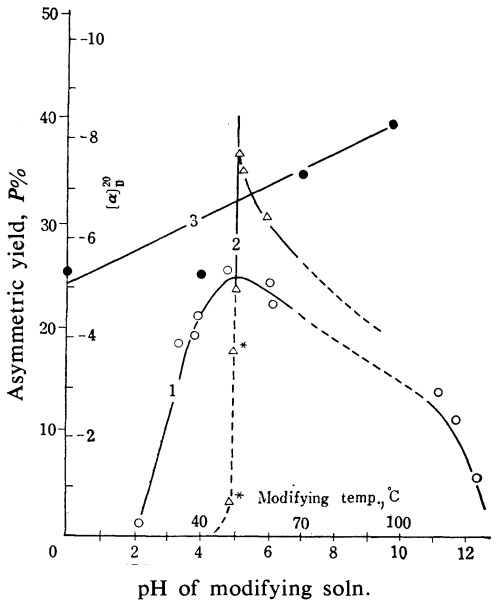

Fig. 2. Effect of modifying pH and temperature.
1 -○- Effect of modifying pH at 0°C
2 -△- Effect of modifying pH at 100°C
3 -●- Effect of modifying temperature
* Calculated value

When the catalyst was treated at 100°C below pH 5.0, the catalyst distinctly decreased its hydrogenating and asymmetric activities as can be seen from curve 2 in Fig. 2.

Effect of Temperature (Table VI-No. 3).— When the temperature of treatment rose, the asymmetric activity increased as shown by curve 3 in Fig. 2. The pH of the modifying solution moved towards alkaline after treatment at higher temperature.

Effect of Temperature (Table VI-No. 4). — The asymmetric activity of catalysts at various immersion time are presented in Fig. 3. The activity became almost constant in 30 min. and one and a half hours is sufficient to gain the constant asymmetric activity.

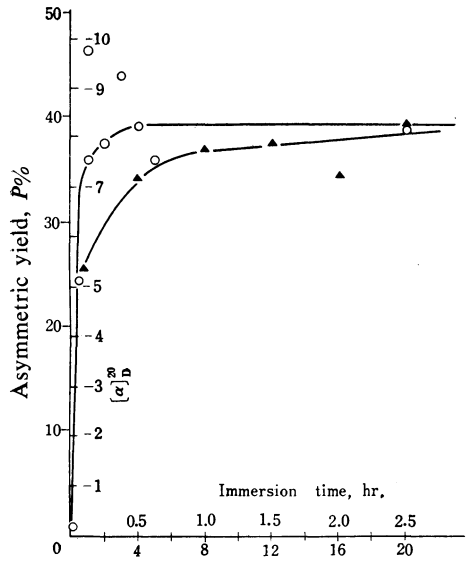

Fig. 3. Effect of concentration of modifying solution and immersion time of catalyst.
-○- Effect of amount of tartaric acid
-▲- Effect of immersion time

Effect of the Concentration of Modifying Solution (Table VI-No. 5).—Effect of the concentration of modifying solution on the asymmetric activity of a catalyst was tested by the treatment with the solution which contained various amounts of tartaric acid. The results are shown in Fig. 3. The constant aymmetric activity was gained when the catalyst was treated with solutions of the concentration above 1.0 per cent. The lowest limit of the concentration is much higher than that of Glu, because tartaric acid has less buffer action than Glu.

2) L-Malic Acid (Table VI-No. 6, 7). — In the case of L-malic acid the greatest asymmetric activity was obtained on the treatment with the solution near its pH jump, as shown in Table I. The asymmetric activity of the catalyst treated at 100°C was greater than that treated at 0°C. The asymmetric activity of this catalyst was about a half of that of the catalyst treated by tartaric acid under the same condition as shown in Table IV.

Discussion

From the results of the three reports of this series[1], it is concluded that asymmetric catalysts are obtained by contacting R-Ni with the solution containing asymmetric compounds.

The modifying reagents used in the experiments must have the substituents of high affinity to nickel, such as $-NH_2$, $-COOH$ and $-OH$ groups at the asymmetric center. With amino acid $RCH(NH_2)COOH$ which have residues (R) possessing higher affinity to nickel gave catalysts of higher asymmetric activity.

Absolute configuration of methyl 2-hydroxybutyrate was affected by the structure of amino acid which was used to modify the R-Ni. The catalysts modified at 0°C with the L-amino acids of small molecular size (sweet taste) predominantly produce the D-form of hydrogenation products, while with L-amino acids of large molecular size (no sweet taste) predominantly produce L-form products.

The *N*-substituted amino acid, acyl, dimethyl or cyanoethyl derivatives, produce much less asymmetric activity of the catalyst. From this evidence, $-NH_2$ residue might greatly participate in making the asymmetric center of the catalyst. From the results described above it could be concluded that the lone pair of nitrogen atom in amino residue must touch on the surface of the catalyst to make asymmetric center.

The treatment with malic acid and tartaric acid cause the powerful asymmetric activity of the catalyst, but the treatment with diethyl tartrate does not. The catalyst treated with Glu dissolved in acetate buffer has much less asymmetric activity than that treated with aqueous Glu solution. These facts show that, with amino or hydroxy acid, the carboxyl group is important to make the asymmetric center on R-Ni. These facts also agree with the results reported by Welch[2] et al. who describe that ester is slightly adsorbed and two different fatty acids are competitively adsorbed by the R-Ni catalyst.

Asp and malic acid resemble each other in the structure, but the asymmetric activity of a catalyst treated with Asp is considerably smaller than that of a catalyst treated with

2) C. M. Welch, H. A. Smith and J. B. Cole, *J. Phys. Chem.*, **65**, 705 (1961).

malic acid. The same relation is found in homocysteinic acid and Glu. The asymmetric activity of a catalyst treated with tartaric acid is much higher than that of a catalyst treated with malic acid. This result corresponds to that tartaric acid and malic acid are 170 and 135 in molecular weight and have two and one active center, respectively. So far as the Stuart's model is used for consideration, it is assumed that these differences depend on whether the molecules on the modifying reagents can attach to the surface of R-Ni without any steric hindrance or not.

Absolute configuration of D-tartaric acid opposed to that of L-malic acid, and the optical rotation of methyl 2-hydroxybutyrate which was produced by the hydrogenation of methyl acetoacetate in the presence of the catalyst treated with these acids, opposed each other. L-Asp and L-malic acid have the same absolute configuration, but the asymmetric activity of a catalyst treated with these reagents have opposit asymmetric activity. From these results, it seems that there are some differences of structure between the asymmetric center of catalysts produced with amino acids and hydroxy acids.

Moreover, the fact that L-Pro produces slightly asymmetric activity is a clear evidence that the asymmetric center of hydrogenation can not be produced by the two-points attachment with carboxyl and amino groups. If this center is produced by the two points-attachment the pyrrolidin ring must stand up outside of the R-Ni surface and a strong steric effect must be produced.

It is concluded that the following two considerations are required for producing the asymmetric activity of R-Ni.

1) R-Ni must adsorb the asymmetric compounds which contain three substituents with affinity to Ni.

2) In order to obtain higher asymmetric activity of the catalyst, it is essential that the molecules of modifying reagents are adsorbed on the R-Ni easily and tightly.

Experimental

Preparation of the catalyst, hydrogenation of methyl acetoacetate and measurement of asymmetric yield were carried out in the same manner as described in the previous paper[1].

Modification of the Catalyst.—The R-Ni catalyst was modified under the conditions shown in Tables IV and VI. The procedure is quite similar to the modification with Glu which was described in the previous paper. The aqueous solution which contained acidic modifying reagent was neutralized with 1 N sodium hydroxide solution and adjusted to a suitable pH.

Effect of Acetic Acid. — *Experiment No. 2 in Table V.* — One and a half unit of R-Ni catalyst treated with 5 M acetate buffer (pH 5.0) at 0°C for 10 min., washed with 50 ml. of cold water, then was modified with 25 ml. of 2% Glu at 0°C for 1.5 hr. as usual method.

Experiment No. 3 and 4 in Table V.—One and a half unit of R-Ni catalyst was modified with the solution containing 225 ml. of 2% Glu which was adjusted to pH 5.02 and 5 ml. (or 50 ml.) of 5 M acetate buffer (pH 5.0) at 0°C for 1.5 hr.

Summary

1) The asymmetric R-Ni catalysts were prepared by the treatment of R-Ni with various asymmetric compounds, and the asymmetric activity of a catalyst was measured by the hydrogenation of methyl acetoacetate

2) Optical rotatory direction and power of the reduced product was affected both by the configuration and molecular size of amino acid which was used as modifying reagent.

3) The asymmetric activity of catalysts treated with *N*-substituted amino acids, *N*-acyl, *N*-dimethyl and *N*-cyanoethyl derivatives of Glu and Asp, were much less than the activity of the catalyst treated with the corresponding amino acids.

4) The asymmetric activity of the catalyst treated with D-tartaric acid and L-malic acid was tested at various conditions. The asymmetric yield in the hydrogenation of methyl acetoacetate in the presence of the catalyst treated with D-tartaric acid solution of pH 5.1 ~5.2 at 100°C was about 45 percent.

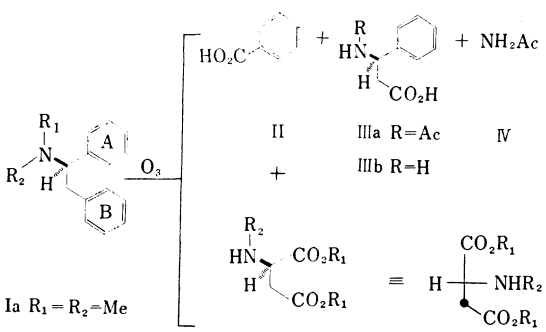
*The Absolute Configuration of (−)-N, N-Dimethyl-1, 2-diphenylethylamine and its Analgesic Activity**

By Masao NAKAZAKI, Itaru MITA and Nobuo TOSHIOKA

(Received October 1, 1962)

The (−)-antipode of *N*, *N*-dimethyl-1, 2-diphenylethylamine (Ia) derived from (−)-1, 2-diphenylethylamine (Ib) has been found to possess 1/2∼1/3 the analgesic activity of morphine, whereas the (+)-enantiomer shows negligible activity[1]. This is but one of numerous instances[2,3] in which only one optical active antipode of a compound is physiological efficacious. In this paper, the determination of the absolute configuration of the (−) analgesic Ia is reported.

Acetylation of (−)-1, 2-diphenylethylamine (Ib) gave (+)-*N*-acetyl-1, 2-diphenylethylamine (Ic), which was exhaustively ozonized; the reaction mixture was oxidized with peracetic acid. Upon working up the reaction mixture,



Ia $R_1=R_2=Me$

Ib $R_1=R_2=H$

Ic $R_1=H, R_2=Ac$

Va $R_1=Me, R_2=Ac$

Vb $R_1=R_2=H$

Vc $R_1=H$, $R_2=Bz$

benzoic acid II and (+)-2-acetylamino-2-phenylpropionic acid (IIIa) were isolated and identified, IIIa being then further hydrolyzed to (+)-2-amino-2-phenylpropionic acid (IIIb).

Treatment of the mother liquor of II and IIIa with diazomethane, followed by distillation in vacuo, afforded acetamide IV and dimethyl *N*-acetylaspartate (Va), which was then hydrolyzed with diluted sulfuric acid. The reaction mixture, freed from sulfate ions, was subjected to paper chromatography (methanol: conc. aq. ammonia=3:1). Only a single spot of aspartic acid (R_f 0.24), and no spot corresponding to phenylalanine (R_f 0.63) nor to glycine (R_f 0.46), was detected. This indicates that the carbon atom to which the phenyl and acetamino groups are attached is vulnerable to oxidation and that the B ring is oxidized preferentially to the A ring, probably for steric reasons. The sulfate-free filtrate was concentrated to afford D-aspartic acid (Vb) (decomp. p. 320°C, $[\alpha]_D^{20}$ −23.2° (*c* 1.9 in 1 N hydrochloric acid)), the infrared absorption spectrum of which was superimposable on that of natural L-aspartic acid (decomp. p. 320°C, $[\alpha]_D^{21}$ +23.4° (*c* 2.2 in 1 N hydrochloric acid)).

The identity was further checked by preparing benzoyl-D-aspartic acid (Vc), which gave a racemic compound (with one mole of water of crystallization; m. p., 162∼165°C, after drying at 115°C) with enantiometric benzoyl-L-aspartic acid.

These findings established the (R)-configuration of analgesic active (−)-*N*, *N*-dimethyl-1, 2-diphenylethylamine (Ia)[4]. Inspection of a molecular model of Ia reveals a close stereochemical resemblance with natural (−)-morphine (VI)[5,6].

Since the A and B rings of morphine are almost perpendicular to each other, Ia might be expected to take an analogous eclipsed conformation VII, rather than the energetically favorable conformation VIII, in approaching some reactive surface in the nervous system. A recent observation[7] seems to support this assumption. Neither of the enantiomers of 9-dimethylamino-9, 10-dihydrophenanthrene (IX), in spite of their close resemblance to Ia, show any pronounced analgesic activity.

The reason for this may lie in the fact that

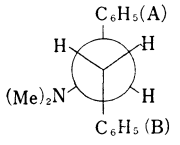
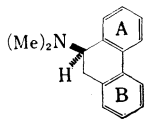
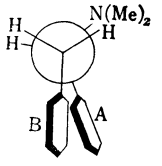
VII



VIII



IX



X

IX can not have a conformation in which the A and B rings are perpendicular to each other due to the linkage between two benzene nuclei (projection formula X).

Experimental

(+)-Tartarate of (—)-1, 2-Diphenylethylamine.—The (+)-tartarate of (−)-Ib was recrystallized from diluted acetic acid to give crystals; m. p., 229~230°C (decomp.), $[\alpha]_D^{19}$ −55.3° (*c* 0.92 in water)[8].

(—)-1, 2-Diphenylethylamine (Ib).—Into a solution of 10 g. of sodium hydroxide in 100 cc. of water was added 25 g. of (+)-tartarate of (−)-1,2-diphenylethylamine; the milky emulsion was then extracted with ether. After being washed with a saturated sodium chloride solution and dried over potassium hydroxide pellets, the solvent was removed to afford a pale yellow oil, which distilled at 122~124°C/3 mmHg and weighed 18.1 g. $[\alpha]_D^{19}$ −51.2° (*c* 3.7 in ethanol).

(+)-*N*-Acetyl-1, 2-diphenylethylamine (Ic).—To a solution of 16 g. of Ib in 30 cc. of ether, 10 g. of acetic anhydride in 35 cc. of ether was added. After the crystals which had precipitated were filtered (19 g.) and washed with ether, these were recrystallized from ethanol to give Ic (m. p., 166~167°C), which weighed 16.4 g. $[\alpha]_D^{18}$ +35.7° (*c* 1.5 in acetic acid).

Found: C, 80.5; H, 7.4. Calcd. for $C_{16}H_{17}ON$: C, 80.30; H, 7.16%.

Exhaustive Ozonolysis of (+)-*N*-Acetyl-1, 2-diphenylethylamine (Ic).—A stream of ozone (about 2%) was passed into a solution of 10 g. of Ic in 90 cc. of acetic acid at 19°C for 39 hr., during which time 8.5 cc. of water was added twice. After 10 cc. of 30% hydrogen peroxide had been added, the reaction mixture was allowed to stand for 24 hr. at room temperature. The solution was then warmed on a water bath for 2 hr., and the excess hydrogen peroxide was destroyed by heating the solution with a small amount of palladium on a carbon catalyst.

To remove the acetic acid, 20 cc. of water was added, and the aqueous solution was concentrated at reduced pressure. This process was repeated three times. When the viscous pale yellow residue was dissolved in 20 cc. of water and kept at room temperature, 0.2 g. of leaflets precipitated; these were recrystallized from water to give crystals (m. p., 120~121°C). Their identity with benzoic acid was established by mixed melting point determination with an authentic specimen. When the filtrate from benzoic acid was again concentrated, 0.3 g. of prismatic crystals precipitated; these were identified as (+)-2-acetylamino-2-phenylpropionic acid (IIIa) (vide infra). The filtrate was concentrated again at reduced pressure. The viscous yellow residue (7.5 g.) was dried in a vacuum desiccator over concentrated sulfuric acid overnight to give a glassy solid (7.0 g.), which was then dissolved in 40 cc. of methanol and treated with 140 cc. of an ether solution of diazomethane prepared from 14 g. of nitrosomethylurea. After being kept at room temperature for 3 hr., the excess diazomethane was destroyed with 10 drops of acetic acid, and a small amount of fluffy material was removed by filtration. Removal of the solvent gave a viscous dark red liquid (6 g.) which was distilled at 0.01 mmHg to give 0.1 g. of a sublimate on the wall of the receiver. This sublimate was collected and recrystallized from benzene to give crystals (m. p., 75~78°C) which were identified as acetamid by mixed melting point determination with an authentic specimen.

The main fraction consisted of a viscous yellow oil[9] (b. p., 100~125°C/0.01 mmHg), which weighed 3.5 g. This oil (1.30 g.) was refluxed with 15 cc. of 2.07 N sulfuric acid for 3 hr. and the sulfate ion was removed by adding 82.5 cc. of 0.38 N barium hydroxide (pH 3.4). The barium sulfate was removed by centrifuging and washed with water twice. The filtrate and washings were then combined and filtered through a layer of a Hyflo super cell. The clear solution was concentrated to give 0.199 g. of crystals; further concentration of the mother liquor gave the second crops, 0.27 g. The combined crystals were recrystallized from water to afford 0.405 g. of crystals, which decomposed at 320°C (in a sealed capillary). $[\alpha]_D^{20}$ −23.2° (*c* 1.9 in 1 N hydrochloric acid). Their infrared absorption spectrum in Nujol was found to be superimposable on that of authentic natural L-aspartic acid, $[\alpha]_D^{21}$ +23.4° (*c* 2.2 in 1 N hydrochloric acid).

Found: C, 36.1; H, 5.5; N, 10.5. Calcd. for $C_4H_7O_4N$: C, 36.09; H, 5.30; N, 10.52%.

Benzoyl-D-aspartic Acid (Vc).—The above-mentioned D-aspartic acid (0.198 g.) obtained from Ic was dissolved in 3.3 cc. of water and benzoylated with 1.1 g. of sodium hydrogen carbonate and 0.6 g. of benzoyl chloride, according to Fischer's procedure[10], to give 0.160 g. of needles after recrystallization from water (m. p., 178~179°C, $[\alpha]_D^{18}$

8) R. Söderquist (*J. prakt. Chem.*, (2) **101**, 297 (1921)) reported the following physical constants: (−)-Ib, b. p., 159°C/9 mmHg, $[\alpha]_D^{15}$ −11.80°; (+)-tartarate, m. p., 220~221°C, $[\alpha]_D^{20}$ −43°; the acetyl derivative of (+)-amine prepared by resolution via the (−)-malate, m. p., 168.5°C, $[\alpha]_D^{20}$ −15° (*c* 0.66 in ethanol).

9) E. Hardegger and H. Braunschweiger (*Helv. Chim. Acta*, **41**, 1125 (1961)) obtained dimethyl *N*-acetyl-L-aspartate (b. p., 160~169°C, high vacuum; m. p., 60~61°C, $[\alpha]_D$ −13.4°,) by the exhaustive ozonolysis of *N*-acetyl-L-tryptophane.

$-26.9°$ (c 1.49 in 0.1 N potassium hydroxide)). Their infrared absorption spectrum (in Nujol) was found identical with that of benzoyl-L-aspartic acid (m. p., 180~181°C, $[\alpha]_D^{19}$ $+27.7°$ (c 2.2 in 0.1 N potassium hydroxide)) prepared from natural L-aspartic acid.

Found: C, 55.5; H, 4.9; N, 6.1. Calcd. for $C_{11}H_{11}O_5N$: C, 55.69; H, 4.67; N, 5.91%.

Racemic Benzoyl-aspartic Acid. — A mixture of the same amount (49 mg.) of benzoyl-D-aspartic acid obtained from the ozonolysis of Ic and authentic benzoyl-L-aspartic acid was recrystallized from water to give the racemic compound with one mole of water of recrystallization[10].

Found: C, 52.0; H, 5.0; N, 5.5. Calcd. for $C_{11}H_{13}O_6N$: C, 51.76; H, 5.13; N, 5.49%.

Anhydride obtained by drying at 115°C for 1 hr. at reduced pressure melted at 162~163°C[10].

(+)-2-Acetylamino-2-phenylpropionic Acid (IIIa). —The prismatic crystals obtained from the reaction mixture of ozonolysis of Ic (vide supra) was recrystallized from water to give prisms (m. p., 193~195°C, $[\alpha]_D^{21}$ $+75.0°$ (c 1.48 in 0.1 N potassium hydroxide), $[\alpha]_D^{21}$ $+116.2°$ (c 0.28 in ethanol)) whose infrared absorption spectrum was found to be superimposable on that of racemic 2-acetylamino-2-phenylpropionic acid (m. p. 162~165°C), prepared according to Posner's procedure[11] and recrystallized from diluted aqueous dimethylformamide[11].

Found: C, 63.7; H, 6.6; N, 7.0. Calcd. for $C_{11}H_{13}O_3N$: C, 63.75; H, 6.32; N, 6.76%.

(+)-2-Amino-2-phenylpropionic Acid (IIIb). — A mixture of 0.23 g. of IIIa and 4.2 cc. of 10% hydrochloric acid was refluxed for 2 hr. After 10.90 cc. of 0.1 N potassium hydroxide had been added, the solution was concentrated at reduced pressure to precipitate crystals which were recrystallized from 4 cc. of water to afford 0.09 g. of crystals (m. p., 221°C, $[\alpha]_D^{20}$ $+9.5°$ (c 1.07 in water))[12]. The crystals' infrared absorption spectrum (in Nujol) showed almost the same pattern as racemic 2-amino-2-phenylpropionic acid[13] (decomp. p., 221°C), but a slight discrepancy was observed.

Found: C, 65.3; H, 6.8; N, 8.7. Calcd. for $C_9H_{11}O_2N$: C, 65.44; H, 6.71; N, 8.48%.

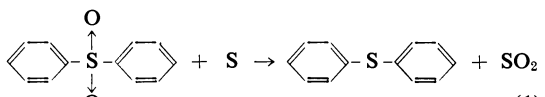
The Tracer Study of the Reactions of Diphenyl Sulfone and Diphenyl Sulfoxide with Sulfur

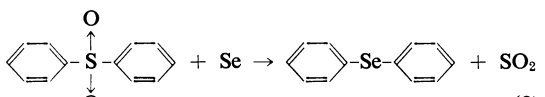
By Shigeru OAE and Shunichi KAWAMURA

(Received October 18, 1962)

Many years ago, Krafft and Vorster[1] obtained diphenyl sulfide and sulfur dioxide (Eq. 1) when they heated diphenyl sulfone with sulfur in nitrogen atmosphere. They also performed many other thermal reactions between organic sulfur compounds and sulfur or selenium. Among their observations an especially interesting reaction is that between diphenyl sulfone and selenium as expressed by Eq. 2, because the displacement of SO_2 group in the sulfone with elemental selenium



(1)



(2)

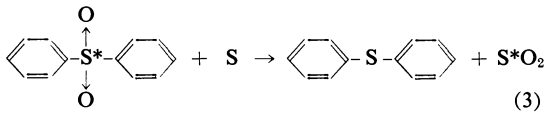
may imply that a similar replacement of sulfur atom of diphenyl sulfone with elemental sulfur is taking place in the reaction.

1) F. Krafft and Vorster, *Ber.*, **26**, 2813 (1893).

TABLE I. REACTIONS OF ORGANIC SULFUR COMPOUNDS WITH SULFUR

	Original	Sulfide (after converted to sulfone)	Reduction	Replacement	Conditions	Yield
	c.p.m./mg.	c.p.m./mg.	%	%		%
Diphenyl sulfone	2520	673	26.7	73.3	304°C*(30 min.)	80
	2520	641	25.4	74.6	394°C (15 min.)	
Diphenyl sulfoxide	3776	3548	94.0	6.0	280°C (30 min.)	93

* Air-bath temperature



(3)

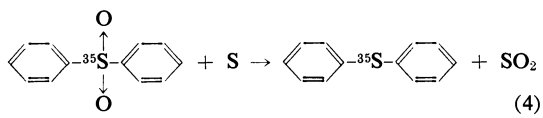
Years later, Böeseken[2] extended this reaction to *p,p'*-halogeno and *p*-bromo-*p'*-methyl derivatives of diphenyl sulfone but found that they react in entirely different manners; namely, the former gave dihalogen substituted products of benzene and sulfur dioxide and the latter only hydrogen sulfide. However, all the past observations seem to indicate that once C–S bond cleavage takes place, SO_2 group of the sulfone leaves off quite readily. In the case of *p,p'*-halogenated diphenyl sulfones, halogeno-phenyl radical formed in the sulfur-induced cleavage perhaps easily abstracts halogen from other molecule.

It is known that the force constant of S–O bond in sulfone calculated from infrared data, 9.5×10^5 dyn./cm.[3a], is appreciably higher than that of sulfoxide (7×10^5 dyn./cm.)[3a], therefore, unlike those in sulfoxide groups, the sulfur-oxygen links in sulfone groups are not easily cleaved[3b]. In this thermal reaction between diphenyl sulfone and sulfur, it is not unreasonable to consider that SO_2 group in the sulfone may be replaced by sulfur with no cleavage of S–O bonds, while the S–O link in the sulfoxide would be merely reduced with sulfur to sulfide, although the latter reaction has never been reported.

We have investigated the mechanism of these reactions by examining the accompanying exchange of sulfur atom in the reaction of sulfur-35 labeled diphenyl sulfone with ordinary sulfur. Diphenyl sulfide-^{35}S was prepared by Friedel-Crafts reaction of benzene with radioactive sulfur and was converted to the sulfone by oxidation with potassium permanganate. This diphenyl sulfone-^{35}S was treated with ordinary sulfur. The reaction was rather sluggish below 300°C but proceeded nicely at above 300°C giving diphenyl sulfide over 80% yield. The sulfide thus obtained was reoxidized back to the sulfone whose specific activity was compared with that of the original sulfone. These results are tabulated in Table I. Inspection of the data suggests that one-fourth of the over-all reaction proceeded by apparent reduction and the other three-fourths underwent by replacement as one could foresee from the reaction of diphenyl sulfone with selenium.

If one assumes that the over-all reaction is consisted with two simultaneous reactions, i.e., reduction and replacement, and that the reactions have different energies of activation, then one would expect that the ratio of two reactions may change at different temperatures. However, if the two reactions have similar temperature factors, the ratio would remain the same. When the reaction was performed nearly at the boiling temperature of sulfone, 379°C, however, no apparent difference was observed.

In the meantime the over-all reaction could be considered as a combination of two successive reactions, i.e., the initial reduction and the following sulfur exchange reaction between the sulfide and remaining sulfur as shown below:



(4)

(5)

Incidentally we found that this type of exchange (Eq. 5) actually occured when diphenyl sulfide-^{35}S was refluxed for two hours at 313°C together with natural sulfur.

2520 c.p.m./mg.* 1425 c.p.m./mg.* (56.5%) (6)

* Converted to the sulfone

Supposing the exchange rate is much faster than the reduction rate, the amount of radioactivity remained in the sulfide at the end of the reaction will be shown by the following simple equation (see appendix);

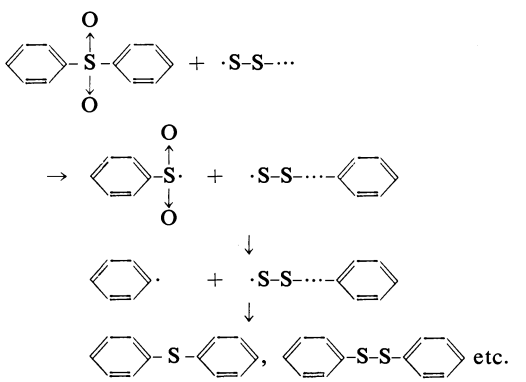
2) J. Böeseken, *Rec. trav. chim.*, **30**, 137 (1911).

3a) These values are of alkyl sulfoxides and sulfones, C. C. Price and S. Oae, "Sulfur Bonding", Ranald Press, Inc., New York (1962), p. 66; 3b) ibid., p. 132.

$$\frac{y}{a}=1-\frac{1}{e}=0.632 \qquad (7)$$

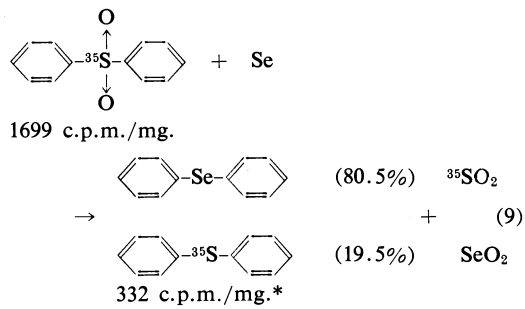
where a is the specific activity of the sulfone used and y is the specific activity of the sulfide formed. This indicates that the exchange will transport only 36.8% in total activity from the sulfide to sulfur and major portion of activity, i.e., 63.2% will remain in the sulfide. Therefore, this mechanism also cannot explain the radiochemical results.

The most likely pathway for the main reaction will be the initial cleavage of C–S bond of the sulfone, followed by the formation of diphenyl sulfide, a part of which further undergoes sulfur exchange. It is known that sulfur behaves as biradical chain at high temperature[4] and diphenyl sulfide was obtained together with by-products such as hydrogen sulfide, diphenyl disulfide, etc. when a mixture of benzene and sulfur was heated at 350°C[5]. We also found that a little amount of diphenyl disulfide and polymer-like substance formed in the reaction of diphenyl sulfone with sulfur (Eq. 1). From these facts, it is quite certain that the C–S bond of the sulfone cleaves first, induced by the biradical chain of sulfur, then sulfur dioxide leaves off and the sulfide and a small portion of the disulfide forms in the main reaction. As to the apparent reduction which amounts to about 25%, there are two possibilities, the one is a straight forward reduction that takes place simultaneously with the replacement and the other is the sulfur-exchange reaction between sulfur and diphenyl sulfide. In view of the small percentage, 6%, of replacement reaction in the case of diphenyl sulfoxide, major portion of the apparent reduction reaction of the sulfone would be the real reduction and only several percentage of the apparent reduction originate from the exchange between sulfide formed by the initial replacement and the remaining sulfur.



(8)

If the reduction takes place in parallel with the replacement, the sulfide must be formed in the reaction of diphenyl sulfone with selenium, too. In this reaction, however, diphenyl sulfide cannot be separated easily from diphenyl selenide because both the sulfur and the selenium compounds display quite similar chemical properties. To overcome this difficulty, diphenyl sulfone-^{35}S was reacted with selenium for 1 hr. at 305°C and it was found that about one-fifth of the activity of the original diphenyl sulfone-^{35}S remained in the reaction product, apparently the mixture of diphenyl selenide and sulfide. This means that the reduction indeed occured (Eq. 9).



* Converted to the sulfone and selenone

It is interesting to note that benzene or biphenyl was not found among the reaction products of the reaction between diphenyl sulfone and sulfur and biphenyl was not found in the direct reaction of benzene with sulfur[5], while the reaction of p,p'-dihalogeno diphenyl sulfone with sulfur did not give dihalogeno diphenyl sulfide, but did give dihalogeno benzene[2]. We can not offer any satisfactory explanation, however, most of phenyl radicals formed are perhaps immediately caught by sulfur chain before they recombine or abstract hydrogen in the former reaction, while halogen-substituted phenyl radicals easily abstract chlorine in the latter.

Meanwhile we found that diphenyl sulfoxide reacted readily with sulfur at lower temperature than the sulfone giving diphenyl sulfide in quantitative yield if mechanical loss was considered. A similar tracer technique was applied in this reaction, too. Diphenyl sulfoxide-^{35}S was used in this reaction which was prepared by oxidation of diphenyl sulfide-^{35}S with an equivalent amount of hydrogen peroxide and this ^{35}S-labeled sulfoxide was treated with ordinary sulfur. The reaction proceeded quite readily at around 280°C and diphenyl sulfide was obtained in nearly quantitative yield. The sulfide thus obtained was converted

5) H. B. Glass and E. E. Reid, *J. Am. Chem. Soc.*, **51**, 3428 (1929).

to diphenyl sulfone whose activity was counted. The fact that most of the activity in the original sulfoxide remained in the sulfide formed (as shown in Table I) suggests that simple reduction of sulfoxide to sulfide with elemental sulfur took place by the abstraction of labile oxygen atom with sulfur and only a small portion of the reaction proceeded by replacement contrary to the reaction of the sulfone. This is a clear cut reduction. Similar oxygen-transfer reactions from sulfoxides to divalent sulfur compounds are known. For example, thiacyclopentane-1-oxide was reacted with dibenzyl sulfide in acetic acid to give some dibenzyl sulfoxide[6], and alkyl sulfoxide is known to form when dimethyl sulfoxide and alkyl sulfide are mixed and heated at 160~175°C[7].

A small portion of the apparent replacement reaction can be interpreted either as resulted from the direct exchange between diphenyl sulfide formed and ordinary sulfur during the reaction or as the initial induced cleavage of the C–S link of the sulfoxide followed by the cleavage of S–O bond and the attack of sulfur chain, as in the case of the sulfone. At present, we have very little knowledge to select one from the other.

Experimental

Diphenyl Sulfide-^{35}S was prepared by Friedel-Crafts reaction addopted by Dougherty and Hammond[8]. Diluted and recrystallized active sulfur was added to anhydrous aluminum chloride suspended in refluxing benzene and diphenyl sulfide separated was distilled twice, obtaining oil of b. p. 115°C/2.5 mmHg.

Diphenyl Sulfoxide-^{35}S.—To the solution of 7.7 g. of diphenyl sulfide-^{35}S dissolved in glacial acetic acid containing several drops of concentrated sulfuric acid, was added an equimolar amount of 30% hydrogen peroxide slowly with cooling and stirring. Stirring was continued at room temperature for one hour and then the reaction mixture was kept at 50°C overnight. After a large amount of water added, oil separated was crystallized by adding a small piece of crystalline sulfoxide. White hard crystals was recrystallized from benzene-ligroin, obtaining 4.8 g. (57%) of the sulfoxide, m. p. 69~71°C.

Diphenyl Sulfone-^{35}S was prepared by oxidizing diphenyl sulfide-^{35}S with 1.8 times in mole of potassium permanganate in glacial acetic acid containing a few drops of concentrated sulfuric acid with cooling and stirring. After the addition was over it was warmed at 50°C for 30 min., and then an excess of potassium permanganate was reduced by bubbling sulfur dioxide through the solution. The solution was then poured into a large amount of water, and the precipitate formed was recrystallized from benzene-ligroin, yielding brilliant white crystals, m. p. 122~123.5°C, in 44%.

The Reactions of Diphenyl Sulfone with Sulfur.—Diphenyl sulfone-^{35}S (2520 c.p.m./mg.), 0.01 mol., was thoroughly mixed with 0.01 g. atom of natural sulfur in a Claisen-flask and was put quickly in a pre-heated air-bath, passing nitrogen gas through the reaction flask. Reaction started at about 300°C (air-bath temperature) and sulfur dioxide evolved was trapped in a few traps cooled with dry-ice-acetone. After 15 min. when gas evolution ceased, bath temperature was kept at around 304°C for 15 min. and then diphenyl sulfide was distilled slowly by elevating bath temperatue. When diphenyl sulfide came out, there remained a small amount of sludge insoluble in most organic solvents and water. Crude diphenyl sulfide obtained was redistilled once more, and crystals remained in the distilling flask, m. p. 59°C was found to have the same melting point with diphenyl sulfide when it was mixed with the authentic sample. Diphenyl sulfide was repeatedly distilled untill it became transparent, usually two to three times, then was converted to diphenyl sulfone using the previous method (673 c.p.m./mg.). By the same way as above diphenyl sulfone-^{35}S was treated at 394°C (air-bath temperature), and the activity for the final sulfone was found to be 641 c.p.m./mg.

The Exchange Reaction of Diphenyl Sulfide-^{35}S and Sulfur.—A mixture of diphenyl sulfide-^{35}S (2520 c.p.m./mg. converted to the sulfone), 2.32 g. and 0.39 g. of sulfur was refluxed for 2 hr. at 313°C in nitrogen atmosphere. The sulfide was recovered by distillation. Light yellow oil was redistilled once and converted into sulfone to be subjected to counting analysis (1425 c.p.m./mg.).

The Reaction of Diphenyl Sulfone-^{35}S and Selenium.—Colloidal red selenium was freshly prepared by bubbling sulfur dioxide through the water solution of selenium oxide. Diphenyl sulfone-^{35}S (1699 c.p.m./mg.) and selenium, 0.01 g. atom, respectively, was thoroughly mixed and heated in nitrogen atmosphere. Gas evolved from air-bath temperature of 288°C for 30 min. Bath temperature was kept at 304~306°C for additional 30 min. and then distilled. The oil obtained was redistilled three times, b. p. 300°C, 0.59 g. This oil was oxidized using the previous method. An excess of potassium permanganate was reduced with sulfur dioxide with cooling and it was poured into a large amount of water before oily selenide came out by reduction with excess of sulfur dioxide. After recrystallization from benzene-ligroin, m. p. 135~136°C, 0.3 g. (332 c.p.m./mg.) was obtained.

The Reaction of Diphenyl Sulfoxide with Sulfur.—Diphenyl sulfoxide-^{35}S (3776 c.p.m./mg. converted to the sulfone), 0.01 mol., was mixed with 0.005 g. atom of natural sulfur in a Claisen-flask and treated by the same way as in the reaction of the sulfone. Sulfur dioxide evolved at 280°C (air-bath temperature). The sulfide obtained in quantitative yield was converted to the sulfone (3548 c.p.m./mg.).

6) F. G. Bordwell and B. M. Pitt, ibid., **77**, 572 (1955).
7) S. Searles, Jr. and H. R. Hays, *J. Org. Chem.*, **23**, 2028 (1958).
8) G. Dougherty and P. D. Hammond, *J. Am. Chem. Soc.*, **57**, 117 (1935).

Counting Analysis. — All the compounds was converted into the sulfone or selenone and was counted by Packard, Tri-Carb, liquid scintillation counter, in toluene solution using POPOP as scintilator.

Summary

Diphenyl sulfoxide-^{35}S was reduced to the sulfide-^{35}S nearly quantitatively by heating with sulfur at 280°C, while diphenyl sulfone did not react with sulfur at the same temperature. At around 300°C, diphenyl sulfone-^{35}S started to react with sulfur and gave diphenyl sulfide that lost nearly 75% of the original activity of ^{35}S of the sulfone used. The main reaction of the sulfone was found not to be reduction, but substitution involving induced C–S cleavage and replacement with sulfur chain.

Appendix

For convenience in the discussion, the following mechanism and conditions (a—c) will be assumed in the reaction shown below, Eqs. 1 and 2.

$$\mathrm{Ph\text{-}{}^{35}S(\overset{\uparrow}{\underset{\downarrow}{O}})\text{-}Ph + S \rightarrow Ph\text{-}{}^{35}S\text{-}Ph + SO_2} \qquad (1)$$

$$\mathrm{Ph\text{-}{}^{35}S\text{-}Ph + S \rightarrow Ph\text{-}S\text{-}Ph + {}^{35}S} \qquad (2)$$

a) There is no exchange of sulfur atom between diphenyl sulfone and the sulfide or between the sulfone and sulfur.

b) The rate of sulfur exchange shown by Eq. 2 is much faster than the rate of reduction, i. e. Eq. 1.

c) Sulfur dioxide formed will escape from the system so rapidly that there is no time for sulfur dioxide to participate in sulfur-exchange reaction.

Here, let us define x as an amount (in mole) of diphenyl sulfone undergone to the sulfide, y, the specific activity (c.p.m./mol.) of the sulfide when x mol. of the sulfone is converted into the sulfide, v, total amount (in mole) of the sulfone used which is equal to total amount of sulfur or total amount of the sulfide formed in the reaction and a, the specific activity of the sulfone (c.p.m./mol.).

When $(x+\mathrm{d}x)$ mol. of the sulfone is converted to the sulfide, the total activity of the resulting sulfide will be $(xy+a\mathrm{d}x)$; therefore the specific activity will be expressed by $(xy+a\mathrm{d}x)/(x+\mathrm{d}x)$. Meanwhile, the total activity of sulfur at that time will be $[v-(x+\mathrm{d}x)]y$. After an rapid equilibrium is attained between the sulfide and sulfur by exchange, the specific activity will become

$$\frac{[v-(x+\mathrm{d}x)]y+xy+a\mathrm{d}x}{v}$$

Therefore the small variation of specific activity, $\mathrm{d}y$ can be expressed as,

$$\mathrm{d}y=\frac{[v-(x+\mathrm{d}x)]y+xy+a\mathrm{d}x}{v}-y$$

$$=(a-y)\frac{\mathrm{d}x}{v}$$

Integrating this equation, one can get

$$\ln\frac{a}{a-y}=\frac{x}{v}$$

When the reaction is completed, x becomes equal to v; therefore the above equation gives

$$y=a-\frac{a}{e}$$

The ratio of the specific activity of the sulfone and that of the sulfide, y/a, will then be

$$\frac{y}{a}=1-\frac{1}{e}=0.632.$$

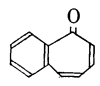
The Formation and Reactions of 3, 5, 7-Trinitrotropolone

By Tetsuo NOZOE, Minoru OYAMA* and Katsuo KIKUCHI**

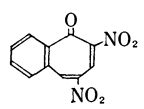
(Received September 26, 1962)

From the result of the molecular orbital calculation on tropone (I) it was predicted that the cationoid substitution reactions would occurr at 2 position of tropone nucleus[1], while the detailed studies of bromination[2] and Diels-Alder reactions[3] of I showed that it has a considerable degree of an unsaturated character compared with tropolone (II).

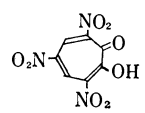
Recently Buchanan and others[4] obtained a dinitro derivative IV from the reaction of 2,3-benzotropone (III) with concentrated nitric acid, and they thought it must be produced through addition-elimination reaction of III and dinitrogen tetroxide, being produced by mutual oxidation-reduction of III and nitric acid. Doering[5], some years ago, stated in his lecture that the reaction of tropone (I) and nitric acid gave a complex (VI) of 3, 5, 7-trinitrotropolone (V) and I, but the details of which is not available yet. On the other hand, Nozoe, Kitahara and others[6] reported that the action of excess nitric acid on tropolone (II) or on ammonium salt of its 5-sulfonic acid afforded yellow needles (VII), m. p. 238°C (decomp.), and they thought it to be 3, 5, 7-trinitrotropolone, but because of its low yield, the detailed studies on its chemical behavior were not possible.



III



IV



V

As excellent methods for synthesizing tropone (I) from tropilidene were developed recently[7], we attempted to study the action of nitric acid on I as one of the wide range of examination on the properties of I. In this study, we ascertained the formation of 3, 5, 7-trinitrotropolone-tropone complex (VI) as stated by Doering[5], obtained 3, 5, 7-trinitrotropolone (V) therefrom and observed some interesting behaviors of them, and these results will be reported herein.

The reaction condition of tropone (I) and nitric acid to obtain VI is fairly sensitive. Under room temperature, the reaction does not occur practically, while once the reaction started it sometimes proceeds with explosive violence; such a case was already experienced by one[8] of us when hinokitiol was nitrated under variety of conditions. The following procedure is however found to be satisfactory; after the reaction is started by the preliminary addition of a small amount of I into a mixture of fuming nitric acid (4 mol. equiv.) and acetic acid, I (1 mol. equiv.) is added cautiously with stirring while the temperature is maintained at 60~70°C by which the yellow needles (VI), m. p. 228°C (decomp.), of the formula $C_{14}H_9O_9N_3$ are obtained in about a 55% yield.

The compound VI is sparingly soluble in non-polar solvents but very soluble in water and alcohol. With aqueous sodium bicarbonate it gives yellow sodium salt (VIII), $C_{14}H_8O_9N_3Na$, which regenerates original substance by hydrochloric acid. On being left stand at room temperature with aqueous sodium hydroxide or heated with aqueous sodium bicarbonate, VI is converted to colorless crystals (IX), m. p. 132°C (decomp.), which is identified as a 1 : 1-complex of 2, 4, 6-trinitrobenzoic acid (X) and I. VI is not affected with 4 N hydrochloric acid in acetone at refluxing temperature, but gives X when heated with concentrated hydrochloric or hydrobromic acid, and gives 1, 3, 5-trinitrobenzene (XI) when refluxed with aqueous acetic acid (50%). Heating of VI in methanol or ethanol affords methyl ester XII or ethyl ester XIII of X, with the liberation of tropone (I) which is identified as its picrate, m. p. 99~100°C. These facts indicate

that VI is 1 : 1-complex of 3, 5, 7-trinitrotropolone (V) and tropone (I) and it is thought to be identical with what Doering stated to have obtained[5].

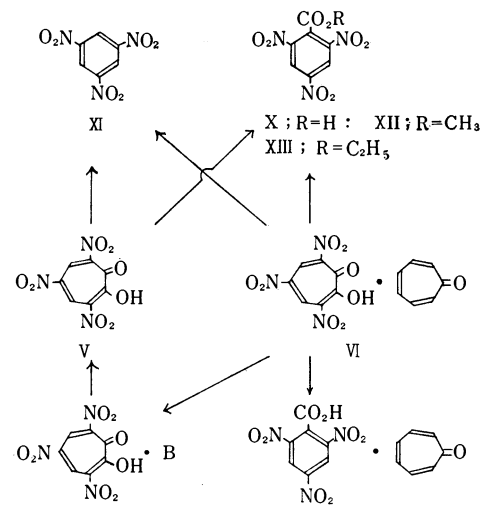
As mentioned above, the treatment of VI with sodium hydroxide or sodium bicarbonate did not yield V, and then the attempt was made to obtain salts of various amines through which V could be obtained as described below.

Treatment of the complex VI with ammonia gives red microcrystals which, when treated with dilute hydrochloric acid, is converted to yellow needles (XIV), m. p. 235°C (decomp.). Similarly, respective treatment of VI with methylamine and pyridine gives yellow needles (XV), m. p. 203°C (decomp.) and yellowish orange needles (XVI), m. p. 201°C (decomp.), respectively. From the fact that the ultraviolet spectra of XIV, XV and XVI resemble that of V (see below) and from the analytical values of them, these are showed to be 1 : 1-salts of V with ammonia, methylamine and pyridine respectively. By the reaction of VI with *p*-toluidine, there are obtained yellow needles (XVII), m. p. 123°C (decomp.) which is thought to be 1 : 1 : 1-complex of V, I and *p*-toluidine from the analytical value and ultraviolet spectrum.

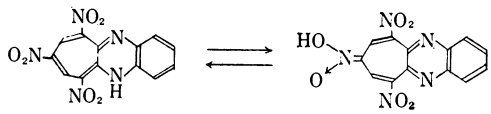
Attempted removal of bases from XIV or from XV with dilute hydrochloric acid does not succeed and heating of XV at 160°C under reduced pressure (4 mmHg) also resulted in the recovery of original substance. But, when pyridinium salt XVI is treated with concentrated hydrochloric acid at room temperature, 3, 5, 7-trinitrotropolone (V) is obtained in about 80% yield with the addition of a small amout of the rearranged product X. Similar treatment of XIV or XV with concentrated hydrochloric acid also gives V but with rather poor yields. Treatment of V and I regenerates VI.

The compound V, yellow needles of m. p. 175°C (decomp.), shows red coloration with ferric chloride in ethanol or dioxane though not colored in water, benzene or chloroform, and gives yellowish orange sodium salt and a yellowish green copper complex. No liberation of nitrogen is observed when treated of V with diazomethane and only a small amount of yellow crystals of unknown structure is obtained. Heating of V with concentrated hydrochloric acid or with sodium hydroxide gives X, and refluxing of V with aqueous acetic acid (50%) gives XI. Treatment of V with methanol or ethanol gives XII or XIII respectively ; these properties are quite similar to those of VI.

The reaction of *o*-phenylenediamine with the compound V or with VI gives dark red crystals (XIX), m. p. over 240°C, soluble in alkaline solution, which is thought to be 6, 8,-



10-trinitrocyclohepta[b]quinoxaline from its analytical value and ultraviolet spectrum[9]. Attempted synthesis of 1, 3-diazaazulene derivative through the reaction of V or VI with guanidine gives only guanidinium salt (XX) of V, yellowish brown needles of m. p. 258°C (decomp.). Heating of V with aniline on a water bath gives colorless scales (XXI), m. p. 245.5°C, the structure of which is not clarified yet.



XIX

It seems of interest to note that the compound V, while it is easily rearranged into aromatic compounds on treatment with acid or alkali and on mere heating with alcohols, forms stable salts with various amines.

Ultraviolet spectra of V in methanol and alkaline solution are shown in Fig. 1 ; the absorption curve in methanol resembles those of 5-nitro-[5] and 3, 5-dinitrotropolones[6]. The ultraviolet absorption curve of VI (shown in Fig. 1) corresponds to a superposition of those of V and I. The infrared spectrum of V in Nujol is given in Fig. 2.

Now, the compound VII[6], previously obtained by the nitration of tropolone (II) is considered not to be true 3, 5, 7-trinitrotropolone. We reexamined these experiments and found that

9) S. Ito, *Sci. Repts. Tohoku Univ., Ser. I*, 43. 216 (1959).

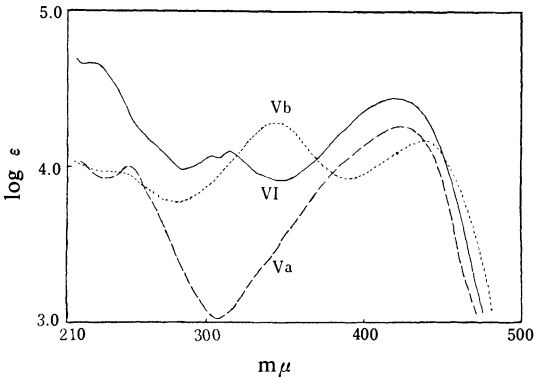


Fig. 1. UV spectra of V in methanol (Va) and in methanolic 0.1 N NaOH (Vb) and of VI in methanol.

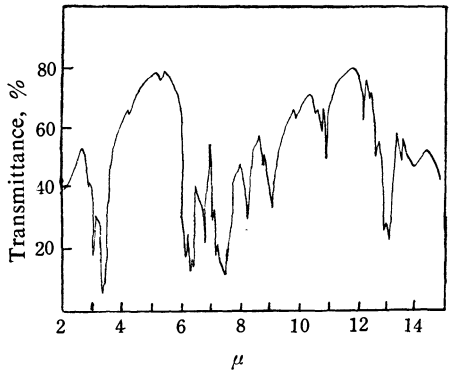

Fig. 2. IR spectrum of V in Nujol.

the fraction, considered to be polynitrotropolone, gave a small amount of the compound VI on adding tropone (I), but the compound VII could not be isolated; in this reaction condition trinitrotropolone once formed must have suffered from further destructive oxidation or rearrangement. On the other hand, the present synthetic procedure for V starting from I is excellent because it is easily isolated as a stable and sparingly soluble complex VI with tropone.

As to the formation of the complex VI from I, two main routes may be considered; one in which VI is formed through the addition-elimination reaction on tropone nucleus and the other in which VI is formed by the preliminary oxidation of I to tropolone (II) followed by the nitration. If the latter is the case, a distinct increasing in the yield of VI may be expected when the mixture of I and II is nitrated under similar conditions, but only slight increasing is actually realized, while the intermediate addition product that might be expected to be formed in the former case is not actually isolated, and the mechanism of its formation remains to be examined.

It is well known from the previous examination that 4-alkyl-5, 7-dinitrotropolones (XXII: R; CH_3[10], C_2H_5[11], *iso*-C_3H_7[12]) are easily rearranged into 3-alkyl-4, 6-dinitrobenzoic acids or their esters by mere warming with various alcohols or with aqueous acetic acid, while 5, 7-dinitrotropolones having substituent at 3 position (XXIII: R; H[6], Br[6], *iso*-C_3H_7[13]) are not rearranged in these conditions as above though they do in alkaline media, and it has been considered that in such rearrangement reactions steric interference between an alkyl group in 4 position and a nitro group in 5 position plays an important role. It seems noteworthy to say that 3, 5, 7-trinitrotropolone (V), having no such substituents at 4 position as to cause steric interaction, is now shown to undergo such a specific rearrangement.

XXIII

Experimental

Reaction of Tropone (I) with Nitric Acid.—After the reaction was induced at 60~70°C by adding several drops of I to a mixture of 14 g. of 94% fuming nitric acid and 15 ml. of acetic acid, a solution of 5 g. of I dissolved in 5 ml. of acetic acid was carefully added to this mixture with stirring while the reaction temperature was maintained at 60~70°C by external cooling. After a violent evolution of nitrogen dioxide ceased, the crystals that formed were collected by filtration to obtain 3.2 g. of yellow crystals, m. p. 218°C (decomp.). Recrystallization from dioxane containing a small amount of water gave yellow needles (VI), m. p. 228°C (decomp.). These crystals showed red coloration in ethanol or dioxane with ferric chloride solution. λ_{max}^{MeOH} mμ (log ε): 225 (4.66), 302 (4.08), 310 (4.09), 420 (4.42); $\lambda_{max}^{H_2O}$ mλ (log ε): 228 (4.49), 313 (3.98), 422 (4.27).

Found: C, 46.22; H, 2.33; N, 11.69. Calcd. for $C_{14}H_9O_9N_3$: C, 46.29; H, 2.50; N, 11.57%.

The filtrate was evaporated under reduced pressure at room temperature and 0.6 g. of colorless crystals, m. p. 97~98°C, was obtained. These crystals were reacted with ethereal diazomethane solution to give colorless crystals, m. p. 54°C., which showed no depression on admixture with dimethyl oxalate.

Nitration of a Mixture of Tropone (I) and Tropolone (II) with Nitric Acid.—To a solution

of 4.0 g. of 94% nitric acid (6 mol. equiv. for II) dissolved in 5 ml. of acetic acid was added a mixture of 1.0 g. of I and 1.2 g. of II in 5 ml. of acetic acid in drops under stirring at 30~40°C, and the reaction mixture was allowed to stand for 3 hr. and the yellow crystals were collected by filtration to afford 1.49 g. of VI, m. p. 224°C (decomp.), which showed no depression on admixture with the sample obtained above and the infrared spectra were also identical.

Reaction conditions and the yields of VI were shown in Table I.

Table I. Nitration of mixture of tropone (I) and tropolone (II) with 94% nitric acid

I g.	II g.	Nitric acid g.	React. temp. °C	Yield of VI g.
5.0	0	14	60~70	3.2
1.0	1.2	2.7	40~50	0.63
1.0	1.2	2.7	60~70	0.41
1.0	1.2	4.0	30~40	1.49
1.0	1.2	5.4	30~40	1.27

Reaction of the Compound VI and Aqueous Sodium Bicarbonate or Sodium Hydroxide.—a) Addition of 300 mg. of VI in 2 ml. of saturated aqueous sodium bicarbonate gave deep red solution, and the crystals that precipitated after sometime were collected by filtration and washed with a small amount of water to give 200 mg. of yellow prisms (VIII), m. p. 185°C (decomp.). $\lambda_{max}^{H_2O}$ mμ (log ε): 228 (4.56), 313 (4.08), 420 (4.24), 500 (inf.). $\lambda_{max}^{0.1N\text{-}NaOH}$ mμ (log ε): 224 (4.56), 304 (4.25), 442 (4.27).

Found: C, 43.65; H, 2.35; N, 10.70; Na, 5.54. Calcd. for $C_{14}H_8O_9N_3Na$: C, 43.65; H, 2.09; N, 10.91; Na, 5.97%.

Acidification of an aqueous solution of 50 mg. of VIII with 2 N hydrochloric acid gave 30 mg. of yellow crystals, m. p. 220°C (decomp.). Recrystallization from dioxane containing a small amount of water gave yellow needles, m. p. 228°C (decomp.), which were shown to be identical, by a mixed melting point and the infrared spectra, with VI.

b) A mixture of 200 mg. of VI and 6 ml. of saturated sodium bicarbonate solution was heated for 10 min. on a water bath, and the reaction mixture was acidified with 2 N hydrochloric acid and extracted with ether. The solvent was evaporated from the extract, and 150 mg. of a brown residue thereby obtained was recrystallized from benzene to give 1:1-complex IX of 2, 4, 6-trinitrobenzoic acid and tropone (I) as colorless microneedles, m. p. 132°C (decomp.). The mixed melting point with an authentic sample which was obtained by mixing these two components was not depressed and the infrared spectra were identical. λ_{max}^{MeOH} mμ (log ε): 225 (4.63), 301 (4.10).

Found: C, 46.31; H, 2.43; N, 12.17. Calcd. for $C_{14}H_9O_9N_3$: C, 46.29; H, 2.50; N, 11.57%.

c) A mixture of 200 mg. of VI and 4 ml. of aqueous sodium hydroxide solution was allowed to stand at room temperature for 30 min. The reaction mixture was acidified with 2 N hydrochloric acid, extracted with benzene and the solvent was removed from the extract to give 150 mg. of colorless crystals, m. p. 130°C (decomp.). Recrystallization from a mixture of acetone and benzene gave colorless microneedles, m. p. 132°C (decomp.), identical with IX obtained above.

Reaction of VI and Hydrochloric or Hydrobromic Acid.—a) A mixture of 90 mg. of VI and 2 ml. of concentrated hydrochloric acid was heated at 60~70°C for 30 min., cooled and 40 mg. of colorless crystals, m. p. 195°C (decomp.), that obtained was recrystallized from water to give colorless microneedles (X), m. p. 198°C (decomp.). The mixed melting point with an authentic sample of 2, 4, 6-trinitrobenzoic acid was not depressed and the infrared spectra were identical.

b) Heating of VI and 47% hydrobromic acid at the refluxing temperature for 2 hr. also gave X.

Reaction of VI and Aqueous Acetic Acid.—A mixture of 150 mg. of VI and 2 ml. of 50% aqueous acetic acid was refluxed for 5 hr., cooled and 70 mg. of colorless crystals, m. p. 120°C that obtained was recrystallized from the same solvent to afford colorless microneedles (XI), m. p. 120~121°C. These crystals showed no depression of the melting point on admixture with 1, 3, 5-trinitrobenzene and the infrared spectra were identical.

Reaction of VI and Methanol or Ethanol.—a) A mixture of 50 mg. of VI and 2 ml. of methanol was refluxed for 1 hr., the solution was concentrated and the crystals thereby obtained were collected by filtration to give colorless scales (XII), m. p. 157°C. These crystals showed no depression of the melting point on admixture with methyl 2, 4, 6-trinitrobenzoate and the infrared spectra were also identical.

b) Similar treatment of 30 mg. of VI and 2 ml. of ethanol as in the reaction of VI and methanol gave 15 mg. of colorless scales (XIII), m. p. 154°C, which showed no depression of the melting point on admixture with ethyl 2, 4, 6-trinitrobenzoate and the infrared spectra were identical.

Separation of Tropone (I) from the Complex VI.—A solution of 300 mg. of VI in ethanol was passed through an alumina column and the solvent was evaporated from the elute. The residue was dissolved in a mixture of ether and benzene and the solution was washed with 6 N hydrochloric acid. The aqueous layer was neutralized with sodium bicarbonate, extracted with chloroform and the solvent was removed from the extract to give 45 mg. of pale yellow oil (λ_{max}^{MeOH}: 225, 302 mμ) which afforded a picrate as yellow needles, m. p. 99~100°C. These crystals showed no depression of the melting point on admixture with an authentic sample of tropone picrate.

The solvent was removed from the original benzene-ether solution and the pale yellow crystals that were obtained were recrystallized from ethanol to afford 120 mg. of colorless scales, m. p. 154°C, undepressed on admixture with the authentic sample of XIII.

Reaction of VI and Aqueous Ammonia.—To the suspension of 100 mg. of VI in 1 ml. of ethanol was added 0.2 ml. of 28% aqueous ammonia and the precipitate thereby formed was collected by

filtration and washed with ethanol to give 70 mg. of red crystals which did not show a clear melting point.

The solution of 70 mg. of these red crystals in 1 ml. of water was acidified with concentrated hydrochloric acid and 50 mg. of yellow needles, m. p. 228°C (decomp.), that were obtained was recrystallized from a mixture of acetone and benzene to give 20 mg. of yellow needles (XIV), m. p. 235°C (decomp.). These crystals showed red coloration with ferric chloride in ethanol. λ_{max}^{MeOH} mμ (log ε) : 245 (4.18), 420 (4.40).

Found : C, 30.46; H, 2.25; N, 20.06. Calcd. for $C_7H_6O_8N_4$: C, 30.67; H, 2.21; N, 20.44%.

Reaction of VI and Methylamine Hydrochloride.—A mixture of 40 mg. of methylamine hydrochloride, 200 mg. of VI, 2 ml. of ethanol and 1 ml. of water was refluxed for 30 min., the solution was concentrated and 140 mg. of yellow crystals, m. p. 191°C (decomp.), was obtained. Recrystallization from a mixture of ethanol and benzene gave yellow needles (XV), m. p. 205°C (decomp.). λ_{max}^{MeOM} mμ (log ε) : 243 (4.25), 420 (4.40).

Found : C, 32.64; H, 2.75; N, 18.66. Calcd. for $C_8H_8O_8N_4$: C, 33.34; H, 2.80; N, 19.44%.

Reaction of VI and Pyridine.—A mixture of 50 mg. of VI and 0.2 ml. of pyridine was heated for several minutes on a boiling water bath and benzene was added to the mixture to precipitate orange crystals, m. p. 197~198°C (decomp.). Yield 40 mg. Recrystallization from a mixture of ethanol and pyridine gave yellowish orange needles (XVI), m. p. 201°C (decomp.). λ_{max}^{MeOH} mμ (log ε) : 245 (4.16), 422 (4.36).

Found : C, 43.23; H, 2.36; N, 16.62. Calcd. for $C_{12}H_8O_8N_4$: C, 42.86; H, 2.40; N, 16.67%.

Reaction of VI and *p*-Toluidine.—A mixture of 200 mg. of VI, 60 mg. of *p*-toluidine and 3 ml. of ethanol was refluxed for 30 min., the solvent was removed and a reddish brown oily residue that was obtained was extracted with hot benzene. The benzene extract gave 120 mg. of yellow crystals, m. p. 119~120°C, which was recrystallized from benzene to give yellow needles (XVII), m. p. 123°C. λ_{max}^{MeOH} mμ (log ε) : 232 (4.62), 300 (4.63), 420 (4.40).

Found : C, 53.97; H, 3.97; N, 11.18. Calcd. for $C_{21}H_{18}O_9N_4$: C, 53.62; H, 3.86; N, 11.91%.

Separation of 3, 5, 7-Trinitrotropolone (V) from Amine Salts of V.—a) Trituration of 1.3 g. of pyridinium salt XVI with 20 ml. of concentrated hydrochloric acid at room temperature gave a clear solution from which yellow crystals were reprecipitated. After the mixture was allowed to stand for one hour the crystals were collected by filtration to obtain 0.82 g. of yellow microneedles (V), m. p. 178°C (decomp.). Recrystallization was carried out from benzene but with some difficulty. These crystals showed red coloration in ethanol or dioxane with ferric chloride, but not colored in water, benzene or chloroform. λ_{max}^{MeOH} mμ (log. ε) : 245 (4.20), 420 (4.40).

Found : C, 32.66; H, 1.29; N, 15.63. Calcd. for $C_7H_3O_8N_3$: C, 32.70; H, 1.18; N, 16.34%.

Na Salt.—Yellow microprisms, m. p. 133°C (decomp.).

Cu Complex.—Yellowish green crystals, m. p. over 300°C.

The original filtrate was extracted with ether and the solvent was removed from the extract to give 110 mg. of yellow crystals, m. p. 203~206°C (decomp.). Addition of a solution of 50 mg. of tropone in ether to these crystals, extraction with hot benzene followed by the removal of the solvent gave 80 mg. of IX, m. p. 132°C, and 20 mg. of VI, m. p. 221°C (decomp.).

b) Similar treatment of 30 mg. of ammonium salt XIV with 0.3 ml. of concentrated hydrochloric acid as in the case of a) gave 10 mg. of yellow needles (V), m. p. 178°C (decomp.).

c) Similar treatment of 150 mg. of salt (XV) with 1 ml. of concentrated hydrochloric acid gave 95 mg. of yellow needles (V), m. p. 178°C (decomp.).

Reaction of V and I.—To a solution of 50 mg. of V dissolved in 5 ml. of ether was added 30 mg. of I, and the yellow crystals thereby precipitated were collected by filtration and washed with benzene to give 68 mg. of yellow needles, m. p. 227°C (decomp.). The mixed melting point with authentic sample of VI was not depressed and the infrared spectra were identical.

Reaction of V and Diazomethane.—To a solution of 100 mg. of V in 15 ml. of ether was added an equivalent amount of ethereal diazomethane. No evolution of nitrogen gas occurred though transient red coloration was observed on mixing both solutions. Yellow crystals which precipitated were collected by filtration to give 30 mg. of yellow needles which sintered at about 80°C and decomposed at 170°C, but the purification was not possible.

Reactions of V with Acids, Alkali and Alcohols.—*a) Hydrochloric Acid.*—A mixture of 50 mg. of V and 2 ml. of concentrated hydrochloric acid was refluxed for one hour to give 40 mg. of colorless needles (X), m. p. 204~205°C (decomp.).

b) Aqueous Acetic Acid.—Similar treatment of 50 mg. of V and 2 ml. of 50% aqueous acetic acid as in the reaction of VI and the same acid gave colorless needles (XI), m. p. 120~121°C.

c) *Sodium Hydroxide Solution.*—A mixture of 100 mg. of V and 1 ml. of 2 N sodium hydroxide solution was heated for 2 min. on a water bath and acidified with 2 N hydrochloric acid to obtain 90 mg. of orange crystals, m. p. 188°C (decomp.). Recrystallization from a mixture of benzene and ethanol gave colorless crystals (X), m. p. 194°C (decomp.).

d) Methanol.—Similar treatment of 50 mg. of V with 2 ml. of methanol as in the case of VI gave 25 mg. of colorless scales (XII), m. p. 157°C.

e) Ethanol.—Similar treatment of 30 mg. of V with 2 ml. of ethanol as in the case of VI afforded 25 mg. of colorless scales (XIII), m. p. 154°C.

Reaction of V and VI with *o*-Phenylenediamine.—a) A mixture of 200 mg. of VI, 60 mg. of *o*-phenylenediamine and 2 ml. of ethanol was refluxed for 10 min. and the precipitates thereby formed were collected by filtration and washed with ethanol to afford 140 mg. of a dark reddish violet amorphous solid (XIX), m. p. over 240°C. These

crystals were sparingly soluble in usual organic solvents, but soluble in aqueous sodium hydroxide solution. λ_{max}^{MeOH} mμ (log ε) : 236 (4.54), 321 (3.92), 480 (4.35).

Found : C, 47.73 ; H, 2.35. Calcd. for $C_{13}H_7O_6N_5$: C, 47.42 ; H, 2.14%.

b) Similar treatment of 100 mg. of V as in the case of a) gave 100 mg. of XIX, m. p. over 240°C.

Reaction of V and VI with Guanidine Sulfate.—a) To a mixture of 65 mg. of guanidine sulfate and 50 mg. of sodium methoxide in 2 ml. of methanol was added 200 mg. of VI. The mixture was refluxed for one hour, diluted with 10 ml. of water and 150 mg. of yellow crystals, m. p. 253°C (decomp.), that was obtained, was recrystallized from methanol to give 120 mg. of yellowish brown needles (XX), m. p. 258°C (decomp.). λ_{max}^{MeOH} mμ (log ε) : 245 (4.18), 423 (4.43).

Found : C, 30.73 ; H, 2.41 ; N, 26.51. Calcd. for $C_8H_8O_8N_6$: C, 30.39 ; H, 2.55 ; N, 26.58%.

b) Similar treatment of 100 mg. of V as in the case of a) afforded 110 mg. of XX, m. p. 258°C (decomp.).

Reaction of V and Aniline.—A mixture of 100 mg. of V and 0.5 ml. of aniline was heated for one hour on a water bath and the crystals that precipitated were collected by filtration to afford 55 mg. of pale yellow scales, m. p. 244°C. Recrystallization from acetone gave colorless scales, m. p. 245.5°C. λ_{max}^{MeOH} 275 mμ.

Found : C, 70.29 ; H, 4.69 ; N, 11.31%.

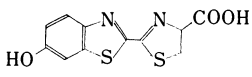
Cycloheptathiazole Derivatives. II. Synthesis of a Seven-membered Analog of Firefly Luciferin

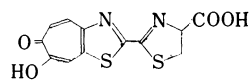
By Shuichi SETO, Kyozo OGURA and Yukio NISHIYAMA

(Received November 17, 1962)

In the preceding paper of this series[1], syntheses of cyclohepta[d]thiazole derivatives from 3-bromo-5-aminotropolone were described. As a further investigation of this series, the synthesis of a seven-membered analog of firefly luciferin[2] was reported. Since tropolone is similar to phenol in their chemical properties, it would be interesting from the point of biological actions to synthesize such a compound as II which has a tropolone ring in place of the phenol ring in luciferin (I).



I

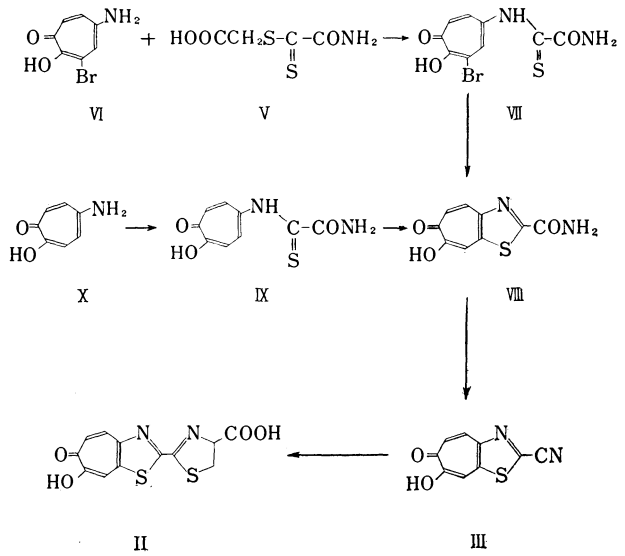


II

For this purpose the preparation of 2-cyano-7-hydroxycyclohepta[d]thiazol-6-one (III) is desirable, for it can be expected that III reacts with cysteine to afford II in the same manner described in the synthesis of I [2,3]. 2-Amino-7-hydroxycyclohepta[d]thiazol-6-one (IV) which has been easily obtained[1] seems apparently suitable for the starting material, but application of Sandmeyer reaction on IV was not successful. As the authors found a convenient method of carbamoylthiocarbonylation of aromatic amines by using carbamoylthiocarbonylthioacetic acid (V), this method was applied to 3-bromo-5-aminotropolone (VI). The reagent V reacted with VI in alkaline solution at room temperature, and *N*-(3-bromotropolon-5-ylthiocarbamoyl)carbamide (VII) was obtained. It shows absorption bands at 3390, 3240 and 1706 cm^{-1} due to its amide group.

Treatment of VII with pyridine resulted in intramolecular nucleophilic reaction[1] to give 2-carbamoyl-7-hydroxycyclohepta[d]thiazol-6-one (VIII). The structure of VIII was confirmed by comparison of its infrared and ultraviolet absorption spectra with those of

1) S. Seto, Y. Nishiyama and K. Ogura, This Bulletin, 35, 1998 (1962).
2) E. H. White, F. McCapra, G. F. Field and W. D. McElroy, *J. Am. Chem. Soc.*, 83, 2402 (1961).
3) S. Seto, K. Ogura and Y. Nishiyama, This Bulletin, in press.



cycloheptathiazole derivatives obtained previously[1]. The amide VIII could be also prepared by the action of bromine to a pyridine solution of *N*-(tropolon-5-ylthiocarbamoyl)carbamide (IX) which was obtained by the reaction of 5-aminotropolone (X) and the reagent V. Infrared spectrum of VIII exhibits absorption at 3370, 1690 and 1665 cm^{-1} for its amide residue, and other absorption bands correspond to those of the known cycloheptathiazole derivatives[1]. Reaction of VIII with phosphorus oxychloride gave 2-cyano-7-hydroxycyclohepta-[d]thiazol-6-one (III), which showed absorptions at 3190 and 2230 cm^{-1} due to a hydroxyl group on tropolone nucleus and a cyano group respectively. The reaction of III with D-cysteine proceeded smoothly in the same way as in the case of 2-cyano-6-hydroxybenzothiazole[2,3], and the analog II was obtained as pale yellow granular crystals. II shows absorption bands at 3200 cm^{-1} for a hydroxyl group in tropolone ring and at 2600 (broad) and 1734 cm^{-1} for a carboxyl group. Ultraviolet spectrum of II is similar to those of III, VIII and other cycloheptathiazoles obtained previously[1].

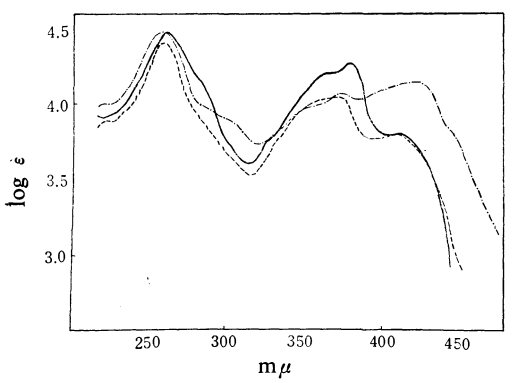


Fig. 1. Ultraviolet spectra of II(——), III(·-·-) and VIII(----) in methanol.

Alkaline solutions of 2-cyano-6-hydroxybenzothiazole and luciferin exhibit greenish blue luminescence on exposure to ultraviolet light[3], while neither II nor III shows such property.

Experimental*

***N*-(3-Bromotropolon-5-ylthiocarbamoyl)carbamide (VII).**—To a solution of VI (500 mg.) in aqueous potassium hydroxide (potassium hydroxide, 130 mg.; water, 2 ml.), the reagent V prepared from 800 mg. of trichloroacetamide was added, and the mixed solution was allowed to stand at room temperature overnight. Orange crystals that formed was collected, and it was acidified with 6 N sulfuric acid to give yellow powder, which was collected, washed well with hot methanol, 200°C (darken). Yield, 270 mg. Evaporation of the methanol filtrate gave 130 mg. of the starting material VI. λ_{max}^{MeOH} mμ (log ε) : 253 (4.34), 420 (4.23).

Found: C, 35.52; H, 2.46; N, 8.56. Calcd. for $C_9H_7O_3N_2SBr$: C, 35.62; H, 2.31; N, 9.24%.

2-Carbamoyl-7-hydroxycyclohepta[d]thiazol-6-one (VIII).—a) When a solution of VII (270 mg.) in pyridine (4.2 ml.) was allowed to stand at room temperature for two days, yellow crystals deposited. The crystals were collected, washed with pyridine, water and hot methanol to afford pale yellow prisms, m. p. 317~325°C (decomp.). Yield, 100 mg. λ_{max}^{MeOH} mμ (log ε) : 258 (4.41), 370 (4.05), 410 (3.80).

Found: C, 48.19; H, 2.96; N, 12.13: Calcd. for $C_9H_6O_3N_2S$: C, 48.66; H, 2.72; N, 12.61%.

b) When a solution of bromine (30 mg.) in pyridine (0.5 ml.) was added to a suspension of IX (40 mg.) in pyridine (3 ml.), the whole was dissolved to form

* All melting points were uncorrected. The microanalyses were carried out by misses Yôko Endô and Yukiko Endô of this Institute, to whom the authors are indebted.

a dark red solution. After the solution was allowed to stand at room temperature for 3 days, pale yellow crystals separated out. The crystals were collected, washed with pyridine, water and hot methanol. Yield, ca. 5 mg.

***N*-(Tropolon-5-ylthiocarbamoyl) carbamide (IX).** —To a solution of X (100 mg.) was added, and the mixed solution was allowed to stand at room temperature for two days. The crystals that formed were collected and acidified with 6 N hydrochloric acid to give yellow powder. Recrystallization from ethanol afforded yellow needles, m. p. 215~220°C (decomp.). λ_{max}^{MeOH} mμ (logε) : 228 (4.36), 305 (3.95), 380 (4.07). IR 3370, 3270, 1692 cm^{-1} (KBr).

Found : C, 48.88 ; H, 3.57 ; N, 12.24. Calcd. for $C_9H_8O_3N_2S$: C, 48.22 ; H, 3.60 ; N, 12.50%.

2-Cyano-7-hydroxycyclohepta[d]thiazol-6-one (III).—A mixture of VIII (50 mg.) in phosphorus oxychloride (2 ml.) was refluxed for 2 hr. During this time the mixture turned dark brown. After removal of an excess of phosphorus oxychloride under a reduced pressure, cracked ice was added to the residue and the precipitate was collected. It was sublimed in reduced pressure (4 mmHg) at 140°C and the sublimate was recrystallized from ethanol to afford pale yellow needles, m. p. 211~215°C (decomp.) Yield, 20 mg. λ_{max}^{MeOH} mμ (logε) : 255 (4.48), 375 (4.07), 420 (4.15).

Found : C, 52,98 ; H, 2.33 ; N, 13.90. Calcd for $C_9H_4O_2N_2S$: C, 52.92 ; H, 1.97 ; N, 13.72%.

2-(4'-Carboxy-2'-thiazolin-2'-yl)-7-hydroxycyclohepta[d]thiazol-6-one (II). — A mixture of III (40 mg.), potassium carbonate (30 mg.), D-cysteine hydrochloride (40 mg.) in 50% aqueous methanol (2 ml.) was stirred under nitrogen stream for 1.5 hr. After removal of methanol in a reduced pressure the mixture was filtered to remove a small amount of insoluble substance. The precipitate which was formed by neutralization with dilute hydrochloric acid was collected, washed with hot benzene and recrystallized from ethanol to afford pale yellow crystals, m. p. 198~201°C (decomp.). Yield, ca. 5 mg. λ_{max}^{MeOH} mμ (logε) : 260 (4.48), 370(4.20), 380 (4.27).

Found : C, 46.23 ; H, 3.08 ; N, 9.35. Calcd. for $C_{12}H_8O_4N_2S$: C, 46.76 ; H, 2.62 ; N, 9.09%.

The Kinetics of Substitution Reactions Involving Metal Complexes. VII. Effect of Acetate Ions on the Reaction between Lead(II) and Zinc-Ethylenediaminetetraacetate Complexes

By Nobuyuki TANAKA and Hiroshi OGINO

(Received September 28, 1962)

Recent studies on a series of substitution reactions between metal ions and metal-ethylenediaminetetraacetate (EDTA) complexes in acetate buffer solutions[1-5] have revealed that these reactions proceed through both the hydrated metal ions and the metal acetato complexes. The reaction through acetato complexes was suggested in some of the previous papers[1-3], while in the others it was treated somewhat quantitatively by the approximate method[4,5].

In this study, a rigorous treatment of the effect of acetate ions on the substitution reaction has been developed and applied to the reaction between lead(II) ions and zinc-EDTA complexes. The reaction mechanisms which involve reaction paths through hydrated ions and those through acetato complexes have been assumed and the rate constants for the rate-determining steps in those reaction paths have been determined.

Experimental

Reagents.—The preparation of the solutions of lead(II) nitrate and disodium ethylenediaminetetraacetate was described in the previous papers[2,6]. A solution of zinc nitrate was prepared by dissolving an appropriate amount of pure zinc metal in nitric acid, and standardized amperometrically against

the standardized EDTA solution. All other chemicals used were of analytical reagent grade.

Apparatus and Procedure.—The rate of the reaction between lead(II) ions and zinc-EDTA complexes was followed by measuring the decrease of the polarographic diffusion current of lead(II) ions with time in acetate buffer solutions. For the measurements of the current-time curves, a Yanagimoto PB-4 pen-recording polarograph was used. A dropping mercury electrode used had an m value of 2.12 mg./sec. and a drop time t_d of 3.92 sec., being measured at −0.60 V. vs. SCE in an air-free 0.2 M potassium nitrate solution containing 0.01% gelatin at 25.0°C. The pH of the solution was measured accurately with a Hitachi EHP-1 pH meter, after the measurement of the current-time curves. Ionic strength of the solution was adjusted to be 0.2 with potassium nitrate, and gelatin was added as a maximum suppressor by 0.01% in concentration. All measurements were carried out at 25.0°C.

Results and Discussion

In the solution containing acetate ions up to 0.2M in concentration, lead(II) forms mono- and diacetato complexes, whereas zinc(II) forms only a monoacetato complex[7]. The overall substitution reaction between lead(II) and zinc-EDTA complexes is written as the following:

$$\left\{\begin{matrix}Pb^{2+}\\ \downarrow\uparrow\\ PbOAc^{+}\\ \downarrow\uparrow\\ Pb(OAc)_2\end{matrix}\right\} + ZnY^{2-} \rightleftharpoons PbY^{2-} + \left\{\begin{matrix}Zn^{2+}\\ \downarrow\uparrow\\ ZnOAc^{+}\end{matrix}\right\} \quad (1)$$

where Y^{4-} denotes a tetravalent EDTA anion.

When both zinc ions and zinc-EDTA complexes are present in a large excess over lead ions, the substitution reaction 1 can be treated as a pseudo-first-order reaction,

$$\left\{\begin{matrix}Pb^{2+}\\ \downarrow\uparrow\\ PbOAc^{+}\\ \downarrow\uparrow\\ Pb(OAc)_2\end{matrix}\right\} \underset{k^-}{\overset{k^+}{\rightleftharpoons}} PbY^{2-} \quad (2)$$

The rate equation for the reaction 2 is expressed as[1]

$$-\frac{d[Pb^{2+}]_{app}}{dt} = k^+[Pb^{2+}]_{app} - k^-[PbY^{2-}] \quad (3)$$

where $[Pb^{2+}]_{app}$ is the concentration of lead(II) that can be determined polarogaphically as the simple ion, and given by the equation

$$[Pb^{2+}]_{app} = [Pb^{2+}] + [PbOAc^{+}] + [Pb(OAc)_2] \quad (4)$$

Integrating Eq. 3,

$$\ln\{[Pb^{2+}]_{app} - [Pb^{2+}]_{e,app}\} = -(k^+ + k^-)t + \ln\{[Pb^{2+}]_{0,app} - [Pb^{2+}]_{e,app}\} \quad (5)$$

is obtained, where subscripts 0 and e represent the initial and the equilibrium conditions, respectively. The left-hand side of Eq. 5 is plotted against time and from the slope the value of $(k^+ + k^-)$ is determined. At the equilibrium of the reaction, the relation

$$\frac{k^+}{k^-} = \frac{[PbY^{2-}]_e}{[Pb^{2+}]_{e,app}} \fallingdotseq K^{Pb}_{Zn,app}\frac{[ZnY^{2-}]_0}{[Zn^{2+}]_{0,app}}$$

may be satisfied, where $K^{Pb}_{Zn,app}$ represents the apparent equilibrium constant for reaction 1 expressed as

$$K^{Pb}_{Zn,app} = \frac{[Zn^{2+}]_{e,app}[PbY^{2-}]_e}{[Pb^{2+}]_{e,app}[ZnY^{2-}]_e}$$

The values of $K^{Pb}_{Zn,app}$ were determined polarographically to be 10.3 and 5.0 in acetate buffer solutions which contain 0.05M and 0.1M of acetate ions, respectively.

The apparent rate constants of the forward reaction 1, $k^+/[ZnY^{2-}]_0$, were obtained at various pH's and at two different concentrations of Zn(II) and acetate ions. The plots of $k^+/[ZnY^{2-}]_0$ versus $[H^+]$ gave straight lines as shown in Fig. 1.

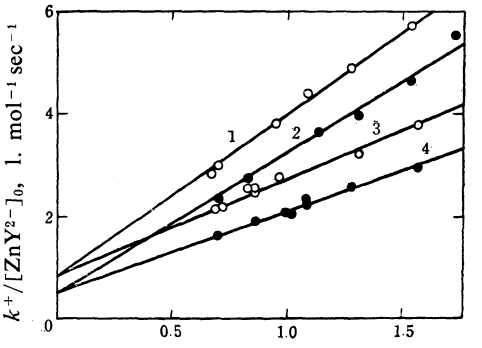

Fig. 1. $k^+/[ZnY^{2-}]_0$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 25°C. Initial concentrations are: $[Pb^{2+}]_{0,app}=2.06\times10^{-4}$ M; $[ZnY^{2-}]_0=5.25\times10^{-3}$ M; $[Zn^{2+}]_{0,app}=5.05\times10^{-3}$ M (curves 1 and 2) and 1.02×10^{-2} M (curves 3 and 4). Concentrations of free acetate are 0.049 M for curves 1 and 3 and 0.098 M for curves 2 and 4.

Bril, Bril and Krumholz[8] found that the reaction proceeds simultaneously through three different reaction paths. This was confirmed by Tanaka and Kato[3], who presumed that the reaction proceeds not only through hydrated metal ions but also through acetato complexes. Considering these facts, the following mechanisms were set down for reaction 1.

7) N. Tanaka and K. Kato, ibid., 33, 417 (1960).

8) K. Bril, S. Bril and P. Krumholz, *J. Phys. Chem.*, 59, 596 (1955); 60, 251 (1956).

$$\text{(i)}\quad Pb^{2+}+ZnY^{2-} \overset{k^{+}_{1h}}{\rightleftharpoons} PbY^{2-}+Zn^{2+} \qquad (6)$$

$$PbOAc^{+}+ZnY^{2-} \overset{k^{+}_{1c}}{\rightleftharpoons} PbY^{2-}+ZnOAc^{+} \qquad (6')$$

$$\text{(ii)}\quad ZnY^{2-}+H^{+} \rightleftharpoons ZnHY^{-} \qquad (7)$$

$$Pb^{2+}+ZnHY^{-} \overset{k^{+}_{IIh}}{\rightleftharpoons} PbHY^{-}+Zn^{2+} \qquad (8)$$

$$PbOAc^{+}+ZnHY^{-} \overset{k^{+}_{IIc}}{\rightleftharpoons} PbHY^{-}+ZnOAc^{+} \qquad (8')$$

$$PbHY^{-} \rightleftharpoons PbY^{2-}+H^{+} \qquad (9)$$

$$\text{(iii)}\quad ZnY^{2-}+H^{+} \underset{k_a^{-}}{\rightleftharpoons} Zn^{2+}+HY^{3-} \qquad (10)$$

$$Pb^{2+}+HY^{3-} \overset{k^{+}_{IIIh}}{\rightleftharpoons} PbY^{2-}+H^{+} \qquad (11)$$

$$PbOAc^{+}+HY^{3-} \overset{k^{+}_{IIIc}}{\rightleftharpoons} PbY^{2-}+H^{+}+OAc^{-} \qquad (11')$$

In reaction paths (iii), the concentration of HY^{3-} is expected to be extremely small during the reaction, and the steady state approximation may be applied. In addition, the condition,

$$k_a^{-}[Zn^{2+}] \gg k^{+}_{IIIh}[Pb^{2+}]+k^{+}_{IIIc}[PbOAc^{+}]$$

is satisfied, as was justified by Bril et al.[8]

In the present treatment, it is assumed that the equilibria between hydrated ions and acetato complexes are maintained while the substitution reaction takes place. This assumption seems to be reasonable from the results in Table II given below. From these assumptions one obtains Eq. 12 for the rate equation for reaction 1, where

$$k^{+}_{1c}=k^{+}_{1c}K_{PbOAc},\quad k^{+}_{2h}=k^{+}_{IIh}K^{H}_{ZnHY},$$

$$k^{+}_{2c}=k^{+}_{IIc}K^{H}_{ZnHY}K_{PbOAc},\quad k^{+}_{3h}=\frac{k^{+}_{IIIh}}{K_{ZnY}K_{HY}},$$

$$k^{+}_{3c}=\frac{k^{+}_{IIIc}}{K_{ZnY}K_{HY}}K_{PbOAc} \qquad (13)$$

$$-\frac{d[Pb^{2+}]_{app}}{dt}=$$

$$\frac{k^{+}_{1h}+k^{+}_{1c}[OAc^{-}]+(k^{+}_{2h}+k^{+}_{2c}[OAc^{-}])[H^{+}]+(k^{+}_{3h}+k^{+}_{3c}[OAc^{-}])\dfrac{1+K_{ZnOAc}[OAc^{-}]}{[Zn^{2+}]_{app}}[H^{+}]}{1+\sum_{n=1}^{2}K_{Pb(OAc)_n}[OAc^{-}]^{n}}$$

$$\times[Pb^{2+}]_{app}[ZnY^{2-}] \qquad (12)$$

$$\frac{k^{+}}{[ZnY^{2-}]_0}=$$

$$\frac{k^{+}_{1h}+k^{+}_{1c}[OAc^{-}]+(k^{+}_{2h}+k^{+}_{2c}[OAc^{-}])[H^{+}]+(k^{+}_{3h}+k^{+}_{3c}[OAc^{-}])\dfrac{1+K_{ZnOAc}[OAc^{-}]}{[Zn^{2+}]_{o,app}}[H^{+}]}{1+\sum_{n=1}^{2}K_{Pb(OAc)_n}[OAc^{-}]^{n}} \qquad (14)$$

Table I. Rate constants in Eq. 14 obtained experimentally at ionic strength 0.2 at 25°C

Rate constant		
k^{+}_{1h}	5	$l.mol^{-1}sec^{-1}$
k^{+}_{1c}	4×10	$l^2mol^{-2}sec^{-1}$
k^{+}_{2h}	$\sim2\times10^5$	$l^2mol^{-2}sec^{-1}$
k^{+}_{2c}	$\sim7\times10^6$	$l^3mol^{-3}sec^{-1}$
k^{+}_{3h}	4×10^3	$l.mol^{-1}sec^{-1}$
k^{+}_{3c}	1×10^5	$l^2mol^{-2}sec^{-1}$

$K_{Pb(OAc)_n}$ and K_{ZnOAc} represent the overall formation constants of acetato lead(II) and acetatozinc(II) complexes, respectively. K^{H}_{ZnHY} represents the equilibrium constant of reaction 7, K_{ZnY}, the formation constant of ZnY^{2-} and K_{HY}, the fourth dissociation constant of ethylenediaminetetraacetic acid.

From Eqs. 3 and 12, Eq. 14 is obtained, where the initial concentrations, $[Zn^{2+}]_0$ and $[ZnY^{2-}]_0$, are substituted for $[Zn^{2+}]$ and $[ZnY^{2-}]$, respectively. Since both Zn^{2+} and ZnY^{2-} are present in the solution in a large excess over lead ions, the change of their concentrations during the reaction can be neglected.

The rate constants in Eq. 14 were obtained from the analysis of plots in Fig. 1, and are given in Table I. The formation constants of acetatolead(II) and acetatozinc(II) complexes which were used in the calculation are reported in the previous paper[7]. The concentration of uncomplexed acetate in the solution was calculated by successive approximation.

The rate constants for reactions 6, 6', 8, 8', 11 and 11' were calculated from the relations given in Eqs. 13. The values of K^{H}_{ZnHY}, K_{ZnY} and K_{HY} which were used in the calculation were reported previously[3]. The obtained rate constants for reactions 6, 6', 8, 8', 11 and 11' are given in Table II. The values in Table II indicate that the all reactions proceeding

TABLE II. RATE CONSTANTS FOR REACTIONS 6, 6', 8, 8', 11 AND 11' AT IONIC STRENGTH 0.2 AT 25°C

Rate constant, l. mol^{-1} sec^{-1}					
k^+_{1h}	k^+_{1c}	k^+_{IIh}	k^+_{IIc}	k^+_{IIIh}	k^+_{IIIc}
5	0.3	$\sim 3\times10^2$	$\sim 7\times10$	3×10^9	6×10^8

through Pb^{2+} are faster than the corresponding reactions through $PbOAc^+$. It is considered to be mainly due to the difference in charge of the reacting species.

From Eq. 12, it is predicted that the reaction rate decreases with the increase of acetate ion concentration. With Eq. 14, $k^+/[ZnY^{2-}]_0$ was calculated as a function of the concentration of acetate ion, using the rate constants given in Table I and the formation constants of acetato complexes. Two sets of calculations which were made at two different hydrogen ion concentrations are shown in Fig. 2, where the experimental values of $k^+/[ZnY^{2-}]_0$ measured at various acetate concentrations are also given. These are in satisfactory agreement with the calculated curves. This fact leads to a definite conclusion that the reaction proceeds not only through hydrated metal ions but also through acetato complexes. It also suggests that the contribution of the reaction through diacetato complexes is of least significance.

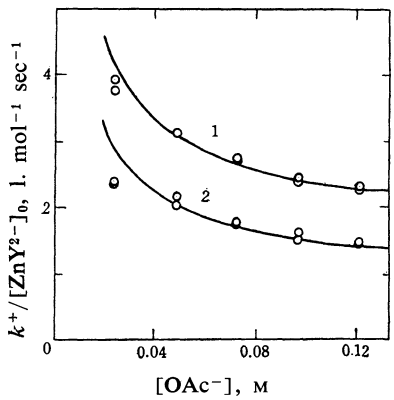

Fig. 2. $k^+/[ZnY^{2-}]_0$ as a function of the acetate concentration in acetate buffer-potassium nitrate solutions of $[H^+]=1.17\times10^{-5}$ M (curve 1) and $[H^+]=0.63\times10^{-5}$ M (curve 2). Initial concentrations are: $[Pb^{2+}]_{0,app}=1.65\times10^{-4}$ M; $[ZnY^{2-}]_0=5.00\times10^{-3}$; $[Zn^{2+}]_{0,app}=1.00\times10^{-2}$ M.
— indicates the theoretical curve and ○, the experimental value.

Summary

The effect of acetate ions on the substitution reaction between lead(II) and zinc-EDTA complexes has been investigated. The reaction was treated as to proceed through both hydrated metal ions and monoacetato complexes, and the rate equation was derived. The rate constants for six elementary reactions of which three involve the hydrated lead(II) ion and the others involve the monoacetatolead-(II) complex were determined at ionic strength 0.2 at 25.0°C. The values indicate that all the reactions proceeding through hydrated lead ions are faster than the corresponding reactions through monoacetato lead complexes. The results also suggest that the rate of the reaction through diacetatolead(II) complexes is much slower than those of the reactions through hydrated ions and monoacetato complexes.

*Synthesis and Pyrolysis of N-Substituted γ-Aminobutyrates and N-Substituted Bis(β-ethoxycarbonylethyl)amines**

By Shiro MOROSAWA and Akira YOKOO

(Received October 31, 1962)

Some *N*-substituted γ-aminobutyrates and *N*-substituted bis(β-ethoxycarbonylethyl)amines were synthesized and their behaviors upon pyrolysis were investigated. Ethyl *N*-benzoyl-γ-(β-ethoxycarbonylamino)butyrate (III) and ethyl γ-[bis(β-ethoxycarbonylethyl)amino]-butyrate (II) were obtained from the reaction mixture of ethyl γ-aminobutyrate and ethyl acrylate by benzoylation. Direct distillation of the mixture did not give ethyl γ-(β-ethoxycarbonylethylamino)butyrate (I), but gave *N*-(β-ethoxycarbonylethyl)-2-pyrrolidone (V). III was also derived from II by heating with benzoyl chloride as McElvain[1] did about tris-(β-ethoxycarbonylethyl)amine (XIII). V was also obtained by heating II. Both III and V gave γ-(β-carboxyethylamino)butyric acid (IV) on hydrolysis. On heating IV above its melting point, *N*-(β-carboxyethyl)-2-pyrrolidone (VI) was formed, which returned to IV by hydrolysis. IV gave ethyl *N*-ethoxycarbonyl-γ-(β-ethoxycarbonylethylamino)butyrate (VII). Reaction of ethyl β-benzylaminopropionate[2] and ethyl γ-bromobutyrate afforded ethyl *N*-benzyl-γ-(β-ethoxycarbonylethylamino)butyrate (VIII) along with a small amount of *N*-benzyl-2-pyrrolidone (IX)[3]. IX also formed on heating VIII. IX was hydrolyzed to γ-benzylaminobutyric acid (X), which reformed IX by heating. Ethyl *N*, *N*-dibenzyl-γ-aminobutyrate (XI), which was synthesized from ethyl γ-aminobutyrate and benzyl chloride, cleaved into IX and benzyl ethyl ether on heating at about 280°C. When XI was heated in acetic anhydride, it was recovered unchanged. Hydrochloride XII of XI, on the other hand, decomposed readily at about 170°C to yield IX, benzyl chloride and ethanol. Tris(β-ethoxycarbonylethyl)amine (XIII) began to decompose at about 200°C and gave ethyl acrylate, ethanol and a substance which probably could be a condensation product of β-alanine. *N*-Benzyl-bis(β-ethoxycarbonylethyl)amine (XIV)[2,4] also split ethyl acrylate at about 197°C, but the composition of the residual substance was so complicated and could not be determined. *N*-Benzoyl-bis(β-ethoxycarbonylethyl)amine (XV)[1] resisted to decompose, and gave ethyl acrylate and ethyl *N*-benzoyl-γ-aminopropionate at a higher temperature, about 304°C. (Figs. 1 and 2).

(VIII) (IX) (X)

Fig. 2

Consideration of the Pyrolytic Mechanism.—The ring formation of II during the heating may be driven by the intramolecular nucleophillic attack of nitrogen to carbonyl carbon to split ethyl acrylate and form the stable five-membered ring. (Fig. 3). Likewise, in the case of VIII, XI and XII, the same mechanism was considered. Especially the pyrolysis of XII took place more readily, and this was certainly assumed to be resulted from the positively charged nitrogen, which splits benzyl cation. (Fig. 4).

The decomposition of XIII, XIV and XV was, on the other hand, considered to proceed through an ammonium compound, reversely to the additive reaction between an amino compound and ethyl acrylate. The resistance observed in the pyrolysis of XV may be due to the decrease in electron density at the nitrogen by the neighboring carbonyl group.

The liberation of ethyl acrylate in the reaction between II and benzoyl chloride, on the contrary, will proceed like Hofmann's degradative reaction as shown in Fig. 5.

Experimental

Ethyl γ-[Bis(β-ethoxycarbonylethyl)amino]butyrate (II) and Ethyl *N*-Benzoyl-γ-(β-ethoxycarbonylethylamino)butyrate (III).—To an ice-cold solution of 26.4 g. of sodium in 1 l. of absolute ethanol was added 190 g. of ethyl γ-aminobutyrate hydrochloride under stirring, followed, after 1 hr., by the addition of a solution of 115.6 g. of ethyl acrylate in 300 cc. of the same solvent. After stirring for 7 hr., the mixture was heated at 70~73°C with stirring. The solvent was removed under reduced pressure, and 100 cc. of dry benzene was added and distilled to expel completely any of the ethanol present. A solution of 160 g. of benzoyl chloride in 250 cc. of dry benzene was added to the residue and refluxed for 20 hr. Then 100 cc. of absolute ethanol was added and refluxed for 1.5 hr. After cooling, ice was added, and the benzene layer was washed successively with cold 10% sodium hydroxide solution, water, 10% hydrochloric acid, water and 5% sodium carbonate solution, and dried over calcium chloride. Removal of benzene and distillation of the residue gave 26 g. of III as a colorless viscous oil of b. p. 200~205°C/0.3 mmHg.

Found: C, 63.95; H, 7.46; N, 4.16. Calcd. for $C_{18}H_{25}O_5N$: C, 64.46; H, 7.51; N, 4.18%.

The above-mentioned acidic washes were united and made alkaline with sodium hydroxide solution. An oil liberated was taken up in ether and dried over calcium chloride. After removal of ether, vacuum distillation gave 129 g. of II as a colorless oil of b. p. 178~183°C/3.0 mmHg.

Found: N, 4.17. Calcd. for $C_{16}H_{29}O_6N$: N, 4.23%.

Reaction of II with Benzoyl Chloride.—A mixture of 66.3 g. of II and 34 g. of benzoyl chloride was heated in a round-bottomed flask attached to a fractionating column in an oil bath. At about 180°C (bath temp.), ethyl acrylate began to distil, and hydrogen chloride evolved vigorously. After 5 hr. at 185~195°C (bath temp.), 30 cc. of absolute ethanol was added to the remainder and refluxed for 1 hr. After cooling, sodium hydroxide solution

was added and extracted with ether. The ethereal solution was washed successively with 2 N hydrochloric acid, water, 5% potassium carbonate solution and water. Drying with calcium chloride and distillation gave 61 g. of III, boiling at 200~205°C/0.3 mmHg. III was not obtained from II and benzoyl chloride in xylene.

***N*-(β-Ethoxycarbonylethyl)-2-pyrrolidone (V).**—a) On heating 2 g. of II in an oil bath, ethyl acrylate and ethanol began to distil at about 190°C (bath temp.). The pyrolysis completed in about 1 hr. at 195~200°C (bath temp.), and 0.7 g. of a distillate was obtained. Distillation of the remainder gave 0.9 g. of V as a colorless oil of b. p. 130~131°C/3.0 mmHg.

Found: N, 7.52. Calcd. for $C_9H_{15}O_3N$: N, 7.56%.

b) By the same procedure in the preparation of II, 60 g. of ethyl γ-aminobutyrate hydrochloride and 35.8 g. of ethyl acrylate, using 8.2 g. of sodium, were allowed to react and directly vacuum-distilled to yield 25.6 g. of V, b. p. 129~131°C/2.5 mmHg (Found: N, 7.60%).

γ-(β-Carboxyethylamino)butyric Acid (IV).—a) After a mixture of 5 g. of III and 30 cc. of 6 N hydrochloric acid was refluxed for 4 hr., it was evaporated under reduced pressure. Water was added to the residue and again evaporated. The residue was taken up in a small amount of ethanol, and acetone was added until turbidity occurred. After standing, crystals formed were collected, washed with a little ethanol. The crystals were dissolved in hot ethanol, and ether was added until the solution became turbid to afford 1.6 g. of hydrochloride of IV as hygroscopic colorless crystals of m. p. 105~106°C.

Found: N, 6.64. Calcd. for $C_7H_{13}O_4N \cdot HCl$: N, 6.63%.

A solution of 1.2 g. of the hydrochloride in 30 cc. of water was treated with an excess of silver oxide, hydrogen sulfide and was evaporated under reduced pressure. The residue was dissolved in a small amount of water, and ethanol was added. Crystals which formed on being left to stand were recrystallized as before to give 0.9 g. of free IV as colorless needles of m. p. 151~152°C (decomp.).

Found: C, 47.85; H, 7.31; N, 8.20. Calcd. for $C_7H_{13}O_4N$: C, 47.99; H, 7.48; N, 8.00%.

b) A mixture of 5 g. of V and 50 cc. of 30% barium hydroxide solution was refluxed for 5 hr. The mixture was treated with carbon dioxide and filtered. The filtrate was adjusted at pH 4.0 with sulfuric acid, filtered and evaporated under reduced pressure. The residue was dissolved in a small amount of water, and ethanol was added. The resulting solution, on standing, gave 3.7 g. of colorless crystals, melting at 151~152°C under decomposition. These did not depress their melting point on admixture with the crystals obtained in a).

c) A mixture of 0.5 g. of VI and 5 cc. of 30% barium hydroxide solution was refluxed for 5 hr. and treated as mentioned in b) to give 0.35 g. of colorless crystals of m. p. 151~152°C (decomp.). These were found to be identical with the crystals in a) by mixed fusion.

***N*-Tosyl Derivative.**—A mixture of 0.1 g. of the hydrochloride of IV and 0.2 g. of *p*-toluenesulfonylchloride in sodium hydroxide solution was stirred for 4 hr. After removal of an excessive unreacted substance by extracting with ether, the solution was acidified by hydrochloric acid and taken up in ether. Ether was expelled, and the residue was recrystallized twice from dilute ethanol to give colorless crystals of m. p. 138~139°C.

Found: N, 4.45. Calcd. for $C_{14}H_{19}O_6NS$: N, 4.24%.

***N*-(β-Carboxyethyl)-2-pyrrolidone (VI).**—a) On heating 0.2 g. of IV in an oil bath at 160~165°C for 10 min., water was lost under melting. The cooled mass was dissolved in ethanol, and ether was added until turbidity took place. Crystals which formed were recrystallized as before to afford 0.15 g. of colorless crystals of m. p. 108~109°C.

Found: N, 9.04. Calcd. for $C_7H_{11}O_3N$: N, 8.91%. Found: equivalent to sodium hydroxide (phenolphthalein as an indicator), 158.5. Calcd. 157.17.

b) The filtrate of the hydrochloride of IV, which was mentioned in a) of preparation of IV, was evaporated, and water was added. The solution was treated with silver oxide and hydrogen sulfide, and was evaporated under reduced pressure to leave a viscous oily substance. Distillation of the oily substance gave an oil of b. p. 190~195°C/0.5 mmHg, which crystallized on standing. Recrystallization from ethanol gave 0.8 g. of colorless crystals of m. p. 108~109°C. These were identified with the crystals in a) by mixed fusion.

Ethyl *N*-Ethoxycarbonyl-γ-(β-ethoxycarbonylethylamino)butyrate (VII).—To a solution of 4 g. of sodium hydroxide in 50 cc. of water was added 11 g. of ethyl chlorocarbonate under stirring and cooling with water. After stirring for 5 hr, the solution was acidified with hydrochloric acid, and extracted twice with 50 cc. of benzene and twice with 50 cc. of ether. The extracts were combined, washed with water and dried over calcium chloride. The solvent was removed completely under reduced pressure. The residue was heated on a water bath (at 60~70°C) with 5 g. of thionyl chloride for 1.5 hr., and the whole was further heated for 1 hr. with 15 cc. of absolute ethanol. Removal of ethanol and distillation of the residue gave 4 g. of a colorless oil of b. p. 163~165°C/2.0 mmHg.

Found: N, 4.60. Calcd. for $C_{14}H_{25}O_6N$: N, 4.62%.

Ethyl *N*-Benzyl-γ-(β-ethoxycarbonylethylamino)-butyrate (VIII).—A mixture of 107 g. of ethyl β-benzylaminopropionate and 50 g. of ethyl γ-bromobutyrate was left to stand for 5 days at room temperature. Ethyl γ-benzylaminopropionate hydrobromide formed was separated by filtration and washed with ether. The filtrate and the ether washings were united, and ether was removed under reduced pressure. The residue was heated on a water bath for 3 hr. and left to stand overnight. The hydrobromide again formed was treated as above. The filtrate and ether washings were united, washed with 10% sodium carbonate solution and water, and dried over calcium chloride. Evaporation of ether and vacuum distillation gave 60 g. of an

oil of b. p. 171~173°C/0.1 mmHg.

Found: N, 4.42. Calcd. for $C_{18}H_{27}O_4N$: N, 4.36%.

***N*-Benzyl-2-pyrrolidone (IX).**—On heating 0.8 g. of VIII in an oil bath at 200°C, ethyl acrylate began to smell. After holding the temperature of the bath at 265~270°C for 2 hr., the remainder was vacuum-distilled to give 0.3 g. of an oil of b. p. 142~144°C/3.0 mmHg.

Found: N, 7.83. Calcd. for $C_{11}H_{13}ON$: N, 7.99%.

γ-Benzylaminobutyric Acid (X).—A mixture of 0.3 g. of IX and 10 cc. of 30% barium hydroxide solution was refluxed for 5 hr. to cause solution of the former. The mixture was diluted with 30 cc. of water, treated with carbon dioxide while hot, and filtered. The filtrate was evaporated to dryness and taken up in absolute ethanol. Ether was added to the ethanolic solution until turbidity took place. Crystals which formed on standing were collected and recrystallized in the same way to yield 0.2 g. of colorless crystals of m. p. 139~140°C (decomp.).

Found: C, 68.10; H, 7.72; N, 7.20. Calcd. for $C_{11}H_{15}O_2N$: C, 68.37; H, 7.82; N, 7.25%.

On fractional distillation of the foreruns in the distillation of VIII, 1.5 g. of an oil of b. p. 141~142°C/3.0 mmHg was obtained. Hydrolysis of the oil as above gave colorless crystals of m. p. 139~140°C (decomp.), which did not show any depression of the melting point on adimixture with the above crystals.

Ethyl *N*, *N*-Dibenzyl-γ-aminobutyrate (XI).—To a solution of 5 g. of sodium in 200 cc. of absolute ethanol was added 37.5 g. of ethyl γ-aminobutyrate hydrochloride. After 30 min., 56.5 g. of benzyl chloride was added and the resulting mixture was refluxed for 2 hr., followed by the further heating for 20 hr. with 61 g. of anhydrous potassium carbonate. The insoluble matters were separated and washed with absolute ethanol. The filtrate and the washings were combined, and ethanol was removed. Vacuum distillation of the residue gave 13.5 g. of a colorless viscous oil of b. p. 175~177°C/1.0 mmHg.

Found: N, 4.65. Calcd. for $C_{20}H_{25}O_2N$: N, 4.50%.

Pyrolysis of XI.—a) On heating 2.8 g. of XI in an oil bath, the decomposition began at about 280°C. The distillate, which was obtained during the heating for 3 hr., was taken up in ether, washed with water and dried over calcium chloride. Evaporation of ether and distillation of the residue gave 0.7 g. of a colorless oil of b. p. 184~187°C. The oil was found to be identical with benzyl ethyl ether by infrared spectrum.

Found: C, 79.65; H, 8.59. Calcd, for $C_9H_{12}O$: C, 79.37; H, 8.83%.

The residue of the pyrolysis gave, on vacuum distillation, 0.9 g. of an oil of b. p. 142~144°C/3.0 mmHg, corresponding to IX. Crystals of m. p. 139~140°C (decomp.) were derived from the oil by the same treatment as described in the preparation of XI, and were identified with XI by mixed fusion.

b) A solution of 3 g. of XI in 25 cc. of acetic anhydride was refluxed for 4 hr. The solvent was removed under reduced pressure, and the residue was vacuum-distilled to recover 2.7 g. of an oil of b. p. 175~177°C/1.0 mmHg. The formation of benzyl ethyl ether was not appreciated thereby.

Ethyl *N*, *N*-Dibenzyl-γ-aminobutyrate Hydrochloride (XII).—Dry hydrogen chloride was passed through a solution of 7 g. of XI in absolute ethanol. The solution was evaporated to dryness under reduced pressure. The residue was dissolved in the same solvent and again evaporated. After two repetitions of this treatment, the residue was dried over potassium hydroxide in a vacuum desiccator. On being left to stand in a refrigerator, the residue became crystalline. A small amount of benzene was added, and the crystalline substances were collected. These were dissolved in a small amount of absolute ethanol, diluted by adding twice the volume of benzene, and the solution was filtered from any undissolved matter present. Addition of ether and seeding caused crystallization. The formed crystals were collected and washed with benzene to yield 6.5 g. of colorless crystals, which began to soften at 146°C with effervescence and melted clearly at 160°C.

Found: N, 3.95. Calcd. for $C_{20}H_{25}O_2N \cdot HCl$: N, 4.02%.

Pyrolysis of XII.—On heating 5 g. of XII in an oil bath at 190~200°C for 1 hr., a fraction running over at 75~78°C was collected. This was assumed to be ethanol. Then 1.6 g. of a distillate was collected during the heating at 220°C. After washing the distillate with sodium carbonate solution and water, followed by drying over calcium chloride, distillation gave 1.1 g. of a colorless oil of b. p. 176~177°C.

Found: C, 66.60; H, 5.82. Calcd. for C_7H_7Cl: C, 66.42; H, 5.54%.

The oil was found to be benzyl chloride by the following procedure. That is, a mixture of 1 g. of the oil, 1.2 g. of anhydrous potassium carbonate and 1 g. of aniline was heated at 180°C for 3 hr. Water was added to the mixture and extracted with ether. After drying over anhydrous potassium carbonate, ether was expelled, and the residue was vacuum-distilled to give an oil of b. p. 180°C/14 mmHg, which crystallized to colorless crystals of m. p. 36°C by recrystallization from ligroin. These did not depress their melting point on admixture with the specimen prepared from benzyl chloride and aniline in the same way. Both hydrochlorides, on recrystallization from ethanol and ether, gave the same crystals which softened at 201°C in green and melted at 202~203°C, turning clear light brown.

On vacuum distillation of the residue in the above pyrolysis, 1.9 g. of IX of b. p. 140~142°C/3.0 mmHg was obtained. (Found: N, 7.80%). This was converted to *N*-benzyl-γ-aminobutyric acid by hydrolysis as before and identified by mixed fusion with the authentic sample.

Pyrolysis of Tris(β-ethoxycarbonylethyl)amine (XIII).—On heating 10 g. of XIII in an oil bath, decomposition began to occur at about 200°C. The bath temperature was held at 210~215°C until no distillate came out. Thereby 6.9 g. of a distillate was collected, which was fractionated into four parts: b. p. 79~85°C (0.5 g.), b. p. 85~90°C (0.4 g.), b. p. 90~96°C (0.4 g.) and b. p. 96~99°C (5.1 g.) (ethyl acrylate). The residue was impossible

to be distilled at 280°C (bath temp.) and 3 mmHg, but solidified on standing. A mixture of 1 g. of the residue and 6 N hydrochloric acid was refluxed for 5 hr. and evaporated under reduced pressure. The remainder was dissolved in water, treated with silver oxide and hydrogen sulfide. The resulting solution was evaporated to a smaller volume, and ethanol was added to cause crystallization. Crystals formed were collected and recrystallized from water and ethanol as before to yield 0.65 g. of colorless crystals of m. p. 197~198°C (decomp.). These were not depressed on admixture with the authentic β-alanine.

Pyrolysis of *N*-Benzyl-bis(β-ethoxycarbonylethyl)amine (XV).—On heating 5 g. of XV in an oil bath, decomposition began to occure at about 307°C. During the heating for 2 hr. at 310~320°C, 1.1 g. of a distillate of b. p. 95~98°C which was assumed to be ethyl acrylate was obtained. The remainder, on vacuum distillation, gave 1.8 g. of an oil of b. p. 157~158°C/2.5 mmHg. This was considered to be ethyl *N*-benzoyl-β-aminopropionate from the analytical values and the experiment below.

Found: C, 69.93; H, 8.42; N, 6.91. Calcd. for $C_{12}H_{17}O_2N$: C, 69.54; H, 8.27; N, 6.77%.

A mixture of 1 g. of the oil and 15 cc. of 6 N hydrochloric acid was refluxed for 4 hr. Benzoic acid which formed overnight was separated, and the filtrate was evaporated under reduced pressure. The residue was dissolved in water, treated with silver oxide and hydrogen sulfide, and again evaporated as before. The final residue was dissolved in a small amount of water, and ethanol was added to form 0.3 g. of β-alanine, melting at 197~198°C.

Studies on Antibiotics and Related Substances. XVI. Syntheses of β-Acetochloro Derivatives of 3-Amino-3-deoxyglucose and 6-Amino-6-deoxyglucose

By Sumio UMEZAWA, Shinkiti KOTO and Yukio ITO

(Received November 10, 1962)

Acetohalogeno derivatives of sugars are important intermediates for the synthesis of glycosides. However, the corresponding derivatives of aminosugars represent a relatively unexplored territory. In the preceding paper in this series, the syntheses of α-acetobromo derivatives of 3-carbobenzoxyamino-3-deoxy- and 6-carbobenzoxyamino-6-deoxy-glucose have been developed. This paper reports the synthesis of 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-β-1-chloro-1,3-dideoxy-D-glucopyranose (III) and 2,3,4-tri-*O*-acetyl-6-carbobenzoxyamino-β-1-chloro-1, 6-dideoxy-D-glucopyranose (VII). These β-acetochloro derivatives are significant for preparing α-glycoside of aminosugars, as shown here in the prepartion of methyl 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-α-D-glucopyranoside (IV) and methyl 2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-α-D-glucopyranoside (VIII).

The synthesis of III and IV are outlined in the following Chart A:

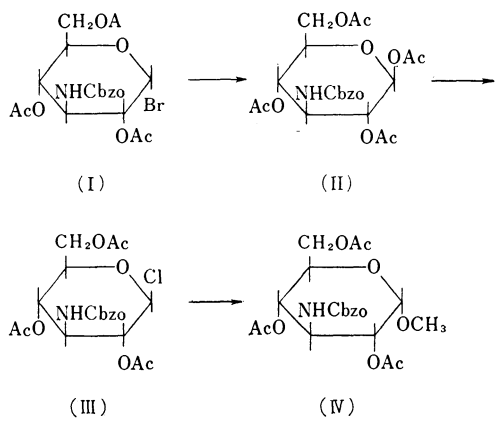

Chart A

2, 4, 6-Tri-*O*-acetyl-1-α-bromo-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose (I) prepared by our method[1] was acetylated by refluxing with silver acetate in dried benzene to give 1, 2, 4, 6-tetra-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranose (II) in 77% yield.

TABLE I

Compound	Specific rotation: Observed in $CHCl_3$	Specific rotation: Calcd.	IR-Absorption, cm^{-1}
II	$[\alpha]_D^{7.5}$ +17.5° (*c* 0.87)	+ 14.8°	898 (Nujol)
III	$[\alpha]_D^{15}$ − 3.5° (*c* 0.85)*	+ 6.3°	890 (KBr)
IV	$[\alpha]_D^{15}$ +75.6° (*c* 0.91)	+116°	847 ($CHCl_3$)
VI	$[\alpha]_D^{12}$ +10.2° (*c* 1.6)	+ 14.8°	892 (Nujol)
VII	$[\alpha]_D^{15}$ + 0.17° (*c* 1.7)**	+ 6.3°	901 (KBr)
VIII	$[\alpha]_D^{15}$ +81° (*c* 0.91)	+116°	847 ($CHCl_3$)

* A rotation change from −3.5 to +55° (192 hr.) was observed.
** A rotation change from +0.17 to +56.3° (144 hr.) was observed.

Zemplén and Mester[2], and Korytnyk and Mills[3] reported on the preparation of so called "unstable chlorides" from fully acetylated aldopyranoses by treatment with aluminum chloride in cold chloroform. When a similar procedure was applied to II at room temperature, a 92.7% yield of 2, 4, 6-tri-*O*-acetyl-1-β-chloro-3-carbobenzoxyamino-3-deoxy-D-glucose (III) was obtained. As detailed below, the specific rotation of III changed very slowly from −3.5 to +55° in dried chloroform during 192 hr.

An attempt to prepare an α-glycoside from III proved to be practical. When shaken with methanol in the presence of silver carbonate and anhydrous calcium carbonate by the procedure of Wolfrom[4], methyl 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-α-D-glucopyranoside (IV) was obtained in 67.3% yield.

2, 3, 4-Tri-*O*-acetyl-6-carbobenzoxyamino-1-β-chloro-1, 6-dideoxy-D-glucopyranose (VII) and the corresponding methyl α-glycoside (VIII) have been synthesized by an analogous route outlined in the following Chart B:

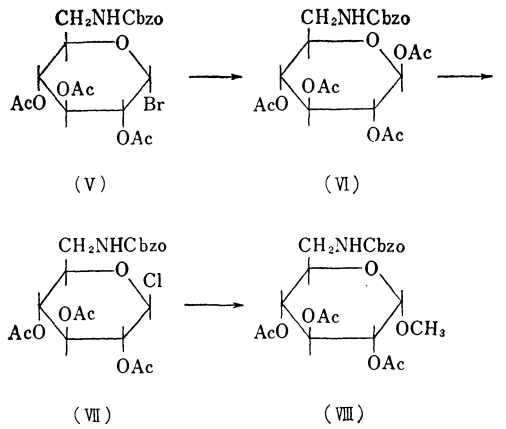

Chart B

2, 3, 4-Tri-*O*-acetyl-6-carbobenzoxyamino-1-β-chloro-1, 6-dideoxy-D-glucopyranose (VII) was obtained in an 89.5% yield and, when subjected to the procedure of Wolfrom mentioned above, VII gave an α-glycoside, methyl 2, 3, 4-tri-*O*-acetyl-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranoside (VIII) in 61% yield.

Infrared spectra of the acetochloro derivatives (III, VII) showed absorption near 890 cm^{-1} which is characteristic of β-configuration, while the methylglycosides (IV, VIII) showed absorptions near 840 cm^{-1}, indicating that the methylglycosides have α-configuration as expected from the solvolytic mechanism. Moreover, determination of specific rotation of the above-mentioned derivatives consisted with the spectroscopic results, as shown in Table I, where these data are shown together with the calculated values using Hudson's rules modified by Korytnyk[5].

The agreement between the observed and calculated values of the glycosides (IV, VIII) is not so good, but the results seem to be allowable. The observed differences probably are to be ascribed to concomitance of β-anomer and an orthoester derivative, which are rather often the main product of the Koenigs-Knorr reaction. When the glycoside (IV) was deacetylated with methanolic ammonia and then catalytically reduced to remove the carbobenzoxyl group, there was obtained a mixture of methyl 3-amino-3-deoxy-α-D-glucoside and 3-amino-3-deoxy-D-glucose, which were identified by paper chromatography. The former was a main product and identified by comparison with an authentic specimen obtained by methanolysis of kanamycin. The formation of 3-amino-3-deoxy-D-glucose probably indicates the concomitance of orthoester derivative in the glycoside (IV), provided that the glycosidic linkage is stable enough in the above-mentioned series of reactions. Since the methyl α-glycoside was obtained as a main product, it is probable that, in the case of acetochloro derivatives of

3-carbobenzoxyamino-3-deoxyglucose and 6-carbobenzoxyamino-6-deoxyglucose, the replacement reaction[6] took place more rapidly than the interconversion of isomeric halides.

It should be noted also that the reaction of 1, 3, 4, 6-tetra-*O*-acetyl-2-carbobenzoxyamino-2-deoxy-D-glucose (IX) with aluminum chloride by a similar procedure to that used for the preparation of III and VII afforded 4, 5-(3, 4, 6-tri-*O*-acetyl-D-glucopyrano)-2-oxazolone which had been described by Konstas et al.[7]

Experimental

1, 2, 4, 6-Tetra-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranose (II).—A mixture of 3.0 g. of 2, 4, 6-tri-*O*-acetyl-1-α-bromo-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose (I) prepared by our method[1] and 2.0 g. of well dried silver acetate in 100 ml. of benzene was refluxed for 8 hr. and cooled. A small quantity of active charcoal was added to the resulting mixture, followed by filtration. The filtrate was concentrated under reduced pressure and the residue was recrystallized from isopropanol to yield 2.17 g. (77%) of 1, 2, 4, 6-tetra-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranose, m. p. 165.5~166°C, $[\alpha]_D^{7.5}$ +17.5° (*c* 0.87, $CHCl_3$). The infrared spectrum of the product in Nujol contains absorption bands at 3350 (νNH), 1757 (νC=O in OAc), 1713 (νC=O in Cbzo), 1550 (δNH), 1231, 1215 (νC-O in OAc), 898 (type 2b of pyranose ring), 775, 738, 696 (phenyl).

Found: C, 54.46; H, 5.64; N, 3.08. Calcd. for $C_{22}H_{27}NO_{11}$ (481.5): C, 54.88; H, 5.67; N, 2.91%.

2, 4, 6-Tri-*O*-acetyl-1-β-chloro-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose (III).—A mixture of 0.25 g. of 1, 2, 4, 6-tetra-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-β-D-glucopyranose (II) and 0.3 g. of freshly prepared aluminum chloride in 5 ml. of chloroform was shaken at room temperature for 40 min. After addition of 60 ml. of benzene, the resulting mixture was washed with each 8 ml. of ice water thrice. The benzene-layer was dried over sodium sulfate and evaporated to dryness under reduced pressure and the residue was recrystallized from ether-petroleum ether and then ether to yield 0.22 g. (92.7%) of colorless crystals of 2, 4, 6-tri-*O*-acetyl-1-β-chloro-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose, m. p. 151~151.5°C, $[\alpha]_D^{15}$ −3.5° (initial) → +55° (final, 192 hr.) (*c* 0.85, $CHCl_3$). The infrared spectrum of the product in potassium bromide contains absorption bands at 3160 (νNH), 1763 (νC=O in OAc), 1715 (νC=O in Cbzo), 1545 (δNH), 1228 (νC-O in OAc), 890 (type 2b of pyranose ring), 774, 738, 696 (phenyl).

Found: C, 52.50; H, 5.04; N, 3.08; Cl, 7.30. Calcd. for $C_{20}H_{24}NO_9Cl$ (458.0): C, 52.35; H, 5.27; N, 3.08; Cl, 7.76%.

Methyl 2, 4, 6-Tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-α-D-glucoside (IV).—A mixture of 60 mg. of silver carbonate prepared by the procedure of Wolfrom et al.[4] and 400 mg. of anhydrous calcium sulfate in 4 ml. of anhydrous methanol was shaken in dim light for 15 min. at room temperature. To the suspension were added 0.15 g. of 2, 3, 4-tri-*O*-acetyl-1-β-chloro-3-carbobenzoxyamino-1, 3-dideoxy-D-glucopyranose (III), 10 mg. of silver perchlorate and a small quantity of anhydrous calcium sulfate and the mixture was shaken in dim light for 3.5 hr. at room temperature. After removal of silver salts by filtration, the solvent was removed by evaporation under reduced pressure and the residue was dissolved in chloroform and allowed to stand overnight. After removal of an insoluble matter by filtration the filtrate was evaporated to give a crystalline residue, which was recrystallized from isopropanol-hexane to yield 0.1 g. (67.3%) of crystals of methyl 2, 4, 6-tri-*O*-acetyl-3-carbobenzoxyamino-3-deoxy-α-D-glucopyranoside, m. p. 129~130°C, $[\alpha]_D^{15}$ +75.6° (*c* 0.91, $CHCl_3$). The infrared spectrum of the product in chloroform contains absorption bands at 3350 (νNH), 1753 (νC=O in OAc), 1730 (shoulder) 1523 (δNH), 1210 (νC-O in OAc), 847 (type 2a pyranose ring), 695 cm^{-1} (phenyl).

Found: C, 55.83; H, 5.76; N, 3.15. Calcd. for $C_{21}H_{27}NO_{10}$ (453.5): C, 55.77; H, 5.76; N, 3.07%.

A sample of 20 mg. of the above product was dissolved in 4 ml. of methanol saturated with ammonia and allowed to stand overnight in a refrigerator and evaporated to dryness under reduced pressure. The residue was taken up in about 4 ml. of aqueous methanol and 40 mg. of paladium chloride-charcoal catalyst was added to the solution. pH of the mixture was adjusted to about 2 with dilute hydrochloric acid and hydrogenated at room temperature for 3 hr. As the reaction mixture gradually became alkaline, a small quantity of dilute hydrochloric acid was repeatedly added to adjust pH to about 2. After removal of the catalyst by filtration, the solution was evaporated to dryness under reduced pressure. The residue was dissolved in 0.4 ml. of water and subjected to paper chromatography, using two solvent systems. The spots were identified by coloration with ninhydrin and silver-ammonia. The solvent system butanol-pyridine-acetic acid-water (6 : 4 : 1 : 3) gave two spots of R_f 0.43 and 0.30 which were identical with the spots of authentic specimen of methyl 3-amino-3-deoxy-D-α-glucoside (R_f 0.43) obtained by methanolysis of kanamycin and a synthetic specimen of 3-amino-3-deoxy-D-glucose[8] (R_f 0.30). The solvent system butanol-acetic acid-water (10 : 2 : 5) gave two spots of R_f 0.23 and 0.14, which were identical with the spots of the above-mentioned specimens (R_f 0.23, 0.15).

1, 2, 3, 4-Tetra-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-β-D-glucopyranose (VI).—A mixture of 0.3 g. of 2, 3, 4-tri-*O*-acetyl-1-bromo-6-carbobenzoxyamino-1, 6-dideoxy-D-glucopyranose (V) prepared by our method[1] and 0.2 g. of silver acetate in 10 ml. of benzene was refluxed for 8 hr. and then worked up

6) The anomeric replacement by the Koenigs-Knorr reaction was discussed in detail by H. L. Frush and H. S. Isbell, *J. Research Natl. Bur. Standards*, **27**, 413 (1941); E. Pascu, *Advances in Carbohydrates Chemistry*, **1**, 78 (1945); and R. U. Lemieux, ibid., **9**, 1 (1954).

in a similar manner to that used for the compound II. The crude product was recrystallized from ethanol repeatedly to yield 0.18 g. (63.6%) of 1,2,3,4-tetra-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-β-D-glucopyranose, m. p. 144~145°C, $[\alpha]_D^{12}$ +10.2° (*c* 1.6, $CHCl_3$). The infrared spectrum of the product in Nujol contains absorption bands at 3385, 1760, 1745, 1550, 1240, 1212, 892, 774, 736, 700 cm^{-1}.

Found: C, 55.22; H, 5.75; N, 3.18. Calcd. for $C_{22}H_{27}NO_{11}$ (481.5): C, 54.88; H, 5.67; N, 2.91%.

2,3,4-Tri-*O*-acetyl-6-carbobenzoxyamino-1-β-chloro-1,6-dideoxy-D-glucopyranose (VII). — This material was prepared from 0.33 g. of 1,2,3,4-tetra-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-β-D-glucopyranose and 0.42 g. of aluminum chloride by the method used for the preparation of compound III. The crude product was recrystallized from ether-petroleum ether and then from benzene-ether to yield 0.28 g. (89.5%) of colorless crystals of 2,3,4-tri-*O*-acetyl-6-carbobenzoxyamino-1-β-chloro-1,6-dideoxy-D-glucopyranose, m. p. 158~158.5°C (decomp.), $[\alpha]_D^{15}$ +0.17° (initial) → +56.3° (final, 144 hr.) (*c* 1.7, $CHCl_3$). The infrared spectrum of the product in potassium bromide contains absorption bands at 3235, 1753, 1728, 1520, 1252, 1220, 901, 772 751, 696 cm^{-1}.

Found: C, 52.58; H, 5.29; N, 2.95; Cl, 7.36. Calcd. for $C_{20}H_{24}NO_9Cl$ (458.0): C, 52.35; H, 5.27; N, 3.08; Cl, 7.76%.

Methyl 2,3,4-Tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-α-D-glucopyranoside (VIII). — A mixture of 60 mg. of silver carbonate prepared by the method of Wolfrom et al.[4] and 300 mg. anhydrous calcium sulfate in 4 ml. of anhydrous methanol was shaken in dim light for 15 min. at room temperature. To the suspension was added 0.124 g. of 2,3,4-tri-*O*-acetyl-6-carbobenzoxyamino-1-β-chloro-1,6-dideoxy-D-glucopyranose and 10 mg. of silver perchlorate and the mixture was shaken in dim light for 2 hr. and then worked up in a similar manner to that used for the compound IV. The crude product was dissolved in isopropanol and *n*-hexane was added to the solution to yield a syrup, which was triturated with *n*-hexane to yield 0.075 g. (61%) of a crystalline powder of methyl 2,3,4-tri-*O*-acetyl-6-carbobenzoxyamino-6-deoxy-α-D-glucopyranoside, $[\alpha]_D^{15}$ +81° (*c* 0.91, $CHCl_3$). The infrared spectrum of the product in chloroform contains absorption bands at 3460, 1758, 1735, 1520, 1233, 1213, 847, 697 cm^{-1}.

Found: C, 55.30; H, 6.22; N, 3.10. Calcd. for $C_{21}H_{27}NO_{10}$ (453.5): C, 55.77; H, 5.76; N, 3.07%.

1,3,4,6-Tetra-*O*-acetyl-2-carbobenzoxyamino-2-deoxy-D-β-glucose (IX).—A mixture of 350 mg. of 2,4,6-tri-*O*-acetyl-1-bromo-2-carbobenzoxyamino-1,2-dideoxy-α-D-glucopyranose[9] and 245 mg. of silver acetate in 25 ml. of benzene was refluxed for 7 hr. and then worked up in a similar manner to that used for the compound II. The crude product was recrystallized from isopropanol-hexane to yield 250 mg. of the title compound, m. p. 147~148°C. Repeated recrystallization raised the m. p. to 150~150.5°C[10], $[\alpha]_D^{23}$ +28.1° (*c* 1.4, $CHCl_3$).

Found: C, 54.98; H, 5.70; N, 2.96. Calcd. for $C_{22}H_{27}NO_{11}$ (481.2): C, 54.88; H, 5.67; N, 2.91%.

Formation of Oxazolone Derivative from Tetra-acetyl Derivative of 2-Carbobenzoxyamino-2-deoxy-D-glucose.—A mixture of 630 mg. of 1,3,4,6-tetra-*O*-acetyl-2-carbobenzoxyamino-2-deoxy-D-glucose and 630 mg. of freshly prepared aluminum chloride in 9.5 ml. of chloroform was shaken at room temperature for 40 min. After addition of 150 ml. of benzene, the resulting mixture was washed with water and the benzene-layer was dried over sodium sulfate and evaporated to dryness under reduced pressure. Trituration of the residue with ether-petroleum ether yielded crystals of 4,5-(3,4,6-tri-*O*-acetyl-D-glucopyrano)-2-oxazolone; yield 450 mg. (75%). Recrystallization from benzene gave m. p. 170.5~174°C[11].

Found: N, 4.08. Calcd. for $C_{13}H_{17}NO_9$ (331.3): N, 4.02%.

The authors wish to express their appreciation for stimulating advice and interest in this research to Dr. Horace S. Isbell of the Organic Chemistry Section, National Bureau of Standards, U. S. A. The authors are also grateful to Mr. Saburo Nakada for microanalysis and Mr. Shin-ichi Nakamura and Mr. Yoshiaki Ito for helping their experiments.

*Permeability of Acidic Amino Acid through Anion Exchange Membrane**

By Yujiro HARA*

(Received January 22, 1962)

In order to obtain necessary information on the applicability of an ion-exchange membrane to the separation and purification of amino acids, experiments were carried out to study the permeability of an acidic amino acid through an anion exchange membrane comprised of a styrene-butadiene copolymer, and also to find membranes suitable for the separation of amino acids from chloride ions, conditions for electrolysis, and under what conditions acidic amino acids might or might not permeate through the membrane.

It was found that the permselectivity coefficient, T, of an acidic amino acid through an anion exchange membrane varied according to the current density, the total concentration of acidic amino acid and of chloride ions in the mixed solution used, the hydrogen ion concentration of the mixed solution and of the adjacent solution, separated by a membrane, and the character of the ion-exchange membrane used.

The permeability of ions through an ion-exchange membrane is very complicated, for it is affected by many factors. When an ion dialyzes through an ion-exchange membrane, the permeability of the ion is affected by the equilibrium according to the adsorption of ions by the ion-exchange membrane if the size of the ion is sufficiently smaller than that of the pores of the ion-exchange membrane. However, the permeability of an acidic amino acid through an ion-exchange membrane becomes more complicated when the size of the ion is approximately the same as that of the pore. Also, the hydrogen ion concentration in the membrane may have a very marked effect on the mobility of the amino acid in the membrane as acidic amino acid is an amphoteric electrolyte.

An experiment was carried out with a mixed solution of acidic amino acid and of a chloride ion system in order to examine the permeability of an acidic amino acid through an anion exchange membrane; the permselectivity coefficient, T, was also defined.

$$T=\frac{[A]_t}{[Cl]_t}\cdot\frac{[Cl]_s}{[A]_s} \quad (1)$$

where

$[A]_t$: Moles of acidic amino acid permeated
$[Cl]_t$: Moles of chloride ion permeated
$[A]_s$: Moles of acidic amino acid in the mixed solution
$[Cl]_s$: Moles of chloride ion in the mixed solution

Consequently, the value, T, is a criterion of the permeability of amino acid, with chloride as the standard.

Experimental

Properties of the Anion Exchange Membranes Used.—Membranes A-1 to A-3 were prepared by forming a styrene-butadiene copolymer with a styrene content of 50% into a thin membrane with heating rolls; cross-linkage was carried out by a Friedel-Crafts type catalyst such as the aluminum chloride-ether complex or titanium tetrachloride, followed by chloromethylation and quartenarization[1]. The pore size of the membrane can be changed to any desired size during this process by adjusting the cross-linkage of the resin component of the membrane[2]. The pore size of these membranes is in the decreasing order of A-1, A-2 and A-3

Membranes A-4 to A-6 were prepared by coating the A-3 membrane with a thin layer of such high-molecular substances as styrenesulfonic acid-butadiene copolymer, polyvinylbutyral polymer, and phenolsulfonic acid-formaldehyde condensate to form a porous net. The cation exchange membrane was prepared by sulfonating the above-mentioned thin membrane of styrene-butadiene copolymer with concentrated sulfuric acid[1]. Table I summarizes the properties of these anion and cation exchange membranes. The pore sizes of anion exchange membranes derived from styrene-butadiene copolymer were compared according to the values of water content, W (the amount of water per unit weight of the dry resin), the water penetration ratio[3] (K) of the membrane, and the specific

a) Degree of permeation of a diaphragm is a value indicating the size and distribution of pores derived from Poiseville's law on the assumption that the cross-section of pores of diaphragm is round. This is ordinarily indicated by the quantity (cc.) which transfer through 1 cm^2 of diaphragm having a thickness of 1 cm. in one hour under a static pressure of 1 cm. of water column when 0.5 M sucrose solution and water are placed on the opposite sides of the diaphragm.

b) See Table II.

TABLE II. METHOD FOR PRODUCING AN ION-EXCHANGE MEMBRANE COATED WITH HIGH MOLECULAR SUBSTANCES

Notation	Method for producing coated membrane
A-4	A benzene solution of styrene-butadiene copolymer with a styrene content of 50% is coated on one surface of the A-3 membrane and then sulfonated by dipping it in a 96% sulfuric acid solution for 6 hr.
A-5	One surface of the A-3 membrane is coated 3 times with an ethyl acetate solution of a 3% polyvinylbutyral solution with a brush.
A-6	A solution composed of 4 mol. of phenol, 1 mol. of *p*-phenolsulfonic acid, 3 mol. of sodium hydroxide, and 7 mol. of formaldehyde solution is left standing overnight and then heated to 70~80°C, by which means a viscous solution is obtained. The methanol solution of this is coated on one surface of the A-3 membrane, air-dried at 60°C, and cured by heating it at 120°C for 3~4 hr.

resistance (Ω-cm.). Although these values are the products of the size and number of pores of the membranes and do not indicate the size of the pores themselves, these were used as approximate comparative values.

Apparatus and Procedure.—An electrolytic cell*1, separated by 4 sheets of 7.5 cm. × 7.5 cm. anion and cation exchange membranes, as illustrated in Fig. 1, was used, with carbon (7 cm. × 14 cm. × 0.8 cm.) as the anode and nickel plate (7 cm. × 7 cm. × 0.3 mm.) as the cathode. In the intermediate compartments A and C, a 0.2% sodium sulfate solution was placed, a definite quantity of the mixed solution containing acidic amino acid and chloride ion (a quantity such that the reduction of acidic amino acid and chloride ions before and after the experiment is below 1%) is circulated in the direction of the arrow in compartment B, and a 3% sodium sulfate solution was circulated as the electrode solution in the direction of the arrow at a rate of 0.1~11./hr. in order to neutralyze the hydrogen ions and hydroxide ions produced in the electrode solution at all times and thus to prevent any effect of pH value fluctuation in the intermediate solution. A current of 5000~10000 coulombs was passed through each time. The solution in compartment C was removed after the current had been passed through, a quantitative analysis of the chloride

ions was made by the Volhard or Mohr method, the acidic amino acid was analyzed by colorimetry[5], and then the T values were determined from these values by using Eq. 1. The transport numbers of the acidic amino acid and of the chloride ions (t_G or t_A*2 and t_{Cl}) were calculated from the following equations from the quantity of electricity Q (coulomb), which had been determined by the use of a copper voltameter:

$$t_G \text{ or } t_A = \frac{Q[A]_t}{96496} \times 100 \quad (2)$$

$$t_{Cl} = \frac{Q[Cl]_t}{96496} \times 100 \quad (3)$$

The experiment was carried out in the temperature range of 15~25°C, but no temperature correction of the T value was made as it was assumed that the relative change in mobility between the acidic amino acid and the chloride ions could be ignored within this temperature range. The electrolytic cell was provided with two pairs of anion and cation exchange membranes, A_1 and C_1, and A_2 and C_2, as is illustrated in Fig. 1, of which, the A_1, C_1 and C_2 membranes were fixed throughout the experiment; only the anion exchange membrane A_2 was changed. Thus, the A-2 membrane was used for the A_1 membrane in Fig. 1, and the C-1 membrane for the C_1 and C_2 membranes.

Results and Discussion

Tables III and IV and Figs. 2—1~2—11 show the experimental conditions and results.

Effect of Current Density.—The permselectivity coefficient, T, should be little affected by varying the current density if the ion-exchange resin pores are sufficiently larger than the size of the acidic amino acid molecules; if this T value changes considerably with the current density, this indicates that the ion-exchange membrane is obstructing the permeation of the ions. Figure 2-1 shows the case of A-2 membrane-glutamic acid (neutral solution). It can be seen that there is a tendency for the ion-exchange membrane to obstruct the

Number in parentheses indicates the transport number of glutamic acid which migrated toward the cathode by passing through cation exchange membrane (C_1).

permeation of acidic amino acid and also that the T value is very low at a low current density but increases with a rise in the current density, irrespective of the concentration. Figure 2–2 shows the relationship between the T value and the current density when the concentration of glutamic acid is fixed and when the molar ratio of chloride ion and glutamic acid is changed variously; almost the same tendency can always be observed despite the changes. This may be assumed as being due to the sieve effect of ions which can be observed when two kinds of ions having different sizes permeate through the ion-exchange membrane. Such a sieve effect is weakened by an increase in the current density, and larger ions will then also begin to permeate. Consequently, the sieve effect of glutamic acid and chloride ions on the ion-exchange membrane increased as the current density becomes lower.

As can be seen in Figs. 2–1 and 2–2, a horizontal movement or a lowering of the T value appears when the current density is increased to a range of 1.0~1.5 amp./dm² in the case of a low-concentration solution. This is due to the participation of hydrogen ions and hydroxide ions arising from the dissociation of water within the membrane as a result of insufficient supplies of glutamic acid and chloride ions resulting from the flow of electric current when the current density is increased more than necessary. Besides this, the relationship between the T value and the current density is affected by the kind and concentration of acidic amino acid, the properties of the membrane, and the hydrogen ion concentration of the mixed solution and of the solution in intermediate compartment C (referred to as the adjacent solution hereafter).

Effect of the Composition of the Mixed Solution.—A change in the composition of the mixed solution should naturally affect the T value due to the change in the ion concentration in the membrane, according to Donnan's membrane equilibrium theory. Figure 2–2 shows the relationship between the current density and the T value with the A-2 membrane when the concentration of glutamic acid is fixed and when the concentration of chloride ions is changed; the increase of the ratio of glutamic acid is accompanied by an increase in the T value when the current density is below 1.5 amp./dm². When the current density is 1.5 amp./dm², dissociation of water takes place above $[G]_S/[G]_S+[Cl]_S=0.65$ and there is a tendency toward a lowering of the T value. On the other hand, if the sum of the concentration of glutamic acid and chloride ions is made constant, the T value does not change very much, even when the solution composition is changed, as is shown in Fig. 2–3. It appears from the above results that the T value has a close relationship with the sum of the concentrations of glutamic acid and chloride ions; and this was also found to be true when comparing the experiments (Runs No. 8 and 9) when the sum of the concentrations of glutamic acid and chloride ions is the same but the concentration of each is reversed, there being almost the same tendencies in the relationship between the T value and the current density of both.

Effect of Concentration.—The effect of concentration on the permeability of glutamic acid through the A-2 membrane is shown in Fig. 2-4. There is a tendency for the T value to decrease as the concentration increase, and there is almost no permeation of glutamic acid when the concentration of the mixed solution is over 4×10^{-1} M, even if the current density is increased. The permeability of glutamic acid increases in a dilute solution,

but water dissociation starts at a high-current density. It was observed from these results that the conditions which make the permeation of glutamic acid through A-2 membrane easiest are the concentration of the mixed solution at 1×10^{-1} M and a current density in the neighborhood of 1.0 amp./dm², and that

chloride ions permeate selectively when dialyzed at a high concentration and in a low current density. Figure 2-5 shows the permeability of glutamic acid the A-1 membrane, which has larger pores than the A-2 membrane and in which quite a large T value was found even at a high concentration of over 4×10^{-1} M and in which quite a large penetration of glutamic acid was found through the A-1 membrane. The permeability of aspartic acid through the A-2 membrane was investigated in Run No.

24—26, in which it was observed that the effect of the change in concentration on the T value was more sensitive in the case of aspartic acid than in glutamic acid, since permeability with a dilute solution of below 1×10^{-1} M was good, and also, that it was dialyzed slightly even with a concentrated solution of over 4×10^{-1} M (Fig. 2-10).

Effect of the pH Value.—Amino acids are amphoteric electrolytes, with both anion and cation radicals in the molecule, and naturally their mobilities change according to the pH value when the dissociation condition of these radicals changes. In the present experiment, the permeability of glutamic and aspartic acids was examined under the conditions of hydrogen ion concentration at which the amino radical of acidic amino acid dissociates (near a pH value of 1.8), near the isoelectric point (pH value 3), near the neutral point when the first carboxyl dissociates, and at a pH value of 11.4~11.6 when the second carboxyl dissociates. As a general rule, it can be said that the permeability of an acidic amino acid through an anion exchange membrane is proportional to the degree of the dissociation of its carboxylic radical, which increases as the pH value rises. Consequently, it is advantageous to effect the migration of acidic amino acids in a bivalent state. In looking at the permeability of glutamic acid through the A-2 membrane indicated in Fig. 2-6, it can be observed that the T value increases with a rise in the pH value and that it is advantageous to dialyze glutamic acid in the bivalent rather than in the univalent form. A comparison of Runs No. 10 and 15 indicates that the T value does not increase so much on the weak alkaline side with the A-1 membrane, which has larger pores than the A-2 membrane, and that, consequently, it is not necessarily disadvantageous to dialyze glutamic acid in the univalent state. The same tendency can be observed in the case of aspartic acid (compare Runs No. 27 and 28). Besides the migration of acidic amino acid toward the anode by permeation through the anion exchange membrane (A_2), approximately the same amount migrates toward the cathode by passing through the cation exchange membrane (C_1) within the pH value range near the isoelectric point (Run No. 13). This is proof that amino acid is not in an electrical uncharged state at the isoelectric point but is present as zwitterion, having both negative and positive charges, and is neutral in appearance. It is also of interest to note that in an acid solution (pH value: 1.85) in which the amino radical of acidic amino acid dissociates sufficiently, glutamic acid migrates toward the anode by permeation through the anion exchange membrane (A_2), in addition to its movement toward the cathode through the cation exchange membrane (C_1). (Run No. 14). These results are in accord with those of the report by Yamabe et al.[6], in which they used a heterogeneous ion-exchange membrane, and indicate that amino acid in an aqueous solution is in an equilibrium relations as in the following equation (4);

$$\begin{aligned} NH_3^+\text{-}CH(R)\text{-}COOH &\rightleftharpoons NH_3^+\text{-}CH(R)\text{-}COO^- \\ &\quad + OH^- \qquad\qquad + H_2O \\ &\rightleftharpoons NH_2\text{-}CH(R)\text{-}COO^- \\ &\quad + H_3O^+ \end{aligned} \tag{4}$$

Effect of the Adjacent Solution.—When the anion in the intermediate compartment **B** solution permeates toward the anode through the anion exchange membrane (A_2), the hydrogen ion migrates toward the cathode through A_2 membrane since it can pass through the anion exchange membrane easily from the opposite direction if the hydrogen ion concentration in the adjacent solution (the intermediate compartment C solution) is high; as a result, the transport number of anions (acidic amino acid and chloride ions) in the anion exchange membrane becomes lower. Furthermore, dissociation of the carboxyl radical of acidic amino acid is suppressed and the transport number of acidic amino acid is lowered considerably if the hydrogen ion concentration in the membrane becomes high. Figure 2-7 shows the permeability of glutamic acid through the A-2 membrane when solutions with varying hydrogen ion concentrations (dilute sulfuric acid) were used as the adjacent solution. There was almost no dialysis of glutamic acid when a 0.1 N sulfuric acid solution was used as the adjacent solution, even when the current density was increased. Inhibition of the same degree against glutamic acid was observed when an 1N sulfuric acid solution was used as the adjacent solution with a A-1 membrane, which has a larger pore size. Furthermore, as a general tendency, the transport number (t_G) of glutamic acid becomes higher at a low current density if such an acidic solution is placed as the adjacent solution. It was made clear from these results that the hydrogen ion concentration of the adjacent solution has a great effect on the permeability of acidic amino acid; a hydrogen ion concentration of even about 0.1 N obstructs

6) T. Yamabe, M. Seno and N. Takai, This Bulletin, **32**, 1383 (1959); *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kogyo Kagaku Zasshi*), **64**, 556 (1961).

the dialysis of acidic amino acid considerably, and this becomes more marked as the pores of the anion exchange membrane become smaller.

Effect of the Properties of the Anion Exchange Membrane.—Figure 2–8 shows the relationship between the pore size of the membrane and the permeability of glutamic acid. It can be seen from Runs No. 1, 10 and 20 that the permeation of glutamic acid is obstructed considerably with membranes A-2 and A-3, which have small pores, while permeation is not obstructed to such an extent by membrane A-1; a horizontal movement of the T value is observed with a current density of over 1.0 amp./dm^2, and the permselectivity of anions as a whole becomes lower at a high current density. It can, therefore, be seen that A-1 is an appropriate membrane for the permeation of glutamic acid and that A-3 is the most unsuitable membrane of the three for the dialysis of glutamic acid.

Membranes coated with high-molecular substances (A-4 to A-6 membranes) were prepared in order to extend the characteristics of the A-3 membrane to retain the acidic amino acid, pass chloride ions selectively, and increase the mutual-sieving capacity of anions. The permeability of glutamic acid through these coated membranes and the basic A-3 membrane are compared in Fig. 2–9 and Runs No. 21–23, from which it can be seen that, as a common tendency, the permeation of glutamic acid is obstructed over a wide range of current densiy in coated membranes and that there is only a slight dialysis of glutamic acid. However, not only glutamic acid but also the permeation of chloride ions is obstructed by such a coated membrane; a very marked water dissociation takes place over a wide range of current densities in the coated membrane, as is observed from the sum of the transport numbers ($t_G + t_{Cl}$) of glutamic acid and chloride ions. The obstruction of glutamic acid dialysis by membranes coated with high molecular substances is in the decreasing order of A-6, > A-5 and > A-4 membranes; this is assumed to be correlated to the pore size intrinsic to the high molecular substances coated on the membrane. The membrane coated with phenolsulfonic acid-formaldehyde condensate (the A-6 membrane) obstructs the permeation of glutamic acid the most, and this tendency becomes weaker in the order of membranes coated with polyvinylbutyral (the A-5 membrane) and the product of styrenesulfonic acid - butadiene copolymer (the A-4 membrane). An inverse increase in T value is observed in the current density region in all of these coated membranes, but this is due to the fact that the transport number (t_G) of glutamic acid does not lower relative to that (t_{Cl}) of chloride ions.

Comparison of the Permeability of Glutamic Acid and Aspartic Acid.—A comparative study was made of glutamic acid and aspartic acid as representatives of acidic amino acids having a different number of methylene carbons. The permeability of glutamic acid and aspartic acid through the A-2 membrane is shown in Fig. 2–10, from which it can be seen that the permeability of aspartic acid is generally better than that of glutamic acid. The change in T value due to the change in current density with a concentrated solution in the case of aspartic acid is very slight, but the change is more violent with a dilute solution than in the case of glutamic acid. However, in the case of glutamic acid, the dissociation of water takes place with a dilute solution as the current density is increased; this results in a lowering of the T value. It is believed that glutamic acid encounters considerable resistance when permeating through the A-2 membrane. Figure 2–11 compares the permeability of these two acids through the A-1 membrane; it can be seen that the T value of aspartic acid is almost unaffected by the current density in the neutral or weakly alkaline states. In other words, the A-1 membrane does not obstruct the permeation of aspartic acid, but it does obstruct that of glutamic acid slightly. It is clear from this that ions which can permeate perfectly through the A-1 membrane have fewer than four carbon atoms.

The author is deeply indebted to Dr. T. Yawataya and his co-workers of Asahi Glass Co. for the generous supply of ion-exchange membranes used in this work. He is indebted to Mr. K. Tahara for his aid in performing some of the experiments reported on this work.

Crystal Growth of Magnesium Oxide Prepared by the Thermal Decomposition of Magnesium Hydroxide

By Yoshihide KOTERA, Tatsuo SAITO and Matsuo TERADA*

(Received September 11, 1962)

It is well known that active metallic oxides are prepared by the thermal decomposition of hydroxide or carbonate and that their physicochemical properties are determined by the temperature at which they are formed and by the duration of the calcination. It is, therefore, important to clarify the process which occurs during the decomposition of such a compound as hydroxide or carbonate and the subsequent calcination. We select the crystal growth of magnesium oxide prepared from hydroxide for this purpose, because this process, especially in a relatively low temperature range, has not been studied so much as have its surface properties[1-3]. It is pointed out in our study that the growth is rather complex and that it might nevertheless be possible to clarify that mechanism which is important in the preparation of magnesium oxide.

The present work is an attempt to examine the effect of the temperature of calcination, and of the duration of heating at a fixed temperature, on the crystal growth of magnesium oxide prepared by the dehydration of precipitated magnesium hydroxide and native brucite. The growth is discussed in the light of kinetics, and the activation energy calculated is compared with that for other oxides.

Experimental

Materials.—Two series of magnesium hydroxides have been examined; one of them was prepared by precipitation from a 0.1 N solution of reagent-grade magnesium chloride with a 2.5 N solution of reagent-grade sodium hydroxide, while the other was a piece of native brucite from Nevada, U. S. A.

In the preparation of former series, care was taken to ensure that all air coming in contact with the carbonate-free sodium hydroxide solution and with the mixture of this solution and the magnesium chloride solution had been freed from carbon dioxide. The precipitate obtained by the reaction between the two solutions was washed until a test for chloride ions with a silver nitrate solution gave only a faint milkiness; it was then decanted. Drying of the precipitate was carried out at 60°C for 50 hr. in a vacunm obtained by means of a water pump. The native brucite contains the following impurities: CaO : 0.82%, Fe_2O_3 : 0.79%, Al_2O_3 : 0.23%, SiO_2 : 0.14%.

Apparatus and Procedure.—The samples of magnesium hydroxide were ground into fine powder by a mortar and calcined in air at a definite temperature ranging from 500 to 900°C for varying periods. The fluctuation of the calcination temperature was kept within ± 5°C by means of an automatic temperature controller. After calcination, the products were cooled in a desiccator.

The X-ray specimens of magnesium oxide were smeared on a microscopic slide to give a flat surface approximately 2 cm. square. A Rigaku Denki "Geigerflex" (Geiger counter X-ray diffractometer) was employed to determine the mean apparent crystal sizes of the samples on the basis of the broadening of their X-ray diffraction lines. Measurements were made on the magnesium oxide (200) line using copper radiation. The calculation of particle size was carried out following the procedure of Birks and Friedman[4].

Experimental Results

Calcination at Temperatures Ranging from 500 to 900°C. — Precipitated magnesium hydroxide and brucite were calcined at 500, 600, 700, 800 and 900°C for periods ranging from 5 min. to 24 hr. The mean apparent crystal sizes, d, of the magnesium oxide thus obtained are plotted against the time of calcination, t, in Figs. 1 and 2 for precipitated magnesium hydroxide and for brucite respectively. From these results it can be seen that the crystal growth proceeds during the calcination, its rate being highest immediately after the end of dehydration and decreasing with the increase in the time of heating. In Figs. 3 and 4 the relation between the crystal size and time is plotted on a logarithmic scale. In these figures for all calcination temperatures, the curves are composed of two straight lines intersecting at about 100 min. It is concluded from these results that the calcination process is divided into earlier and later stages for all calcination temperatures. Further, it is possible to divide

the results into three groups when the slopes of these straight lines are calculated, the first consisting of a whole period at 500°C and an earlier stage at 600°C, the second consisting of a later stage at 600°C and an earlier at a temperature between 700 and 900°C, and the third, of later stages at a temperature between 700 and 900°C.

Calcination at Temperatures Ranging from 700 to 950°C.—Magnesium hydroxide samples were dehydrated at 700°C for 10 hr. and the magnesium oxide samples thus obtained were used as starting materials to clarify the calcination process at a temperature between 700 and 950°C. Magnesium oxide samples were calcined at 800, 850, 900 and 950°C for periods varying from 1 to 8 hr. When the crystal sizes were plotted on logarithmic scale, Fig. 5 was obtained for magnesium oxide from precipitated magnesium hydroxide, and Fig. 6 for magnesium oxide from brucite. Their sizes before the calcination are 350 Å for the former and 530 Å for the latter. It was found that the crystal size increases exponentially with the reciprocal of the calcination temperature, as is implicit for a typical case in Fig. 7.

From the results obtained it is possible to express the crystal sizes as the function of the temperature, T°K, and of the time, t, by the following equations:

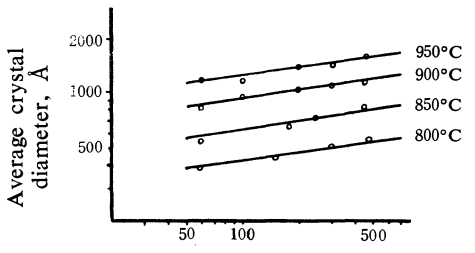

Fig. 5. Logarithmic plot of diameter change during heating between 800 and 950°C for MgO prepared from ppt. $Mg(OH)_2$ at 700°C.

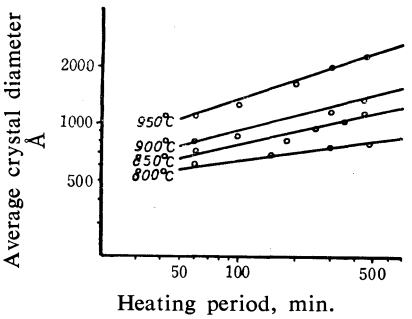

Fig. 6. Logarithmic plot of diameter change during heating between 800 and 950°C for MgO prepared from brucite at 700°C.

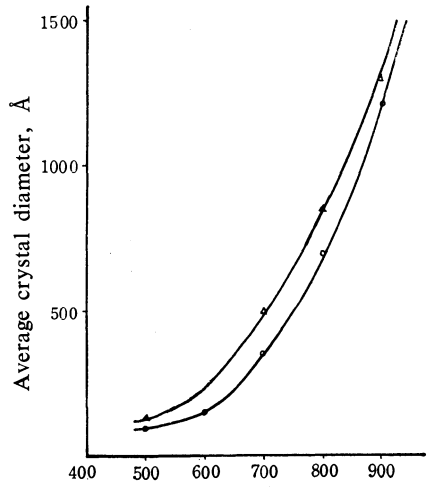

Fig. 7. Average crystal diameter as a function of calcination temperature. (calcination time: 24 hr.)

○—○ MgO prepared from ppt. $Mg(OH)_2$
△—△ MgO prepared from brucite

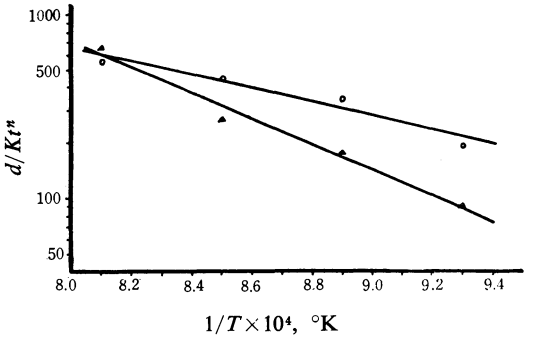

Fig. 8. Arrhenius plot for crystal growth of magnesium oxide samples prepared from ppt. magnesium hydroxide and brucite.

○—○ MgO prepared from ppt. $Mg(OH)_2$
△—△ MgO prepared from brucite

$d=K_1t^{1/6}\exp(-E_1/RT)$ for MgO from precipitated $Mg(OH)_2$ and

$d=K_2t^{1/4}\exp(-E_2/RT)$ for MgO from brucite, where K_1 and K_2 are constans, and E_1 and E_2 are activation energies for the crystal growth of magnesium oxide. It is probable that K_1 or K_2 may depend on the initial value of the crystal size.

In Fig. 8 the relation between $\log(d/Kt^n)$ and $1/T$ is plotted for both magnesium oxide samples; the values of the activation energy calculated from the figure are 17 kcal. for magnesium oxide from precipitated magnesium hydroxide and 32 kcal. for that from brucite.

Discussion

The effect of the conditions of preparation of the active metallic oxide in the thermal decomposition of hydroxide or carbonate upon its physico-chemical properties has been briefly studied. When the surface properties of magnesium oxide prepared from precipitated magnesium hydroxide or from brucite were studied by Gregg et al.[1], Livey et al.[2] and Razouk and Mikhail[3], it was found that these properties depend on the time as well as the temperature of decomposition of a parent substance, viz., precipitated magnesium hydroxide or brucite. Meanwhile, Birks and Friedman[4] studied the particle size determination of magnesium oxide prepared from the carbonate by means of an X-ray line broadening method; they compared the results with direct measurement by means of electron microscopy. They concluded that the results obtained by the two methods agree $\pm$ 10 per cent except for particles smaller than 100 Å. Their results show the dependence of particle size on the time and temperature of calcination, but no explanation was given in their study.

In the present study, precipitated magnesium hydroxide was used as a starting material as well as brucite. It might be necessary to compare the results of the former with those of the latter in order to elucidate the disagreement which seems to be present in the results based on the surface properties of magnesium oxide prepared from precipitated magnesium hydroxide[3]. On the other hand, brucite contains more impurities than precipitated magnesium hydroxide, and this fact may make it impossible to obtain accurate results on crystal growth kinetics which depend upon the purity of a parent substance. The naturally-occuring crystalline brucite chosen was as pure as possible, but it still contains the small amount of impurities described above.

The crystal sizes of magnesium oxide prepared from hydroxide increase with a rise in the calcination temperature and with its duration, a tendency similar to that in the case of carbonate. Comparing Birks' results[4] with ours shows that the increase in crystal size with a rise in the temperature is more prominent for oxide from hydroxide than for that from carbonate. The stages found for oxide from hydroxide are not found in the results by Birks, in which the shortest time of calcination carried out was 2 hr. In the study of the sintering of active magnesium oxide, Gregg et al.[1] found that the micellar length calculated under the assumption that the material exists as equal cubelets increases proportional to the square root of the time between 1 and 350 hr. at temperatures between 400 and 600°C. It is probable that the lowering of the temperature may serve to increase the value of the exponent relative to time in the equation expressing the relation between crystal size and calcination time, such a tendency being seen in our experiments. Nevertheless, it seems to be difficult to compare the micellar length calculated from the surface area with the crystal size obtained by the X-ray broadening method.

According to Hüttig's views[5], which have been verified by others, sintering is caused by three processes, viz., surface adhesion, surface diffusion and lattice diffusion. The first process may occur even at room temperature at the points of contact between neighboring micelles. The shearing stress exerted by the micelles near the region of contact leads to the deformation of the micelles and an increase in the area of contact over which adhesion occurs. As the rise in temperature reduces the rigidity of solids, adhesion will increase with the rise in temperature, and so also will sintering. This process occurs at temperatures above one-fourth of the melting point of the solid. Surface diffusion resulting from the mobility of the ions of the solid at its surface becomes sensible at a temperature about one-third of the melting point of the solid, while lattice diffusion, where the ions can move through the bulk of the micelles, occurs only at temperature above half the melting point. The last effect probably does not play an important part in the present work, as the highest temperature used was 950°C, which corresponds to 40% of the melting point (3100°K). Meanwhile, it has been pointed out[6] that there is a period during which surface roughness is destroyed and which is followed by an adhesion period. In the present study, it was found that there are three groups in the results for the calcination between 500 and 900°C; it may be assumed that they correspond to surface smoothing, surface adhesion and surface diffusion. In the explanation of the results concerning the sintering of magnesium oxide at temperatures between 400 and 600°C, Gregg et al.[1] pointed out that the temperature is so low that both surface diffusion and bulk diffusion seem to be ruled out, leaving adhesion alone, but they also pointed out that simple adhesion cannot represent the whole process. It is probable that surface smoothing remains before an adhesion period in their experiments. This

5) F. Hüttig, *Kolloid-Z.*, **98**, 263 (1942); **99**, 262 (1942).
6) F. S. Stone, "Reactivity of Solids", Elsevier, Amsterdam (1961), p. 15.

idea is supported by the fact that the decreasing rate of surface area is very high, even at such a low temperature as 500 or 600°C[1], while the increase in crystal size is not so rapid at such a low temperature (Figs. 1 and 2). However, the later stage at 600°C may be explained as the beginning of surface adhesion. In the second group, viz., the later stage at 600°C and earlier stages at a temperature between 700 and 900°C, surface adhesion would occur. Furthermore, the crystal growth occurs in the last group, viz., the later stages at a temperature between 700 and 900°C, according to the mechanism associated with surface diffusion.

In the last group, the value of the exponent to time in the equation expressing the relation between crystal size and calcination time, as well as the value of activation energy for the crystal growth, are different in magnesium oxide obtained from precipitated hydroxide and that obtained from brucite. The values of activation energy, 17 kcal. for the former and 32 kcal. for the latter, are nearly the same as those of the surface diffusion in other oxides. Latty[7] studied the crystal growth of rutile-type titanium oxide and obtained a value of 16,68 kcal./mol. for alkali-free oxide in the temperature region between 585° and 750°C, where surface diffusion can be expected to be operative. Further, in their study of the sintering reactions of zinc oxide, Lee and Parravano[8] calculated the activation energy of the diffusion of excess zinc ions through the very thin oxidized layer to be about 18 kcal./mol. in the temperature range between 700 and 900°C. It might be assumed that surface diffusion occurs in this case. The difference in activation energy between precipitated magnesium hydroxide and brucite is difficult to explain in this work, and it is probable that lattice diffusion occurs in the case of brucite. That lattice diffusion occurs at such a low temperature might be due to the presence of impurities.

Summary

The particle size of magnesium oxide crystals prepared by the thermal decompositions of pure precipitated magnesium hydroxide and native brucite at various temperatures between 500 and 900°C has been measured by the X-ray line broadening method, and the effect of the calcination temperature and its duration on the crystal size of magnesium oxide has been examined.

It has been found that the particle size of magnesium oxide crystals increasese with the increase in the calcination temperature and that the rate of crystal growth obeys a different law between the earlier stage of the calcination process at a definite temperature and the later stage. It has also been found that the crystal growth of magnesium oxide proceeds proportional to t^n, (t: time), where n is 1/6 for the later stage of the calcination of magnesium oxide from precipitated magnesium hydroxide at temperatures ranging from 700 to 900°C and 1/4 for the same calcination of that from brucite. The values of the activation energy calculated by Arrhenius plot are 17 and 32 kcal./mol. for magnesium oxide obtained from precipitated hydroxide and from brucite respectively.

*The Menschutkin Reaction in Liquid Sulfur Dioxide**

By Niichiro TOKURA and Yasuhiko KONDO

(Received September 13, 1962)

Liquid sulfur dioxide has been said to be one of the most ionizing solvents[1]. It has been previously reported that the cationic polymerization[2] and the intramolecular rearrangements such as the Beckmann[3] and Wagner-Meerwein rearrangements[4] in liquid sulfur dioxide are carried out at extraordinarily fast rate. The reasons for such an accelerating effect of sulfur dioxide have also been discussed. Such a conspicuous property of sulfur dioxide perhaps is due to 1) the large ionizing power, 2) the solubility both to organic (olefin and aromatic compounds) and inorganic (aluminum chloride, stannic chloride and so on) materials, 3) the aprotic and protophobic nature with no affinity to proton or carbonium ion.

Among many nucleophilic reactions studied, the Menschutkin reaction is one of the most discussed and well established reaction[5]. Moreover, since the first kinetic study by Menschutkin appeared in 1890[5a], the effect of the solvents on this reaction has been comprehensively studied and summarized in many articles and reviews[5]. Although the rate of solvolysis of alkyl halides depends upon the ionizing power of the solvent, that of the Menschutkin reaction does not. The plot of the specific rates of the latter reaction against the *Z* values[6] of the corresponding solvents does not give a linear correlation.

The object of this investigation has been to study the effect of liquid sulfur dioxide as solvent on the Menschutkin reaction, since no kinetical comparison has been made between the rates in sulfur dioxide and other solvents by this time.

Study of the nucleophilic attack of fluoride anion, amines or pyridine on *m*-chlorobenzhydryl chloride in liquid sulfur dioxide was undertaken by Ingold et al.[7], wherein they observed a peculiar phenomenon, the so-called borderline case, the reaction being classified neither as S_N1 nor S_N2. The aprotic and even protophobic character of liquid sulfur dioxide would be the reason why they performed the reaction in this solvent, though the reaction in liquid sulfur dioxide resulted in more complexity than was expected.

Ingold et al. used electric conductivity measurement of the reaction mixture to trace the kinetics. The organic halides in liquid sulfur dioxide have often been shown to have considerable conductivities[8]. In addition, the presence of a trace of water which could not be eliminated from liquid sulfur dioxide by the ordinary method[9] may perhaps affect largely the results of the kinetic measurement.

The present authors have chosen a reaction, the Menschutkin reaction between methyl or ethyl halide and a base in liquid sulfur dioxide, in which the ionization of the alkyl chloride was surpressed in order to eliminate the S_N1 type reaction as much as possible. The kinetics was followed by a potentiometric titration of iodide ion produced. Dimethylaniline, dimethyl-*o*-toluidine or pyridine was used as a base. The reaction rate in liquid sulfur dioxide has been compared with those in other solvents, such as methanol, nitrobenzene, nitromethane, tetrahydrofuran, acetone, acetonitrile, dimethylformamide and dimethylsulfoxide.

Experimental

Materials. — Methyl, ethyl or isopropyl iodide was washed with sodium thiosulfate solution, water, sodium carbonate solution and water successively, dried and distilled: methyl iodide, b. p. 42.5～43.0°C, ethyl iodide, b. p. 68～72.3°C (impurity was below 1% by V. P. C.), isopropyl iodide, b. p. 88.2～89.0°C. Dimethylaniline or dimethyl-*o*-toluidine was refluxed with acetic anhydride and distilled.

The distillate was again treated with potassium hydroxide and distilled. Pyridine, rigorously dehydrated and distilled was donated by Ikenoue[10]. Liquid sulfur dioxide was dried with phosphorus pentoxide and distilled. Tetrahydrofuran, acetonitrile, nitromethane, acetone, dimethylformamide and dimethylsulfoxide were purified by known methods[11].

Kinetic Procedure.—The method and the apparatus used were demonstrated elsewhere[12]. An alkyl iodide (0.2~0.6 mol./l.) was reacted with a base (0.2~0.6 mol./l.) in liquid sulfur dioxide in a thermostat. After a definite time, reaction mixture was mixed with petroleum benzine (b. p. 60~80°C) and the iodide ion produced was extracted thrice with water. After evaporation of sulfur dioxide gas from the aqueous extract in vacuo, the iodide ion in the solution was titrated with silver nitrate solution potentiometrically. A typical run of the reaction between methyl iodide and pyridine in liquid sulfur dioxide is listed in Table I. The reaction in acetone or other solvent was also conducted to compare with the result in liquid sulfur dioxide, which is indicated in Table II.

Results

Reaction of Alkyl Iodide with Pyridine. — Alkyl iodide (0.2~0.6 mol./l.) was reacted with a base (0.2~0.6 mol./l.) in liquid sulfur dioxide. The reaction followed a second order rate law, being first order both in alkyl iodide and in pyridine. The second order rate constants were calculated according to the equation, $kt = \{1/(b-a)\} \ln [a(b-x)/b(a-x)]$ and the Arrhenius parameters were estimated as is listed in Table III.

Table III. The rate of the reaction between methyl iodide and pyridine*

Reaction temp., °C	$k \times 10^5$ l. mol^{-1} sec^{-1}	$\Delta E^{\ddagger}$ kcal./mol.	$\Delta S^{\ddagger}$ e. u.
20	3.38		
30	9.00	17.8	−22.2(40°C)
40	24.70		

* The concentration of pyridine was equal to that of methyl iodide.

The similar reactions with the concentration range (0.2~0.6 mol./l. of each reactant) have been conducted in acetone (Table II), dimethylformamide, dimethylsulfoxide, nitromethane, acetonitrile or tetrahydrofuran to find out that the reactions were all of the second order. A comparison of the second order rate constants in these solvents is listed in Table IV.

Table IV. Comparison of second order rate constants

Solvent	k, (40°C) l. mol. sec^{-1}	Ratio $k_{solvent}/k_{SO_2}$
Tetrahydrofuran*	1.74×10^{-4}	0.7
Liq. SO_2	2.47×10^{-4}	1
Acetone	6.37×10^{-4}	2.6
Acetonitrile	1.13×10^{-3}	4.6
Nitromethane	1.48×10^{-3}	6.0
Dimethylformamide	3.12×10^{-3}	12.6
Dimethylsulfoxide**	6.85×10^{-3}	27.7

* The reaction was partly heterogeneous.

** However dimethylsulfoxide reacts with methyl iodide as,

$$CH_3I + (CH_3)_2SO = (CH_3)_3SO^+ + I^-$$

the Menschutkin reaction is so fast that the reaction of sulfonium ion formation is not competitive[13].

Reaction of Alkyl Iodide with Dimethylaniline or Dimethyl-*o*-toluidine. — In the series of these experiments, the reaction was also of the second order. The results are listed in Table V.

13) a) S. G. Smith and S. Winstein, *Tetrahedron*, **3**, 317 (1958); b) R. Kuhn and Trischmann, *Ann.*, 611, 117 (1958).

TABLE V. THE RATE CONSTANTS OF THE REACTIONS BETWEEN ALKYL HALIDES AND DIMETHYLANILINES

Reaction temp., °C	k l. mol^{-1} sec^{-1}	$\Delta E^{\ddagger}$ kcal./mol.	$\Delta S^{\ddagger}$ e. u.
(a) Dimethylaniline - methyl iodide			
30	1.72×10^{-5}		
40	4.77	17.2	−27.3(40°C)
50	9.93		
(b) Dimethyl-*o*-toluidine - methyl iodide			
40	1.65×10^{-5}		
50	3.62	15.9	−33.7(50°C)
60	7.81		
(c) Dimethylaniline - ethyl iodide			
40	3.41×10^{-6}		
50	8.63	17.9	−30.4(50°C)
60	21.80		
(d) Dimethylaniline - isopropyl iodide			
50	1.28×10^{-6}		
60	3.14	18.9	−31.0(60°C)
65	4.77		

As is seen in Table III, the reaction rate decreases as the alkyl halides varies from methyl to isopropyl iodide. When dimethyl-*o*-toluidine was reacted with methyl iodide in place of dimethylaniline, the rate depressed slightly. (Table VII).

Comparison of the reaction rate in liquid sulfur dioxide with that in methanol or in nitromethane is listed in Table VI.

TABLE VI

(a) Comparison of the second order rate constants

Dimethyl aniline - methyl iodide

$k_{\text{methanol}}{}^{14)}/k_{SO_2}=4.18$ (50°C)

$k_{\text{nitrobenzene}}{}^{15)}/k_{SO_2}=4.40$ (40°C)

(b) Comparison of the Arrhenius parameter

Solvent	$\Delta E^{\ddagger}$, kcal./mol.	$\Delta S^{\ddagger}$ e. s.
Liq. SO_2	17.2	−27.3
Methanol[14)]	15.2	−31
Nitrobenzene[15)]	12.8	−38

Among the three of the solvents, the rate in liquid sulfur dioxide is the least. The effect of the ortho-methyl group on the benzene ring of aniline derivative on the rate is described in Table VII.

TABLE VII. EFFECT OF *o*-METHYL IN DIMETHYLANILINE

Solvent	k_H/k_{o-Me}
Liq. SO_2	2.74 (50°C)
Methanol[14)]	28.5 (65°C)

k_H/k_{o-Me} is the ratio of the rate constant in the reaction of methyl iodide with dimethylaniline (k_H) against that with dimethyl-*o*-toluidine (k_{o-Me}). However the temperatures in the reaction in comparison are somewhat different, the ortho-effect in liquid sulfur dioxide (2.74) is very small as compared with that in methanol (28.5).

Discussion

In the preceding studies on the cationic reactions, i. e. both in the Beckmann rearrangement[3)] and in the cationic polymerization[2)], the reaction rates were found to be the fastest in liquid sulfur dioxide as compared with the organic solvents generally used. It is, therefore, a question why the Menschutkin reaction in liquid sulfur dioxide is so slow, whereas the rearrangement and the cationic polymerization in the same solvent are so fast.

Here, the role of the solvation as well as the ionizing power of the solvent in the nucleophilic substitution must be considered. A general survey of the solvation is indicated in Chart 1, in which RX may be either a covalent

Chart 1

Classification of the solvation of a solvent on a substrate

$RX=R^+S+X^-S$	(A) Biphilic solvation
$RX=R^++X^-S$	(B) Electrophilic solvation
$RX=R^+S+X^-$	(C) Nucleophilic solvation
$RX=R^++X^-$	(D)

link compound such as alkyl halide or an ionophore[16)] such as tetraethylammonium chloride. In Chart 1, only a general feature of solvation is demonstrated and the detailed discussion on the extent of the ionization or the dissociation may be reserved for further investigation at the present stage. In addition, the number of the solvent molecules solvating on an ion is also not considered. The letter S in Chart 1 thus indicates an indefinite number of the solvent molecules solvating on a cation or an anion. However the strength of each solvation may also be varied as the solvent changes, the four models, A—D, used only to elucidate the role of the solvent on the solvation.

A, (biphilic solvation), is often the case in hydroxylic solvent (a solvent having the OH group) such as water or alcohol, where both ions are solvated by the solvent, the cation being coordinated with the O atom of the solvent and the anion being hydrogen bonded

14) D. P. Evans, H. B. Watson and R. Williams, *J. Chem. Soc.*, **1939**, 1345, 1348.

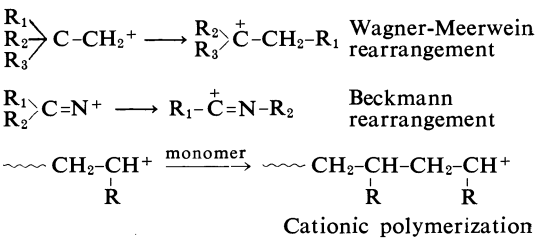
16) R. M. Fuoss, *J. Chem. Educ.*, **32**, 527 (1955).

by the solvent. This is the most popular and the most well established case of the solvation. D, (no solvent solvation) may be the case of no actual existence, but in gaseous state or in extremely inert solvent, a case close to D seems likely to take place. Special attention should be added to the cases, B and C, where either an anion (case B) or a cation (case C) is solvated, the counter ions (a cation in B and an anion in C) being unsolvated by the respective solvents and kept free. B (electrophilic solvation) is the case of liquid sulfur dioxide or sulfuric acid. C (nucleophilic solvation) is the case of the solvent of a basic character such as dimethylformamide, dimethylsulfoxide or acetone. The concept of the *unsolvated ion* or the *bare ion*[17] may be of some importance in the ionic reaction, since such a *bare ion* may be unstable and reactive, and could offer an appropriate driving force for the reaction.

Although sulfur dioxide is a strongly ionizing solvent, the ionizing power is due to the highly selective complexing of the solvent (sulfur dioxide) to the anion, thus the *bare caton* (unsolvated cation) is remaining as an unstable and reactive species. However, since the cation or the carbonium ion is surrounded by the cage of sulfur dioxide molecules which repel the ion, the cation is alive as long as no foreign substance is present in the solution and the counter anion is strongly solvated and supported by liquid sulfur dioxide. The unusual reactivity[2-4] is also consistent with the production of some new types of the nonclassical cations[18] in sulfur dioxide, because in both reactions strong solvation of anions is of utmost necessity.

Since sulfur dioxide is a Lewis acid, the affinity to proton or cation may be extremely small. There have been many evidences which support the denial of the proton affinity of sulfur dioxide[19,20], whereas anion or base is strongly solvated in this solvent. The *bare cation* (carbonium ion or immonium ion) produced in liquid sulfur dioxide as is depicted in Chart 1 may be quite useful to carry out the reactions (rearrangement and polymerization) in unusual speed.

Chart 2



The reverse situation may be found in the Menschutkin reaction. In this case the strong solvation of sulfur dioxide with anion or base may greatly retard the reaction velocity. It is worthy to note that the reaction favored by sulfur dioxide as listed in Chart 2 is a cationic intramolecular reaction or a cationic reaction in which a cation is reacting with a neutral molecule such as a vinyl monomer, the interfering anion being eliminated by complexing with sulfur dioxide.

In a nucleophilic substitution, S_N1 or S_N2, whichever the reaction may be, the attacking reagent, an anion or a base, may be strongly seized by liquid sulfur dioxide. The number of the reacting anion or base available for the reaction must then be reduced greatly. The complexed base may sometimes be able to participate in the reaction, but the reaction rate may be far more depressed. The consideration on the diffusion velocity or on the steric effect of the bulky complexes may also support this view. That a borderline case[7] is observed in a substitution which may otherwise be an S_N1 reaction is accordingly easily understood, since the rate-determining step (the ionization of RX) is not followed by a fast step of the combination of the R^+ (carbonium ion) with an anion or a base. In liquid sulfur dioxide the anion or the base is complexed with sulfur dioxide, so the rate of the second step is not so fast and even a case in which the second step is rate-determining may also be probable. Even if the alkyl halide may be a strong ionizing substrate such as *t*-butyl iodide, the situation that the reaction is very slow will not be improved. In the experimental conditions applied, isopropyl iodide reacted in the slowest rate among the alkyl iodides obeying the second order rate law as is seen in Table VI, which may be attributed to the steric effect[21]. The observed, comparatively small ortho-effect (Table VII) in liquid sulfur dioxide as compared to that in methanol in the reaction of methyl iodide with dimethyl-*o*-toluidine may perhaps due to the smaller solvation of dimethyl-*o*-toluidine by sulfur dioxide.

17) N, Tokura, *Kagaku*, **17**, 575 (1962). The present authors would like to use the term "*bare ion*" instead of the frequently used, "*free ion*", since the latter term has been confusedly adopted both for unsolvated and solvated ions.

18) a) H. Dauben, F. A. Gadecki, K. M. Harmon and D. L. Pearson, *J. Am. Chem. Soc.*, **79**, 4577 (1957); S. Winstein and C. Ordonneau, ibid, **82**, 2084 (1960); c) R. R. Story and M. Saunders, ibid., **82**, 6199 (1960).

19) H. Hart and G. Levitt, *J. Org. Chem.*, **21**, 921 (1956).

20) The view suggested earlier by Sidgwick (W. A. Waters, "Physical Aspect of Organic Chemistry", Routledge and Kogan, London (1950), p. 230.) that liq. SO_2 may have solvations both for cation and anion must be amended.

21) See Ref. 5c), p. 75.

Among the solvents used, the Menschutkin reaction in liquid sulfur dioxide was the slowest (Tables IV and VI). However, the Menschutkin reaction may be greatly favored by the solvent in which a *bare base* is permitted. This is the reason why the reaction in dimethylformamide or in dimethylsulfoxide is very fast. Of course, the quaternization reaction may be facilitated by the ionizing power of the solvent as may be seen by the fact that the rate constant in dimethylformamide is larger than in acetone (Table IV), since the product of the reaction is an ion pair.

Inspection of Table VI reveals that activation energy increases and the activation entropy also increases in liquid sulfur dioxide, the solvation being decreasing in approach to the transition state. The reaction in tetrahydrofuran was slow and comparable to the rate in sulfur dioxide, however, the reaction was heterogeneous owing to the lower solubility of the reactants in this solvent and the rate can not be discussed on the same basis.

The rate in nitromethane was six umes faster as that in liquid sulfur dioxide. No adequate explanation has been prepared for the rate increase except that nitromethane is a very ionizing solvent and the solvation to the base may not be so large by steric reason.

Summary

1) The Menschutkin reaction (reaction of methyl, ethyl or isopropyl iodide with pyridine, dimethylaniline or dimethyl-*o*-toluidine) has been carried out in liquid sulfur dioxide. The reaction rate has been compared with those in other commonly used solvents.

2) The reaction rate in liquid sulfur dioxide is the slowest, whereas the previously performed reactions such as the Beckmann rearrangement and the cationic polymerization in this solvent were the fastest among the solvents ordinarily used.

3) The reason for such a discrepancy has been discussed. Importance of the *bare* (or unsolvated) ion or species in an ionic reaction is presented.

The authors are indebted to the Seitetsu Kakagu K. K. for the denotion of liquid sulfur dioxide. Part of the expensed for this study has been defrayed by the grant-in-aid from the Ministry of Education.

The Surface Activities of Bivalent Metal Alkyl Sulfates. I. On the Micelles of Some Metal Alkyl Sulfates

By Iwao SATAKE, Ichiro IWAMATSU, Shizuko HOSOKAWA and Ryohei MATUURA

(Received September 21, 1962)

Innumerable data have been accumulated by a number of authors in the field of surface chemical studies of long chain alkyl sulfates and sulfonates of monovalent metals, especially of sodium. However, only a little work has been performed on the surface chemical properties of water-soluble detergents containing bivalent metals. The first publications on their surface chemical properties were produced by Lottermoser and Stoll[1], and by Lottermoser and Püschel[2] for various bivalent metal dodecyl sulfates, in which the electrical conductivities and the surface tensions of aqueous solutions were reported. Giers and Boide[3] synthesized zinc, calcium and magnesium dodecyl sulfates and measured the viscosities and contact angles of the solutions against solids. Recently Miyamoto[4-6] has determined the solubilities of various bivalent metal dodecyl sulfates in water and the critical micelle concentration (CMC) of the solutions by the surface tension method. He has found that the CMC values of these detergents are

almost independent of the kind of metal ion and are about 1×10^{-3} mol./l. Further discussions on the surface activity of calcium dodecyl sulfate were presented by Lange[7] in connection with the effects of addded electrolytes on the CMC values of detergent solutions, and later by Corkill and Goodman[8] on the micelle formation in an aqueous solution. Tartar and Lelong[9] determined the micellar molecular weight of magnesium dodecyl sulfonate in an aqueous solution. Bone and O'Day[10] have reported the antibacterial activities of various bivalent metal dodecyl sulfates.

It is true that all these works have given us some information on the nature of the surface activity of metal alkyl sulfate, but no deep insight into this surface activity has yet been achieved because of the scarcity of fundamental data on the properties of the solutions of metal alkyl sulfates. The purpose of the present paper is to obtain a knowledge of the micelles of some bivalent metal alkyl sulfates which have not yet been studied fully. As Miyamoto[5] showed, the Krafft point of some metal salts is so high that the determination of the micellar properties is experimentally difficult for them. Therefore, here we have used cobalt, nickel, copper and magnesium salts which had Krafft points near room temperatures.

Experimental

Materials. — The bivalent metal alkyl sulfates were synthesized from pure sodium alkyl sulfate and inorganic salt according to the method used by Lottermoser and Püschel[2]. They were purified by repeated recrystallization. Sodium alkyl sulfate was prepared from the purified fatty alcohol obtained by the fractional distillation of commercial samples, as has been stated earlier[11]. The purity of the metal alkyl sulfates was confirmed by elementary analysis and surface tension measurement. The results of the elementary analysis of these detergents are summarized in Table I.

Method.—The CMC's of the aqueous solutions of bivalent metal dodecyl sulfates were determined by the conductivity method at 30°C using a Yanagimoto conductivity outfit model MY-7. The CMC values of copper tetradecyl and hexadecyl sulfates were determined by the surface tension method at the temperature above each Krafft point; the same surface tension method was adopted for the determination of the CMC's of the detergent solutions with inorganic salts added.

Table I. The elementary analysis of various bivalent metal alkyl sulfates

Detergent		Metal content %	C, %	H, %

DS: Dodecyl sulfate radical; TS: Tetradecyl sulfate radical; HS: Hexadecyl sulfate radical

The micellar molecular weights were estimated by the light scattering method, using a Shimadzu photoelectric light-scattering photometer and a Brice Phoenix universal light scattering photometer at 436 and 546 mμ with a semi-octagonal cell. The dependence of the refractive indices on the concentration of the detergents were measured by a Brice Phoenix differential refractometer at the same wavelength. The measurements were performed in the salt free and 0.1 M metal sulfate solutions.

The micellar charge was evaluated from the data of conductivity and light scattering using the equation previously reported[12].

Results and Discussion

The CMC's of Various Bivalent Metal Dodecyl Sulfates.—The critical micelle concentration is one of the most fundamental quantities in determining the surface activity of the detergent solution. Table II shows the CMC values of various bivalent metal alkyl sulfates. The CMC values obtained are almost the same within the range of experimental error, and no differences can be observed among various metal dodecyl sulfates. The CMC value of about 1.2×10^{-3} mol./l. obtained for various bivalent metal dodecyl sulfates in the present experiment is in good agreement with the value of 1.7×10^{-3} mol./l. at 40°C obtained by Lottermoser and Püschel[2] and the value of 1×10^{-3} mol./l. at various temperatures obtained by Miyamoto[6].

These CMC values are quite small compared with those of the corresponding monovalent metal dodecyl sulfates, e. g., sodium salt, indicating the increased surface activity of bivalent

$Cu(HS)_2$	47	5.8×10^{-5}	Surface tension

salts. Miyamoto[5,6] reported that quite similar CMC values are also obtained for calcium, lead and strontium dodecyl sulfates; however, their Krafft points are 50, 53 and 64°C respectively, which are considerably higher than those of copper, cobalt and magnesium salts, which are 24, 23 and 25°C respectively. Also, the solubility of these salts is quite different from each other. Nevertheless, the CMC values are nearly identical for all these bivalent metal dodecyl sulfates. This means that the fundamental factor responsible for determining the CMC value of a detergent is the valency of the metal ion; varying the kind of metal ion having the same valency has little or no detectable effect on the CMC value, provided that the anionic group is the same.

When the alkyl chain length of the anionic group increases for the same metal salt, copper salt in the present case, the CMC value varies according to the formula:

$$\log(\mathrm{CMC}) = AN + B \qquad (1)$$

as is the case with usual monovalent detergents. Here N is the number of carbon atoms in the alkyl chain, and A and B are constants. Figure 1 shows the relation between log (CMC) and N in the copper alkyl sulfates. The value of -0.32 is obtained for A, which is in good agreement with the value of -0.3 obtained for various alkyl sulfates of sodium.

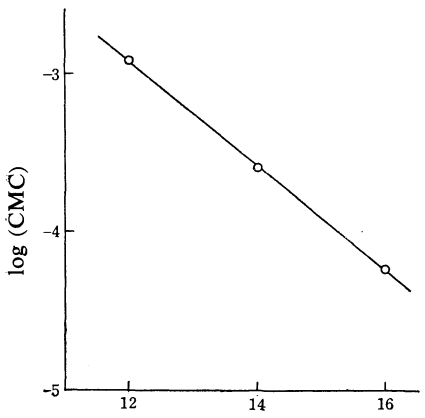

Fig. 1. Relation between log (CMC) and the number of carbon atoms in the chain of copper alkyl sulfates.

Effects of the Added Electrolytes on the CMC Value.—The effects of added electrolytes on the CMC value of the detergent have been widely studied by many authors. Especially, Corrin and Harkins[13] have investigated the effects of added electrolytes on the CMC values of various detergents and have found the following empirical equation between the CMC value and the total gegen-ion concentration:

$$\log(\mathrm{CMC}) = a\log m^+ + b \qquad (2)$$

Here a and b are constants, and $m^+ = (\mathrm{CMC}) + C'$, where C' is the concentration of added electrolytes. Subsequent investigation of this problem was carried out by Lange[7], who obtained the same empirical relation when the valencies of the ion of the added electrolyte and the detergent gegen-ion are identical. However, he pointed out that Eq. 2 is not applicable if the valency of the ion of the added electrolyte is different from that of the gegen-ion, although he suggested that when the concentration of the added electrolytes is higher than that of detergent gegen-ions, a similar type of equation can be applied, one in which the concentration of added electrolytes, C, is substituted for m^+ in Eq. 2:

$$\log(\mathrm{CMC}) = a\log C + b \qquad (3)$$

Theoretical considerations of these empirical relations have been undertaken by Stainsby and Alexander[14], Hobbs[15] and Shinoda[16,17].

The effects of added copper sulfate and sodium sulfate on the CMC values of sodium dodecyl sulfate (SDS) and copper dodecyl sulfate ($Cu(DS)_2$) are shown in Figs. 2 and 3. The general features of the curves shown in Figs. 2 and 3 are quite similar to those obtained by Lange[7] for calcium dodecyl sulfate. At first the CMC value of SDS rapidly decreases with the addition of copper sulfate to about one fourth, and thereafter it gradually decreases as the concentration of copper sulfate increases. In the case of $Cu(DS)_2+Na_2SO_4$, the CMC value of $Cu(DS)_2$ decreases gradually compared with the case of $SDS+CuSO_4$.

In the solutions with the excess salt added, the CMC curve of the $SDS+CuSO_4$ system has a tendency to approach the curve of the $Cu(DS)_2+CuSO_4$ system, and the curve of $Cu(DS)_2+Na_2SO_4$ approaches that of $SDS+Na_2SO_4$. These facts suggest that the nature

of the detergent in excess salt solutions is characterized by the added cations and that there occurs a rearrangement of the detergent micelle, i. e., the variation of the micellar aggregation number and the formation of a new, surface, gegen-ion layer of the micelle caused by the exchange between salt cations and the surface layer gegen-ions of the original detergent micelle. In both cases in which the gegen-ion is different from the added salt cation, there are no linear relationships between log (CMC) and $\log m^+$, as is shown in Fig. 3. On the contrary, for the $Cu(DS)_2+CuSO_4$ system a good linearity is found to exist. Shinoda[17] derived an equation which expresses the effect of added electrolytes on the CMC value of the detergent solution. Using this equation we found that the degree of dissociation of micelle forming ion of copper dodecyl sulfate is 0.52. The degree of dissociation can also be determined by conductivity measurement, as will be described later.

The Determination of Micellar Molecular Weight by the Light-scattering Techinique.— The light-scattering technique is one of the most useful methods of estimating the molecular weight of the colloidal aggregate. However, the effect of micellar charge must be taken into cosideration in the application of this method to the charged system, as has already been pointed out by, for instance, Dosher and Mysels[18] and Hutchinson[19]. Dosher and Mysels[18] pointed out that Eq. 5 should be employed for charged systems in place of the usual scattering formula, Eq. 4.

$$(HC/\tau)_{C\to 0}=1/M \tag{4}$$

$$(HC/\tau)_{C\to 0}=(1+P)/M \tag{5}$$

Here, P is the number of simple ions associated with one charged, colloidal ion, M is the molecular weight of the colloidal particle, τ is the turbidity of the solution, C is the concentration in g./ml., and

$$H=32\pi^3n^2(dn/dc)^2/3N\lambda^4$$

where n is the refractive index of the solution and λ is the wavelength of the incident light. The true molecular weight of the solute particle can be obtained from the scattering experiment in an excess salt solution because P in Eq. 5 tends to zero in this condition. The measurements were conducted at 436 and 546 mμ and at 30°C. The values of micellar molecular weight obtained at 436 and 546 mμ were approximately the same within the range of experimental error. The scattering was observed by using a semi-octagonal cell at the angle of 45 90 and 135° with relation to the incident light, but the dissymmetries of the scattering can not be detected. Thus, the limiting condition in the application of Eqs. 4 or 5, that the dimension of the solute particle must be smaller than $\lambda/20$, is considered to be quite satisfied.

In Fig. 4, the typical scattering curve of copper dodecyl sulfate is given. The abscissa represents the micellar concentration $C-C_o$, where C_o is the CMC value. Table III shows the micellar molecular weights of nickel,

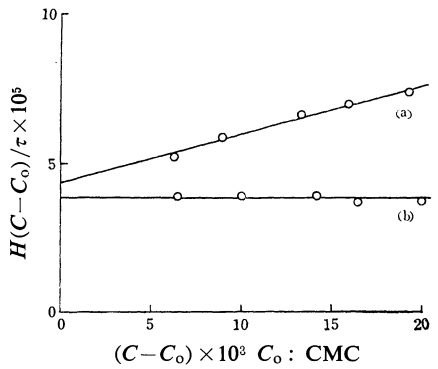

Fig. 4. $H(C-C_0)/\tau\sim(C-C_0)$ curves for copper dodecyl sulfate in H_2O at 436 mμ (a), and in 0.1 M $CuSO_4$ at 546 mμ (b), at 30°C.

cobalt, copper and magnesium dodecyl sulfate in salt free solutions and in corresponding metal sulfate solutions. For the salt free solutions, Eq. 4 was also assumed to hold.

Only small differences are found among the micellar molecular weights of the various bivalent metal dodecyl sulfates studied. The values of the micellar molecular weight in salt free solutions fall in the comparatively narrow range between 23000 and 27000, and those in salt solutions, in the range between 25000 and 31000. The micellar molecular weights of the detergents in salt solutions are slightly larger than those in salt free solutions. The P values calculated from Eq. 5 by using the data of micellar molecular weight in Table III are of the order of 0.1 to 0.2, indicating the almost complete screening action of the bivalent metal ions, even in salt free solutions. The micellar aggregation number, i. e., the number of dodecyl chains in a micelle, of bivalent metal dodecyl sulfates is about 100, which is almost twice the value (41) for SDS[20]. The same order of aggragation number was reported by Tartar and Lelong[9], who obtained the micellar molecular weight of 28500 and the aggregation number of 107 for magnesium dodecyl sulfonate in a salt free solution.

Thus, the marked increase in surface activity, especially the solubilizing power of the bivalent metal dodecyl sulfates, may be expected because of the increased micellar aggregation number of the micelle and their decreased CMC value. The solubilizing power of these detergents will be reported on in another paper.

The Estimation of Micellar Charge from Conductivity Data.—The micellar charge of the detergent can be evaluated from the conductivity of the aqueous solution and from the micellar aggregation number obtained by the light-scattering technique, as has been reported[12].

Using some basic assumptions[12], the following equations can be derived:

$$[(\Lambda_0-\Lambda)/(\Lambda_0-\Lambda_m)]^2=\{(Z_d-Z_c)+(Z_g+Z_c)C/C_m\}/(Z_d+Z_g) \quad (6)$$

$$Z_c=\{Z_m^2-Z_g(nZ_d-Z_m)\}/nZ_d \quad (7)$$

Here, Λ_0 is the equivalent conductivity of the detergent at infinite dilution, Λ_m is the equivalent conductivity at the CMC value, and Z_d and Z_g are the valencies of the detergent ion and gegen-ion respectively. The value of Z_c can be evaluated from the slope of the straight line by plotting the quantity $[(\Lambda_0-\Lambda)/(\Lambda_0-\Lambda_m)]^2$ as the function of the reduced concentration, C/C_m. Moreover, the value of the micellar charge, Z_m, can be calculated from Eq. 7 by using the micellar aggregation number, n, obtained by the light-scattering experiment. Figure 5 shows one of the typical relations between $[(\Lambda_0-\Lambda)/(\Lambda_0-\Lambda_m)]^2$ and C/C_m for copper dodecyl sulfate. The calculated micellar charge, Z_m, and the dissociation degree of the micellar ion, α, are given in Table IV.

The dissociation degrees of the micellar ion, α, obtained in the present experiment are comparatively small, suggesting that about half of the micelle-forming detergent molecules are undissociated. The value of α decreases

TABLE IV. THE MICELLAR CHARGE AND THE DISSOCIATION DEGREE OF THE MICELLAR ION OF VARIOUS METAL DODECYL SULFATES AT 30°C

Solute	n (In a salt solution	Z_c	Z_m	α
$Co(DS)_2$	114	47	75	0.66
$Cu(DS)_2$	97	34	58	0.60
$Mg(DS)_2$	118	20	50	0.42

Here α equals Z_m/nZ_d.

in the order cobalt>copper>magnesium, but the difference among them is said to be not very large. The value of 0.60 for copper dodecyl sulfate micelle is approximately the same as the value of 0.52 obtained from the effect of the added electrolyte on the CMC value mentioned above.

These experimental results suggest that, above the CMC value, the micelle of the bivalent metal dodecyl sulfate must be treated as a weak electrolyte. The bivalent metal dodecyl sulfates are composed of a weak base and a strong acid; therefore, the effect of the hydrolysis of the bivalent gegen-ion must be considered. This problem will, in the near future, be treated in another paper in connection with the change in the pH value of the detergent solutions with concentration.

Summary

Dodecyl sulfates of bivalent nickel, cobalt, copper and magnesium were synthesized, and studies were carried out on the CMC values of these detergents, the effects of the added electrolytes on these CMC values, on micellar molecular weights, and on micellar charges. The CMC values of the detergents were independent of the kind of metal, and the CMC value of 1.2×10^{-3} mol./l. was obtained. The micellar aggregation numbers of bivalent metal dodecyl sulfates were of the order of 100, which is about twice that of sodium dodecyl sulfate. The dissociation degrees of the micelles were also evaluated from the conductivity data. The α values obtained were 0.66 for cobalt, 0.60 for copper and 0.42 for magnesium. The dissociation degree of the copper dodecyl sulfate micelle was also estimated to be 0.52 from the depression of the CMC value by the added electrolyte; this figure is approximately the same as the value of 0.60 obtained from the conductivity data. These results suggest that the fundamental factor responsible for determining the surface activities of bivalent metal dodecyl sulfates is the valency of the gegen-ion and that the kind of metal has little or no detectable effect on them.

The authors wish to thank to Professor Tomoo Oyama in the Faculty of Technology and to Professor Satoru Akune in the Faculty of Agriculture, both of Kyushu University, for helping in the light-scattering experiment.

Infrared Absorption Spectra of Hydrazides. VI. Benzoylhydrazine

By Mitsuo MASHIMA

(Received October 18, 1962)

The infrared absorption spectra of benzoylhydrazine in the solid state and in an acetonitrile solution have previously been observed by the present author[1]. However, the absorption bands observed could not be interpreted with certainty. In the present study, the infrared spectrum of *N*-deuterated benzoylhydrazine is examined in the rock salt region. For the sake of comparison, the infrared spectra of *N*-deuterated benzamide, cyanoacetic acid amide and its *N*-deuterated derivative are also observed. A tentative assignment of the bands of these compounds is described in the present paper. On the basis of results of the assignment, the frequencies characteristic of the $-CONHNH_2$ group are compared with those characteristic of the $-CONH_2$ group.

Experimental

The preparation and purification of benzoylhydrazine and benzamide have been described in a previous paper[1]. Cyanoacetic acid amide was synthesized with cyanoacetic acid ethylester and ammonia and was purified by recrystallization from ethanol, m. p., 119°C. The *N*-deuterated derivatives examined were prepared in sealed tubes in the presence of heavy water (99.8%). The excess heavy water was evaporated in vacuo. The solid spectra of all compounds were studied with potassium bromide disks. The solution spectrum of cyanoacetic acid amide was obtained with acetonitrile as a solvent and with 0.1 mm. cells in the optical path. A double-beam Hitachi infrared spectrophotometer type EPI-2 was used in the rock salt region.

Results and Discussion

Benzoylhydrazine (BH).—The infrared absorption spectra of BH and *N*-deuterated BH (BH-d_3) are illustrated in Fig. 1. The present author has previously investigated the frequencies characteristic of the $-CONHNH_2$ group[2,3]. Cyanoacetylhydrazine[2], for example, has the following bands due to the $-CONHNH_2$ group: NH_2 or NH stretching, 3320, 3180 cm^{-1}; amide I, 1698 cm^{-1}; NH_2 bending, 1625 cm^{-1}; amide II, 1534 cm^{-1}; NH_2 twisting, 1313 cm^{-1}; amide III, 1258 cm^{-1}; NH_2 wagging, 1105 cm^{-1}; NH_2 rocking 1009 cm^{-1}.

The 1664 cm^{-1} band of BH was taken as the amide I band in a previous paper[1]. This assignment is supported by the fact that BH-d_3 has the corresponding band at 1627 cm^{-1}, the ν_H/ν_D ratio being 1.023. BH has an intense band at 1618 cm^{-1}, and this band is displaced by a band at 1209 cm^{-1} on *N*-deuteration, the ν_H/ν_D ratio being 1.338. Therefore, the 1618 cm^{-1} band may surely be assigned to the NH_2 bending vibration, $\beta(NH_2)$. For BH a shoulder band at 1527 cm^{-1}, which is accompanied by the band at 1582 cm^{-1}, vanishes on *N*-deuteration. BH-d_3 has a new band at 1416 cm^{-1}. In cyanoacetylhydrazine the amide II band at 1534 cm^{-1} is displaced by a band at 1451 cm^{-1} on *N*-deuteration. Therefore, the 1527 cm^{-1} band of BH is very probably to be assigned to the amide II band, and the 1416 cm^{-1} band of BH-d_3 may probably be taken as the amide II' band. The 1349 cm^{-1} band of BH has not yet been assigned with certainty. This band vanishes on *N*-deuteration and BH-d_3 has a new band at 1098 cm^{-1}, the ν_H/ν_D ratio being 1.229. Therefore, it seems that the 1349 cm^{-1} band may best be assigned to the NH_2 twisting vibration ($\tau(NH_2)$) because it is close in frequency to the corresponding band at 1313 cm^{-1} of cyanoacetylhydrazine. BH has two additional moderately strong bands, which disappear on *N*-deutration, at 1118 and 987*1 cm^{-1}. These two bands are considered to correspond to the bands at 936 and 897 cm^{-1} for BH-d_3 and are close in frequency to the bands at 1105 and 1009 cm^{-1} of cyanoacetylhydrazine. Therefore, they are considered to be assigned to the NH_2 wagging and rocking vibrations, ($\omega(NH_2)$ and $\gamma(NH_2)$) respectively. BH has a very weak band at 1250 cm^{-1}, which disappears on *N*-deuteration, and BH-d_3 has a new band at 1058 cm^{-1}, the ν_H/ν_D ratio being 1250/1058 (1.182). In consequence, the 1250 cm^{-1} band is can probably best be assigned to an amide III band.

In order to ascertain the assignments above described, the vibrations of a monosubstituted aromatic ring will be considered. Schmid,

*1 This is a mean value of the frequencies of the two peaks at 990 and 984 cm^{-1}.

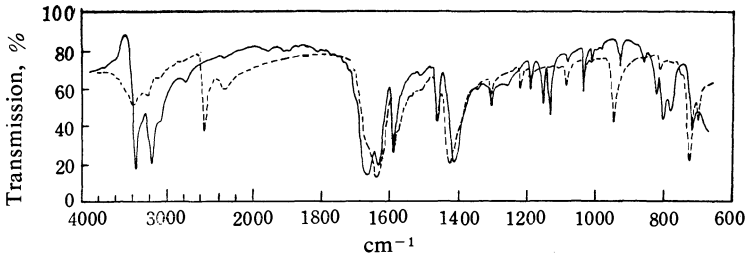

Fig. 1. Infrared spectra of $C_6H_5CONHNH_2$, ——, and $C_6H_5CONDND_2$, ----, in KBr disks.

Brandmeuller and Nonnenmacher[4] have made a calculation of the normal vibrations of the monosubstituted aromatic compounds. On the basis of calculations, they have proposed detailed assignments of the infrared absorption bands and Raman lines for several monosubstituted benzenes. These assignments may be referred to for an interpretation of the bands observed for BH (and also benzamide (BA), infrared spectrum of which is shown in Fig. 3) in the 1600~650 cm^{-1} region. The frequencies of this region due to an aromatic ring are summarized in Table I, in which the corresponding frequencies and their detailed assignments for toluene and chlorobenzene[4] are also represented for the sake of comparison. Four bands (near 1600, 1580, 1500 and 1450 cm^{-1}) of the monosubstituted aromatic compounds are usually used in correlation work[5], and the bands corresponding to them are easily found for BH, BA and their *N*-deuterated derivatives, as is shown in Table I. Four further bands, near 1300, 1180, 1070 and 1020 cm^{-1}, are observed for both BH and BA, and for their *N*-deuterated derivatives also. Those bands can, therefore, very probably be assigned to the in-plane C–H deformation vibrations, δ(C–H). Five of the δ(C–H) vibrations can be reasonably expected to occur, so the 1154 cm^{-1} band of BH (and the 1142 cm^{-1} band BA) is to be taken as another δ(C–H) band. However, this assignment is not certain because no band corresponding to it is found for BH-d_3 (nor for BA-d_2).

Two bands near 1330 and 1000 cm^{-1} are observed for all compounds of BH, BA and their *N*-deuterated derivatives. Therefore, these two bands also are surely assigned to the vibrations of an aromatic ring.

The out-of-plane C–H deformation vibrations (π(C–H)) are expected to occur in the region below 1000 cm^{-1} because they have been obtained in that region for the monosubstituted aromatic compounds[4], as is shown in Table I. The 966 cm^{-1} band of BH, which is observed as a shoulder band at the foot of the more intense band at 987 cm^{-1}, corresponds in frequency to the band at 967 cm^{-1} for BH-d_3. BA also has a very weak band at 987 cm^{-1} which is considered to correspond to the 966 cm^{-1} band of BH. The band near 920 cm^{-1} is observed for BH, BA and all of their *N*-deuterated derivatives. The 863 cm^{-1} band of BH corresponds in frequency to the band at 848 cm^{-1} for BA and 847 cm^{-1} for BA-d_2, while for BH-d_3 the corresponding band can not be ascertained because it is overlapped by the more intense band at 897 cm^{-1} which was already assigned to the $\gamma(ND_2)$ vibration. Thus, the 966, 917 and 863 cm^{-1} bands of BH

a) ν; stretching, β; bending, δ; in-plane deformation, π; out-of-plane deformation, τ; twisting, ω; wagging, γ; rocking

are considered to be assigned to the π(C-H) vibrations.

BH has three further bands at 801, 747 and 690 cm^{-1} not yet accounted for. In the region below 800 cm^{-1}, BH-d_3 has also three bands at 797, 705 and 674 cm^{-1}. For monosubstituted aromatic compounds, two bands in the 770～730 and 710～690 cm^{-1} ranges are usually used in correlation work[5]. Although a detailed assignment of the three bands of BH can not be made, it seems certain that they are due to the aromatic ring vibrations.

The infrared frequencies of BH and their assignments are summarized in Table II.

Cyanoacetic Acid Amide (CAA).—The infrared absorption spectra of CAA and CAA-d_2 in the solid state are illustrated in Fig. 2, in which the spectrum of CAA in acetonitrile is also shown. Recently Suzuki[6] studied the infrared spectra of $HCONH_2$ and its three kinds of deuterated derivatives in the 3600～300 cm^{-1} region. He also made a calculation of the normal vibrations for these four kinds of molecules. Suzuki[7] further observed the infrared spectra of CH_3CONH_2 and its three kinds of deuterated derivatives in the 1800～300 cm^{-1} region. He made a calculation of the normal vibrations for those four kinds of molecules and discussed in detail the nature of the absorption bands observed. An assignment of the absorption bands of CAA can, therefore, rather easily be made by a comparison of the spectrum with those of $HCONH_2$ and CH_3CONH_2.

The 3000 cm^{-1} Region. — CAA in the solid state has two strong bands at 3330 and 3140 cm^{-1}. Since these two bands are close in frequency to the 3330 and 3190 cm^{-1} bands of $HCONH_2$[6], they can surely be assigned to the asymmetric and symmetric NH_2 stretching vibrations, $\nu_a(NH_2)$ and $\nu_s(NH_2)$. The fact that they move to higher frequencies in an acetonitrile solution is consistent with the above assignments. CAA-d_2 has $\nu_a(ND_2)$ and $\nu_s(ND_2)$ bands at 2505 and 2350 cm^{-1} respectively. The $\nu(CH_2)$ vibrations are also considered to give rise to bands in this region.

6) I. Suzuki, This Bulletin, 33, 1359 (1960).
7) I. Suzuki, ibid. 35, 1279 (1962).

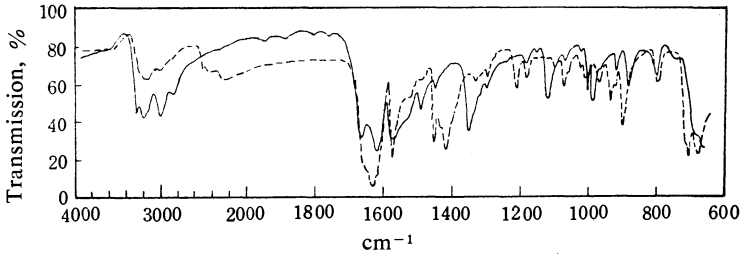

Fig. 3. Infrared spectra of $C_6H_5CONH_2$, ——, and $C_6H_5COND_2$, ----, in KBr disks.

In fact, CAA has two weak bands at 2930 and 2760 cm^{-1} which are probably to be ascribed to the $\nu(CH_2)$ vibrations.

The 2250 cm^{-1} band of CAA is surely to be assigned to the $\nu(C\equiv N)$ vibration because CAA-d_2 has a corresponding band at 2260 cm^{-1}, which is observed as a shoulder band accompanied by the band at 2350 cm^{-1}.

The 1700~700 cm^{-1} Region. — In this region the amide bands and NH_2 deformation bands are expected to appear. In primary amides the amide I band has been obtained near 1650 cm^{-1} [5]. CAA has also the amide I band at 1675 cm^{-1} (solid) and 1703 cm^{-1} (in acetonitrile). The band corresponding to it is shown at 1655 cm^{-1} in CAA-d_2. The 1615 cm^{-1} band of CAA disappears on *N*-deuteration, and CAA in acetonitrile has also a corresponding band at 1618 cm^{-1}. Suzuki[7] has shown that the 1632 cm^{-1} band of CH_3CONH_2 is mainly associated with the NH_2 bending vibration and that the 1189 cm^{-1} band of CH_3COND_2 is to be assigned to an almost pure ND_2 bending vibration. He[6] has also obtained the pure $\beta(NH_2)$ band at 1608 cm^{-1} for $HCONH_2$ and the $\beta(ND_2)$ band at 1118 cm^{-1} for $HCOND_2$. CAA-d_2 has the band at 1100 cm^{-1} instead of the 1615 cm^{-1} band of CAA. Therefore, the 1615 cm^{-1} band is undoubtedly assigned to be to the $\beta(NH_2)$ vibration and the 1100 cm^{-1} band of CAA-d_2, to the $\beta(ND_2)$.

Primary amides usually have a moderately strong band in the 1420~1400 cm^{-1} range[5]. For CH_3CONH_2[7] the 1404 cm^{-1} band was ascribed to the C–N stretching vibration (ν(C–N)) interacting with other kinds of normal vibrations. In CH_3COND_2 the ν(C–N) band moves to a higher frequency and appears at 1427 cm^{-1}. The ν(C–N) band has been obtained at 1309 cm^{-1} for $HCONH_2$ and 1338 cm^{-1} for $HCOND_2$[6]. It is noticeable that a frequency shift of the ν(C–N) band of $HCONH_2$ and CH_3CONH_2 on *N*-deuteration is in the direction shown by the corresponding shift of the ν(C–N) band for urea[8] and oxamide[9], as is summarized in Table III. CAA has two strong bands at 1408 and 1378 (more intense) cm^{-1}. One of them is considered to be due to the CH_2 bending vibration, $\beta(CH_2)$. Cyanoacetylhydrazine[2] has the $\beta(CH_2)$ band at 1396 cm^{-1}, which is rather closer in frequency to the 1408 cm^{-1} band than to the 1378 cm^{-1} band of CAA. Therefore, the 1408 cm^{-1} band is considered to be assigned to the $\beta(CH_2)$ vibration, and the 1378 cm^{-1} band may be assigned to the ν(C–N) vibration. On the other hand, CAA-d_2 has a relatively broad and intense band with its absorption maximum near 1398 cm^{-1}. This band is considered as the ν(C–N) band overlapped by the $\beta(CH_2)$ band near 1400 cm^{-1}. In that case, the 1378 cm^{-1} band of CAA moves to a higher frequency on *N*-deuteration. This frequency shift is in accordance (in direction and value) with those of the ν(C–N) band of compounds containing the $-CONH_2$ group, as may be seen from Table III.

Table III. The frequency shift of the ν(C–N) band on *N*-deuteration

CAA has a further intense band at 1259 cm^{-1} which is displaced by a band at 1016 cm^{-1} on *N*-deuteration. In an acetonitrile solution CAA has a corresponding band at 1264 cm^{-1}. For CH_3CONH_2[7] the NH_2 rocking vibration ($\gamma(NH_2)$), which interacts a little with the ν(C–N) vibration, has been found at 1152 cm^{-1}, while for CH_3COND_2 it has been shown that the $\gamma(ND_2)$ vibration takes part in both the 934 and 809 cm^{-1} bands. $HCONH_2$[6] has the $\gamma(NH_2)$ band at 1090 cm^{-1}, while $HCOND_2$ has the $\gamma(ND_2)$ band at 912 cm^{-1}. Therefore, the 1259 cm^{-1} band of CAA is considered to be assigned to the $\gamma(NH_2)$ vibration and the 1016 cm^{-1} band of CAA-d_2, to the $\gamma(ND_2)$ vibration.

Next the CH_2 deformation vibrations, except for the $\beta(CH_2)$ vibration already considered, must be assigned. For cyanoacetylhydrazine[2] the 1347, 1205 and 1009 cm^{-1} bands have been assigned, respectively, to the CH_2 wagging, twisting and rocking vibrations, $\omega(CH_2)$, $\tau(CH_2)$ and $\gamma(CH_2)$. CAA has three weak bands at 1320, 1197 and 972 cm^{-1} which are probably to be assigned, respectively, to the $\omega(CH_2)$, $\tau(CH_2)$ and $\gamma(CH_2)$ vibrations. For CAA-d_2 the $\omega(CH_2)$ and $\tau(CH_2)$ bands can not be observed. However, the $\gamma(CH_2)$ vibration of CAA-d_2 is considered to interact with the $\gamma(ND_2)$ vibration, and two bands appear at 953 and 1016 cm^{-1} assigned above to $\gamma(ND_2)$.

In the region below 930 cm^{-1} CAA has three moderately strong bands at 925, 851 and 787 cm^{-1}, and CAA-d_2 also has three bands, at 913, 848 and 731 cm^{-1}. Of these, two bands may be assigned to the C–C stretching vibrations which are expected to occur in CAA. The ν(C–C) band has been obtained at 874 cm^{-1} for CH_3CONH_2 and at 809 cm^{-1} for CH_3COND_2[7]. In cyanoacetylhydrazine[2] the 924 and 913 cm^{-1} bands were assigned to the ν(C–C) vibrations. The 925 and 851 cm^{-1} bands of CAA can, therefore, be assigned to the ν(C–C) vibrations. These assignments are supported by the fact that those band are little changed in frequency on *N*-deuteration.

The NH_2 wagging and twisting vibrations and skeletal deformation vibrations are not yet accounted for. In CH_3CONH_2[7] a broad band near 700 cm^{-1} was taken as the NH_2 wagging band overlapped with the NH_2 twisting band. $HCONH_2$[6] has the $\omega(NH_2)$ band at 750 cm^{-1}. The 787 cm^{-1} band of CAA is probably to be ascribed to the NH_2 wagging or twisting vibration because no band corresponding to it is observed for CAA-d_2. The 731 cm^{-1} band of CAA-d_2 is tentatively ascribed to the O=C–N deformation vibration, δ(O=C–N). However, this assignment is not certain because the δ(O=C–N) band has been found at 581 cm^{-1} for CH_3CONH_2[7] and 608 cm^{-1} for $HCONH_2$[6].

TABLE IV. INFRARED FREQUENCIES OF CAA AND THEIR ASSIGNMENTS

Assignment[a]	CAA		CAA-d_2
	Solid	in CH_3CN	
$\nu_a(NH_2)$	3330 (s)	3430	
	3260 (sh)	3320

ν(C–C)	925 (m)	920	913 (w)
ν(C–C)	851 (m)	842	848 (w)
$\omega(NH_2)$ or $\tau(NH_2)$	787 (m)	759	
δ(O=C–N)			731 (w)

a) ν; stretching, a; asymmetric, s; symmetric, β; bending, ω; wagging, γ; rocking, δ; in-plane deformation

The observed frequencies of CAA and their assignments are summarized in Table IV.

Benzamide (BA).—Weckherlin and Leuttke[10] observed the infrared spectrum of benzamide containing ^{15}N and aimed at defining the positions of those bands due to vibrations of the $-CONH_2$ group. In the present study the infrared spectrum of BA-d_2 was observed in the rock salt region*2. As has been mentioned already, the $-CONH_2$ vibrations may now be located rather easily.

The infrared spectrum of BA-d_2 is illustrated, along with that of BA, in Fig. 3. An assignment of the vibrations of an aromatic ring has been described already with those of BH (see Table I). In a previous paper[1] the 1656 and 1623 cm^{-1} bands of BA were taken as the amide I and the NH_2 bending bands respectively. These assignments are also supported

10) S. Weckherlin and W. Leuttke, *Z. Elektrochem.*, **64**, 1228 (1960).

*2 The spectrum of BA has been published by the present author (see Ref. 1).

by the present observation for BA-d_2. BA-d_2 shows a very strong band at 1629 cm^{-1} which is surely to be ascribed to the amide I band. On the other hand, the 1623 cm^{-1} band of BH disappears on *N*-deuteration; instead of it, BA-d_2 has a new band at 1209 cm^{-1}, the ν_H/ν_D ratio being 1.342. They correspond in frequency, respectively, to the 1631 cm^{-1} band for CH_3CONH_2[7] and 1189 cm^{-1} band for CH_3COND_2[7]. The 1403 cm^{-1} band of BA shifts to 1415 cm^{-1} on *N*-deuteration. From a consideration similar to the foregoing (see Table III also), they are undoubtedly to be assigned to the ν(C–N) vibration.

BA has two moderately strong bands at 1142 and 1124 cm^{-1}, both of which vanish on *N*-deuteration. Of these, the former band has already been ascribed to the δ(C–H) vibration of an aromatic ring. The latter band may be assigned to the $\gamma(NH_2)$ vibration, because it is close in frequency to the $\gamma(NH_2)$ band at 1152 cm^{-1} for CH_3CONH_2[7]. In BA-d_2 the moderately strong band at 936 cm^{-1} is considered to correspond to the 1124 cm^{-1} band of BA, the ν_H/ν_D ratio being 1.201. The 936 cm^{-1} band of BA-d_2 is very close in frequency to the 934 cm^{-1} band of CH_3COND_2[7], which has been assigned to the $\gamma(ND_2)$ vibration interacting with the ν(C–N) vibration and others. Thus, the 936 cm^{-1} band can probably be assigned to the $\gamma(ND_2)$ vibration. The relatively strong band at 1142 cm^{-1} may be considered to arise from the δ(C–H) vibration resonating with the $\gamma(NH_2)$ vibration. Owing to the fact that the $\gamma(NH_2)$ frequency decreases in value on *N*-deuteration, the δ(C–H) band is considered to be so weakened that we can not define its position.

For BA two moderately strong bands, which vanish on *N*-deuteration, are found at 793 (more intense) and 770 cm^{-1}. One of the two bands may be assigned to the $\omega(NH_2)$ or $\tau(NH_2)$ vibration because the corresponding band has been obtained at 750 cm^{-1} for $HCONH_2$[6] and at 700 cm^{-1} for CH_3CONH_2[7]. Another band is considered to arise from one of the vibrations of an aromatic ring. In the region below 820 cm^{-1}, BA has two further bands at 811 and 705 cm^{-1}. These two bands are very close in frequency to the 801 and 690 cm^{-1} bands of BH; accordingly, they can probably be ascribed to the vibrations of an aromatic ring. In addition to these BH has a band, which is due to an aromatic ring vibration, at 747 cm^{-1}. This band is rather closer in frequency to the 770 cm^{-1} band than to the 793 cm^{-1} band of BA. Therefore, the 793 cm^{-1} band is tentatively taken as the $\omega(NH_2)$ or $\tau(NH_2)$ band. BA-d_2 has three bands, at 801, 713 and 691 cm^{-1}, and BA in an acetonitrile solution*3 has corresponding bands at 805, 720 and 695 cm^{-1}. These three bands can probably be ascribed to the aromatic ring vibrations. BA in acetonitrile has a further band at 755 cm^{-1} which is probably to be assigned to the $\omega(NH_2)$ or $\tau(NH_2)$ vibration. The change in frequency on the change of states (793 to 755 cm^{-1}) is in the right direction for NH_2 deformation vibrations.

In the 3000 cm^{-1} region BA has two intense bands, at 3330 and 3140 cm^{-1}, which are displaced by the bands at 2525 and 2280 cm^{-1} on *N*-deuteration. Therefore, they can surely be assigned to the $\nu_a(NH_2)$ and $\nu_s(NH_2)$ vibrations respectively. A shoulder band at 3050 cm^{-1} and a weak band at 2760 cm^{-1} are scarcely changed in frequency on *N*-deuteration. These two bands are assigned to the aromatic ν(C–H)

Table V. Infrared frequencies of BA and BA-d_2 in the rock salt region

a) See Ref. 6 b) See Ref. 7 c) Present observations

vibrations. The observed frequencies of BA and their assignments are summarized in Table V.

The present assignments for BA are in conformity with those proposed by Weckherlin and Leuttke[10] except for a few points.

Frequencies Characteristic of the $-CONHNH_2$ and $-CONH_2$ Groups. — For compounds containing the $-CONHNH_2$ group, the present author[2,3] has observed the infrared absorption spectra in the rock salt region and the frequencies characteristic of the group have been proposed. In the 1700～800 cm^{-1} region, a part of the -CONH- in the $-CONHNH_2$ group shows the amide I, II and III bands and a part of the NH_2- shows four bands due to the deformation vibrations. As has already been described in the present paper, BH also has the amide I, II and III bands at 1664, 1527 and 1250 cm^{-1} and the NH_2 deformation bands at 1618, 1349, 1118 and 987 cm^{-1}. These seven frequencies can, with confidence, be taken as characteristic of the $-CONHNH_2$ group. Of these, the amide I, II and III frequencies are within the normal ranges for the corresponding frequencies in secondary amides. On the other hand, four NH_2 deformation frequencies have been found in the 1635～1600, 1365～1260, 1180～1050 and 1050～800 cm^{-1} ranges for the ten compounds hitherto examined by the present author*4.

Spectroscopic investigations of primary amides have been reported by many workers[5], but the vibrations of the $-CONH_2$ group have not yet been located definitely. In recent years, infrared measurements and the calculation of normal vibrations have been made for formamide and acetamide by Suzuki[6,7]. On the basis of the results of Suzuki's studies, the infrared spectra of CAA and BA were rather easily interpreted in the present paper. The frequencies characteristic of the $-CONH_2$ group may now be obtained with certainty. They are summarized in Table VI for frequencies in the 1700～700 cm^{-1} region. It may be seen from the table that the NH_2 deformation frequencies of the $-CONH_2$ group lie in the 1630～1600 (bending), 1150～1090 (rocking) and 800～700 (wagging or twisting) cm^{-1} ranges.

A comparison of the NH_2 deformation frequencies shows that the compounds containing the $-CONHNH_2$ group have a band in the 1365～1260 cm^{-1} range which is not shown by the compounds containing the planar $-CONH_2$ group. This band is close in frequency to the non-planar NH_2 twisting band which has been found at 1320 cm^{-1} for solid hydrazine[11] and at 1455 cm^{-1} for methylamine vapor[12]. Therefore, that band can very probably be ascribed to the NH_2 twisting vibration which is expected for the NH_2 group, being in a pyramidal form. A band observed in the 1635～1600 cm^{-1} range may be ascribed to the NH_2 bending vibration. It is noteworthy that the NH_2 bending band is shown in that region both by compounds containing the non-planar NH_2 group and by those containing the planar NH_2 group.

The author is grateful to Professor Sunao Imanishi of Kyushu University for his generous permission to use the spectrophotometer, and to Dr. Yoshiya Kanda of Kyushu University for his encouragement throughout the work. He is also indebted to the Ministry of Education for financial support.

The Polarographic Reduction and Electronic Structures of Organic Halides

By Kenichi FUKUI, Keiji MOROKUMA, Hiroshi KATO and Teijiro YONEZAWA

(Received October 19, 1962)

In the last fifteen years the polarographic reduction of a number of conjugated hydrocarbons has been extensively studied, both experimentally and theoretically. Their pH-independent reversible half-wave reduction potentials, $E_{1/2}$, have been found to be linearly related to the energy, $\varepsilon_{1v}{}^{\pi}$, of their lowest unoccupied π orbital[1,2], the energy which would be needed in order to bring an electron to the orbital, as follows:

$$-E_{1/2}=\lambda_{1v}{}^{\pi}\beta_{\pi}+C$$

where $\lambda_{1v}{}^{\pi}$ is the coefficient of the energy of the level $\varepsilon_{1v}{}^{\pi}=\alpha_{\pi}+\lambda_{1v}{}^{\pi}\beta_{\pi}$ and α_{π} and β_{π} are the standard Coulomb and the standard resonance integrals of the π orbitals. From the inclination of the line the value of the resonance integral, β_{π}, was estimated to be -2.23 eV., which seemed to be reasonable in comparison with the value estimated from other physicochemical sources. The higher the energy of the level, that is, the smaller the value of $\lambda_{1v}{}^{\pi}$, the less reducible the hydrocarbon and, therefore, the more negative the half-wave reduction potential. A similar linear relationship between the lowest unoccupied π levels and the reduction potentials and a similar value of the integral β_{π} have been found for a variety of compounds, such as substituted stilbenes, substituted nitrobenzenes, aromatic ketones and vinyl compounds[3].

Furthermore, the structures of the products of the corresponding controlled potential electrolysis of hydrocarbons have been examined in terms of the π electron distribution of the hydrocarbon anions[2], in which an excess electron is accepted in the lowest unoccupied π levels and from which products will be yielded by protonation. Protons add to those positions which have a large electron density, and a product results in which a double bound or more is reduced. For instance, naphthalene is reduced to give 1, 2-dihydronaphthalene and 1, 4-dihydronaphthalene.

On the other hand, it has been elucidated that halogenated, saturated hydrocarbons are polarographically reducible, showing half-wave potential independent of the pH value and giving products in which carbon-halogen bonds are reduced to carbon-hydrogen bonds[4]. For instance, the half-wave reduction potential of methyl iodide is -1.63 V. vs. S. C. E. (saturated calomel electrode), and it is converted into methane when reduction is performed at that voltage. Further, it is interesting to notice that some of the halogenated, unsaturated hydrocarbons are reduced at a potential less negative than the potential at which the mother hydrocarbons are reducible, and carbon-halogen bonds are reduced in these compounds as well as in saturated halides[4].

With respect to the problems of the polarographic reduction of saturated compounds which have no π conjugated system, theoretical studies have never been carried out in relation to their electronic structure.

The present authors have established a simple molecular orbital method for calculating the σ electronic structure of saturated hydrocarbons and their derivatives[5,6] and have applied this method further to discussing the electronic structure of the σ skeleton in conjugated compounds[7,8]. By the aid of this method, one can calculate the energy levels and charge distribution of σ electrons.

In the present paper, the relations between the half-wave reduction potentials of saturated halides and their lowest unoccupied σ levels, and the connection between the distribution of the lowest unoccupied level and the structures of the reduction products will be discussed first. Then, similar discussions will be made for unsaturated halides and, at the end, a possibility that in polyhalogenated compound the lowest unoccupied σ level may creep below the lowest unoccupied π level will be suggested.

Method of Calculation

The electronic structures of π and σ electron systems have been calculated by using a simple LCAO MO (linear-combination-of-atomic-orbital molecular orbital) method, disregarding overlap integrals and electronic interactions.

In saturated compounds in which carbon atoms are sp^3-hybridized, molecular orbitals are written as linear combinations of all σ atomic orbitals—hydrogen 1s orbitals, sp^3-hybridized orbitals of carbons, and σ atomic orbitals of halogens. The energy, ε_i, of the ith molecular orbital is expressed as:

$$\varepsilon_i = \alpha_{sp^3} + \lambda_i^{sp^3} \beta_{sp^3-sp^3} \qquad (2)$$

where α_{sp^3} and $\beta_{sp^3-sp^3}$ indicate the Coulomb intergral of a sp^3-hydbridized orbital of carbon and the resonance integral between sp^3 orbitals, making a standard σ bond. The larger value of $\lambda_i^{sp^3}$ corresponds to the lower energy since the resonance integrals is minus in sign. The Coulomb and the resonance integrals of each atom and bond adopted in the calculation are the same as were employed previously[5,6], they will not be repeated for the sake of brevity.

The method can be extended to the calculation of the σ electronic structures of conjugated compounds if, in this case, one regards the π electrons as making a field where σ electrons move. Then the energy of the ith σ molecular orbital, ε_i^{σ}, may be written as:

$$\varepsilon_i^{\sigma} = \alpha_{sp^2} + \lambda_i^{sp^2} \beta_{sp^2-sp^2} \qquad (3)$$

where α_{sp^2} and $\beta_{sp^2-sp^2}$ are the standard Coulomb and the standard resonance integrals of the sp^2 σ orbitals. Similarly, the energy of the jth π molecular orbital calculated by the simple LCAO MO method is given as:

$$\varepsilon_j^{\pi} = \alpha_{\pi} + \lambda_j^{\pi} \beta^{\pi} \qquad (4)$$

Calculated σ electron densities could clearly explain the experimental results of physicochemical properties — for instance, dipole moments, halogen coupling constants in PQR spectra, and proton chemical shifts in NMR spectra — as has been reported previously[7,8].

A no table finding of the calculation in halogenated compounds is that the substitution of hydrogens by halogens, while it does not change the energy of σ occupied levels very seriously, does give rise to a remarkable change in the energy of σ unoccupied levels. There occurs especially a considerable lowering of the lowest unoccupied σ level; this lowering becomes larger as the number of halogen atoms increases.

The Polarographic Reduction and σ Electronic Structures of Haloalkanes

Haloalkanes belong to one of the few groups of compounds which include no conjugated system but which can nevertheless be reduced polarographically. As was pointed out in the previous section, halogen substitution causes a lowering of the lowest unoccupied σ levels.

Imitating Eq. 1, we compared the first half-wave reduction potential of halomethanes with the energy of their lowest unoccupied σ level, obtaining the following relation:

$$-E_{1/2} = \lambda_{1v}^{sp^3} \beta_{sp^3-sp^3} + C' \qquad (5)$$

TABLE I. FIRST HALF-WAVE REDUCTION POTENTIAL AND ENERGY AND ELECTRON DISTRIBUTION OF THE LOWEST UNOCCUPIED LEVEL OF HALOMETHANES

Compound	Half-wave reduction potential[4],*, $E^{1/2}$ V. vs. SCE	Energy of the lowest unoccupied level, $\lambda_{1v}^{sp^3}$	Partial bond order of the lowest unoccupied level on C–X bond	Sum of the distribution of the lowest unoccupied level on C–X bonds

CI_4	—	+0.095	−0.108	1.00

* NW indicates that the compound gives no reduction wave.

As can be seen in Table I, a parallelism between them was obtained for each series of halomethanes. A similar relation is obtained also in haloethanes. The discrepancy which is observed in comparing bromo- and iodomethanes is probably due to an inappropriate choice of energy parameters for halogen atomic orbitals which have never strictly tested nor improved; it is also perhaps due to the effect of disregarding the overlap integrals.

Although the linear relation represented by Eq. 5 was not precisely adopted to the values in Table I, we roughly estimated the magnitude of $\beta_{sp^3-sp^3}$ by means of Eq. 3 and so obtained a value of ca. -5 eV. This value is very close to that of $\beta_{sp^3-sp^3}$ obtained in the discussion of the NMR chemical shifts of halides (-5.7 eV.)[11] and also in that of the ionization potentials of halides (ca. -5 eV.)[11]. Furthermore, this would be rather rational in comparison with the above cited value of β_π, -2.23 eV.

From these correspondences between $E_{1/2}$ and $\lambda_{1v}^{sp^3}$, it can safely be said that the potential-determining step in the polarographic reduction of haloalkanes is the electron transfer from the electrode to their lowest unoccupied σ level. The fact that methane and other saturated hydrocarbons do not give a reduction wave is clearly because of the high energy of their lowest unoccupied σ levels.

The electron distribution of the lowest unoccupied level is greatly localized on the carbon-halogen bonds, and the bond order of the level on the bond is negative and large in absolute value, as may be seen in the fourth and fifth columns in Table I and Fig. 1. These calculated results suggest that, in a state which has an electron in that level, the carbon-halogen bonds are very easy to break down. The anion, which might be produced at the first step of the polarographic reduction of halides, corresponds to this case. One may consider a second process in which a carbon-halogen bond of the anion breaks and in which the resultant anion, or radical, reacts with a proton, or with a proton and an electron, in the solution (a 75% dioxane and 25% water solution was used as the solvent), as was suggested by Stackelberg and Stracke:

$$\left.\begin{aligned} &R-X+e^- \rightarrow (R-X)^- \\ &(R-X)^- \rightarrow R\cdot + X^- \\ &R\cdot + e^- + H^+ \rightarrow RH \end{aligned}\right\} \quad (6)$$

or

$$\left.\begin{aligned} &R-X+e^- \rightarrow (R-X)^- \\ &(R-X)^- \rightarrow R^- + X\cdot \\ &R^- + H^+ \rightarrow RH \\ &X\cdot + e^- \rightarrow X^- \end{aligned}\right\} \quad (7)$$

Thus, one may clearly explain theoretically such a result of controlled potential reduction as that, for instance, methyl bromide was reduced to give methane, while ethyl bromide gave ethane. This connection seems to support the conclusion derived above that the first reduction potential of saturated halides corresponds to the electron transfer to the lowest unoccupied σ level. It has not yet been decided in which one of the two mechanisms, Eq. 6 or 7 the real breakdown of carbon-halogen bonds occurs. On the basis of the electron affinities of halogen and carbon atoms, however, the first mechanism, Eq. 6, seems to be more probable than the second one. If so, one who carried out the controlled potential electrolysis of halides in an aprotic solvent could observe the ESR spectra of the radical.

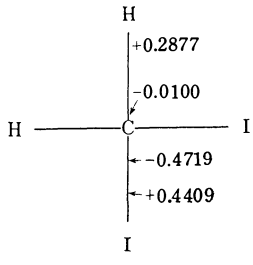

Fig. 1. Coefficient of atomic orbitals in the lowest unoccupied σ MO of diiodomethane.

The Polarographic Reduction and σ and π Electronic Structures of Conjugated Halides

In this section relations between the half-wave reduction potential and the energy of the lowest σ and the lowest π unoccupied levels will be investigated. The experimental $E_{1/2}$ and the calculated height of the lowest unoccupied levels, $\lambda_{1v}^{sp^2}$ and λ_{1v}^{π}, of chlorobenzenes and chloroethylenes, as examples, are tabulated in Table II.

The height of the lowest unoccupied π level hardly varies in these series and seems to have no connection with their half-wave reduction potential, $E_{1/2}$. Even if one forcibly applies Eq. 1 to their relation, one is led to the irrational finding that the absolute value of β must exceed 20 eV. On the other hand, the height of the lowest unoccupied σ levels of these compounds is shown to be parallel to the half-wave potential, as in haloalkanes:

$$-E_{1/2}=\lambda_{1v}^{sp^2}\beta_{sp^2-sp^2}+C'' \quad (8)$$

From the parallelism the magnitude of $\beta_{sp^2-sp^2}$ is estimated to be -6.88 eV. (in the case of chlorobenzene), a value which seems to be appropriate in view of these of β_π and $\beta_{sp^3-sp^3}$.

* NW indicates that the compound gives no reduction wave.

Furthermore, as to the reduction products, for instance, naphthalene from α-bromonaphthalene and ethylene from 1,2-diiodoethylene, an explanation similar to that in the case of haloalkanes would be possible based on the localizing and anti-bonding nature of the carbon-halogen bonds of the lowest unoccupied σ level, as is shown in Table II and Fig. 2.

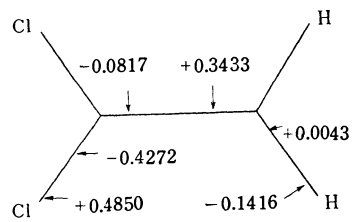

Fig. 2. Coefficient of atomic orbitals in the lowest unoccupied σ MO of 1,1-dichloroethylene.

Thus, the polarographic reduction of conjugated halides would represent the electron transfer process from the cathode to the lowest unoccupied σ, not π, level, in contrast with the case of other conjugated compounds, in which an electron runs into the lowest unoccupied π level, satisfying Eq. 1.

As the entropy change will not be very different between the both processes, that in which the electron transfers to the σ unoccupied level and that in which it transfers to the π unoccupied level, it may be said that the lowest unoccupied σ level would be lower than the lowest unoccupied π level. This conclusion is more certain as the number of halogen atoms in the molecule increases or as the halogen changes in the order $F \rightarrow Cl \rightarrow Br \rightarrow I$.

One may raise the objection that the lowest unoccupied σ level into which an electron jumps may not be the lowest level of all, for, if the selective adsorption of carbon-halogen bonds occurs, an electron will have to run into the level which is localized in the bonds. However, the experimental finding that α-bromonaphthalene is reduced at a voltage (−1.96 V.) less negative than that at which naphthalene can first be reduced (−2.50 V.) renders the objection invalid.

In Fig. 3 is shown the energy diagram of lowest unoccupied levels, which is mainly deduced from the linear relationship (cf. Eqs. 1 and 8) between λ_{1v} and $E_{1/2}$. The value of the energies of the levels might include errors of the order 0.1 to 0.2 eV. The origin of the energy is arbitrary. One can see the inversion of the π and σ lowest unoccupied levels.

It is well-known that the nucleophilic substitution of unsaturated halides takes place exclusively at the halogen atom as follows:

$$Ar-X + Y^- \rightarrow Ar-Y + X^- \qquad (9)$$

where Y^- is a nucleophilic reagent. It seems very interesting to connect this fact with the

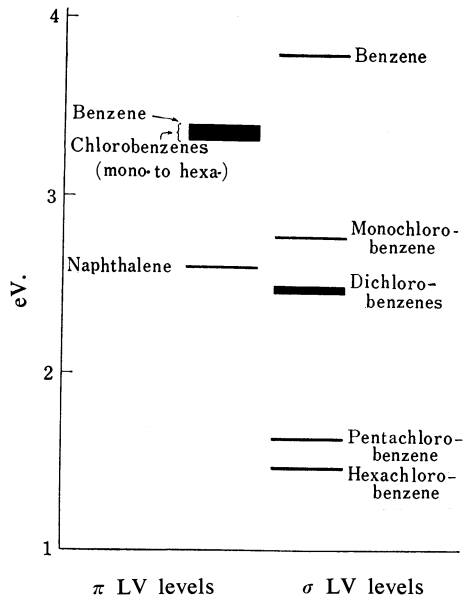

Fig. 3. Estimated lowest vacant π and σ levels.

inversion of energy levels. That is to say, when the reagent comes near the substrate, for instance, electrons on the substrate easily delocalize to the lowest unoccupied level, that is, the lowest unoccupied σ level, which causes a weakening of the carbon-halogen bonds, and so substitution occurs. Therefore, the mechanism of the nucleophilic substitution of unsaturated halides might differ from that of the ordinary substitution reactions of conjugated compounds in which π levels play a dominant role.

Furthermore, the inversion of the lowest unoccupied levels in unsaturated halides would result in a weak and broad transition from the highest occupied π level (the highest occupied of all) to the lowest unoccupied σ level (the lowest unoccupied of all), which would be seen in the range of larger wavelengths; this may be named the $\pi \rightarrow \sigma^*$ transition. An $n \rightarrow \sigma^*$ transition wave observed in saturated halides by Mulliken[9], but the $\pi \rightarrow \sigma^*$ transition in conjugated halides has not yet been observed nor even suggested. A more precise calculation by the LCAO ASMO CI method, which confirms our present conclusion, will be published elsewhere[10].

The Polarographic Reduction of Other Saturated Compounds

It is worth noticing that haloalkanes and alkylperoxides are the only saturated compounds that can be polarographically reduced. Alkylperoxide gives an almost pH value-independent wave at a much less negative potential; for instance, methyl hydroperoxide is reduced at -0.25 V. both in 0.01 N hydrochloric acid and 0.01 N sodium hydroxide. The lowest calculated unoccupied σ level in alkylperoxides, as well as in haloalkanes, is very low. For instance[11],

$$CH_3OOH \quad \lambda_{1v}^{sp^3} = -0.0956^*$$
$$C_2H_5OOH \quad \lambda_{1v}^{sp^3} = -0.0940$$
$$(CH_3)_3COOH \quad \lambda_{1v}^{sp^3} = -0.0898$$

The lowering of the lowest unoccupied σ level in peroxides would have an intimate connection with their polarographic reduction, as one might except from the discussion on saturated halides.

The distribution of the lowest unoccupied level is also very localizing on the oxygen-oxygen bond, and the partial bond order on the bond is negative and large in absolute value (Fig. 4). Thus, after the electron transfer to the level, the breakdown of the bond will follow.

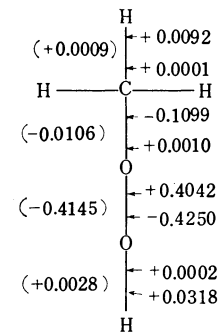

Fig. 4. Coefficient of atomic orbitals and partial bond order (in parentheses) of the lowest unoccupied MO.

Generally speaking, the lowering of the lowest unoccupied level is to be expected if a compound has one or more bonds whose resonance integrals are relatively small and, at the same time, one or both of the atoms constructing it are relatively electronegative. Peroxides and halides are typical examples.

Inversion of the lowest unoccupied σ and the lowest unoccupied π level may occur in the case where the lowering of the lowest unoccupied σ level is large, as has been stated above, and where the lowest unoccupied π level remains rather high. An electronegative atom in the compound necessarily causes a

* The parameters used in the calculation will be published elsewhere[11].

lowering of all levels, but when the atom has a lone pair to conjugate with neighboring atoms, the lowest unoccupied π level stays relatively high. The conjugated halides discussed in this paper and some conjugated peroxides seem to be the only examples where inversion may be expected.

Summary

The polarographic reduction potential of haloalkanes is connected with the energy of their lowest unoccupied σ level. Moreover, the reduction products are well explained in terms of the anti-bonding nature of the carbon halogen bond of the level. The polarographic reduction potential of conjugated halides is also correlated to their lowest unoccupied σ, not π, level. It has also been suggested that, in conjugated halides, the lowest unoccupied σ level might be lower than the lowest unoccupied π level and that the $\pi \rightarrow \sigma^*$ transition might be observed.

The Polymer-like Property of a Non-ionic Detergent Having a Long Polyoxyethylene Chain

By Fumikatsu TOKIWA

(Received August 13, 1962)

Generally, detergent molecule is composed of one large hydrophobic portion and one hydrophilic portion to render the molecule amphipathic. In the case of non-ionic detergents of the polyoxyethylene series, it is possible to start with a substance such as long chain alkyl alcohol and progressively to introduce a controlled number of ether groups by means of ethylene oxide, thereby conferring on it any desired hydrophilic property. The various properties of non-ionic detergent depend, of course, on the number of ethylene oxide groups. In addition, it is possible to consider that the " polymer-like property ", not directly related to the hydrophilic property, will appear in the detergent molecule when the polyoxyethylene chain becomes sufficiently long.

Isemura et al.[1] have shown from the surface tension data of a detergent-like compound, poly-DL-alanine dodecylamide, that at low concentrations the slope of the surface tension vs. concentration curve is the steepest for a certain degree of polymerization and is more gentle when the degree of polymerization is larger than this value; they ascribed this effect to the polymer-like property of poly-DL-alanine dodecylamide. Furthermore, Maruta[2] has observed that the surface tension and foaming power of a non-ionic detergent show, respectively, a minimum and a maximum value at a definite chain-length of polyoxyethylene; he has inferred that these phenomena are also due to the polymer-like behavior of the detergent.

In this paper an attempt is made to interpret tentatively the behavior of a non-ionic detergent with a long polyoxyethylene chain by taking into account the polymer-like property of the detergent. The lengthening of the polyoxyethylene chain of a non-ionic detergent not only increases the hydrophilic property of the molecule but also gives the molecule a polymer-like property. The present paper deals with the nature of the non-ionic detergent with relation to the chain-length of polyoxyethylene. It deals especially with the solubilization and viscosity in connection with the ultracentrifugal data[3] reported previously.

Experimental

Materials.—The detergents studied are polyoxyethylene dodecyl ethers (abbreviated to PODE),

1) T. Isemura, S. Ikeda, F. Tokiwa and J. Noguchi, This Bulletin, **34**, 1236 (1961).

2) I. Maruta, *J. Chem. Soc. Japan, Pure Chem. Sec. (Nippon Kagaku Zasshi)*, **83**, 861, (1962).

$C_{12}H_{25}O(CH_2CH_2O)_nH$, which have been prepared from dodecyl alcohol of a high purity. The samples of PODE used are the same samples as those used in a previous investigation[3]. The degree of the polymerization of ethylene oxide, p, of these samples are listed in Table I, where the number written after PODE represents the value of p, i.e., the average number of oxyethylene groups per molecule. Polyethyleneglycol[3] (abbreviated to PEG) (Carbowax-4000), the molecular weight of which was approximately 4000, was obtained from the Carbide and Carbon Chemicals Co.

Yellow-OB, an oil-soluble dye which was used as a solubilizate, was purchased from the Wako Pure Chemicals Co. and was purified by repeated recrystallization from an ethanol-water mixture.

Measurements of Solubilization. — In order to attain equilibrium, the solubilizations were run in a water bath at a constant temperature of 30±0.1°C for 20 hr. The desired amounts of yellow-OB were taken in test tubes, and then appropriate volumes of detergent solutions of various concentrations were pipetted in. The tubes were sealed and fastened to a revolving drum in the water bath. After equilibrium had been attained, the unsolubilized yellow-OB was filtered off.

This filtration was followed by dilution of an aliquot of the filtrate with ethanol to a final mixture of 7 : 3, by a volume ratio of ethanol to water, ethanol being introduced to prevent precipitation of insoluble matter. Colorimetric measurements were made with a Shimadzu Model B60 spectrophotometer to determine the amount of dye solubilized in terms of optical density at a wavelength of 445 mμ.

Measurements of Viscosity. — The viscosities of detergent solutions were measured with an Ostwald-type viscometer at 25±0.01°C. The efflux time for pure water was 141.2 sec.

Results

Solubilization.—The solubilization of yellow-OB vs. the concentration of PODE curves are illustrated in Figs. 1 and 2, where S is the extent of the solubilization of yellow-OB. The value of S decreases with the increasing length of the polyoxyethylene chain at each concentration of PODE, if an abscissa is expressed in grams per 100 ml. of solution, as is shown in Fig. 1. However, if the abscissa is expressed in moles per liter of solution, as is illustrated in Fig. 2, the value of S is seen to increase with an increasing p value until the maximum value corresponding to PODE of $p \fallingdotseq 27$ is reached while it is seen to decrease beyond this maximum. PEG shows no sign of solubilizing power.

Viscosity. — Figure 3 shows the η_{sp}/c vs. c curves for each PODE in aqueous solutions, where η_{sp}, c and η_{sp}/c represent a specific viscosity, a concentration and a reduced viscosity, respectively. The curves run linearly with c, except for the PODE of the smallest p value, as is shown in Fig. 3. In the case of the PODE where $p=6.2$, its viscosity can not be measured with the viscometer used in the region of higher concentrations because of an extraordinarily high viscosity. This may be attributed to the low cloud-point of this sample. PEG also showed a linear relation.

Intrinsic viscosity, $[\eta]$, was obtained by extrapolating the linear plots of η_{sp}/c to $c=0$. The values of $[\eta]$ for PODE having various polyoxyethylene chains are summarized in Table I. The intrinsic viscosity increases with the increasing chain-length except in PODE in which $p=7.6$. An anomaly found in the value of $[\eta]$ in PODE where $p=7.6$, whose slope of the $\eta_{sp}/c-c$ curve is fairly steep, may also be

caused by the relatively low cloud-point of this sample.

Discussion

At a given molar concentration, the number of the molecules per micelle decreases and, at the same time, the number of micelles increases with the increasing length of the polyoxyethylene chain[3-5]. Therefore, the amount of dye solubilized by PODE is expected to increase with the polyoxyethylene chain-length, if the concentration of PODE is expressed by moles per liter of solution. In fact, the polyoxyethylene chain-length is responsible for the solubilizing power up to the PODE where $p \fallingdotseq 27$ at high concentrations, while the amount of dye solubilized decreases as the p value exceeds this value. When the polyoxyethylene chain of PODE becomes quite long, the nature due to the polyoxyethylene chain predominates over that due to the alkyl chain and the characteristics of PEG become obvious; thus the effect of the alkyl chain is reduced and a polymer-like property appears in the molecule. This might be the reason why PODE where $p \fallingdotseq 27$ has the maximum solubilizing power. This is also supported by the observation that PEG shows no solubilization.

Solubilization isotherms above the critical micelle concentration for the oil-soluble dyes can in some instances be fitted to the general form[6,7]:

$$S = Kc^n \qquad (1)$$

where K and n are constants. If the data of the solubilization shown in Fig. 2 are replotted in a logarithmic scale, straight lines are obtained for all cases, irrespective of p value, some of which are illustrated in Fig. 4. We thus confirm that Eq. 1 holds in the present experiment. The values of the constant, n, which can be estimated from the slope of the straight line, are listed in Table I.

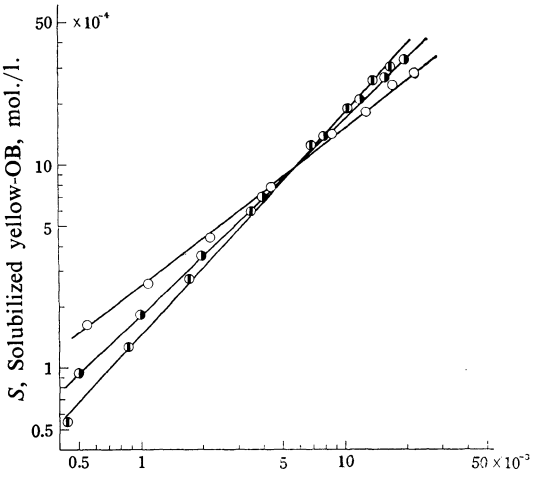

Fig. 4. Log-log plots of solubilization vs. concentration.
○ p=6.2 ◑ p=15.8 ◐ p=38.6

7) A. M. Mankowich, *J. Colloid Sci.*, **14**, 131 (1959).

As is seen in Table I, the value of n increases with the p value and is greater than unity for PODE of $p>27$. This indicates that solubilization curves plotted in a ordinary scale change from convex to concave upward from around $p=27$. Since the n values are smaller than unity for ordinary detergents[7], the behavior of PODE of $n<1$ in solubilization may also be interpreted as PODE acting as an ordinary detergent[8], though the reason for this action is not clear. On the other hand, the case of an n value larger than unity implies that the solubilizing power increases with acceleration as the concentration of the detergent increases, although the amout of increase is not very much. A similar tendency was observed in the solubilization curve of polysoap[9].

This presumably indicates that there occurs some interaction, which seems to promote the solubilization, among different micelles or aggregates of the detergent, as will be described below. Evidence for some kinds of interaction will be provided by the Huggins' k' and by an effective volume of PODE calculated from the viscosity and other data[10,11], and it is inferred that the interaction might have some relation to the increment of polyoxyethylene chain-length.

As for the interactions among different aggregates of PODE, the initial slopes of the η_{sp}/c against c plots expressing these interactions depend both on the extension of aggregates and on the affinity between aggregate and solvent relative to the aggregate-aggregate and solvent-solvent affinities[11-13]. It has been shown that these two factors can be resolved by expressing the slope as a product of $[\eta]^2$ and a quantity k'[12]. The value of k' can thus be computed by means of Huggins' familiar equation[12]:

$$\eta_{sp}/c=[\eta]+k'[\eta]^2c \qquad (2)$$

Although no completely quantitative theory concerning Huggins' constant k' is available for such colloidal solutions as a PODE solution, the k'-value can be assumed to be a measure of aggregate-solvent affinity[11]. By the use of the k'-value, which leads to a tentative interpretation of some observed effects of the polyoxyethylene chain on the viscosity of PODE solutions, information concerning the interaction among aggregates or the polymer-like behavior of PODE will be obtained.

The fifth column of Table I shows the dependence of the k'-value upon the polyoxyethylene chain-length. The k'-value at first decreases and then somewhat increases with the increasing p value; it then decreases again, finally approaching the k'-value for PEG, with the exception of a high k'-value for PODE in which $p=7.6$, which is caused by an anomalous aggregation. It is noticeable that the increase in k'-value exists in the region of larger p values in spite of increasing hydrophility. This indicates either that the aggregate-aggregate affinity increases more than the hydrophility of PODE, which increases with the p value, or that the affinity increases with the hydrophility, when polyoxyethylene chain becomes sufficiently long. Furthermore, this suggests probably that some interaction occurs among different aggregates by the help of long polyoxyethylene tails, being ascribed to the polymer-like property of the detergent having a long hydrophilic tail.

On the other hand, it is worth while to consider the viscosity data in the light of the theoretical viscosity equation proposed by Guth and Simha[14]:

$$\eta_r=1+2.5\phi+14.1\phi^2 \qquad (3)$$

This equation is applicable to the dispersion systems of spherical particles, where η_r is a relative viscosity and ϕ is a volume fraction of the particle. The use of Eq. 3 in the present experiment involves the assumption that the aggregates of PODE are spherical[5]. From

Eq. 3 the volume fraction, ϕ, was computed, and the effective volume, ϕ/c, shown in Table I denotes the volume occupied by one gram of the detergent in the solution.

The value of ϕ/c is nearly independent of concentration and increases with the increasing polyoxyethylene chain-length, except in the case of PODE in which $p=7.6$, as is shown in Fig. 5. Nakagawa and Inoue[5] have obtained results corresponding to the present ones in the same way, using methoxy polyoxyethylene alkyl ether, in a relatively limited extent of chain-length.

The author has previously shown from the data of ultracentrifugal experiment[3] that the aggregation number, i. e., a number of molecules per aggregate, is highly dependent on the chain-length of polyoxyethylene and decreases with an increase in the chain-length. Considering this result in connection with the values of ϕ/c, therefore, we may say that the number and effective volume of aggregates at a given concentration of PODE increase with the polyoxyethylene chain-length. In concentrated solutions, thus, chances for different aggregates to approach and/or contact each other might be more frequent with the increasing chain-length. The interaction among different aggregates, caused by these chances, is presumably that which results in the polymer-like property of the non-ionic detergent with a long polyoxyethylene tail. From this point of view, the experimental finding that the value of n is slightly greater than unity in the case of PODE with a sufficiently long polyoxyethylene chain, can be attributed to the polymer-like behavior of PODE.

Summary

The solubilization and viscosity of polyoxyethylene dodecyl ether (PODE) solutions were studied as a function of the polyoxyethylene chain-length (p). The solubilization is in accordance with the isotherm $S=Kc^n$, where S is the extent of solubilization, c, the concentration of detergent, and n and K, constants. The value of n increases with the p value and is slightly greater than unity for PODE of $p>27$. The k'-value calculated from Huggins' equation, which is dependent on the p value, decreases at first with the p value and then somewhat increases in spite of the increasingly hydrophilic nature. The effective volume, ϕ/c, of PODE, which is nearly independent of c except for the case of PODE in which $p=7.6$, increases regularly as the p value becomes larger. On the basis of these results, the polymer-like property of PODE of a considerably large p value and the interaction among aggregates of PODE were discussed in connection with ultracentrifugal data reported previously.

NOTE

The Difference in Free Energy between Equatorial and Axial Isopropyl Groups

By Nobuo MORI and Fumie SUDA

(Received September 11, 1962)

The differences in free energy between equatorial and axial lower alkyl groups are the fundamental quantities on which conformational analysis is based; the values for the methyl and ethyl groups are known to be near -1.8 kcal./mol.[1-4,7,8,10] while those for the isopropyl group are in the wide range of $-2.5\sim-3.55$[3,4] kcal./mol. or are at least often taken[5] to be considerably greater those of methyl and ethyl. Further, an isopropyl group was often assumed to be almost as big as a *t*-butyl group[6].

Recently, however, Lewin and Winstein[7] have given a value of ca. -2.3 kcal./mol. for the isopropyl group from the chemical shifts in the NMR of the 1-proton in isomeric 4-isopropylcyclohexanols. Allinger and his co-workers[8] reported a lower value of -2.1 kcal./mol. from the equilibrium points for the isomerization of *cis*- and *trans*-diisopropylcyclohexanes and of isomeric 4-isopropylcyclohexanecarboxylic acid ethyl esters.

In the present work, the difference in free energy between equatorial and axial isopropyl groups has been determined in the following way. New *cis*- and *trans*-4-isopropylcyclohexylcarbinyl *p*-tosylates have been prepared and acetolyzed, and from the observed rates (k), the difference in free energy (ΔF) between the equatorial and axial isomers* have first been calculated by using the equations[3,9,10]: $K=(k_a-k)/(k-k_e)$ and $\Delta F=-RT\ln K$, where K is the equilibrium constant between equatorial and axial isomers and k_a and k_e are, respectively, the rates for *cis*- and *trans*-4-*t*-butylcyclohexylcarbinyl *p*-tosylates in the same reaction. The calculated values are shown in Table I, along with the relative rates and the mole fractions (N_a) of the axial isomers.

Therefore, the difference in free energy (ΔF_{i-Pr}) between equatorial and axial isopropyl groups may be calculated as follows: The ΔF value of $+0.32$ or 0.42 kcal./mol. for the *cis*-4-isopropyl compound may be regarded as the sum of an energy needed for moving the tosyloxymethyl group from an equatorial to an axial position (i.e., $\Delta F_{Tos}=-1.7$ at 100 and -1.8 kcal./mol. at 110°C[10]) and an energy needed for moving the isopropyl group from an axial to an equatorial position (i.e., $-\Delta F_{i-Pr}$), as illustrated by the relationship: $\Delta F=-\Delta F_{i-Pr}+\Delta F_{Tos}$; thus, the ΔF_{i-Pr} is -2.02 or -2.22 kcal./mol. The averaged value is -2.1 kcal./mol. The good agreement of this value with those obtained by Lewin and Winstein and by Allinger and his co-workers supports the conclusion[8] that the isopropyl group is essentially the same size as a methyl or ethyl group and is in quite a separate class from the *t*-butyl group.

On the basis of the above findings, the energy level of the diaxial conformation of the *trans*-4-isopropyl compound should be $2.1+1.75$ kcal./mol. higher than that of its diequatorial conformation. This corresponds to a K value of about 150 and leads to the prediction, borne out experimentally, that the acetolysis rate for *trans*-4-isopropylcyclohexylcarbinyl *p*-tosylate is identical with k_e within the range of experimental error.

Experimental

***cis*- and *trans*-4-Isopropylcyclohexylcarbinyl *p*-Tosylates** were prepared from the corresponding known carbinols[11] in the usual manner[12], by

SHORT COMMUNICATIONS

Formation of Paramagnetic Chemical Species of Aromatic Hydrocarbons on Vanadium Pentoxide

By Kozo Hirota and Keiji Kuwata

(Received September 6, 1962)

Recently, formation of radical or radical ion has been demonstrated repeatedly[1,3] by ESR measurement in the chemisorption of anthracene, perylene, 1, 1-diphenylethylene[4], and *p*-phenylenediamine[5] on silica-alumina catalysts in relation to the mechanism of the acid-site of catalysts. It is interesting to find among these researches some contradicted results on the effect of oxygen; i. e., the intensity of the spectrum became larger by the presence of oxygen according to Fogo[3], while the effect is reversed according to Brouwer[2] and Leftin[4]. Such a discrepancy seems not to be explained by the difference of adsorbates, since the results of Brouwer and Fogo are obtained by the same adsorbates, perylene and anthracene.

In order to investigate such an oxygen effect, we measured the ESR spectrum of benzene, naphthalene and anthracene on vanadium pentoxide which would supply oxygen chemically to the adsorbate. These aromatic hydrocarbons were brought about to the oxide surface as a vapor state and/or a *n*-heptane solution*. ESR measurements were carried out using an X-band apparatus as already reported[6], operating with 455 kc. field modulation.

A slightly asymmetric broad line could be observed always in the spectrum of vanadium pentoxide, degassed (less than 10^{-3} mmHg) at 350°C for one hour. According to the data hitherto published[7], this spectrum could be ascribed to V^{4+} or VO_2^{2+} ion, because it is characterized by a *g*-factor of 1.97, its shape and its half-width of 185 gauss. Now, if anthracene and naphthalene were brought into contact with the oxide treated at 350°C, a small but narrow signal appeared at the shoulder of the broad line, especially markedly in the case of anthracene (cf. Fig. 1). By an

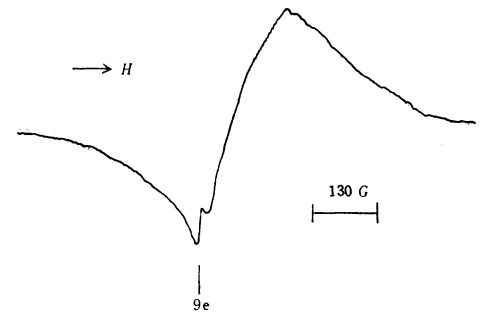

Fig. 1. ESR spectrum of anthracene on vanadium pentoxide.

introduction of air the signals increased their intensity and the corresponding one appeared even in the case of benzene. It is noteworthy that the radicals produced are so stable as can be kept under the atmosphere for a long time. Their half-width and *g*-factor are as follows:

Anthracene	$g=2.0025\pm0.0008$	$H_{msl}=19\pm2$
Naphthalene	2.01 ± 0.005	18.5 ± 3
Benzene	2.00 ± 0.005	18.5 ± 3

In every case no hyperfine structure of the narrower signal could be observed as well as the color change of the adsorbate. These results are not coincident with the systems of anthracene and perylene on silica-alumina[2,4] and on aluminum chloride[8]. However, the effect of oxygen seems to coincide with Fogo's result[3]. Allotting the role of an electron-acceptor to oxygen atom, Fogo ascribed his signal to a hydrocarbon cation-radical formed on Lewis acid site, similarly as Leftin et al.[4] assumed in the chemisorption of 1, 1-diphenylethylene.

It is possible, however, that the same

conclusion cannot be applied to the present research, because the paramagnetic species here observed may have a possibility to include some other intermediate species, e. g. semiquinone, formed as the result of oxidation of these aromatic hydrocarbons besides the cation-radical. Such a presumption is in harmony with the oxidative property of the vanadium pentoxide degassed at high temperature. In connection to the above consideration, sample-tube containing anthracene adsorbed on the oxide was heated up to 200°C in the atmosphere, in order to investigate the stability of the radical. Then the shoulder signal disappeared at all; i. e., the radical on the oxide was completely oxidized at higher temperatures.

Added in Proof. In order to investigate the nature of this signal in detail, hydroquinone which is one of the oxidation products of benzene was used as the adsorbate. A signal (g-factor=2.002 $\pm$0.001) appeared also at once, and became very strong at 200°C. The color of the sample became dark-purple, suggesting that quinhydrone is formed, i. e, equimolar complex of quinone and hydroquinone. The signal had no hfs and was narrow as compared to that observed in the case of aromatic hydrocarbons, but it may be allowed to consider that it is due to semiquinone. A similar experiment was carried out, making *p*-phenylenediamine as the adsorbate, and a signal with no hfs could be obtained as reported by Okuda[5] on silica-alumina. This will be another finding to support our viewpoint.

Such being the matter, it will be reasonable to propose that if anthracene, naphthalene or benzene is adsorbed, corresponding semiquinone radical is formed on the degassed vanadium radical.

Details of the study will be published elsewhere.

Recoil Reactions in the Irradiated Aquopentamminecobalt(III) Complexes

By Nobufusa SAITO, Takeshi TOMINAGA and Hirotoshi SANO

(Received December 4, 1962)

The present authors previously studied recoil chemistry of various hexamminecobalt(III) complexes and found that outer anions of the

target compound might play an important role in the recoil reactions[1]. In the present work, they have investigated the effects of outer anions on the recoil reactions in the irradiated aquopentamminecobalt(III) complexes.

Six kinds of aquopentamminecobalt(III) complexes listed in Table I were irradiated for one hour at pile temperature in the JRR-1 reactor, at a thermal neutron flux of approximately 3×10^{11} n/cm^2 sec. All irradiations were made in the presence of air. After the bombardments the target salt was stored at dry-ice temperature for one to five days. Then it was dissolved in distilled water and the percentages of ^{60}Co-labeled species present in the aqueous solution were determined by means of separation procedures involving ion exchange, precipitation, or paper electrophoresis (in the acetate buffer)*.

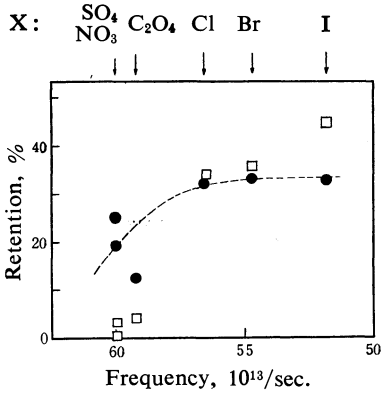

Fig. 1. The relationship between retention and frequency of the maximum in the first absorption band of $Co(NH_3)_5X$.

● Retention of $[Co(NH_3)_5H_2O]X_3$
□ Retention of $[Co(NH_3)_6]X_3$

The results summarized in Table I indicate that the distribution of recoil species in these salts was largely influenced by the kind of outer anions in the target. In Fig. 1 is plotted the retention (percentage of $^{60}CoA_5H_2O^{3+}$) of aquopentamminecobalt(III) complex salts against the frequency of the maximum in the first absorption band of $Co(NH_3)_5X$ (X denotes the outer anion in the target). It appears that the retention is generally increased with the decrease in the frequency of the maximum, or the decrease in stability of the outer anion X as complexed with cobalt. It will be seen that this retention-stability relationship is essentially similar to that already observed for the corresponding hexamminecobalt(III) complexes[1], which are shown together in Fig. 1. Since the corresponding salts in the both series containing the same kind of outer anion may be rather alike in chemical composition except that a ligand NH_3 is replaced by H_2O, and vice versa, such a similarity in the recoil reactions may not be surprising.

In explanation of the results it may be presumed that the recombination process involving NH_3 and H_2O molecules to restore the parent form competes with the substitution processes involving outer anions where the facility of their incorporation into ligands may mainly depend upon the stability of such anions as complexed with cobalt.

* Retentions obtained by paper electrophoresis were somewhat lower than those obtained by ion exchange. The latter values were used in Table I.

Effects of Outer Anions on the Recoil Reactions in the Irradiated Nitropentamminecobalt(III) Complexes

By Nobufusa SAITO, Takeshi TOMINAGA, and Hirotoshi SANO

(Received December 4, 1962)

It was already reported that recoil reactions in the irradiated hexammine- and aquopentamminecobalt(III) complex salts were greatly influenced by the kind of outer anions in the target compound[1,2]. In this work, the investigation of the effects of outer anions has been extended to a group of nitropentamminecobalt-(III) complex salts.

Seven kinds of nitropentamminecobalt(III) complex salts (listed in Table I) were irradiated for one hour in the JRR-1 reactor at a thermal neutron flux of approximately 3×10^{11} n/cm^2 sec. All irradiations were made at pile temperature in the presence of air. After irradiation the ^{60}Co-labeled species present in aqueous solutions of the target salt were separated by means of ion exchange, precipitation, or paper electrophoresis*1.

The results are summarized in Table I. For nitropentamminecobalt(III) nitrate, chloride, bromide and iodide (i.e., X=NO_3, Cl Br and I), however, $^{60}CoA_5X^{2+}$ fraction in Table I did not represent real retention but was composed of two divalent complex cations containing different acidic ligands. These two species were further separated by fractional precipitation (recrystallization to constant specific activity), or ion exchange after aquotization*2. Table II shows percentages of the two species: species a represents "retention", whereas species b is a substituted product formed through incorporation of outer anions.

In Fig. 1 are plotted percentages of the species a and b against the frequency of the maximum in the first absorption band of $Co(NH_3)_5X$, where X denotes the outer anion of the target salt*3. It will be seen that, as

2) N. Saito, T. Tominaga and H. Sano, ibid., 36, 231 (1963).
*1 Sometimes, paper electrophoresis method gave slightly lower retentions than those obtained by ion exchange method. The latter values were used in the present paper.
*2 For example, when the solution containing $CoA_5NO_2^{2+}$ and CoA_5Br^{2+} is warmed in adequate conditions, CoA_5Br^{2+} is rapidly aquotized to give $CoA_5H_2O^{3+}$ whereas $CoA_5NO_2^{2+}$ remains practically unchanged. Then the trivalent and divalent cations can be readily separated by ion exchange method.
*3 Since the oxalate and sulfate containing divalent anions may be different from the other salts as to the crystal structure and the outer anion-to-cobalt ratio, they are not included in Fig. 1.

TABLE II. PERCENTAGES OF ^{60}Co-LABELED SPECIES IN THE FORM OF $^{60}CoA_5X^{2+}$

	b : CoA_5Br^{2+}	5 ± 1
$[Co(NH_3)_5NO_2]I_2$	a : $CoA_5NO_2^{2+}$	23 ± 1
	b : CoA_5I^{2+}	3 ± 1

* Species a represents retention; species b represents a substituted product in each target salt.

the frequency of the maximum decreases, the percentage of species b decreases while the percentage of the parent species a (retention) remains almost unchanged or slightly increases.

As in the preceding works[1,2] the results may be presumably explained by assuming that fragmented NH_3 or NO_2 groups and outer anions compete with each other in the recoil reactions involving complex formation, upon which the stability of the outer anions as complexed with cobalt may be reflected, as indicating the facility of co-ordination.

A New Spraying Reagent for Ferrous Ion in Paper Chromatography

By Ichiro MORIMOTO

(Received December 5, 1962)

Separation of ferrous and ferric ions from each other, and the detection of these ions are important from the practical point of view. In the previous paper[1], a colorimetric method was described for the determination of iron by making use of its colored complex with 2, 4, 6-pyridinetricarboxylic acid.

2, 4, 6-Pyridinetricarboxylic acid gives a purple complex with ferrous ion and the absorbance of this colored complex increases considerably by the presence of a small amount of pyridine. Therefore, a mixed solution of 2, 4, 6-pyridinetricarboxylic acid and pyridine can be used as a new reagent for ferrous ion in paper chromatography.

One to 2 μg. of ferrous or ferric ion were spotted on a filter paper strip for chromatography (Tôyô Roshi, No. 51, 51 A or No. 53). The paper strips were developed for about 2 hr. by the ascending method in a mixed solvent of 4 N hydrochloric acid-*n*-butanol-acetic acid-acetone[2] (1 : 1 : 1 : 1). The solvent front moved about 15 cm. at 15±2°C. The paper strip was, then, dried and the following solution was sprayed on them: 0.1 g. of 2, 4, 6-pyridinetricarboxylic acid dissolved in 100 ml. of methanol, with the addition of 5 ml. of pyridine. Ferrous ion was detected as a purple spot which did not fade away within about 24 hr. After marking the ferrous ion spot, the paper strip was sprayed with 10% hydroxylamine hydrochloride in methanol. Ferric ion was reduced to ferrous ion and it was clearly detected as a purple band. The detection limit was about 0.1 μg. for ferrous ion. The color reaction is specific for ferrous ion and it does not interfere with other ions.

TABLE I. R_f VALUES OF Fe^{2+} AND Fe^{3+} WITH THE DEVELOPER, 4N HCl-*n*-BUTANOL-ACETIC ACID-ACETONE (1 : 1 : 1 : 1)

Filter paper	R_f	
	Fe^{2+}	Fe^{3+}
No. 51	0.18	0.54
No. 51 A	0.15	0.55
No. 53	0.17	0.57

The results are given in Table I. The separation of ferrous and ferric ions from each other in the mixed solvent gave satisfactory results. Other solvent mixtures were studied, but the results were unsatisfactory in the separation of ferric ion from ferrous ion. This new reagent is much sensitive and more convenient than any other reagents[2] like ammonia or cyanides used frequently in paper chromatography.

Further work is in progress and the results will be published later.

Direct Introduction of Ethoxycarbonyl Radical into Hydrocarbons by Photochemical Reactions

By Chyongjin PAC and Shigeru TSUTSUMI

(Received December 11, 1962)

Recently, it has been reported that methoxycarbonyl radical is produced by the abstraction of chlorine atom in methyl chloroformate with methyl radical[1].

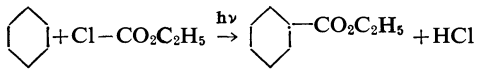
It would also be expected that alkoxycarbonyl radical might be produced from alkyl chloroformate by light in the same manner as the photolysis of phosgene[2] and of oxalylchloride[3],

$$Cl-CO_2R \xrightarrow{h\nu} \cdot Cl + \cdot CO_2R$$

being accompanied by the direct introduction of the radical into hydrocarbons.

Therefore, the photochemical reactions of ethyl chloroformate with hydrocarbons were studied, and it was found that the ethoxycarbonyl radical produced by a high pressure mercury arc (600 W) from ethyl chloroformate was introduced into hydrocarbons, such as cyclohexane, benzene and cyclohexene.

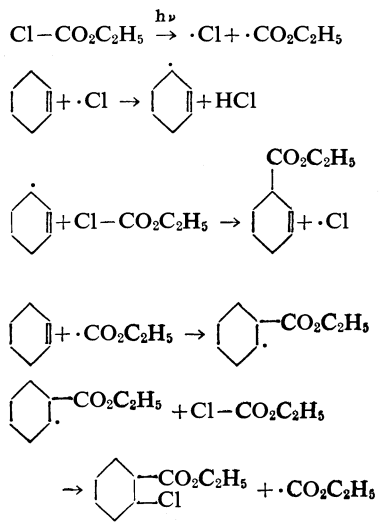
The over-all reaction with respect to cyclohexane is shown as follows;



The irradiation of a mixture of cyclohexane (168 g.) and ethyl chloroformate (83 g.) (mole ratio; 3:1) gave the following liquid products at room temperature for 6 hr. in the atmosphere of nitrogen; 1 g. of an ester (b. p. 93~96°C/35 mmHg, n_D^{26} 1.4510) and 1.5 g. of bicyclohexyl (b. p. 65~70°C/3 mmHg, n_D^{25} 1.4743). The above ester was identified as ethyl cyclohexanecarboxylate by infrared absorption spectra, gas chromatographic analyses and the mixed-melting point test of its anilide with an authentic sample (m. p. 143~143.5°C, recrystallized from ligroin). During the irradiation, gases were evolved and analyzed by gas chromatography, which consisted of large amounts of carbon dioxide and ethane, small amounts of ethylene and a trace of ethyl chloride.

In a similar way, a mixture of benzene and ethyl chloroformate afforded only a small amount of ethyl benzoate, without the formation of gaseous products. Ethyl benzoate was confirmed by gas chromatographic analyses.

In the case of cyclohexene, ethyl cyclohexanecarboxylate and 3, 3'-bicyclohexenyl were obtained as major products, although we expected 3-ethoxycarbonylcyclohexene or 1-ethoxycarbonyl-2-chlorocyclohexane as a major product, taking into account the previous experimental results which are shown as bellow;



or

In spite of irradiation for a longer time, the amounts of gaseous products were very small compared with those found in the case of cyclohexane. Details of this reaction are now under investigation.

The method of direct carboxylation into hydrocarbons with ethyl chloroformate has never been reported, thus we are intending to carry out further researches in this field.

The Interpretation of Absorption Spectra of Condensed Polycyclic Aromatic Hydrocarbons by Using a Simple Resonance Theory. I. The Resonance Structure of the Excited State in Correlation with Platt's Theory

By Takashi HANDA

(Received February 25, 1961)

Many theoretical investigations have been made for the purpose of interpreting the absorption spectra of condensed polycyclic aromatic hydrocarbons by such hypotheses as the valence-bond, molecular orbital, and free-electron theories. It is very difficult, however, to understand intuitively the chemical meanings of the upper-state.

With this in mind, the present author has undertaken to learn whether the transition energies of these molecules may be directly related to the differences in empirical resonance energy between the ground and excited states of these molecules. In this case, it is assumed that a chemical resonance structure corresponds to the defined excited state proposed and classified by Platt[1,2].

The estimation of these differences in empirical resonance energy have been carried out by applying Carter's empirical equation to the excited state. We have examined what types of chemical resonance structure correspond to the individual excited states.

The Introduction of the Approximation Formula. — The light-absorption energies of substances can be expressed generally as follows;

$$E_2 - E_1 = \bar{\nu} \qquad (1)$$

where E_2 and E_1 are the total energies of the excited and ground states respectively. These energies, E_2 and E_1, which are caused by the mobile π-electrons in the case of polycyclic aromatic hydrocarbons, can be divided into two pats : bonding-energy (H°) and resonance energy (R), where R means the empirical resonance energy which is the sum of calculated resonance energy and the compression energy. Thus, Eq. 1 can be rewritten into Eq. 2:

$$\bar{\nu} = (H^\circ_E - H^\circ_G) - (R_E - R_G) \qquad (2)$$

where the term $(H^\circ_E - H^\circ_G)$ may be understood to correspond to the light-polarization energies between two polarized carbon atoms on the periphery of the molecule without resonance and to be approximately constant for this series of molecules.

It is assumed that, for the estimation of resonance energies in the excited state, Carter's empirical equation, which is consolidated for the estimation of those in the ground state, can be applied, except for the constant term:

$$R = -20 + 12\,D + 69 \log N \ \text{(kcal./mol.)} \qquad (3)$$

where D is the number of double bonds and N is that of the canonical Kekulé resonance structures in this state. Therefore, Eq. 2 can be rewritten into Eq. 4:

$$\bar{\nu} = A - 69 \log (N^*/N) \quad \text{(kcal./mol.)} \qquad (4)$$

where A is constant and N^* is the number of canonical Kekulé resonance structures of the residual parts of the structure of the molecule defined as an excited state and N is that of a ground state.

An excited state of a molecule in this series may be chemically represented by the resonance among a specified group of an N^* number of elementary polarized-resonance, structures with the same weights, and their symmetrical character probably can not be reduced to a particular, designative symmetry-group. Therefore, it is considered that they include imaginary unit polarizations which cancel each other out finally, in contrast to the irreducible representation which characterizes the discriminative state in other representations. Hence, we must correlate, in some way, the above method of the representation of an excited state with the theoretical method, which pictures a characteristic excited state with a universal designation over all the molecules of this series, irrespective of the different symmetry-characters of their configuration of π-orbitals or electrons, with a few exceptions.

Platt has already classified and assigned the absorption spectra of acenes and phenes into the L_a-, L_b-, B_a-, B_b-, C_a- and C_b-types of polarization by using his free-electron orbital method.

The chemical resonance structures of polycyclic acenes and phenes corresponding to a

1) H. B. Klevens and J. R. Platt, *J. Chem. Phys.*, **17**, 470 (1949).
2) J. R. Platt, ibid., **17**, 484 (1949).

given type of polarization, such as ^1L_a, ^3L_a, ^1L_b, ^3L_b, ^1B_a, ^1B_b, ^1C_a and ^1C_b, are expressed and their numbers of resonance structures (N^*) are estimated in the following section.

As a conclusion, the correctness of the preceding expression of an excited state by resonance structures corresponding to a given type of polarization according to Platt's idea, is judged by plotting $\log(N^*/N)$ versus $\bar{\nu}$ assigned as corresponding to that state, thus determining whether the linear relation prescribed in Eq. 4 is held, and by examining the direction of the resulting electric moment, which is the sum of the elementary moments of each contributing resonance structures, or by examining the oscillator strength due to these structures, as compared to the empirical ones.

Classification of Resonance Structures in Correlation with Platt's Model. — Platt has postulated a convenient diagram for determining the polarizations of transitions from the ground state. The distinctive feature in his theory exists in that he replaces the sign of a free-electron standing-wave to that of a point-charge to picture the transition from the ground state. The polarization of the transition from the ground state will be the same as if we locate + and − point charges at alternate anti-nodes, shrink the perimeter back to its normal shape, and determine the direction of the resulting electric moment. Although it should be emphasized that such a polarization diagram is a device for visualization and not a classical model, it is a very convenient modeling for our purpose in that it pictures an excited state by the resonance of a given type of polarized chemical structures.

For example, the polarization diagrams of each level are illustrated in Fig. 1* for anthracene. The orbital ring quantum number (q) is equal to the ring number (n) in the cata-condensed series, where the number of π-electrons is $2(2n+1)$. Therefore, the total momentum number, Q, is equal to 1 for the B-state and $(2n+1)$ for the L-state.

On the basis of the above considerations, we set resonance structures of a given type of polarization corresponding in our sense to the above polarization diagram of a respective excited state in Platt's sense, as we locate + and − charges along the periphery of the molecule according to the law of alternating polarity. However, the respective transitions from the ground state have been assigned to a simple designation based on the molecular orbital method in the simple and lower molecules. Therefore, it is considered that the above representation of an excited state includes imaginary unit polarizations which cancel each other out finally, in addition to the real representation of an excited state by unit polarizations.

If we separate charges at the cross-linking atoms into $(1-ai)$ and ai in order to eliminate the effect of the cross-linking as we estimate the energy of the ^1L_a and ^3L_a transitions in the following section, and if we select the specified group of polarized structures corresponding to an adequate group designation, the sum of the number of polarized resonance structures of an excited state in this method of computation might be suggested as satisfying Carter's equation in plotting $\log(N^*/N)$ versus the $\bar{\nu}$ value assigned to that excited state.

A Modification of Platt's Idea.—In order to eliminate the effect of cross-linking carbon atoms for the computation of the weights of the resonance structures for the L-state, we will make a little modification of Platt's idea. We will introduce an imaginary point charge vector i to the cross-linking carbon atoms in the ground state in order to divide the corresponding charge-density 1 to $(1-\alpha i)$ and αi; thereby we can divide one cross-linking carbon atom into two imaginary ones with charge-densities of $(1-\alpha i)$ and αi.

It is assumed that that electric current resulting from the motion of the π-electron is not circular on one plane, moving in one direction along the periphery of the molecule, but that it passes through a twisted path imagined to consist of each constituent benzene nuclei as a loop via an imaginary ethylene-linkage formed by cross-linking carbon atoms with the imaginary charges $(1-\alpha i)$ and αi in one direction. In this model, the angular momenta of the π-electrons of each benzene nucleus are not perpendicular to the imaginary twisted orbital plane, but they become parallel as we draw the imaginary atom A with the imaginary charge of αi near to another imaginary atom, A′, with the imaginary charge of $(1-\alpha i)$. The imaginary distance between them may be considered to determine the degree of condensation of the two nuclei. The quantity of the angular momenta is defined as qh where q is the orbital quantum number and the energy is given by q and 1, as in Eq. 5. It is considered that the sum of the orbital ring quantum numbers, q_1 and q_2 of each imaginary twisted path is invariant to the original q, while the sum of each bond-length of the perimeter is increased by an i in an imaginary unit. It is considered in this case that the imaginary bond-length in carbon-atoms is defined as the mean distance multiplied by

* This polarization diagram is just the same as that shown in the paer of Platt. However, for convenience of explanation it is re-illustrated in this paper.

two charge densities at both ends.

When we switch two of the four imaginary atoms, αi, $(1-\alpha i)$, αi, and $(1-\alpha i)$, the imaginary increase in the perimeter-length by imaginary cross-linking ethylene-linkage is equal to $2\alpha i(1-\alpha i)$ and the imaginary decrease in the bonds among cross-linking carbon atoms and their neighbors is 2 for naphthalene. Therefore, each cross-linking ethylene increases $2\alpha i+2(\alpha^2-1)$ in perimeter-length for acenes. The estimated real length of this imaginary path is determined to be $\sqrt{10^2+2^2}$ by vector-synthesis in the case where α is equal to 1 for the naphthalene molecule. For the phenanthrene molecule, it is proposed that the following operations shall be made as illustrated in Fig. 2. We separate each cross-linking carbon atom in the f-position into two imaginary ones with a charge vector of βi on f and $(1-\beta i)$ on f'; then we rotate the i, h, g, and f' atoms upside down to the molecular plane with the $j-k$ bond as an axis, so as to superpose the f' on the carbon atom in the l-position. The charge-rotation vector $\boldsymbol{r}$ is introduced into this operation, and consequently the charge-density of the rotated atoms in the i, h, g, and f'-positions become $\boldsymbol{r}$, $\boldsymbol{r}$, $\boldsymbol{r}$, and $\boldsymbol{r}+1$ by rotation, where $i\times\boldsymbol{r}=0$ and $\boldsymbol{r}\times\boldsymbol{r}=1$. It is also assumed that the ring quantum number which indicates the angular-momentum is invariant in this operation. Therefore, the same procedure is considered as in the case of the anthracene molecule by separating the charge in the $(l+f')$-position into $\{i(\alpha+\beta)+r\}/2$ and $1-\{(\alpha+\beta)i-r\}/2$. The imaginary length of the perimeter l is estimated as $11.68+3.18i+2\boldsymbol{r}$ when α is equal to 1, and the real number of the imaginary perimeter length becomes $\sqrt{11.68^2+2^2+3.18^2}$, treating i and $\boldsymbol{r}$ as orthogonal vectors.

According to Platt's free-electron orbital method, the energy of light-absorption corresponding to that of the center of gravity (E) is given in Eq. 5;

$$E=\frac{q^2h^2}{2ml^2} \tag{5}$$

where q is the ring quantum number of acenes, m is the mass of the electron, and l is the length of the perimeter in the Ångstrom unit. As is illustrated in Fig. 2, the imaginary perimeter lengths of pseudo-anthracene converted from phenanthrene by rotation may be given as follows:

$$\begin{aligned} l_1&=(8.5+3\alpha^2+\alpha\beta)+(3\alpha+\beta)i+2r \\ l_2&=(7.5+3\alpha^2+2\alpha\beta)+(5\alpha+\beta)i+2r \end{aligned} \tag{6}$$

The real values of l_1 and l_2 should be equal. Therefore, the following relations are deduced from Eq. 1:

$$3\alpha^2\beta^2+(27+6\alpha^2)\alpha\beta+10\alpha^2-16=0 \tag{7}$$

When we put $\alpha=0.775$ as the ^1L_a case in Table II, β is estimated to be about 0.4. As a result, we obtain the imaginary perimeter length l corresponding to the ^1L_a-polarization by substituing α and β into Eq. 6. In the same procedure, we obtain β as nearly equal to 0 when we put α as equal to 1.225, which corresponds to the ^3L_a-polarization. When we put α as equal to 1.0, β is estimated to be 0.18, which corresponds to the case of the center of gravity of L_a-polarization. The estimated values of $\bar{\nu}$ from Eq. 5 corresponding to ^1L_a, ^3L_a and $^{c\cdot g}L_a$ polarization are fairly satisfactory. In the same way, we can estimate β in the case of such simpler phenes as 1, 2-benzoanthracene, 1, 2-benzotetracene, chrysene, and 1, 2-5, 6 dibenzoanthracene. The estimated values of $\bar{\nu}$ corresponding to the ^1L_a, ^3L_a and $^{c\cdot g}L_a$ polarizations are considered to be reasonable. The estimated values of the energies of absorptions of the L_a-state of respective compounds are shown in Table I*.

When we switch other two combinations of four imaginary atoms with charges αi and $(1-\alpha i)$, such as αi and αi or $(1-\alpha i)$ and $(1-\alpha i)$, energy-values of the B_a-state are obtained which correspond to the estimated number of resonance structures in the analogous B_a-state, which means that we have imaginarily varied the actual perimeter length or the shape of the potential box of the molecule instead of varying the angular momentum q. The imaginary length of the perimeter of naphthalene with an imaginary increase of $\alpha^2i^2+(1-\alpha i)^2$ in two cross-linking ethylene atoms and a decrease of $2\alpha i+2(1-\alpha i)-4$ in four bonds among cross-linking carbon atoms and their neighbors, is equal to $(9-2\alpha^2)-2\alpha i$. Those of anthracene, naphthacene and phenanthrene are illustrated in Table II. In the case of phenanthrene obtained by being rotated, the residual imaginary charge on the f atom is equal to $(1-\alpha i)$, in contrast to the value of αi in the case of the L_a-state; therefore, the imaginary charge in the $(l+f')$-position is 1, while other elements are equal to those in the above case. The values of $\bar{\nu}$ B_a estimated

* We can empirically obtain satisfactory values of $\bar{\nu}$ in respective polarizations when we put α_1 as equal to 0.775 in the case of the ^1L_a-polarization, α_3 as equal to 1.225 in the case of the ^3L_a-polarization, and $\alpha_{c\cdot g}$ as equal to 1.0 in the case of the $^{c\cdot g}L_a$-polarization in the acene series. The following relations are observed empirically in the case of acenes:

$$\begin{aligned} \bar{\nu}^1L_a+\bar{\nu}^3L_a &\fallingdotseq 2\bar{\nu}^{c\cdot g}L_a \\ \alpha_1+\alpha_3 &\fallingdotseq 2\alpha_{c\cdot g} \end{aligned} \tag{8}$$

where α is considered to determine the degree of the condensation of mutually neighboring benzene nuclei.

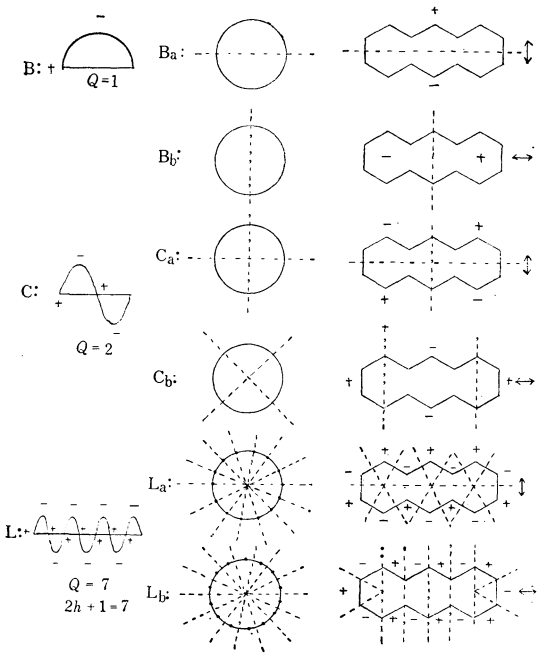

Fig. 1. Polarization diagram of the anthracene molecule according to Platt.

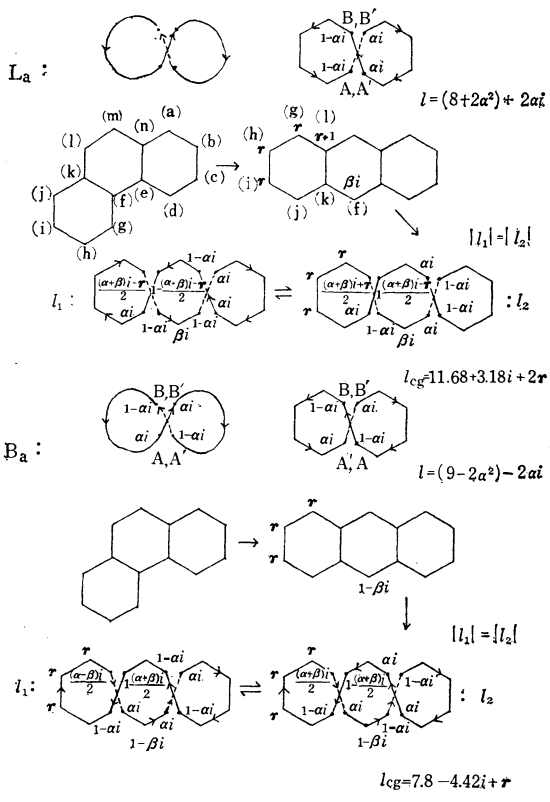

Fig. 2. Imaginary perimeter in the case of L_a- and B_a-polarization.

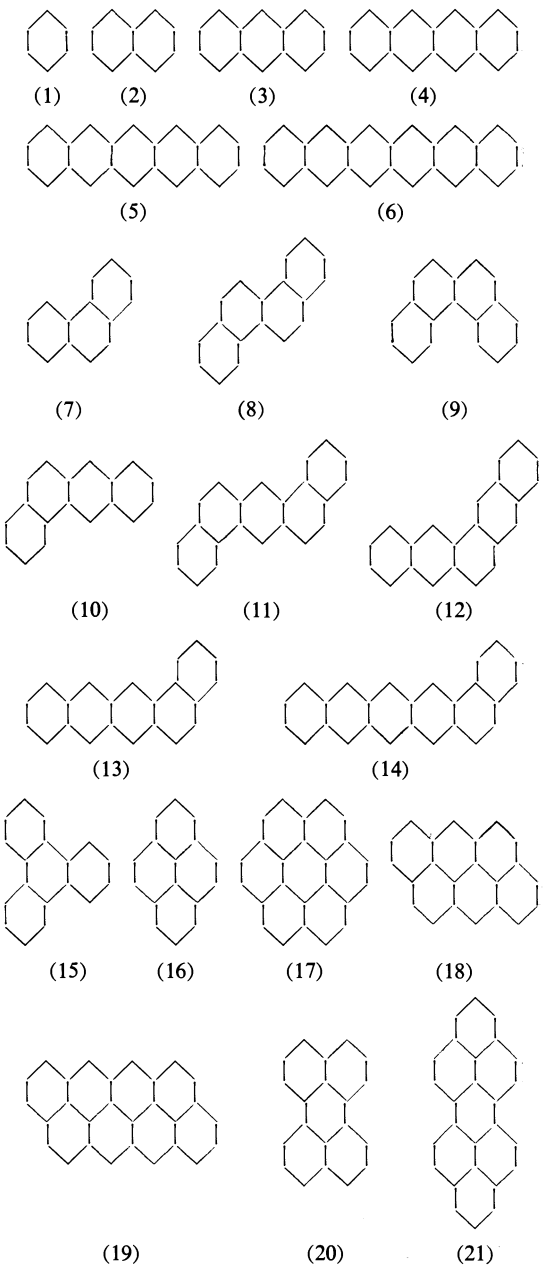
from the perimeter length are given in Table I. The estimated values corresponding to the ^1L_a- and ^3L_a-excitation illustrated in Table I are considered to be in good agreement, irrespective of their rough estimation.

The above procedure corresponds to the fact that, in the estimation of resonance structures, we put the imaginary charge, i, on the cross-linking atom on the perimeter and separate the imaginary ethylene-linkage with charges $(1-i)$ and $-(1+i)$ at both ends in the representation of the L_a-state, while we put $(1-i)$,

Table I



on the perimeter and separate the imaginary ethylene linkage with charges i and i in the case of the B_a-state.

To the problem of the estimation of the number of resonance structures in acenes and phenes, this imaginary point-charge-vector and rotation-vector are also introduced. The correlation with an estimation of their resonance structures will be discussed in the following section. The numbers of Kekulé resonance structures will be given in the analogous form as $a+bi+c\boldsymbol{r}$; their real value is estimated as $\sqrt{a^2+b^2+c^2}$ for phenes and other complex-molecules which are converted into pseudo-acenes, from which we take a given type of resonance structure as corresponding to a given polarization as defined by Platt.

Resonance Structures Corresponding to L_a-type Polarization.—The chemical resonance structures corresponding to the L_a-type polarization of the naphthalene molecule are illustrated in Fig. 3, where + and − point charges are located alternatively on individual elementary carbon atoms on the periphery of the molecule. A combination of one +-labeled atom with all five other −-labeled atoms holding the canonical resonance structures with the residual parts of the molecule produces the 5 or $(2n+1)$ polarized form. The same operation with the four other +-charged atoms produces the 5^2 or $(2n+1)^2$ polarized form, with 32 Kekulé resonance structures.

By superposition of these 5^2 or $(2n+1)^2$ polarized form, Platt's model corresponding to the L-state has been considered to be made. Therefore, the −-charge density on each −-labeled carbon atom in one polarized structure must be $1/4\times1/32$ in estimating the elementary dipole, the 1/4 factor of which will be discussed in a later section. The summation of the elementary dipoles of 32-resonance structures gives only a transversal electric dipole of $11ae'$, where e' is equal to $e/32$. However, it is known intuitively that the weights of the existence of the resonance structures asterisked by * and ** may be different from those asterisked by *** and ****, which include polarization on the cross-linking carbon atoms. The effects of cross-linking are eliminated by introducing the imaginary point charge vector i to the cross-linking carbon atoms, which, positively or negatively, separate the independent ethylene-linkage with the imaginary charges $(1-i)$ and $-(1+i)$, in order to supplement the decrease in total electric dipoles with this polarization, which is illustrated in Fig. 4.

The summation of elementary dipoles with the group asterisked by * gives only a transversal dipole with a magnitude of $12ae'$, while that with the group asterisked by ** gives $2ac'$ dipoles, that with the ***-asterisked group gives a transversal dipole of $-2ae'$, and that with the ****-asterisked group gives $-ae'$ in the same direction. Therefore, the first group asterisked by * possesses a predominant influence for polarization compared with the latter three. The electric dipole of the third group, asterisked by ***, may be substituted by that of the imaginary ethylene-linkage in the above model with charges of $-(1+i)$ and $(1-i)$ at both ends. Both dipoles possess a $-2ae'$ unit of strength. The last group, asterisked by ****, may be equivalent to the polarized structure among imaginary cross-linking carbon atoms with charges of i and i.

As has been mentioned above, the number of resonance structures belonging to the second group (**) may be substituted by those belonging to the imaginary ethylene, in estimating which we may count the resonance structures of the residual benzene nuclei or parts. For example, they are 1, 2, 3, 4 and 5 for naphthalene, anthracene, naphthacene and pentacene, in that order. As for the actual number of resonance structures in the estimation, they are multiplied by $(1+i)\times(1-i)$ or 2. The resonance number for the ***-group is equivalent to that polarized in the i and i position. They are all equal to 1 in one polarized structure. The numbers of polarization among cross-linking atoms mutually with imaginary charges of i are 1 for naphthalene, 4 for anthracene, 6 for naphthacene, etc. This polarization is equivalent to that of the *-type elementary structure in unit strength and hence may be included in the first *-group instead of the **-group, the members of which are mutually canceled. They are also expressed in real number in the above-mentioned imaginary point-charge vector method, while the ***-groups may be expressed in imaginary number and mutually canceled in symmetric acenes.

The second group, asterisked by **, possesses a moment of $2ae'$ in naphthalene and hence takes little part in the main polarization. The members of this group are considered to be caused among two neighboring atoms; hence, in that sense they must include some of the polarization asterisked by *** and ****, which polarizations are substituted for by the effect of the introduced imaginary ethylene-linkage with charges $(1-i)$ and $-(1+i)$. For the convenience of the estimation of the number of resonance structures of the ^1L_a- and ^3L_a-states and of the visualization of the excited states in terms of chemical resonance structures, the polarization among mutually neighboring atoms and imaginary ethylene-linkage are considered to be of the ^3L_a-type judging from their small dipole strength. The polarization

including the *-group and imaginary ethylene-linkage is considered, on the basis of their strong dipoles, to correspond to the ^1L_a-type. The former model of resonance is pictured as if individual dipoles are embedded in combined benzene nuclei independently. The latter model of the ^1L_a-type is pictured as if the electric current flows on the twisted loop along the perimeter of the benzene nuclei and their combining imaginary ethylene-linkage. Their types of polarization are applied to phenes and other higher condensed compounds, where they are developed to be converted into symmetric pseudo-acenes, which process will be referred to in later sections.

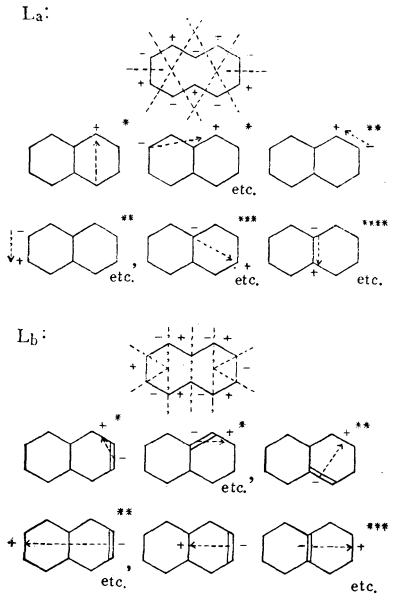


Fig. 3. Resonance structures of naphthalene corresponding to the L_a- and L_b-polarized state.

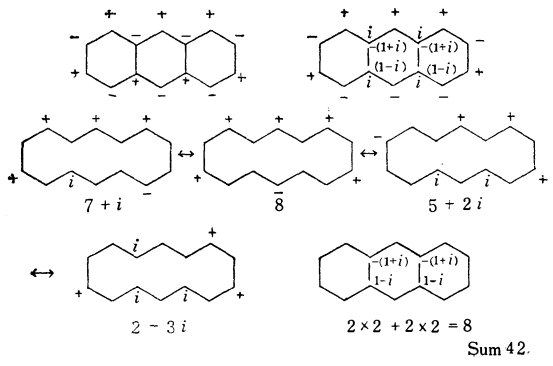

Fig. 4. Resonance structures of anthracene corresponding to the ^1L_a-polarized state, eliminating the effect of cross-linking carbon atoms by introducing the imaginary vector *i*.

Resonance Structures Corresponding to L_b-Levels.—The L_b-state is considered to be the case where the nodal cuts fall on the atoms or where the nodes are located on the middle point of individual bonds in Platt's model. It is pictured by removing charges on the atoms a half bond length along the perimeter in order to locate them on the middle point of the bonds.

In the usual representation of resonance structures, two ways are considered to remove the charge on the cross-linking atoms among the cross-linking bonds and their neighboring bonds. It seems to be a problem of the conjugation of four imaginary atoms which combine in two benzene nuclei. In order to solve this problem, the modified model will be re-examined. We remove unit charges on the atoms in that model corresponding to the ground state a half bond length along the perimeter of the twisted loop in one direction so as to locate them on the middle point of individual bonds, as is illustrated in Fig. 5. The conjugations of four imaginary atoms are then switched as they are in the case of the b-state. For example, an anthracene molecule is used which possesses a meso-position where the charges are considered to be somewhat localized in the ground state. Then, we remove the unit charges which are on the atom in order to locate them on the middle-point of bonds. It is considered that charges flow along the perimeter of the molecule by polarization and that the excitations are caused in the same locations as in the ground state, thus separating the solutions of the b-state from those of original Platt's model. The imaginary path among meso-positions does not alter the path-length compared to the case in which they are not imagined, as with the a-state.

We switch the four imaginary atoms in the b-state to locate them on bonds in one direction in order that, in the switched two-benzene nuclei and in the half-benzene nuclei in the meso-position, the current will flow in the same direction, giving angular momentum with an opposite vector towards the molecular plane that would be mutually cancelled if they are separated. This gives the features of the L_b-state, which is not such a strongly-polarized state. Using this procedure for other acenes, the perimeter-lengths and the $\bar{\nu}$ values of the L_b-state given on Table I are obtained from Eq. 5. We will represent this L_b-polarized state with the chemical resonance structures shown in Fig. 5 and Fig. 6. In Fig. 5, the location of the + and − charges on the bond is interpreted as meaning that if we fix the bond there, we can hold the residual part of the molecule in the canonical Kekulé structure.

Because the charge is re-located to the neighboring bond through the twisted path, the polarized structures or the position of the bonds that are negatively charged, for instance, become different from those made from the untwisted path along the perimeter. For that reason, the + and − polarizations which occur in ordinary forms are inhibited in order to hold the residual part in the Kekulé canonical form. The polarizations are allowed mainly in the same benzene nucleus or in the neighboring nuclei, and the long-range polarizations among the separate benzene-nuclei are not allowed for the most part, illustrating that, in the L_b-type, the polarizations occur mainly in the same benzene nucleus, so that each

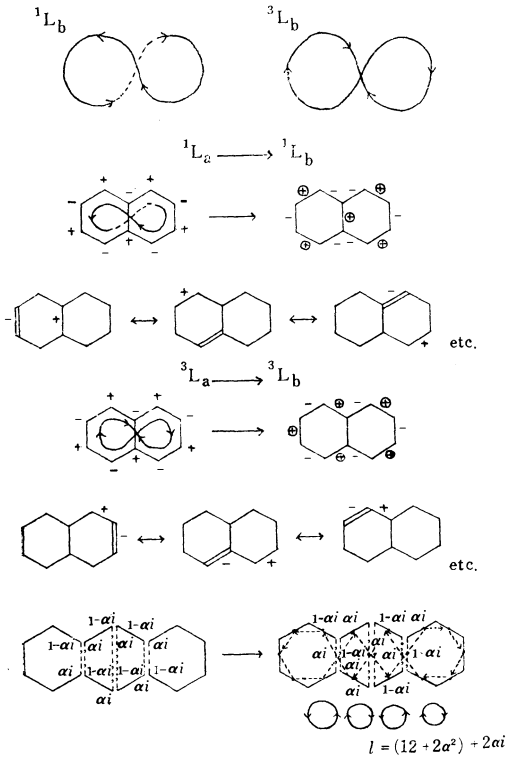

Fig. 5. Resonance structures corresponding to the ^1L_b- and ^3L_b-polarized state of naphthalene.

elementary dipole is canceled in that nucleus. It is suggested that, therefore, the strength of absorption in the position where polarization occurs is very similar to that where ^3L_a-type polarization occurs. Therefore, it is easily supposed that the numbers of resonance structures corresponding to ^3L_b-type polarizations are nearly equal to those corresponding to the ^1L_b-state. The sum of the elementary dipoles of individual structures described in Fig. 3 possesses only a longitudinal component and is small compared to the case of ^1L_a; similarly, each sum of the *-, **- and ***-asterisked groups possess only a longitudinal component and are small.

The general diagram for determining the number of th resonances of ^1L_b- and ^3L_b-structures is shown in Fig. 6. The same relation has been found for phenes and for other circular molecules when they are converted into pseudo-acenes. We can find the numbers of Kekulé resonance structures of the ^1L_b- or ^3L_b-type for acenes and phenes, the estimations of the position of polarization and the method of the estimation of the resonance numbers being like those in the case of ^3L_a.

The Estimation of Resonance Structures Corresponding to the L-State.—In the case of ^1L_a-

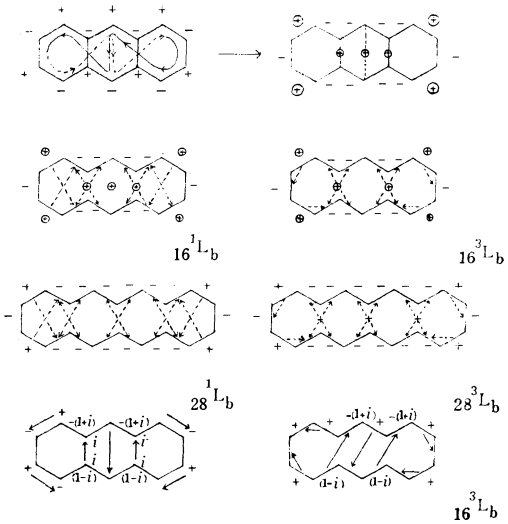

Fig. 6. Resonance structures corresponding to the ^1L_b- and ^3L_b-polarized state of anthracene converted by the half-bond length removal along the perimeter from the polarization diagram corresponding to the ^1L_a-polarization.

polarization, those among neighboring atoms are principally inhibited, except those in the case of imaginary ethylene, as has been stated in a preceding section. The estimated numbers of resonance structures (N_{L_a}) of polyacenes are illustrated in Table III. The correlation of $\log(N_{L_a}/N)$ with $\bar{\nu}_{L_a}$ is illustrated in Fig. 7. They retain the straight-linear relation in Eq. 4 with gradients of 69 kcal./mol. Phenes are transformed into pseudo-polyacene by introducing the charge rotation vector which is illustrated in Fig. 8.

After this procedure, the charges on the (g), (h), and (i) atoms become $-\boldsymbol{r}$, $\boldsymbol{r}$ and $-\boldsymbol{r}$. That on the $(l+f')$ atom becomes $1+\boldsymbol{r}$ where it is assumed that $i\times\boldsymbol{r}$ is equal to zero. Therefore, the separation of the imaginary ethylene-linkage with the charges $(1-i)$ and $-(1+i)$ charges the charge on the superposed cross-linking atoms $(l+f')$ to $(i+\boldsymbol{r})$ and that on atom (k) to i. The number of resonance structures is estimated to be (N), which is enumerated without a vector and multiplied by $\boldsymbol{r}$ or $N\times\boldsymbol{r}$ where one of the two atoms is labeled with vector $\boldsymbol{r}$, and is estimated to be $N\times\boldsymbol{r}^2$ or N where both atoms are labeled with vector $\boldsymbol{r}$. For instance, the numder of resonance structures corresponding to polarization between atoms (g) and (b) is estimated to be $N_{gb}\times\boldsymbol{r}$, while that between (g) and (h) is estimated to be $N_{gh}\times\boldsymbol{r}^2$ or N_{gh} where N_{gb} is the number of resonance structures corresponding to those between atoms (g) and (b) in the ordinary phenanthrene molecule.

TABLE III

* Number of resonance structures of ^1L_b or ^3L_b obtained by the conversion following Fig. 12.

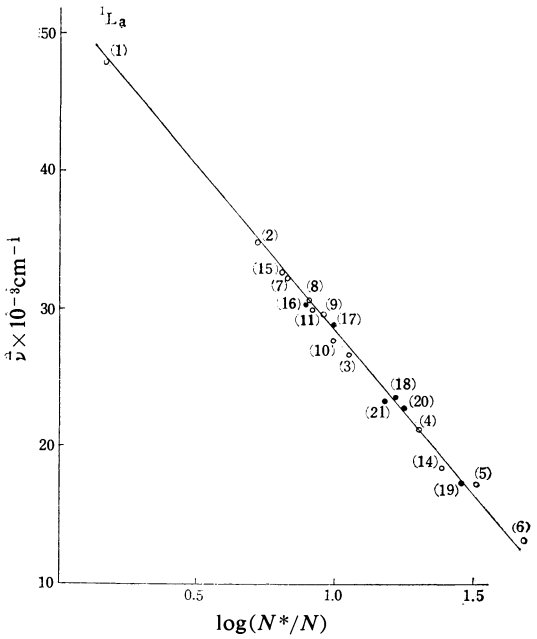

Fig. 7. Correlation of $\bar{\nu}_{^1L_a}$ with $\log(N_{L_a}/N)$, keeping the linear relation with a gradient of about 69 kcal./mol.

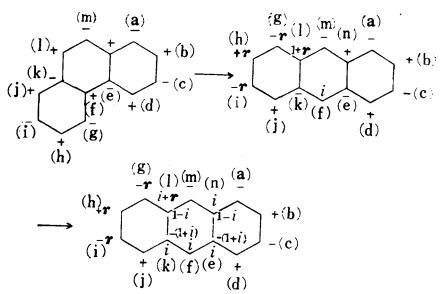

Fig. 8. Estimation of the number of resonance structures of phenanthrene converted by rotation to pseudo-anthracene corresponding to L_a-polarization.

In this way, the numbers of resonance structures corresponding to the ^1L_a-state of phenanthrene, benzoanthracene, benzotetracene, and benzopentacene are estimated in Table III.

As for the chrysene and 1,2-5,6-dibenzoanthracene molecules, which are transformed into pseudo-naphthacene and pseudo-pentacene by separating the charge at the joint of the concaved benzene, the imaginary charge densities on the new joint become $i+r$ and $i-r$

respectively. In the cases of pyrene, perylene, and coronene, the transformations are convert them into pseudo-tetracene, pseudo-pentacene, and pseudo-hexacene. Their numbers of resonance structures are illustrated in Table III. When the $\log(N_{L_a}/N)$ of the above compounds is plotted versus $\bar{\nu}_{L_a}$, they keep the straight-linear relation set forward in Eq. 4 and illustrated in Fig. 7.

The Estimation of the Number of Resonance Structures Corresponding to the ^1L_a-Type Polarization of Acenes and Circular Molecules.— The above procedure for estimating the number of resonance structures corresponding to ^1L_a has been devised for acenes and phenes or for long-shaped hydrocarbons with inner ethylene-linkage. All these molecules have been converted to acenes by imaginary separation and rotation. However, it is very difficult, using the above procedure, to reduce such circular molecules as pyrene, triphenylene, and coronene to pseudo-acenes. They become pseudo-acenes only after complicated trials. Therefore, another approximation method for estimating the number of resonance structures has been devised; it is illustrated in Fig. 9.

The cross-linking carbon atoms of acenes and other molecules are separated into two imaginary atoms with charges of i and $(1-i)$, leaving the inner ethylene-linkage with a charge of $(1-i)$, etc. Then, it is converted into hexagon by rotation. For instance, in the anthracene molecule (A), the imaginary carbon atoms with a charge of i in the cross-linking positions on the perimeter are converted into the structure (B) in Fig. 9 by rotation perpendicular to the molecular plane; after this procedure, the atoms in the meso-position are converted into structure (C) by rotation in the second step. In the first-step rotation, the charges i on the cross-linking position are converted to $i \times \boldsymbol{r}$, which is equal to zero owing to the orthogonality of both vectors defined. In the second-step rotation, the meso-carbon atoms which are rotated in the first-step procedure are afflicated by the second-step rotation. Therefore, the charges of meso-atoms in the converted positions are equal to $\boldsymbol{r}^2$ or 1. Therefore, we select two atoms with alternative + and − signs on the new perimeter to form the polarized resonance structures except for those between neighboring atoms. The number of resonance structures corresponding to the ^1L_a-state is estimated to be the sum of all those mentioned above and of those of two ethylene-linkages.

In the case of phenanthrene as an example of a convex molecule, the charge separations in the concaved positions are different from those in acenes, and the four linked carbon

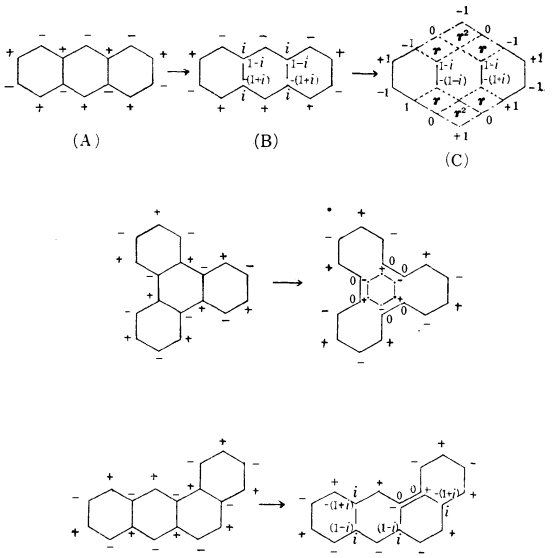

Fig. 9. Estimation of the number of resonance structures of those acenes and phenes corresponding to ^1L_a-polarization by rotation and by imaginary charge separation.

atoms are separated as in butadiene, as is illustrated in Fig. 9. The same example is an instance of a triphenylene molecule. The charge-separation in the concaved positions leaves six carbon atoms linked as a benzene nucleus, with charges alternately signed by $(1-i)$ and $-(1+i)$. The numbers of resonance structures in the case of phenanthrene are the sum of the 26 structures with atoms on the perimeter and of the 8 separated structures with inner butadiene. The number of resonance structures in the case of the triphenylene molecule is the sum of the 51 structures concerning atoms on the perimeter and of the 6 structures concerning atoms on the inner benzene nucleus.

1,2-Benzoanthracene is converted into pseudo-anthanthrene, which is further converted into a hexagon, leaving one imaginary butadiene and one imaginary ethylene inside the molecule. The number of resonance structures concerning the perimeter is equal to $45+18\,\boldsymbol{r}$, while those concerning the inside dienes and ethylene are equal to 20. The pyrene molecule is converted into outer and inner structure. The number of resonance structures concerning atoms on the perimeter is equal to 43 and those concerning the inner conjugation are 5, as has been mentioned above. The total number of resonance structures is equal to 48 in the pyrene molecule. The correlation of $\log(N^*_{L_a}/N)$ versus $\bar{\nu}_{L_a}$ is illustrated in Fig. 7 by the black spot. The values of the absorption

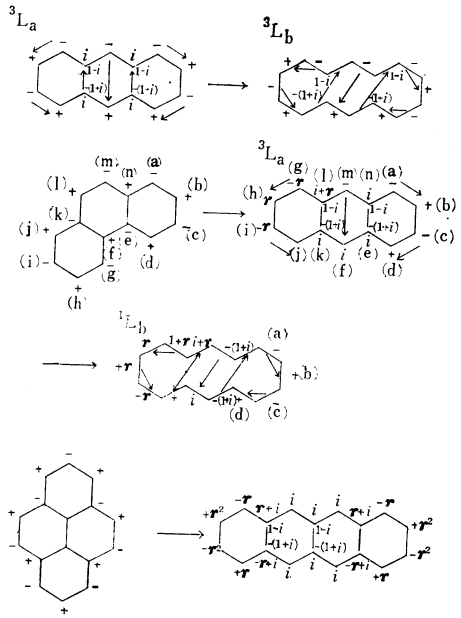

Fig. 10. Estimation of the number of the resonance structures crresponding to ^1L_b- and ^2L_b-polarization from those corresponding to ^3L_a-polarization.

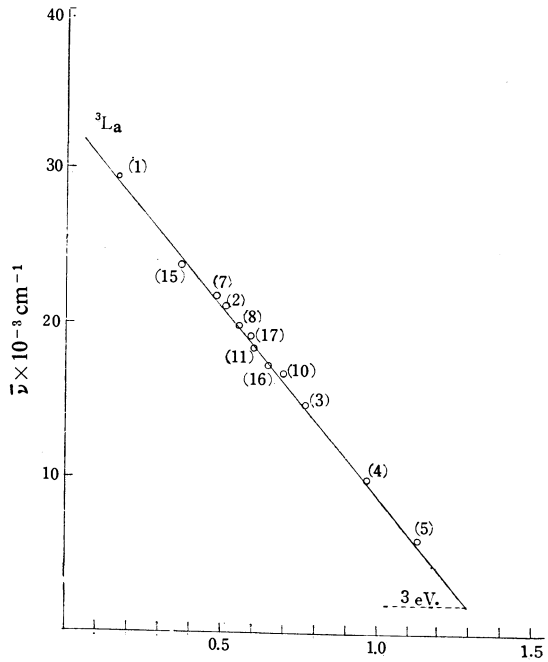

Fig. 11. Correlation of the $\bar{\nu}_{^3La}$ value of the polycyclic aromatic hydrocarbons with their log ($N_{^3La}/N$).

energies $\bar{\nu}_{La}$ are mostly based on the data of Klevens and Platt[1]. Those of coronene, pyrene, peropyrene, etc. are based on the data on p-bands reported by Clar and on those of Matsen[4].

The Estimation of the Number of Resonance Structures Corresponding to the ^3L_a-Polarized State.—The preceding section has discussed how the resonance structures of the naphthalene molecule are classified into groups which possess different sums of elementary dipoles. One of those groups, that whose polarizations are among neighboring atoms and an imaginary ethylene-linkage, possesses too small an electric dipole to be classified as the ^3L_a-state. The ^3L_a-type of polarization is pictured in Fig. 10, where, in the case of anthracene, polarization among meso-positions (9 and 10) is included as the ^3L_a-type.

When the log ($N_{^3La}/N$) of acenes is plotted versus the $\bar{\nu}_{La}$ value assigned in the report of Klevens and Platt, they keep the linear correlation with gradients of 69 kcal./ml. set forth in Eq. 4, which suggests that the above classification of resonance structures corresponding to the ^3L_a-state and the estimation of their number of resonance structures are adequate, as well as the results of oscillator-strength which will be mentioned later.

With a series of phenes, they are transformed into corresponding pseudo-aceness, as in the case of the ^1L_a-state discussed in the preceding section.

Pyrene, coronene, and triphenylene are transformed into pseudo-naphthacene, pseudo-hexacene, and pseudo-naphthacene, as they are in the case of the ^1L_a-state. Their number of resonance structures are given on Table III. The correlation with their log (N_{La}/N) and E_{ST} values given by McClure illustrates the linear relation illustrated in Fig. 11, which is consistent with the same relation in the case of acenes.

The Estimation of the Number of Resonance Structure Corresponding to the ^1L_b-Type Polarization.—The features of chemical resonance structures corresponding to the ^1L_b-level have been mentioned in the preceding section. In these ^1L_b-type resonance structures, + and − polarizations in the separate benzene nuclei do not hold the residual part of molecule in the Kekulé form. Therefore, it seems that there is little difference between ^1L_b- and ^3L_b-type polarizations. The resonance structures corresponding to the L_b-type polarizations of naphthalene and anthracene molecules are illustrated in Figs. 5 and 13. Generally, resonance structures corresponding to ^1L_b-type polarization can be obtained by a half bond-length removal of the charge from atoms to

4) F. A. Matsen, *J. Chem. Phys.*, 24, 602 (1956).

bonds along the perimeter, irrespective of inner ethylene-linkage, from ^3B_a structures.

The number of resonance structures of ^1L_b-type and ^3L_b-type polarizations are approximately equal in acenes, as is illustrated in Table II.

The ^1L_b-type polarization of phenes and other circular-type molecules considered to be in the form of converted pseudo-acenes should be enumerated in such a way as is equal to the number of resonance structures of this polarization in the original molecule multiplied by the charges on polarized atoms in the converted form.

The estimated numbers of resonance structures corresponding to phenanthrene, chrysene, pyrene, etc. are given in Table II. The relation of their $\log(N^1_{Lb}/N)$ and $\log(N^3_{Lb}/N)$ to the

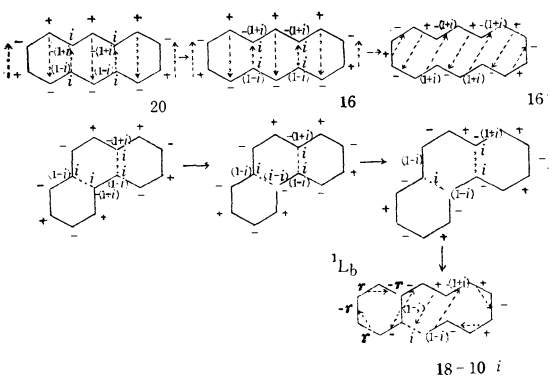

Fig. 12. Relations and estimation of the number of the resonance structures corresponding to ^1L_b, ^1B_b, and other types of resonance structures.

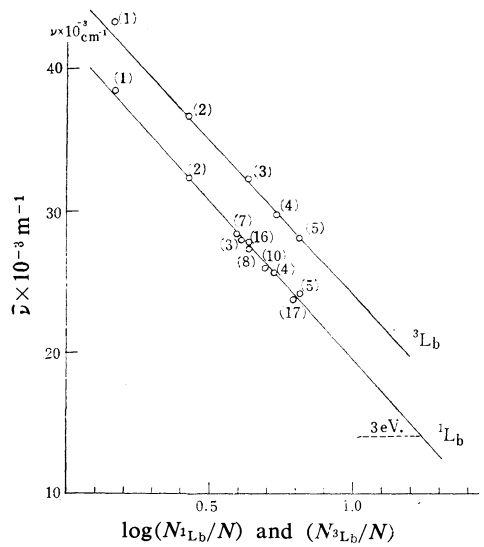

Fig. 13. Correlation of $\bar{\nu}^1_{Lb}$ and $\bar{\nu}^3_{Lb}$ values with their $\log(N^1_{Lb}/N)$ and $\log(N^3_{Lb}/N)$ values respectively.

absorption energies of these levels, $\bar{\nu}_{Lb}$ and $\bar{\nu}_{Lb}$, is illustrated in Fig. 13. They are satisfied by the linear correlations described in Eq. 4. These $\bar{\nu}$ values are mostly based on data of Klevens and Platt[1]. Those of pyrene and coronene are based on the data concerning the energies of α-bands obtained by Clar[5]. The ^1L_b-absorptions of these compounds correspond to those assigned as α-bands by Clar[5], while the p-bands assigned by him correspond to the ^1L_a-absorption.

These results suggest that the assumptions concerning resonance structures of the ^1L_b and ^3L_b states are reasonable.

Results and Discussion

The foregoing results support our assumptions concerning the chemical features of individual excited states, which are represented in terms of hybrid resonance structures corresponding to the characteristic polarization of standing waves of individual excited states, as well as the validity of Carter's empirical equation for the estimation of the empirical resonance energies. There is no mixing or confusion of properties in representing L-excited states in terms of chemical resonance structures.

They are considered to be fairly visualized as corresponding to the motion of mobile π-electrons as currents in interpreting Platt's theory.

The complicated absorption peaks of higher condensed aromatic hydrocarbons can be explained and assigned to their respective levels by this approximation method. In general, the α-bands and p-bands assigned by Clar are considered to correspond to ^1L_b-bands and ^1L_a-bands in this case.

Imaginary charges are introduced in order to eliminate the effect of cross-linking and also in order to visualize easily the hybrid resonance structures corresponding to Platt's theory. We have replaced the sign of the standing wave in his theory to that of the real charge in the above discussion. The differences between the L and B types of polarization may be considered to be reduced to the difference in the method of the conjugation of the switch of four imaginary cross-linking carbon atoms with the charge-densities $(1-i)$, i, $(1-i)$ and i. It is assumed that the angular momenta and other characteristic states, shells and configurations are invariant in this operation. In the above procedure, the perimeter length, which may be interpreted as defining the depth and shape of the constant potential box is given in imaginary units,

5) E. Clar, "Aromatische Kohlenwasserstoffe", Zweites Band, Springer Verlag, Berlin (1952).

which may be expected to include the length to the free end-point of the standing wave.

The difference between a and b types of polarization may be interpreted as having been reduced in this model to the difference in the method of the conjugation of individual benzene nuclei considered as independent closed circuits, in either the parallel (twisted loop) or anti-parallel (perimeter loop) direction, which may be considered as producing the difference in synthesized electric dipole-vector or oscillator strength relating to absorption-intensities in their estimation from corresponding resonance structures.

The estimated number of resonance structures corresponding to L_a, L_b, B_a and B_b states are considered as a result of the above discussions to be fairly consistent with Carter's empirical equation in representing the excitation-energies corresponding to the respective polarization as the difference in empirical resonance energies as well as the absorption intensities estimated from the unit-dipoles in the resonance structures which are described above.

Summary

The chemical resonance structures of the excited states are assumed to correspond to the type of polarization in each state. This theory can explain the absorption energies as the difference in the empirical resonance energies between the ground and excited states by an application of Carter's empirical equations. Imaginary charges are introduced to estimate the number of resonance structures, thus eliminating the influence of cross-linking atoms; the meaning of the resonance hybride corresponding to each levels is easily interpreted in correlation with Platt's theory. As a result, the individual excited state can be represented as a chemical resonance hybride consisting of a group of simple polarized structures; this theory may be said to be adequate from the view-point of absorption energies and of absorption intensities in relation to the direction of electric dipoles.

The author wishes to express his hearty thanks to Professor Hideo Akamatu for his kind guidance and encouragement throughout this study and to Dr. Yoshio Matsunaga and Dr. Hidetsuru Matsushita for their kind abvice and discussions. The Electrical Properties of Microcrystalline Selenium. I. Chlorine-doped Selenium

By Tsuneo ARAKI

(Received on May 10, 1962)

Several studies have been made of the electrical properties of micro-crystalline hexagonal selenium[1,2]. Most of them have dealt with pure selenium, iodine-doped selenium or bromine-doped selenium. The present series of studies has been undertaken to inquire into the effect of chlorine and metallic impurities on the electrical properties of selenium.

The conductivity of microcrystalline selenium changes greatly as a result of heat-treatment, because nucleation and the crystal growth occur in it[1,3]. In the present study, the electrical conductivity of chlorine-doped selenium is measured as a function of its crystallinity. The thermoelectric power and the capacity variation with various bias voltages were also measured for this substance, and the carrier concentration was calculated according to Schottky's theory.

Experimental

The selenium used in this investigation was purified from five-nine purity selenium obtained

1) H. W. Henkels, *J. Appl. Phys.*, **22**, 1265 (1951).
2) K. W. Plessner, *Proc. Phys. Soc. London*, **B64**, 681 (1951).
3) H. Rebstock and K. O. Seilier, *Z. Naturforsch.*, **9a**, 49 (1954).

from the Mitsubishi Mining Co. The purification was carried out by the following steps: (1) oxidation with nitric acid, (2) treatment with ion exchange resin, (3) reduction with sulfur dioxide, and (4) distillation in vacuum.

This purified selenium was mixed with various quantities of selenium monochloride at 250°C and then quenched by pouring it onto a cooled marble plate to prepare amorphous selenium. The quantity of chlorine was measured by chemical analysis for each specimen, because some doped chlorine escaped during the heat-treatment.

Specimens used for the measurement of resistivity and thermoelectric power were prepared by the hot press method. Namely, chlorine-doped amorphous selenium was ground into powder of 80~120 μ and was pressed for 5 minutes under a pressure of 250 kg./cm^2. The pressing was done between two thin mica sheets placed on electrically-heated plattens which were thermoelectrically controlled at a temperature of 130°C. The shape of the specimen was a disk. 0.5 mm. thick and 10 mm. in diameter.

The specimen for the capacity measurement was pressed on an iron base plate which had been chemically etched and nickel-plated for the purpose of making ohmic contact. The procedure of the treatment was the same as in the hot press method described above. The thickness of the selenium of this specimen was about 0.1 mm. The specimen was crystallized by heat-treatment at 217°C, and then molten Cd-Sn eutectic alloy (m. p. 177°C) was sprayed onto the selenium surface, which was then used as a counter electrode. The simple barrier layer between the selenium and the counter-electrode alloy was formed by this procedure.

The measurement of electrical resistivity was carried out by the four-point probe method, and the Valdes correction was applied for the thin-sheet selenium[4]. A floating potential difference between inner probes was measured by a vibrating-reed voltmeter (internal resistance was about 10^{15} ohm), while the current through the outer pair of probes was about 5~10 μA.

The measurement of the resistivity of the specimen prepared for the capacity measurement was obtained from the voltage drop due to the current through the selenium layer. Results were in fairly good accord with those obtained from the four-point probe method.

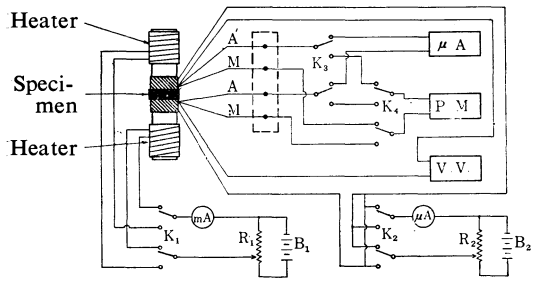

Fig. 1. Experimental arrangements for resistivity and thermoelectric power measurements.

4) L. B. Valdes, *Proc. I. R. E.*, **42**, 420 (1954).

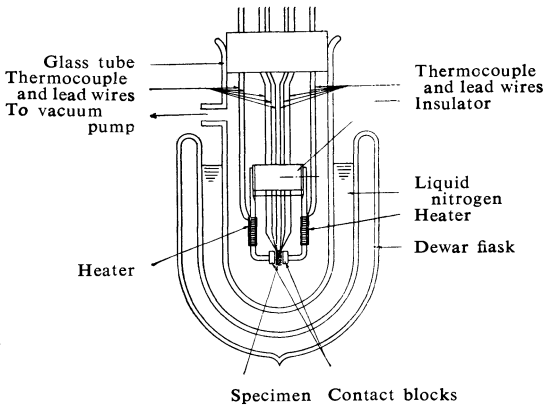

Fig. 2. Experimental arrangements for resistivity and thermoelectric power measurements.

The device used for the measurement of thermoelectric power and resistivity is shown in Figs. 1 and 2. The two points used for the measurement of thermoelectric power were arbitrarily chosen on both sides of the disk. The temperature difference between the two points was measured by an advance and manganin thermocouple. For the thermocouple, a wire homogenous in composition and small in diameter (0.12 mm.) was used, because these conditions reduced the errors due to the thermal conduction. Blocks in contact with the specimen were heated by 0.2-watt coils of of nichrome wire. The surfaces of the blocks were nickel-plated so that their good thermal and electrical contact with the specimen was protected. The temperature difference in a specimen was always maintained within 0.5~1.0°C, and the temperature was measured by a high sensitive potentiometer with an electronic galvanometer (7×10^{-11} A).

The thermoelectric voltage was determined from the measurement of the potential difference between the two advance wires, a high-sensitivity vibrating reed voltmeter being used. All the measurement heads were placed in a vacuum (about 10^{-3} mmHg) in order to reduce the thermal convection and the condensation of water in the measurement at a low temperature. The error in the thermo-electric power measurement was approximately 5 per cent, it was very difficult to maintain the reference junction within 0.02°C even if it was placed in a stirred ice-water bath. Since the resistivity of the specimen became very large at a low temperature, the charge which remained on the surface of the specimen afer the resistivity measurement produced an error in the thermoelectric power measurement. Therefore, these two measurements had to be carried out in different temperature cycles.

The capacity variation due to the bias voltage was measured by the substitution bridge method[5], in which a small AC signal (3 kc./sec., −30 db) was superimposed on the bias voltage.

5) H. Henisch, "Metal Rectifier", Clarendon Press, Oxford (1949), p. 48.

In order to investigate the effect of crystallization time, photomicrographs of the selenium surface were taken. The disk specimen prepared for the resistivity measurement was also used for this investigation.

Results

The results of the resistivity measurement for the specimens containing chlorine in various concentrations are shown in Fig. 3. In this figure, curves a, b, c and d show the resistivity of specimens which were kept for crystallization at 217°C for 0, 20, 60 and 500 min. respectively. The figure shows that there is a resistivity minimum in the curve for each heat treatment. The concentration of chlorine corresponding to the minimum changes with the duration of the heat treatment. The longer the heat treatment the lower the concentration. The observed values for the chlorine-free specimens were smaller than those reported by previous investigators[1,6]. This difference may have been caused by the effect of the atmosphere during the preparation. The specimens in the present experiment were treated in air because they had to be compared with those containing chlorine. Previous investigators had treated them in a vacuum. The present experiment shows that the atmospheric oxygen has some effect on the resistivity of chlorine-free specimens.

shows a specimen after a 500-min. heat-treatment with the same concentration of chlorine as b. These photographs show that the higher the chlorine concentration, the smaller the grain size, and that the longer the heat treatment, the larger the grain size.

The thermoelectric power for semiconductors of the one-type, non-degenerate carrier is expressed by[7]:

$$Q=Q'+\frac{k}{e}\left[\frac{3}{2}\log T-\log n+\log\left\{\frac{2(2\pi mk)^{3/2}}{h^3}\right\}\right] \quad (1)$$

where k is the Boltzmann constant, n is the carrier concentration, m is the mass of the carrier, and h is the Planck constant. Q' is a number decided by the scattering of the carrier; usually 2 is given for this value for the selenium crystal with simple lattice scattering[8,9]. In the case of selenium containing much impurities, as in this experiment, a larger value of Q' should be used. However, in this report the value 2 was taken for the sake of simplicity. It is well-known that the carrier concentration, calculated from Eq. 1, is in fairly good accord with the results obtained from the Hall effect[9,10].

The carrier concentrations for the specimens were calculated from Eq. 1 and are plotted in Fig. 5. They are scarcely influenced by the chlorine concentration, and their values are in the range of $10^{16}\sim10^{17}/cm^3$.

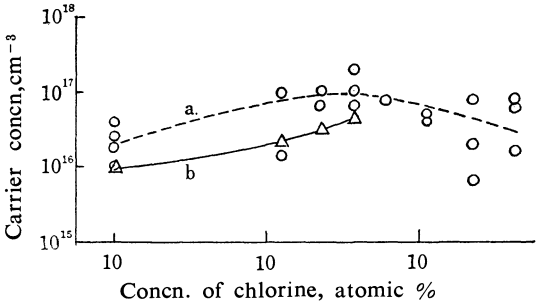

Fig. 5. Carrier concentration against chlorine content.

According to Schottky[11], the carrier concentration near a barrier layer is obtained by the equation:

$$n=2/KeF^2\,dU/d(1/C^2) \quad (2)$$

where $-e$ is the electron charge, F is the surface area, U is the bias voltage, C is the capacity of the barrier layer, and K is the dielectric constant. The dielectric constant for microcrystalline hexagonal selenium at 3 kc. has not yet been reported. In the present calculations, the value of 11 was used for this constant, which is obtained by extrapolation from the data of Hippel[12]. Most of the previous reports[5,13,14] used 6 for this value, but this figure is regarded as that for amorphous selenium.

According to Schottky's[11] theory, the relation between dU and $d(1/C^2)$ is linear for the simple contact between metal and semiconductor. However, it is actually not always linear in the measurement of selenium rectifiers, especially in the neighborhood of zero-bias voltage. Moreover, the relation changes with a lapse of time. The diffusion of the counter-electrode element to the selenium layer or the chemical reaction of these elements has been suggested as the cause of this change[15]. For this reason, the capacity measurement was carried out immediately after the counter electrode was applied.

The carrier concentrations obtained by the capacity measurement are plotted by curve b of Fig. 5. The values are somewhat smaller than those obtained from the thermoelectric power. The variation of specific resistivity with temperature is shown in Fig. 6. Curves, a, b and c, stand for the chlorine-free specimens crystallized by 20-, 60- and 500-min. heat treatments respectively. Each specimen increases

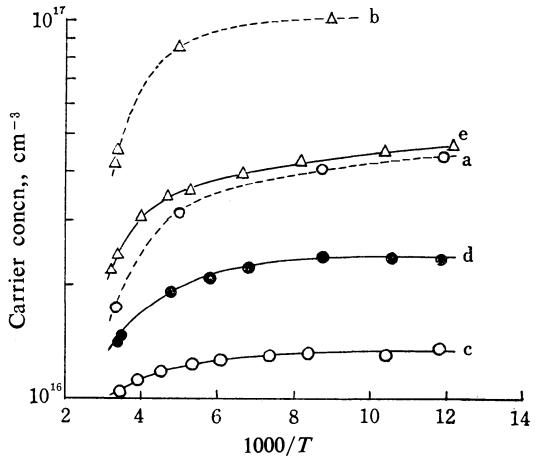

Fig. 7. Carrier concentration against temperature.

its resistivity at a low temperature. The resistivity does not change linearly with $1/T$. The gradient becomes slow at low temperatures. The gradient for the chlorine-free specimen becomes steep with the longer heat treatment, but that for the specimen containing chlorine was not so steep.

The carrier concentrations in the specimens after a 20-min. heat-treatment are shown in Fig. 7. Curves a and b show the results obtained from the thermoelectric power measurement of the chlorine-free and the chlorine-doped specimens respectively.

The temperature variation in carrier concentration obtained from capacity measurements is shown in curves c, d and e of Fig. 7. The results obtained from these two methods show nearly the same tendency. The gradient is steep at room temperature and becomes slow at a low temperature.

Discussion

The resistivity of selenium was at its minimum at a concentration of chlorine. The minimum value varied with the condition of the heat treatment, as is shown in Fig. 3. This fact has been noticed by Schweickert[16], and the results of the present experiment are in good accord with his report.

According to the microscopic observation, the grain size of selenium was affected by the chlorine concentration and by the heat treatment condition, as is shown in Fig. 4. It is well-known that the crystallization usually depends on two factors; (a) the nucleation rate, and (b) the grain-growth rate. The fact that the grain size of the specimen containing chlorine is small shows that the contamination with chlorine promotes the creation of crystalline nuclei. On the other hand, the heat treatment increases the grain-growth rate. The crystallization of selenium from the amorphous to the hexagonal state decreased the resistivity at the beginning of the heat-treatment. However, the resistivity increased gradually again as a result of the long heat treatment. Schweickert has suggested that the chlorine was very loosly bound to the selenium and so was apt to escape from the surface of the specimen during the heat treatment. It was also seen that pure selenium increased its resistivity gradually as a result of the long heat treatment. Henkels[1] suggested that the increase in resistivity is due to the purification process by crystal growth, while Rebstock and Seiler[3] suggested that it is due to the decrease in inter-crystalline volume during the heat treatment.

The addition of chlorine did not increase the carrier concentration in selenium, which remained at an almost constant value in the range of $10^{16}\sim10^{17}/cm^3$. This tendency is similar to that reported in an experiment on selenium containing iodine or bromine performed by Henkels[1] and Plessner[2].

According to the measurements by Henkels[8] and Plessner[9], the selenium single crystal prepared from the liquid or vapor phase had a carrier concentration in the range of $10^{13}\sim10^{14}/cm^3$. Plessner considered that the acceptor centers in selenium did not consist of "impurities" in the form of foreign atoms, but only of imperfections in the selenium crystal lattice. He also considered that most of the chlorine atoms doped in selenium were concentrated in the grain boundary and had an effect on the mobility. However, the mobility calculated from the resistivity and the carrier concentrations is less significant.

According to Nijland[17], the carrier concentration obtained from the Hall coefficient corresponds to the value of a well-conducting phase; on the other hand, that obtained from thermoelectric power corresponds to the value of a low-conducting phase which surrounds the well-conducting phase. Meanwhile, the carrier concentration obtained from the capacity variation due to bias voltage is that near the barrier layer or that in the space-charge transition region itself. Henkels[11] reported that the carrier concentration of selenium obtained from the capacity measurement was not in accord with that obtained from the thermoelectric power or from the Hall coefficient, but details were not reported in his paper.

16) H. Schweickert, *Z. Phys.*, **128**, 47 (1950).

17) L. N. Nijland, *Philips Res. Rep.*, **9**, 259 (1954).

According to Moriguchi[18], the carrier concentration, which was obtained from the capacity measurement for the commercial selenium rectifier, decreased at low temperatures. Therefore, he considered that the mechanism of the barrier layer in the rectifier was very complicated and was not suited for the calculation of its carrier concentration. However, the carrier concentration obtained from the capacity measurement in the present experiment increased at low temperatures, This result was in fairly good accord with that obtained from the thermoelectric power. The present agreement seems to come from the methods of preparing the specimens. Both specimens were prepared from the same selenium material, and the measurement of capacity was carried out immediately after the application of the counter electrode for the purpose of avoiding the formation of other complicated barrier layers.

The resistivity of all the specimens for the present experiment increased at low temperatures. However, it was doubtful whether this resistance was caused by the real bulk resistivity of selenium. The resistance showed departures from Ohm's law at the low fields, and it was supposed that there were some barrier layers. Rebstock and Seiler[3] reported that the resistivity of microcrystalline selenium measured at a high frequency was not so much increased at a low temperature; they considered that the increase of DC resistivity at the low temperature was caused by the grain boundary of microcrystalline selenium. For these reasons, the apparent decrease in mobility calculated from the resistivity and the carrier concentration, especially at a low temperature, might not occur in the bulk phase but might be caused by the intercrystalline structure.

18) Y. Moriguchi, *Kurume Univ. Journal (Nat. Sci.)*, **6**, 9 (1955).

Summary

1. The resistivity of microcrystalline selenium doped with chlorine was changed by heat treatment. The results were in fairly good accord with the measurements obtained by Schweickert. Selenium doped with chlorine had the same characteristics as that doped with iodine or bromine.

2. The results of microscopic observation showed that the grain size became smaller with the higher chlorine concentration. This tendency was similar to that found in iodine- or bromine-doped selenium.

3. The resistivity variation with temperatures below room temperature was affected by the heat treatment of the specimen. The effect was greater for the specimen free from chlorine.

4. Carrier concentrations were obtained from the measurement of capacity and also from the thermoelectric power. These two methods gave results which were in agreement with each other. The concentrations were shown to be increased at low temperatures.

The author wishes to express his thanks to Dr. Takehiko Shimanouchi of The University of Tokyo and to Dr. Juichi Osawa, Dr. Yukimatsu Takeda, Dr. Sueo Hattori, Mr. Yoshinori Mihara and Dr. Yoshiro Moriguchi of his company for their kind advice throughout this work. The Behavior of Fission Products Captured in Graphite Powder by Nuclear Recoil. VI. The Chemical State of Iodine-131 Diffused out from Graphite, Uranium Dioxide and Thorium Dioxide

By Seishi YAJIMA, Koreyuki SHIBA and Muneo HANDA

(Received June 22, 1962)

A large portion of the enormous energy of nuclear fission is converted into the kinetic energy of nuclear fission fragments. This energy forces the fission fragments to move in the material, in which the kinetic energy is finally absorbed in the form of heat. The range of the fission products is about 5 μ in uranium dioxide and about 12 μ in graphite. Within this short distance, about 0.8 MeV. of the fission fragment energy is imparted to the material, violently disturbing the arrangement of atoms in the material; the fringes of a fragment track are instantly heated to an extremely high temperature. Such a track is called a thermal spike. The chemical behavior of the fission products in the thermal spike belongs to the field of hot atom chemistry. The authors have studied the diffusion of krypton, xenon, tellurium, and iodine trapped in graphite by fission recoil, thus clarifying the following facts. The diffusion rates of the above elements in natural graphite were much larger than in artificial graphite[1]. The diffusion of xenon in graphite was found as not governed by a simple diffusion mechanism, but to depend on the state of imperfection in the graphite crystal[2]. The distribution of the activation energy of xenon diffusion in natural graphite was determined by making a heating curve of xenon-133 or -135 in natural graphite. The distribution of the activation energy shifted to a higher temperature with an increase in the fission product concentration in the graphite[3].

These studies were carried out in connection with the development of a semi-homogeneous fuel in which uranium dioxide or uranium carbide is dispersed in graphite. In the present investigation, the chemical states of the fission fragment iodine-131 diffusing out of uranium dioxide and thorium dioxide and diffusing after being caught by fission recoil in graphite, were studied by means of thermochromatography. The primary fission yield of iodine-131 from uranium-235 (n, f reaction) and thorium-232 (γ, f reaction) is so small that it has little chance to react with the material surrounding the recoiled iodine-131 track in the hot atom state, but it is still of interest to study the diffusion behavior of the iodine-131 generated by its precursor, on account of the high chemical affinity of the iodine-131 and the thermal spike. The results obtained show that the chemical state of the iodine-131 diffusing out of uranium dioxide and graphite was not that of an elementary iodine (I^0) but of iodide (I^-), and that, irrespective of the diffusing matrix concerned, the iodide species were fairly stable at high temperature and deposited on the graphite powder heated to 500~600°C in an argon atmosphere. These facts should be useful in developing an internal trap for the semi-homogeneous fuel element whose features are high burn-up and high temperature.

Experimental Method and Results

Preparation of Samples.—*Sample No. 1 (Uranium Dioxide Powder Containing Fission Products).*— Uranium dioxide powder of a particle size of less than 1 μ was reduced with hydrogen for 5 hr. at 1000°C to obtain a stoichiometric uranium dioxide. About 100 mg. of this uranium dioxide was sealed in a polyethylene bag placed in a glove box filled with nitrogen gas. Then it was neutron-irradiated in the reactor JRR-1 (water-boiler type, thermal neutron flux: about 5×10^{11}n/cm^2·sec.) for 15 hr.

3) S. Yajima, S. Ichiba, K. Iwamoto and K. Shiba, ibid., 35, 1263 (1962).

After irradiation, the sample was cooled for 5 days to cause the other short-lived isotopes of iodine, as well as the precursor of iodine-131, to decay out. The impurities contained in the uranium dioxide are shown in Table I.

Sample No. 2 (Mixture of Natural Graphite Powder and Uranium Dioxide Containing Fission Products).—Natural graphite powder previously degassed (in vacuum, 1000°C, 24 hr.) was mixed with the stoichiometric uranium dioxide powder in a weight ratio of 2 : 1 in a glove box filled with nitrogen gas. Three handred milligrams of the mixture was sealed in a polyethylene bag, neutron-irradiated and cooled in a way similar to that for sample No. 1. The impurities contained in the graphite are shown in Table II.

TABLE II. ANALYTICAL DATA OF IMPURITIES IN GRAPHITE

Impurities	
Ash	0.8%

B_2O_3	0.5 p.p.m.

Sample No. 3 (Natural Graphite Powder Containing Fission Products). — Formbar was dissolved in dioxane, and stoichiometric uranium dioxide powder was suspended in this solution. The suspended solution was then spilled out on a glass plate, and the dioxane was evaporated. The formbar film was removed from the glass plate and cut into chips (500 mg. of chips containing 300 mg. of uranium dioxide). Five hundred milligrams of the formbar chips was mixed with 500 mg. of natural graphite powder, and the mixture was sealed in a polyethylene bag placed in a glove box. The sample was neutron-irradiated and cooled in a way similar to that for samples Nos. 1 and 2. After cooling, the formbar chips were removed from the sample by screening them through a brass sieve. The graphite powder was found to contain sufficient fission products for the experiment.

Sample No. 4 (Natural Graphite Powder Containing Fission Products).—Three hundred milligrams of the same mixture as sample No. 2 was irradiated in JRR-1 and cooled. The mixture was then treated with a nitric acid solution to eliminate uranium dioxide, washed with water, and dried. Most of the fission products were found to be captured in this treated graphite.

Sample No. 5 (Thorium Dioxide Containing Fission Products).—Thorium dioxide powder wrapped in aluminum foil was gamma-irradiated in a linear accelerator for 5 hr. (maximum gamma-energy, 20 MeV.). Fission products were generated in the thorium dioxide by the (γ, f) nuclear reaction, and then the sample was cooled for 5 days. The impurities contained in the thorium dioxide are shown in Table I.

Sample No. 6 (Mixture of Natural Graphite Powder and Thorium Dioxide Containing Fission Products).—Degassed natural graphite powder was mixed with thorium dioxide powder to a weight ratio of 1 : 2. Three hundred milligrams of the mixture was wrapped in aluminum foil, gamma-irradiated, and cooled in a way similar to that for sample No. 5. Most of the fission products were found to have recoiled out of the thorium dioxide powder and to have been captured in the graphite powder.

Sample No. 7 (Elementary Iodine (I_2) Labeled with Iodine-131).—Five hundred milligrams of uranium dioxide powder was irradiated in JRR-1 for 15 hr. and cooled for 5 days. The irradiated uranium dioxide was dissolved in 10 ml. of a 7 M nitric acid solution, to which was added successively 1 ml. of a 0.05 M potassium iodide solution as a carrier and 1 ml. of a 0.1 M sodium nitrite solution as an oxidizing reagent. Iodine-131 was extracted, together with the carrier, with carbon tetrachloride and back-extracted with a mixed solution of sodium hydrogen sulfite and sodium hydroxide. When this procedure was repeated three times, iodine-131 was completely separated from the other fission products, uranium and neptunium.

The Apparatus.—The apparatus used is shown schematically in Fig. 1. The quartz tube seen in the figure (0.6 cm. in inner diameter, 100 cm. long) was packed, in some experiments, with natural graphite powder, and in others with α-alumina powder or copper powder. The sample was placed on the powder. The graphite and α-alumina were degassed (in vacuum, 1000°C, 24 hr.) before use. The atmosphere in the tube was replaced by purified argon after packing. Then the tube was heated with external resistance wires so as to produce a

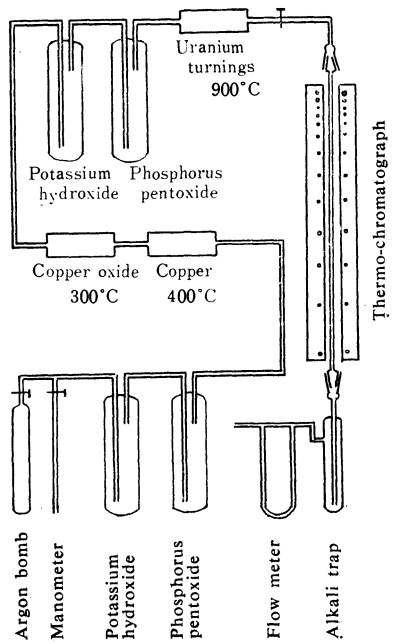

Fig. 1. Apparatus.

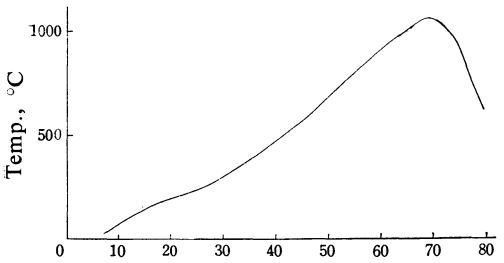

Fig. 2. Condition of the electric furnace when an equilibrium was attained.

linear temperature gradient of about 14°C/cm. ranging from 1000°C to room temperature. This condition, which is shown in Fig. 2, was maintained for 2 hr. after attaining an equilibrium. Then the sample was cooled in a stream of purified argon. After cooling, the specimen tube was surveyed along its whole length in order to locate the iodine-131 activity. An RCL 256 channel gamma-ray scintillation spectrometer connected with a sodium iodide crystal with a lead slit 1 cm. wide was used.

Purification of Argon Gas.—Commercial grade argon was dried over phosphorus pentoxide, and all the carbon dioxide was removed with potassium hydroxide. All the oxygen was removed through a copper net at 300°C. Traces of hydrogen and carbon monoxide were oxidized with copper oxide at 400°C to carbon dioxide and water. After then passing through potassium hydroxide and phosphorus pentoxide tubes, all the gases except argon were removed by passage over uranium turnings at 900°C.

Packing Materials for Quartz Tubes. — *Natural Graphite Powder.*—The natural graphite powder shown in Table II was degassed by heating it in a vacuum at 1000°C for 24 hr. The treated graphite was kept in a helium gas atmosphere until used for the experiment.

α-Alumina Powder. — γ-Alumina commercially available for gas chromatography was heated and kept at 1100°C for 5 hr. By this treatment, the γ-modification was converted into the α-modification, the alumina being degassed.

Copper Powder.—Commercial, triangularly-shaped copper powder was used.

Determination of the Chemical State of Iodine-131.—Iodide (I^-), iodine (I^0), iodate (IO_3^-) and periodate (IO_4^-) states were taken into consideration for the iodine-131 diffusing out of the samples and depositing on the graphite powder. The portion of graphite powder in the quartz tube containing the deposited iodine-131 was removed by cutting the tube, and the graphite powder thus obtained was treated with carbon tetrachloride to determine whether or not iodine-131 (I^0) existed in the graphite powder. The carbon tetrachloride solution was filtered to separate the graphite powder, and the filtrate was assayed with a gamma-ray spectrometer. The separated graphite powder was transferred into an aqueous solution containing 3 mg. of potassium iodide and 8 mg. of potassium iodate and left for 1 hr. to bring about a complete homogeneous mixing of the iodine-131 and its carriers. After 1 hr., the graphite powder was separated by filtration and its radioactivity was measured with a gamma-ray spectrometer. To acidify the filtered solution, small amounts of nitric acid were added. By this treatment the iodide ion (I^-) in the solution was completely

converted into iodine (I^0) The reaction occurring in the solution is as follows:

$$5I^- + IO_3^- + 6H^+ = 6I^0 + 3H_2O$$

The produced iodine (I^0) was extracted and measured with a gamma-ray spectrometer*. The iodate ions (IO_3^-) remaining in the solution was converted into iodine (I^0) by the addition of excess iodide ions (I^-), and the remaining, superfluous iodide ion (I^-) was oxidized into iodine (I^0) by sodium nitrite. The iodine (I^0) thus produced was extracted by carbon tetrachloride, and the radioactivity was measured with a gamma-ray spectrometer**.

As is shown in Figs. 3 to 10, iodine-131 from uranium deposited in only one position, whereas iodine-131 from thorium deposited in two positions on the graphite powder. Experiments were carried out for each portion of the graphite containing the deposited iodine-131. The results obtained are shown in Table III.

The activities of the iodine-131 from uranium and from thorium, which deposited on the lower temperature portion of the graphite powder, were all found to be in iodide fractions. Consequently, the chemical state of the iodine-131 which diffused out of the sample and deposited on the graphite powder should be iodide (I^-). The iodine-131 deposited on the higher temperature portion was in various chemical states. This may be due to the oxygen sensitivity of iodine-131, i. e., the iodide under these conditions may have been decomposed when it was moved into the air from the tube filled with argon. The presence of a considerably large amount of iodine-131 in the graphite may have been caused by the absorption of iodine-131 in the graphite powder or by the intercalation of iodine-131 with graphite.

Thermo-chromatograms.—The results obtained with graphite powder as the packing material are shown in Figs. 3 to 11. A carrier gas of purified argon was made to flow at a rate of 0.5 ml./min., and the sample was heated for 2 hr. at 1000°C. The fission iodine-131 diffusing out was carried by the argon stream and deposited on graphite powder in the tube. The thermo-chromatograms obtained under these conditions with samples of uranium dioxide (sample No. 1), a mixture of uranium dioxide and graphite (sample No. 2), and graphite (sample Nos. 3 and 4) are shown in Figs. 3, 4, 5 and 6 respectively. In each case, the iodide deposisted at the same position of the graphite; the temperature of the position was 580°C. Figures 7 and 8 show the results obtained when the experiments lasted 0.5 and 6.0 hr. respectively; the iodine deposited at 670°C and at 520°C respectively. All the

* It has been shown by W. H. Burgus and T. H. Davies[4] that the exchange reaction between iodide ions (I^-) and iodine (I^0) in an aqueous solution is rapid, but that the reaction between other chemical states is hardly appreciable. The exchange reaction occurs according to the chemical equation:

$$2I^0 + H_2O = HIO + H^+ + I^-$$

In a carbon tetrachloride solution, however, such a reaction cannot occur. In an acid solution, five chemical equivalents of iodide ions (I^-) react with one equivalent of iodate ions (IO_3^-). In the present experiment, the chemical equivalent ratio of iodide ions (I^-) to iodate ions (IO_3^-) was about 13:18, so that if the iodine-131 existed in the iodate state when it diffused out of the sample, about one-seventh of the iodine-131 would be converted into iodine (I^0).

** The iodine (I^0) extracted by the reduction assay of the iodate ions (IO_3^-) contained six-seventh of the indine-131 which had diffused out of the sample as the iodate (IO_3^-). The activity of the iodate fraction was small, so that the fraction of the reduced iodate ions (IO_3^-) did not contribute much to the activty of the iodide fraction. Similarly, no further separation of periodate ions (IO_4^-) from the iodate ions (IO_3^-) was made, because the periodate ions (IO_4^-) behaves in a way very similar to that for the iodate ions (IO_3^-) in the above reactions and, as is shown in Table III, the activity of the iodate fraction was small.

4) W. H. Burgus and T. H. Davies, "National Nuclear Energy Series: Radiochemical Studies: The Fission Products", Book I, Mcgraw-Hill Book Co., Inc., New York (1951), pp. 209—219.

experimental conditions except the time were the same as in the case of Fig. 6. As compared with the results given in Fig. 6, the location of the fission iodine-131 deposited moved toward a lower temperature as the duration of the experiment increased. The experiment which was repeated three times showed that the reproducibility of the deposition temperature was within ±20°C in each case.

The thermo-chromatograms obtained from the thorium dioxide (sample No. 5) and from the mixture of thorium dioxide and graphite (sample No. 6) are shown in Figs. 9 and 10 respectively. It was found that two peaks appeared in both thermo-chromatograms; the corresponding temperatures were 520°C and 430°C in both cases. Figure 11 gives the thermo-chromatogram of the elementary iodine (sample No. 7) obtained under the same conditions as in Figs. 3, 4, etc. The location of radioactivity when using copper powder as the packing material is shown in Figs. 12 and 13. The fission iodine-131 (sample No. 2) was located at 700°C, and the elementary iodine (sample No. 7), at 920°C. When α-alumina was used as the packing material under the same experimental conditions as above, the fission iodine-131 (sample No. 2) deposited at a temperature higher than 950°C, while elementary iodine (sample No. 7) deposited at 80°C.

Conclusion

The data obtained may be summarized as follows:

1) The thermo-chromatograms of the fission iodine-131 were extremely different from that of elementary iodine, whichever packing material was used, i. e., graphite, α-alumina or copper powder.

2) The fission iodine which deposited on graphite at a temperature of 580°C was iodide in terms of its chemical state.

3) Elementary iodine deposited on graphite at 80°C as elementary iodine itself under these experimental conditions. That is, the elementary iodine was not reduced by either graphite, impurities in the graphite, or carrier gas. These results [1), 2) and 3)] indicate that the fission iodine-131 was not diffused out as elementary iodine but as iodide.

4) The displacement of the iodine-131 peak toward a lower temperature, as shown in Figs. 6, 7 and 8, was not the result of the oxidation of iodide to iodine by impurities in the carrier gas. It must be related to the vapor pressure of the fission iodide, since the velocity of the movement tends to decrease sharply with an increase in the diffusion time.

5) The data obtained from samples Nos. 1, 2, 3 and 4, using graphite as the packing material, coincided well with each other. The most reasonable conclusion to be drawn under these circumstances is that the fission iodine-131 exists in the same chemical state and species in all the samples.

6) Since the fission iodine-131 exists as iodide, it should be thought that the fission iodine combines with other fission products, with impurities in uranium dioxide, thorium dioxide, etc., or with the fissionable material, i. e., uranium or thorium.

7) As shown in Figs. 3 and 9, the locations of the fission iodine-131 obtained from uranium on the graphite were different from that of thorium. This eliminates the possibility that the fission iodine-131 combines with the other fission products, even if the fission product-yield curve of uranium is different from that of thorium.

8) The combination of the fission iodine-131 with impurities in uranium dioxide, etc., is not supported by the coincidence of the thermo-chromatograms obtained from samples Nos. 1 and 3, whose impurities are different.

9) Lastly, the combination of fission iodine-131 with fissionable materials, in the present instance, uranium and thorium, may be considered. The fact that the thermo-chromatogram of the fission iodine-131 originating in uranium differs from that of thorium and the results discussed in 7) and 8) lead to the conclusion that the iodine-131 combines with fissionable materials, uranium or thorium. Also, it has been observed by Ershler and Lapteva[5] that, when a foil of uranium metal is neutron-irradiated in high vacuum, a large number of uranium atoms are vaporized from the foil. The present authors cannot help thinking, on the basis of the foregoing data, that a considerable number of uranium or thorium atoms are brought into the graphite crystal by primary fission fragments. The fission iodine-131 would center in the imperfection composed of unstable atoms of uranium or thorium caused by fission, born uranium or thorium iodide, and would diffuse out of the samples.

10) The fission iodine-131 diffusing out of the sample reacts with α-alumina at temperatures higher than 950°C. This finding indicates that α-alumina is a suitable material for use as an internal trap in a semi-homogeneous fuel reactor characterized by high temperature and high burn-up.

11) To determine precisely the chemical species of the iodide, thermo-chromatograms or uranium iodide and thorium iodide must

5) B. V. Ershler and F. S. Lapteva, *J. Nuclear Energy*, **II 4**, 471 (1957).

be studied, and the presence of uranium or thorium in thermal spikes must be confirmed.

The authors wish to express their thanks to Dr. Eizaburo Nishibori, director of the institute, for his valuable advice and discussions, and also to Dr. Toshio Nakai, chief of the division of chemistry, for his encouragement in this work.

The Behavior of Fission Products Captured in Graphite Powder by Nuclear Recoil. VII. The Activation Energy of the Diffusion of Iodine-131 in Graphite

By Seishi YAJIMA, Koreyuki SHIBA and Muneo HANDA

(Received June 22, 1962)

The authors have studied the behavior of fission products captured in graphite by fission recoil and have obtained much interesting information. For example, fission products do not leach out of graphite into nitric acid to any extent, unless the graphite is heated to a high temperature before the leaching assay[1]. Xenon, iodine, and tellurium diffuse more rapidly out of natural graphite than out of artificial graphite[2]. The heating curve and the activation energy of the diffusion of xenon indicate that the diffusion mechanism is not simple, but is related to imperfections in the graphite crystal[3]. The distribution of the activation energy of the diffusion shifts to higher temperatures with an increase in the concentration of fission products in graphite crystal[4]. Iodide is the chemical form of iodine diffusing out of graphite crystal[5].

These studies have been carried out in connection with the development of a semi-homogeneous fuel, that is, a dispersion-type fuel of uranium dioxide or uranium carbide in a graphite base; at the same time, they brought out many facts very interesting from the standpoint of hot atom chemistry.

Taking account of the fact that the iodide is the chemical form of iodine diffusing out of a graphite-uranium dioxide-system fuel, the authors undertook to determine the activation energy of the diffusion of iodine in graphite crystal and to elucidate the mechanism of the diffusion and formation of the iodide.

Experimental

Preparation of Samples.—Natural graphite (NG-1) was used throughout the experiments. The use of natural graphite, which has fewer imperfections than artificial graphite, made analysis of the experimental results clearer and easier; our studies made it clear that the diffusion rates of xenon, iodine, and tellurium in the natural graphite specimen were much larger than those in artificial graphite. Its properties are given in Table I, and those of the uranium dioxide used, in Table II.

A mixture of 1 g. of graphite and 0.5 g. of uranium dioxide powder was irradiated for 15 hr. in a JRR-1 reactor (water boiler type; thermal neutron flux: about 5×10^{11} n/cm^2/sec.) and cooled for 5 days. This cooling time facilitated the analysis of the behavior of iodine-131 by allowing short-lived iodine nuclides and the precursor of iodine-131 to decay out. The cooled sample was then treated with a hot nitric acid solution to separate

uranium dioxide from the graphite; this was then filtered off, washed with water and acetone, and dried at about 100°C. It was shown that about 60 per cent of the fission products are captured in graphite under these experimental conditions.

Apparatus Used.—The flow system of the apparatus used is shown in Fig. 1. It may be divided broadly into three parts: an argon gas purifier, diffusion equipment, and a trapping device for the diffused iodine.

In the argon gas purifier, carbon dioxide, water, and the major portion of oxygen in the argon gas were eliminated with potassium hydroxide, phosphorus pentoxide, and copper net, heated to 400°C, respectively. Copper oxide heated to 300°C was effective in oxidizing carbon monoxide and hydrogen to carbon dioxide and water, which were then absorbed in potassium hydroxide and phosphorus pentoxide respectively. Finally, nitrogen gas and a trace of oxygen gas were removed with uranium turnings heated to 900°C.

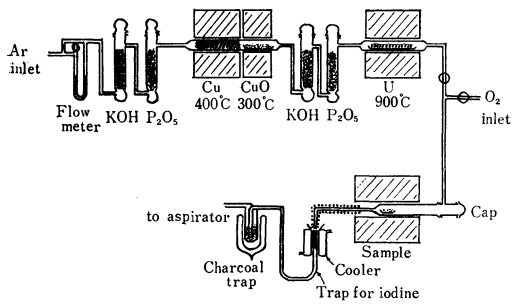

Fig. 1. Apparatus.

A graphite sample placed in a quartz tube was heated in a resistance furnance with nichrome windings. The temperature was controlled with a slide transformer. Diffused iodine-131 was carried by the purified argon gas and introduced into a slender quartz pipe heated to 600°C with a nichrome heater to prevent the iodine-131 from depositing on the wall of the pipe. The absence of such deposits was verified by gamma-assay of a sodium hydroxide solution with which the wall had been rinsed at the end of the experiments.

The trapping of the iodine was given the most careful consideration in setting up the apparatus. It has been established that iodide is the chemical form of iodine diffusing out of graphite into an inert atmosphere and that the iodide deposits on the copper powder surface at about 700°C under certain conditions[5]. Consequently, these facts must be taken into consideration in trapping iodine-131.

A trapping tube for iodine-131 was replaced by a new one at short intervals, whenever a heating curve was obtained or when the activation energy was determined, because a gap was then left between the trap and the pipe. The iodine-131 caught in the trap must be stable in air at room temperature. Such stability was obtained with iodine-131 deposited on copper metal. Before reaching the trap, a portion of the diffused iodine would be oxidized to iodine (I^0) by air entering through the gap. Iodine (I^0) is converted into silver iodide by contact with silver metal at any temperature above that of the room, and the product is stable in air at room temperature. Copper metal also combines with iodine (I^0) at room temperature to form cuprous iodide. The metal, however, is oxidized to copper oxide at a high temperature by air. The authors, therefore, used a trap comprising a glass tube (10 mm. inner diameter; 100 mm. long) stuffed with silver-plated copper netting to a depth of 10 mm. from the end of the tube facing the opening of the pipe, beyond which was copper netting to a depth of 30 mm. The trap was cooled with water circulating through a jacket surrounding the glass tube.

The flow rate of the argon stream through the quartz tube was 150 ml./min.; the narrow opening of the pipe caused the iodine-131 carried with the argon stream to be injected past the gap into the trap. The gas was evacuated through the trapping materials by an aspirator with a capacity of 170 ml./min. With this arrangement, a preliminary experiment showed that all the iodine-131 diffusing out of graphite was in the trap within a depth of 10 mm. from the inlet end.

Making the Heating Curves.—A graphite sample was placed in a quartz boat, which was then inserted through the entrance into the heating part of the diffusion apparatus after taking off the cap. After replacing the cap, the purified argon gas was introduced into the apparatus at a flow rate of 150 ml./min. in order to scavenge the air. At the same time, the slender pipe was set to heat up. As soon as the pipe temperature reached 600°C, the sample was made to start heating, beginning at a temperature of approximately 40°C in all the experiments due to the effect of the slender, highly-preheated pipe. The sample was heated at a rate of 5°C/min., this rate being controlled with a transformer adjusted by hand. The temperature was measured with a platinum-platinum rhodium thermocouple. After reaching 1100°C, the temperature of the sample was lowered to 1000°C, and the argon gas stream was replaced by oxygen gas, flowing at a rate of 150 ml./min., in order to burn out the graphite and to catch remaining iodine-131. Throughout this experiment, the trapping tube was renewed every 10 min. The activity of the iodine-131 caught in each trap was measured with an RCL 256 channel gamma-ray spectrometer equipped with a sodium iodide crystal (3 inch diameter × 3 inch thickness). Errors due to the absorption of gamma-ray from iodine-131 by the glass wall and copper netting of the traps cancelled out, because

the glass tube thickness and diameter, as well as the packing conditions of the trapping materials in the traps, were identical.

The ratio of the iodine-131 counts of each trapping tube to the aggregate count of all the tubes was divided by the temperature increment covering the trap in question, the quotient being plotted against the absolute temperature. The histogram thus obtained was redrawn in the form of a smooth curve equivalent in area, as shown in Fig. 2.

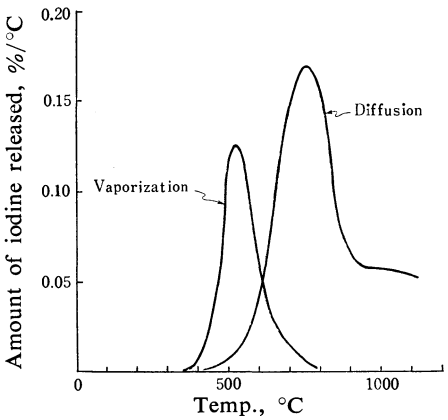

Fig. 2. Heating curves (5°C/min.) of iodine-131.

It is believed that iodine-131, after having diffused, interacts physically or chemically with the graphite crystal on the surface and then leaves the graphite. It would, therefore, be useful to obtain the heating curve of the iodine-131 which, having diffused out of the graphite crystal, has then deposited on the surface of graphite powder of a similar nature. For this purpose, an iodine sample was prepared by means of the thermo-chromatographic method described in a previous report[5]. The heating curve obtained is also shown in Fig. 2.

Determination of Acitivation Energy.—The heating curve of iodine-131 diffusion in graphite crystal has a peak at 750°C, indicating the existence of a mechanism of diffusion predominant at that temperature. Consequently, isotherms for diffusion were determined at 676, 718, 746, and 780°C, temperatures selected in the vicinity of 750°C.

Before putting a sample in the diffusion apparatus, the slender connecting pipe was preheated and kept at 600°C, and the heating section was kept at the designated temperature, while argon gas was allowed to flow at 150 ml./min. through the apparatus. As soon as the graphite sample, placed on a quartz boat, was inserted in the heating section under these conditions, the cap was fastened and the sample heated. The trap was renewed at appropriate intervals. The time of the beginning of diffusion was taken to be the instant the cap was in position.

After being kept at a constant temperature from 2 to 4 hr. in order to get an isotherm, the temperature of the sample was raised to 1000°C and the sample was fired by replacing the argon atmosphere with oxygen gas; the iodine-131 remaining in the graphite was caught in the trap. The trapping tubes were handled and put through spectrometry in the same way as has been described for making heating curves. The amount of diffused iodine-131 is plotted against the diffusion time in Fig. 3.

According to Dienes[6], in the relaxation process, the relaxation time, t, and the activation energy, E, are related by the equation:

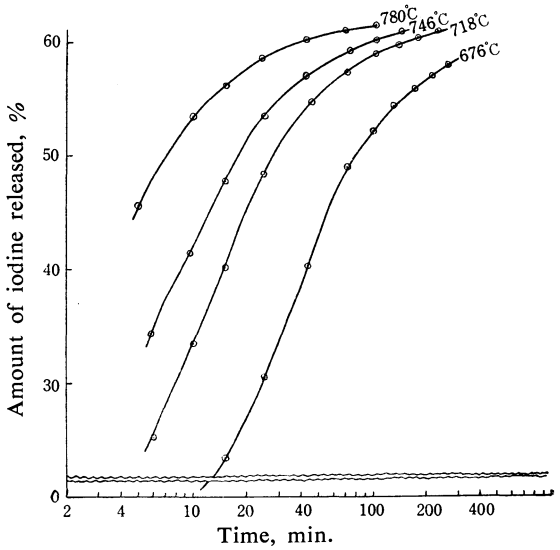

Fig. 3. Isotherms for diffusion of iodine-131.

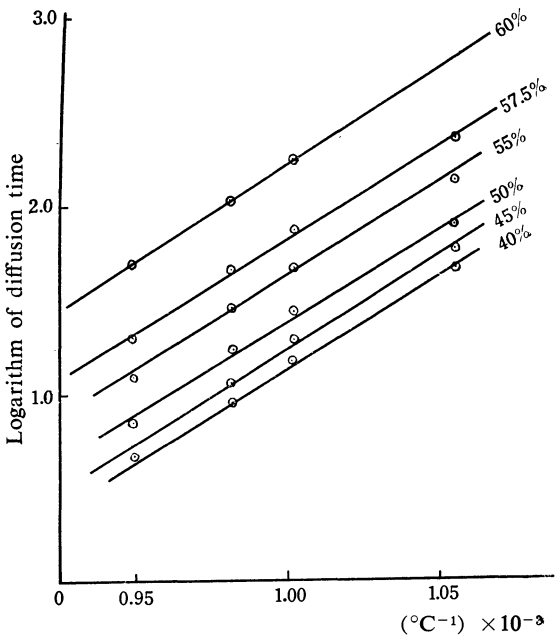

Fig. 4. Activation energies of diffusion of iodine-131.

6) G. J. Dienes and W. E. Parkins, "An Improved Method for Determining Activation Energies of Relaxation Process", NAA-SR-60 (1950).

$$t \times \exp(-E/RT) = \text{constant}$$

where R: gas constant

T: absolute temperature.

In order to apply this to diffusion phenomena and to determine activation energy, the logarithms of diffusion time corresponding to 40, 45, 50, 55, 57.5, and 60 per cent of the total iodine-121 content on each isotherm were plotted against the reciprocal of the absolute temperature, as is shown in Fig. 4. The groups of points stand along lines with the same gradient. This evidently means that the activation energy of the diffusion of iodine-131 is single. The activation energy calculated from each gradient is given in Table III.

TABLE III. ACTIVATION ENERGIES OF DIFFUSION OF IODINE-131

Per cent	Slope, deg.	Activation energy, kcal./mol.
40	1.01×10^4	46.3

50	1.00×10^4	45.8
55	1.02×10^4	46.7
57.5	1.02×10^4	46.7
60	1.05×10^4	49.2

Discussion

It has been clarified that iodide is the chemical form of iodine-131 diffusing out of graphite in an inert atmosphere. In the heating curve of the iodide deposited on graphite powder, a peak appears at 530°C, as is shown in Fig. 2. If there should be no chemical interaction between the iodide diffused out of graphite and graphite crystals on the surface, the heating curve is to be related to the vaporization of the iodide. Most compounds have a measurable vapor pressure in the neighborhood of their melting points; therefore, by a first approximation, the iodide can be considered to have its melting point in the range between 400 and 600°C.

The heating curve of deposited iodide has a peak at 530°C, while the peak of the heating curve of "diffusion" is found at 750°C, which is 200°C higher than that of the iodide. This leads to the conclusion that the iodide which had diffused in graphite and had reached the surface did not stay there, but was carried immediately off by the argon gas stream; that is, the peak at 750°C originated in the very diffusion of iodine-131.

Figures 2 and 3 and Table III show that the bulk of the iodine-131 diffusion in graphite at temperatures lower than 1100°C occurs around 750°C, based on a single mechanism with an activation energy of 47 kcal./mol.

In order to compare the diffusion in graphite crystal of iodine with that of xenon, a typical heating curve and the activation energies of the diffusion of xenon have been reproduced from the fourth and fifth papers of this series; they are given in Fig. 5 and Table IV. Whereas, in the heating curve of xenon, peaks appear at 200, 500, 750, 1000 and 1400°C, that of iodine has only one, at 750°C. Attention is drawn to the fact that a peak at 750°C appears also in the xenon diffusion curve and that the activation energies are approximately equal, as is seen in Table IV. This means that the diffusion of xenon and iodine are governed by one and the same mechanism.

It is also interesting to compare the heating curves of volatile fission products, xenon and iodine, diffusing out of graphite, with the annealing curves of graphite irradiated with fast neutrons. To depict the neutron damage to artificial graphite, differential annealing curves of several physical properties are shown in Figs. 5 and 6, based on work carried out by Woods et al.[7] and by Kinchin[8]. In Table

Iodine diffusion	2.6×10^{14} fp/cm^3		47		Present work

IV is given the activation energy of the annealing of electrical resistivity determined by using a pulse-annealing technique.

The peaks of the heating curve of the diffusion of xenon and those of the annealing of neutron damage coincide very well with each other except for the one at 750°C; this coincidence is the more remarkable when one considers the differences in such factors as irradiation conditions of the samples, experimental method, and treatment of data. This indicates that the xenon-tracer technique can match other methods with respect to high sensitivity and simplicity when studying the process of the annealing of imperfections in graphite crystal. Furthermore, the activation energies of the diffusion of xenon at 200 and 1000°C are nearly equal to those of the annealing of electrical resistivity. This means that, so far as these peaks are concerned, the damage due to fast neutrons is the same as that due to fission fragments, and that xenon is released on the annealing of these imperfections.

It has been established that fission fragment damage caused by the recoil of fission fragments into graphite crystal is far greater than fast neutron damage[4,9]. The absence of a peak at 750°C in the annealing curves of the neutron damage would indicate either that this damage is characteristic of fission fragment damage or that other methods less sensitive than the xenon-tracer technique obscure the presence of the 750°C-peak caused by fast neutron damage. However, the latter suggestion cannot be easily affirmed. Therefore, the imperfection corresponding to the 750°C-peak may have its origin in the fission fragments themselves or in fissionable materials, in the present instance, uranium atoms brought into the graphite crystal by fission fragments, because the physical interaction of fission fragments with graphite atoms is not considered to be fundamentally different from those of fast neutrons with graphite atoms.

These assumptions lead to the conclusion that iodine-131 was initially distributed evenly over the various imperfections in the graphite crystal, as was the xenon which had recoiled. However, because of the chemical affinity of iodine, iodine-131 caught in the imperfections (C_2, C_3, C_4,—clusters)[10] corresponding to temperatures below 750°C had a very small probability of migrating between layers or of diffusing out of the graphite crystal, and so tended rather to combine successively with clusters corresponding to higher temperatures at the time of the disappearance of the imperfections. Thus, as clusters begin to disappear at lower temperatures, iodine-131 shifts to clusters corresponding to higher temperatures and is trapped there. Consequently, in the case of iodine, no peak is observed at temperatures lower than 750°C. Finally, iodine-131 combines with those foreign atoms which constitute imperfection corresponding to the peak at 750°C to form the iodide species and to diffuse out. This assumption is supported by the fact that, at 2.6×10^{14} fission products per cubic centimeter of graphite, the amounts of iodine and xenon diffusing at temperatures below 900°C are 42 and 44 per cent respectively, which figures are nearly equal. Another evidence is that many halides of metals like UCl_4, UO_2Cl_2 intercalate graphite in the vicinity of 300°C[11]; this quite low temperature facilitates the diffusion of the iodide species in graphite crystal. To confirm the presence of uranium atoms and to determine the concentrations of the atoms along the range of fission fragments in graphite would further consolidate this assumption.

The authors intend further to pursue their studies of the chemical form and diffusion behavior of the iodine-131 remaining in the graphite without diffusing out at temperatures over 900°C.

Syntheses of Polyhydroxybenzene Derivatives from Furfural

By Masuo MURAKAMI and Jong-Chen CHEN

(Received June 25, 1962)

It has been impressed that 2-substituted 2, 5-dimethoxydihydrofurans and 2, 5-dimethoxytetrahydrofurans are easily converted into aromatic compounds by hydrolysis in acid solution. For example, Clauson-Kass and co-workers[1] described the hydrolysis and spontaneous recyclization of 2-acetyl-2, 5-dimethoxytetrahydrofuran dimethylketal to catechol and Boehme[2] reported the formation of hydrourushiol (XVII) from the acid hydrolysis of 2-heptadecanoyl-2, 5-dimethoxytetrahydrofuran. Respect of the activated character of hydrogens in the α-position to carbonyl group (such as in the case of the compounds VI and XII) had let to the preparation of polyhydroxybenzenes (Fig. 1) and catechol derivatives including hydrourushiol (Fig. 2).

The compounds VI, VII, VIII and X are new substances. Their structures were determined from the synthetic process, analyses and from the infrared spectra.

The method of synthesis of VII was partly based on a route of its methyl analog developed by Clauson-Kass[1], VII was prepared by hydrolysis of VI at room temperature as well as at 100°C in dilute hydrochloric acid. The reaction at lower temperature produced a larger amount of VII (51.5% yield at room temperature and 21.2% at 100°C). VII showed a green color with ferric chloride and significant infrared

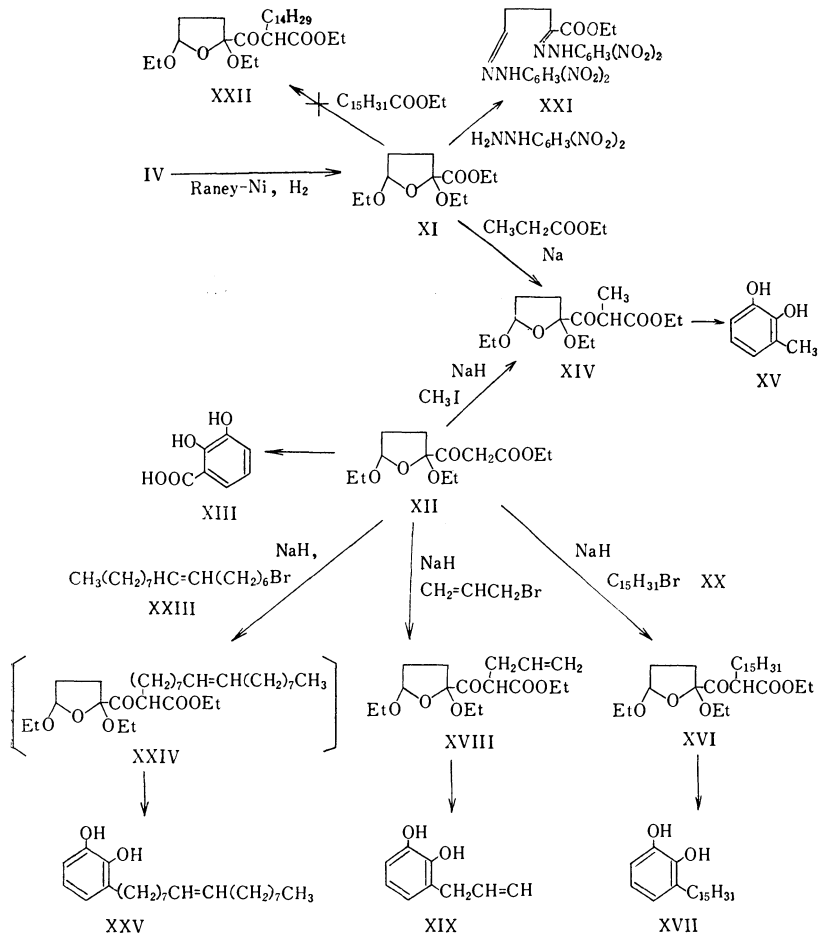

Fig. 2

absorption bands at 2.89~2.94 μ (-OH), and 5.92 μ (ester C=O).

X was obtained through 1,6-intramolecular condensation of the intermediate (IX) which was prepared by acid hydrolysis of VIII. X showed a green color with ferric chloride and gave a red 2,4-dinitrophenylhydrazone. The seven-membered ring compound which was expected from 1,7-intramolecular condensation of IX, was not found in the reaction mixture. The yield of X was 58% and the rest was polymerized in this reaction.

The compounds XII, XIV, XVI, XVIII and XXV are new substances.

XI was prepared by reduction of IV with Raney nickel as a catalyst. IV and XI are distinguished easily by the color of their bishydrazons (V and XXI). V is red and decomposes at 248°C, while XXI is yellow and melts at 194~196°C.

The compound XIII was identified with an authentic sample of commercial 2,3-dihydrobenzoic acid through mixed fusion test and by comparison of infrared spectra.

Pentadecyl bromide (XX) was prepared by the Hunsdiecker reaction[3] from silver salt of palmitic acid.

XVI was prepared (24.6%) by boiling the *n*-butyl ether solution of XII and XX for 5 hr. A large amount of XII and XX was recovered from the reaction mixture. A higher yield of XVI can be expected when the time of reaction is extended. At a lower temperature such as the boiling temperature of a mixture of ether and benzene, only a trace of XVI was obtained.

Very recently Hanafusa and Yukawa[4] have synthesized hydrourushiol (XVII) starting from catechol. Hydrourushiol, one of the Japanese lac urushiol[5] or poison-ivy compound[6], was prepared here by acid hydrolysis of XVI. The

colorless, waxy crystals of synthetic hydrourushiol were identified with an authentic sample[7] by mixed fusion test and comparison of infrared spectra.

On the Claisen condensation of XI with ethyl acetate and ethyl propionate, the yields were 52.3 and 13.0% respectively. Ethyl palmitate failed to condense with XI in the presence of metallic sodium, sodium alkoxide, sodium hydride or triphenylmethyl-sodium using the ether, benzene or *n*-butyl ether as a solvent respectively. The condensation also failed when the timer of reaction was extended,

XVIII was a yellow oil and turned to brown when it was stored in the dark place for a long time. It reacted rapidly with bromine and permanganate. Infrared spectra of XVIII showed terminal double bond at the peaks of 6.06, 10.05, 10.83 μ and carbonyl groups at two peaks of 5.16~5.76 μ.

XIX was obtained by acid hydrolysis of XVIII. 3-Allylcatechol was prepared formerly by the reaction of catechol and allyl bromide through the Claisen rearrangement of monoallyl ether of catechol[9]. XIX was practically colorless just after the distillation and rapidly became golden yellow, but it soon turned to reddish brown on exposure to air. The terminal olefinic bond of XIX was readily detected from the infrared spectra. XIX rapidly decolorized bromine and permanganate and gave an olive green color with ferric chloride.

1-Bromoheptadencen-8 (XXIII) was also prepared by the Hunsdiecker reaction[3] from silver salt of oleic acid. Acid hydrolysis was carried out after the reaction of XII and XXIII had been completed. Lead salt of XXV was isolated from the acid solution with lead acetate. XXV was obtained as a pale yellow oil by means of treating lead salt of XXV with hydrogen sulfide. This manner gave XXV in a high yield (52.4% yield based on reacted XII). When a solution of XXV in alcohol was treated with a drop of aqueous permanganate, the color disappeared after standing for a minute. XXV gave a green color with ferric chloride. Negative Beilstein test of XXX showed that bromine did not add to a double bond of oleic acid under the Hunsdiecker reaction.

It is interesting that application of XIX and XXV to the skin caused a marked blister within a few hours, but on application of hydrourushiol to the skin no blister edema was found. Dawson[9] reported that the 3-(8'-pentadecenyl)catechol caused the marked edema and blister characteristic of poison-ivy dermatitis. It is undoubted that 3-olefinic catechol caused dermatitis. Instead of urushiol, 3-allylcatechol (XIX) may be available for clinical study. Further study of olefinic catechols, some materials which have a characteristic of "Urushi" for paint will be expected. It is believed that the above methods will be available to synthesize the compounds having another substituent in 1-position of 2, 5, 6-trihydroxybenzene (method of Fig. 1) and substituents in 3-position of catechol (method of Fig. 2).

Experimental

2-Furoic Acid (II).—This compound was prepared by the method given earlier[10].

Ethyl 2-Furoate (III).—56.0 g. (0.50 mol.) of II was dissolved in amixture of 300 ml. of ethanol and 56 g. of concentrated sulfuric acid. After the reaction mixture had been heated at a reflux temperature for 6 hr, the ethanol was removed by distillation, the residue was dissolved in ether and a small amount of ice water was added. The ethereal solution was washed with saturated sodium hydrogen carbonate, with water and dried over magnesium sulfate. The ether was removed by distillation, the residue was distilled further, and 67.5 g. (96.5% yield) of III was obtained, b. p. 129~130°C (115 mmHg).

Found: C, 60.01; H, 5.75. Calcd. for $C_7H_8O_3$: C, 59.99; H, 5.75%.

2, 5-Diethoxy-2, 5-dihydrofurancarboxylic Acid Ethyl Ester (IV).—III (55.9 g., 0.40 mol.) was mixed with 230 ml. of methanol and 1.0 ml. of concentrated sulfuric acid. The electrolysis of the solution was carried out by the Clauson-Kaas method[1]. From the fraction at b. p. 115~136°C (11 mmHg), 56.25 g. (61.5%) of IV was obtained as a colorless liquid, n_D^{15} 1.4420.

Found: C, 57.80; H, 7.27. Calcd. for $C_{11}H_{18}O_5$: C, 57.38; H, 7.88%.

V was obtained in a quantitative yield from 1 mol. of IV and 2 mol. of 2, 4-dinitrophenylhydrazine. Crude crystals of V were twice recrystallized from nitrobenzene. V was red crystals, decomp. p. 248°C.

Found: C, 44.18; H, 3.65; N, 21.80. Calcd. for $C_{19}H_{16}O_{18}N_8$: C, 44.19; H, 3.12; N, 21.12%.

Ethyl (2, 5-Diethoxy-2, 5-dihydro)furfuroylacetate (VI).—14.0 g. (0.061 mol.) of IV and 20 ml. of benzene were placed in a three-necked flask fitted with a stirrer, a dropping funnel and a reflux condenser carrying a soda-lime tube and heated with stirring to about 100°C. 21.5 g. (0.244 mol.) of ethyl acetate and 5.6 g. (0.244 mol.) of sodium powder were added at the interval of 30 min. in six portions. After the reaction, ethanol was added dropwise to remove unreacted sodium and the

mixture was left to stand with stirring and heating for 10 hr. The solution was cooled to 0°C and acidified by acetic acid. The dark brown mixture was added to cold water and the benzene layer was separated, washed with saturated sodium hydrogen carbonate then with water, and dried over magnesium sulfate. Benzene was removed by distillation and the residue distilled further, 6.60 g. (40.0%) of VI was obtained as a slightly yellow oil, b. p. 130~140°C/5 mmHg, n_D^{15} 1.4420.

Found: C, 57.02; H, 7.10. Calcd. for $C_{13}H_{20}O_6$: C, 57.34; H, 7.40%.

Ethyl 2, 3, 6-Trihydroxybenzoate (VII).—Two grams of VI was shaken at room temperature for 5 hr. with 20 ml. of 0.1 N hydrochloric acid and left to stand for 2 weeks. A light violet precipitate was collected by filtration, washed with water and dried. The yield of crude VII was 0.82 g. (56.1%), m. p. 149~151°C. Two recrystallizations from 30% ethanol raised the melting point to 154~155°C.

Found: C, 54.26; H, 5.20. Calcd. for $C_9H_{10}O_5$: C, 54.54; H, 5.09%.

VII was also obtained by heating 2.0 g. of VI in 20 ml. of 0.1 N hydrochloric acid at the boiling temperature for an hour. After cooled, a precipitate was removed by filtration, washed with water and dried. The yield of crude VII was 0.31 g. (21.2%). By two recrystallizations of this crude product from 30% ethanol, white crystals of VII, m. p. 154~158°C, were obtained. The product was identified with the sample which was prepared at room temperature by mixed fusion test and comparison of infrared spectra.

Found: C, 54.54; H, 5.20. Calcd. for $C_9H_{10}O_2$: C, 54.54; H, 5.09%.

Ethyl α-(2, 5-Diethoxy-2, 5-dihydro)furfuroyl-γ-oxovalerate (VIII).—Sodium hydride (0.0277 mol.) and 20 ml. of benzene were placed in a three-necked flask fitted with a mechanical stirrer, a dropping funnel and a reflux condenser carrying a soda-lime tube. 7.5 g. (0.0277 mol.) of VI was added dropwise to the stirred contents of the flask at room temperature. 4.56 g. (0.032 mol.) of bromoacetone was added after heating at reflux temperature for an hour, and the reaction mixture was heated for 10 hr. After the reaction, a small amount of ice water was added and acidified with acetic acid. The benzene layer was separated, washed with saturated sodium hydrogen carbonate solution then water, and dried over magnesium sulfate. Benzene and unreacted bromoacetone were removed by distillation, and further fractional distillation of the residue gave 0.7 g. of unreacted compound of VI, and 3.2 g. (45.0%) of VIII boiling at 114~120°C (1.8 mmHg). VIII was redistilled to give a yellow oil, b. p. 118~120°C (1.8 mmHg). n_D^{17} 1.4763. This yellow oil turned to brown when stored.

Found: C, 58.80; H, 6.91. Calcd. for $C_{16}H_{24}O_7$: C, 58.52; H, 7.73%.

2, 3, 6-Trihydroxyphenylacetone (X).—This compound was prepared from 1.90 g. (0.0071 mol.) of VIII as described above for preparation of VII (method of heating at reflux temperature). The yield was 0.80 g. (58.0%) of crude X. After two recrystallizations from water, white crystals of X, m. p. 140~142°C, were obtained. The product gave a green color with ferric chloride.

Found: C, 56.50; H, 6.18. Calcd. for $C_9H_{10}O_4$: C, 56.46; H, 5.92%.

2, 5-Diethoxytetrahydrofurancarboxylic Acid Ethyl Ester (XI).—XI was prepared in a quantitative yield by reduction of IV in ethanol under hydrogen of 50 kg./cm², using the W-6 Raney nickel[11] as a catalyst at room temperature for 7 hr. XI was a colorless liquid, b. p. 109~120°C (11 mmHg), n_D^{15} 0.4378.

XXI (quantitative yield) was prepared by the usual method from XI. Yellow crystals of XXI (m. p. 194~196°C) were obtained by three recrystallizations from nitromethane.

Found: C, 44.92; H, 3.62; N, 21.48. Calcd. for $C_{19}H_{18}O_{10}N_8$: C, 44.02; H, 3.49; N, 21.03%.

Ethyl (2, 5-Diethoxytetrahydro)furfuroylacetate (XII).—This compound was prepared from XI (21.0 g.) and ethyl acetate (23.9 g.) as described above for the preparation of VI. 12.9 g. (52.3%) of XIII was obtained as a light yellow liquid, b. p. 115~124°C (3.5 mmHg), n_D^{17} 1.4612.

Found: C, 57.28; H, 8.21. Calcd. for $C_{13}H_{22}O_6$: C, 56.92; H, 8.08%.

2, 3-Dihydroxybenzoic Acid (XIII).—One gram of XII in a mixture of 36 ml. of 0.1 N hydrochloric acid and 65 ml. of dioxane was heated at reflux temperature for 11 hr. After the reaction, the solvent was removed by distillation and the residue was sublimed under 6 mmHg on an oil bath (120~130°C). The product was identical with an authentic sample of commercial 2, 3-dihydroxybenzoic acid from mixed fusion test and comparison of infrared spectra.

Found: C, 54.73: H, 3.94. Calcd. for $C_7H_6O_4$: C, 54.55; H, 3.92%.

Ethyl α-(2, 5-Diethoxytetrahydro)furfuroyl-α-methylacetate (XIV).—This compound was prepared from 3.1 g. (0.0114 mol.) of XII and 2.61 g. (0.0171 mol.) methyl iodide by heating for 1.5 hr. in the ethereal solution as described above for the preparation of VIII. 2.20 g. (67.5%) of XIV was obtained as a yellow oil which turned to brown after a long time storage. B. p. 105~124°C (3 mmHg). This product was redistilled at 119~124°C (3 mmHg), n_D^{17} 1.4930.

Found: C, 56.25; H, 8.16. Calcd. for $C_{13}H_{24}O_6$: C, 56.56; H, 8.76%.

XIV was also prepared from 2.32 g. (0.01 mol.) of XI and 4.08 g. (0.04 mol.) of ethyl propionate as described above for preparation of VI. The yield of XIV was 0.37 g. (13.0%). Its infrared spectra showed this product was identical with the product which was prepared from XII and methyl iodide by the method described above.

1-Methyl-2, 3-dihydroxybenzene (XV).—0.90 g. of XIV in a mixture of 3.6 ml. of hydrochloric acid (0.1 N) and 6.5 ml. of dioxane was heated at reflux temperature for 3.5 hr. After the reaction, the solvent was distilled off at a reduced pressure. The residue was solidified on cooling. The product was purified by three recrystallizations from benzene to give 0.04 g. (13.0%) of XV which were

11) "Organic Syntheses", Vol. 29, 24 (1949).

colorless crystals, m. p. 46.5~47°C (reported m. p. 47°C). The product gave a green color with ferric chloride.

Found: C, 67.68; H, 6.62. Calcd. for $C_7H_8O_2$: C, 57.63; H, 6.50%.

Ethyl α-(2, 5-Diethoxytetrahydro)furfuroyl-α-heptadecylacetate (XVI).—This compound was prepared from 7.53 g. (0.026 mol.) of XII and 8.3 g (0.0263 mol.) of XX by reflux in *n*-butyl ether for 5 hr. as described above for preparation of VIII. After a fore-run of XII (1.90 g.), 2.0 g. (25.87% yield based on unrecovered XII) of XVI was obtained, b. p. 133~135°C (0.1 mmHg). The product was solidified (colorless) at room temperature, m. p. 46~47°C.

Found: C, 69.60; H, 11.58. Calcd. for $C_{28}H_{52}O_6$: C, 69.38; H, 10.81%.

Hydrourushiol (XVII).—One gram of XVI in a mixture of 10 ml. of 0.1 N hydrochloric acid and 10 ml. of dioxane was heated at reflux temperature for 10 hr. After the reaction, the solvent was distilled off. The residual oil[12] was dissolved in ethanol and treated with an excess of ethanolic solution of lead acetate trihydrate. The dense precipitate of lead salt was filtered off, washed with ether. The lead salt was suspended in ethanol and treated with hydrogen sulfide. The lead sulfide was removed by filtration and the solvent was distilled off from the filtrate, leaving an oil which solidified at room temperature as a colorless wax. The yield was 0.230 g. (34.7%) of XVII, m. p. 57~68.5°C, which was recrystallized from ether. The infrared spectra and melting point of the synthetic product were identical with those of an authentic sample.

Found: C, 78.26; H, 11.21. Calcd. for $C_{21}H_{36}O_2$; C, 78.09; H, 11.32%.

Ethyl α-(2, 5-Diethoxytetrahydro)furfuroyl-α-allylacetate (XVIII).—This compound was prepared from 6.20 g. (0.0228 mol.) of XII and 4.14 g. (0.0342 mol.) of allyl bromide by reflux in benzene for 7 hr. as described above for the preparation of VIII. The yield was 3.2 g. (45.0%) of XVIII, b. p. 125~134°C (3.5 mmHg), n_D^{20} 1.4640. The yellow oil XVIII turned to brown when stored for a few hr. A sample of XVIII reacted with bromine and permanganate.

Fund: C, 61.30; H, 8.72. Calcd. for $C_{16}H_{26}O_6$: C, 61.13; H, 8.34%.

1-Allyl-2, 3-dihydroxybenzene (XIX).—This compound was prepared from 2.70 g. of XVIII in 86 ml. of 0.1 N hydrochloric acid and 50 ml. of dioxane by reflux for 9 hr. After the reaction the solvent was distilled off. The residue was distilled under a reduced pressure to give a colorless liquid of b. p. 140~145°C/15 mmHg. The weight was 0.41 g. (32.0%) of XIX, which reacted rapidly with bromine and with permanganate. A sample of XIX gave an olive color with ferric chloride. The portion, b. p. 144~145°C (15 mmHg.) was analyzed.

Found: C, 72.10; H, 6.65. Calcd. for $C_9H_{10}O_2$: C, 71.98; H, 6.71%.

3-(8'-Heptadecenyl)catachol (XXV).—0.0246 mol. of sodium hydride in 30 ml. of *n*-butyl ether was placed in a three-necked flask with a mechanical stirrer, a dropping funnel and a reflux condenser carrying a soda-lime tube. 6.7 g. (0.0246 mol.) of XII was added dropwise to the stirred contents of the flask at room temperature for an hour, 5.2 g. (0.0164 mol.) of XXIV was added and the reaction mixture was heated for 10 hr. After the reaction, the reaction mixture was acidified with acetic acid and then *n*-butyl ether was removed by vacuum distillation. The residue was added to 30 ml. of 0.1 N hydrochloric acid and 20 ml. of dioxane and heated at reflux temperature for an hour. The reaction mixture was treated as described above for preparation of XVII. 0.298 g. (52.4%) of XXV was obtained as a pale yellow substance, b. p. 215~220°C (0.8 mmHg), m. p. 33~36°C, which gave a green color with ferric chloride and reacted with permanganate.

Found: C, 79.51; H, 11.19. Calcd. for $C_{23}H_{38}O_2$: C, 79.71; H, 11.05%.

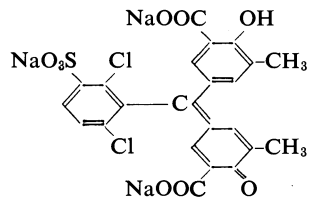
Chelate Formation between Thorium(IV) and Sulfodichlorohydroxydimethylfuchson Dicarboxylic Acid (Trisodium Salt). Studies on the Composition and Stability of the Chelate and Analytical Applications of the Reaction

By Suresh C. SRIVASTAVA*, Surendra Nath SINHA and Arun K. DEY

(Received July 2, 1962)

Several members of the dyes of the hydroxytriphenylmethane group are known to form characteristic colored products with inorganic ions in solution, and due to this property, they are used variously as metallo-chromic indicators in complexometric titrations, as colorimetric reagents for detection and determination of microamounts of metals and as spot reagents.

One of the important members of this group of dyes is sulfodichlorohydroxydimethylfuchson dicarboxylic acid (trisodium salt, commonly known as Chrome Azurol S and abbreviated here as CAS; Color Index 723) represented by the following structure:



The main use of the reagent, hitherto, has been as a metallochromic indicator in complexometric titrations due to its tendency of forming characteristic colored chelates in solution with certain metal ions. It has been used by Willard and Horton[1] as an indicator in the titration of fluoride with thorium. Theis, and Musil and Theis[2] employed the reagent in the chelatometric determination of aluminum, copper and zinc, and for detecting beryllium in weakly acidic solutions. The utility of Chrome Azurol S as an indicator for zirconium was examined by Fritz and Fulda[3] who found it not to be satisfactory. Under varied specific conditions, Malát and Tenérova[4] used the reagent as an indicator for the complexometric determination of nickel, cerium and lanthanum. The simultaneous determination of iron(III) and aluminum(III) by EDTA titration using Chrome Azurol S as an indicator has also been described by Matsuo[5]. Sangal and Dey[6] have carried out the complexometric determination of thorium using Chrome Azurol S as an indicator.

Few applications of the reagent, except for its use in the determination of fluoride by the bleaching of its colored lakes with metals have been reported in the realm of colorimetric analysis. Ravinson and Harley[7] suggested the spectrophotometric determination of fluoride ion, which prevents the color development of the thorium-Chrome Azurol S lake. Macnulty and Woolard[8] described the use of an aluminum Chrome Azurol S chelate for the micro-determination of fluoride, and also Silverman and Shideler[9] made studies on the spectrophotometric determination of beryllium and fluoride with the reagent.

In view of the interesting chromophoric reactions of Chrome Azurol S, the present investigations were undertaken. It was observed to form very stable colored chelates in aqueous solution with copper(II), beryllium(II), magnesium(II), cadmium(II), aluminum(III), lanthanum(III), cerium(IV), titanium(IV), zirconium(IV), lead(II), thorium(IV), molybdenum(VI), uranium(VI), iron(III), cobalt(II), nickel(II), and palladium(II) under specific experimental conditions. This communication records the investigations with the thorium(IV)-chelate. The composition and stability have been determined by two different methods using absorbance measurements, and the results further corroborated by performing electrical conductance studies.

Experimental

Materials. — *Standara Thorium Solution.* — BDH (AnalaR) sample of thorium chloride was dissolved in double distilled carbon dioxide-free water. The metal was estimated as oxalate in 4% hydrochloric acid and weighed as thorium(IV) oxide after ignition. A 0.1 M stock solution was prepared.

Reagent Solution.—BDH indicator Chrome Azurol S (trisodium salt; Color Index 723) was employed for making the solutions, which were standardized by determining the sulfur content of the compound. Double distilled carbon dioxide-free water was used and always fresh solutions were prepared.

Solutions of Diverse Ions.—These were prepared by dissolving the respective compounds (all reagent grade) in distilled water and made to suitable strengths.

Protective Colloid.—A 0.1% solution of dextrin was prepared in distilled water and filtered. Suitable amounts of this solution were added to the mixtures to avoid any chances of the precipitating out of the lake, as such a tendency was observed at certain concentrations. It was found that although dextrin slowly loses its protective properties with the passing of time, yet, it is by far, the most suitable reagent for the present purpose.

Other Reagents.—All other reagents were of analytical grade and were used without further purification.

Instruments Procedure and Calculations.—*Absorbance Measurements.*—A Unicam SP 500 spectrophotometer was employed for the measurements of absorbance. This was operated by a Doran's Mains unit connected to 220 V./50 cycle a. c. mains, further stabilized by a constant voltage transformer. One centimeter thickness of the solutions was employed by using matched silica cells supplied along with the instrument and distilled water blanks were used. The ultrasensitive phototube was used at wavelengths of 625 mμ or below, and the red sensitive phototube for those above 625 mμ. The phototube circuit was maintained at maximum sensitivity. Under these conditions, the slit width corresponded to very nominal band widths and usually ranged between 0.030 and 0.065 mm.

Colorimetric Measurements.—For these, a Klett Summerson photoelectric colorimeter was employed using the Klett filter No. 54 green (transmission 510~580 mμ). The Klett test tubes in which the solutions were kept for measurements had a uniform diameter of 1 cm.

pH Measurements. — Hydrogen-ion concentration of the solutions was measured with a Leeds and Northrup direct reading pH indicator with a glass calomel electrode system, operated on the aforementioned power mains. The instrument was standardized from time to time with a standard buffer of pH 6.8 supplied along with the same.

Electrical Conductance Measurements.—The measurements of electrical conductance were carried out with a Leeds and Northrup Kohlrausch slidewire with an audio-frequency oscillator in the circuit, operated on the same mains and using a dip type measuring cell having a cell constant 0.580.

Conditions of Study.—All experiments were performed in an air-conditioned room maintained at 30±1°C. The total volume of all the mixtures prepared for the measurements was kept at 50 ml. (variation in the method of continuous variations was done within 25 ml., and the volume then raised to 50 ml. after adding suitable amounts of dextrin and ammonium nitrate, the latter being used for swamping of the system). The individual solutions and mixtures were kept immersed for about an hour, a time which was sufficient for their equilibration and for attaining the temperature of the bath, in a Townson and Mercer's precision thermostat maintaining a temperature of 30±0.01°C. The pH of all the solutions and mixtures was adjusted to 4.5±0.2, by the addition of suitable amounts of sodium hydroxide or perchloric acid. Ionic strength in all the mixtures was also kept constant at 0.15 by the addition of proper amounts of a solution of ammonium nitrate.

Procedure.—The composition of the chelate has been established by employing two different methods viz., (i) the method of continuous variations[10] (using absorbance and electrical conductance measurements) and (ii) the mole ratio method of Yoe and Jones[11] (using absorbance measurements).

Job's method of continuous variations involves the preparation of a series of mixtures with varying mole per cent of the two interactants forming the complex, and the measurement of some physical property of these solutions. A plot of the difference between the observed value and the calculated value of the particular physical property assuming no reaction, should show a maximum or minimum at the mole per cent corresponding to the complex formed.

Despite the various criticisms[12] that have been put against this method, it is still very popular for the study of the composition of complexes in solution, and it is agreed that the results are reliable when absorbance measurements are carried out. In the course of the present studies, electrical conductance was also chosen, besides absorbance, as the index property, and it has been observed that the method yields reliable results not only with absorbance measurements, but with measurements of electrical conductance as well.

In the mole ratio method, a series of solutions is prepared containing a constant amount of the metal ion, but with increasing ratios of reagent to the ion (or vice versa). When the absorbances of these solutions are measured and plotted against the concentration ratios, the plot should be a straight line that rises until the combining ratio of reagent to the metal ion is reached. The curve from this point on should become horizontal unless the reagent itself has some absorbance at the wavelength employed. In such a case the curve should abruptly change slope, but instead of becoming perfectly horizontal, it would have a positive slope, the angle depending upon the degree of absorbance of the reagent solution[13]. No abrupt break in the

curve occurs, however, in the case of a complex undergoing appreciable dissociation. In such a case, the continuous curve becomes approximately parallel to the molar ratio axis only when an excess of the variable compound is added. Results obtained by extrapolation of this curve are uncertain but it is found in many cases, that such a curve may be made to break sharply at the correct molar ratio by adjusting the ionic strength to a suitable value by the addition of an indifferent electrolyte[14].

Evaluation of the Stability Constant.—The stability constant of the complex has been calculated with the help of absorbance data by two different methods. Anderson and coworkers[15] have described a convenient method for the calculation of the stability of colored complexes in solution based on the composition of mixtures having identical color i.e., the same absorbance values. Their method suffers from a limitation that both the interacting solutions forming the complex should be colorless and should not have any absorbance at the λ_{max} of the complex species. This difficulty has been overcome by a modification of this method by Dey and coworkers[16] who described a procedure for calculating the stability in the case of complexes where one of the interactants may be colored. The method has thus been found to be more useful and applicable under a wider variety of conditions. The method, in precise, is as follows. Continuous variations method is employed using equimolecular solutions and the total volume is kept constant. The absorbances of the mixtures which are noted at the λ_{max} of the complex are plotted against mole fractions of the metal ion i.e., [M]/([M]+[Ke]) ([M] is the concentration of the metal ion and [Ke] that of the chelating agent). The absorbance of the mixtures is due to the color of the chelate and the reagent, since most of the metal ions are colorless at very high dilutions. When the concentration of the metal ions increases progressively (e.g. in the descending portions of the curves), the ligand concentration decreases, and on any point in the descending portions of the curves, a large majority of the reagent may be assumed to be bound up in the complex, and the free chelating agent is negligible to contribute significantly to the total absorbance of the system. The absorbance in these portions is hence, due to the chelate alone, and at the same value of absorbance in a number of such curves, the respective amounts of the complex formed in the individual cases are identical. The concentration of the chelate can be calculated by the following procedure:

In an equilibrium of the type involving a metal ion and a chelating agent in the ratio of 1 : 1,

$$M+Ke \rightleftarrows MKe$$

the stability constant is given by:

$$K=\frac{x}{(a-x)(b-x)} \quad (1)$$

where x is the concentration of the chelate at equilibrium and a and b respectively are the initial concentrations of the metal ion and the chelating agent. Taking two concentrations of the reactants, i.e., two values of a and b, where absorbance is the same, the value of x will also be the same.

Hence

$$K=\frac{x}{(a_1-x)(b_1-x)}=\frac{x}{(a_2-x)(b_2-x)} \quad (2)$$

or

$$x=\frac{a_1b_1-a_2b_2}{(a_1-b_1)(a_2-b_2)} \quad (3)$$

Thus, it is possible to calculate x, and therefrom the value of K with the help of expression 1.

The value of the stability constant, thus calculated, has also been corroborated by the value obtained by the mole ratio method through a calculation of the degree of dissociation, as suggested by Harvey and Manning[17].

Results and Discussion

Rehavior of the Reagent as a Colloidal Electrolyte.—In view of the behavior of a number of dyes as colloidal electrolytes, electrical conductance studies were performed with aqueous solutions of Chrome Azurol S to investigate its colloidal characteristics, if any[18]. The reagent has been found to behave as a colloidal electrolyte and hence, as emphasized by Dey[19] that in the case of colloidal solutions, the characteristics of a true solution are often displayed when extremely dilute solutions are used, very dilute solutions of the order $\approx 10^{-4}$ and 10^{-5} M were employed in the present studies.

Rate of Color Formation and Stability of Color at Room Temperature.—The color formation does not depend upon reaction time and is instantaneous. However, the mixtures were kept for one hour after preparing, to allow for equilibration. A mixture containing 5.0×10^{-5} M thorium chloride and 5.0×10^{-5} Chrome Azurol S at pH 4.5 retained its absorbance value x even after seventy two hours.

19) A. K. Dey, ibid., **3**, 473 (1948).

Influence of Temperature.—The color intensity changes slightly above 40°C, as evident from Table I.

Order of Addition of Reagents.—No appreciable change in observations was found to occur when the order of the addition of reagents was alternated. However, a slightly better sensitivity was obtained, when the reagent solution was added to the metallic ion after the pH and ionic strength of the latter were adjusted to the proper values.

Beer's Law.—A calibration curve was prepared in order to determine whether or not the thorium-Chrome Azurol S complex obeys Beer's law. A series of solutions containing varying amounts of thorium ions and excess reagent were prepared. The color intensity was measured against a reagent blank. A plot of the data showed that the complex concentration is proportional to the absorbance between the concentration limits of 0.23 and 8.35 p. p. m. of thorium, as indicated by the straight lines over this range (Figs. 1 and 2).

Nature of the Complex in Solution. — The method of Vosburgh and coworkers[20] was employed to determine the nature of the complexes formed in solution. Mixtures containing thorium chloride and Chrome Azurol S in different stoichiometric ratios (e. g., 3 : 1, 2 : 1, 1 : 1, 1 : 2, 1 : 3, etc.) were prepared and absorbance of each of them was measured at suitable intervals between a range of

wavelength from 350 to 750 mμ The results plotted graphically in Fig. 3 show that reagent has its maximum absorption at 470 mμ at pH 4.5 (curve A). In curves B, C, D, E and F, the wavelength of maximum absorbance shifts to 550 mμ. In curves E and F, where Chrome Azurol S is present in excess slight peaks near about 485 mμ may be seen to occur. However, in every case, there is a clear indication of the formation of only one complex in solution under the conditions of study having λ_{max} at 550 mμ. (This fact is further confirmed by the results obtained at different wavelengths of study.)

that the thorium-Chrome Azurol S chelate consists of one thorium ion to one molecule of reagent, and hence, may be represented as Th (CAS).

Results of the mole ratio method also (Figs. 10 and 11) lend a corroboration for the same composition of chelate.

Calculation of the Stability Constant.—The values of the stability constant (log K), as determined by two different methods outlined earlier, are described in Table IV. The particular values of pH and ionic strength, which were maintained constant, are also mentioned. Also, the free energy change of formation has been calculated with the help of the expression.

$$\Delta F° = -RT\ln K$$

the terms having their usual meaning:

The results obtained by both the methods agree fairly with each other. The values and the methods may, hence, be taken as reliable.

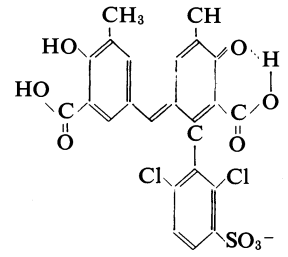
Suggestions on the Structure of the Chelate.—It may be seen from the structure of the reagent Chrome Azurol S, that the trisodium salt is ionizable and in neutral solutions, the compound probably exists as a trivalent anion.

According to the color changes that the compound undergoes with variation in hydrogen-ion concentration of the medium, it may be concluded that it exists in at least three different structural forms. The wavelength of maximum absorbance of the reagent depends upon the pH as follows.

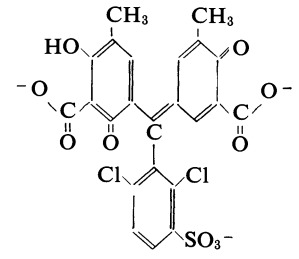
TABLE V

pH	Wavelength of maximum absorbance, λ_{max}, mμ
1.50~5.15	465, 490
6.00~10.15	425
11.65 and above	595

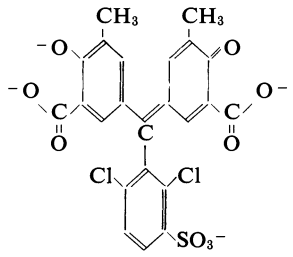
The following structures, therefore, appear to be reasonable for the reagent in the acidic, neutral and alkaline media:



(I) Acidic medium



(II) Neutral medium



(III) Alkaline medium

It is not possible to obtain definite information on the position of the chelate ring in the thorium-Chrome Azurol S chelate from the experimental results described in the present paper. Still it may be evident that there are two alternative positions where chelation might occur. The metal ion may be coordinated either between the quinoid oxygen and the adjacent oxygen of the carboxylic group, or between the phenolic oxygen and the adjacent carboxylic oxygen. It may be noted that the wavelength of maximum absorbance of the chelate is 550 mμ. The λ_{max} of the reagent alone lies at 595 mμ in a strongly alkaline medium, where the structure seems to suggest the removal of the phenolic hydrogen by ionization. In a neutral medium on the other hand, the reagent is observed to have maximum absorption at 425 mμ. Since the wavelength of maximum absorbance of the chelate is more near to that of structure III, rather than to structures II and I it is very likely that the phenolic hydrogen gets replaced during the process of chelation. Hence, it appears reasonable to suggest that the chelation in this case occurs between the phenolic and the carboxylic oxygens and not between the quinoid oxygen and the adjacent carboxylic oxygen.

Effect of Hydrogen-Ion Concentration.—The absorbances of mixtures containing thorium chloride and Chrome Azurol S in the ratio 1 : 1 (concentration of each 8.0×10^{-5} M) at different pH were measured at various wavelengths. Figure 13 shows the results, where it is clearly seen that the wavelength of maximum absorbance of the chelate is 550 mμ from pH 2.50 to 7.25, indicating thereby that the same is stable within this range of pH. The variation with pH in color intensity of the

chelate at its λ_{max} is also represented in Fig. 12.

Sensitivity of the Reaction. — According to Sandell's expression, the sensitivity is 0.0047 γ/cm² at 550 mμ. The practical sensitivity, based on an absorbance of 0.010 unit, is 0.047 γ/cm².

Effect of Diverse Ions.—The effect of a large number of cations and anions has been studied and the tolerance limits calculated out in each case. For tolerance limit, that concentration of foreign ion has been chosen which affects the absorbance of the system by less than ±2%. It has been found that copper(II), beryllium(II), aluminum(III), iron(II), iron-(III), uranium(VI), zirconium(IV), oxalate, borate, citrate, tartrate, carbonate, fluoride and thiocyanate interfere at all concentrations as shown by the results listed in Table VI:

Suggested Procedure for the Colorimetric Determination of Thorium.—For the determination of thorium, using Chrome Azurol S as a reagent, the following procedure may be suggested: The interfering substances should be removed from the sample by the usual methods. The pure solution of thorium ions, thus obtained may directly be treated with a freshly prepared solution of Chrome Azurol S. The reagent should be added in about ten fold molar excess. The temperature should be maintained below 40°C and the pH at 4.5±0.2. The absorbance may be measured with a spectrophotometer and compared with a standard calibration curve to give the amount of thorium.

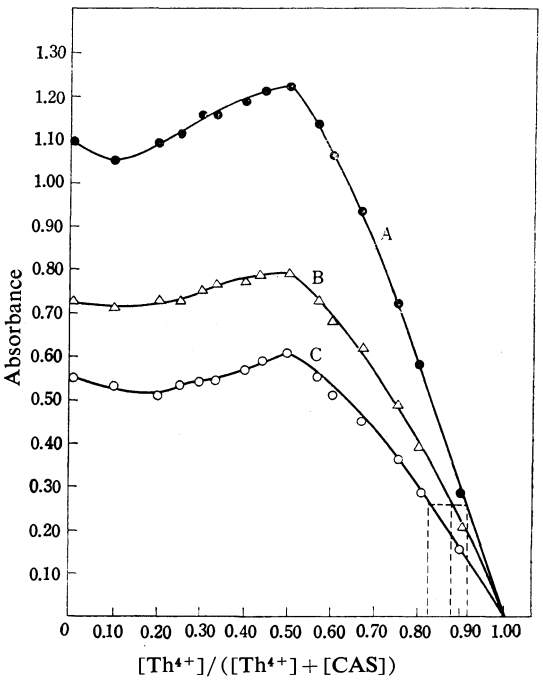

Fig. 14. Determination of the stability constant from absorbance data at 550 mμ. Concentrations, pH and μ same as in Fig. 4.

*The Cationic Copolymerization of Styrene and p-Bromostyrene in Liquid Sulfur Dioxide**

By Niichiro TOKURA, Minoru MATSUDA and Masashi IINO

(Received August 11, 1962)

The effect of a solvent on the monomer reactivity ratios in cationic polymerization has been the subject of recent study. Overberger et al., carrying out the cationic copolymerization of styrene and *p*-chlorostyrene in carbon tetrachloride and nitrobenzene respectively, found no appreciable difference in r_1's and r_2's[1a,b]. However, in the cationic polymerization of *p*-chlorostyrene with isobutene, r_1 and r_2 varied as the solvent used was changed[1c]. They therefore suggested that the independence of r_1 and r_2 in the former case was due to the similarity of the structure of the comonomers applied[1b].

Marvel and Dunphy[2] have shown that the cationic copolymerization of 2-chloroethyl vinyl ether with α-methylstyrene and its derivatives resulted in a marked difference in the monomer reactivity ratios according to the solvents applied. Pepper[3] first found that the rate of cationic polymerization is largely dependent on the dielectric constants of the solvents applied. However, other examples have also been shown in which anomalies in the relationship between the dielectric constants of the solvents and the rates have been observed[4,5].

This paper aims at the elucidation of the effect of liquid sulfur dioxide on the cationic polymerization. A cationic copolymerization of styrene and *p*-bromostyrene in liquid sulfur dioxide has been undertaken; the results will be described below. The cationic polymerization in liquid sulfur dioxide differs from that in any other solvent; viz., in liquid sulfur dioxide, (1) the polymerization is much faster than that which would be expected from the dielectric constant of the solvent (liquid sulfur dioxide)[6a], (2) the reaction is assisted by a number of sulfur dioxide molecules in the transition state[6b], and (3) the chain transfers, both to the monomer and the solvent, are very small[6a]. Accordingly, somewhat different results have been expected in this copolymerization.

Experimental

Materials.—Styrene (U.C.C. product) was distilled twice in vacuo in a nitrogen atmosphere. *p*-Bromostyrene was prepared by a known method[7]; b. p., 89°C/13 mmHg, n_D^{20}, 1.5931. Boron trifluoride etherate was distilled twice in a nitrogen atmosphere. Liquid sulfur dioxide was dried over phosphorus pentoxide and distilled. Carbon tetrachloride was refluxed with sodium hydroxide and distilled. Benzene was purified by the ordinary method. Nitrobenzene was washed with a sodium hydroxide solution and with water, dried with phosphorus pentoxide, and distilled in vacuo. Ethylene dichloride was washed with sodium hydroxide and then with water, dehydrated with phosphorus pentoxide, and distilled. *p*-Cymene was washed with concentrated sulfuric acid, an aqueous sodium hydroxide solution, and water successively, dehydrated with calcium chloride, and distilled in vacuo in a nitrogen atmosphere. Cyclohexane was shaken with a mixture of ten per cent of concentrated sulfuric acid and one per cent of fuming sulfuric acid for 24 hr., washed with water, a sodium hydroxide solution, a potassium permanganate solution and water successively, dehydrated with calcium chloride, and distilled over sodium wire.

Method of Polymerization.—Styrene, *p*-bromostyrene and solvent were pipetted into a glass pressure vessel of 20 ml. capacity. The mixture was then, with the catalyst (borontrifluoride etherate), added to liquid sulfur dioxide. The polymerization was started in a constant temperature bath. The reaction was stopped by mixing in a large quantity of methanol. The precipitate was washed with methanol and dried in vacuo. From the weight of the copolymer produced, the rate of the polymerization was calculated. The composition of the copolymer was calculated from the elementary analysis.

Results and Discussion

The Overall Rate of Copolymerization.—To a system consisting of styrene $(St)_0$ (3.0 ml.), *p*-bromostyrene $(BSt)_0$, and liquid sulfur dioxide $(SO_2)_0$ (3.0 ml.) with a catalyst $(BF_3Et_2O)_0$, was added 3.0 ml. of solvent of various dielectric constants. The reaction mixture then consisted of, $(St)_0$ 2.2, $(BSt)_0$ 1.9 and $(BF_3Et_2O)_0$ 5.7×10^{-3} mol./l., respectively. The added solvents were nitrobenzene (dielectric constant at 20°C $D=34.8$), ethylene dichloride ($D=10.4$), carbon tetrachloride ($D=2.3$) and benzene ($D=2.3$). The polymerization was conducted at −15°C.

The relationship between the mixed solvents and the rates of the copolymerization at −15°C is visualized in Fig. 1. As is seen in the figure, the copolymerization in pure liquid sulfur dioxide is the fastest among those in the solvent mixtures. This result is also consistent with the previous finding from the cationic polymerization in liquid sulfur dioxide[6a]. In Fig. 2, similar experiments with added solvents of small dielectric constants are compared: ($(St)_0$, 3.0 ml. (1.9 mol./l.), $(BSt)_0$, 3.0 ml. (1.6 mol./l.), $(BF_3Et_2O)_0$, 3.0×10^{-3} mol./l., $(SO_2)_0$, 3.0 ml., added solvent 5.0 ml., respectively, at −10°C). Although the dielectric constants of the added solvents were very close to each other, it is to be noted that a marked difference among the rates is to be found.

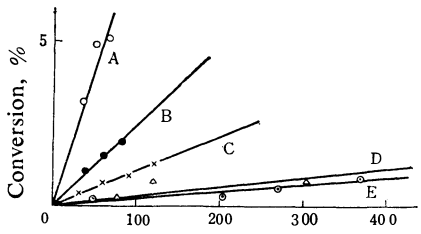

Fig. 1. Conversion vs. time plots.

A Cyclohexane with liq. SO_2
B Carbon tetrachloride with liq. SO_2
C *p*-Cymene with liq. SO_2
D Benzene with liq. SO_2
E Ethylene dichloride with liq. SO_2

The rate of copolymerization may be varied as the interaction of the solvent in this system changes. By the addition of cyclohexane to this system the rate is hardly affected. The order of rate is:

cyclohexane ($D=2.0$) > carbon tetrachloride ($D=2.3$) > *p*-cymene ($D=2.2$) > benzene ($D=2.3$)

and the largest rate drop is brought about by the addition of benzene. Despite the larger dielectric constant of ethylene dichloride ($D=10.4$), its rate ranks among the smallest, as may be seen in Fig. 2. The action of the added solvent on the rate of the cationic polymerization in liquid sulfur dioxide has already been shown and discussed in a previous article[6b], in which aromatic hydrocarbons in the liquid sulfur dioxide-polymerizing system also has a rate retarding effect.

Monomer Reactivity Ratio. — The monomer reactivity ratios were calculated according to

c) As the rate of the copolymerization (without liquid sulfur dioxide) was very slow, the catalyst content was increased.

the intersection method of Mayo and Lewis[8]. A typical example is shown in Figs. 3 and 4. In Fig. 3, feed vs. copolymer composition plots for the copolymerization in pure liquid sulfur dioxide at the temperatures of −20, −15 and 10°C with BF_3Et_2O are visualized. In Fig. 4, r_1 and r_2 are plotted to obtain the most suitable value of the monomer reactivity ratio for the result in Fig. 3 (−20°C). The MRR's (monomer reactivity ratios) of styrene (r_1) and *p*-bromostyrene (r_2) in liquid sulfur dioxide were found to be 0.8 and 0.4, respectively. As is shown in Fig. 3, the MRR's in liquid sulfur dioxide were independent both of the temperature of the reaction and of the quantity of the catalyst (BF_3Et_2O) used in the copolymerization.

The r_1's and r_2's were also calculated, by the same method, in the binary mixtures of

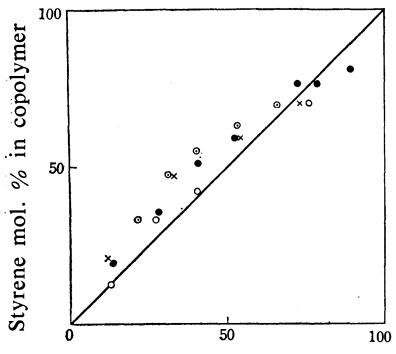

Fig. 5. Feed vs. copolymer composition plots in mixed solvents.

○ CCl_4 × Ethylene dichloride

solvent and liquid sulfur dioxide and in pure solvents. The results are summarized in Table I. Figures 5 and 6 are the summarized plots of the feed vs. copolymer composition diagram in various solvents.

The MRR's were measured in equi-volume mixtures of liquid sulfur dioxide and the added solvents at −15°C. In system without liquid sulfur dioxide, since the rate of the copolymerization is too slow to permit the adequate performance of the experiment, the catalyst was increased to 10×10^{-3} in nitrobenzene and to 30×10^{-3} mol./l. in the other solvents respectively, as is described in Table I. The MRR's in the mixture of liquid sulfur dioxide with equi-volumes of *p*-cymene, *p*-xylene and cyclohexane were each also estimated by the same procedures; 0.9 and 0.4 were the values found for r_1, and r_2 respectively, which figures were similar to those of benzene.

The copolymerization in liquid sulfur dioxide is very fast. This fact is consistent with the previous finding that cationic polymerization

8) F. R. Mayo and F. M. Lewis, *J. Am. Chem. Soc.*, **66**, 1594 (1944).

is the fastest in liquid sulfur dioxide[6a] and with the fact that the Beckmann rearrangement in liquid sulfur dioxide is instantaneous[9].

In liquid sulfur dioxide, the monomer reactivity ratios are independent both of the temperatures and of the concentration of the catalyst in the reaction.

It is a very interesting finding that the MRR's in the respective solvents are very similar ($r_1=1.6$ and $r_2=0.3$), whereas by adding liquid sulfur dioxide the MRR's of r_1 drop to 1~0.7, while in liquid sulfur dioxide r_1 is 0.8 in spite of the similarity in the comonomer structure. When sulfur dioxide is added to the system the chain end of the styryl carbonium ion may lose its selectivity to styrene, the reactivity for *p*-bromostyrene being increased. The product of $r_1 \times r_2$ in liquid sulfur dioxide is 0.32, and the composition of the copolymer approaches that of the alternative copolymer. This finding is also in good accordance with the explanation above mentioned.

Summary

1) The cationic copolymerization of styrene and *p*-bromostyrene in liquid sulfur dioxide using boron trifluoride etherate as a catalyst has been carried out; the monomer reactivity ratios (MRR) have been found to be $r_1=0.8$ and $r_2=0.4$. The MRR value was independent of the temperature and of the quantity of the catalyst in the copolymerization.

2) The effect of added solvents in liquid sulfur dioxide has also been examined. However, the MRR's have been little affected by the added solvents, the rates of the copolymerization have largely been depressed, and the rates were not dependent on the dielectric constants of the added solvents, the rate in pure liquid sulfur dioxide being the fastest.

3) The same cationic copolymerization has been conducted in benzene, carbon tetrachloride, nitrobenzene and ethylene dichloride.

The MRR's were almost equal in all ($r_1=1.8$ and $r_2=0.3$).

The authors are indebted to the Seitetsu Kagaku K.K., Ltd., for its donation of liquid sulfur dioxide. A part of the expense for this project has been defrayed by a grant-in-aid by the Ministry of Education.

A Study of the Properties of Mixed Solutions of Sodium Dodecyl Sulfate and Dodecyl Alcohol

By Fumikatsu TOKIWA

(Received September 7, 1962)

A number of studies have reported on the effect of long-chain alcohols on such properties of solutions of surface active agents as their electrical conductivity and solubilizing power. Most of these studies have been made with solutions in which the additives have been dissolved completely by solubilization. However, it is also of importance to study the properties of those mixed solutions in which the amount of additives far exceeds that solubilized.

In previous papers[1-4] studying mixed solutions of sodium dodecyl sulfate and dodecyl alcohol, it was established that there exist some complexes composed of sodium dodecyl sulfate and dodecyl alcohol in the mixed solutions. Spectral experiment[2] on the mixed solutions indicated that the metachromatic color of toluidine blue changes abruptly to a normal color at a certain concentration of sodium dodecyl sulfate, the point depending on the amount of dodecyl alcohol. A similar color change has also been observed for the solution in the temperature 37~40°C range[2].

In the present paper electrical conductivity and viscosity measurements have been carried

out in order to study the properties of the mixed solutions in further detail.

Experimental

Materials.—Dodecyl alcohol (DA) was purified by repeated fractional distillation under reduced pressure. Gas chromatography failed to detect its homologues. The hydroxyl value of DA was found to be 301.0 (calcd. 301.1). Sodium dodecyl sulfate (SDS) was prepared from DA by the method of Dreger et al.[5] and was purified by repeated recrystallization from ethanol, followed by extraction with petroleum ether.

Preparation of Mixed Solutions.—A previously described method[1,2] was used for preparing the mixed solutions of SDS and DA. When a precipitate appeared in the stock solution during storage, it was heated to about 50°C before use, causing the precipitate to disappear.

Electrical Conductivity and Viscosity Measurements.—Electrical conductivity was measured with a conductance bridge, a Yanagimoto Model MY-7. The platinum electrodes were slightly platinized, and the cell constant was 0.482. The water used in preparing the solutions had a specific conductance of $1.0\sim1.5\times10^{-6}$ ohm^{-1} cm^{-1}. The observed values were checked by measuring the equivalent conductances of potassium chloride solutions.

Viscosity was measured with an Ostwald-type viscometer, the flow time for water being 140.5 sec. The measurements were performed at varying temperatures ranging from 20 to 50°C with an accuracy of ±0.01°C.

Results and Discussion

In Fig. 1 the equivalent conductance of an aqueous solution of SDS is plotted against the square root of the SDS concentration with the addition of varying amounts of DA at 30°C. In some cases, the conductance decreased slightly with time in the regions indicated by dotted lines in Fig. 1. Therefore, the reading was taken after the constant value had been attained, which required from 70 to 90 min. Most of the curves represent averages of at least two series of measurements. The addition of DA lowered the conductance, the degree of lowering increasing with an increasing amount of DA for a fixed concentration of SDS.

It has been shown in previous papers that SDS molecules or ions form a complex with DA molecules in the mixed solution, even in the region of a low concentration of SDS. Spectral studies[3,6], furthermore, have suggested that the ion-head of SDS is markedly affected

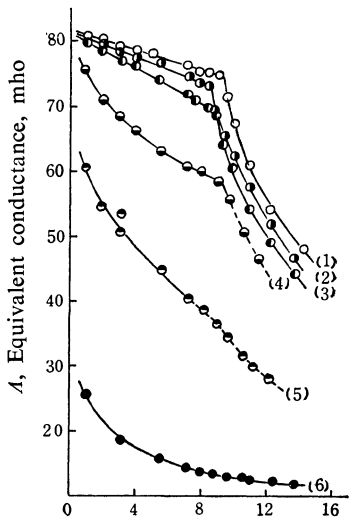

Fig. 1. The equivalent conductance plotted against the square root of the concentration of SDS with the addition of varying amount of DA at 30°C. The relative mole fractions of SDS and DA are; (1) 1.00 : 0.00, (2) 0.94 : 0.06, (3) 0.85 : 0.15, (4) 0.70 : 0.30, (5) 0.50 : 0.50, (6) 0.30 : 0.70.

by the hydroxyl group of DA in the complex formation. Therefore, one may explain the decrease in electrical conductance by the complex formation.

It can been seen in Fig. 1 that, in the mixed solutions, SDS exhibits a conductance behavior typical of ionic detergents up to a 0.3 mol. fraction of DA in SDS-DA. These curves exhibit a break point characteristic of critical concentration at a definite concentration of SDS. It is known that, when DA molecules are present in small amounts, they promote micelle formation and thus lower the critical concentration[7,8]. We can also observe a similar tendency in Fig. 1, though the effect there is not so distinct.

Previous investigation[2] has shown that the metachromatic color of toluidine blue in SDS-DA solutions returns abruptly to a normal color at a certain concentration of SDS, depending on the amount of DA present. The break point of the conductance concentration curve is considered to correspond to the point of this color change. In the present experiment, however, the effect of DA on the critical concentration seems to be not so marked.

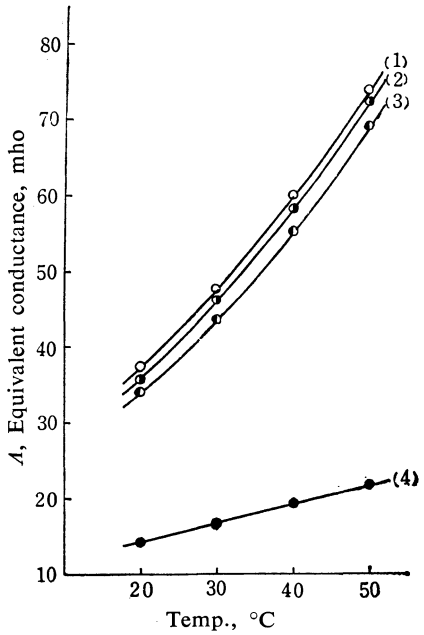

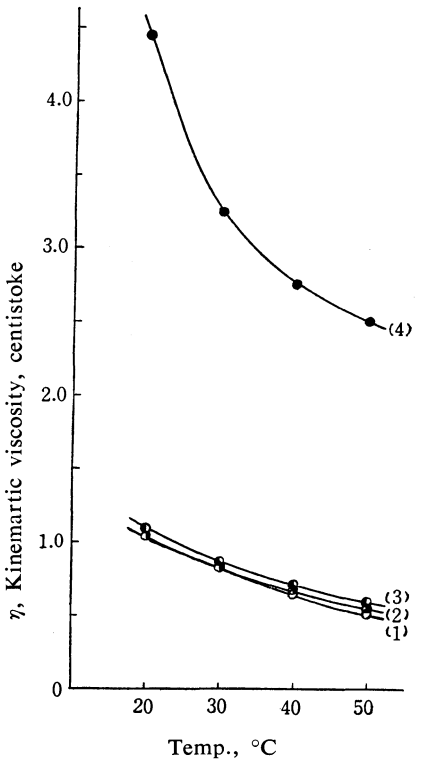

Fig. 2 and Fig. 3. The equivalent conductance and kinematic viscosity plotted against the temperature, for 0.02 molar SDS alone and with DA. The relative mole fractions of SDS and DA are; (1) 1.00 : 0.00, (2) 0.94 : 0.06, (3) 0.85 : 0.15, (4) 0.50 : 0.50.

The variation of the conductance with temperature is shown in Fig. 2 for 0.02 mol. SDS with varying amounts of DA. Figure 3 illustrates the variation of the viscosity for the same solutions. It may be seen in Figs. 2 and 3 that the presence of DA has little effect on the nature of the conductance and viscosity, except for the mixed solution containing a 0.5 mol. fraction of DA in SDS-DA.

In most aqueous solutions the change in conductance with the change in temperature is mainly caused by the change in viscosity, according to Walden's rule[9]. This is true insofar as the solution contains SDS alone, as is shown in Fig. 4, where the product of the conductance and of the viscosity is almost independent of the temperature. However, for mixed solutions with 0.06 and 0.15 mol. fractions of DA in SDS-DA, the product increases slightly with the increasing temperature. This may be explained either by an anomalous increase in conductance or by a decrease in viscosity with the increase in temperature. The results of the present experiment are consistent with the former explanation in that a change in the metachromatic color of toluidine blue in the mixed solutions occurs at relatively high temperatures (37~40°C)[2]. Since this

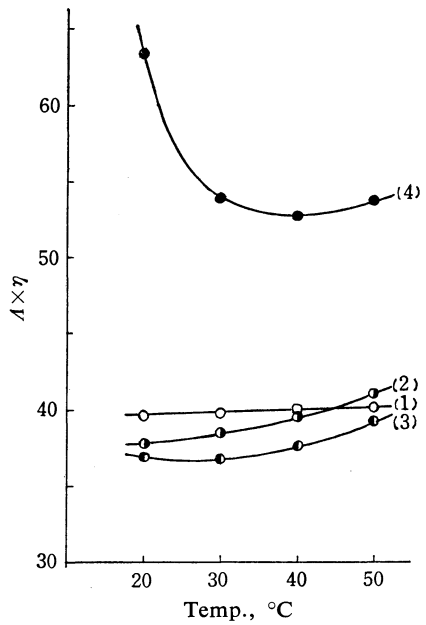

Fig. 4. The product of the equivalent conductance and the kinematic viscosity plotted against the temperature, for 0.02 molar SDS alone and with DA. The relative mole fractions of SDS and DA are; (1) 1.00 : 0.00, (2) 0.94 : 0.06, (3) 0.85 : 0.15, (4) 0.50 : 0.50.

9) A. F. Ward and A. G. Chitale, *Proc. 2nd. Int. Cong. Surface Activity*, 1, 319 (1956).

observation of color change can be interpreted in terms of the decomposition of the SDS-DA complex into SDS and DA, the slight increase in the product may be explained as due to the decomposition of the complex. In the presence of 0.5 mol. fraction of DA, the viscosity behavior somewhat differs. The fact that at low temperatures the mixed solution is very viscous and still shows a relatively good conducting property is an indication of the formation of involved complexes through which the positive ions can easily move.

Summary

Measurements have been made of the electrical conductivity and the viscosity of mixed solutions of sodium dodecyl sulfate (SDS) and dodecyl alcohol (DA). The addition of DA caused a lowering of the conductance, a phenomenon probably related to the formation of a complex composed of SDS and DA, but it did not essentially alter the form of the $\Lambda-\sqrt{c}$ curves up to 0.3 mol. fraction of DA in SDS-DA. The $\Lambda-\sqrt{c}$ curves of the mixed solution exhibit a break point which corresponds to a critical concentration of SDS, up to a 0.3 mol. fraction of DA in SDS-DA; the break point becomes obscure when the amount of DA present is larger than this value. The effect of the amount of DA on the critical concentration was not very large in this experiment.

The variation of the conductance and viscosity with the temperature was measured on the solution of SDS with varying concentrations of DA. For the solution of SDS without DA, the product of the conductance and the viscosity is almost independent of the temperature, while for the mixed solutions the product is dependent on the temperature, especially in the case of the mixed solution containing a considerable amount of DA.

The author wishes to express his hearty thanks to Professor Toshizo Isemura of Osaka University for his kind advice and encouragement throughout this work. Thanks are also due to Mr. Zenichi Miyagawa, Director of this Research Laboratory, for permission to publish this paper, and to Dr. Iwao Maruta for his encouragement.

Sterically-hindered Organosilicon Compounds Containing Cyclohexyl Groups. II[1]. *Hydrogenation of Phenylsilicon Compounds*

By Michio TAKAKUSA

(Received September 24, 1962)

Since Cusa and Kipping[2] studied the reaction of cyclohexylmagnesium chloride with phenyltrichlorosilane, much effort has been made to overcome the steric hindrance of a cyclohexyl group and prepare highly substituted organosilicon compounds with the cyclohexyl groups. Recently, reactions between fluorosilanes and organolithium compounds[3] were shown to be quite effective ways to obtain those compounds, and preparation of a series of tricyclohexylalkyl- and -aryl-silanes by this method was studied by the present author[1]. Steric hindrance of three cyclohexyl groups attached to one silicon atom does not allow the introduction of a *sec*-alkyl group as the fourth substituent even with this powerful combination of reagents.

The steric hindrance here implies merely that the formation of an intermediate complex is prevented, or simply, attack of the reagent on the silicon atom is obstructed. In these cases, dimensions of both reagents should be naturally considered, as well as their reactivities. It is also quite obvious that magnitude of steric hindrance varies with a type of reaction.

Cyclohexane derivatives are often prepared by hydrogenation of corresponding benzene derivatives, and the method can be applied to the preparation of organosilicon compounds

1) Part I: M. Takakusa, This Bulletin, **36**, 31 (1963).
2) N. W. Cusa and F. S. Kipping, *J. Chem. Soc.*, **1933**, 1040.

containing cyclohexyl groups[4,5]. As this reaction involves attack on the phenyl group surrounding silicon, not on the silicon atom, by the smallest hydrogen atom[6], the steric hindrance will be much less important. Kanazashi and Takakusa prepared tetracyclohexylsilane[5a], hexacyclohexyldisilane[5b], and some other related compounds in this way.

The present paper reports hydrogenation of several phenylsilicon compounds as a route to cyclohexylsilicon compounds, and the results are compared with those of organolithium compound route obtained in the preceding paper[1]. Attempts were made to prepare tricyclohexyl-isopropylsilane and -*t*-butylsilane through the interactions of triphenylfluorosilane with the corresponding alkyllithiums followed by hydrogenation of the products, since they are expected to be the most hopeful ways for the preparation of these compounds.

Experimental*

Triphenylbutylsilane.—*From Triphenylchlorosilane.* —Triphenylbutylsilane was prepared from the interaction of the chlorosilane with *n*-butyllithium in a yield of 55%. M. p. 87.8~88.5°C (reported[7], 87.5~88°C).

From Butyltrichlorosilane.—A mixture of 9.6 g. of butyltrichlorosilane and 17 g. of chlorobenzene was added dropwise to a mixture of 7 g. of sodium sand and 120 ml. of benzene, the whole mixture refluxed for 2 hr., and then treated with water. Evaporation of the solvent from the benzene layer yielded a crude solid from which 2 g. of triphenylbutylsilane, m. p. 87.5~88°C, was separated. The mixed melting point measurement of both materials did not show any depression.

Triphenylisopropylsilane (Attempted). — Isopropyllithium was prepared in ethyl ether from 0.7 g. of lithium and 5.3 g. of isopropyl bromide in a 300 ml. three-necked round-bottomed flask equipped with a reflux condenser, protected with a calcium chloride tube, a mercury-sealed stirrer and a dropping funnel under nitrogen atmosphere. To the isopropyllithium solution was added 40 ml. of triphenylfluorosilane (6.5 g.) solution in ethyl ether, the mixture refluxed, the solvent replaced by petroleum ether (b. p. 70~90°C), and then the mixture refluxed for 7 hr. From the reaction mixture, 0.2 g. of crude hexaphenyldisiloxane and 1.8 g. of triphenylfluorosilane were recovered.

Triphenyl-*t*-butylsilane (Attempted).—To *t*-butyllithium solution prepared from 4.0 g. of lithium and 22.2 g. of *t*-butyl chloride in petroleum ether (b. p. 30~50°C) was added 7.15 g. of triphenylfluorosilane. The mixture was refluxed with stirring, the solvent gradually replaced by higher boiling petroleum ether, the content of the flask kept refluxing for 16 hr. From the reaction mixture 84% of triphenylfluorosilane and 10% of hexaphenyldisiloxane were recovered. The repeated run using 10.1 g. of lithium and 54.3 g. of *t*-butyl chloride also failed to yield the desired product.

Tricyclohexylphenylsilane. — Prepared in a previous report[1]. M. p. 207~208°C.

Triphenylphenoxysilane. — To sodium phenoxide prepared from 18.6 g. of phenol and 2.5 g. of sodium in benzene 26.7 g. of triphenylchlorosilane dissolved in benzene was added dropwise, and the mixture refluxed for 6 hr. The solvent was distilled off, and 9.2 g. (30%) of triphenylphenoxysilane, m. p. 101~103°C, obtained. Recrystallization from petroleum ether gave 8.4 g. of th material melting at 103~105°C (reported[8], 103~104°C). Found: C, 81.04; H, 5.38. Calcd. for $C_{24}H_{20}OSi$: C, 81.77; H, 5.72%.

Raney Nickel Catalyst. — The catalyst, Adkins' "W-6"[9], was prepared in the same way as that in a previous paper[5a], and stored under absolute alcohol in a refrigerator. The alcohol was replaced by the reaction solvent before being used. Several attempts to obtain more active catalysts showed that lower temperature in development and digestion caused much loss of the catalyst during washing process, though the catalyst appeared to carry higher activity.

Hydrogenation Procedure. — Unless otherwise described, phenylsilanes were dissolved in 40~50 ml. of cyclohexane, and hydrogenated over Raney nickel catalyst. A 100 ml. stainless steel autoclave equipped with a magnetic inner agitator was used, and about 100~110 atm. of hydrogen was charged. Other conditions are listed in Table I.

Tricyclohexylbutylsilane.—(a) (Table I, No. 1) Evaporation of solvent from the hydrogenated mass yielded a crude material melting at about 100°C. Crystallization of the material from ethanol gave 0.35 g. of impure tricyclohexylbutylsilane melting at 149~154°C, and, from its mother liquor, 0.1 g. of another material melting at 86~100°C was obtained. The latter was subjected to chromatography on alumina and separated into two components, one melting at 92~98°C and the other at 111~122°C, but further purifications were not successful. Recrystallization of the impure tricyclohexylbutylsilane raised the melting point to 157~158°C.

(b) From the hydrogenation of 1.6 g. of triphenylbutylsilane was obtained 0.7 g. of a crude material melting at 151~156°C. Three recrystallizations from ethanol-benzene (3 : 1) yielded 0.4 g. of tricyclohexylbutylsilane, m. p. 159~160°C (see the previous paper[1]). (Found: C, 78.87; H, 12.22. Calcd. for $C_{22}H_{42}Si$: C, 78.95; H, 12.65%).

From the mother liquor of the first recrystallization, 0.02 g. of a compound which melts at 97~106°C was obtained, but further purification was not successful.

Tetracyclohexylsilane.—*From Tricyclohexylphenylsilane (Table I, No. 2).* — The solvent was distilled off, and 2.2 g. of a solid melting at 271~275°C was obtained. Recrystallization from benzene gave 1.8 g. of tetracyclohexylsilane, m. p. 276~278°C. Mixed melting point with an authentic sample[5a] did not show depression.

From Tetraphenylsilane (Table I, No. 3). — In a similar way, tetracyclohexylsilane was obtained. The concentrated mother liquor was chromatographed on alumina, but no solid but tetracyclohexylsilane was obtained.

Tricyclohexylphenylsilane. — (Table I, No. 4). Products of partial hydrogenation were separated by chromatography on alumina with petroleum ether as an eluent, and 0.4 g. of a solid melting at 200~230°C, 0.2 g. of a solid melting at about 200°C and 0.3 g. of material melting at 120~140°C were obtained. The middle fraction, melting at 200°C, was recrystallized from ethanol and ethanol-benzene to give pure tricyclohexylphenylsilane, m. p. 204~206.5°C. (Found: C, 81.80; H, 10.77. Calcd. for $C_{24}H_{38}Si$: C, 81.28; H, 10.80%.)

Mixed melting point with an authentic sample[1] did not show any depression.

Hydrogenation of Triphenylsilanol at Higher Temperature. — The reaction mixture of the Run No. 8 of Table I was a very sticky viscous liquid, from which neither tricyclohexylsilanol nor hexacyclohexyldisiloxane was separated. Its infrared spectrum does not show an absorption near 4.7 μ of Si-H bond. From another run carried out at about 150°C, a sticky liquid was obtained, from which only a low yield of tricyclohexylsilanol was separated.

Tricyclohexylcyclohexoxysilane (Attempted). — (Table I, No. 10). Hydrogenation of triphenylphenoxysilane gave a material melting at 168~171°C, but not tricyclohexylcyclohexoxysilane. The product was recrystallized twice from petroleum ether to give a compound melting at 175~176.5°C, which was identified as tricyclohexylsilanol by mixed melting point measurement. Cyclohexanol seemed to be also formed.

Results and Discussion

Isopropyltriphenylsilane or *t*-butyltriphenylsilane has not been reported yet in the literature. Incidentally, attempts to prepare them by treating triphenylfluorosilane with the corresponding alkyllithiums were also unsuccessful probably due to steric hindrance, and hence, only tricyclohexylbutylsilane and tetracyclohexylsilane were prepared by hydrogenation as members of a tricyclohexylalkylsilane series. Tricyclohexylphenylsilane was prepared by partial hydrogenation of tetraphenylsilane.

Hydrogenation of hexaphenyldisilane and hexaphenyldisiloxane, which was the subject of a previous paper[5b], was also carried out under similar conditions for comparison. The reaction conditions are shown in Table I. Apparent difference in reaction conditions does not lead to any significant conclusion, since the activity of the catalyst used could not be uniform throughout the series of experiments, and all starting materials were finally converted into the desired products. The greatest difficulty was encountered with hexaphenyldisilane, where the product should have the largest steric requirement among the compounds studied here. With this compound, hydrogen absorption occasionally ceased, but every addition of some fresh catalysts to the system started the reaction again until the calculated amount of hydrogen was completely absorbed. One possible explanation is not steric hindrance but simply low solubility of the product. As the hydrogenated disilane is hardly soluble in the solvent, it probably covered the surface of nickel catalyst, reducing its activity temporarily. It was actually observed that a pretty strong activity had still remained in the used catalyst after completion of the reaction. Furthermore, the difficulty was reduced when a diluted sample was hydrogenated.

The series of studies on hydrogenation of phenylsilicon compounds showed that steric hindrance is not important in hydrogenation process of those compounds and allows the formation of several cyclohexylsilicon compounds that can not be obtained by other

a) Partial hydrogenation b) Methylcyclohexane was used as a solvent.

conventional methods. The steric effects of the residual or pre-existing groups are also small, and limitation of this method for preparation of cyclohexane derivatives in silico-organic chemistry does not lie in steric hindrance.

Si–C and Si–Si bonds are stable enough in the hydrogenation process, and many sterically-hindered cyclohexylsilanes were prepared by hydrogenation without any cleavage of those bonds. The siloxane bond is also stable to hydrogenation, but hydrogenation of triphenylsilanol at higher temperature often yielded a very sticky liquid. The optimum temperature for obtaining tricyclohexylsilanol seems to be 100~120°C, and at a higher temperature a yield of tricyclohexylsilanol was largely reduced. Stability of triphenylsilanol under hydrogen at higher temperature was studied by Dolgov et al.[10], and it was shown that the silanol was converted into hexaphenyldisiloxane at 280°C. Under the present conditions, however, no solid product but tricyclohexylsilanol was obtained, nor any compound with Si–H bond was detected by infrared measurement. An attempt to obtain tricyclohexylcyclohexoxysilane by hydrogenating triphenylphenoxysilane was unsuccessful, and only tricyclohexylsilanol was obtained, probably as a result of hydrolysis.

10) B. N. Dolgov and Yu. N. Volnov, *Zhur. Obshchei Khim., Ser. I*, 91 (1931); *Chem. Abstr.*, **25**, 4535 (1931).

Summary

Tricyclohexylbutylsilane, tetracyclohexylsilane and tricyclohexylphenylsilane were prepared by hydrogenation of triphenylbutylsilane and phenyltricyclohexylsilane and partial hydrogenation of tetraphenylsilane, respectively. Preparation of tricyclohexylisopropylsilane and tricyclohexyl-*t*-butylsilane was unsuccessful due to failure of obtaining corresponding triphenyl derivatives. An attempt to obtain tricyclohexylcyclohexoxysilane by hydrogenating triphenylphenoxysilane was also unsuccessful. In preparation of highly-substituted cyclohexylsilicon compounds, the steric factor is of less importance in the hydrogenation process, while it is very much enhanced in reactions with organolithium compounds.

The author expresses his hearty thanks to Dr. Motonori Kanazashi for kind advice during this work.

Sterically-hindered Organosilicon Compounds Containing Cyclohexyl Groups. III.[1,2] *Notes on Petrov and Chernysheva's Tetracyclohexylsilane and Tricyclohexyl-n-butylsilane*

By Michio TAKAKUSA

(Received September 24, 1962)

It occasionally happens that two or more melting point values are given to a single compound by separate workers in silico-organic chemistry[3].

The present author[10] obtained tetracyclohexylsilane, m. p. 279~281°C, by hydrogenation of tetraphenylsilane, while Petrov and Chernysheva[11] reported tetracyclohexylsilane melting at 198°C, which was obtained by the reaction of cyclohexyllithium with tetrafluorosilane or dicyclohexyldifluorosilane. The two tetracyclohexylsilanes have been generally

thought to be stereoisomers due to steric hindrance[12]. Stereoisomerism in the silane would be possible in the case that free rotation around the Si-C_6H_{11} bond is hindered, but actual existence of isomers, which is the case in tetra-*o*-tolylsilane[13], seems to be less probable in tetracyclohexylsilane because of a squat shape of the cyclohexyl group. Moreover, if there exist some isomers of steric origin, the product of hydrogenation of tetraphenylsilane should be a mixture of the isomers. Our repeated studies on hydrogenation of tetraphenylsilane and phenyltricyclohexylsilane[2] were not successful in an attempt to isolate any other compound than the one melting at 281°C which was previously reported[10]. Interaction of tricyclohexylfluorosilane and cyclohexyllithium was reinvestigated by the present author[1], and the fourth cyclohexyl group could not be introduced under conditions similar to Petrov and Chernysheva's.

Eaborn[14] obtained tricyclohexylcyclohexoxysilane during the reaction of cyclohexylmagnesium bromide with dicyclohexyldifluorosilane at 70°C. A similar example has been reported by Cusa and Kipping[15] who obtained phenyldicyclohexylcyclohexoxysilane from the reaction of cyclohexylmagnesium bromide with phenyltrichlorosilane. The present author separated tricyclohexylcyclohexoxysilane, m. p. 201~203°C, from the reaction mixture of cyclohexyllithium with tetrachlorosilane. The result obtained here seems to be the first example of formation of such a type of compound during the reaction of organolithium compounds with halosilanes. The process seems to involve formation of $C_6H_{11}OLi$ in the reaction system and its successive interaction with tricyclohexylchlorosilane.

$$(C_6H_{11})_3SiCl + C_6H_{11}OLi \rightarrow (C_6H_{11})_3SiOC_6H_{11}$$

Though the cyclohexoxysilane was not obtained in the reaction[1] of tricyclohexylfluorosilane (2.5 g.) with an excess of cyclohexyllithium under a forced condition, about 2~5% (to tetrachlorosilane) of the compound was obtained in every larger scale reaction in which tetrachlorosilane or dicyclohexyldichlorosilane was used. Hence, the compound melting at 198°C, which Petrov and Chernysheva reported as tetracyclohexylsilane, might possibly be tricyclohexylcyclohexoxysilane[16], instead of a stereoisomer.

In addition to the case of tetracyclohexylsilane, tricyclohexylbutylsilane[2] obtained by hydrogenation of triphenylbutylsilane showed a different melting point, 159~160°C, from that of the compound, m. p. 133~135°C, obtained by Petrov and Chernysheva[11] through the substitution reaction with butyllithium. The existence of two isomeric tricyclohexylbutylsilanes can not be accounted for in terms of stereoisomerism due to steric hindrance.

A previous paper[1] reported that the reaction of butyllithium with tricyclohexylfluorosilane gives a compound (41%) identical with that obtained in hydrogenation study, m. p. 159~160°C, instead of Petrov and Chernysheva's tricyclohexylbutylsilane.

Tricyclohexylbutoxysilane was prepared by treating tricyclohexylchlorosilane with sodium butoxide. The butoxysilane was first reported here, but again, its melting point, 132~133°C, is close to that of Petrov and Chernysheva's tricyclohexylbutylsilane[17], 133~135°C; the fact suggests that their compound might be possibly tricyclohexylbutoxysilane.

The infrared spectra of the compounds obtained in our laboratory are shown in Fig. 1, being thought to be of some use for identification.

Experimental*

Formation of Tricyclohexylcyclohexoxysilane.— A dry 1 l. three-necked flask equipped with a mercury-sealed stirrer, a reflux condenser and a dropping funnel was flashed with nitrogen, and 400 ml. of petroleum ether was placed in it. Fourteen grams of lithium shots were transfered to the flask under nitrogen atmosphere, and then nitrogen was bubbled through petroleum ether. A long calcium chloride tube connected to a washing bottle containing alkaline pyrogallol solution was attached to the top of the reflux condenser for protection against moisture and oxygen. Ten milliliters of cyclohexyl chloride was added, and the reaction mixture warmed to start the reaction. Over a period of 2 hr., 103 g. of cyclohexyl chloride was added dropwise, and the mixture was kept warm with stirring for an additional 3 hr. Then, 17.6 g. (0.104 mol.) of silicon tetrachloride in 50 ml. of petroleum ether was added slowly, and the mixture refluxed for 5 hr. The reaction mixture was filtered. To the precipitates was added about 400 ml. of petroleum ether, and the mixture treated with diluted hydrochloric acid and fractionated. A fraction boiling at 160~175°C under 6 mmHg gave 3.2 g. (10 %) of tricyclohexylchlorosilane and 4.3 g. (14%) of tricyclohexylsilanol. The distillation residue was subjected to chromatography on alumina, and 1.8 g. of a white solid melting at 192~195°C was obtained. Recrystallization from carbon tetrachloride-ethanol and then from petroleum ether-ethanol raised the melting point to 201~203.5°C.

Found: C, 76.67; H, 11.91. Calcd. for $C_{24}H_{44}OSi$: C, 76.52; H, 11.77%. A mixed melting point measurement with an authentic sample[18] indicated that this compound is tricyclohexylcyclohexoxysilane. Two additional runs also gave about 2~5% of tricyclohexylcyclohexoxysilane, but one case did not give the compound, where treatment with hydrochloric acid solution was so vigorous that cyclohexanol was liberated.

Preparation of Tricyclohexylbutoxysilane.— Sodium butoxide was prepared by dissolving about 0.6 g. of sodium in 50 ml. of dry freshly-distilled *n*-butyl alcohol. The mixture of the solution and 1.7 g. (0.0058 mol.) of tricyclohexylchlorosilane was refluxed for 5 hr. After being cooled, 100 ml. of petroleum ether was added to it, and the solution poured onto cold water. The organic layer was washed and dried over sodium sulfate. The solvent was driven off, and 1.0 g. of crude material obtained, m. p. 117~127°C. Recrystallization twice from ethanol gave pure tricyclohexylbutoxysilane, m. p. 132~133.4°C.

Found: C, 75.31; H, 12.00. Calcd. for $C_{22}H_{42}OSi$: C, 75.35; H, 12.05%.

Summary

Discrepancies among reported melting ponints for tetracyclohexylsilane and tricyclohexylbutylsilane were discussed. Tricyclohexylcyclohexoxysilane was obtained in 2~5% yield in addition to tricyclohexylchlorosilane from the reaction of cyclohexyllithium with silicon tetrachloride. Petrov's compound melting at 198°C is most likely to be tricyclohexylcyclohexoxysilane and not a stereoisomeric tetracyclohexylsilane. Tricyclohexylbutoxysilane, m. p. 133°C, was prepared by treating sodium butoxide with tricyclohexylchlorosilane, and it was pointed out that Petrov's "tricyclohexylbutylsilane" is probably tricyclohexylbutoxysilane.

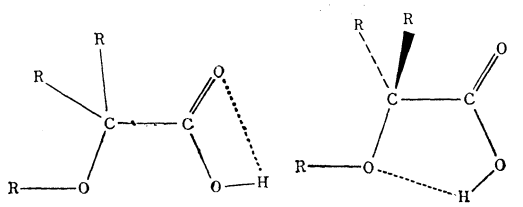
Intramolecular Hydrogen Bonding in α-Keto- and α-Alkoxy-carboxylic Acids. VI. Substituent Effects on the Energy of the Hydrogen Bonding in α-Alkoxy- and α-Aryloxyacetic Acids[1]

By Michinori Ōki and Minoru Hirota

(Received September 25, 1962)

Infrared spectra of various carboxylic acids which are supposed to be capable of hydrogen bonding between the carboxyl group and a substituent at α-position have led to the conclusion that an intramolecular interaction exists between the O–H group and the C=O in a carboxyl group[1-3]. The conclusion is based on the following phenomena. (i) The cis structure I, otherwise less advantageous from the stand point of steric effect than the trans structure II, is exclusively realized when the carboxylic acid has no hydrogen accepting group at the α-position. (ii) The C=O stretching absorption attributed to the cis structure appears at 1760 cm^{-1} region, which is ca. 30 cm^{-1} lower than the C=O stretching frequency of the trans structure (1790 cm^{-1}) in carbon tetrachloride, the fact being reasonably explained from the effect of the increasing polarity of the C=O bond, and more contribution of the polar structure C^+-O^- of less force constant value of the C=O bond. (iii) The intramolecular interaction IIIa of the O–H group with an aromatic nucleus or with a halogen atom at α-position was not observed in phenylacetic acid and chloroacetic acid.



cis

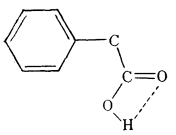
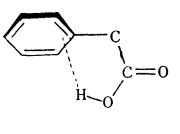
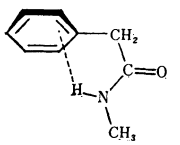
trans
II



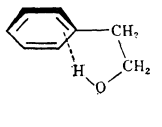
Phenylacetic acid
III



IIIa



N-Methyl-phenylacetamide
IV



β-Phenylethanol
V

The absence of the interaction in phenylacetic acid would be contradictory with the results obtained with phenylacetamide IV[4] and β-phenylethyl alcohol V[5] which is in the similar steric condition with phenylacetic acid[6].

The temperature dependence of the intensity ratio of the two ν_{O-H} bands was measured in order to determine the energy difference of the cis and trans forms of these acids. This energy difference (ΔH) may give the measure of the relative strength of the hydrogen bond between the carboxylic O–H group and the α-proton acceptor, because the energy of the cis form is thought to be almost unchanged throughout these series. Although the measurement, giving only the energy difference between the cis and the trans forms, cannot be related directly to the stability of the cis form, it may provide an important clue to the energy estimation when compared with the ordinary hydrogen bonding of O–H···O type. Thus the measurements were carried out with the carboxylic acids, ROCR'R''COOH, and the electronic and the steric effects of the substituents will be discussed in this paper in connection with the ΔH values.

Experimental

Preparation of Materials.—Methoxyacetic, ethoxyacetic, isopropoxyacetic and *t*-butoxyacetic acids were prepared from the corresponding alkoxides (2 mol.) and chloroacetic acid (1 mol.) in the corresponding alcohols. This method has been described for ethoxyacetic acid in "Organic Syntheses"[7] and the authors followed this method.

Similarly, α-methoxypropionic and α-methoxyisobutyric acids were prepared from sodium methoxide and the corresponding α-bromo-acids. The analyses and physical constants are reported below with ether new or doubtful compounds.

Isopropoxyacetic acids, b. p. 108°C/25 mmHg. Found: C, 50.73; H, 8.50, Calcd.: C, 50.83; H, 8.53%.

α-Methoxypropionic acid, b. p. 98°C/18 mmHg. Found: C, 45.98; H, 7.91. Calcd.: C, 46.15; H, 7.75%.

α-Methoxyisobutyric acid, b. p. 99.5°C/18 mmHg. Found: C, 51.08; H, 8.78. Calcd.: C, 50.83; H, 8.53%.

Preparation of aryloxyacetic acids and their homologs was already reported[1] in the preceding paper.

Measurement of the Infrared Spectra and Calculation of the Energy Difference (ΔH).—Infrared spectra are determined with a Perkin-Elmer 112 G spectrophotometer as reported previously. The absorption intensities of the two O-H stretching bands attributed to the cis and the trans isomers (ε_c and ε_t, respectively) are measured at various temperatures between 5°C and a temperature near the boiling point of carbon tetrachloride. The temperature of the solution was kept within the range of 1.5° during the measurement and the T (°K) value was obtained as the mean of the temperatures of the solution at the beginning and at the end of the absorption measurement. From these infrared measurements, the intensity ratios ($\varepsilon_t/\varepsilon_c$) were calculated at various temperatures. Assuming that ε-values are proportional to the populations of the cis and the trans isomeric melecules and the linear relation (Eq. 5) is present between the log ($\varepsilon_t/\varepsilon_c$) and $1/T$ values, the energy difference (ΔH) between the cis and the trans isomers are obtained from the gradient of log ($\varepsilon_t/\varepsilon_c$) versus $1/T$ line.

The gradient and the intercept of the line are calculated, by the least square method by the following formulae, where n is the number of the measurement:

$$\sum[\log(\varepsilon_t/\varepsilon_c)] - n\cdot[\Delta S - \boldsymbol{R}\ln a] - [\sum(1/T)]\cdot[\Delta H] = 0 \quad (1)$$

$$\sum\{[\log(\varepsilon_t/\varepsilon_c)]\times[1/T]\} - [\sum(1/T)] \times [\Delta S - \boldsymbol{R}\ln a] - [\sum(1/T^2)]\cdot[\Delta H] = 0 \quad (2)$$

In these formulae, the values $\sum[\log(\varepsilon_t/\varepsilon_c)]$, n, $\sum(1/T)$, $\sum[\log(\varepsilon_t/\varepsilon_c)\cdot 1/T$ and $\sum(1/T^2)$ are known, and ΔH and $(\Delta S - \boldsymbol{R}.\ln a)$ are obtained.

Results and Discussion

Results of the measurement of the O-H stretching absorption intensity of the cis (I) and the trans (II) isomers at various temperatures are shown in Tables I—IX.

Assuming that the absorption intensity of the isomers are proportional to their concentration (x_c and x_t, respectively), the energy difference (ΔH) and the ($\Delta S/\boldsymbol{R} - \ln a$) term are calculated by applying the van't Hoff's equation (Eq.3).

$$-\boldsymbol{R}T\cdot\ln K=\Delta F=\Delta H-T\Delta S \qquad (3)$$

The equilibrium constant K can be represented by multiplying the integrated intensity ratio by a constant which is a factor showing the ratio of intensity per molecule due to trans and cis forms and is assumed to be invariable throughout the temperature range in this investigation. Then, Eq. 4 is obtained.

$$K=x_t/x_c=a\,A_t/A_c=a\frac{\varepsilon_t\times(\Delta\nu_{1/2})_t}{\varepsilon_c\times(\Delta\nu_{1/2})_c} \qquad (4)$$

Combining Eq. 3 and Eq. 4 gives

$$\log(\varepsilon_t/\varepsilon_c)=-\frac{\Delta H}{2.30\,\boldsymbol{R}}\times\frac{1}{T}+\frac{1}{2.30}\left(\frac{\Delta S}{\boldsymbol{R}}-\ln a\right)-\log\frac{(\Delta\nu_{1/2})_t}{(\Delta\nu_{1/2})_c} \qquad (5)$$

The authors have found that the separation of two bands due to cis and trans forms are generally good and the half band widths are invariable in the spectra at various temperatures. It is then allowed to use the ratio of apparent molecular extinction coefficients instead of intensities to estimate the enthalpies. An example of these cases is shown with α-methoxyacetic acid in Fig. 1. The absorption spectra of this compound shows two separate O–H stretching bands and the approximation of Eq. 6 holds good, the correction of $\log[(\Delta\nu_{1/2})_t/(\Delta\nu_{1/2})_c]$ being accounted to calculate the entropy term $(\Delta S/\boldsymbol{R}-\ln a)$.

$$\varepsilon^a_{t_{max}}\doteqdot\varepsilon_{t_{max}},\quad \varepsilon^a_{c_{max}}\doteqdot\varepsilon_{c_{max}} \qquad (6)$$

In Eq. 6, $\varepsilon^a_{c_{max}}$ and $\varepsilon^a_{t_{max}}$ are the apparent maximal extinction coefficients of the cis and the trans ν_{O-H} bands.

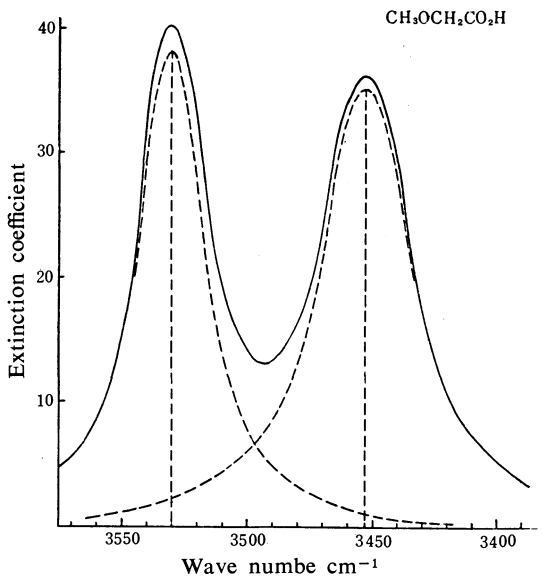

Fig. 1.

A considerable overlap of the two O–H stretching bands was observed in the spectra of phenoxyacetic and α-phenoxypropionic acids and the following corrections (Eq. 7 for phenoxyacetic and Eq. 8 for α-phenoxypropionic acids) were necessary. An example of this correction

is shown in Fig. 2. Coefficients of the correcting terms were calculated from Eq. 9 by assuming the Lorentz envelopes for the two O–H stretching bands.

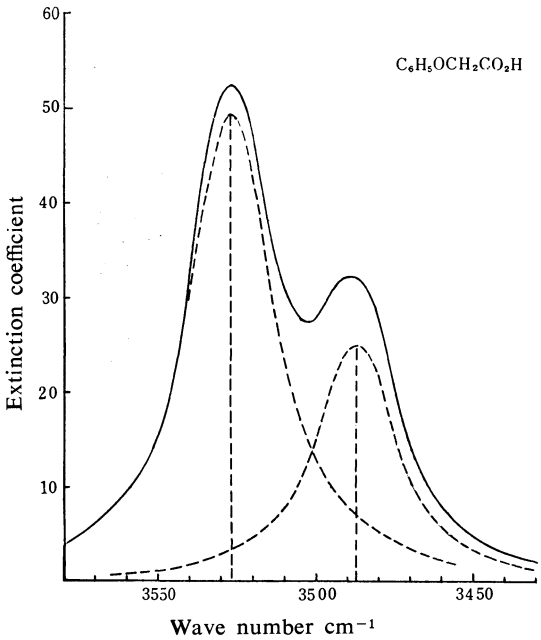

Fig. 2.

$$\left.\begin{aligned}\varepsilon_{c_{max}} &\fallingdotseq \varepsilon^{a}_{c_{max}} - (1/7.9)\,\varepsilon^{a}_{t_{max}} \\ \varepsilon_{t_{max}} &\fallingdotseq \varepsilon^{a}_{t_{max}} - (1/7.2)\,\varepsilon^{a}_{c_{max}}\end{aligned}\right\} \quad (7)$$

$$\left.\begin{aligned}\varepsilon_{c_{max}} &\fallingdotseq \varepsilon^{a}_{c_{max}} - (1/7.3)\,\varepsilon^{a}_{t_{max}} \\ \varepsilon_{t_{max}} &\fallingdotseq \varepsilon^{a}_{t_{max}} - (1/10.7)\,\varepsilon^{a}_{c_{max}}\end{aligned}\right\} \quad (8)$$

$$f(\nu) = a/[(\nu-\nu_{max})^2 + b^2]^{8)} \quad (9)$$

where $\varepsilon_{max} = a/b^2$ and $\Delta\nu_{1/2} = b$.

The $(\varepsilon_t/\varepsilon_c)$ versus $1/T$ relationship is illustrated in Figs. 3, 4, 5 and 6.

In Table X are listed the calculated ΔH and $(\Delta S/R - \ln a)$ values together with the exact band properties of the ν_{O-H} due to the cis and the trans isomers at the ordinary temperature (20~25°C). In Table XI are also summarized the relation between ΔH values and the frequency difference of the two absorption maxima ($\Delta\nu_{max}$). Though the general relationship could not be establishd, monotonous relation is found between the ΔH and $\Delta\nu_{max}$ values within each series of these acids and larger $\Delta\nu_{max}$ generally corresponds to larger ΔH.

From the constancy of the ν_{O-H} frequency of the cis isomer, the energy of the cis-isomer can be considered to be nearly constant in these substituted acetic acids. The ΔH value will, therefore, be a relative value of the energy of the intramolecular hydrogen bonding. The factors which affect the facility of the hydrogen bond formation are i) acidity (hydrogen donating power) of the carboxyl group, ii) basicity (hydrogen accepting power) of the ether oxygen of the alkoxyl or aryloxy group, and iii) steric effects of the alpha and other substituents. The factor i) may be neglected, because the inductive effect of the α-methyl

substituent does not greatly affect the pK_a values of acetic acids (pK_a values of acetic, propionic and isobutyric acids are known to be 4.76, 4.88 and 4.86[9], respectively), nor the O–H stretching absorption frequencies[10], and the hydrogen donating powers of the acids in the present discussion seem to be nearly the same.

The ΔH value is largely affected by the *O*-substituent and to the lesser extent by the *α*-substituent, though the $\Delta\nu_{max}$ value is affected by both factors in almost the same way. Extreme is the case of phenoxy-acids, in which the ΔH value is nearly equal while the acid changes from phenoxyacetic to phenoxyisobutyric acid. The results may be attributed to the fact that the O–H···O hydrogen bond formation occurs between the carboxylic O–H group and the lone pair electrons of the ether oxygen which conjugates with the aromatic *π*-electrons. The effects of nuclear substitution on the ΔH value also support this hypothesis and the electron-repelling substituent gives higher ΔH value than the electron-attracting substituent.

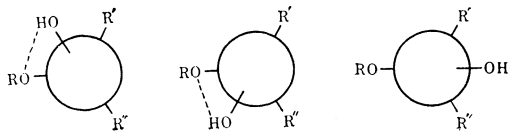
9) J. F. J. Dippy, *Chem. Revs.*, **25**, 151 (1939).
10) Effects of the acidity on the O–H stretching frequency has been investigated widely by Goulden (J. D. S. Goulden, *Spectrochim. Acta*, **6**, 129 (1954)).

The substituents on oxygen gives the stronger effect than the methyl groups at α-position as shown in Table XI. It is clear that both the steric and the electronic (inductive) effects should be considered to discuss the effect of the α-substituent on the hydrogen bonding.

TABLE XI. THE ΔH AND $\Delta\nu_{max}$ INCREASE BY THE SUBSTITUTION OF ONE ADDITIONAL METHYL GROUP

Acid	ΔH Increase	$\Delta\nu_{max}$ Increase
Methoxyacetic		
Ethoxyacetic	0.35	7.8
Isopropoxyacetic	0.42	13.0
Methoxyacetic		
α-Methoxypropionic	0.39	20.2
α-Methoxyisobutyric	0.13	22.1
Phenoxyacetic		
α-Phenoxypropionic	−0.04	11.8
α-Phenoxyisobutyric	0.11	42.7

The carboxylic acid may include three rotational isomers with respect to the axis between the carboxylic carbon and the alpha carbon ($C_{C=O}-C_{\alpha}$), being represented by VII, VIII and IX. The oxo-groups are omitted in the formulae VII—IX for the sake of simplicity. As is clear from the Newman projections, the methyl group at the α-position increases the steric interaction with the hydroxyl group in the isomer IX in which the hydrogen-bonded structure is impossible, and consequently, the relative stability of the rotational isomers VII and VIII, which have the possibility of existing as hydrogen-bonded structure II, may rise.



Rotamers of alkoxyacetic acid

VII VIII IX

Therefore, formation of hydrogen-bonding in α-alkoxyisobutyric acid is favored over that in α-alkoxyacetic acid, as far as the steric influence is concerned.

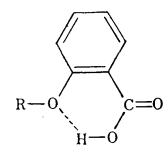
As to the electronic effect of the methyl groups at α-position of the carboxyl group, they will strengthen the basicity of the ether oxygen through the inductive effect, leaving the acidity of the carboxyl group intact as mentioned above. However, the extent of the effects cannot be estimated separately at the present stage. Thus both steric and electronic effects of the methyl groups favor the formation of hydrogen-bonding.

The effect of methyl group substituting methoxyl moiety of methoxyacetic acid seems to be of inductive nature, since the basicity of the corresponding alcohols are in the order; methanol < ethanol < isopropyl alcohol (< *t*-butyl alcohol), and this is the same order as the ΔH and $\Delta\nu_{max}$ values increase, although the ΔH measurement has not been complete with *t*-butoxyacetic acid. The result is in accordance with the fact that no serious steric hindrance is expected from the Fischer's molecular scale models between the alkyl group and *trans*-O–H group.

The order of A_t/A_c ratio (Table X) is not the same as the order of the basicity of oxygen atom. Namely abrupt decrease of A_t/A_c ratio is observed with *t*-butoxyacetic acid in spite of increasing $\Delta\nu_{max}$. The fact may be attributed to the steric effect of bulky *t*-butyl group hindering appoach of the hydroxyl group to ether oxygen, but, even in this compound no serious steric effect was foreseen from the model. Therefore, this phenomenon remains unexplained.

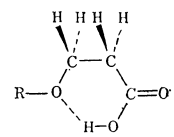
This intramolecular hydrogen bonding forms a five-membered ring and the maximal energy difference (ΔH) is 1.53 kcal./mol. This ΔH value is much smaller than the case of a six-membered intramolecularly hydrogen-bonded system of the same type. The ΔH values for *o*-methoxybenzoic and *o*-phenoxybenzoic acids are 3.3 kcal./mol.[11] and 1.89 kcal./mol.[12], respectively.

In spite of the greater energy, the hydrogen bonding of six-membered ring X has been found only in benzoic acid derivatives which carries an oxygen atom at ortho-position to the carboxyl group and neither β-alkoxy- nor β-aryloxy-propionic acid shows[13] the hydrogen bonding of this type XI.



o-Alkoxybenzoic acid

X



β-Alkoxypropionic acid

XI

These facts may be attributed to the following reasons: i) the six-membered hydrogen-bond system of *o*-alkoxybenzoic acids is a conjugate system, and ii) β-alkoxypropionic acids are enforced to assume the sterically unfavorable

cis-rotational form (as illustrated by XI) to make a planar six-membered hydrogen-bond system.

Temperature dependence study of the intensities of two ν_{O-H} bands at 3630 cm^{-1} and 3280 cm^{-1} in a ternary system of acetic acid, dibutyl ether and carbon tetrachloride indicates the enthalpy of hydrogen bond be 4.56 ± 0.3 kcal./mol. Provided that this value is applicable for the internal hydrogen bond as in methoxyacetic acid, then it is concluded that the cis form of the carboxyl group is stabilized by 3～4 kcal./mol. over the trans form.

The entropy term has an ambiguity of ($-\ln a$) and no quantitative relation with other physical properties can be fonud, although it increases with the increase of ΔH value.

A Study of Metal Complexes of Analytical Importance. II[1]. *Complexes of Salicylaldoxime and C-Methyl-salicylaldoxime with Vanadium(V)*[2]

By Hiroji NAKAMURA, Yoichi SHIMURA and Ryutaro TSUCHIDA

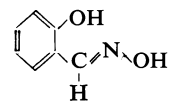
(Received November 24, 1962)

About the complexes of quinquevalent vanadium, there are few reports, and most of them concern studies of the so-called "solution complexes". Very few vanadium(V) complexes have been isolated. One of the purposes of this work is to isolate new complexes of vanadium(V).

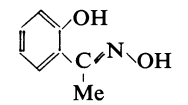
Quinquevalent vanadium has no d-electrons, so its complexes would show no ligand field band, which comes from the d-d transition, and they would be colorless or yellow. Some complexes of vanadium(V), however, have a deep color. One of the examples of these colored complexes is the 8-quinolinol complex, which was reported on in Part I of this series[1]. The strong bands of this complex in the visible region are considered to be electron-transfer bands.

2-Methyl-8-quinolinol was found to form two complexes[1], one of them colored black, due to the charge-transfer bands, and the other, yellow. It was concluded that in the black complex the ligands were coordinated to the central metal as bidentate ligands, while in the yellow complex the ligands were coordinated as unidentate ligands[1].

In order to investigate further the relation between the charge-transfer bands in the visible region and the structure of ligands or the configuration of complexes, we used salicylaldoxime and its methyl derivative, *C*-methyl-salicylaldoxime (*o*-hydroxyacetophenoneoxime), as ligands and investigated the color and the structure of their vanadium(V) complexes.



Salicylaldoxime
(symbol: $salmH_2$)



C-Methyl-salicylaldoxime
(symbol: $Me\text{-}salmH_2$)

Results and Discussion

Complexes of Salicylaldoxime with Vanadium(V).—The reaction of vanadate with salicylaldoxime at a pH value of 1 produces a black precipitate. Flagg and Furman[3] reported that in the black precipitate, the ratio of vanadium to salicylaldoxime was 2:3; i.e., the complex had the formula $C_{21}H_{21}N_3O_{10}V_2$. The complex represented by this formula is very queer, because in it vanadium should be quadrivalent. The experiments were, therefore, repeated by us. The complex which was formed under almost

1) Part I of this series: H. Nakamura, Y. Shimura and R. Tsuchida, This Bulletin, **34**, 1143 (1961).

2) A part of this study was presented at the Symposium on Coordination Compounds of the Chemical Society of Japan, Osaka, November, 1961.

3) J. F. Flagg and N. H. Furman, *Anal. Chem.*, **12**, 663 (1940).

the same conditions as mentioned above had the empirical formula approximately represented by $C_{21}H_{21}N_3O_{11}V_2$, and repeated experiments showed that the composition of the precipitate varied with a slight difference in the experimental conditions. As the infrared absorption spectra of the precipitate were not very sharp, it was concluded that the precipitate was not a pure substance. In order to prepare a pure complex having a structure similar to that of the 8-quinolinol vanadium(V) complex (1 : 2-complex), a large excess of the ligand was used, but the attempt was unsuccessful. In aqueous solution, no experiments with different pH values or temperatures were successful in the preparation of the desired complex.

As will be seen below, the recrystallization of the precipitate from benzene containing free salicylaldoxime gave the 1 : 2-complex in a pure crystalline state. The salicylaldoxime-vanadium(V) complex thus obtained may have a structure similar to that of the 8-quinolinol-vanadium(V) complex (Fig. 1a or 1b); its color is black in the crystalline state and violet in benzene and carbon tetrachloride. The absorption spectrum of the complex in benzene is shown in Fig. 2a. The intensity

c --- Free salicylaldoxime in benzene

of the absorption band at 54.6×10^{13} sec^{-1} is as large as that of the corresponding band of the 8-quinolinol complex. The absorption spectrum of [VO(OH)(salmH)$_2$] in carbon tetrachloride coincided with that in benzene. In many other solvents, however, the complex changed its color as time passed after dissolution. In acetone, for example, the complex dissolved immediately after dissolution to show a violet color, which was quite like the color of the benzene solution, but it gradually changed to brown, and finally the color became almost yellow. The absorption spectrum of the complex in acetone about fifteen minutes after dissolution is shown in Fig. 2b. It is considered that the change of color is due to the decomposition of the complex.

The Absorption Spectrum of the Salicylaldoxime Complex in Dimethylformamide.—As was mentioned above, the salicylaldoxime complex dissolved in some solvents to show a violet color immediately after dissolution. This was not the case with dimethylformamide, which formed a solution showing a different color. Although the absorption bands of the complex in dimethylformamide decreased in intensity with time, the color of the solution immediately after dissolution was not violet, but a deep, reddish brown. The absorption curves of the complex in the 460~600 mμ range in dimethylformamide are shown in Fig. 3. In dimethylformamide the complex dissolved very rapidly, so it was possible to measure the change in the absorption intensity with time from the

--- in benzene

instant when the complex was dissolved. From Fig. 3, optical densities at 5, 10, 15, 30, 45 and 60 min. after dissolution at 460 mμ were obtained. Similarly, the values at 600 mμ after 6, 11, 16, 31, 46 and 61 min. were obtained. (It took one minute for the curves to be drawn from 460 mμ to 600 mμ). Optical densities at other wavelengths were also obtained. The logarithmic plot of the optical densities vs. time gave straight lines, showing that the decomposition of the complex was of the first order reaction (Fig. 4). By extrapolating the lines to zero, the optical densities of the complex at "zero time" were obtained. Thus, with similar measurements of other ranges, the absorption spectrum of the complex in dimethylformamide was obtained (Fig. 5). A comparison of the absorption spectra of the salicylaldoxime complex in benzene and in dimethylformamide shows a distinct difference which cannot be regarded as the effect of the solvent. In dimethylformamide the bands are broader and are situated at longer wavelengths than in benzene. 8-Quinolinol-vanadium(V) complex has two isomers, the cis and the trans[1] (Fig. 1). The absorption spectra of these isomers are shown in Fig. 6. From a comparison of the spectra of the salicylaldoxime complex with those of 8-quinolinol complexes, it has been concluded that the salicylaldoxime complex has the trans structure (Fig. 1b) in benzene or in carbon tetrachloride and the cis structure (Fig. 1a) in dimethylformamide.

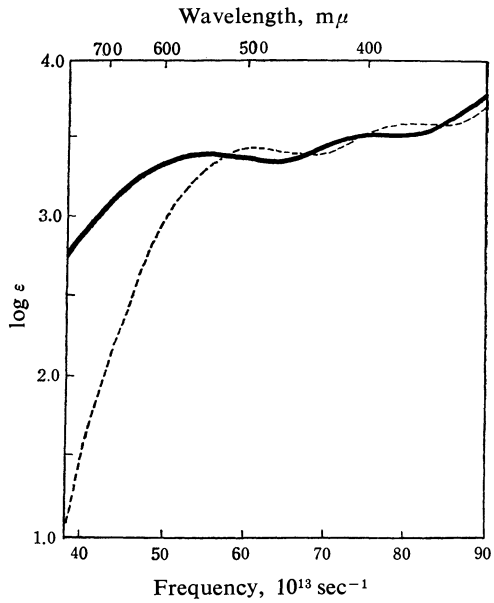

Fig. 6. Absorption spectra of 8-quinolinol-vanadium(V) complexes[1].
—— cis-form --- trans-form

The Esterified Complex of Salicylaldoxime with Vanadium(V). — The 1:2-complex of salicylaldoxime could be recrystallized from ethanol. The complex thus recrystallized from ethanol was esterified in OH, that is, [VO·(O–Et)(salmH)$_2$]. The absorption spectrum of [VO(O–Et)(salmH)$_2$] in benzene is shown in Fig. 7. It has large charge-transfer bands which are quite similar to that of [VO(OH)·(salmH)$_2$], and the esterification does not effect any such remarkable change of color as was reported for 8-quinolinol complexes[1].

The Complex of *C*-Methyl-salicylaldoxime with Vanadium(V).—As was reported in Part I of this series[1], the difference between the reactions of 8-quinolinol and 2-methyl-8-quinolinol

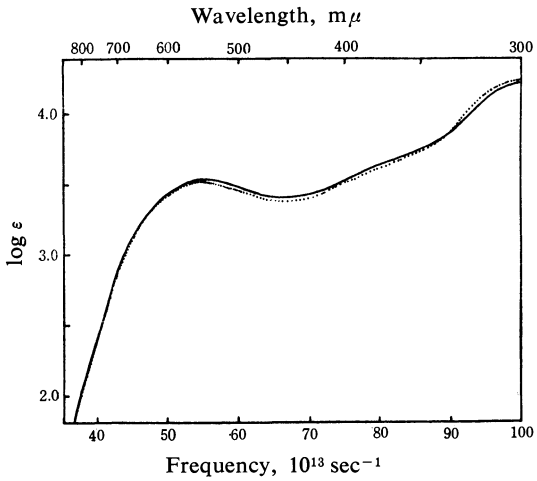

Fig. 7. Absorption spectra of [VO(O-Et)·(salmH)$_2$] (——) and [VO(OH)(salmH)$_2$] (·····) in benzene.

with vanadate is a very interesting problem. At pH values between 3 and 5 the former produced a black complex, whereas the latter gave a yellow complex under the same experimental conditions[1]. Concerning this phenomenon, the color and the structure of the complexes of salicylaldoxime and *C*-methyl-salicylaldoxime with vanadium(V) are problems of great interest.

C-Methyl-salicylaldoxime produced, with vanadate at a pH value of 1, a reddish-brown precipitate, not a black one. It was found that the color of the precipitate depended on the pH value of the solution of vanadate. At a higher pH value, the color of the precipitate was yellow. Contrary to the 2-methyl-8-quinolinol complex, the yellow precipitate did not change in color upon heating or drying. The yellow precipitate has no water of crystallization.

The preparation of a black complex like that of the salicylaldoxime complex was attempted. Lowering of the pH value of the solution of vanadate was effective in producing a rather dark-colored precipitate, but from an aqueous solution it was not possible to obtain a black complex. The precipitate which had been separated from the aqueous solution dissolved in many solvents to show yellow colors. After many attempts, it was found that the precipitate dissolved gradually in boiling benzene and that the color of the solution became violet. Evaporation of the solvent from the violet solution, however, produced a brown precipitate. Therefore, the benzene solution saturated with the complex at the boiling point was cooled rapidly and frozen. After separation of the frozen solvent, brownish-black crystals were obtained. It was observed under a microscope that the crystals were a mixture of yellow and black crystals. As the yellow crystals were soluble in warm alcohol, the black crystals were obtained in a pure state by washing the mixture repeatedly with warm alcohol. The black complex was the 1:2-complex of *C*-methyl-salicylaldoxime corresponding to that of salicylaldoxime. The absorption spectrum in benzene of the former was quite similar to that of the latter (Fig. 8).

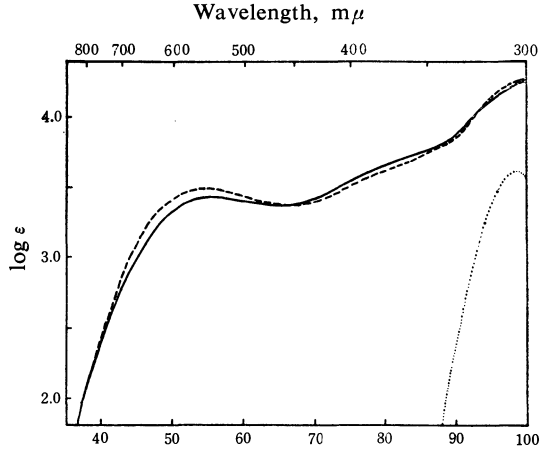

Fig. 8. Absorption spectra of [VO(OH)(Me-salmH)$_2$] (——), [VO(OH)(salmH)$_2$] (- - -) and free *C*-methyl-salicylaldoxime (·····) in benzene.

The Absorption Spectrum of *C*-Methyl-salicylaldoxime in Dimethylformamide. — In a way similar to that used for the salicylaldoxime complex, the absorption spectrum of the *C*-methyl-salicylaldoxime complex in dimethylformamide was determined (Fig. 9a).

By a comparison of Figs. 6 and 9, it can be seen that the *C*-methyl-salicylaldoxime complex has the cis structure in dimethylformamide and the trans structure in benzene, as has the salicylaldoxime complex.

The Yellow Form of the *C*-Methyl-salicylaldoxime Complex. — Recrystallization of the crude complex from toluene gave a yellow complex. The absorption spectrum of the yellow form is shown in Fig. 9c. The great difference between the colors of the black and the yellow forms cannot be ascribed only to the cis-trans isomerization.

The infrared absorption spectra of these black and yellow complexes give us some suggestions about their structures. Although the black form exhibits an O–H stretching band of =N–OH[4] at 3380 cm^{-1}, the yellow form

4) G. Duyckaerts, *Bull. soc. roy. sci. Liège*, **21**, 196 (1952).

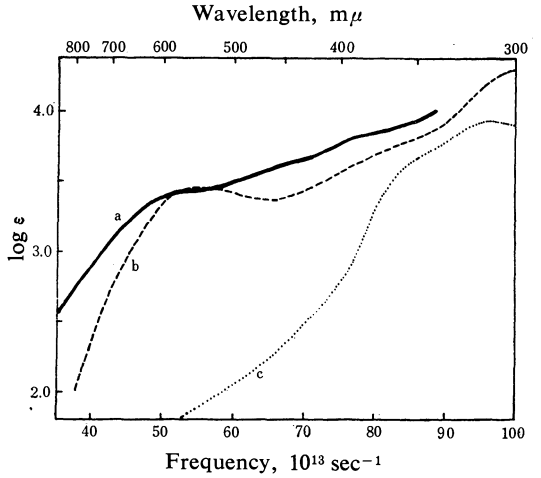

Fig. 9. Absorption spectra of *C*-methyl-salicylaldoxime-vanadium(V) complexes.

c ····· [V(OH)(Me-salm)$_2$] in dimethylformamide

does not show any band above the 4000~3000 cm^{-1} region. This suggests that in the yellow form the oxygen atoms of a oxime character are bound to the vanadium ion. That is, it is probable that in the yellow form, the ligands are coordinated to the vanadium ion with two oxygen atoms. This view is supported by the elementary analysis of V(OH)(Me-salm)$_2$ and also by the fact that the band at 1620 cm^{-1} of the black form shifts to 1642 cm^{-1} in the yellow form[5].

5) L. J. Bellamy, "The Infrared Spectra of Complex Molecules", 2nd Ed., John Wiley & Sons, Inc., New York (1958).

The Complex Recrystallized from Methanol. —Recrystallization of the yellow form from methanol gave brown planar crystals. The color of the benzene solution of the crystals was also brown (Fig. 10a). Adding *C*-methyl-salicylaldoxime to the solution made its color violet, a color which was similar to that of the black form in the same solvent (Fig. 10b). The composition of the brown crystals was, however, very complicated ($C_{30}H_{43}N_3O_{18}V_4$), and further investigation is nescessary to solve this problem.

Experimental

Preparation of the Salicylaldoxime-Vanadium Complex. — The 1 : 2-complex was prepared as follows : 1.9 g. (1/100 mol.) of sodium metavanadate tetrahydrate ($NaVO_3 \cdot 4H_2O$) was dissolved in 50 ml. of 0.2 N sodium hydroxide. The pH value of the solution was adjusted to about 1 by the use of 2 N sulfuric acid. After the solution had been stirred for thirteen minutes, the black precipitate was filtered, washed and dried in the air. Six hundred milligrams of dried precipitate were refluxed with 200 ml. of benzene containing 500 mg. of salicylaldoxime for one hour. After filtration, the solution was concentrated to about 30 ml. and was left to cool. The black crystals separated were filtered and washed with benzene.

Found : C, 55.38 ; H, 4.24 ; N, 6.75 ; V, 11.80. Calcd. for $C_{20}H_{19}N_2O_6V$=[VO(OH)(salmH)$_2$]·C_6H_6 : C, 55.30 ; H, 4.41 ; N, 6.45 ; V, 11.73%.

The ethyl ester of the complex was prepared by recrystallization from ethanol.

Found : C, 49.70 ; H, 4.13 ; N, 7.59 ; V, 13.42. Calcd. for $C_{16}H_{17}N_2O_6V$=[VO(O-Et)(salmH)$_2$] : C, 49.99 ; H, 4.46 ; N, 7.28 ; V, 13.27%.

Preparation of the *C*-Methyl-salicylaldoxime-Vanadium(V) Complex.—*C*-Methyl-salicylaldoxime was prepared by the method of Poddar[6].

The complex was prepared as follows : 1.9 g. (1/100 mol.) of sodium metavanadate tetrahydrate was dissolved in 50 ml. of 0.2 N sodium hydroxide. The pH value of the solution was adjusted to 1.2 by diluted sulfuric acid. To the solution was added 3.1 g. (2/100 mol.) of *C*-methyl-salicylaldoxime dissolved in 6 ml. of acetone. After three hours, the crude precipitate was filtered and washed with water.

The black form was prepared as follows : 1.0 g. of the crude precipitate was refluxed for three hours with one liter of benzene. After filtration, the solution was cooled with ice and left in a refrigerator. The frozen colorless solvent, which did not contain the complex was removed from the frozen mass with a spoon. The residue was melted at room temperature, and the crystals were separated by filtration. A mixture of yellow and black crystals was thus obtained. The mixture was put into 100 ml. of warm alcohol and stirred. After filtration the crystals were washed several times more with warm alcohol. The crystals thus obtained

6) S. N. Poddar, *Z. anal. Chem.*, **154**, 254 (1957).

were black in color. The absence of yellow crystals was confirmed microscopically.

Found: C, 52.63; H, 4.68; N, 7.10; V, 12.20. Calcd. for $C_{18}H_{19}N_2O_6V$=[VO(OH)(Me-salmH)$_2$]·1/3C_6H_6: C, 52.75; H, 4.67; N, 6.83; V, 12.42%.

The yellow form was prepared as follows: 0.75 g. of the crude complex was dissolved in 500 ml. of toluene at 95°C. After filtration, the solution was left in a refrigerator. The reddish-brown crystals which separated were washed repeatedly with carbon tetrachloride to remove the black form.

Found: C, 52.32; H, 4.16; N, 7.29; V, 13.70. Calcd. for $C_{16}H_{15}N_2O_5V$=[V(OH)(Me-salm)$_2$]: C, 52.47; H, 4.13; N, 7.65; V, 13.91%.

Measurement. — Visible and ultraviolet absorption spectra were determined with a Beckman DU and a Hitachi EPS-2 spectrophotometer using cells with light paths 1.0 and 0.10 cm. in length respectively.

The infrared absorption measurements were made by the KBr pressed-disk technique in a Hitachi EPI-2 infrared spectrophotometer.

Summary

New complexes of salicylaldoxime (symbol: salmH$_2$) and *C*-methyl-salicylaldoxime (symbol: Me-salmH$_2$) with vanadium(V), [VO(OH)·(salmH)$_2$] (A), [VO(O–Et)(salmH)$_2$] (B), [VO·(OH)(Me-salmH)$_2$] (C) and [V(OH)(Me-salm)$_2$] (D) were prepared. A, B and C complexes were dark-colored, while the D complex was light-colored.

The absorption spectra of A and C in dimethylformamide were determined. Based on the measurements of the visible, ultraviolet and infrared absorption spectra of these complexes, the following conclusions were drawn:

1) In benzene complex A has the trans structure, while in dimethylformamide it has the cis structure.

2) Complex C has the same properties as A.

3) The esterification of A does not cause any remarkable change in color.

4) The great difference between the color of C and that of D comes from the difference in the donor atoms of the ligand. In the former the ligands are coordinated as N, O-chelates, and in the latter, as O, O-chelates.

The Separation of Trace Amounts of Tellurium from Iron by Solvent Extraction

By Yasumitsu UZUMASA, Kenjiro HAYASHI and Saburo ITO

(Received October 26, 1962)

According to the standard method of the Japan Institute of the Promotion of Science and Techniques[1], when a steel sample containing tellurium is treated with a mixture of ammonium hydrogen fluoride and sulfuric acid, most of iron goes into solution while tellurium, silica, carbon, etc., together with a little iron, are left undissolved. This method of dissolving can be applied to a sample containing as much as 0.1 mg. of tellurium. When we investigated this method in detail, our experiments revealed, however, that when the tellurium content is less than this amount, the separation of tellurium from iron is never complete. It was found that a part of the tellurium passes through the filter paper, the amount of tellurium in the residue being thus reduced. After these studies, therefore, we abandoned this procedure and investigated another method in which tellurium, together with iron, is dissolved in a suitable solvent and the former is separated from the latter by the extraction method.

Experimental and Results

Apparatus.—A Beckman model DU spectrophotometer with 1 cm. silica cells was used.

Procedure.—One gram of solid thiourea is added to 15 ml. of the sample solution; this is equivalent to 2 N of a hydrochloric acid concentration. After the mixed solution is made up to 20 ml. with 2 N hydrochloric acid, it is allowed to stand for 20 min. and absorbance is measured at 350 or 370 mμ[2,3].

Change in the State of Tellurium During the Dissolution of the Steel Sample. — As to the state of a minute amount of tellurium in steel, very little consideration has been paid it so far. As may be seen from the Fe–Te diagram (Fig. 1)[4], it is quite possible that it exists as $FeTe_{0.90}$. Iron telluride of this niccolite type may produce, by the action of an acid, hydrogen telluride, which may further yield metallic

tellurium as indicated by the following equation:

$$H_2Te(aq) = Te + 2H^+ + 2e$$
$$E^\circ_{298} = +0.69\ V.^{5)}$$

It is also possible that a part of the hydrogen telluride thus produced might remain not oxidized and volatilize as gas, since its boiling point is $-1.8 \sim 0°C$ at 1 atm.[6] In order to examine this possibility, 5 g. of the steel sample containing 0.3 mg. Te/g. was dissolved in 6 N hydrochloric or sulfuric acid and the gas evolved was introduced into ammonia. The amount of tellurium absorbed in ammonia was found always to be less than 10 μg. This indicates that the volatilization may be disregarded.

Another possibility is that in acidic media metallic tellurium might be oxidized by ferric iron to tellurium(IV) and dissolve into the solution:

$$Te + 2H_2O \rightleftharpoons TeO_2 + 4H^+ + 4e$$
$$E^\circ_{298} = -0.529\ V.^{5)}$$
$$Fe^{2+} \rightleftharpoons Fe^{3+} + e \qquad E^\circ_{298} = -0.771\ V.$$

Therefore, metallic tellurium suspended in a acidic medium will more or less dissolve in the presence of iron(II) as the latter is oxidized to iron(III) by air. This was confirmed by the following experiment.

The precipitate of metallic tellurium prepared by adding stannous chloride to a hydrochloric acid solution of potassium tellurite was centrifuged and washed with water thoroughly. When this precipitate was suspended in 6 N hydrochloric acid containing ferric chloride, rapid dissolution of the precipitate took place. It is, therefore, possible that, in the practical analysis of steel, the existence of ferric iron brings about the solution of metallic tellurium, if it is present. The time necessary for the complete dissolution of steel samples differs according to type. In cases where it takes a longer time, the partial oxidation of iron(II) to iron(III) occurs, resulting in a partial dissolution of the metallic tellurium. This is illustrated in Table I.

TABLE I. DISSOLUTION OF METALLIC TELLURIUM WITH FERRIC IRON IN HYDROCHLORIC OR SULFURIC ACID

Sample No.	Acid	Dissolving time, min.	Tellurium	
			In the sample, mg.	In the soln., μg.
1	HCl	8	1.03	4.3
2	HCl	18	0.695	7.7
3	HCl	20	0.45	16.5
4	HCl	90	1.35	610.0
1	H_2SO_4	10	1.03	25.3
2	H_2SO_4	17	0.695	12.1
3	H_2SO_4	20	0.45	4.3
4	H_2SO_4	30	1.35	0

Acid concentration : 6 N
Volume of the solution : 25 ml.
Steel sample taken : 1 g.

When sulfuric acid was used, the steel sample dissolved more rapidly and the particles of metallic tellurium coagulated in larger aggregates. Moreover, the oxidation of ferrous iron in sulfuric acid is more difficult.

Reexamination of the Precipitation Method. —There is a conventional method of separation in which the steel sample containing tellurium is dissolved in a suitable solvent and the solution is treated with such a reducing agent as stannous chloride and then the tellurium is reduced and precipitated. The precipitate is filtered off, the tellurium being thus separated from the iron. A critical examination of this method was undertaken.

Ten grams of solid stannous chloride were added to 150 ml. of 3 N hydrochloric acid containing sodium tellurite equivalent to 66 μg. of tellurium. The solution was then boiled

for 5 min. After the liquid had been allowed to stand for one hour at room temperature, the precipitate formed was filtered through Toyo No. 5C filter paper and washed with hydrochloric acid. The precipitate was then brought into solution by nitric acid, and the amount of tellurium was determined spectrophotometrically with thiourea. The results are shown in Table II.

Table II. Fraction of precipitated tellurium

Tellurium, μg.		Recovery %
Taken	Found	
66.0	30	45.5
66.0	26	39.4
66.0	25	37.9
66.0	25	37.9
66.0	24	36.4
66.0	24	36.4
	Ave.	39.0

It is obvious from this table that this precipitation method can not be applied to a sample whose tellurium content is very small.

Extraction of Tellurium with an Organic Solvent. — Ferric iron in highly concentrated hydrochloric acid can be extracted quite efficiently with some organic solvents such as ethyl acetate, *n*-butyl acetate or methyl isobutyl ketone, while the extractability of tellurium under similar conditions has not previously been well known. Tellurium(IV) is oxidized into tellurium(VI) by potassium dichromate. It has already been confirmed by the authors that, in a highly concentrated hydrochloric acid solution, the behavior of the tellurium thus oxidized is remarkably different from that of ordinary tellurate ions[7]. Accordingly, it is expected that the extractability of tellurium-(VI) formed with potassium dichromate into ethyl acetate, *n*-butyl acetate or methyl isobutyl ketone will differ from that of tellurite or tellurate. Therefore, experiments on the extractability of tellurium into the above-mentioned solvents were carried out under various conditions.

Twenty milliliters of a 6 N or 9 N hydrochloric acid solution containing a definite amount of tellurium, together with or without potassium dichromate, was placed in a separatory funnel whose capacity was 100 ml. To this was added 10 ml. of an organic solvent. After 10 sec. shaking, the two layers were separated. The aqueous layer was evaporated to dryness on the water-bath. The tellurium in the organic solvent was extracted back into water, and the aqueous solution thus obtained was also evaporated to dryness. After dissolving each of these two residues, the amount of tellurium in each of them was measured by the spectrophotometric method using thiourea and the extractability of the element was calculated. When potassium dichromate was present, 1 ml. of 30% hydrogen peroxide was added to the aqueous solution, and, after being evaporated to dryness, each residue was dissolved in 6 N hydrochloric acid. When this acid solution was shaken with methyl isobutyl ketone, tellurium went into the organic solvent quantitatively. After the organic layer had been washed twice with 6 N hydrochloric acid, the tellurium in the organic layer was extracted back again into water and determined spectrophotometrically. The extractability is summarized in Table III.

As shown in Table III, of the three solvents used, *n*-butyl acetate seemed to be most suitable since the extractability of tellurium into this

solvent is the smallest. It was also observed that potassium dichromate tends to reduce the extractability of the element. Accordingly, further experiments were carried out to study the extractability in detail, varying the concentration of hydrochloric acid over a wide range. The results are shown in Table IV.

Tellurium taken: 330 μg.

It has been known that the ferric iron is extracted from a concentrated hydrochloric acid solution into *n*-butyl acetate quite rapidly and quantitatively. When, for example, 20 ml. of 9 N hydrochloric acid containing 1 g. of ferric iron was treated with 10 ml. of *n*-butyl acetate, 99.8% of the iron(III) was found to be removed. Only 1.7 to 2.0 mg. of ferric iron remained in the hydrochloric acid layer after one extraction. Accordingly, this process possibly allows for the separation of a minute amount of tellurium from a large amount of iron.

The extraction of a small quantity of tellurium(IV) with methyl isobutyl ketone was also studied. Table V shows the results, which agree fairely well with those obtained by Goto et al.[8], who investigated the extractability of many metals by this solvent.

When the concentration of hydrochloric acid was adjusted to a normality of 4.5 to 6, tellurium(IV) was extracted into this liquid quantitatively, whereas chromium(III) was not removed at all under the same conditions. This fact suggests that tellurium(IV) and chromium(III) may be separated from each other by this extraction.

Tellurium taken: 330 μg.

The Separation of Iron and Tellurium with *n*-Butyl Acetate and Methyl Isobutyl Ketone.— It is clear from Table III that tellurium is partly extracted into *n*-butyl acetate when conditions allow a complete extraction of ferric iron. Therefore, further experiments were carried out to find a means of drawing a little tellurium extracted to the aqueous layer back again, leaving ferric iron in the organic layer.

Twenty milliliters of a 9.5 N hydrochloric acid solution containing 330 μg. of tellurium and 1 ml. of 5% potassium dichromate solution was shaken with 10 ml. of *n*-butyl acetate; nearly 30% of the tellurium was extracted into this organic layer. After being separated, the *n*-butyl acetate layer was washed several times with a 5 ml. portion of 9 N hydrochloric acid containing 1 ml. of 5% potassium dichromate. The results are shown in Table VI.

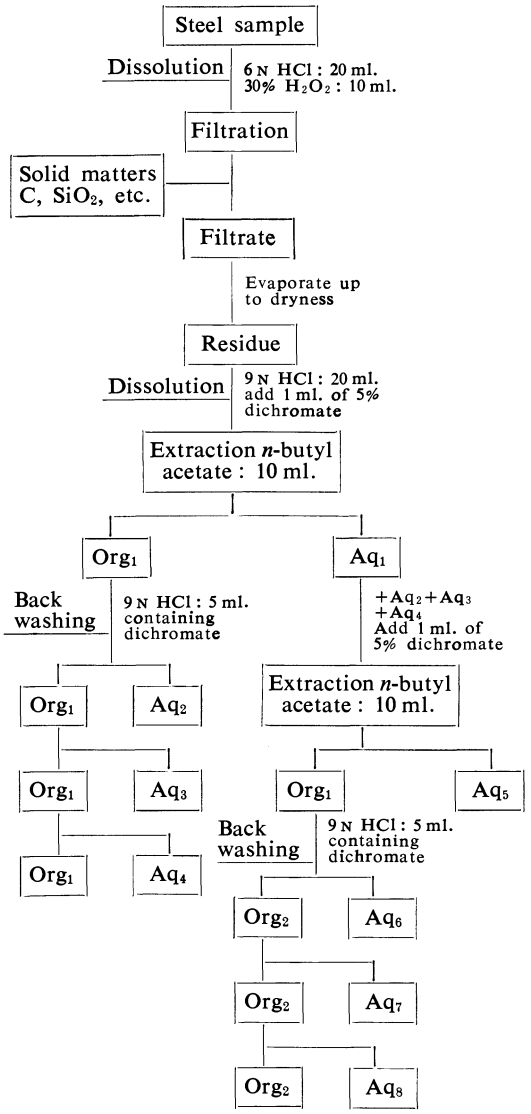
As is evident from Table VI, the tellurium in the organic layer can be shaken completely back to the aqueous layer in three back washings. Another trouble occurred, however, when, by this procedure, ferric iron also turned back, though only slightly, to the aqueous layer. Experiments were repeated, therefore, to find out a means of overcoming this difficulty. Finally the following scheme, by which a fairly satisfactory result was obtained, was obtained.

TABLE VI. BACK WASHING OF TELLURIUM(IV) FROM THE ORGANIC LAYER

No. of back washing	Tellurium remaining in the organic layer, %	
0	33.2	30.0
1	13.0	11.0
2	5.6	4.5
3	1.5	0.0

Back washing solution: 5 ml. of 9 N hydrochloric acid containing 1 ml. of 5% potassium dichromate.

TABLE VII. SCHEME OF THE SEPARATION PROCEDURE FOR TELLURIUM FOR STEEL



According to this scheme, tellurium is concentrated in the combined aqueous solution ($Aq_5+Aq_6+Aq_7+Aq_8$); the amount of iron in this solution is negligible. Chromium(III) as well as chromium(VI) are enriched in this aqueous layer, so that the removal of this element is necessary prior to the determination of the tellurium. Extraction with methyl isobutyl ketone is recommended for this purpose. The procedure is as follows:

Two milliliters of 30% hydrogen peroxide is added to a hydrochloric acid solution containing tellurium, together with chromium as a dichromate. After chromium(VI) is reduced to chromium(III), the excess of hydrogen peroxide is decomposed by heating and the total volume of the solution is regulated to 20 ml. The acid concentration is adjusted to a normality of 4.5 to 6, and the tellurium is extracted with 10 ml. of methyl isobutyl ketone. One extraction is sufficient for the complete separation of the two elements. The tellurium extracted into the organic layer is successfully transferred back to the aqueous layer by treating it twice with 5 ml. of distilled water. Iron does not interfere in the spectrophotometry since the amount of this metal behaving with tellurium is less than 0.1 mg., even when 1 g. is contained in the original solution. Table VIII shows that a large amount of ferric iron can be separated from tellurium(IV) by this method.

Aqueous layer : 20 ml.; organic layer : 10 ml.; when 1.02 g. of iron was taken, aqueous layer : 40 ml.; organic layer : 20 ml.

It has been made clear that our new method furnishes a quantitative means for separating iron and tellurium.

The Determination of Tellurium in Steel. — Since we had no standard sample at hand whose tellurium content was known, the same sample was analyzed both by our method and by the conventional precipitation method and the two results were compared for reference.

In our method, 0.5 g. of the steel sample was heated in a mixture of 20 ml. of 6 N hydrochloric acid and 10 ml. of 30% hydrogen peroxide until it dissolved; the insoluble matters

(carbon, silica, etc.) were then filtered off. After washing the residue with 10 ml. of 6 N hydrochloric acid, the filtrate, together with the washing, was evaporated to dryness on a water bath. The residue obtained was then treated according to the procedure described above.

As was pointed out above, in the precipitation method the amount of tellurium can not be determined accurately unless it is more than 0.1 mg. Therefore, we took many samples of at least 1 g. or more. The samples were dissolved in 20 to 30 ml. of 6 N sulfuric acid. When the solid matter nearly disappeared, 10 g. of stannous chloride was introduced. After having been left standing for 30 min., the solution was filtered and the solid remaining on the filter paper was washed with hydrochloric acid (1 : 10) containing stannous chloride and then with water. The washed precipitate of tellurium was dissolved in hot hydrochloric acid (1 : 2) containing hydrogen peroxide, the excess of which was decomposed by heating. After adjusting the acid concentration and the volume of the solution to about 3 N and 100 ml. respectively, tellurium was precipitated by adding 5 g. of stannous chloride. The results are summarized in Table IX. The two values are in good accord.

Conclusion

1) In the precipitation method, foreign substances existing in the solution tend to coprecipitate and lower results for tellurium are occasionally obtained, especially when the total amount of tellurium is less than 0.1 mg. The authors' method gives better results even when the amount of tellurium falls under this amount.

2) After being separated from iron, tellurium is determined by the spectrophotometric method with thiourea, i. e., by measuring the absorption at 350 and 370 mμ. In this procedure, the variety as well as the quantity of coexisting anions markedly affects the result of analysis, so they must be accurately regulated. When our extraction procedure is applied, however, these troubles are considerably minimized.

3) The amount of the sample to be taken in our method should preferably be not more than 0.5 g. If a larger amount is taken, some time-consuming treatment must be added and the rapidity of the method is lost.

A Note on the Exchange Interaction between Different Electron Spins in Organic Molecular Complexes

By Minoru KINOSHITA

(Received October 30, 1962)

In a previous paper the electron spin resonance in the complex of 2,2'-dinaphthyl disulfide with antimony pentachloride was presented[1]. It was reported there that the g-value of the complex was found to take two values, depending on the sample chosen; one of these values was 2.0074 ± 0.0001, and the other 2.0051 ± 0.0002 in the powdered state, the origin of which was not clarified. However, yet another g-value, 2.0063 ± 0.0002, has recently been observed in the same complex. This value is a mean of the above values. It is known that such a phenomenon can be interpreted on the basis of the exchange interaction between the species with different g-values.

If there are two electron spins with different g-values, g_1 and g_2, in an external static magetic field, H, and if an exchang interaction is present between them, then the Hamiltonian for this system can be given as:

$$\mathscr{H}=g_1\beta HS_{1z}+g_2\beta HS_{2z}+2J\vec{S}_1\cdot\vec{S}_2 \qquad (1)$$

By the use of the vector model, Hamiltonian (1) can be written as:

$$\mathscr{H}=g_1\beta H(S_z-\gamma S_{2z})+J\{S(S+1)-\frac{3}{2}\} \qquad (2)$$

where S_z is the component of the electron spin operator $\vec{S}=\vec{S}_1+\vec{S}_2$; $S(S+1)$ the eigenvalue of $\vec{S}^2$, and $\gamma=1-g_2/g_1$. Omitting the constant term, the energy levels will be obtained as follows:

$$E_{0,0}=J-(J^2+\frac{1}{4}g_1^2\beta^2H^2\gamma^2)^{1/2} \quad \text{for } S=0,\ M=0$$

$$E_{1,-1}=2J-g_1\beta H(1-\frac{1}{2}\gamma) \quad \text{for } S=1,\ M=-1$$

$$E_{1,0}=J+(J^2+\frac{1}{4}g_1^2\beta^2H^2\gamma^2)^{1/2} \quad \text{for } S=1,\ M=0$$

$$E_{1,1}=2J+g_1\beta H(1-\frac{1}{2}\gamma) \quad \text{for } S=1,\ M=1$$

Now two limited cases will be considered.

In the first case, that of $J\gg g_1\beta H\gamma/2$, the $E_{1,0}$ expression may be given as;

$$E_{1,0}=2J+\frac{1}{2}J(g_1\beta H\gamma/2J)^2$$

According to the selection rule, $\Delta S=0$ and $\Delta M=\pm1$, the two transitions are derived as:

$$h\nu_1=\frac{1}{2}(g_1+g_2)\beta H+\frac{1}{2}J(g_1\beta H\gamma/2J)^2 \text{ and}$$

$$h\nu_2=\frac{1}{2}(g_1+g_2)\beta H-\frac{1}{2}J(g_1\beta H\gamma/2J)^2$$

When J is sufficienty large, only one transition can be observed;

$$h\nu_1=h\nu_2=\frac{1}{2}(g_1+g_2)\beta H$$

In the second case, that of $\frac{1}{2}g_1\beta H\gamma\gg J\approx0$, on the other hand, two absorption lines should be obtained:

$$h\nu_1=g_1\beta H-J, \text{ and } h\nu_2=g_2\beta H+J$$

These circumstances are demonstrated in Figs. 1 and 2.

In the complex of 2,2'-dinaphthyl disulfide with antimony pentachloride, the phenomenon mentioned above may be ascribed to the first

(A) Carbazol
(B) 2, 2'-Dinaphthyl disulfide
(C) The mixed complex of carbazol and 2, 2'-dinaphthyl disulfide
(D) Each complex of (A) and (B) is placed in different capillaries and measured at the same time.

case considered. This assignment is supported by the following experiments. The complex of carbazol with the same reagent gave the resonance line at $g=2.0026\pm0.0003$, while the mixed crystal, which was made by adding the antimony pentachloride solution in chloroform to the mixed solution of carbazol and 2, 2'-dinaphthyl disulfide, gave the line at $g=2.0042\pm0.0002$ (Fig. 3). This value is very near the mean value (2.0045) of 2.0063 for the complex of 2, 2'-dinaphthyl disulfide and 2.0026 for the complex of carbazol, showing that there are sufficiently large exchange interactions between the paramagnetic electron spins produced by the reaction of carbazol and 2, 2'-dinaphthyl disulfide with antimony pentachloride. In this case, the exchange interaction, J, is much greater than $\frac{1}{2}g_1\beta H\gamma \approx 4\times 10^{-8}$ eV.

A similar result was obtained in the mixed complex of carbazol and thio-β-naphthol with antimony pentachloride. The system of thio-β-naphthol with antimony pentachloride has already been reported as giving the spin resonance at $g=2.0076\pm0.0002$ or $g=2.0051\pm0.0002$[1]. The mixed complex showed the resonance at $g=2.0036\pm0.0003$, which was very near the mean of the 2.0051 and 2.0026 values. Again, a sufficiently large exchange interaction between paramagnetic species should be taken into account.

Although antimony pentachloride has been considered to take a diamagnetic form in the complexes[2-4], it is not clarified from this investigation whether the spin exchange between the radicals could occur only in the organic substances, or through the electron-accepting molecules also. It is expected, however, assuming the homogeneous distribution of the radicals in the complex, that the exchange interactions cover over several molecules, since the spin concentration in the complexes studied here was found to be less than 10% of the organic substances.

2) H. Kainer and K. H. Hausser, *Chem. Ber.*, 86, 1563 (1953).
3) M. Kinoshita, This Bulletin, 35, 1137 (1962).
4) G. E. Blomgren and J. Kommandeur, *J. Chem. Phys.*, 35, 1636 (1961).

It has been shown that the complex of *p*-phenylenediamine with *p*-chloranil gives two electron spin-resonance absorption lines; they have been assigned to the free radicals produced from the respective components[5]. However, a number of charge transfer complexes, such as aromatic compounds with tetracyanoethylene, haloanils, iodine, etc., have been shown to give only a single resonance line. It is not clear whether the radicals responsible for a single resonance line are formed from only one of the two components or from both components of the complex. If a single resonance line of a complex is due to the radicals generated from both donor and acceptor, it seems very likely that a single resonance line can be explained by the exchange interaction between the radicals.

However, there seems to be no regularity in *g*-values for the aromatics-iodine system. In general, the ESR absorption for the iodine cmplexes is composed of only a single line; in this case, it is supposed, as one of the possibilities, that the strong ESR absorption is due to the strong electron transfer from donor to acceptor molecules. If this is the case, the *g*-values of the iodine complexes are expected to lie at about the average of the *g*-values of an aromatic monopositive ion and of an iodine negative ion (I_2^-). The available data are given in Table I for the iodine complexes, together with the *g*-values of the monopositive ion of aromatic compounds. It seems for the iodine complexes that the observed *g*-values are rather close to, but somewhat higher than, the *g*-value of the monopositive ion of the corresponding aromatic compounds.

The violanthrene-iodine system forms the complex of a non-stoichiometric composition[6,7]; its iodine content can be varied over a very wide range. Uchida and Akamatu[7] have shown that the *g*-value of this system does not depend on the iodine content in the range from a 10^{-4} to a 3-mol. ratio to violanthrene; they have, therefore, concluded, considering the other electronic properties of the system, that the localized charge-transfer state is not the state of paramagnetism and that the free hole, which is produced by the thermal excitation with the activation energy which is correlated with the electrical conduction and that is delocalized over several violanthrene molecules, is responsible for the electrical conductivity and also for the paramagnetism. The coincidence of the activation energy for the

generation of charge carriers with that of unpaired electron spins has been found in the complexes of pyrene-iodine and perylene-iodine by Singer and Kommandeur[8].

If we consider that the spin-orbit coupling constant ($-5060\ cm^{-1}$)[9] of iodine is very large, then the width of the electron spin-resonance of the iodine mononegative ion (I_2^-) might be broadened too much to observe its absorption. In consequence, it may be concluded that the *g*-values of the iodine complex can be expected to be near that of the monopositive ion of the corresponding aromatic compound, as there should be expected no strong interaction between the iodine negative ion and the free hole produced by the scheme which has been proposed by Uchida and Akamatu[7].

The author wishes to express his hearty thanks to Professor Hideo Akamatu for his valuable advice and discussion.

Vinyl Polymerization. LXVII. The Polymerization of Vinyl Acetate in the Presence of Zinc Chloride

By Minoru IMOTO, Takayuki OTSU and Toshio ITO

(Received October 31, 1962)

In the previous paper[1], we have found that photopolymerization of vinyl acetate initiated by azobisisobutyronitrile (AIBN) in the presence of zinc chloride proceeds in the heterogeneous system. The present paper deals with the effect of zinc chloride on the radical polymerization of vinyl acetate and on the properties of the resultant polymers.

Experimental

Materials.—Vinyl acetate was purified as follows: Commercial vinyl acetate was washed successively with 5% sodium thiosulfate solution and dilute sodium hydroxide solution and then dried over calcium chloride. Pure vinyl acetate was obtained by distillation in the presence of 2% azobisisobutyronitrile in a nitrogen atmosphere. Commercial grade zinc chloride was used without further purification and dehydrated according to the method described in a previous paper[1]. Azobisisobutyronitrile and other reagents were purified by the usual method.

Polymerization Procedure.—In a 100 ml. hard glass tube, a given amount of zinc chloride was placed and the tube was heated at about 300°C for 15 min. under vacuum. Pure vinyl acetate was then added and the tube was shaken to make a solution. The resulting solution was rapidly transfered by pipetting into the polymerization tubes. The tubes were then degassed and sealed under vacuum.

Polymerizations were allowed to take place on shaking in a thermostat. Photopolymerizations were carried out in a thermostat, irradiating by the Madzuda SHL type high pressure mercury lamp. After a given time, the tube was removed from the thermostat and the content of the tube was rapidly filtered to separate the monomer-insoluble polymer. Then the filtrate was poured into a large amount of petroleum ether to precipitate the polymer. Both polymers were washed with dilute hydrochloric acid and then purified by the reprecipitation method with petroleum ether from acetone solution. Conversion was calculated from the weight of the dry polymer obtained.

Treatment of the Polymer.—Intrinsic viscosity of polyvinyl acetate was determined by viscosity measurement of its dilute acetone solution at 30°C. Hydrolysis of polyvinyl acetate was performed as follows: 2 g. of polyvinyl acetate was dissolved in 100 ml. of methanol and 3 ml. of 5% aqueous sodium hydroxide solution was added. After standing overnight at room temperature and then refluxing for an hour, polyvinyl alcohol was isolated. Intrinsic viscosity of polyvinyl alcohol was determined from the viscosity measurement in water solution. Reacetylation was carried out by heating polyvinyl alcohol in pyridine-acetic anhydride at 95°C for 3 hr.

Experimental Results

Polymerization of Vinyl Acetate (VAC) with Zinc Chloride.—Results of the polymerization of VAC with zinc chloride are shown in Table I.

As can be seen from Table I, the polymerizations of VAC with zinc chloride proceeded with a slow rate to yield the colored polymer which was insoluble in the VAC monomer. Tho resulting dried polymer melted at 106~108°C and was a low molecular weight polymer. Carbon and hydrogen contents of this polymer were 61.39 and 7.40%, respectively and these values widely differ from those calculated for pure polyvinyl acetate (C, 54.54; H, 9.09%). This polymer was easily soluble in most organic solvents, such as methanol and acetone, to make a colored solution which was decolorized by the addition of bromine. Infrared spectra of this polymer showed the absorption bands of hydroxyl, carbonyl and carbon-carbon double bonds.

It was also found that the polymerization could not be retarded by the addition of hydroquinone. Accordingly, it might be considered that the polymerization of VAC with zinc chloride proceeded with the carbonium ion mechanism and the resulting polymer then reacted with zinc chloride to yield the colored polymer having a complexed structure.

Table II shows the results of the polymerization of VAC by the system AIBN and zinc chloride. Although AIBN is a typical radical initiator, the yields of polymer were approximately equal to those obtained by zinc chloride alone. It was assumed that the polymerization with both initiator and zinc chloride proceeded with carbonium-ion mechanism and the resulted colored polymer served as an inhibitor for the radical polymerization of VAC by AIBN.

Effect of Zinc Chloride on the Photopolymerization of VAC Sensitized by AIBN.— Results of the photopolymerization of VAC sensitized by AIBN are shown in Tables III and IV.

As can be seen from Tables III and IV, the rates of polymerization of VAC at rather high temperatures (> 30°C) decreased with the addition of zinc chloride. However, at lower temperatures below 10°C, the rates increased with the addition of zinc chloride and the resulting polymer contained the VAC-insoluble polymer which was dissolved in most organic solvents after purification. The amount of the VAC-insoluble polymer increased with decreasing the polymerization temperature. It is also

proved from these tables that at rather high temperatures, cationic and radical polymerizations occured simultaneously and the resulting colored polymer served as inhibitor for the radical polymerization.

Since the low-temperature photopolymerization of VAC sensitized by AIBN in the presence of zinc chloride proceeded in a heterogeneous system, it was difficult to study kinetically this polymerization. As can be seen from Fig. 1, however, the time-conversion curve of the polymerization showed a straight line at the initial stage of the polymerization. Accordingly, it may be possible to investigate kinetically this polymerization.

Figure 1 shows time-conversion curve for the photopolymerization of VAC sensitized by AIBN in the presence of zinc chloride at −30°C. Time-conversion curve shows a straight line up to 2% conversion, but in general the rate decreased with the proceeding of the polymerization. Figure 2 shows the relationship

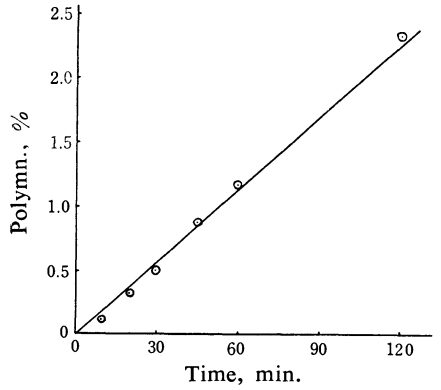

Fig. 1. Time-conversion curve for the photopolymerization of VAC with AIBN-$ZnCl_2$ at −30°C: [AIBN] = 6.1×10^{-3}, [$ZnCl_2$] = 0.215 mol./l.

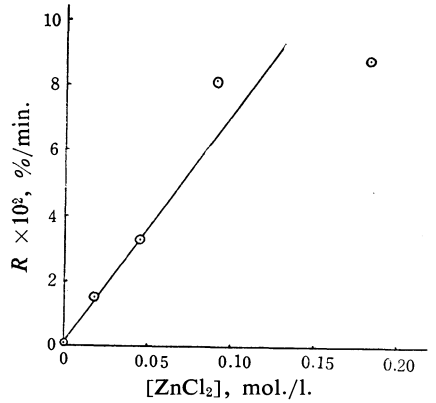

Fig. 2. Relationship between R_p and [$ZnCl_2$] for the photopolymerizations of VAC at −30°C: [AIBN] = 6.1×10^{-3} mol./l.

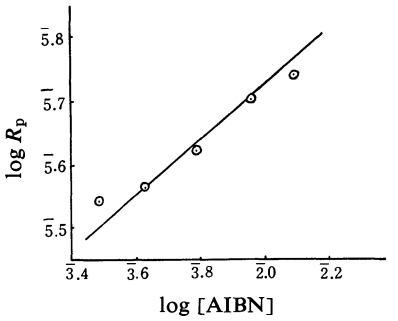

Fig. 3. Relationship between R_p and [AIBN] for the photopolymerizations of VAC at −30°C: [$ZnCl_2$] = 0.341 mol./l.

between the rate of polymerization (R_p) and the concentration of zinc chloride. At lower concentrations of zinc chloride, it was clear that R_p is proportional to the concentration of zinc chloride. Figure 3 shows the relationship between R_p and the concentration of AIBN at constant concentration of zinc chloride. From this figure, it was deduced that R_p was proportional to the square root concentration of AIBN.

Properties of the Resulting Polymer.—A large amount of zinc chloride was detected in the crude VAC-insoluble polymer obtained by the photopolymerization of VAC in the presence of zinc chloride at −30°C. For example, 0.245 mol./l. of zinc chloride was occluded in the polymer isolated at 3.32% conversion, using [$ZnCl_2$] = 0.413 mol./l. This crude polymer was very hygroscopic, but the polymer purified through the reprecipitation method to remove zinc chloride was soluble in VAC, methanol, acetone, ethyl acetate and benzene. Accordingly, it was clear that the formation of the VAC-insoluble polymer was due to a complex formation of PVAC with zinc chloride.

Elementary analysis and infrared spectra also showed that the pure polymer had the structure of ordinary polyvinyl acetate. Intrinsic viscosities of these polymers were lower than those of polymers obtained in the absence of zine chloride, as indicated in Table IV. The result suggested that zinc chloride served as a chain transfer agent for the polymerization.

Experiments of the hydrolysis of this polymer to yield polyvinyl alcohol and of further reacetylation were carried out. During these treatments, it was confirmed by infrared spectra that these reactions proceed completely. Viscosity changes of the polymers are shown in Fig. 4. As understood from this figure, intrinsic viscosities and k'-values of polyvinyl acetates did not change during the hydrolysis and then reacetylation. This fact indicated

that PVAC obtained by the polymerization in the presence of zinc chloride had no long chain branch of the ester type which is capable of scission by hydrolysis. Solubilities in hot water, phenol and dimethyl sulfoxide and the crystallinities by X-ray analysis of these polyvinyl alcohols coincided almost with the ordinary polyvinyl alcohol.

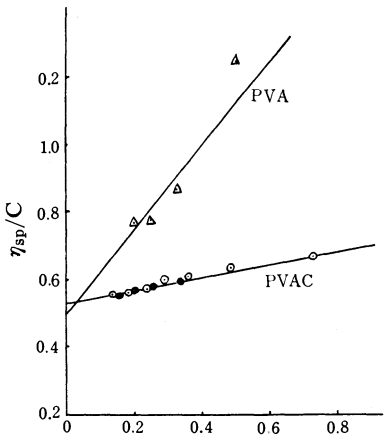

Fig. 4. Relationship between η_{sp}/C and C for polyvinyl acetate (PVAC) and polyvinyl alcohol (PVA) obtained from the photopolymerizations with AIBN-$ZnCl_2$: ⊙ before hydrolysis, ● after hydrolysis and then reacetylation for PVAC.

The Complex Formation of VAC with Zinc Chloride.—In order to isolate the complex of VAC with zinc chloride, a required amount of zinc chloride was dissolved by shaking in an excess of VAC and then the excess of VAC was rapidly removed by vacuum distillation. Pale yellow viscous liquid was obtained. From the weight and chlorine analyses it was proved that the complex was composed of 1 : 1 molar ratio of VAC to zinc chloride.

This complex was very hygroscopic and unstable. When the complex was allowed to stand in a sealed tube at room temperature, the cationic polymerization occured explosively after standing about 20 hr. to produce the colored polymer.

Discussion

It has been generally known that zinc chloride can initiate the cationic polymerization. In polymerization of vinyl acetate, it was observed in the present paper that zinc chloride could also initiate the cationic polymerization. In this case, however, the polymerization was accompanied by side reactions such as hydrolysis, deacetylation or dehydration and the resultant polymer was a yellow or reddish brown powder with a low molecular weight. These results agreed with those obtained by Higashimura and Okamura[2] that tin(II) chloride could initiate the cationic polymerization of vinyl acetate.

The rate of cationic polymerization of vinyl acetate was so slow that it hardly proceeded at rather low temperatures. Therefore, when AIBN as an initiator for radical polymerization was used together with zinc chloride, both radical and cationic polymerizations proceeded at the same time at higher temperatures ($>30°C$).

The polymer obtained in the latter reaction served as an inhibitor for the radical polymerization. At lower temperatures ($<10°C$), however, no inhibition of polymerization was observed, since the cationic polymerization might be retarded and only the polymerization proceeded through the radical mechanism.

The presence of zinc chloride may characterize the photopolymerization of vinyl acetate at lower temperatures using AIBN as photosensitizer, in two respects: acceleration of polymerization and progress of polymerization in a heterogeneous system. Although the rate of decomposition of AIBN could not be affected by the presence of zinc chloride[1], the effect of zinc chloride in the polymerization system might be considered as follows: (1) Complex formation with the monomer (VAC), (2) interaction with the growing radical and the monomer at the transition state of the propagation step, and (3) influences on the transfer and termination reactions. If the interaction of (2) was the most important among them, a stereoregular polymer should be obtained as Kargin et al.[3] pointed out. In fact, this effect of zine chloride could be neglected, since no stereoregular polymers were obtained through radical polymerizations as shown in a previous[1] and in the present paper. As for influences of (3), Table IV showed that smaller values of intrinsic viscosity were obtained in the presence of zinc chloride, indicating that zinc chloride served as a chain transfer agent.

The present authors[4] observed that zinc chloride could readily form a complex with methyl methacrylate or acrylonitrile. It was

reported by Matsumoto[5] that vinyl acetate made a complex in a molar ratio of 1 : 1 with $Cd(C_2H_5)_2$. A complex of zinc chloride with vinyl acetate in a molar ratio of 1 : 1 could also be isolated in the present work. However, since the complex was so unstable that the cationic polymerization proceeded explosively on standing. Since it was hygroscopic, the present authors could not determined infrared absorption spectra. Nevertheless, both the results of Matsumoto[5] and of the present authors[4] have almost made it clear that the carbonyl group of vinyl acetate might contribute to the complex formation with zinc chloride.

The probable formation of such a complex might cause polarization of double bands. As the *e* value for vinyl acetate was −0.3, the reactivity of uncomplexed vinyl acetate radicals with complexed vinyl acetate was considered to be increased. Therefore, as Bamford et al.[6] pointed out, the acceleration by zinc chloride might be explained in terms of copolymerization of complexed and uncomplexed vinyl acetate. It was confirmed by the fact that a large amount of zinc chloride was detected in the resultant polymer which was insoluble in the monomer, or that polymerization begins in a heterogeneous system.

Summary

A study of the effect of zinc chloride on the polymerization of vinyl acetate has been made. Zinc chloride can initiate the cationic polymerization of vinyl acetate at above room temperatures to yield the colored low-molecular weight polymer. However, in the low-temperature photopolymerization of vinyl acetate initiated by azobisisobutyronitrile, zinc chloride accelerates the radical polymerization and the colorless polymer which is insoluble in the monomer is obtained. Elementary analysis, infrared spectra and X-ray analyses show that the structure of this polymer after purification does not differ with that of ordinary polyvinyl acetate and polyvinyl alcohol obtained through the hydrolysis of this polymer has no crystallinity superior to that of the ordinary sample.

Vinyl Polymerization. LXX. Preparation of 3-(4'-Pentenyl)cyclopentene-1 and its Alternative Copolymerization with Maleic Anhydride*

By Minoru IMOTO, Kazuichi TSUDA and Takayuki OTSU

(Received November 5, 1962)

3-(4'-Pentenyl)cyclopentene-1 (PCP) was prepared from tetrahydrofurfuryl alcohol and cyclopentadiene, by the scheme as shown in Fig. 1.

Tetrahydrofurfuryl alcohol was chlorinated by thionyl chloride into tetrahydrofurfuryl chloride, and the ring cleavage of the chloride formed by metallic sodium led to the formation of 4-penten-1-ol. By the bromination of 4-penten-1-ol with phosphorous tribromide, the unsaturated alcohol was transformed into 5-bromo-1-pentene, which was then converted into its Grignard compound.

3-Chlorocyclopentene-1 was prepared by

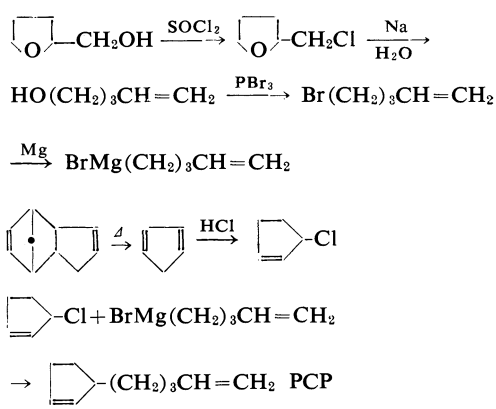

Fig. 1. The process of PCP synthesis.

hydrochlorination of cyclopentadiene, which was the pyrolysis product of dicyclopentadiene. A coupling reaction was carried out between the 1-pentenylmagnesium bromide and the 3-chlorocyclopentene-1 at −30∼−35°C. By this reaction, PCP was yielded. The infrared spectrum of PCP is shown in Fig. 2A.

In order to synthesize polyperhydroazulene or poly(methyleneperhydroindene) by intra- and inter-molecular polymerization, radical polymerization was attempted by azobisisobutyronitrile (AIBN) at 60°C for 30 hr. Polymerization by Ziegler catalyst was also tried at 30, 5 and −70°C for 72 and 120 hr., respectively. In the case of using Ziegler catalyst, the Al/Ti molar ratio was changed from 0.93 to 3.39. A little brown methanol-soluble oil was obtained and most of the monomer PCP was recovered in both cases. Cationic polymerization was performed by titanium tetrachloride or boron trifluoride etherate at 30, 5 and −70°C for 72 and 120 hr., respectively, under nitrogen atomosphere. When titanium tetrachloride was employed, the results were the same as in radical and Ziegler polymerization, but by boron trifluoride etherate initiator, a trace of reddish brown gel polymer was obtained. This polymer did not dissolve in common organic solvents, and most of the monomer PCP was recovered. From the above results, it may safely be said that PCP does not homopolymerize under these conditions.

PCP was copolymerized with maleic anhydride (MA) by the use of a radical initiator at 60°C for 3 hr. Under these conditions, neither maleic anhydride nor PCP homopolymerized and the copolymers of PCP with MA were obtained in a good yield.

When the molar ratio in the monomer mixture of PCP to maleic anhydride was varied from 1 : 1 to 1 : 2, 2 : 1 and 2.8 : 1, no change was observed in the copolymer composition (the proportion of PCP to maleic anhydride being 1 to 2), as shown in Table I. The infrared absorptions of vinyl type double bond and unsaturated cyclopentene ring of PCP in copolymer disappeared in the infrared absorption spectrum as shown in Fig. 2B, so it is assumed that both the double bonds participated in the copolymerization and formed glassy gelled pale-yellow copolymer. These

results indicated an alternative copolymerization.

Experimental

Preparation of 4-Penten-1-ol.—Tetrahydrofurfuryl chloride was obtained by Brooks and Snyder's method[1]. Tetrahydrofurfuryl alcohol was chlorinated by thionyl chloride; yield 68~72% (lit. 73~75%); b. p. 40~42°C/11mmHg (lit. 41~42°C/11mmHg).

4-Penten-1-ol was prepared with ring cleavage of tetrahydrofurfuryl chloride by metallic sodium. The yield of b. p. 136~137°C was 71~74% (lit. 76~83%); n_D^{20} 1.4300 (lit. 1.4299). (Found: C, 69.75; H, 12.31. Calcd. for $C_5H_{10}O$: C, 69.77; H, 11.63%.)

Preparation of 5-Bromo-1-pentene.—5-Bromo-1-pentene was prepared by a modification of La Forge's method[2]. 1.6 mol. of 4-penten-1-ol and 0.5 mol. of pyridine were placed in a four-necked flask. The contents of the flask was held, being stirred, at about −30 to −35°C and 0.6 mol. of phosphorus tribromide was added into the flask over a period of about 5 hr. dropwise to prevent vigorous exothermic reaction; stirring was continued one hour more. The reflux condenser was then replaced by a Vigreux column and the product of the reaction was distilled on an oil bath until the temperature in the flask rose to 160~170°C. The distillate was washed with water, dilute sodium hydroxide, and lastly with water. After being dried on calcium chloride, the product was distilled several times. The yield of pure 5-bromo-1-pentene, boiling between 125.5 and 126.0°C at atmospheric pressure, was 55~57%: d_{25}^{25} 1.2595; n_D^{25} 1.4645.

Found: C, 40.55; H, 6.30; Br, 53.60*. Calcd. for C_5H_9Br: C, 40.31; H, 6.08; Br, 53.65%.

3-Chlorocyclopentene-1. — The chlorohydrogenation of cyclopentadiene, which was obtained by the pyrolysis of dicyclopentadiene, yielded 3-chlorocyclopentadiene[3].

Synthesis of PCP.—3.3 g. of magnesium was placed in a four-necked flask, and the mixture of 5-bromo-l-pentene and ether contained in a funnel was added dropwise into the flask which was cooled in a water bath. Stirring was continued two more hours even after the addition was made to complete the reaction. To this 1-pentenylmagnesium bromide, a mixture of 3-chlorocyclopentene-1 (15 g.) and ether (25 g.) was added dropwise, during which time the flask was cooled between −30 to −35°C under nitrogen atmosphere. A vigorous reaction followed immediately and white magnesium halide was precipitated. The addition was made for about 1 hr. and stirring was continued for an additional 2 hr., and then the temperature of the reaction mixture was risen gradually to 25°C. Stirring was carried on for another 2 hr. The reaction product was then poured into a large amount of water and the unreacted compound was decomposed. The ether layer was separated and dried over magnesium sulfate. After the removal of the ether by distillation, the residue was distilled through a Vigreux column. The yield of PCP was 88~91%; b. p. 46.0~47.0°C/7 mmHg. n_D^{25} 1.4582: d_{25}^{25} 0.8267.

Found: C, 88.05; H, 11.91. Calcd. for $C_{10}H_{16}$: C, 88.16; H, 11.84%.

Polymerization of PCP.—*Radical Polymerization.*—AIBN, m. p. 102.0~102.5°C, recrystallized twice from methanol, was used for radical polymerization. The polymerization was carried out in benzene. The benzene solution of PCP (3 ml. of PCP mixed with 7 ml. of benzene or 3 ml. with 3 ml.) and AIBN ($2.303\sim6.911\times10^{-2}$ mol./l. and $1.352\sim3.577\times10^{-1}$ mol./l.) as initiator, were charged into a tube, and sealed in vacuo under cooling in a dry ice-methanol bath. The polymerization was carried out in a thermostat at 60°C under shaking for 30 hr. After polymerization, the content of the tube was poured into methanol.

Anionic Polymerization.—Anionic Polymerization was carried out in *n*-hexane, which was distilled twice over sodium wire. Commercial *n*-butyl lithium was used as initiator which was diluted with *n*-hexane to 0.193~0.385 mol./l. The hexane solution of PCP (2 ml. of PCP in 1 ml. of *n*-hexane) and of *n*-butyl lithium were fed into a tube, and sealed under nitrogen atmosphere. The polymerization was carried out at 30, 5 and −70°C from 72 to 120 hr.

Polymerization by Ziegler Catalyst.—The triisobutylaluminum ($Al(i\text{-}Bu)_3$), supplied by Ethyl Corporation, was diluted with *n*-hexane and titanium tetrachloride was distilled three times and used as *n*-hexane solution. The hexane solution of triisobutylaluminum was charged into a tube and then titanium tetrachloride solution was added under nitrogen atomosphere, and a reddish brown precipitate appeared immediately. An addition of titanium tetrachloride was made and then the tube was stood for 15 min., the monomer, PCP, was added and the tube was sealed under nitrogen atomosphere. The polymerization was carried out at 25, 5 and −70°C for 120 hr. and the tube was shaken at times during the process. In these polymerizations, Al/Ti molar ratio was changed from 0.93 to 1.23, 2.16, 2.47 and 3.39, and the total catalyst concentration to the monomer was varied between 2.04~4.18 wt.%.

After polymerization, the content of the tube was poured into a large amount of methanol, but no polymer was precipitated. In the polymerizations by radical and Ziegler type initiators, a small quantity of brown methanol-soluble oil was obtained, when monomer PCP was recovering.

Cationic Polymerization.—Cationic polymerization was carried out by titanium tetrachloride or boron trifluoride etherate catalysts.

A mixture of 2 ml. of PCP, 2 ml. of *n*-hexane and $6.593\sim13.19\times10^{-2}$ mol./l. of titanium tetrachloride were fed into a tube and sealed under nitrogen atomosphere. The polymerization was carried out at 30 and 50°C for 120 hr. Then the content of the tube was poured into excess methanol. The same results were obtained as both in radical and

* After hydrolyzed by 10% KOH for 50 hr. Theoretical value for 1 : 2 copolymer: C, 58.69%; H, 6.57%; O, 34.75%.

Ziegler catalyst polymerizations and no polymer was formed.

Freshly distilled boron trifluoride etherate was added to a tube containing 2 ml. of PCP and 2 ml. of benzene. The concentration of boron trifluoride etherate was changed between $3.910\sim7.820\times10^{-2}$ mol./l. When the initiator was added to the benzene solution of PCP, the solution immediately turned pale brown. Polymerization was performed at 30, 5°C and room temperature for 72 hr.

After polymerization, when the mixture in the tube was poured into a large excess of methanol, a trace of brown polymer precipitated.

In view of the above results, another polymerization, in which the concentration of boron trifluoride etherate was increased to 1.56×10^{-1} and 7.95×10^{-2} mol./l. was performed at 50°C and room temperature. The results obtained in the secnd series of these polymerizations were the same as those in the first series of the same polymerization of boron trifluoride etherate initiated polymerization. This polymer was swelled a little in tetrahydrofuran only. No double bond being found in infrared absorption spectrum, we assume that PCP is polymerized by boron trifluoride etherate to form a cross-linked polymer. The polymer obtained was a very small quantity.

Copolymerization of PCP with MA.—MA, m. p. 53~54°C, was recrystallized three times from chloroform. AIBN was used as polymerization initiator. Polymerization was carried out as usual, monomers and initiator being charged into a tube and sealed in vacuo, in a thermostat at 60°C under shaking. During the polymerization, a pale yellow waxy polymer precipitated from polymerization system. After 3 hr., the content of the tube was poured into a large amount of methanol. The precipitated polymers were filtered and dried under 40°C in a desiccator. The polymers appeared like a pale yellow glassy substance and swelled a little in tetrahydrofuran, dioxane and dimethylformamide.

The polymers were refluxed in tetrahydrofuran and methanol for 3 hr. to remove as much initiator as possible. Then the polymers were hydrolyzed by 10% potassium hydroxide or hydrochloric acid as catalyst in water for 50 hr. Hydrolyzed polymers by potassium hydroxide catalyst is shown in Table II. The values of carbon % in Table II are somewhat larger than the theoretical value and the values of oxygen % are rather small due to the difficulty in complete hydrolysis: these polymers were gelled and did not dissolve in the solvent.

As Table II shows, PCP and maleic anhydride were copolymerized and when the monomer mixture ratio was changed, the polymer composition was not changed but always kept the constant ratio of 1 to 2. After hydrolysis, the absorption band of carboxyl group appeared in the infrared absorption spectrum.

These results indicate that two unsaturated double bonds of PCP participate in the copolymerization with maleic anhydride to form a glassy gelled alternative copolymer, the ratio of PCP to maleic anhydride being 1 to 2.

Summary

3-(4'-Pentenyl)cyclopentene-1 (PCP) was prepared through the reaction of 1-pentenyl magnesium bromide and 3-chlorocyclopentene-1. An attempt was made for the polymerization and copolymerization of PCP. In the polymerizations by radical (azobisisobutyronitrile) and Ziegler [Al(*i*-Bu)$_3$-TiCl$_4$] initiators, a little brown methanol-soluble oil was obtained. By cationic initiator ($BF_3\cdot OEt_2$), however, a trace of reddish brown polymer which did not dissolve in common organic solvents was formed.

PCP was copolymerized with maleic anhydride by the use of a radical initiator. When the monomer mixture ratio of PCP to maleic anhydride was varied, no change was observed in the copolymer composition (the proportion of PCP to maleic anhydride being 1 to 2). In the infrared spectrum of the copolymer, the absorption bands of the vinyl type double bond and the unsaturated cyclopentene ring of PCP disappeared in the copolymer, so it was to be assumed that both double bonds participated in the copolymerization to form glassy gelled pale-yellow copolymer. These results indicate that an alternative copolymerization took place.

Hydrogenation and Hydrogenolysis. VI.[1] *The Stereochemisty of the Catalytic Hydrogenation of Some Allylic Alcohols Related to Cholest-4-ene**

By Shigeo NISHIMURA** and Kazuko MORI

(Received November 5, 1962)

Catalytic hydrogenation of cholest-4-ene-3β,6β-diol with platinum oxide in ethanol gives 5β-cholestane-3β,6β-diol exclusively[2], while in the presence of a trace of hydrochloric acid a much more rapid reduction occurs and 5α-cholestane is obtained as the main product[3] along with 5α-cholestan-3β-ol. The exclusive formation of the 5β-cholestanediol in ethanol seems rather unusual, because it indicates that hydrogen was added preferentially from the β-side which appears to be more hindered than the α-side. A similar phenomenon was observed by Dart and Henbest[4] in hydrogenation of cholest-4-en-3β-ol and other cyclic allylic alcohols, a more β-addition of hydrogen being observed in cholest-4-en-3β-ol than in cholest-4-ene in hydrogenation with platinum oxide in ethanol in the presence of a small amount of sodium nitrite, which depressed hydrogenolysis causing the yield of 5β-cholestanol to increase.

In order to clarify the effects of the accumulative β-hydroxyl groups at C_3 and C_6 carbon atoms and also of solvents on the stereochemistry of the hydrogenation of the 4, 5-double bond, the catalytic hydrogenation of cholest-4-ene, cholest-4-en-3β-ol and cholest-4-ene-3β,6β-diol has been carried out in ethanol and also in acetic acid with (7 : 3)rhodium-platinum oxide[5] as catalyst. This catalyst was used because it can hydrogenate these allylic alcohols with only slight hydrogenolysis in acetic acid[6].

Experimental

Catalysts.—Platinum oxide was prepared by fusion of chloroplatinic acid with sodium nitrate according to the method of Adams et al.[7]

(7 : 3)Rhodium-platinum oxide was prepared by fusion of the mixture of rhodium chloride and chloroplatinic acid in ratio of 7 : 3 by the weights of the metals as described previously[5].

Hydrogenation.—Hydrogenation was carried out at ordinary temperature and pressure. The substrate (0.2~0.5 mmol.) was added after the oxide (20~50 mg.) was reduced to black with hydrogen in the solvent.

Cholest-4-ene.—The hydrogenation of this compound in ethanol proceeded with difficulty and was completed by addition of a new portion of catalyst. The last trace of the starting material remaining in the products was further hydrogenated with addition of a small amount of acetic acid. The hydrogenation in acetic acid proceeded rapidly to completion. The products (5α-cholestane and 5β-cholestane) were analyzed by the method of infrared absorption in carbon disulfide solution. Characteristic bands at 957 and 985 cm^{-1}, respectively, were used for this analysis.

Cholest-4-en-3β-ol.—The hydrogenation products were analyzed by gas-liquid partition chromatography with GC-1B (hydrogen flame detector type) of Shimadzu Seisakusho, Ltd. and a column of 0.1% SE-30 silicone on Chromosorb W (60~80 mesh)*.

The product from ethanol solution consisted of about 36% hydrocarbons (mainly 5α-cholestane) and 64% saturated alcohols (52% 5β-cholestan-3β-ol and 48% 5α-cholestan-3β-ol). The product from acetic acid solution consisted of 13% hydrocarbons (mainly 5α-cholestane) and 87% saturated alcohols (16% 5β-cholestan-3β-ol and 84% 5α-cholestan-3β-ol).

Cholest-4-ene-3β,6β-diol.—The product from hydrogenation in acetic acid was analyzed by gas-liquid partition chromatography as described above and also by elution chromatography. The gas chromatogram indicated that the product consisted of about 2% hydrocarbons (mainly 5α-cholestane), 13% mono-ols (mainly 5α-cholestan-3β-ol) including a very small amount of an unidentified product,

and 85% diols (54% 5β-cholestane-3β, 6β-diol and 46% 5α-cholestane-3β, 6β-diol). By elution chromatography 2% hydrocarbons, 10% mono-ols[8] and 85 to 90% diols were obtained. The product from ethanol solution was almost pure 5β-cholestane-3β, 6β-diol. Its infrared spectra showed no absorption due to 5α-cholestane-3β, 6β-diol. The product obtained by hydrogenation with platinum oxide in ethanol in the presence of a trace of hydrochloric acid was chromatographed on silica gel. The product (197 mg.) gave 122 mg. of 5α-cholestane (60%), m. p. and mixed m. p. 80~81°C, by elution with petroleum ether. Further elution with benzene gave 41 mg. of 5α-cholestan-3β-ol (20%), m. p. and mixed m. p. of it sacetate after recrystallization being 108~109°C.

Results and Discussion

Table I summarizes the compositions of products (hydrogenolysis products are excluded) obtained in hydrogenation with (7 : 3)rhodium-platinum oxide along with those obtained with platinum oxide. It shows that in ethanol more 5β-compounds are formed than 5α-compounds and 5β-cholestane-3β, 6β-diol is formed quantitatively in case of cholest-4-ene-3β, 6β-diol. The other two compounds give smaller yields of 5β-compounds not much different from each other. In the presence of sodium nitrite the β-addition of hydrogen is slightly greater in cholest-4-en-3β-ol than in cholest-4-ene[4]. It may be concluded from these results that the 6β-hydroxyl group exerts a definite directing effect to increase the β-addition of hydrogen, but the 3β-hydroxyl group has little effect, if any. Dart and Henbest[4] suggested that the 3β-hydroxyl group of cholest-4-en-3β-ol is likely to be in a quasi-equatorial conformation, from its relatively slight directing effect. In accord with their suggestion, the present results, which show a great difference of the directing effect between the 3β- and 6β-hydroxyl groups, strongly support that cholest-4-ene-3β, 6β-diol is in the conformation shown in Fig. 1a where the 3β-hydroxyl is

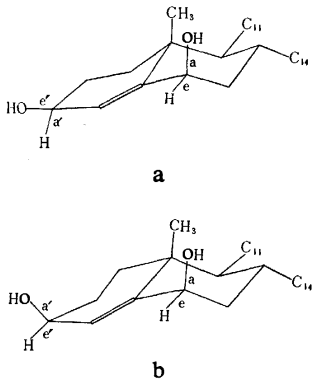

Fig. 1. Conformations of cholest-4-ene-3β, 6β-diol.

quasi-equatorial and the 6β-hydroxyl axial, rather than in the conformation shown in Fig. 1b where the 3β-hydroxyl is quasi-axial. The conformation in Fig. 1a is also consistent with the fact that the 6β-hydroxyl group is more easily hydrogenolyzed than the 3β-hydroxyl group in acidic medium since about 20% of 5α-cholestan-3β-ol was obtained along with 60% of 5α-cholestane, but no 5α-cholestan-6β-ol in hydrogenation of the cholestene-diol with platinum oxide in the presence of hydrochloric acid. The hydrogenolysis of a β-hydroxyl group caused by the α-attack of hydrogen[9] seems to be hindered more at C_3 by the quasi-axial 3α-hydrogen than at C_6 by the equatorial 6α-hydrogen.

In acetic acid the yields of 5α-compounds generally increase. The increase is more pronounced in cholest-4-en-3β-ol (48→84%) and in cholest-4-ene-3β, 6β-diol (0→46%) than in

TABLE I. PROPORTIONS OF 5β- AND 5α-CHOLESTANE DERIVATIVES IN THE PRODUCTS OF HYDROGENATION OF CHOLEST-4-ENE, CHOLEST-4-EN-3β-OL AND CHOLEST-4-ENE-3β, 6β-DIOL[a]

Compound	With (7 : 3)Rh-Pt oxide in EtOH		With (7 : 3)Rh-Pt oxide in AcOH		With Pt oxide in EtOH	
	5β	5α	5β	5α	5β	5α
Cholest-4-ene	73	27	54	46	55[b]	45[b]
Cholest-4-en-3β-ol	52	48	16	84	67[b]	33[b]
Cholest-4-ene-3β, 6β-diol	~100	~0[c]	54	46	~100	~0[c]

a) Hydrogenolysis products are excluded.
b) Dart and Henbest, Ref. 4 (a small amount of sodium nitrite was added).
c) No infrared absorption due to 5α-cholestane-3β, 6β-diol was detected.

8) The infrared absorption spectra showed that this fraction contained a small amount of a carbonyl compound probably resulting from the migration of the 4, 5-double bond during hydrogenation.

9) That the hydrocarbon obtained by hydrogenolysis is always nearly pure 5α-cholestane shows that the hydrogenolysis of a β-hydroxyl group is caused more easily by the α-attack of hydrogen than the β-attack probably by S_{N2} mechanism (cf. Ref. 4).

cholest-4-ene (27→46%). Acetic acid probably weakens the directing effect of the hydroxyl group and increases the steric hindrance to the β-addition of hydrogen. This kind of directing effect of the hydroxyl group probably results from its affinity for the catalyst metals, which may be expected from the theory of catalyst poisons largely developed by Maxted[10].

With platinum oxide in acetic acid as solvent cholest-4-ene-3β, 6β-diol is hydrogenolyzed to an extent of 65% as indicated by hydrogen uptake (Table II). The proportion of hydrogenolysis is further increased in the presence of hydrochloric acid. But, with (7 : 3) rhodium-platinum oxide the cholestenediol and cholest-4-en-3β-ol give good yields of the corresponding saturated alcohols in acetic acid (see Table II and also the experimental part).

The Selective Chelatometry of Calcium in the Presence of Magnesium with Ethylene Glycol-bis(β-aminoethyl ether)-N, N, N′, N′-tetraacetic Acid

By Genkichi NAKAGAWA, Motoharu TANAKA and Hiroko WADA

(Received November 12, 1962)

A difference in the stability constants of ethylene glycol-bis(β-aminoethyl ether)-*N*, *N*,-*N*′, *N*′-tetraacetic acid (EGTA) chelates of calcium and magnesium ($K_{Ca\text{-}EGTA}/K_{Mg\text{-}EGTA} = 10^{5.8}$)[1-3] allows the selective chelatometry of calcium in the presence of magnesium if an appropriate method is available to indicate the equivalence point. Several methods have been reported for this purpose: potentiometric titration using a mercury electrode[2], photometric titration using murexide as an indicator[4], visual titration using Zn-EGTA-zincon system as an indicator[3,5], and visual titration using calcon as an indicator and tartrate to prevent the precipitation of magnesium[6].

In our own previous investigation[7], some theoretical considerations were made of the color change in the vicinity of the equivalence point of chelatometry, using the NY-HA system as an indicator, and more recently a method for the selective chelatometry of calcium has been worked out using the Zn-EGTA-PAN system as an indicator[8]. The choice of an indicator system, the conditions for the titration of calcium with EGTA, and the experimental results from the titration of calcium using the Zn-EGTA-PAN system as an indicator constitute the present paper.

The desirable properties of the metal indicator for the chelatometry of calcium in the

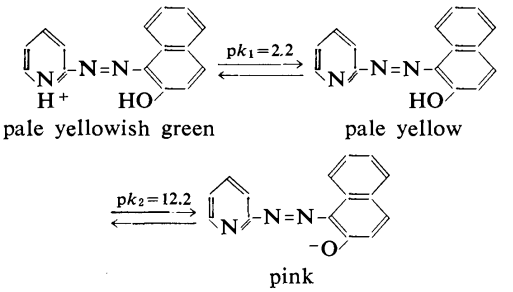
presence of magnesium may be summarized as follows: the indicator should react with calcium to give a sensitive coloration but should not react with magnesium under the condition where the precipitation of magnesium does not occur, e.g., at pH<10 unless a masking agent such as tartrate is used. No metal indicator having such properties has been reported. Thus an indicator system such as the NY-HA system ought to be used for a successful visual titration of calcium in the presence of magnesium. Even in this case, HA must not react with magnesium; hence, the use of the *o*, *o'*-dihydroxyazo compounds often utilized in chelatometry has to be given up for the present purpose. On the other hand, *o*-hydroxyazo compounds having a pyridine ring[9,10], such as 1-(2-pyridylazo)-2-naphthol (PAN) and 4-(2-pyridylazo)-resorcinol (PAR), or a thiazol ring[11,12], such as 1-(2-thiazolylazo)-2-naphthol, react with neither calcium nor magnesium, but they are known to exhibit a sensitive coloration with copper, zinc, cadmium, nickel, etc. and they are of current use in the chelatometry of these metals[9,10]. Therefore, an appropriate combination of such dyes and these metals would serve as a useful indicator in the chelatometry of calcium in the presence of magnesium. Some theoretical consideration will be given below to the use of the Zn-EGTA-PAN system as an indicator.

The indicator transition in the vicinity of the equivalence point in the chelatometry of M using the NY-HA system as an indicator can be expressed by Eq. 1 according to our previous paper[8]:

$$[Y]_t''/[M]_t = 1 - \frac{[NA_n]}{[A]^n}\cdot\frac{1}{K_1[NY]} + \frac{[A]^n}{[NA_n]}\cdot\frac{K_2[NY]}{[M]_t} \qquad (1)$$

where $K_1 = K_{MY}K_{NA_n}/K_{NY}\beta_{(M)}$, where $K_2 = K_{NA_n}\alpha_{H(Y)}/K_{NY}$[13], and where $[M]_t$ and $[Y]_t''$ denote the total concentrations of M and of the complexan used as a titrant respectively.

The acid-base properties of PAN may be described as follows[14,15];



Thus, an aqueous solution of PAN is pale yellow in the pH value range of 3~10.

Since PAN forms a 1:2 chelate with zinc at pH values higher than 6 when its quantity exceeds that of the metal[15], it is certainly $Zn(PAN)_2$ that participates in the indicator transition in the vicinity of the equivalence point of the chelatometry of zinc at pH value higher than 6, using PAN as an indicator. In the absence of the third chelating agent (an auxiliary chelating agent), $\beta_{(Ca)}=1$, $K_{ZnA_2}/(\alpha_{H(A)})^2 = K_{ZnA_2}'$ and $K_{ZnY}/\alpha_{H(Y)} = K_{ZnY}'$. Designating the undissociated PAN as HA, Eq. 1 is transfomed into Eq. 2:

$$[Y]_t''/[Ca]_t = 1 - \frac{[ZnA_2]}{[HA]^2}\cdot\frac{K_{ZnY}}{K_{CaY}K_{ZnA_2}'[ZnY]} + \frac{[HA]^2}{[ZnA_2]}\cdot\frac{K_{ZnA_2}'[ZnY]}{K_{ZnY}'[Ca]_t} \qquad (2)$$

where $[ZnA_2]/[HA]$ is a function of the percentage of color change. The second and third terms on the right side of Eq. 2 mainly concern the color change before and after the equivalence point respectively. From Eq. 2 it may easily be seen that the color change is affected by the pH value, by [ZnY] and, when a 1:2 complex such as ZnA_2 participates, by [HA]. Let

$$K_{ZnY}/K_{CaY}K_{ZnA_2}'[ZnY][HA] = f_1$$

and

$$K_{ZnA_2}'[ZnY][HA]/K_{ZnY}'[Ca]_t = f_2$$

It then follows that the color change in the vicinity of the equivalence point becomes sharper the lower the f_1 and f_2 values. However, it should be remembered that higher values of K_{CaY}' and $[Ca]_t$ are always desirable since $f_1f_2 = 1/K_{CaY}'[Ca]_t$. When dealing with a 10^{-2}~10^{-3} M solution of calcium, the titration has to be carried out at a pH value where K_{CaY}' is higher than 10^8 (see Fig. 1). As is well known, $\alpha_{H(Y)}$ is given by formula 3, in which K_1,.....,K_4 are the formation constants of the proton complexes of the fully dissociated species of EGTA:

$$\alpha_{H(Y)} = 1 + K_1[H] + K_1K_2[H]^2 + K_1K_2K_3[H]^3 + K_1K_2K_3K_4[H]^4 \qquad (3)$$

The conditional stability constants, K_{CaY}', can

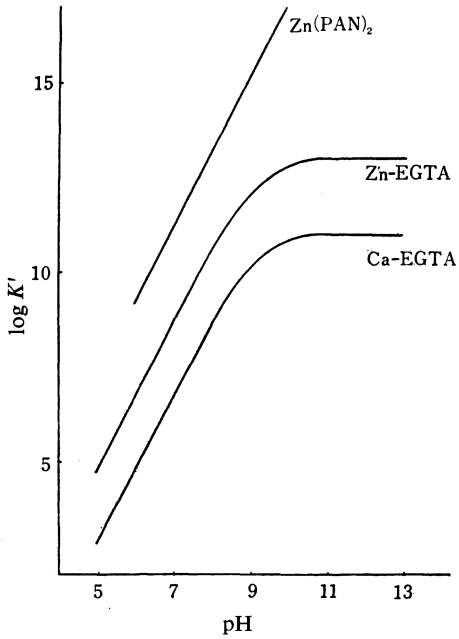

Fig. 1. Conditional stability constants of $Zn(PAN)_2$, Zn-EGTA and Ca-EGTA.

be calculated at various pH values by means of the relationships $K_{CaY'}=K_{CaY}/\alpha_{H(Y)}$ and $\log K_{CaY}=11.0$ (Fig. 1). Similarly, the conditional stability constants of the PAN chelate can be computed for various pH values using the value of $\log K_{ZnA_2}=21.7$ (Fig. 1)[15-17]. For an ordinary condition of chelatometry, viz. $[HA]=10^{-5}$ M and $[ZnY]=10^{-4}$ M, f_1 and f_2 have been computed for various pH values; the results are tabulated in Table I.

From these results it is anticipated that at the pH value of 7 decoloration will occur before the equivalence point, while at the pH value of 10 it will occur gradually after the equivalence point. Therefore, the titration might be successfully carried out in the intermediate pH value range, viz., pH 8~9 (cf. Fig. 1 of Ref. 7).

In the presence of magnesium, the excess EGTA will be bound with magnesium to form MgY. We know that [Y] in equilibrium with Mg and MgY is given by Eq. 4 and that it is a function of $[Mg]_t/[MgY]$ over a considerable range of pH values, viz., pY after the equivalence point is buffered at a higher level by the excess magnesium[13].

$$[Y]=\frac{[MgY]}{([Mg]_t-[MgY])K_{MgY}} \quad (4)$$

Thus the change in pY in the vicinity of the equivalence point is smaller in the presence of magnesium than in its absence, and the indicator transition after the equivalence point becomes sluggish.

TABLE I. f_1 AND f_2 AT VARIOUS pH

Results and Discussion

All the results summarized in Figs. 2, 3 and 4 were obtained by the trial procedure given in the Experimental section below. $Zn(PAN)_2$ being sparingly soluble in water, it precipitates out near the equivalence point[18]. Therefore, the rate of reaction (5) to the right side is slow and the indicator transition is somewhat irreversible.

$$Zn(PAN)_2 + Y \rightleftharpoons ZnY + 2\,PAN \quad (5)$$

18) Organic solvents such as dioxane and alcohol have been employed to solubilize Cu(PAN). However, since the solubility of $Zn(PAN)_2$ does not increase appreciably by the addition of such organic solvents, which hardly improves the present situation.

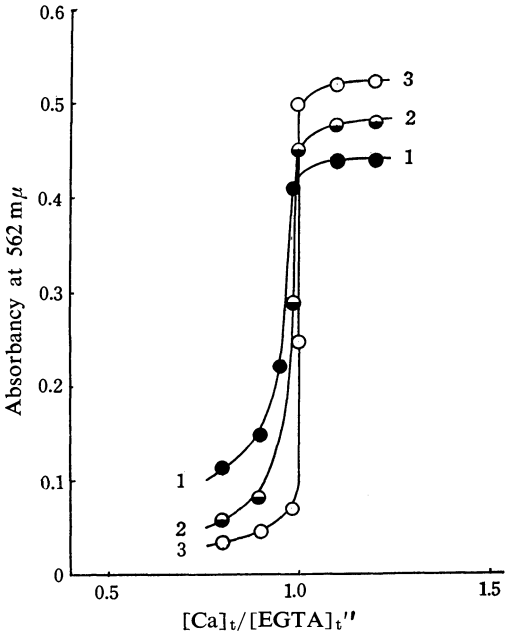

Fig. 3. Effect of Zn-EGTA concentration.
Conditions: $[EGTA]_t'' = 10^{-3}$ M
$[PAN]_t = 2\times10^{-5}$ M, pH 8.0

Curve 2: 10^{-3} M
Curve 3: 10^{-2} M

Therefore, it is preferable to titrate the excess EGTA with the calcium standard solution in order to have the reaction 5 proceed from right to left near the equivalence point. Moreover, it is recommended that the solution be heated to about 50~60°C near the equivalence point and that the calcium solution be added drop by drop under vigorous stirring.

Influence of Various Factors.—*The Effect of the pH Value.*—Figure 2 shows the indicator transition in the vicinity of the equivalence point: at a pH value of 7 the color of $Zn(PAN)_2$ is not fully developed even after the equivalence point, while at a pH value of 10 a considerable coloration is observed before the equivalence point. In the intermediate pH range, viz. pH 7.5~9, a very neat color change from pale yellow to pink is realized. Thus within this pH value range the visual titration of calcium will be possible.

The Effect of the Zn-EGTA Concentration.—The effect of the Zn-EGTA concentration is illustrated in Fig. 3: a distinct indicator transition is observed at the optimum concentration of $(2.5\sim5)\times10^{-5}$ M Zn-EGTA.

The Effect of the PAN Concentration.—Theoretically the lower the PAN concentration, the sharper the indicator transition near the equivalence point. However, for the visual

titration the PAN concentration of 2×10^{-5} M is the most satisfactory; a lower concentration of PAN makes the indicator transition obscure because of a faint coloration of $Zn(PAN)_2$.

The Effect of Magnesium. — The effect of magnesium on the calcium determination is shown in Fig. 4. The presence of magnesium gives rise to a pink shade of $Zn(PAN)_2$ before the equivalence point. Thus, in order to secure a distinct indicator transition at the equivalence point in the presence of magnesium, the concentrations of PAN and Zn-EGTA and the pH value of the solution should be kept as low as practical; the most distinct color change is observed under the following conditions: 2×10^{-5} M of PAN, 2.5×10^{-5} M of Zn-EGTA and a pH value of 8 (Fig. 4-b)[19].

In the chelatometry of calcium in the presence of magnesium, the back titration of the excess EGTA with a calcium standard solution is preferable. Denoting the total concentrations of calcium present in the sample and used as a titrant as $[Ca]_{sample}$ and $[Ca]_{titrant}$ respectively, the total concentration of EGTA, $[Y]_t''$, at the equivalence point is given by:

$$[Y]_t'' = [Ca]_t = [Ca]_{sample} + [Ca]_{titrant}$$

Hence, in such a back titration the effect of magnesium on the indicator transition is not determined by $[Mg]_t/[Ca]_{sample}$ but by $[Mg]_t/[Ca]_t$: the color change at the equivalence point becomes less distinct with an increasing $[Mg]_t/[Ca]_t$ ratio (Fig. 4). For a sample with a high $[Mg]_t/[Ca]_{sample}$ ratio, the indicator transition is much improved by the addition of a large excess of EGTA, viz., making the $[Mg]_t/[Ca]_t$ ratio low. As shown in Fig. 4-b, the visual titration of calcium ($[Ca]_t=10^{-3}$ M, $[Ca]_{sample}=0.5\times10^{-3}$ M) in the presence of ten times as much as magnesium ($[Mg]_t=5\times10^{-3}$ M) is possible by the procedure recommended below.

Recommended Procedure.—Fifty milliliters of a buffer solution (pH value: 8) and 5~20 ml. of a 10^{-2} M EGTA solution[20] are added to 25 ml. of a neutral sample solution containing 1~4 mg. of calcium and less than 10 mg. of magnesium[21]. After the addition of 2.5~3 ml. of a 10^{-3} M Zn-EGTA solution and 2 ml. of a 10^{-3} M PAN solution, the excess EGTA is titrated with a 10^{-2} M calcium standard solution. Near the equivalence point, the solution is heated to about 50~60°C and the titration is continued drop by drop while vigorously stirring the solution. A color change from pale yellow to pink is observed at the equivalence point. Titrate to a pink with no yellowish shade.

19) Though the effect of magnesium is less at pH 7.5, appropriate buffer solution of this pH is hardly available.

20) Total concentration of EGTA to be added is preferably more than 1.5 times calcium or 1/2 of magnesium in the sample solution.

21) By means of the photometric titration, presence of about 100 mg. of magnesium is tolerable.

Experimental

Solutions. — *10^{-2} M EGTA Standard Solution.* — 3.8036 g. of EGTA (Dojindo Chemical Co., Kumamoto, Japan) are dissolved in 20 ml. of 1 N sodium hydroxide and the whole is diluted to one liter. The solution is standardized chelatometrically with a 10^{-2} M zinc standard solution using Eriochrome black T as an indicator.

10^{-2} M Calcium Standard Solution.—1.000 g. of calcium carbonate is dissolved in a small amount of hydrochloric acid, the excess of which is expelled completely by evaporation to dryness on a steam bath. The residue is taken up in distilled water and diluted to one liter. The solution is standardized chelatometrically with an EDTA standard solution.

(1~5)$\times10^{-3}$ M Zn-EGTA Solution. — An equivolume mixture of a 10^{-2} M EGTA solution and a 10^{-2} M zinc solution is diluted to an appropriate concentration.

10^{-3} M PAN Solution.—Twenty-five milligrams of PAN (Dojindo Chemical Co., Kumamoto, Japan) are dissolved in 100 ml. of methyl alcohol.

Buffer Solution with a pH Value of 8.—1 N hydrochloric acid is added to a saturated solution of borax until the pH value of the solution is brought to 8.0.

Apparatus.—Filter photometer and conventional titration cell (Hirama Co., Tokyo, Japan).

Trial Procedure.—To a cell for the photometric titration are added 10 ml. of a buffer solution, 2~5 ml. of 10^{-2} M EGTA solution[22] and 0.1~2 ml. of a 5×10^{-3} M Zn-EGTA solution. The solution is then diluted to 20 ml. After the addition of 0.4 ml. of a 10^{-3} M PAN solution, the photometric titration is carried out, using a 10^{-2} M calcium standard solution as the titrant.

Summary

The optimum conditions for the chelatometry of calcium with EGTA have been deduced from the theoretical consideration of the equilibria involved. Some experimental results have been given on the chelatometry of calcium in the presence of magnesium using the Zn-EGTA-PAN system as an indicator. This proposed method seems to be better than earlier ones.

22) Initial concentration of EGTA may be preferably of the order of 10^{-3} M.

The Spectrophotometric Determination of Micro Amounts of Perchlorate by the Solvent-Extraction Method[1]

By Iwaji IWASAKI, Satori UTSUMI and Chisam KANG

(Received November 15, 1962)

It has been reported by Baas Becking, Haldane, and Izard[2] that perchlorate is an important constituent of sea water. If the perchlorate ion is really present in sea water, it is an interesting phenomenon from the geochemical viewpoint. The determination of perchlorate by reducing it to chloride with subsequent titration has been reported[3-5]. Recently, perchlorate has also been determined by the radiochemical method of isotopic dilution[6]. These methods, however, are not suitable for micro quantities of perchlorate.

Nabar and Ramachandran[7] have studied a method for the estimation of perchlorate which is based on the interaction between a known excess of methylene blue and a soluble perchlorate, with a subsequent precipitation of methylene blue perchlorate, and on the photometric estimation of the residual methylene blue. As methylene blue perchlorate is considerably soluble in water, this procedure is subject to serious errors and is also unsuitable for micro amounts of perchlorate Boltz[8] has briefly described a photometric determination of perchlorate depending on the extraction of the complex formed between methylene blue and perchlorate with chloroform; the present authors have investigated this method in greater detail and have reported their findings in a previous paper[9]. However, this method was greatly affected by the temperature upon extraction, owing to the low extration yield, and it did not have a good reproducibility. Lately, it has been found by the present authors that the methylene blue perchlorate is more extractable with dichloroethane than with chloroform. Consequently, the method using extraction with dichloroethane is more sensitive and less affected by temperature than the chloroform method and has a better reproducibility. This improved spectrophotometric method for the determination of perchlorate will be reported on in this paper, and, at the same time, it will be made clear whether or not perchlorate is really present in various sea waters.

Experimental

Apparatus. — The spectrophotometric measurements were made with a Hitachi spectrophotometer, Model EPU-2, with 10.0 mm. cells, at a spectral band width of 1 mμ.

The shaking was done with a Tokiwa shaker, Model TS.

The separation of the organic layer from the aqueous layer was carried out with a separatory funnel approximately 50 ml. fitted in a short leg.

The organic layer was separated from the separatory funnel into a 15 ml. glass tube with a glass stopper.

Materials. — Guaranteed reagent sulfuric acid, 0.1 N.

1,2-Dichloroethane*, guaranteed reagent.

Anhydrous sodium sulfate, guaranteed reagent.

Methylene Blue Solution.—0.030 g. of guaranteed reagent methylene blue ($C_{16}H_{18}N_3ClS \cdot 3H_2O$) was dissolved in distilled water and diluted to 200 ml. with distilled water to give a 4.0×10^{-4} M solution. The solution was stored in a colored bottle and proved to be stable over a period of several months. Recrystallized[7] methylene blue from 50% aqueous alcohol gave the same results as the methylene blue solution mentioned above.

Standard Perchlorate Solution. — Perchloric acid was neutralized with a potassium hydroxide solution to obtain a white precipitate of potassium perchlorate. This was recrystallized and dried at about 130°C for 2 hr. The stock solution which contains 1 mg. of perchlorate ions per ml. was prepared by dissolving 1.393 g. of the potassium perchlorate in distilled water and then diluting it to 1000 ml. The working standard solutions were prepared by diluting the stock solution properly.

Washing Solution.—This was prepared by mixing 10 ml. of 0.1 N sulfuric acid and 20 ml. of the

4.0×10^{-4} M methylene blue solution with 200 ml. of distilled water.

Procedure and Calibration Curves.—10.0 ml. of the standard perchlorate solution is placed in a separatory funnel. Then, 0.5 ml. of 0.1 N sulfuric acid, 1.0 ml. of the 4.0×10^{-4} M methylene blue solution and 10.0 ml. of dichloroethane are added. The separatory funnel is shaken for about 30 sec., whereby the complex formed between methylene blue and perchlorate is extracted into the organic layer. When the two layers have clearly separated, the organic layer is transferred to a glass tube with a glass stopper, about 0.5 g. of the anhydrous sodium sulfate is added, and the mixture is shaken vigorously to make it transparent. The absorbance of the clear solution is measured at 655 mμ, using distilled water as a reference.

The calibration curves (I, II, and III) shown in Fig. 1 were obtained by the procedure with standard perchlorate solutions of known concentrations at 15°C, 20°C and 25°C. As can be seen in Fig. 1, the absorbance and the concentration were in a good linear relationship. Though the temperature has a slight effect, this effect is much less than that in the chloroform method[9].

The extracted complex is very stable; even after 24 hr., no measurable change was found when a glass stopper was used to protect against evaporation of the dichloroethane.

III Methylene blue in distilled water

of the methylene blue and dichloroethane solutions of the complex of methylene blue perchlorate and the methylene blue.

The methylene blue perchlorate complex and the reagent blank have a maximum absorbance at 655 mμ (see I and II); on the other hand, the aqueous solution of methylene blue has a maximum at 660 mμ (see III).

The peak at 655 mμ was used in all subsequent measurements because the difference in the absorbance between the complex of methylene blue perchlorate and the reagent blank is greatest at this wavelength.

Extraction by Organic Solvents.—Benzene, carbon tetrachloride, ethyl ether, butyl alcohol, isoamyl alcohol, *n*-hexyl alcohol, tributyl phosphate, chloroform, and 1, 2-dichloroethane were tried as solvent for this extraction. Nonpolar solvents such as benzene and carbon tetrachloride proved not to be useful. Only 1, 2-dichloroethane and chloroform proved useful. The former, being the better extracting agent, was used in this work. It was found most practical to use a one 10 ml. portion of the solvent in the extraction. Figure 3 shows how the complex of methylene blue and perchlorate is extrated with 10 ml. of dichloroethane.

The extraction yield using one 10 ml. portion of dichloroethane is about 95%. Consequently, the sensitivity of this method is much greater than that of the chloroform method, as can be seen in Fig. 1.

—○— 4.0×10^{-4} M (III)
—●— 8.0×10^{-4} M (IV)
—⊙— 1.3×10^{-3} M (V)

The Effect of the Concentration of Methylene Blue Reagent.—The methylene blue perchlorate complex with a 1.3×10^{-4} M methylene blue solution obeyed Beer's law up to about 0.6 p.p.m. of perchlorate, while that with a 2.6×10^{-4} M solution did so up to about 0.8 p.p.m. However, they then showed an increasing deviation from Beer's law for concentrations higher than 0.6 p.p.m. and 0.8 p.p.m. respectively (see I and II in Fig. 4). On the other hand, the higher the concentration of methylene blue was, the higher the absorbance of reagent blank became, and the absorbances, shown in Fig. 4 (see IV and V), did not form a straight line.

Figure 4 shows that the most suitable concentration of the methylene blue solution for the range up to 1 p. p. m. of perchlorate ions is 4.0×10^{-4} M.

The Effect of the Sulfuric Acid Concentration.—When the aqueous solution is alkaline, the dichloroethane extracts become pink, so the procedure should be carried out below a pH value of 6. Sulfuric acid is used for making the aqueous solution acid. The effect of sulfuric acid concentrations on the method is shown in Fig. 5.

The extractability of methylene blue itself increases, while that of the complex does not undergo any measurable change upon an increase in the concentration of sulfuric acid. Therefore, 0.5 ml. of 0.1 N sulfuric acid was added in the present work.

The Effect of the Shaking Time on Extraction.—The shaking time on extraction did not change the absorbance. The results listed in Table I show that shaking for 30 sec. is sufficient to extract the complex from the aqueous solution.

The Composition of the Complex between Methylene Blue and Perchlorate.—Application of the continuous variation method[10-13] indicated that only a 1 to 1 complex of methylene blue and perchlorate was formed. The resulting curves, in which the reagent blank was subtracted, are shown in Fig. 6. All the curves have a broad maximum in the vicinity of $x=5$, indicating that the complex is partially dissociated in the aqueous solution and that the extraction yield of the complex by dichloroethane is not 100%.

Effect of Diverse Ions. — In measuring the effect of diverse ions on this method, the experiments were made both in the presence of 0.5 p. p. m. of perchlorate ions and in its absence. The experimental results are given in Tables II, III, IV and V.

There are relatively many anions which cause interference. Sodium, potassium, ammonium, and sulfate do not interfere, however, even when present in amounts of 5000 p. p. m., and the iodate does not interfere at a 1000 p. p. m. It is of interst that halide, when listed in order of increasing interference in this method, are chloride, bromide and iodide, while the oxyacid of the halogens are listed, on the contrary, as iodate, bromate and chlorate. The thiocyanate and iodide, which interfere remarkably even at 0.1 p. p. m., could be masked up to 1 p. p. m. by the addition of 50 p. p. m. of mercuric ion.

The Determination of Perchlorate in the Presence of Other Ions.—Several methods were tried by the present authors to determine the trace amounts of perchlorate in the high concentration of chloride as great as that in sea water. Of these, the back-washing method gave the most satisfactory results for removing chloride and other interfering ions

Table VI. Experiments for the perchlorate ion in sea waters

Sea water	Sample taken, ml.	Diluted twice, absorbance	ClO_4^- found, p. p. m.	ClO_4^- added p. p. m.	ClO_4^- recovered p. p. m.
Artificial sea water	5.0	0.079	0	0.10	0.10
Standard sea water	5.0	0.081	no detected	0.10	0.10
Old sea water* No. 1	5.0	0.072	no detected	0.10	0.10
Fresh sea water** No. 2	5.0	0.072	no detected	0.10	0.10
Fresh sea water** No. 3	5.0	0.074	no detected	0.10	0.09

* Determined after three months since the sample was taken 10 km. apart from the north coast of O-sima, Tokyo, March, 1962.

** Samples from two stations on the coast of the Boso Peninsula, Chiba Prefecture, June, 1962.

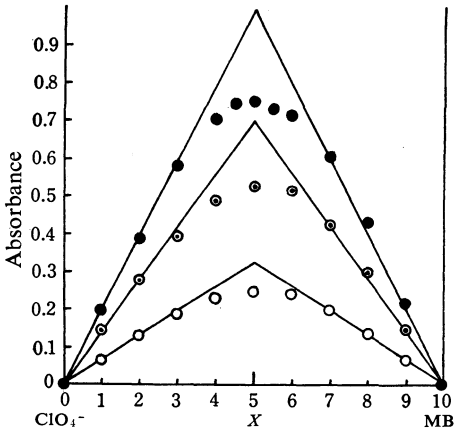

Fig. 6. Method of continuous variation. Concentrations of methylene blue, and perchlorate: 2×10^{-5} M

○ 610 mμ ⊙ 665 mμ ● 655 mμ

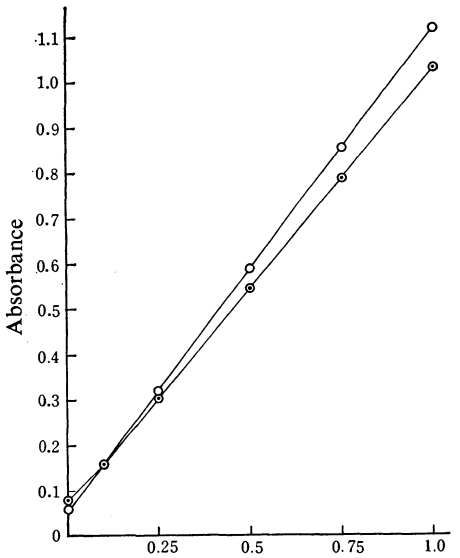

Fig. 7. Calibration curves in the presence of other ions.

-⊙- In artificial sea water diluted twice (I)

-○- In the presence of 10000 p. p. m. Cl^- (II)

to such amounts as are present in sea water.

In order to remove the interfering ions, transfer the organic layer which was separated from the aqueous solution by the procedure mentioned above into another separatory funnel, add 10.0 ml. of the washing solution, and shake for about 30 sec. After the two layers have clearly separated, transfer the organic layer to a glass tube, make it transparent with anhydrous sodium sulfate, and measure the absorbance at 655 mμ.

The results listed in Table II show that one washing is sufficient to eliminate the interference of a 10000 p. p. m. concentration of chloride ions. On the other hand, thiocyanate, periodate, iodide, chlorate, nitrate and nitrite which give remarkably higher results even in small amounts, could not be removed even after two washings. However, most of them are not present in sea water, and the concentration of iodide is too small to consider its interference.

Figure 7 shows the calibration curves of perchlorate ions in the presence of a 10000 p. p. m. of chloride (II) and in artificial sea water[14] diluted twice (I).

The difference between I and II is due in all probability to the fact that there are interfering ions besides chloride in sea water.

The calibration curve (I) was in a good linear relationship for the range from 0.1 to 1.0 p. p. m. of perchlorate ions, but it was not for concentrations lower than 0.1 p. p. m., probably owing to the incomplete removal of magnesium, bromide, and iodide. The concentration of perchlorate in sea water can be readily determined by reference to curve I in

14) J. Lyman and R. H. Fleming, *J. Marine Research*, 3, 134 (1940).

Fig. 7. It was reproducible within the error of ±0.02 p. p. m. of perchlorate ions. It is possible to determine the perchlorate over the range from 0.05 p. p. m. to 2.0 p. p. m. in sea water by this method.

Experiment for the Perchlorate in Various Sea Waters.—Some results of the application of this method to several sea waters are given in Table VI.

As will be seen in Table VI, the experimental results show that the concentration of perchlorate in sea water, if present, is below 0.05 p. p. m., very much less than the figures reported by Baas Becking, Haldane and Izard[2].

Greenhaigh and Riley[15] have investigated the occurrence of perchlorate in sea water by a method they themselves devised, and Johannesson[6] has applied the radiochemical method of isotopic dilution to its determination in sea water. They also detected no perchlorate in natural sea water within the sensitivities of their methods.

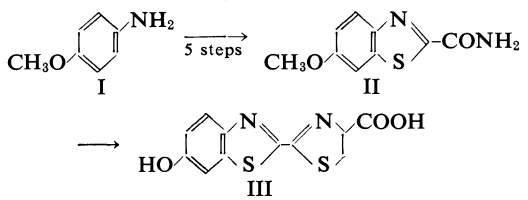
A Convenient Synthetic Method of 2-Carbamoyl-6-methoxybenzothiazole, One of Intermediates for the Synthesis of Firefly Luciferin

By Shuichi SETO, Kyozo OGURA and Yukio NISHIYAMA

(Received November 17, 1962)

White et al. reported in their short communication[1] that firefly luciferin (III) was synthesized from *p*-anisidine (I) through eight steps. According to them, the preparation of 2-carbamoyl-6-methoxybenzothiazole (II), which is one of intermediates in this synthetic route, requires five steps from the starting material I.



The present authors found a convenient preparative route to II by using carbamoylthiocarbonylthioacetic acid (IV) as a carbamoylthiocarbonylation reagent of *p*-anisidine (I), and II was easily synthesized by two steps from I.

The present paper describes the preparation of the reagent IV and its reactions.

The reagent IV was prepared by the reaction of trichloroacetamide, potassium sulfide and potassium monochloroacetate nearly in the same manner as in the case of thiobenzoylthioacetic acid[2]. Being fairly unstable, IV was freshly prepared and used in alkaline solution without being isolated as free acid. Thus obtained alkaline solution which colored deep red reacted various aromatic amines at room temperature to afford corresponding thioamides. Reaction of aniline, *p*-toluidine, α-naphthylamine and β-naphthylamine gave thiooxanilamide (V), 4-methylthiooxanilamide (VI), α-monothiooxal-α'-amide-α(α-naphthylamide) (VII) and α-monothiooxal-α'-amide-α(β-naphthylamide) (VIII) respectively. Compound V, VI and VII are known substances[3,4]. Application of the reagent IV to I gave 4-methoxythiooxanilamide (IX), which showed absorptions at 3360, 3200 and 1702 cm^{-1} due to its amide residue. Treatment of IX with a large excess of alkaline potassium ferricyanide afforded II in a fairly good yield. It shows amide bands at 3330, 3200, 1689 and 1661 cm^{-1}.

Conversion of the amide II into luciferin (III) by White's method was examined, and 2-cyano-6-methoxy- (X), 2-cyano-6-hydroxybenzothiazole (XI) and III were obtained.

IV V: R=H VI: R=CH_3 IX: R=OCH_3

VII VIII

Experimental*

Carbamoylthiocarbonylthioacetic Acid (IV).—A solution of potassium hydroxide (3.0 g.) in ethanol (20 ml.) was divided into halves and one half was saturated with hydrogen sulfide which had been dried through calcium chloride: the other half was then added to the first portion in a 50 ml. flask fitted with nitrogen inlet and dropping funnel. A slow stream of nitrogen was passed and a solution of trichloroacetamide (1.85 g) in ethanol (10 ml.) was added to the mixture with shaking at room temperature. The mixture gradually turned red and the color change from red to brown occurred. As the temperature was raised during this time, the mixture was occasionally cooled with ice-water. A solution of monochloroacetic acid (1.6 g.) in water (10 ml.), neutralized with potassium carbonate, was added to the mixture under nitrogen stream, and the mixture was well shaken. The mixture immediately turned deep red. After being allowed to stand for a few minutes, the mixture was filtered to remove the precipitate of inorganic salt thereby formed. Thus obtained red solution was quickly used for the reaction.

Thiooxanilamide (V).—To a solution of aniline (200 mg.) in 50% ethanol (1 ml.), the solution IV (2 ml.) was added. After the mixture was allowed to stand at room temperature for 3 days, yellow needles that separated out were collected and recrystallized from ethanol to afford yellow needles, m. p. 168~170°C. Yield, 50 mg.

Found: C, 53.61; H, 3.71; N, 14.61. Calcd. for $C_8H_8ON_2S$: C, 53.33; H, 4.48; N, 15.55%.

4-Methylthiooxanilamide (VI).—To a solution of *p*-toluidine (200 mg.) in 50% ethanol (2 ml.), the solution of IV (2 ml.) was added, and the mixture was allowed to stand at room temperature overnight. Yellow crystals that precipitated were collected and recrystallized from ethanol to form yellow needles, m. p. 166~168°C. Yield, 60 mg.

Found; C, 55.74: H, 5.19; N, 13.94. Calcd. for $C_9H_{10}ON_2S$: C, 55.66; H, 5.19; N, 14.43%.

α-Monothiooxal-α'-amide-α(α-naphthylamide) (VI).—To a solution of α-naphthylamine (100 mg.) in 70% ethanol (1.5 ml.), the solution of IV (2 ml.) was added. After the mixture was allowed to stand at room temperature overnight, crystals that separated were collected and recrystallized from ethanol to give yellow needles, m. p. 198~200°C. Yield, 50 mg.

Found: C, 62.41; H, 4.24; N, 12.18. Calcd for $C_{12}H_{10}ON_2S$: C, 62.60; H, 4.38; N, 12.17%.

α-Monothiooxal-α'-amide-α(β-naphthylamide) (VIII).—The solution of IV (2 ml.) was added to a solution of β-naphthylamine (100 mg.) in ethanol (3 ml.), and the mixture was allowed to stand at room temperature for 4 days. Crystals that separated were collected by filtration, washed well with water to remove a small amount of inorganic salt. Recrystallization from ethanol afforded yellow needles, m. p. 163~166°C. Yield, 40 mg.

Found: C, 62.38; H, 4.38; N, 12.18. Calcd. for $C_{12}HO_{10}N_2S$: C, 62.60; H, 4.38; N, 12.17%.

4-Methoxythiooxanilamide (IX).—To a solution of I (1 g.) in 50% aqueous ethanol (10 ml.), the solution of IV prepared from 1.85 g. of trichloroacetamide was added. After the mixture was allowed to stand at room temperature, yellow crystals that separated out were collected and recrystallized from ethanol to form yellow needles, m. p. 182~185°C. Yield, 0.5 g. λ_{max}^{MeOH} mμ (log ε): 228 (4.14), 270 (3.72), 350 (4.00).

Found: C, 51.42; H, 4.80; N, 13.33. Calcd. for $C_9H_{10}O_2N_2S$: C, 51.16; H, 4.74; N, 13.00%.

2-Carbamoyl-6-methoxybenzothiazole (II).—When a solution of IX (0.5 g) in 10% aqueous sodium hydroxide (40 ml.) was added dropwise into a stirred solution of potassium ferricyanide (9 g.) in water (20 ml.), colorless precipitate separated immediately. After stirring for 30 min., the precipitate was collected by filtration, washed with water and recrystallized from ethanol to form colorless scales, m. p. 246~250°C (decomp.). Yield, 0.4 g. λ_{max}^{MeOH} mμ (log ε): 260 (3.85), 315 (4.20).

Found: C, 51.17; H, 4.06; N, 13.11. Calcd. for $C_9H_8O_2N_2S$: C, 51.92; H, 3.87; N, 13.46%.

2-Cyano-6-methoxybenzothiazole (X).—A suspension of II (100 mg.) in phosphorus oxychloride (1.3 ml.) was refluxed for 30 min., and then an excess of phosphorus oxychloride was distilled off under a reduced pressure. Cold water (0.5 ml.) was added to the residue, and the colorless precipitate thereby formed was collected by filtration. The solid was sublimed under a reduced pressure (4 mmHg) at 100°C, and the sublimate was recrystallized from benzene-petroleum ether to afford colorless needles, m. p. 129~130°C. Yield, 80 mg. λ_{max}^{MeOH} mμ (log ε): 262 (3.87), 320 (4.24). ν_{max}^{KBr} 2230 cm^{-1}.

Found: C, 56.95: H, 3.26; N, 14.91. Calcd. for $C_9H_6ON_2S$: C, 56.84; H, 3.18; N, 14.73%.

2-Cyano-6-hydroxybenzothiazole (XI).—After a mixture of X (120 mg.) and pyridine hydrochloride (240 mg.) was heated in a sealed tube at 150~160°C for 4 hr., water (1 ml.) was added to the reaction mixture. The precipitate thererby formed was collected, washed with benzene and recrystallized from benzene to form pale yellow needles, m. p. 205~207°C (decomp.). Yield, 45 mg. Evaporation of the benzene filtrate gave colorless crystals, which were recrystallized from methanol to give colorless needles of the starting material (X).

* All melting points were uncorrected. The microanalyses were carried out by Misses Yoko Endo and Yukiko Endo of this Institute, to whom the authors are indebted.

λ_{max}^{MeOH} mμ (log ε) : 263 (3.88), 323 (4.19). ν_{max}^{KBr} 3220, 2230 cm^{-1}.

Found : C, 54.60 ; H, 2.14 ; N, 15.76. Calcd. for $C_8H_4ON_2S$: C, 54.55 ; H, 2.29 ; N, 15.91%.

Firefly Luciferin (III).—A mixture of XI (20 mg.), D-cysteine hydrochloride (20 mg.), potassium carbonate (16 mg.) and 50% aqueous methanol (1 ml.) was stirred under nitrogen stream. After being stirred for 1.5 hr., the mixture was neutralized with diluted hydrochloric acid. The precipitate was collected, washed with water and recrystallized from methanol to afford pale yellow prisms, m. p. 200~202°C. Yield, 25 mg. λ_{max}^{MeOH} mμ (log ε) : 268 (3.80), 328 (4.24). ν_{max}^{KBr} 3330, 2550, 1700 cm^{-1}.

Found : C, 47.08 ; H, 3.21 ; N, 9.60. Calcd. for $C_{11}H_8O_3N_2S$: C, 47.14 ; H, 2.85 ; N, 10.00%.

The authors wish to express their sincere gratitude to Sankyo Co., Ltd., which defrayed a part of the expense for the present work.

Decomposition of Peroxybenzoic Acid in Solution. VI. Theoretical Consideration of the Induced Decomposition of Peroxides by Radicals

By Katsumi TOKUMARU and Osamu SIMAMURA

(Received October 23, 1962)

In the previous parts of this series[1-5] it has been shown that one of the notable features of the decomposition of peroxybenzoic acid in various solvents is its very facile decomposition, induced by radicals (R·) generated in solution; this takes place according to the following equation:

$$PhCO_3H + R\cdot \rightarrow PhCO_2\cdot + ROH \quad (1)$$

A similar induced decomposition by radicals is generally recognized to occur with various peroxides (POOP')[6,7] with varying degrees of readiness according to the following equation:

$$POOP' + R\cdot \rightarrow ROP + P'O\cdot \quad (2)$$

Thermochemical consideration shows that the induced decomposition takes place exothermically. Thus, since the heat of reaction ($-\Delta H$) is gvien by the difference in bond dissociation energy (D) between the bond formed and the one broken,

$$(-\Delta H) = D(\text{R–OP}) - D(\text{PO–OP}')$$

the heat of reaction for the induced decomposition will be 50~60 kcal./mol., if we assume the generally accepted values of 90[8] and 30~40 kcal./mol.[6] for D(R–OP) and D(PO–OP') respectively. In fact, in accordance with such large exothermicity, the activation energy for the induced decomposition of peroxybenzoic acid by the polymethyl methacrylate radical has been shown to be 6.6 kcal./mol.[9], indicating that this reaction takes place very easily. If the activation energy changes parallel with the heat of reaction, as is usually the case with many reactions, e. g., the abstraction of a hydrogen atom from hydrocarbon by a variety of alkyl radicals[10], the resonance stabilization on the part of the attacking radical would reduce the heat of reaction and would, therefore, be expected to enhance the activation energy thus making the radical the less reactive.

However, the reactivity of a radical in the induced decomposition of peroxides appears to be affected not so much by the resonance stabilization of the radical as by its electron-donating property. Thus, our results[1-5] show that radicals derived from alcohols and ethers, RR'ĊOR'', appear to be the most active; then come the hydrocarbon radicals, e. g., the cyclohexyl radical, and the trichloromethyl radical seems to be least reactive, being unable to cause the induced decomposition of peroxybenzoic acid. This trend suggests that the more electron-donating radical is the more reactive. A similar trend has been observed

in the induced decomposition of benzoyl peroxide[6,7,11,12]. Mashio and Kato[13] have shown that the reactivity of radicals derived from various alcohols towards benzoyl peroxide decreases in the order: 1-hydroxy-1-methylethyl > 1-hydroxyethyl > hydroxymethyl. Apparently this is the order of decreasing electron-donating property as well as the order of decreasing resonance stabilization. Thus we are led to the conclusion that the more electron-donating radical is more reactive in the induced decomposition of peroxides, even if it is the more resonance-stabilized radical.

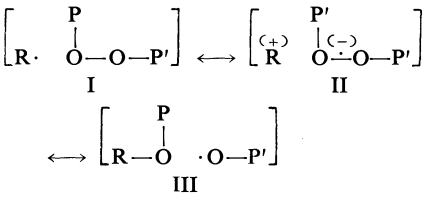
The way in which change in the structure of a radical affects its electron-donating property and the extent of resonance stabilization, leading to the above sequence in regard to those two respects, is understood in terms of a molecular orbital theory. A treatment of 1-hydroxyalkyl radicals according to a simple LCAO-MO method with regard to an odd electron on the carbon and two lone-pair electrons on the oxygen atom shows that the radical as a whole is stabilized with respect to the state in which the odd electron and the lone-pair electrons are localized on the carbon and the oxygen atom respectively; that the molecular orbital occupied by the odd electron is located at a higher energy level than the orbital when the odd electron is localized; and that the more stabilized the radical becomes, the higher the level of the odd electron tends to lie. Obviously such results will generally be obtained when a group carrying a lone-pair of electrons or a group capable of hyperconjugation like a methyl is placed in juxtaposition with the radical centre.

The energy level of the highest occupied orbital is related to the ionization potential of this chemical species in such a way that the higher the former is, the smaller is the latter. For lack of appropriate experimental data for hydroxyalkyl radicals for comparison with the theoretical deduction, we quote the values for alkyl radicals in Table I to show the effect on the resonance energy and the ionization potential brought about by the introduction of an increasing number of electron-releasing methyl groups into a methyl radical. The trend which is apparent in the table is in keeping with the foregoing theoretical prediction.

TABLE I. RESONANCE ENERGIES AND IONIZATION POTENTIALS OF ALKYL RADICALS

Radical	Resonance energy[14] in kcal./mol.		Ionization Potential[15] in eV.
	Calcd.	Obs.	
Methyl	—	—	9.85
Ethyl	7.05	7.2	8.66
n-Propyl	8.6	8.1	7.57
Isopropyl	14.1	12.6	7.45
t-Butyl	21.2	16.7	6.90

The view that the electron-donating property is a factor of primary importance in determining the reactivity of radicals in the induced decomposition under consideration suggests that interaction of the charge-transfer type[16] between an attacking radical as a donor and a molecule of a peroxide as an acceptor is important. This charge-transfer interaction is thought to take place, to the first approximation, between the highest occupied orbital on the radical and the vacant antibonding orbital, $2p\sigma_u$, around the oxygen to oxygen bond in the peroxide. Evidently such a low-lying vacant orbital is responsible for the oxidative action in general or for the electron accepting property of peroxides. Thus, the transition state of the induced decomposition may be schematically expressed by the following structures, form II representing the interaction of the charge-transfer type, which contributes to lowering of the energy of the transition state:



Since such a polar-resonating structure contributes to the structure of the reacting system in charge-transfer interaction, polar solvents like alcohols and ethers would further lower the energy of the system by solvation.

According to the accepted theory[16], the lowering in energy of the reacting system due to the charge-transfer interaction is approximately inversely proportional, other things being equal, to the difference in energy between the highest occupied orbital of the radical and the $2p\sigma_u$ orbital of the peroxide, or to the difference between the ionization potential of the radical and the electron affinity of the $2p\sigma_u$ orbital. Thus, the higher the energy level of the orbital occupied by the odd electron in a radical, the larger is the extent of the charge-transfer, with a corresponding lowering in energy, and, therefore, the more reactive

the radical becomes. This prediction is in agreement with the observed trend in the reactivity of radicals in the induced decomposition.

In the charge-transfer type of interaction, not only the energy difference between the participating orbitals, but also their overlapping, is important. Therefore, the introduction of a bulky group around the radical centre will hinder the overlap sterically, and the introduction of a conjugating group will do so by reducing the electron density at the radical centre of the orbital occupied by the odd electron. In fact, Mashio and Kato[13] have shown that the reactivity towards benzoyl peroxide of radicals derived from primary alcohols decreases as the alkyl chain lengthens. Further, they have shown that the reactivity of the radical derived from benzyl alcohol is twice as large as that from α-tetralol. This difference is probably due to steric hindrance of the overlapping of the relevant orbitals in the charge-transfer interaction, since the energy level of the highest occupied molecular orbital is almost the same for these two radicals. The fact that the reactivity of the radical derived from benzhydrol is lower than that from benzyl alcohol is probably due to the same steric effect as well as to the more extensive delocalization of the odd electron in the former radical.

The rate constant for the chain transfer to a substituted benzoyl peroxide by polymer radicals is known to increase according as the substituent group becomes more electron-attracting[17,18]. This fact is readily understood in light of the fact that an electron-attracting group lowers the energy level of the $2p\sigma_u$ orbital around the oxygen to oxygen bond, resulting in a stronger charge-transfer interaction between the attacking radical and the peroxide, with a corresponding reduction of the activation energy.

The chain transfer constant by the polymer radical generally appears to be larger for hydroperoxides than for benzoyl peroxide[18,19], and as has been previously pointed out[5], peroxybenzoic acid is attacked by radicals more readily than benzoyl peroxide, although benzoyl peroxide might be expected to be more reactive, since the benzoyl group is more electron-attracting than the alkyl group or the hydrogen atom. The disagreement probably is attributable to steric hindrance by the bulky benzoyl group of the overlapping of the two interacting orbitals participating in the charge transfer.

In the induced decomposition of benzoyl peroxide, Swain, Stockmayer, and Clarke[17] have pointed out a contribution of polar resonance structures in which the odd electron is found transferred on the molecule of the peroxide because of the presence of the electron-withdrawing carbonyl group. It is apparent from the foregoing discussion, however, that it is the vacant orbital around the oxygen to oxygen bond that is important in a charge-transfer type interaction in the induced decomposition, and that the role of the carbonyl group, if present in the molecule, is subordinate.

Obviously the charge-transfer concept may readily be applied to the elucidation of the reactions of peroxides with anionoid reagents in general, the nucleophilic attack by the latter being ascribed to the presence in the former of a vacant orbital which is able to accept an electron readily. To cite a few examples, in the reaction of benzoyl peroxides with *N,N*-dimethylanilines, an electron-attracting substituent in the former[20] and an electron-repelling substituent in the latter[21] both accelerate the reaction. This fact can be explained as due to the lowering of the energy level of the antibonding orbital of the oxygen to oxygen bond and to the elevation of that of the lone-pair orbital on the nitrogen atom, the charge-transfer interaction being thus made much easier. It is to be noted in this connection that Imoto and Choe[20] have suggested the coordination of the lone-pair electrons on the nitrogen atom with the peroxidic oxygen. Similarly, reactions of substituted benzoyl peroxides with alkali iodides[22] or with phosphines[23], and reactions of peroxybenzoic acid with olefins[24], sulphides[25] and sulphoxides[26] and the oxidation of sulphides with hydrogen peroxide[27] are to be understood in terms of the charge-transfer interaction.

In the reaction of peroxides with cationoid reagents, e. g., ions of transition metals in the higher oxidation state and Lewis acids, another type of charge-transfer interaction is possible, an interaction in which a lone-pair orbital at

a peroxidic oxygen atom will act as an orbital of the donor type.

The polar effect in radical reactions may generally be interpreted as arising from the change in the magnitude of the charge-transfer interaction between radicals and substrates due to the change in energy level of the interacting orbitals.

Summary

On the basis of observations on the induced decomposition of peroxides by radicals, it has been suggested that the interaction of the charge-transfer type, involving the highest occupied molecular orbital in an attacking radical and the $2p\sigma_u$ antibonding orbital around the oxygen to oxygen bond in a molecule of peroxide, contributes to a lowering of the activation energy of reaction. Possible extension of this idea to elucidation of the reactions of peroxides with other reagents has been pointed out.

*The Synthesis and the Physical Properties of Normal Higher Primary Alcohols. V. Thermal and X-Ray Studies of the Polymorphism of Alcohols of Odd Carbon Numbers from Undecanol to Heptatriacontanol**

BY Akira WATANABE

(Received November 24, 1962)

The transition phenomena in the solid state of normal higher alcohols of the even series from dodecanol ($C_{12}H_{25}OH$) to tetratriacontanol ($C_{34}H_{69}OH$) have already been studied by thermal and X-ray examinatons; the results were reported in a preceding paper[1]. Since it has been known that, in some of the long chain compounds, transition points as well as melting points differ systematically between the odd and even series, it seems important to extend the study to the odd series of the alcohols in order to gain further knowledge on the transition behavior of the compounds. The present paper deals with the thermal analyses and X-ray pattern meaurements of odd alcohols, including the 14 members from undecanol ($C_{11}H_{23}OH$) to heptatriacontanol ($C_{37}H_{75}OH$). It also includes a discussion of the present results of those of the previous studies of the even series, with reference to their relation to the structure analysis data of the selected compounds.

The syntheses of the alcohols investigated here have previously been described in this Bulletin[2-4]. The experimental porcedures used in this study were essentially the same as those used in the previous study of even alcohols. The definition of the terms was given in a previous paper[1] and will be followed in the present paper as well. The crystal modifications will be interpreted briefly. Four modifications, which are called the β, γ_1, γ_2, and α forms, have been known in solid alcohols, the former three modifications being low temperature forms and the latter a high temperature form. When the material is cooled from the melting point, the α form appears at the freezing point, but this form suddenly changes to a low temperature form on further cooling, to either the β, γ_1 or γ_2 form depending upon the carbon number of the compound. This phase change has also been known to occur in some cases on heating the materials. The α form is of interest because of its unique properties. This form is somewhat more transparent than the low temperature forms. It is believed, judging from the X-ray data, that the crystal is nearly hexagonal, that the hydrocarbon chain is

* This study has been carried out at the Department of Physics, Faculty of Science, Kyoto University, as a part of a co-operative research project on "The Synthesis and the Physical Properties of Long Chain Compounds".

perpendicular to the plane of the end group, and that the molecules are less tightly packed than in the low temperature forms. A high dielectric constant value has been found in the α form, the molecule being assumed to rotate around the long axis. In the β form, the chain is perpendicular to the plane, while in the γ_1 and γ_2 forms the chain inclines at an angle to the plane. In these low temperature forms, no rotational freedom of the molecule has been found.

Since the present author, as well as previous workers, has found that small amounts of impurities influence the transition phenomena of long chain compounds, not only final products but starting materials were purified with great care in this study. The alcohols used in the present measurements were recrystallized several times or were subjected to high vacuum distillation, followed by recrystallizations, until constant melting points and transition points were obtained. The stored materials were recrystallized again before the measurements were undertaken.

Results and Discussion

In Fig. 1 the time is plotted against increasing and decreasing temperature for heptadecanol ($C_{17}H_{35}OH$). The forms of the curves are general for all members of the series. As may be seen in the figure, there is a super cooling at the transition point which could not be avoided even though the sample was cooled very slowly. This made it difficult to determine accurately, the transition temperature on cooling. For undecanol, and Reid[7] found no arrest of the time-temperature curve on cooling. This was confirmed by the present thermal studies, in which it was also indicated that this compound does not show the transition on heating. The transition in tridecanol ($C_{13}H_{27}OH$) is not reversible. The heating curve shows that no phase change occurs until the temperature reaches the melting point, while the cooling curve clearly indicates the existence of the transition. The high temperature form, which was confirmed to be the α form by X-ray[5] and dipolemment[6] measurements, showed such a stability that no tendency to change to a more opaque, low-temperature form was observed in visual examination over a 10 hr. period. In the alcohols from pentadecanol ($C_{15}H_{31}OH$) to hentriacontanol ($C_{31}H_{63}OH$), the transition is reversible, appearing both on cooling and heating. The transitions

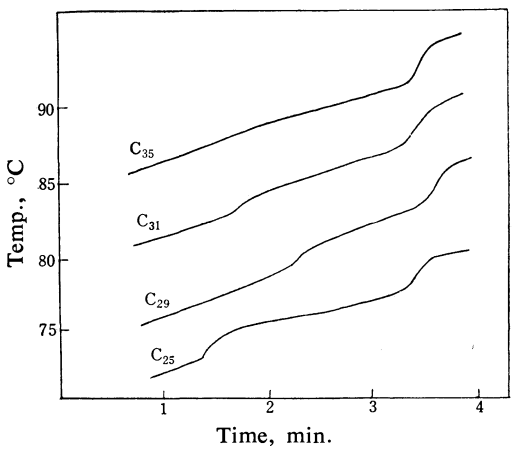

Fig. 2. Heating curves for C_{25}, C_{29}, C_{31} and C_{35} alcohols.

in tritriacontanol ($C_{33}H_{67}OH$) and higher compounds were observed only on cooling. Identification of the phases was made by X-ray pattern measurements, according to which, in the alcohols up to C_{27}, the transition is $\beta \rightleftarrows \alpha$, while in the alcohols above C_{29}, it is $\gamma_2 \rightleftarrows \alpha$. Typical photographs are reproduced in Fig, 3. The data on the transition phenomena for the C_{15}, C_{17} and C_{19} alcohols

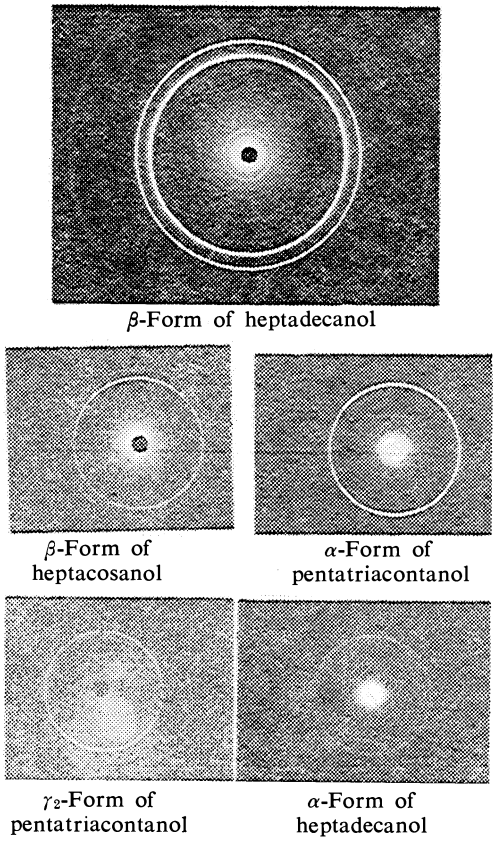

Fig. 3.

were found to agree with those of thermal analyses by Phillips and Mumford[8], while those for other compounds have not yet been reported, except for the X-ray data[9] reported previously from this laboratory. However, some discrepancies were found between the results of the present thermal analyses and those of the X-ray pattern measurements[9]. The X-ray data revealed that the C_{33}, C_{35} and C_{37} alcohols exhibit the transition on heating as well as on cooling. To examine this phenomenon further, pentatriacontanol ($C_{35}H_{71}OH$) was resynthesized and purified, and then the transition was studied with the greatest possible care. The results, however, were identical with those in the previous measurements. It is, therefore, assumed that the appearance of the heating transition can not be ascribed to the presence of impurities. A possible interpretation for the phenomenon is that the γ_2 to α transition is so gradual that it escapes observation in the thermal analyses. This theory is supported by the fact that the inflexion of the heating curve in C_{29} and C_{31} is less sensitive than those in the shorter members, a decrease in the energy barrier at the transition being indicated in the higher members (Fig. 2).

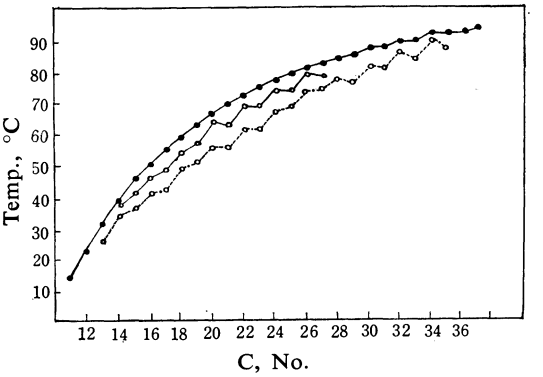

Fig. 4. Melting and transition points of *n*-higher alcohols.
—●— Melting points
—○— Transition point on heating
- -○- - Transition point on cooling

The melting and transition points of the alcohols, including all the odd and even members investigated, are given in Table I and, graphically, in Fig. 4. As may be seen in Fig. 4, the transition points show a definite

alternation in the compounds from C_{13} to C_{37}, the transition points of even members lying on an upper curve. On the contrary, the melting points lie on a smooth curve in the series from C_{11} to C_{29}, but, beginning with C_{29}, the higher series exhibit an alternation relationship.

This melting and transition behavior, with the number of carbon atoms, may be interpreted from the structural point of view. Müller[10] and Malkin[11] interpreted the melting behaviors of normal paraffins with relation to the tilted structure of hydrocarbon chains and to the planes of the end groups. In general, the inclination of the chains to the planes is indicated by the long spacing values, the shorter spacings meaning the more tilted structures, as has already been reported by Malkin[12] for the relatively shorter members of higher alcohols. The series were recently extended in this laboratory with more detailed investigations[9]. The data are represented here in Table II and Fig. 5, from wihch it may be seen that vertical (β) and tilted (γ_1) structures appear alternatively in the series up to C_{29}, the vertical form appearing in odd members and the tilted form in even members. Accordingly, considering the fact that the transition points of even members lie on an upper curve, the tilted structure seems to be more stable than the vertical structure in low temperature forms. This is analogous to the previous observation[1] that, in hexadecanol ($C_{16}H_{33}OH$), the transition point of the γ_1 form was slightly higher than that of the β form. In contrast to the low temperature forms, no difference in structure between the odd and even members seemed to exist in the high temperature forms (Fig. 3). Therefore, it is plausible that the alternation does not appear in the melting points.

Beyond the interpretation made from the long spacing data, a more elaborate interpretation of the phenomena is possible based on the configurations which were determined by the X-ray structure analysis of heptadecanol by Dr. Seto and of eicosanol synthesized by the present author. (For the use of the data the author is indebted to him.) The structures of two compounds are illustrated in Fig. 6. The alcohols form a monoclinic structure made up of a double layer of molecules. The unit cell contains eight molecules in two layers, in which the chains are parallel to one another. The structure of the β form appears to be somewhat unique. The layer of the hydroxyl groups contains methylene groups adjacent to oxygen atoms as may be seen in the figure, the atoms being packed more compactly than in the γ_1 form. The value of the O–O distance in the β form is slightly shorter than that in the γ_1 form. On the contrary, the distance between adjacent hydrocabon

Fig. 6. Crystal structure of *n*-higher alcohols. Black circles represent O atoms.

chains is greater in the β form than in the γ_1 form. These structures suggest that in the β form the layer of the ends takes the more stable arrangement, while the hydrocarbon chains are arranged more stably in the γ_1-form. Accodingly, it seems reasonable that in those shorter members in which the end groups predominate over the hydrocarbon chains (C_{12} and C_{14}), the β structure proves to be favorable, while in longer members, in which the chains predominate over the end groups, the γ_1 structure tends to be favorable. Presumably, a similar interpretation may be given of the existence of the tilted form (γ_2) in the higher members of the odd alcohols, although the structure of this form has not yet been determined.

The properties of the α form in odd alcohols were found to change gradually with an increase in the chain length, as was observed in even alcohols. For example:

1. The inflexions at the transition points in the time-temperature curves become smaller. (Fig. 2)
2. The opacity of the α phase increases.
3. The spacings of α form split into two lines. (Fig. 3)
4. Long-spacing variations with chain length indicate that the hydrocarbon chains increase their inclination to the planes of the ends. (Fig. 5)

These facts would suggest that, as the chain length increases, the structure of the α form increases its deviation from the hexagonal structure found in shorter members and gradually changes to structures similar to those of the low temperature form.

The alteration in the melting point appearing in the series from nonacosanol ($C_{29}H_{59}OH$) to heptatriacontnol ($C_{35}H_{71}OH$) may be ascribed to the difference in the phases existing just below the melting point.

Summary

On the phase transition of *n*-higher alcohols with odd carbon atoms from undecanol (C_{11}) to heptatriacontanol (C_{37}), thermal analyses and X-ray pattern measurements were made, with the following results:

1. Tridecanol (C_{13}) shows an irreversible transition which appers only on cooling. A reversible transition sets in at pentadecanol (C_{15}) and continues to the end member of the series (C_{37}).
2. X-Ray pattern measurements indicated that, in the alcohols up to nonacosanol (C_{29}), the transtition is β to α, while in the alcohols above C_{29} the transition is γ_2 to α.
3. Presumably, the γ_2 to α transition is gradual.
4. The properties of the α forms change gradually with an increase in the chain length.
5. The results of the present study and those of previous studies with the even series have been discussed from the configurations of the β and γ_1 forms, as determined by X-ray structure analyses.

The author wishes to express his deep thanks to Professor Ryozo Goto and Professor Kenzo Tanaka of Kyoto University for their continual guidance and encouragement. He is also grateful to Dr. Tsuneo Seto of Kyoto University for his kind direction and criticism in the X-ray diffraction measurements. The cost of this work was partly defrayed from a grant (Shigenkagaku Kenkyuhi) from the Ministry of Education.

Viscometric Studies of Solutions of Sodium Phosphates, Graham Salts and Vanadium-containing Graham Salts

By Masayuki NAKAGAKI, Shigeru OHASHI* and Fumiko MINATO

(Received November 26, 1962)

Graham salt (amorphous sodium polyphosphate) has often been interested in by many investigators recently[1,2], and it has been made clear that the substance has typical features as a linear-chain polyelectrolyte in a solution. However, the polymer molecules are sometimes decomposed in the solution, especially when the polymer is branched. The points of branching are belived to capable of being hydrolyzed readily.

In the present paper, the degradation of polyphosphate is studied by viscometry. For the sake of the study, it was necessary to know the relation between the intrinsic viscosity and the molecular weight, especially for low molecular weight polyphosphates. Furthermore, vanadium-containing Graham salt (sodium vanadate-phosphate copolymer) was studied, because the –V–O–P– chain was expected to be hydrolyzed much easier than the –P–O–P– chain. Ohashi and Matsumura[3] previously obtained some information on the structures of the glasses and crystals of sodium vanadate-phosphates from paper chromatographic analysis of their solutions.

Experimental

Sodium Phosphates.—Commercial specimens of a guaranteed reagent grade of sodium dihydrogen orthophosphate ($NaH_2PO_4 \cdot 2H_2O$), disodium hydrogen orthophosphate ($Na_2HPO_4 \cdot 12H_2O$), sodium orthophosphate ($Na_3PO_4 \cdot 12H_2O$) and sodium pyrophosphate ($Na_4P_2O_7 \cdot 10H_2O$) were used without further purification. Sodium tripolyphosphate ($Na_5P_3O_{10} \cdot 6H_2O$) of an extra pure reagent grade was recrystallized four times from an alcohol-water mixture. In order to check the purity and the amount of crystallization water, the content of each phosphate was measured by potentiometric titration, using 0.1 N sodium hydroxide for sodium dihydrogen orthophosphate and using 0.1 N hydrochloric acid for the other four phosphates. All results agreed well with the theoretical values within the range of experimental error.

Graham Salts. — Amorphous sodium polyphosphates (Graham salts) of various degrees of polymerization were prepared[4] by heating under the conditions described in Table I; they were then quenched by being pressed between two sheets of copper plate. The degrees of polymerization, $\bar{n}$, as determined by pH-titration[5], are also cited in Table I.

TABLE I. PREPARATION OF GRAHAM SALTS

Sample	Starting material, g.	Heating	$\bar{n}$
A	$NaPO_3$ 29.6, $Na_4P_2O_7$ 25.8	900°C, 1 hr.	4.4
B	$NaPO_3$ 40.3, $Na_4P_2O_7$ 13.5	900°C, 1 hr.	8.6
C	$NaPO_3$ only	900°C, 1 hr.	92
D	$NaPO_3$ only	alternately at 500 and 700°C, 1 week	100
E	$NaPO_3$ 48.1, $Na_4P_2O_7$ 2.6	900°C, 1 hr.	29

Vanadium-containing Graham Salts.—Calculated amounts of Graham salt ($NaPO_3$), vanadium pentoxide (V_2O_5) and sodium carbonate (Na_2CO_3) were mixed and heated at 900°C for 1 hr. and were then quenched by being pressed with copper plates. It was recognized that a part of the vanadium was reduced to V^{4+} during the heating. The amount of V^{4+} was determined by the volumetric method[3]. The per cent of V^{4+} in the total vanadium is given in Table II.

TABLE II. SODIUM VANADATE-PHOSPHATE COPOLYMERS

vanadate residues) in one molecule, $\bar{n}'$, may be calculated by the equation:

$$\frac{\bar{n}'+2}{\bar{n}'}=\frac{\mathrm{Na}+2\mathrm{V}^{4+}}{\mathrm{P}+\mathrm{V}^{5+}} \quad (1)$$

where Na, P, V^{4+}, and V^{5+} indicate the atomic ratio of these atoms. The value of $\bar{n}'$ is given in Table II. As will be described in a later section, the value of $\bar{n}'$ is too large to explain the intrinsic viscosity. Therefore, it was further assumed that the molecular chain in the solution was cut off at both sides of V^{5+}, probably due to hydrolysis, remaining as the polymer chains containing PO_3^- only and that no V^{5+} atom had been at the end of the original chain. The degree of polymerization, $\bar{n}$, of the remaining phosphate chains could then be calculated by dividing the $\bar{n}'$ value into the number of P atoms (P) and V atoms (V), and by using the following equation:

$$\bar{n}=\frac{(\mathrm{P})}{(\mathrm{V})+1} \quad (2)$$

The value of $\bar{n}$ is also given in Table II.

Preparation of Solutions.—Samples of a known weight were dissolved in an aqueous 0.035 N or 0.07 N solution of sodium bromide at room temperature and were made up to the required volume. Orthophosphates, pyrophosphate, and tripolyphosphate dissolved immediately in the solvent (a sodium bromide solution). The concentration, c (g./100 ml.), of the solution was expressed as that of anhydride. The Graham salt used was in the form of small transparent pieces about 1~2 mm. thick which took time to dissolve when the molecular weight was high. It was, however, dissolved within 30~40 min. under agitation by a magnetic stirrer. Since Graham salt containing vanadium took a long time to dissolve, it was pulverized by using a mortar of agate and dried over P_2O_5 under reduced pressure. This pulverized sample still took about 0.5~1 hr. to dissolve, however.

Viscometry.—The viscosity of the solutions were measured by Ostwald's viscometer in a thermostat at 25.5°C. The correction term for kinetic energy was determined by using water and ethanol, but the value was so small that it was disregarded in further calculations.

The viscosities of solutions of samples C and D changed for 5~6 hr. after the beginning of dissolution. Thereafter, the viscosities were constant and did not change for more than 24 hr. No change of viscosity with time was observed for the other samples.

Density.—The density of the solutions was measured at 25.5°C by using Ostwald's pycnometer, whose content was about 5~6 ml. The density of solutions was linear to the polymer concentration, so that the density increment, Δ, was calculated by the equation:

$$\Delta=100\left(\frac{d}{d_1}-1\right)\Big/c \quad (3)$$

where d and d_1 are the densities of solution and solvent respectively, and where c is the concentration in g./100 ml.

Results and Discussion

The Intrinsic Viscosities and Molecular Weight of Sodium Phosphates and Graham Salts.—The intrinsic viscosities $[\eta]$ of low molecular weight sodium phosphates and of Graham salts which do not contain vanadium were calculated by extrapolating both η_{sp}/c and $\ln\eta_r/c$ to infinite dilution on the basis of viscosity values measured at the polymer concentrations of 0.1, 0.2, 0.4, 0.8, 1.2 1.6 and 2.0 (g./100 ml). For these calculations, the viscosity values divided by the viscosity of solvent was used as the relative viscosity. Since the Graham salt is a kind of polyelectrolyte, its reduced viscosity (η_{sp}/c) should increase steeply when the polymer concentration is decreased if the concentration of the swamping electrolyte is not sufficiently high. This effect was observed in the case of 0.035 N sodium bromide, so that the intrinsic viscosity was obtained by neglecting the data at low polymer concentrations. In the case of 0.07 N sodium bromide, the effect was not observed and the extrapolation was easy, although in some instances abnormal values were obtained at very low concentrations. The results obtained in a 0.035 N sodium bromide

solution and in a 0.07 N sodium bromide solution are given in Table III and Table IV respectively. The value of $[\eta]$ is that for 20~24 hr. after the dissolution, if any time dependency of the viscosity (in the case of sample C and D) was observed. The $[\eta]$ values thus obtained are shown in Fig. 1 and Fig. 2 against the average molecular weight, M, the molecular weight of Graham salts was calculated by:

$$M=(Na_2O)+(NaPO_3)\times\bar{n} \quad (4)$$

Here (Na_2O) and $(NaPO_3)$ indicate their formula weights.

The intrinsic viscosity of Graham salt in a 0.035 N sodium bromide solution had already been measured by Strauss et al.[6], who summarized their results in an empirical equation:

$$[\eta]=1.76\times10^{-5}\times M_w \quad (5)$$

In this equation, the weight average molecular weight, M_w, was used. It has been stated by Van Wazer[7] that the molecular weight of Graham salt shows a Poisson distribution and that the weight average molecular weight is just twice the number average molecular weight, M_n. Therefore, Eq. 5 may be rewritten as:

$$[\eta]=3.52\times10^{-5}\times M_n \quad (6)$$

In Fig. 1, Eqs. 5 and 6 are shown by the straight lines a and b respectively. For the experimental data of Fig. 1, the molecular weight, M, was calculated by Eq. 4, on the basis of $\bar{n}$ values obtained by the determination of the end groups. The experimental molecular weight is, therefore, the number average molecular weight. The experimental data in Fig. 1 are located between the straight lines a and b. This would mean either that the distribution of the molecular weight is not exactly the Poisson distribution, or that the Eq. 5 derived originally for $M_w=7000\sim19000$ has been extrapolated unreasonably to too low a molecular weight.

When 0.035 N sodium bromide is used as the solvent, the experimental values (Fig. 1) showed a linear relationship if $\log[\eta]$ was drawn against $\log M$ at the range of $M=930\sim10300$; the following equation was obtained.

$$[\eta]=6.9\times10^{-4}\times M^{0.61} \quad (7)$$

When 0.07 N sodium bromide was used as the solvent, the experimental data of $[\eta]$ were linear against M, as is shown in Fig. 2. The relation can be expressed for $M=510\sim10300$,

$$[\eta]=0.0348+0.112\times10^{-4}\times M \quad (8)$$

The intrinsic viscosity of sodium phosphates of low molecular weight shows a complicated dependency upon the molecular weight, dependent both on the shape of the molecule and on the degree of hydration. The latter is the greater, the greater the value of the density increment, Δ, because the following equation can be derived readily.

$$\Delta=\Delta V+1/d_1-1/d_2 \quad (9)$$

Here, ΔV (ml./g.) is the volume contraction per 1 g. of solute, and d_1 and d_2 are the densities of the solvent and solute respectively. The value of d_1 is about 1.00 and that of d_2 is pressumed to be about 2.0~2.5, so that the value of the density increment should be equal to 0.5~0.6, if there is no volume contraction, while it should be greater than that value if there is any volume contraction. It

7) J. R. Van Wazer, ibid., **72**, 644, 647 (1950).

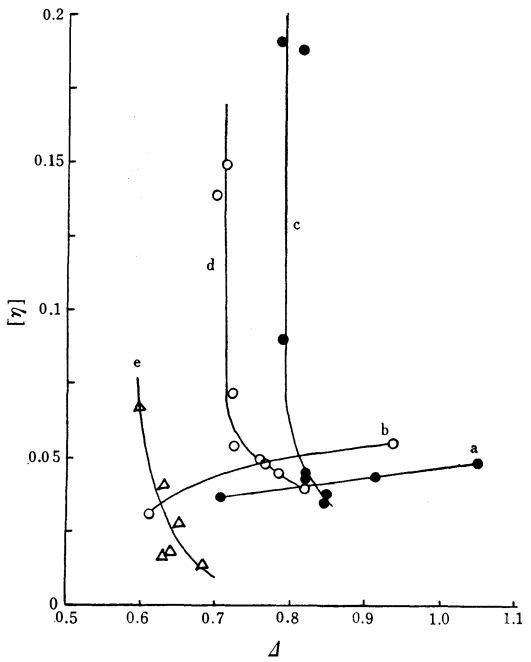

Fig. 3. Relation between $[\eta]$ and Δ of sodium polyphosphate not containing vanadium in 0.035 N NaBr (●) and in 0.07 N NaBr (○), and containing vanadium in 0.07 N NaBr (△).

has been widely accepted that the hydration of ions results in volume contraction.

The relation between the density increment and the intrinsic viscosity is shown in Fig. 3. For the mono-, di- and tri-sodium orthophosphates, the density increment increases in the sequence and the intrinsic viscosity increses according to the increase in the degree of hydration, as is shown by curves a and b. However, the concentration of the swamping electrolyte is the higher, the smaller the degree of hydration, probably because of the dehydrating action of the swamping electrolyte. The value of the intrinstic viscosity, however, does not decrease in accord with the decrease in the density increment, so that the experimental data falls in the different curves a and b in Fig. 3. (Also, compare c and d.)

In the case of the polyphosphates, including pyro- and tripoly-phosphates, the relation between the density increment and the intrinsic viscosity is entirely different from the case with orthophosphates, the data fall on curves c and d. In this case, the shape of the molecule or the value of $\bar{n}$ seems to be more important than the degree of hydration, as has already been described.

The Intrinsic Viscosity of Vanadium Containing Graham Salts.—The intrinsic viscosity of vanadium-containing Graham salts (sodium vanadate-phosphate copolymers) as a function of the average degree of polymerization is shown in Table V and in Fig. 4. No change in viscosity with time was observed, presumably because the rate of hydrolysis at the -V-O-P- junctions was very large and because the vanadium containing specimens took a relatively long time to dissolve. As has already been described, the degree of polymerization, $\bar{n}$, of the copolymer is calculated under the assumptions that the polymer chain has been cut off at both sides of the vanadate residue and that the vanadate residue thus cut off does not contribute to the viscosity. Nevertheless, the intrinsic viscosity of vanadium-containing polyphosphates is smaller than that of polyphosphate of the same degree of polymerization, as is shown in Fig. 4.

The fact that vanadate has a smaller intrinsic viscosity than phosphate is demonstrated further by comparing those of ortho salts. Sodium orthovanadate, Na_3VO_4, cannot be obtained by the usual method, but it can be

TABLE V. INTRINSIC VISCOSITY AND DENSITY INCREMENT OF VANADIUM-CONTAINING GRAHAM SALTS IN 0.07 N NaBr SOLUTION AT 25.5°C

G	42.30	0.0407	0.631
H	7.62	0.0225	0.630
I	5.96	0.0232	0.641
J	3.66	0.0275	0.653
K	0.98	0.0135	0.683

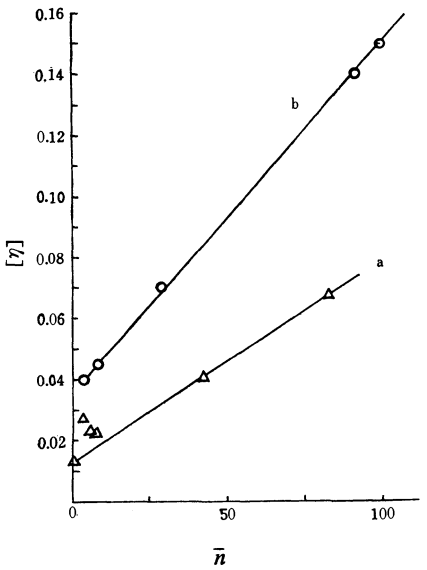

Fig. 4. Relation between $[\eta]$ and $\bar{n}$ of vanadium containing (△) and not containing (○) Graham salt in 0.07 N NaBr.

obtained in solution by dissolving sodium metavanadate ($NaVO_3$) in a strongly alkaline solution. An aqueous solution containing 1 N sodium hydroxide and 0.07 N sodium bromide was used as the solvent to measure the intrinsic viscosity. The result was $[\eta]=0.0118$, which was far smaller than the value of sodium orthophosphate (Na_3PO_4) in the same solvent: $[\eta]=0.0530$.

As for the small intrinsic viscosity of the vanadium-containing Graham salts, there may be several reasons. First, comparing curves d and e of Fig. 3, the hydration of vanadium-containing specimens should be smaller than that of vanadium-free specimens. Secondly, the average degree of the polymerization of vanadium-containing specimens might be smaller than the above-estimated values because of some unknown reasons. According to Fig. 4, curves a and b come together if the real $\bar{n}$ value is one-third of the expected value. Actually, paper chromatographic analysis[3] of solutions of sodium vanadate-phosphate glasses with P/V ratios of 4, 7 and 10 indicated the presence of a relatively large amount of pyrophosphate.

The Time Dependence of Reduced Viscosity. The viscosities of the solutions of samples C and D decreased definitely with time, probably due to the hydrolysis of the branching of the polymer chains[5].

Since the reduced viscosities (η_{sp}/c) of sodium polyphosphate of various molecular weights at various concentrations has been measured, the curves giving the relationship between the molecular weight and the reduced viscosity at a given concentration can be drawn readily. On the basis of these curves, the data on the time dependence of viscosity can be recalculated to the time dependence of the average molecular weight. It may then be assumed that the rate of hydrolysis is proportional to the number of branching B:

$$-dB/dt=kB \qquad (10)$$

It is also assumed that one molecule is produced by the hydrolysis of one branching, so that the decrease in the number of branching is equal to the increase in the number of molecules, N. Therefore, $-dB=dN$ and $B-B_e=N_e-N$, where B_e and N_e are the values of B and N, respectively, at the end of the hydrolysis. (Probably, $B_e=0$). By assuming further that the average molecular weight, M, is reciprocally proportional to the number of molecules, Eq. 10 can be rewritten and integrated to:

$$\ln(1/M_e-1/M)=-kt+\text{const.} \qquad (11)$$

where M_e is the average molecular weight at the end of hydrolysis, which can be obtained from the reduced viscosity of the solution 20 or 24 hr. after the dissolution. The experimental values were obtained in a thermostat at 25.5°C. Experimental data showed the linear relation expected by Eq. 11. The rate constant of the hydrolysis obtained from the slope of the straight lines was 0.39 hr^{-1}, as is shown in Table VI.

TABLE VI. RATE CONSTANT k OF HYDROLYSIS REACTION AT 25.5°C

Samlpe	Polymer concn. g./100 ml.	NaBr concn. N	k hr^{-1}
C	0.8112	0.035	0.39
	0.3703	0.07	0.39
D	1.0436	0.035	0.39
	1.9165	0.07	0.39

Summary

The intrinsic viscosities of sodium orthophosphates, pyrophosphate, tripolyphosphate and Graham salts of relatively low molecular weight (lower than 10300) were measured. The relation between the intrinsic viscosity at 25.5°C and the average molecular weight measured by the end group titration was

$$[\eta]=6.9\times10^{-4}\times M^{0.61}$$

in a 0.035 N sodium bromide solution, and

$$[\eta]=0.0348+0.112\times10^{-4}\times M$$

in a 0.07 N sodium bromide solution.

Vanadium-containing Graham salts (sodium vanadate-phosphate copolymers) seemed to be hydrolyzed immediately by the dissolution. The intrinsic viscosity of the solution was much smaller than that of sodium polyphosphate of the corresponding degree of polymerization.

The rate of the hydrolysis of branched sodium polyphosphate was proportional to the number of branchings, and the rate constant was 0.39 hr^{-1} at 25.5°C.

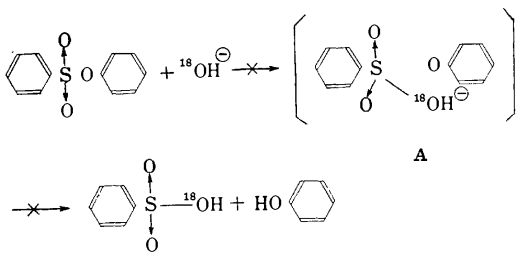
Non-Oxygen Exchange Reaction of Sulfone Group of Phenyl Benzenesulfonate in Acid Hydrolysis

By Shigeru OAE, Tsugio FUKUMOTO and Reiko KIRITANI

(Received November 27, 1962)

The hydrolysis of the esters of carboxylic acids has been shown to proceed through reversible addition intermediates both in acid and in alkaline media[1,2]. The alkaline hydrolysis of phenyl benzenesulfonate has been shown by one of us[3] to proceed through a simple S_{N_2} replacement, without involving prior addition of hydroxide ion on the sulfur atom as shown by (A), which was considered earlier as a posibility[4,5].



A

Fig. 1.

Similar studies on the neutral and alkaline hydrolysis of alkyl phosphinic chlorides and phosphorochlorides by Dostrovsky and Halmann[6,7] and of alkyl phosphate by Brutcher and Westheimer[8] have also indicated that these reactions do not proceed via pentacovalent phosphorous intermediates. Recently, however, Haake and Westheimer[9] have shown that the acid hydrolysis of alkyl hydrogen phosphates was accompanied by oxygen exchange similar to that of esters of carboxylic acids. This observation has prompted us to extend our ^{18}O tracer study on the acid hydrolysis of the titled compound. The acid hydrolysis of phenyl benzenesulfonate was very sluggish, more so than that of dimethyl hydrogen phosphate and was found to take place only at above 160°C in a sealed tube using 10 N hydrochloric acid.

An aliquot portion of phenyl benzenesulfonate was added on to 10 N hydrochloric acid diluted with ^{18}O enriched water and the mixture was sealed in a sealed tube. After heating the sealed tube at 180°C for 24 hr., the products, phenol and benzenesulfonic acid were separated by extracting with ether. The ether layer, containig phenol, was treated with bromine to derive 2, 4, 6-tribromophenol, while the aqueous layer was treated with *S*-benzylthiuronium chloride to give the sulfonic acid salt. By these reactions, the hydrolysis was found to give both phenol and benzenesulfonic acid in nearly quantitative yields. In a few separate experiments the reaction was stopped when it was half completed in order to see if the hydrolysis reaction proceeds through a reversible addition intermediate, and unchanged phenyl benzenesulfonate was recovered together with the hydrolysis products.

All these compounds were subjected to ^{18}O analysis by the usual method[10], and the results are shown in Table I.

There was no incorporation of ^{18}O in the recovered ester in this reaction, contrary to the acid hydrolysis of alkyl hydrogen phosphate. This excludes clearly any reversible prior addition of water molecule or hydronium ion in the hydrolysis of this compound and appears to suggest that the reaction is either an S_{N_1} reaction involving a slow cleavage of S–O bond followed by rapid solvolysis to form sulfonic acid or a simple S_{N_2} type synchronous one step process initiated by attack of water oxygen on the sulfur atom similar to the alkaline hydrolysis[3] or on the carbon atom of benzene ring bearing phenolic oxygen.

Since the S_{N_1} type cleavage of sulfur-oxygen linkage will leave additional positive charge on the sulfur atom which bears double formal positive charges, this process would require an enormous enorgy and is quite unlikely to occur. A simple S_{N_2} attack of water or hydronium oxygen on the carbon atom of the benzene

TABLE I. DISTRIBUTION OF THF LABEL IN HYDROLYSIS PRODUCTS

Run	Reaction time, hr.	^{18}O atom % of aq. HCl solution	^{18}O atom % of products		
			Phenol	Benzenesulfonic acid	Recovered ester
1	6	0.42	0.27	0.29 (0.28)*	0.21
2	6	0.80	0.29	0.35 (0.40)	0.21
3	6	1.50	0.78	0.68 (0.64)	0.21
4	24	0.48	0.44	0.35 (0.30)	—
5	24	0.42	0.38	0.29 (0.28)	—
6	24	0.80	0.42	0.41 (0.40)	—

* Numercical values in parrentheses represent theoretical % of ^{18}O atom by the incorporation of one oxygen atom from solvent heavy water.

ring as shown in Fig. 2 also cannot satisfy the results of ^{18}O analysis, because this process will require the phenolic oxygen to be incorporated with the equal amount of ^{18}O to that of the ^{18}O enriched water used, however, this was not the case.

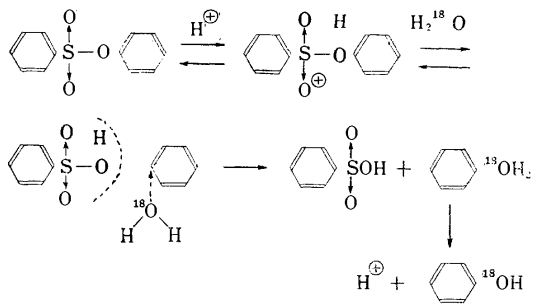

Fig. 2.

Then another, possibly the only, remaining possibility is the S_{N_2} attack of water or hydronium oxygen on the sulfur atom as shown in Fig. 3.

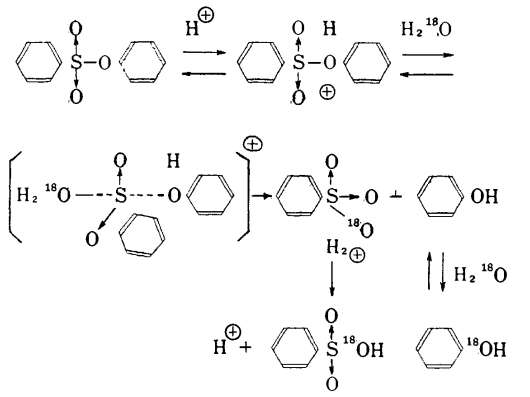

Fig. 3.

If the reaction proceeds through this process, the sulfonic acid will be incorporated with one equivalent amount of ^{18}O and the phenol will remain to be natural just as in the alkaline hydrolysis[3,4,5]. While the sulfonic acid, formed by the hydrolysis, was incorporated with ^{18}O just as much as what is required from this process, phenol was always incorporated with an excess of ^{18}O above the natural concentration and the amount of ^{18}O incorporation appeared to increase with a prolonged heating as shown by Table I.

TABLE II. OXYGEN EXCHANGE REACTION OF PHENOL AND BENZENESULFONIC ACID IN THE ACIDIC SOLUTION

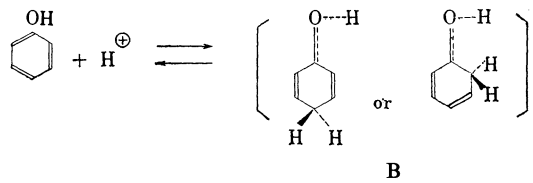
	Reaction time hr.	^{18}O atom % of aq. HCl solution	^{18}O atom % of products
Phenol	5	0.8	0.37
	24	0.77	0.73
Benzene-sulfonic acid	5	0.8	0.23
	24	0.8	0.24

In separate experiments we carried out oxygen exchange reactions of phenol and also benzenesulfonic acid in the same acidic solution. The results are shown in Table II. There was no apparent oxygen exchange in benzenesulfonic acid, even under a prolonged heating, however, all the phenols examined did show rather remarkable oxygen exchange under the condition cited and the amount of ^{18}O incorporation increased with a prolonged heating.

This observation indicates that the phenol formed during the acid hydrolysis of phenyl benzenesulfonate slowly exchange its oxygen with solvent medium.

The overall reaction scheme of this acid-catalyzed hydrolysis of phenyl benzenesulfonate would be the S_{N_2} process in which water molecule attack the sulfur atom, shown by Fig. 3, giving benzene sulfonic acid and phenol that undergoes further slow oxygen exchange with solvent water.

As to the question how phenol exchange its oxygen in acidic medium, we believe that in such a strong acidic medium phenol readily accept a proton at either para or ortho position



B

Fig. 4.

to form a quasi-stable incipient intermediate, B, in which the original hydroxy function aquires more of carbonyl character and hence facilitates the oxygen exchange with heavy water. Incidentally carbonyl group is known to exchange very readily its oxygen in both acidic and alkaline media[11,12].

The carbonyl character of phenolic compounds has been demonstrated only in the case of β-naphthol[13], where β-naphthyl thioglycollic acid was shown to replace hydroxyl group to form. We have also found that other phenols exchange its oxygen in strong acid media.

More detailed investigations on these oxygen exchange reaction of phenols in both acid and alkaline solutions are in progress in our laboratories and will be reported in future.

Experimental

Analysis for Oxygen-18.—Experimental procedure and calculation were similar to those in the previous paper[10].

Phenyl Benzenesulfonate.—This material was prepared by the Schotten-Baumann method[14], and was purified by repeated distillations. The fraction b. p. 152°C/1 mmHg, m. p. 35°C was used.

Hydrolysis of Phenyl Benzenesulfonate in Hydrochloric Acid.—Phenyl benzenesulfonate 1 g. was mixed with 5 ml. of 10 N hydrochloric acid containing water-^{18}O. The mixture was kept for 24 hr. at 180°C in a sealed tube. Then the sealed tube was broken and the whole content was extracted with ether. The ether extract was treated directly with bromine by the usual method, and 1.4 g. of 2, 4, 6,-tribromophenol (m. p. 96°C) was obtained (97%). In a few experiments, phenol formed by the hydrolysis was repeatedly purified by fractional distillation and subjected directly to ^{18}O analysis.

The aqueous layer was evaporated down to 2 ml.. To this solution was added a few drops of hydrochloric acid and *S*-benzylthiuronium chloride, 0.7 g. and *S*-benzylthiuronium salt of benzenesulfonic acid, 1.2 g. white plate, (m. p. 148.5°C) was obtained. This corresponds to 0.5 g. of benzenesulfonic acid (98% yield).

Partial Hydrolysis of Phenyl Benzenesulfonate in Hydrochloric Acid.—This ester 1 g. was mixed with 5 ml. of 10 N hydrochloric acid containing water-^{18}O. The mixture was heated in a sealed tube for 6 hr. at 180°C. The products were treated as described above. The ether extract was distilled and 0.2 g. of phenol and 0.5 g. of phenyl benzenesulfonate (b. p. 152°C/1 mmHg) were collected.

Isotopic Oxygen Exchange Reaction.—Phenol, 1 g. was mixed with 5 ml. of 10 N hydrochloric acid containing water-^{18}O. An aliquot of the mixture was heated in a sealed tube at 180°C for 5 hr. and the other for 24 hr. Benzenesulfonic acid was also treated in the same way as in the case of phenol.

The exchange products, phenol and benzenesulfonic acid, were derived to 2, 4, 6-tribromophenol and *S*-benzylthiuronium salt, respectively, and these derivatives were subjected to ^{18}O analysis.

NOTES

A. C. Polarography of Uranium in Non-complexing and Complexing Media

By K. A. KHASGIWALE, S. C. SARAIYA and A. K. SUNDARAM

(Received June 20, 1962)

A. C. polarography of uranium has been studied at 50 c. p. s. by Breyer and Hacobian[1] and the method has been applied for the estimation of uranium[2]. We have observed earlier[3] that the a. c. peak height does not increase with the increase in the concentration of acid or oxalic acid though an increase in the d. c. current is observed. This paper reports a more detailed study of the a. c. polarography of uranium in non-complexing and complexing media.

Experimental

The apparatus and the method of measurement of the alternating current have been described earlier[4]. An H-cell with a saturated calomel electrode as the reference electrode was used but the current was measured across the mercury pool for low cell resistance (300 ohms)[5].

All experiments were carried out at 30±0.5°C with deaerated solutions. Two capillaries [$m^{2/3} \cdot t^{1/6}(mg^{2/3}\,sec^{-1/2}) = 1.75$ (I) and 1.46 (II)] were used for the work. All solutions were made from reagent grade chemicals. Sodium perchlorate was used to maintain the ionic strength and the pH was adjusted with perchloric acid.

Results and Discussion

Non-Complexing Media.—Uranium gives two waves in weakly acid media and the disproportionation reactions are unimportant[6]. An a. c. polarogram of uranium in 0.1 M sodium chloride and 0.01 M hydrochloric acid showed two peaks corresponding to the two d. c. steps. The peak potentials corresponded to the half-wave potentials. Whereas the height of the second d. c. step was nearly double that of the first, the second a. c. peak was smaller than the first.

The peak currents were measured at different salt concentrations (Table I). The current for the first peak reached a constant value but that for the second increased with an increase in the concentration of sodium chloride. The height of the second peak was greater than that of the first at higher salt concentrations, though never double as in the d. c. polarography. The effect of frequency (Table II) showed that the current for the first peak increased upto 200 c. p. s. but that for the second increased only upto 100 c. p. s. Besides, the second peak height was smaller than the first at 500 c. p. s. The results are understandable as the second step is irreversible and the rates of the two electrode processes may be different.

The ratio of the peak current to uranium in 2 M hydrochloric acid (Table III) decreased

with increasing concentration of uranium contrary to that observed in conventional polarography. The increase in the d. c. current for the first step beyond that corresponding to one-electron diffusion controlled reaction is a function of the rate of disproportionation and as the rate in presence of acids in comparatively smaller than that in the presence of complexing agents, the height of the first peak has been studied in complexing media.

Complexing Media.—The polarography of uranium in thiocyanate[7], lactate[8] and oxalate[9] media has been reported. A shift in the half-wave potential to more negative values occurred in lactate and oxalate medium at pH 5 with no change in the limiting current. At this pH the peak potentials of the a. c. polarograms corresponded to the half-wave potentials and the peak currents were the same as that of the simple ion. The limiting current for the first step in these media increased with the concentration of the complexing agent in acidic solutions whereas the a. c. peak currents for low concentration of oxalate, lactate or thiocyanate were nearly the same as for the simple ion and decreased on further increase in the concentration. The peak potentials were the same viz., −0.18 V. vs. S. C. E. whereas the half-wave potentials in the case of oxalate (−0.13 V.) and thiocyanate (−0.11 V.) shifted to more positive potentials at high concentrations.

In explaining these results, the electrode reaction coupled with the chemical reaction will have to be considered. Uranium(V) produced at the electrode by the reduction of uranium(VI) with the half-wave potential at −0.18 V. vs. S. C. E. undergoes disproportionation to produce more of uranium(VI). This is again reduced at the electrode giving rise to an increase in the current. The half-wave potential is for the overall reaction. In a. c. polarography the peak potential of −0.18 V. corresponds to the electrode reaction. But the reversal of the electrode reaction takes place due to the superimposed a. c. and consequently no chemical reaction occurrs. Hence no increase in the a. c. peak current is observed and the peak potential remains same.

The decrease in the peak current at higher concentrations of the complexing agent might be due to the rate of the electrode recation. It was observed that the peak current reduced with the increasing concentration of the complexing agent (Fig. 1).

Thiocyanate was the only system for which a slope of 30 mV. for the log plot of the first wave was obtained whereas a slope of 60 mV. was obtained in the case of oxalate and lactate. Besides, a linear relationship between current and concentration of uranium and a temperature coefficient of less than 2% in the case of thiocyanate would appear to indicate that no kinetic considerations were involved in the reduction. The observations made herein indicated that this was also a case of disproportionation.

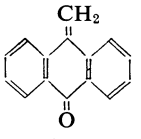
On the Electronic Spectrum of 1, 2-Di-9'-anthrylethane

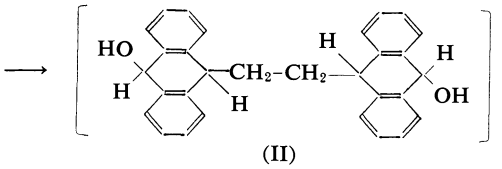
By Shuzo AKIYAMA and Masazumi NAKAGAWA

(Received November 5, 1962)

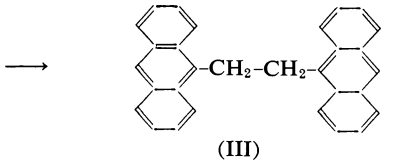
The electronic spectrum of 1, 2-di-9'-anthrylethane (III) with unusual low absorption intensity has been reported in a literature[1]. The low absorption intensity is scarcely understandable in view of the presence of two anthracene nuclei in the molecule. The present authors have carried out the synthesis of the hydrocarbon (III) according to the method of Barnett[2] with a modification starting from 10-methyleneanthrone (I)[3], and the spectrum



(I)



(II)



(III)

was measured. Expectedly, the spectrum exhibited much higher absorption intensity as compared with that of the literature value[1] (Fig. 1), and the fact the ε-value of the absorption maximum at the longest wave-length is found to be approximately the double of the corresponding ε-value of 9-methylanthracene[4] is consistent with the additivity principle of absorption intensity of unconjugated chromophores.

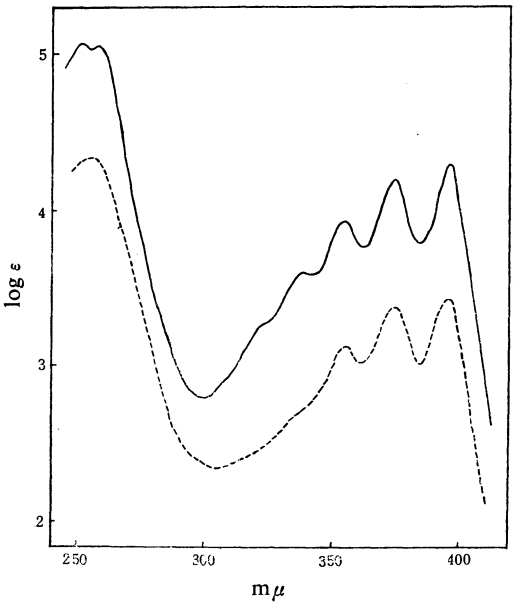


Fig. 1. The electronic spectrum of 1, 2-di-9'-anthrylethane, ——: the result of the present paper, ------: redrawn from Ref. 1).

Experimental*

10-Methyleneanthrone (I). — 10-Methyleneanthrone (I) was prepared according to the procedure of Clar[3] by the reaction of anthrone with formaldehyde. Pale yellow needles, m. p. 148°C (lit. value, m. p. 148°C[3]), 66%.

1, 2-Di-9'-anthrylethane (III).—A mixture of I (3 g., 0.015 mol.), zinc dust (15 g.), 28% aqueous ammonia (35 ml.) and water (35 ml.) was refluxed for 2 hr. After cooling to room temperature, the reaction mixture was washed with water and dried. The dried material (zinc dust, zinc hydroxide and II) was repeatedly digested with boiling ethanol. Five drops of concentrated hydrochloric acid were added to the combined hot alcoholic extract (200 ml.) resulting in the deposition of pale yellow crystals, m. p. 302~307°C (decomp.), 1.4 g., 52%. The crystals were recrystallized three times from toluene yielding pure III, m. p. 314~318°C (decomp.), (lit. values, 310~315°C (decomp.)[1]; 308°C[2]).

Found: C, 93.97; H, 5.97. Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

UV spectrum (in chloroform), λ_{max} (log ε); 252.5 (5.07), 259 (5.05), 324 (3.25)†, 339 (3.59), 356 (3.92), 375 (4.20), 397 (4.29). The dagger indicates shoulder.

The infrared spectrum of III was found to be almost identical with that of the reported one[1].

Isolation of Carrier-free Tellurium from Antimony Target

By Yuji YOKOYAMA, Hisao MABUCHI, Hitoshi SHOJI and Nobufusa SAITO

(Received November 10, 1962)

On the separation of tellurium from antimony, several different procedures were described in the literature, including coprecipitation method,[1] ion-exchange method[2] and so forth. These methods, however, do not give satisfactory results for the separation of trace amounts of tellurium from several grams of antimony. In a study of the energy level schemes of tin nuclei, it became necessary to separate trace amounts of radioactive tellurium in the state of carrier-free from proton-irradiated antimony targets. The radioactive tellurium thus separated is to be electroplated on a metal foil and to be measured with a β-ray spectrometer.

As reported by one of the present authors,[3] tellurium(IV) is extracted with a carbon tetrachloride solution of dithizone. As to antimony, dithizonate of trivalent antimony was reported,[4] but no definite description on the pentavalent state was made. A simple test showed that antimony(V) is not extracted into a carbon tetrachloride solution of dithizone from acidic solution. Considering such properties, the authors devised the following separation procedure and applied it to bombarded samples.

Separation Procedure

Dissolution of Antimony Target and Extraction of Tellurium.—Several grams of antimony target (metal powder) are dissolved in 30 ml. of aqua regia and the solution is slowly evaporated to dryness. To the residue, another 30 ml. of aqua regia are added and again evaporated to dryness. Such treatment should be repeated at least three times for completion of the oxidation of antimony to pentavalent state. After the treatment with aqua regia, the resulting white residue is dissolved in 20 ml. of 6 M hydrochloric acid and the solution is warmed for a while to ensure the tetravalency of tellurium. Then the solution is diluted with distilled water so as to be 3 M in hydrochloric acid. At lower acidity than 3 M in hydrochloric acid, antimony is hydrolyzed and gives a white precipitate which prevents tellurium from being extracted with dithizone. Extraction of tellurium from the hydrochloric acid solution is carried out in a separatory funnel with an equal volume of concentrated dithizone solution. With a volume ratio of 1 : 1, extractabilities of tellurium under the given condition are 30% with a saturated dithizone-carbon tetrachloride solution and 75% with a saturated dithizone-chloroform solution*1. Therefore, extraction process repeated three times may be enough for essentially complete removal of tellurium from the aqueous layer, when a saturated dithizone-chloroform solution is used.

Back-Extraction of Tellurium.—After combined dithizone extracts are washed with dilute hydrochloric acid, they are transferred into another separatory funnel, together with a suitable amount of distilled water. To this separatory funnel, the aqueous solution of cupric chloride is added until the amount of cupric ion becomes a little in excess to the equivalent amounts combining with dithizone, and then the funnel is thoroughly shaken. When dithizone is saturated with copper, tellurium is liberated from dithizone chelate into the aqueous layer. This is because copper has a greater affinity than tellurium does for dithizone.

Then, the aqueous phase is separated. A small amount of copper contained in it can be removed by repeated extractions with a very dilute carbon tetrachloride solution of dithizone ($\sim 10^{-6}$ M/l.). The loss of tellurium during this operation is negligible, if a sufficiently dilute solution is used for the extraction. By this procedure, more than 90% of radioactive tellurium is brought into the aqueous phase.

Results and Discussion

A preliminary experiment showed that, when trace amouts of ^{129m}Te artificially mixed with 1 g. of antimony were separated by the separation procedure described above, the amount of antimony contaminated in tellurium fraction was less than 60 μg.*2 (0.006% of initial antimony). On the other hand, when carbon tetrachloride was used as a solvent of dithizone instead of chloroform, antimony contamination was less than 30 μg. (0.003%).

As good results were obtained in the preliminary experiment, this method was applied to the separation of a bombarded sample. About 5 g. of antimony were irradiated with 56 MeV. proton (beam current 0.4 μamp.) for 24 hr. After the bombardment, the target was dissolved in aqua regia and treated with a chloroform solution of dithizone as described above. Tellurium fraction thus obtained was again purified with a carbon tetrachloride solution of dithizone in a similar way. Figure 1 shows γ-ray spectra of tellurium and antimony fractions. They are clearly different

Assignment of the peaks

No. of Peaks	Energy Mev.	Nuclides
1	0.15	^{119}Sb($\leftarrow^{119}$Te)
2	0.27	^{119}Sb($\leftarrow^{119}$Te)
3	0.51	^{118}Sn($\leftarrow^{118}$Sb$\leftarrow^{118}$Te)
4	0.66, 0.71	^{119}Sb($\leftarrow^{119m}$Te)
5	0.92, 0.95, 0.98	^{119}Sb($\leftarrow^{119}$Te)
6	1.22	^{118}Sn($\leftarrow^{118}$Sb$\leftarrow^{118}$Te), ^{119}Sb($\leftarrow^{119}$Te)
7	1.37	^{119}Sb($\leftarrow^{119m}$Te)
8	1.74	^{119}Sb($\leftarrow^{119m}$Te)
9	2.06	^{119}Sb($\leftarrow^{119}$Te)
10	0.09	^{120}Sn($\leftarrow^{120m}$Sb)
11	0.20	^{120}Sn($\leftarrow^{120m}$Sb)
12	0.58	^{122}Sn($\leftarrow^{122}$Sb)
13	1.03	^{120}Sn($\leftarrow^{120m}$Sb)
14	1.17	^{120}Sn($\leftarrow^{120m}$Sb)

from each other, and the peaks in the spectra of antimony fraction were all assigned to those of antimony isotopes.

The important part of this separation method is the oxidation of antimony with aqua regia, because complete oxidation of gram-scale antimony is fairly difficult. Clear-cut separation depends on the completeness of oxidation.

The authors wish to express their hearty thanks to Dr. Hidetsugu Ikegami of the Institute for Nuclear Study of the University of Tokyo for his cordial guidance to physical problems and careful discussions throughout this research.

Hydrogenation and Hydrogenolysis. VII.[1] *Selective Hydrogenation of Aromatic Compounds Containing C–O Linkages Liable to Hydrogenolysis with a Rhodium-Platinum Oxide under High Pressures*

By Shigeo NISHIMURA and Hisaaki TAGUCHI

(Received November 26, 1962)

In a series of previous papers[1-4], it was shown that (3 : 1) or (7 : 3) rhodium-platinum oxide of Adams' type is not only a highly active catalyst in hydrogenation of various organic compounds, but also very effective for the selective hydrogenation of the compounds having C–O linkages liable to hydrogenolysis[5]. It was also shown that the rhodium-platinum oxides containing 70 to 90% of rhodium by the weight of the metal are even more active and selective than pure rhodium oxide[6]. Subsequently, the use of the rhodium-platinum oxide under high pressures of hydrogen was found to be extremely effective in hydrogenation of various aromatic compounds[7].

This paper describes the high pressure hydrogenation of aromatic compounds containing C–O linkages susceptible to hydrogenolysis with (7 : 3) rhodium-platinum oxide and acetic acid as solvent. As is seen from Table I, most hydrogenations proceed rapidly at room temperature and 100 to 150 kg./cm^2 of hydrogen accompanied with only slight hydrogenolysis.

Hückel et al., *Ann*, **451**, 109 (1927)]. m) B. p. 75～76°C/19 mmHg; n_D^{24} 1.4482.

In four compounds in Table I (phenyl ether, *p*-hydroxybenzoic acid, benzyl acetate and acetophenone) which are all liable to hydrogenolysis with great ease, hydrogenations were carried out also at atmospheric pressure and the results compared with those at high pressures (see Table I). In all the cases the proportion of hydrogenolysis at high pressures decreased to about a half of that at atmospheric pressure, and better yields of the corresponding saturated compounds were obtained at high pressures. Under these conditions, phenol, anisole, acetophenone, benzophenone, benzyl ether, 1- and 2-naphthols, and furfuryl alcohol gave in quantitative or nearly quantitative yields the corresponding saturated alcohols or ethers. Benzyl acetate, where the most extensive hydrogenolysis occurred of the compounds investigated, gave a 62% yield of hexahydrobenzyl acetate. At high pressure *p*-hydroxybenzoic acid gave not only 4-hydroxycyclohexane-1-carboxylic acids in a better yield, but also of a higher melting point than at atmospheric pressure, probably the cis isomer being produced more predominantly at high pressure. 1- and 2-Naphthols also gave the

products of melting points not so much lower than those of the corresponding *cis-cis*-decalols. In both cases almost pure cis-cis isomer was obtained in about 50 to 60% yield by recrystallization of the product twice from petroleum benzine[8]. Thus, the results show that the high pressure hydrogenation of aromatic compounds with (7 : 3)rhodium-platinum oxide is a very effective synthetic method where it is desired to avoid the hydrogenolysis concerning C–O linkages. The described method will also be useful for the synthesis of cis compounds by hydrogenation of substituted aromatic compounds[9].

Experimental

Catalyst.—(7 : 3) Rhodium-platinum oxide was prepared as described previously[6].

Hydrogenation.—Hydrogenation was carried out in a 200 ml. autoclave equipped with a magnetic stirrer. The stirrer was driven at the speed of 1000 to 1500 r. p. m.

Isolation of Product.—The hydrogenation product was separated from acetic acid by neutralization with aqueous sodium hydroxide followed by extraction with ether or by distillation at reduced pressure. The product was then distilled at atmospheric or reduced pressure except in case of *p*-hydroxybenzoic acid. In this case, after most of 4-hydroxycyclohexane-1-carboxylic acids was removed as solid, cyclohexanecarboxylic acid was steam-distilled from the residue. Evaporation of water from the residual solution gave a further portion of the hydroxy acid. When the hydrogenation was quantitative, the yield of the product after distillation was usually about 90%.

The authors are indebted to Mitsubishi Chemical Industries Co. for the support of this work.

The Electronic Structure of Carbazole in the Fluorescent State

By Noboru MATAGA and
Yoshikazu TORIHASHI

(Received December 14, 1962)

The nature of the electronic states of pyrrole, indole and carbazole seems to be not so well understood as those of benzenoid hydrocarbons, aza-aromatics and their derivatives, although there have been some theoretical studies[1].

We have studied various solvent effects on the absorption and fluorescence spectrum of carbazole, including the effect of hydrogen bonding in a nonpolar solvent and the effect of ionic dissociation in an aqueous alkaline solution[3,1b]. We have also made some quantum mechanical studies of the electronic structure and spectra of this series of molecules by the composite system method[4] and have found a nice agreement with the experimental observations. For example, carbazole was regarded as composed of biphenyl and the >N-H group. Wave functions and energies[5] for the ground state as well as for the excited states of planar biphenyl, which reproduce the observed spectra satisfactorily, were used. For the calculation of the lower excited states, it was sufficient[5] to take into consideration three occupied MO's, ϕ_4, ϕ_5, and ϕ_6, and three vacant MO's, ϕ_7, ϕ_8, and ϕ_9, among the twelve π-MO's of biphenyl. Three charge transfer (CT) configurations from nitrogen to ϕ_7, ϕ_8, and ϕ_9, were taken into consideration. The core resonance integral between nitrogen and the nearest neighbor carbon and the energy of the nitrogen orbital were assumed to be -2.0 and -10.25 eV.[6] respectively.

For the sake of simplicity, only the wave functions for the lowest and the second excited singlet state of carbazole are shown here. $^1\chi_{Nk}$ is the CT configuration, and ^{1}L's and ^{1}B's are locally excited states in biphenyl.

$$^1\Psi_1 = 0.1283\ \chi_0 + 0.7811\ ^1L_b - 0.2575\ ^1B_b - 0.5279\ ^1\chi_{N7} + 0.1684\ ^1\chi_{N9}$$

$$^1\Psi_2 = 0.9961\ ^1L_a - 0.0473\ ^1B_a + 0.0739\ ^1\chi_{N8}$$

The oscillator strengths for these states of carbazole were calculated as: $f(\Psi_0 \rightarrow {}^1\Psi_1) = 0.13$: $f(\Psi_0 \rightarrow {}^1\Psi_2) = 1.02$. These two transitions correspond quite well to the observed band at 3.90 eV. with moderate intensity and the strong band at 4.27 eV. respectively. The form of $^1\Psi_1$ calculated here clearly shows that the very weak " hidden transition "[7] of biphenyl (^1L_b) is modified considerably in carbazole because of the mixing with $^1\chi_{N7}$ and also with ^1B_b. Both the replacement of NH hydrogen by alkyl group and hydrogen bonding of the >N-H···X type cause a large red shift of the 3.90 eV. band, but only a slight shift of the 4.27 eV. band. This fact can be explained quite well on the basis of the calculated results because the contribution from the CT configuration is very small in $^1\Psi_2$ compared with that in $^1\Psi_1$, where it is considerably large, and both the alkyl replacement and the hydrogen bonding lower the energy of the CT configuration and increase the core resonance integral between carbon and nitrogen.

The increase of the dipole moment in the fluorescent state,

$$\Delta\vec{\mu} = \langle {}^1\Psi_1 \mid \sum_i e_i \boldsymbol{r}_i \mid {}^1\Psi_1 \rangle - \langle \Psi_0 \mid \sum_i e_i \boldsymbol{r}_i \mid \Psi_0 \rangle,$$

was calculated to be $\sim 1.96\,D$. The value of $\Delta\vec{\mu}$ was determined experimentally by the method proposed by Lippert[8] and by Mataga[9], using the following equation and assuming $a \sim 4$A.

$$hc(\sigma_a^m - \sigma_f^m) \simeq \text{Const} + 2\left[\frac{D-1}{2D+1} - \frac{n^2-1}{2n^2+1}\right] \cdot \frac{(\Delta\vec{\mu})^2}{a^3}$$

9) N. Mataga et al., This Bulletin, **28**, 690 (1955); ibid., **29**, 465 (1956).

The experimental value was estimated to be $\sim$2.2 *D*, which agrees very well with the calculated results.

The $\vec{\Delta\mu}$ values of naphthylamines and naphthols calculated by the ordinary semiempirical ASMO method, with appropriate Hückel MO's delocalized over all cores in the molecule, have been found to be ca. 4$\sim$5 times larger[10] than the observed values. In the present method, however, such a situation does not arise. This fact seems to indicate that the composite system method can give a more reliable charge distribution in the heteroaromatics when appropriate values of semiempirical parameters are chosen.

The Electronic Spectrum and Structure of the s-Triaminobenzenium Ion

By Noboru MATAGA

(Received December 17, 1962)

A quite interesting example of a kind of aromatic carbonium ion seems to be formed in the aqueous solution of *s*-triaminobenzene (TAB). For the equilibrium TAB+$H^+ \rightleftharpoons$ $TABH^+$ (*s*-triaminobenzenium ion), p$K \sim 5.5$[1]. No such protonation on the ring carbon occurs in the case of aniline or *m*-phenylene diamine, where the amino group is protonated[1]. This is a preliminary report on theoretical calculations on the electronic spectra of TAB and $TABH^+$ and on the stabilities of the protonation products of aminobenzenes, which give a basis for interpretation of the observed results[1].

A semi-empirical ASMO CI method[2] was used. The parameters for Hückel MO calculations were the same as given elesewhere[3]. Pyrrole-type nitrogen was assumed, and the valence state ionization potential and electron affinity were obtained from the table[4]. The value of β_{CN}^{core} was taken to be -2.399 eV. All C–C bond distances were assumed to be 1.39 Å, and all C–N distances, 1.36 Å. The hyperconjugation with the CH_2 group in the case of $TABH^+$ was not taken into account. The calculated results are given in Table I, together with the observed values. D_{3h} and C_{2v} symmetries are assumed for TAB and $TABH^+$ respectively.

The calculated spectra are in satisfactory agreement with the observed values. Although the hyperconjugation was excluded in this calculation, it may be taken into account by some approximate method. In the present case, owing to the presence of the three amino groups, the higher occupied orbitals of the local system I (II is the CH_2 group) should be very much elevated compared with the highest occupied orbital of the corresponding local system of the benzenium ion[5]. Therefore, the excitation energies from the higher occupied orbitals of I to the antibonding π-orbital of II may not be so large, and this charge transfer interaction will increase the stability of the protonated aminobenzenes.

Another measure of the stability of the protonated species is the localization energy. The results of calculation by the Hückel MO method are shown in Table II.

In mode A, the destabilization energy of the π-electrons by protonation becomes considerably smaller from aniline to TAB, whereas it is almost constant or even slightly increases in mode B. This result is in accordance with the observed values. The mode A protonation seems to occur also in the case of tri-O^--benzene (TOB) (phloroglucine trianion)[1], for

Table II. Localization energies of some aminobenzenes (in unit of β)[a)]

Mode of protonation	A. Carbon	B. Amino group
Aniline	2.2498[b)]	2.8054
m-Phenylenediamine	1.9562[c)]	2.8058
TAB	1.8294	2.8060

a) The localization energies in this table are given by $(m-m^+)$, where the π energy of the neutral molecule is given by $n\alpha+m\beta$ and that of the protonated system, by $(n-2)\alpha+m^+\beta$.
b) Protonation on para-carbon.
c) Protonation on the carbon at the ortho-position in relation to both amino groups.

which we have calculated the localization energy, assuming suitable Hückel MO parameters ($\delta_{o^-}\sim 0.8$, $\beta_{co^-}\sim\beta$) and $(m-m^+)$ being 1.6861.

Mackor et al.[6)] have demonstrated an approximate linear relation between the localization energy and log K in the case of the protonation of many aromatic hydrocarbons. We have observed that the same linear relation holds for TAB and TOB as for aromatic hydrocarbons.

Another possible structure of $TABH^+$ or $TOBH^+$ may be a kind of π-complex in which the proton is situated on the molecular plane. If the proton is situated at the center of the molecule, the lowest energy transition is still forbidden and we cannot interpret the observed strong band. If the proton moves to the periphery of the molecule, the transition becomes possible. This model may finally lead to the localization or hyperconjugation model described above as the most stable equilibrium form.

Solvent Effects on the Flourescence Spectrum of the Ion-pair (Naphthol-Triethylamine System)

By Noboru MATAGA, Yoshikane KAWASAKI and Yoshikazu TORIHASHI

(Received January 10, 1963)

It has been demonstrated[1] that the strong hydrogen bond between β-naphthol and triethylamine (TEA) in the equilibrium ground state and in the excited Franck-Condon state shifts to the ion-pair in the excited equilibrium state, from which fluorescent transition occurs, in benzene. This phenomenon has been interpreted[1] as due to a strong charge transfer from the nitrogen non-bonding orbital of TEA to the OH antibonding orbital of naphthol in the Franck-Condon excited state, which is followed by an almost complete proton transfer from oxygen to nitrogen in the excited equilibrium state.

We have extended the above work to systems including various solvents of different polarities, thus obtaining results which seem to support the above interpretation. The solvents used here were monochlorobenzene, dichloroethane and acetonitrile. The observed results are summarized in Table I. As one can see from the table, the red shift of the fluorescene band maximum due to the complex formation, ($\Delta\sigma_f$), is larger, the greater the dielectric constant (D) of the solvent, whereas that of the absorption band, ($\Delta\sigma_a$), which is much smaller than $\Delta\sigma_f$, decreases with an increase in the dielectric constant of the solvent.

TABLE I. WAVE NUMBER SHIFTS OF BAND MAXIMA DUE TO COMPLEX FORMATION

Solvent	D	$\Delta\sigma_f$ 10^4 cm^{-1}	$\Delta\sigma_a$ 10^4 cm^{-1}
Benzene	2.284	0.40	0.04
Monochlorobenzene	5.621	0.45	0.03
Dichloroethane	10.36	0.46	0.01
Acetonitrile	37.5	0.58	0.00

As is described elsewhere[2], by using the charge transfer model[3] of the hydrogen bond,

1) N. Mataga and Y. Kaifu, *J. Chem. Phys.*, **36**, 2804 (1962).
2) N. Mataga and Y. Kaifu, to be published.
3) H. Tsubomura, This Bulletin, **27**, 445 (1954); K. Nukasawa, J. Tanaka and S. Nagakura, *J. Phys. Soc. Japan*, **8**, 792 (1953).

the wave function of the proton donor-acceptor pair may be expressed as a superposition of various resonance structures.

$$\Psi = a\Phi(\mathrm{D}-\mathrm{A}) + b\Phi(\mathrm{D}^- - \mathrm{A}^+) + c\Phi(\mathrm{D}^*\mathrm{A}-)$$

where D−A denotes the hydrogen-bonded pair when the proton donor D is in the ground state (no charge transfer), $\mathrm{D}^- - \mathrm{A}^+$, the charge transfer structure, and $\mathrm{D}^*-\mathrm{A}$, the hydrogen-bonded pair when D is in the fluorescent state (on charge transfer).

The energy difference between the charge transfer structure and the infinitely separated D−A pair may be written as:

$$\begin{aligned}\Delta E &= E(\mathrm{D}^- - \mathrm{A}^+) - E(\mathrm{D}-\mathrm{A}) \\ &= I_\mathrm{A} - A_\mathrm{D} + V(\mathrm{D}^- - \mathrm{A}^+) + H_\mathrm{s}\end{aligned}$$

where I_A: the ionization potential of the non-bonding orbital of the proton acceptor, A_D: the electron affinity of the anti-bonding orbital of the O-H bond, $V(\mathrm{D}^- - \mathrm{A}^+)$: interaction energies between the pair, and H_s: the stabilization energy due to the solvation of the ion-pair.

Probably, $\Phi(\mathrm{D}^- - \mathrm{A}^+)$ may interact very strongly with $\Phi(\mathrm{D}^*-\mathrm{A})$, but not so much with $\Phi(\mathrm{D}-\mathrm{A})$, when D and A come close to each other because $E(\mathrm{D}^- - \mathrm{A}^+)$ may be rather small and almost comparable to $E(\mathrm{D}^*-\mathrm{A})$ owing to the quite small I_A value of TEA. Hence, $a \gg b, c$ in the ground state and $b, c \gg a$ in the first excited electronic state of the D−A complex. These circumstances are indicated in Fig. 1,

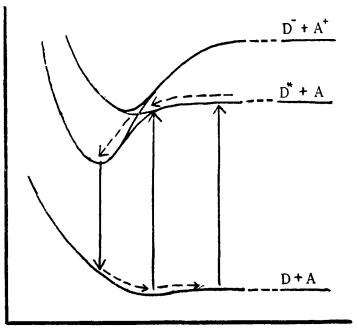

Fig. 1. Potential energy curves for D−A interaction.

where the reaction coordinate represents the D−A distance, the degree of the charge transfer from A to D and the position of the O-H proton.

Furthermore, H_s seems to play an important role in the present case. This quantity seems to be larger in the more polar solvent than in the less polar one, because of the greater dipole-dipole and dipole-polarization forces in the former solvent. The larger H_s value may be a main cause of the greater $\Delta\sigma_\mathrm{f}$ value in the polar solvent. However, hydrogen bonding between D and A may be very weak in the polar solvent, because either D or A may be solvated rather strongly, which seems to result in the very small $\Delta\sigma_\mathrm{a}$ value of this solvent.

Analogous phenomena have been observed when TEA was added to the solution of carbazole in acetonitrile and dichloroethane[4] respectively, and also when a rather large amount of primary or secondary aliphatic amines was added to the cyclohexane or benzene solution of β-naphthol[5]. These phenomena may be interpreted on the basis of similar reasoning.

The ESR Spectrum of the Phthalonitrile Anion Radical

By Kazuo NAKAMURA and
Yasuo DEGUCHI

(Received December 27, 1962)

Though the ESR spectra of many organic anion radicals have been investigated, that of phthalonitrile has not yet been reported on*. When phthalonitrile was reduced in dimethoxyethane (DME) with potassium or sodium, the anion radical was formed.

Thus Fig. 1's ESR hyperfine spectrum of the radical prepared with potassium agrees with the calculated value of Fig. 2, assuming that the coupling constants are $\alpha_{N_{CN}}=1.75$ gauss, $\alpha_{H_5}=\alpha_{H_4}=0.37$ gauss and $\alpha_{H_3}=\alpha_{H_6}=4.11$ gauss respectively.

On the other hand, Fig. 3's ESR spectrum of the same radical reduced with sodium appears to be different from that reduced with potassium, but one can construct a calculated spectrum similar to that of Fig. 2 provided that each line in Fig. 1 will split further into

* The ESR spectra of the electrolytically-generated benzonitrile negative ion have been reported by P. Ludwig and R. N. Adams in *J. Chem. Phys.*, **37**, 828 (1962).

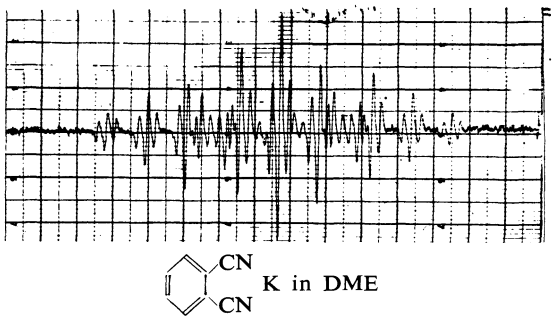

Fig. 1. ESR spectrum of phthalonitrile anion radical reduced with potassium in DME.

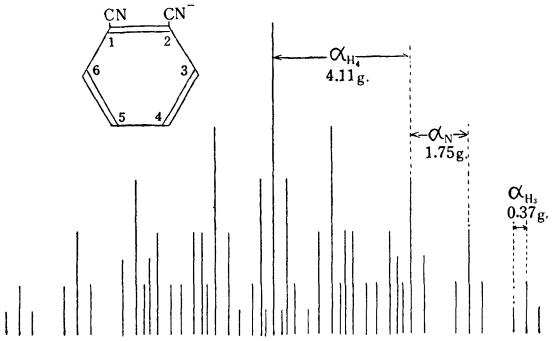

Fig. 2. Calculated spectrum of phthalonitrile anion radical.

Studies of Ion Exchange Membranes. XVI. The Preparation of Ion Exchange Membranes by the "Paste Method"

By Yukio MIZUTANI, Reiichi YAMANE, Hirofumi IHARA and Hiroji MOTOMURA

(Received August 23, 1961)

It is generally accepted that the introduction of ion exchange groups into base membranes prepared beforehand is most practically effective for the preparation of ion exchange membranes. Hence, on the preparation of the base membranes many studies have been presented[1-8], and the present author has proposed a "soaking method"[9,10]. The present paper concerns with a method for the preparation of ion exchange membranes in the manner called the "Paste Method".

Fundamental Ideas for the Present Method

The requirements for the base membrane are as follows:

1) It must involve functional groups suitable for the introduction of ion exchange groups and three-dimensional resinous structures in the base membrane; 2) it must possess chemical and mechanical steadiness on the introduction of ion exchange groups; and 3) it must have excellent mechanical strength, that is, a practical reinforcing material in the membrane.

The present work aims to satisfy not only the above requirements but also 4) easy procedures for the preparation and the control of the properties of ion exchange membranes.

The following materials were used as the components of the paste: a) Mf: a monomer containing a functional group suitable for the introduction of an ion exchange group; b) Mc: a monomer copolymerizable with Mf to control the viscosity of the paste, the content of resinous components in the base membrane, and the content of ion exchange groups in the ion exchange membrane; c) DVB: divinylbenzene as a cross-linking agent; d) PVC: the fine powder of poly(vinyl chloride) which endows the base membrane and the ion exchange membrane with flexibility and toughness; e) DOP: dioctyl phthalate as a plasticizer to control the viscosity of the paste; and f) BPO: benzoyl peroxide as a catalyst.

These components were mixed thoroughly and deaerated under reduced pressure. The paste obtained was coated on a reinforcing material and treated in a hot press to prepare the base membrane after having been wrapped with a wrapping material. PVC was not soluble in the paste and dispersed in the swollen state, and the ratio of components was easily controlled. This is a practical merit, since both the resinous component content in the base membranes and the properties of the ion exchange membranes may be easily controlled.

Since PVC was insoluble in the paste, the paste was fairly viscous, but it was not spinnable. Therefore, the paste was easily coated on a reinforcing material, and no pin-hole could be found in the base membrane.

The paste coated on a reinforcing material was heated, and fine particles of PVC in the paste were fused to form a continuous film. Since fine particles of PVC were swollen in the paste, heating at a temperature lower than, say, 175°C, a most suitable temperature for the molding of PVC dispersion[11], would suffice to fuse the particles into a film. The monomers in the continuous film of PVC were polymerized to produce three-dimensional resinous structures.

Under such conditions, the graft copolymer could be produced, as was shown in a previous paper[9], and the homogeneity of the base membrane would be much improved.

If styrene is used as Mf and if the base membrane is a mere mixture of PVC and cross-linked polystyrene, the base membrane would be white or opaque in appearance, because PVC and polystyrene are mutually insoluble. Therefore, the homogeneity of the base membrane, as shown by its transparency, should be ascribed to the very formation of the graft copolymer of styrene, DVB, and PVC.

The use of reinforcing materials may improve

the dimensional stabilities of the base membranes upon treatment to introduce ion exchange groups; it may also provide ion exchange membranes with sufficient mechanical strength for the practical applications.

Finally, ion exchange groups were introduced to the base membranes by various procedures, depending on the nature of the Mf selected.

Experimental

Material.—PVC, Sumilit PX-A, prepared by the Sumitomo Kagaku Co., Ltd., was used. Styrene (St), 2-methyl-5-vinylpyridine (MVP), DOP, and all other reagents were of chemical grade. From the results of the preliminary examinations on various reinforcing materials, Teviron fabrics from the Teijin Co., Ltd., were adopted. As a wrapping material, Vinylon film from the Kurashiki Rayon Co., Ltd., was used.

Preparation of the Base Membranes and the Introduction of Ion Exchange Groups.—To prepare the base membranes, the pastes prepared from St-DVB-DOP-PVC-BPO (I) or MVP-St-DVB-DOP-PVC-BPO (II) were coated on Teviron fabrics, wrapped with a Vinylon film, and heated in a hot press at 100~120°C for 30 min. and then at 70~80°C for 16 hr. Vinylon films were torn off and ion exchange groups were introduced into the base membranes in the following manner:

The base membrane prepared from the paste I was sulfonated with 98% sulfuric acid, or chloromethylated with chloromethyl methyl ether (CME)-stannic chloride-carbon tetrachloride, and then quaternized with an aqueous solution of trimethylamine. The base membrane prepared from the paste II was quaternized with a petroleum ether solution of methyl iodide.

Electrochemical Properties.—Water content, ion exchange capacity, fixed ion concentration, electric resistance, specific conductivity and transport number were measured at 25°C by the same procedure as in previous papers[9,12-15]. Electric resistance and specific conductivity were measured on the membrane dipped in a 0.5 N aqueous solution of sodium chloride at 25°C. The transport number was calculated by Nernst's equation from the membrane potential of a concentration cell composed of 0.5 N and 2.5 N aqueous solutions of sodium chloride, separated from each other by the ion exchange membrane under consideration.

Diffusion.—In a water/membrane/3 N sodium chloride solution system, the amount of electrolytes diffused from a 3 N sodium chloride solution into water was measured at 25°C while the water and the solution phase were being stirred.

Mechanical Strength.—Mullen test-burst strength was measured.

Dimensional Stability.—Before measurement, the samples were treated with 1 N hydrochloric acid and 1 N ammonia water repeatedly.

Test pieces of 2 cm.×100 cm. were examined. Changes in the length of the test pieces immersed in various solutions were measured after they had been left standing for a long time.

Relative Transport Number.—Relative transport numbers were measured at 25°C for the sodium chloride-calcium chloride solution system, the sodium chloride-magnesium chloride solution system, and the sodium chloride-sodium sulfate solution system by the same procedure as in the preceding paper[12]. During the measurements the test solutions used were stirred[16]. The compositions of the test solutions are as follows: $C_{Cl}=0.5$ N, $C_{Na}=0.375$ N and $C_{Ca}=0.125$ N in the sodium chloride-calcium chloride system; $C_{Cl}=0.5$ N, $C_{Na}=0.375$ N and $C_{Mg}=0.125$ N in the sodium chloride-magnesium chloride system; and $C_{Na}=0.5$ N, $C_{Cl}=0.45$ N and $C_{SO_4}=0.05$ N in the sodium chloride-sodium sulfate system.

The relative transport number (P) is shown as follows:

$$P=(t_2/t_1)/(C_2/C_1)$$

where t_1 is the transport number of monovalent ions through the membrane, t_2 is the transport number of bivalent ions through the membrane, C_1 is the concentration of monovalent ions in the test solution, and C_2 is the concentration of bivalent ions in the test solution.

Results and Discussion

The Preparation of the Cation Exchange Membrane.—The composition of the paste seriously affected the ease with which the base membrane was prepared. The following factors were considered:

I) Appropriate viscosity of the paste for coating on a reinforcing material.

II) Ease of the sulfonation of the base membrane.

III) Chemical and mechanical stabilities of the base membrane in the face of sulfonation.

IV) Quality of the resultant ion exchange membrane.

The appropriate compositions of the pastes I were found to be (St+DVB)/PVC=0.7~1.0 (by weight) and DOP/PVC=0.3~0.5 (by weight).

The base membranes were sulfonated with 98% sulfuric acid at 55~60°C for several hours. On prolonged sulfonation, the membranes were deeply colored and might have been degradated.

□, △: Transport number
■, ▲: Specific conductivity

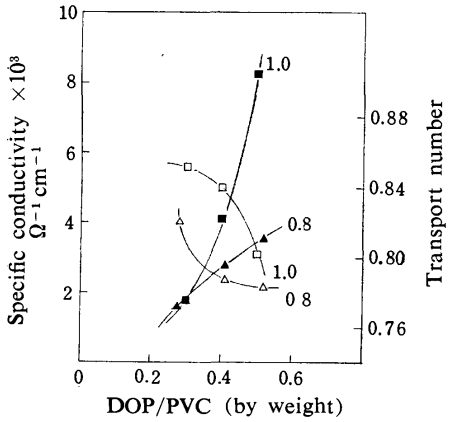

Fig. 2. DOP contents in the pastes—Properties of cation exchange membranes.
The numbers in the figure are (St+DVB)/PVC (by weight).
DVB/(St+DVB)=0.1 (by weight)
□, △: Transport number
■, ▲: Specific conductivity

The relations between the compositions of the pastes and the electrochemical properties of the membranes are shown in Figs. 1 and 2. Figure 1 shows that an increasing (St+DVB)/PVC ratio improves the electrochemical properties of ion exchange membranes by the increase of the density of ion exchange groups per unit volume of the membranes. Figure 2 shows that the increasing DOP content enhances the specific conductivities and depresses the cation transport numbers by the increase of the porosity of the membrane.

The Preparation of Anion Exchange Membranes of the St Type.—The procedures for the preparation of the base membrane were similar to those for cation exchange membranes.

Chloromethylation was considered to be most essential among the treatments to introduce anion exchange groups. The effect of the conditions of chloromethylation, such as temperature, time, and concentration of chloromethyl methyl ether and of stannic chloride, on the quality of the membranes were studied; these factors were found not to be effective enough to change the properties of anion exchange membranes.

These conditions of chloromethylation were considered to be important only for the appearance of anion exchange membranes. In the end, four to eight hours' chloromethylation at room temperature with the solution, $CME/CCl_4=1\sim0.25$ (by volume) and $SnCl_4/(CME+CCl_4)=0.05$ (by volume), was found to be appropriate. Quaternization with trimethylamine was easy, no difficulty being encountered.

The effects of the compositions of the pastes on electrochemical properties are shown in Figs. 3 and 4.

The conditions of chloromethylation and quaternization were as follows:

Chloromethylation: $SnCl_4/(CME+CCl_4)=0.05$ (by volume), $CME/CCl_4=1$ (by volume), at 10°C for 8 hr.

Quaternization with trimethylamine: 30% aqueous solution of trimethylamine, at room temperature, for 16 hr.

With an increasing DVB content in the pastes, the anion transport numbers through the membranes showed only slight changes and specific conductivities were decreased to a greater extent (Fig. 3). This may be attributed to the development of three-dimensional resinous structures.

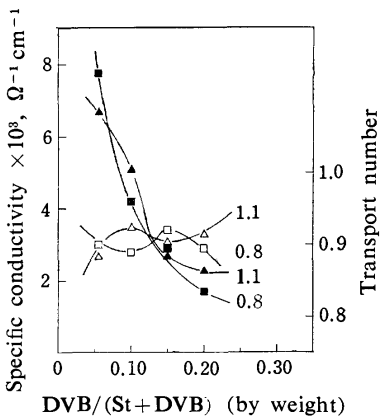

Fig. 3. DVB contents in the pastes—Properties of anion exchange membranes of St type.
The numbers in the figure are (St+DVB)/PVC (by weight).
DOP/PVC=0.2 (by weight)
□, △: Transport number
■, ▲: Specific conductivity

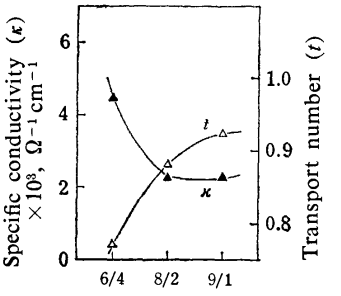

Fig. 4. Composition of the pastes—Properties of anion exchange membranes of St type.
Compositions of the pastes (by weight):
(St+DVB+DOP)/PVC=1.0
DVB/(St+DVB)=0.1

Figure 4 shows the effects of the DOP content of the pastes on the electrochemical properties of the membranes at a fixed (St+DVB)/PVC ratio. With an increasing DOP content, anion transport numbers decreased and specific conductivities increased, since the membranes should become more porous.

The apparent qualities of anion exchange membranes were improved by lowering the DOP content and increasing the DVB content, since the development of the three-dimensional resinous structure depresses the swelling of the base membranes at chloromethylation.

The Preparation of Anion Exchange Membranes of the MVP Type. — Since, at room temperature, PVC was fairly swollen and since the monomers were readily polymerized in paste II, it was recommended that the paste be kept at low temperature.

The following compositions (by weight) of the pastes were found to be appropriate:

when MVP/(MVP+St)=0.8
(St+MVP+DVB)/PVC=1.5～1.8
DVB/(St+MVP+DVB)=0.05～0.1
and DOP/PVC=0.3～0.4 and
when MVP/(MVP+St)=0.6
(St+MVP+DVB)/PVC=1.2～1.4
DVB/(St+MVP+DVB)=0.05～0.1
and DOP/PVC=0.2～0.3

The ratio of methyl iodide to petroleum ether as a solvent does not affect the properties of the membrane very much, but quaternization with methyl iodide by itself injures the appearance of the membrane.

The following conditions were found to be appropriate;

CH_3I/petroleum ether=0.25 (by volume)
at room temperature and for 10～15 hr.

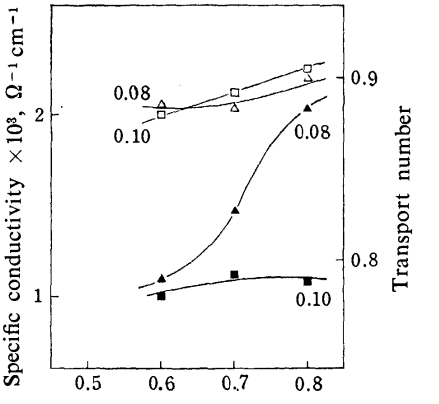

Fig. 5. Ratio of monomers—Properties of anion exchange membranes of MVP type.
The numbers in the figure are DVB/(St+MVP+DVB) (by weight).
Compositions of the paste (by weight):
(St+MVP+DVB)/PVC=1.3, DOP/PVC=0.3
□, △: Specific conductivity
■, ▲: Transport number

TABLE III. RELATIVE TRANSPORT NUMBERS

System	Transport number				
	Total cation or total anion	SO_4^{2-}	Ca^{2+}	Mg^{2+}	P
NaCl-$CaCl_2$-Cation exchange membrane	0.987	—	0.401	—	2.04
NaCl-$MgCl_2$-Cation exchange membrane	0.985	—	—	0.313	1.40
NaCl-Na_2SO_4-Anion exchange membrane of St type	0.971	0.017	—	—	0.16
NaCl-Na_2SO_4-Anion exchange membrane of MVP type	0.986	0.013	—	—	0.12

Figures 5 to 7 show the effects of the compositions of the pastes on the electrochemical properties of the membranes. The higher MVP content improves the properties of the membranes by increasing the content of ion exchange groups in the membranes (Fig. 5). With an increase in the DVB contents, anion transport numbers increased and specific conductivities decreased, because of the development of three-dimensional resinous structures (Fig. 6), and with an increase in the monomer contents, the properties of the membranes were improved (Fig. 7).

Properties of the Membranes. — The various properties of the membranes prepared are shown in Tables I—III. The compositions of the pastes used were as follows: (St+DVB)/PVC=0.75, DOP/PVC=0.35 and DVB/(St+DVB)=0.1 for cation exchange membranes; (St+DVB)/PVC=0.91, DOP/PVC=0.24 and DVB/(St+DVB)=0.1 for anion exchange membranes of the St type; and (St+MVP+DVB)/PVC=1.8, DVB/(St+MVP+DVB)=0.05, MVP/(MVP+St)=0.85 and DOP/PVC=0.3 for anion exchange membranes of the MVP type. The compositions of the pastes are shown by weight.

It was clearly shown that the membranes prepared are excellent in dimensional stabilities, as may be seen in Table I. It was considered from the data shown in Table II that the membranes prepared are useful from the practical point of view. As is shown in Table III, cation exchange membranes were more permselective for calcium ions and magnesium ions than for sodium ions, while anion exchange membranes were less permselective for sulfate ions than for chloride ions. The behavior of sulfate ions through anion exchange membranes is desirable in an electrophoretic concentration of sea water[17], but the behavior of magnesium ions and calcium ions through cation exchange membranes is undesirable[12,16].

The durability of ion exchange membranes prepared by the "paste method" could be considered to be good judging from the results of the electrophoretic concentration of sea water over a long period.

Summary

A method for the preparation of ion exchange membranes, called the "paste method", has

17) Y. Onoue, Y, Mizutani and R. Yamane, *Denki Kagaku*, **29**, 294 (1961); *J. Electrochem. Soc. Japan (Oversea Ed.)*, **29**, No. 4, E220 (1961).

been proposed. The pastes prepared from styrene-divinylbenzene-dioctyl phthalate-poly-(vinyl chloride) powder-benzoyl peroxide or from 2-methyl-5-vinylpyridine-styrene-divinyl benzene-dioctyl phthalate-poly(vinyl chloride) powder-benzoyl peroxide were coated on rein forcing materials of Teviron fabric and were treated in a hot press to prepare the base membranes, to which the ion exchange groups were then introduced. The ion exchange membranes thus prepared were excellent in electrochemical, mechanical and dimensional properties as well as in appearance.

The authors wish to thank Messrs, Wataru Teshima, Sumio Akiyama and Takashi Izuo for their help.

*The A. C. Polarography of Thiamine O-Monophosphate**

By Koichi OKAMOTO

(Received November 22, 1961)

Many investigations of such phosphates of thiamine (B_1) as the monophosphate (TMP), diphosphate (TDP, cocarboxylase) and triphosphate (TTP) of thiamine, have been reported from various points of view because of their importance in the biological and medical fields.

Polarographic studies of such phosphates of B_1 may not yet, however, be considered to have been established. Only a short communication on the polarographic behaviors of TDP has been reported[1], and no precise comparisons to the B_1 findings and no studies of the nature of its electrode process have been carried out.

Among the above three phosphates of B_1, TMP was thought to be the most stable and to have the simplest structure, therefore, it was obtained rather easily as pure crystals.

In this paper, the a. c. polarographic behavior of TMP and a discussion of the differences between the behavior of B_1 reported on in a previous work[2] and that of TMP will be presented.

The d. c. polarographic reduction waves of B_1 and its derivatives were generally ill-defined in the buffer solutions because of the unfavorable influences of hydrogen-discharging currents or pre-sodium waves, while their a. c. polarographic reduction waves were rather well-defined, as was described in the previous paper[2]. Similar results were also obtained in the case of TMP. Therefore, the a. c. method was mainly applied in this investigation.

Experimental

Apparatus and Reagents.—The polarograph used was Yanagimoto model PA-102. (D. C. & A. C.); A. C.: ΔE=15 mV. r.m.s., 50 c.p.s., sinusoidal. The characteristics of the dropping mercury electrode were m=1.003 mg. sec^{-1}, t=4.09 sec. (open circuit), and 3.76 sec. (at −1.273 V.).

The TMP used was prepared by the phosphorisation of B_1[3] and was then hydrolyzed to be monophosphate and purified by the column chromatograph (CG-50) until it gave only one spot on the paper chromatography.

Data for the purified TMP used were as follows: R_f=0.12 (Solvent, acetic acid: *n*-butanol; water=1:4:5); the content of TMP as determined by thiochrome reaction test was 99.1%, m. p.=ca. 200°C (decomp.). Microanalytical data:

Found: C, 31.48; H, 4.01; N, 11.77; H_2O, 8.24. Calcd. for $C_{12}H_{18}N_4O_4PS\cdot HCl\cdot Cl\cdot 2H_2O$: C, 31.80; H, 4.22; N, 12.36; H_2O, 7.95%.

The other reagents used were of reagent grade.

Experiments were carried out two or three times on the same kind of sample at 25±0.5°C, and the values obtained were averaged. All potentials and peak currents were expressed in V. vs. S. C. E. and μamp. r. m. s., respectively.

Results

The Influence of the pH Value on i_s and E_s.—Some of the a. c. polarograms of 5.00×10^{-4} mol./l. TMP in the buffer solutions of pH 0.90~10.65 (their ionic strengths were adjusted

** No wave

to 0.50 by the addition of potassium chloride) and also the method of the measurement of wave height are shown in Fig. 1.

The ralations of the peak currents, i_s, and of the summit potentials, E_s, to the pH value are both summarized in Table I and in Figs. 2 and 3.

One well-defined peaks current was observed at the pH values ca. 2 and ca. 4~8. One peak and an indefinite shoulder (as indicated by an

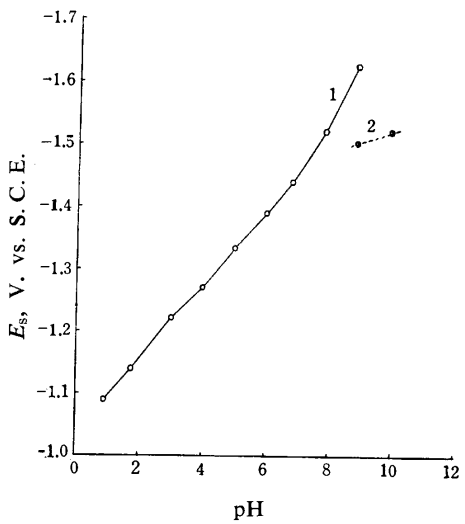

Fig. 2. The relation of pH to E_s.
1, 1st wave 2, pre-wave (indifinite)

arrow in Figs. 1—2.) were observed at the values of pH 1.75 and 3.00.

The behavior of a. c. reduction waves of TMP were not similar to that of B_1[2], as is shown in Fig. 1. Especially the attitude of the second wave of TMP was found to be different from that of B_1; that is, in the case of B_1 a rather definite second peak current was placed at more positive potentials and appeared at the pH value of 4.75, while that of TMP was not observed in the the same pH value region, but at the pH values of 1.75 and 3.00, at more negative potentials.

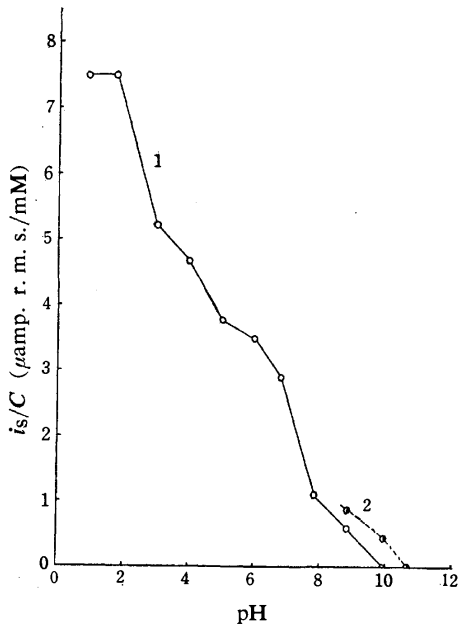

Fig. 3. The relation of pH to i_S.
1 : 1st wave. 2 : pre-wave (indifinite)

The variation of the E_S of TMP was very similar to the E_S of the first wave of B_1 within the pH value range of 4.0~7.0 (Fig. 2).

The peak currents of TMP increased according to the decrease pf pH values, as is shown in Fig. 3, and its heights and that of the first wave of B_1 ware not equivalent, although that of the latter was smaller than the former over all the pH value range studied.

The behavior of the peak current of TMP in basic solutions was almost the same as that of B_1; they both disappeared completely at a pH value of about 10.

The Relation of the Concentration of TMP to i_S and E_S.—In order to learn whether or not the peak current was due to the reduction of TMP itself, the relation between the concentrations and i_S was observed in two kinds of buffer solution, those with pH values of 0.90 and of 4.00. The results obtained are shown in Table II and in Fig. 4.

TABLE II. THE RELATIONS OF THE CONCENTRATIONS TO i_S AT TWO pH VALUES measured at 25°C

* KCl+HCl (μ=0.50) ** 0.25 M acetate buffer (μ=0.50)

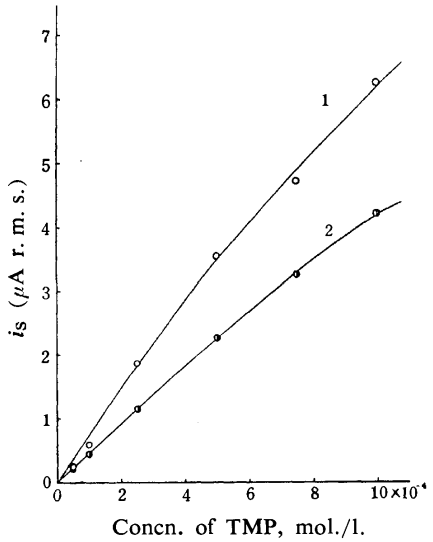

Fig. 4. The relation of the concentrations to i_S.
1, pH 0.90 2, pH 4.00

Almost linear relations between the concentrations and i_S were found for both samples; therefore, the first wave of TMP seemed to be the real reduction wave of TMP itself.

The summit potential, E_S, slightly shifted to negative potentials with the increase in the concentration of TMP.

This variation in of i_S and E_S according to the concentration change was very similar to that of B_1.

The Temperature Coefficients of i_S.—The temperature coefficient of the wave height was obtained as 2.17% between 18~32°C on acetate buffer solutions (μ=0.50) with a pH value of 4.00, containing 5.00×10^{-4} mol./l. of TMP.

The coefficient was larger than the theoretical values, 1.0~1.3%, for a. c. palarographic waves. This was thought to be mainly caused by the irreversible tendency of the electrode process of TMP, not by its kinetic properties.

The Influence of Mercury Heights H to i_S.—The relationship of H to i_S was studied by plotting H (corrected with the reverse pressure of H) against i_S at 25±0.5°C on the acetate buffer solution with a pH value of 4.00, containing 5.00×10^{-4} mol./l. of TMP.

The linear relation obtained may be formulated as follows:

$$i_S = 0.011H + 1.694$$

In the case of a. c. polarography, the i_S values were said to be independent of the H

values. The above relation almost coincided with the theory.

Electrocapillary Curve.—The electrocapillary curve of 5.00×10^{-4} mol./l. of TMP in the acetate buffer with a pH value of 4.00 is drawn in Fig. 5. Over the whole potential range, the drop time, t, in the sample solution was smaller than in the base solution, but at the electrocapillary zero, ca. -0.5 V., the difference was only 0.01 sec. A small step was observed at the potential $-1.25\sim-1.30$ V. corresponding to the summit potential of TMP, -1.273 V. A weak adsorption seemed to take place at the surface of DME over the whole potential range except at electrocapillary zero, but this could not have any remarkable effect upon the apparent a. c. waves.

When the electrocapillary curve of TMP was compared with that of B_1, the adsorption of TMP in the positive side to electrocapillary zero was the most different phenomenon.

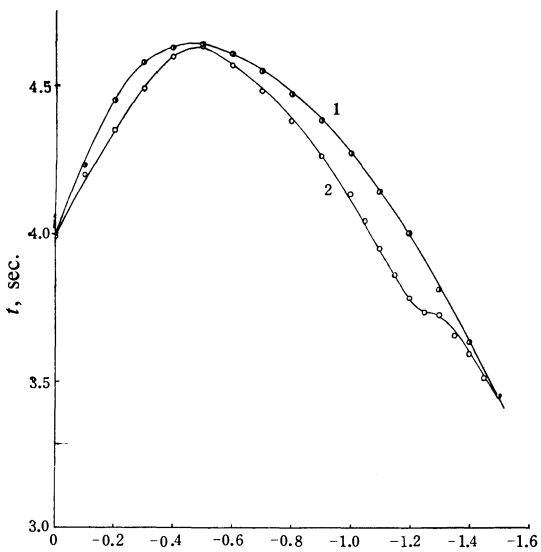

Fig. 5. Electrocapillary curves.
1, Base solution: acetate buffer of pH 4.00, $\mu=0.50$
2, 0.500×10^{-3} mol./l. of TMP in 1

Millicoulometric Determination (D. C. Method) of the *n*-Value.—The electrode reactions of TMP or B_1 have not yet been defined because of their complexity, but comparatively precise investigations of the reduction processes of B_1 have been reported by Asahi[4] recently. Asahi has suggested that B_1 is reduced by DME at the pyrimidine and also that the thiazol ring consumed about 10 electrons.

It was thought that the polarographic reduction process of TMP was similar to that of B_1 considering the reducible groups in a molecule.

Millicoulometric measurement of the n-values, therefore, was employed in order to confirm the number of electrons discharged, but the macro-scale-controlled potential electrolysis with a wide-surface-area mercury cathode was not applied, because the conditions of such a macro-coulometry were thought to be different from those of polarography.

The cell for millicoulometry used was of the Meites type[5], with the external S. C. E. anode separated from the cathodic part by a fine-sintered glass wall and an agar-agar bridge.

The coulometry was carried out on three kinds of bufier solutions, with pH values of 1.45, 3.00 and 4.00. d. c. potentials were applied, and the decrease in the d. c. wave height after electrolysis was measured.

When the pH value of the solution rose above about 4, the d. c. polarogram of TMP came to be very ill-defined, so that in the region with higher pH values than 4, millicoulometric studies could not be carried out.

The results obtained are summarized in Table III.

Table III. The results of millicoulometry

pH	$-E_{applied}$	n-Value
1.45	1.15	9.00
3.00	1.25	8.77
4.00	1.30	7.86

[TMP] $=5.371\times10^{-4}$ mol./l. Volume of solution, 0.25 ml. Electrolysis time, 100 min. Temp., 25 ± 0.5°C. Air was removed by nitrogen gas bubbling.

As is shown in Table III, the n-value of TMP was estimated to be 9 at a pH value of 3.0, but it seemed to decrease at pH values> 4, in accordance with the gradual decrease of the peak current of the a. c. polarogram with the pH value increse (Fig. 3).

The n-values obtained were found nearly to coincide with Asahi's estimation.

Discussion

As has been described in the previous sections, comparatively well-defined a. c. polarographic waves of TMP observed in acidic buffer solutions, were not simple tensammetric waves, but were reduction waves with a few tensammetric properties.

The most remarkable difference between the a. c. polarogram of TMP and that of B_1 was

4) Y. Asahi, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), **80**, 1222 (1960).

5) T. Meites and L. Meites, *Anal. Chem.*, **23**, 1893 (1951).

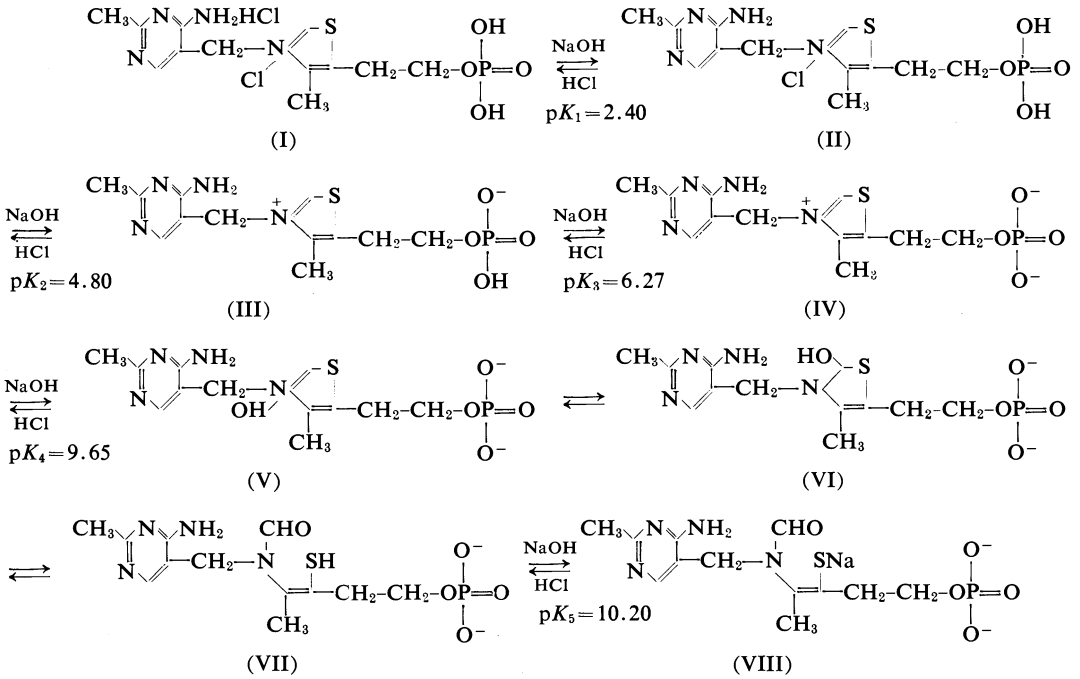

Fig. 6. Acid-base equilibrium of TMP.

the behavior of the second wave, which appeared rather definitely for B_1 at pH values>4.75, while it could not be observed in the same pH value region for TMP, but only as an obscure shoulder in the pH-value region of 1.75~3.

An other different result was the weak adsorption of TMP at the electrocapillary positive range, while the lack of it for B_1 could be observed on the electrocapillary curves.

This different behavior of TMP and of B_1 is thought to be caused by their different acid-base equilibrium processes.

The dissociation equilibrium of TMP when titrated with a sodium hydroxide solution can be shown as in Fig. 6, while its experimental titration curve is as in Fig. 7.

Definite pH-value changes were found at 1 mol. equiv. and at 3 mol. equiv., while an indefinite one was found at about a 5 mol. equiv. of sodium hydroxide.

The pK-values can be approximately estimated on the titration curve as $pK_1=2.4_0$, $pK_2=4.8_0$, $pK_3=6.2_7$, $pK_4=9.6_5$, and $pK_5=10.2_0$.

The obscure shoulder of the a. c. polarograms of TMP which appeared in the region of 1.75 ~3.00 pH values was, therefore, thought to be related to II species, but it could not be defined because of its ill-defined form.

The gradual decrease in the wave height of the a. c. polarograms according to the pH increase was caused by the comparatively continuous transition of the ionic species of

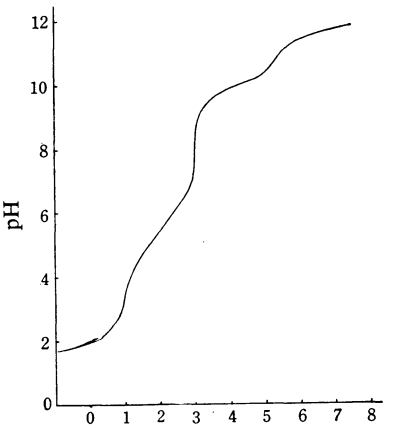

Fig. 7. Potentiometric titration curve of TMP.

TMP and by the complete disappearance of the wave at a pH value of about 10 was due to the disappearance of the thiazol ring as illustrated in Fig. 6.

The electron number discharged was confirmed for I species as 9, and as ca. 8 for II species, but that for other species could not be measured. Such a decrease in the n-values for each ionic species was thought to be mainly due to the reducibility of the pyrimidine rings with or without a proton; the wave height of I species was, therefore, the highest, as is shown in Fig. 3.

When the approximate assignment of the species of TMP in the solution of a certain pH value were made using the titration curve, species I was thought to exist in pH values <2, II in pH values ca. 3.5, III in those ca. 5.5, and IV in those ca. 8.

The comparisons, therefore, of the wave heights at each pH value seemed almost exactly to indicate the reducibility or the distinctive in electrode process of each species. The ratios of i_s at a pH value of 2 and at a pH value of 3.5, and of i_s at a pH value of 3.5 and at a pH value of 5.5 were $i_s^{3.5}/i_s=0.67$ and $i_s^{5.5}/i_s^{3.5}=0.74$ respectively. The apparent reducibility of a pyrimidine ring without hydrogen chloride was lower by about 67% than that of a ring with hydrogen chloride, while that of a thiazol ring without chlorine was also lower by about 74% than that of a ring of with chlorine. The reduction process was considered to be different for each ionic species according to the difference in the state of the amines in them.

The reduction mechanisms of TMP at DME could not be defined in this work, but it was suggested that the reduction may take place at both the pyrimidine ring and the thiazol ring, consuming 8 or 9 electrons.

Summary

A. C. polarographic studies of TMP, as well as a discussion of the polarographic behavior of TMP compared with that of B_1 reported on in a previous paper[1], were carried out.

TMP showed well-defined peak currents of almost the same E_s values as the second peak current of B_1 in the region of pH values <10, and obscure second waves were also observed at pH values between 1.75 and 3.00. The relation of the i_s of the first wave of TMP to the pH value was also similar to the second wave of B_1. The wave corresponding to the first wave of B_1, however, was not recognized for TMP under any of the conditions studied.

The nature of the first wave of TMP was determined to be that of the diffusion currents, not of the adsorption, kinetic, etc.

The number of electrons discharged could be ascertained by the millicoulometric technique as 9 at pH values <3 and 8 at a pH value of 4. The electrode reaction, therefore, of TMP was considered to be the same as that of B_1.

Some explanation of the relation of i_s to the pH value was attempted by reference to the pK values of TMP obtained from its experimental potentiometric titration curve.

The author is very much indebted to Director Munetosi Matsui for affording facilities for this investigation.

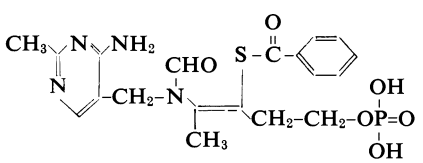
*The A. C. Polarography of S-Benzoylthiamine O-Monophosphate**

By Koichi OKAMOTO

(Received November 22, 1961)

One of the new derivatives of thiamine, *S*-benzoylthiamine *O*-monophosphate (BTMP) (I), has been found to have such predominant pharmaceutical effects as the remarkable increase and prolongation of the thiamine blood level in administration. Many pharmaceutical, chemotherapic and physicochemical studies of on BTMP have, therefore, been reported.



(I)

Some of the polarographic studies of BTMP have been undertaken by the author[1] and by Tachi[2] in order to learn its physicochemical properties.

In a previous work[1] a conventional polarographic study of BTMP was reported, but no theoretical treatment of the d.c. reduction waves of BTMP could be made, because of their irreversibility and ill-defined forms.

Alternating current polarographic techniques were applied in order to make the nature of

the reduction waves of BTMP more definite. By the a.c. method, two very definite peak currents could be observed and it became possible to discuss the reversibility of its electrode reaction.

In this paper, the a.c. polarographic behavior of BTMP and some of the theoretical considerations of the reversibilty of its electrode reaction will be presented.

Experimental

Apparatus.—The polarograph used was Yanagimoto model PA-102 (d.c. and a.c.), a.c.; $\Delta E=$ 15 mV. r.m.s., 50 c.p.s., sinusoidal. The characteristics of the dropping mercury electrode were: $m=1.006$ mg. sec^{-1} (open circuit), $t=4.24$ sec. (open circuit), 4.03 sec. (at −1.164 V.) and 3.73 sec. (at −1.377 V.). The thermostat was Yanagimoto's water bath for polarography with an accuracy of ±0.5°C.

Reagents. — The BTMP used was of purified crystal, as in the previous work[1].

The *S*-*p*-nitrobenzoylthiamine *o*-monophosphate (NBTMP) (II) used was that synthesized in our laboratory by the same method as for BTMP; m.p.=154~156°C (decomp.).

Found: C, 41.73; H, 4.70; N, 12.89. Calcd. for $C_{19}H_{22}N_5O_8PS\cdot2H_2O$: C, 41.68; H, 4.79; N, 12.80%.

Results

The Effect of the pH Value on the Summit Potential, E_s, and the Peak Current, i_s.—In the a.c. polarographic technique, the use of comparatively concentrated buffer solutions is

preferable in order to reduce the resistance of the electrolyte solution; therefore, 0.2 or 0.25 mol./l. buffer solutions were employed in the following experiments.

No maximum suppressor was used, thus avoiding its unfavorable influences upon the electrode reaction.

All experiments, except for some special studies, were carried out at 25±0.5°C, and air was removed by the bubbling of hydrogen.

are expressed in V. vs. S. C. E. and. μamp. r. m. s. respectively.

On account of the somewhat inferior reproducibility of a. c. polarograms, every measurement was repeated two or three times, and the values obtained were averaged.

Typical polarograms are shown in Fig. 1.

As it was necessary to compare the values obtained under the same conditions by the d. c. and a. c. methods, the d. c. polarograms were observed again.

As is shown in Fig. 2, the effect of the pH value on i_s^1 was very different from that on i_d^1, but the effect on E_s^1 was not different from that on $E_{1/2}^1$, as is shown in Fig. 3.

Fortunately, the second wave, which had not been observed well by the d. c. method, could be obtained clearly by the a. c. method.

As is shown in Fig. 2-2, the behavior of the second wave in various buffer solutions is interesting.

All numerical values are shown in Table I.

The Effect of the Concentration on i_s^1 and i_s^2 and on E_s^1 and E_s^2.—For the theoretical considerations, it seemed to be rather simple to chose that condition in which an ionic form of BTMP in the solution had no charge, namely, the condition at the isoelectric point where the pH value=4.05[3]. For this reason, the following studies were carried out on a 0.25 mol./l. acetate buffer solution with a pH value of 4.0.

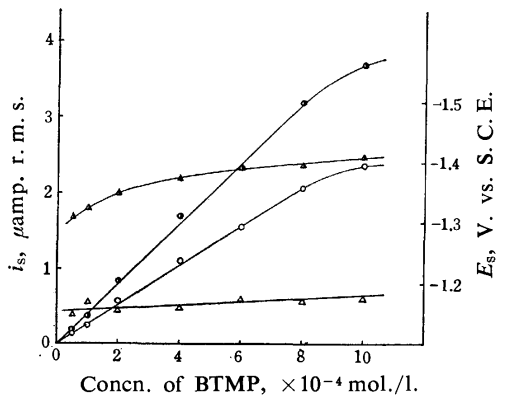

Fig. 4. The relations of the concentrations to i_s and E_s.
1, i_s^1 2, i_s^2 3, E_s^1 4, E_s^2
Base solution: pH 4.00 acetate buffer, 25°C

The relations between the concentrations of BTMP and i_s^1 and i_s^2 were both linear up to 0.8×10^{-3} mol./l. The saturating tendencies were observed over 0.8×10^{-3} mol./l., and they passed exactly through the zero point, as is shown in Fig. 4. Such relationships were

3) A. Ito, ibid, 22, 349 (1961).

considered to indicate that there was no remarkable adsorption or desorption phenomena at the interface of DME and the solution.

The effect of the concentration on E_s^1 and E_s^2 is shown in Fig. 4.

The Effect of the Mercury Reservoir Height on i_s^1 and i_s^2.—In a. c. polarography, the reaction current was not influenced by the height of the mercury reservoir, but it was proportional to the surface area of DME, so that i_s was usually independent of H.

A linear but slight change of i_s for BTMP was observed with these changes in H values:

$$i_s^1 = 0.007H + 0.687$$

$$i_s^2 = 0.004H + 1.404$$

on 0.25 mol./l. acetate buffer solutions of pH 4.0 containing 0.40×10^{-3} mol./l. of BTMP at 25±0.5°C.

The above relations coincide with the theoretical results in a. c. polarography.

Temperature Coefficients of i_s^1 and i_s^2.—In a. c. polarography, the temperature coefficient of i_s was usually smaller than of i_d, so that +1.0~1.3% at about 25°C were considered to be the ordinary values.

When some adsorption-desorption phenomena occur, a negative coefficient was obtained because of the decrease in the number of molecules adsorbed at DME with the rise in temperature. If the measurements of coefficients are carried out at various concentrations of depolarizer, a discontinuous change, such as from positive to negative values, was often observed according to the change in the adsorption state.

TABLE II. TEMPERATURE COEFFICIENTS OF i_s AT VARIOUS CONCENTRATIONS

Concn. mol./l.	i_s, μamp. r. m. s.		Temp. coeff.
	10°C	25°C	%
8×10^{-5}	$i_s^1=0.16$	0.22	+1.97
	$i_s^2=0.19$	0.30	+2.37
4×10^{-4}	0.79	1.10	+1.85
	0.92	1.64	+2.91
8×10^{-4}	1.40	1.96	+1.89
	1.88	3.05	+2.55
2×10^{-3}	2.55	3.65	+2.01
	4.03	5.88	+2.10

The temperature coefficients of BTMP at various concentrations are summarized in Table II. In the range of concentrations of 8×10^{-5}~2×10^{-3} mol./l., the coefficients of both i_s^1 and and i_s^2 were positive, but they were larger than that of the theoretical one. No discontinuous change was obtained; the coefficient of the first wave was in 1.85~2.01%, and the second was in 2.10~2.91%. The i_s^1 and i_s^2 seemed not to be controlled by the adsorption process but by diffusion, and the values larger than the theoretical ones were attributed to the influence of the irreversibility of the electrode reaction.

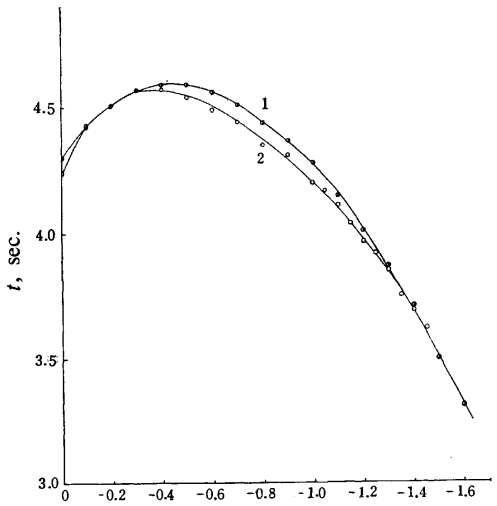

Fig. 5. Electrocapillary curve.
1 Base solution: acetate buffer solution of pH 4.00
2 0.40×10^{-3} mol./l. of BTMP in 1

Electrocapillary Curve.—The electrocapillary curve of 0.40×10^{-3} mol./l. BTMP in a 0.25 mol./l. acetate buffer solution with a pH value of 4.0 and of the base solution are shown in Fig. 5.

Upon the addition of BTMP, a slight decrease of t in the range of potential −0.3~−1.4 V. was observed, and there was no remarkable kink was at any poiential. The values of t were 0.05 sec. and 0.02 sec. smaller than that of the base solution at the potentials corresponding to the first and the second waves.

BTMP was considered to be weakly adsorbed at the positive side of the molecule at the surface of DME in the range of −0.3~−1.4 V., so that there were no predominant influences of adsorption phenomena on i_s^1 and i_s^2.

A Consideration of the Electrode Reaction.—As has been described in previous sections, two definite peak currents of BTMP were considered to be controlled by the electrode reaction, not by the adsorption.

The discussions, therefore, of the reversibility and the mechanism of the electrode reaction were thought to be possible.

The estimations of the diffusion coefficient, D, and the electron number, n, were carried out. Then the calculations of the transfer coefficient, α, and the rate constant, k_G, were also made.

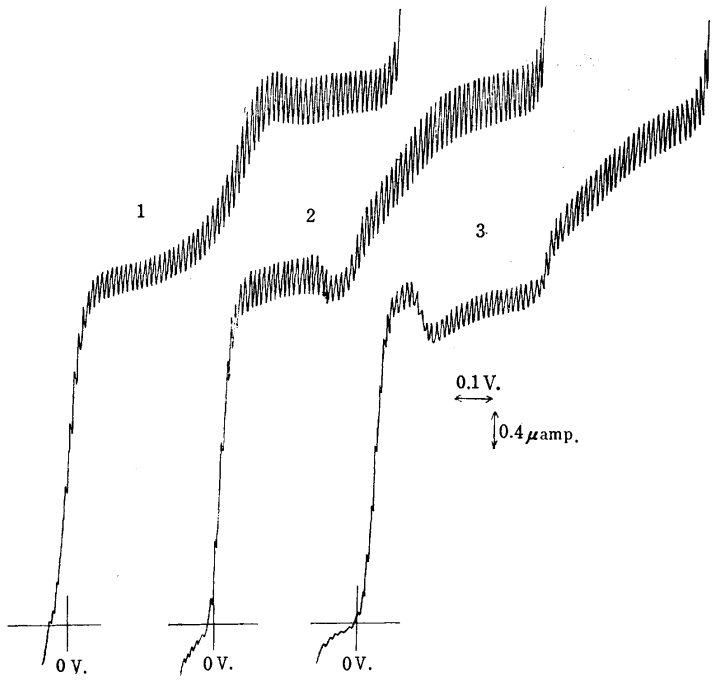

Fig. 6. Some of the d. c. polarograms of NBTMP.
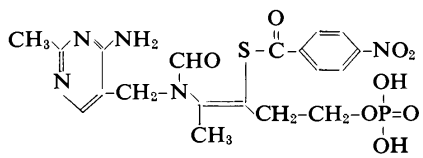
pH 1, 0.81 2, 1.36 3, 1.73 [NBTMP] $=0.477\times10^{-3}$ mol./l., 25°C

The Estimation of the Diffusion Coefficient of BTMP.—The *n*-values and the diffusion coefficient of BTMP could not be obtained because of the irreversibility of the electrode reaction.

When some of the reducible radicals the electrode process of which had already been confirmed were substituted into a suitable position in BTMP, the polarographic diffusion coefficient of the substituted BTMP might be calculated from the reduction wave by the substituted radical.

The nitro radical, therefore, was substituted into the para-position of the phenyl group in BTMP to obtain *S*-*p*-nitrobenzoylthiamine *O*-monophosphate (NBTMP) (II).



(II)

Some of the d. c. polarographic waves of NBTMP are shown in Fig. 6. The first and the second waves were thought to be reduced to the reduction of the nitro group to hydroxylamine ($n=4$) and to amine ($n=2$) respectively. The third wave, which is not drawn in Fig. 6, was due to the reduction of the *S*-acyl bond, as was observed for BTMP.

A minimum at about −0.25 V. which did not disappear upon the addition of Triton-X-100 was thought to be caused by the strong adsorption of NBTMP to the DME surface.

The values obtained for the first wave of 0.239×10^{-3} mol./l. NBTMP in the buffer solution with a pH value of 1.36 were as follows: $i_d=1.76$ μamp., $n=4$, $C=0.239\times10^{-3}$ mol./l. and $m^{2/3}t^{1/6}=1.330$ mg$^{2/3}$ sec$^{-1/2}$.

The diffusion coefficient D could be obtained by Ilkovic' equation as $D=5.22\times10^{-6}$ cm^2 sec^{-1}.

The molar volumes of BTMP and of NBTMP were thought to be approximately equivalent, so that the D value could be applied to that of BTMP.

The number of electrons discharged for BTMP, therefore, at various pH-value conditions could be calculated using the above D-value. They are summarized in Table III.

The change in *n*-values with the change in pH values was found almost to coincide with the change in the wave height, with the largest value of 4 showing in the pH range of 4.5～5.5. These variations of *n*-values with pH-value change are thought to be due to the differences in the reduction process of the ionic species of BTMP in the solutions of various pH values.

Consideration of the Reversibility of the First Wave.—Theoretical equations for the reversible and irreversible a. c. polarograms have already been given by H. Matsuda[4] as follows:

4) H. Matsuda, *Z. Elektrochem.*, **62**, 977 (1958).

TABLE III. THE COMPARISON OF THE REVERSIBILITIES OF THE ELECTRODE REACTION OF BTMP AT VARIOUS pH VALUES

12.05	1.621	1.653	32	55	1.67	0.43	0.26	0.98	0.93	0.94_9	5.83_3	132.9_9

For reversible reaction:

$$[(k_G \cdot f/D^{1/2})/\sqrt{\omega} > 40\alpha^{\alpha}\beta^{\beta}]$$

$$\bar{i}_s = 0.183\bar{i}_d(\tau\omega)^{1/2}(nF\Delta E/2RT) \quad (3)$$

$$E_s = E_{1/2} \quad (4)$$

For irreversible reaction:

$$(k_G \cdot f/D^{1/2})\sqrt{\tau} < 10^{-(1+2\alpha)}$$

$$\bar{i}_s = (2/\pi)\bar{i}_d(\alpha nF/RT)\Delta E[1-1.24(\tau\omega)^{-0.223}] \quad (5)$$

$$E_s = E_{1/2} + (RT/\alpha nF)[\ln k_G f/D^{1/2} - (1/2)\ln\omega - \ln\{1+1.67(\tau\omega)^{-0.490}\}] \quad (6)$$

where: $\bar{i}_d$ = diffusion current (d. c.).

$\bar{i}_s$ = peak current (a. c.).

$\omega = \pi/\theta$, angular frequency of superimposed alternating current

τ = drop time

ΔE = amplitude of superimposed a. c.

α = transfere coefficient ($\alpha+\beta=1$)

k_G = rate constant

D = diffusion coefficient of depolarizer

f = activity coefficient of depolarizer

$E_{1/2}$ = half-wave potential (d. c.)

E_s = summit potential (a. c.)

When the electrode raction is reversible, the half-wave potential $E_{1/2}$ and the summit potential E_s should coincide perfectly, according to Eq. 4, and the rate of $\bar{i}_s/\bar{i}_d$ is 0.183 $(\tau\omega)^{1/2}$ $(nF\Delta E/2RT)$ according to Eq. 3.

The slope of the d. c. wave ($=RT/\alpha nF$) indicates the reversibility of the d. c. electrode reaction. A comparison of the values of $RT/\alpha nF$, $E_{1/2}-E_s$, i_s/i_d, etc. of the first wave at various pH values is shown in Table III and in Fig. 7.

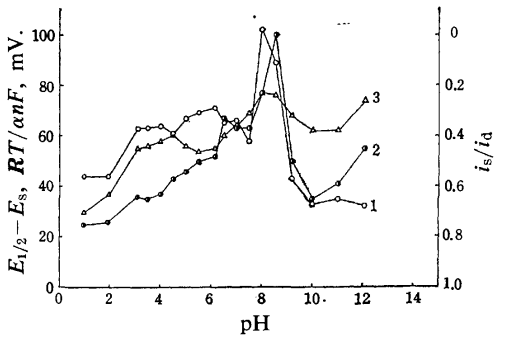

Fig. 7. The relations of pH to $E_{1/2}-E_s$, $RT/\alpha nF$ and i_s/i_d.
1, $E_{1/2}-E_s$ 2, $RT/\alpha nF$ 3, i_s/i_d

As is shown in Fig. 7, the reversibility of the electrode reaction seemed to change in rather a complicated way with the change in the pH-value. The smallest values for $E_{1/2}-E_s$, i_d/i_s and $RT/\alpha nF$ were each obtained at about pH 2~0 and 10 while remarkably large values were obtained at pH 8.0~8.5.

If these three values are taken as indicating the apparent reversibility of the electrode reaction, it is found that the smaller the pH value, the more reversible the electrode reaction in the acidic pH value region.

The stability of the *S*-acyl bond in BTMP was not sufficient in the basic medium, for it therein decomposed to give thiamine *O*-monophosphate, thiamine and other unknown decomposition products. The discussion, therefore, of the electrode reaction of BTMP in the basic medium was thought to be rather impossible. The discontinuous change on the curve in Fig.

7 at pH values 8.0~8.5 seemed to be caused by the decomposition process of BTMP.

In order to calculate the reaction rate constant, Eqs. 5 and 6 were thought to be useful, but they were defined under the condition that the superimposed a. c. amplitude, ΔE, was smaller than 5 mV. r. m. s. In this experiment ΔE=15 mV. r. m. s.; therefore, the accurate value of k_G could not be obtained. However, it seemed possible to estimate k_G and α approximately by the use of the above equations.

The procedure of the calculation may be described in the case of solution with a pH value of 4.00 as follows:

[BTMP] $=1.000\times10^{-3}$ mol./l., T=25°C, ΔE= 15 mV. r. m. s., $i_d=6.80\mu$amp., $i_\lambda=2.83\ \mu$amp. r. m. s., f=1, $\omega=100\pi$ (rad. sec^{-1}), τ=4.03 sec. (at the summit potential of the first wave), $E_{1/2}=-1.100$ V. vs. S. C. E., $E_s=-1.164$ V. vs. S. C. E., n=4.

Equation 6 was rewritten into Eq. 6-1 using the above values:

$$-1.083=1/\alpha n(\log k_G/D^{1/2}-1.2697) \qquad (6\text{-}1)$$

On the other hand, αn was obtained from Eq. 5.

$$\alpha n=1.51;\quad \text{therefore,}\quad \alpha=1.51/4=0.38$$

When αn was introduced into Eq. 6-1, Eq. 6-2 was obtained:

$$k_G/D^{1/2}=4.31_1\times10^{-1} \qquad (6\text{-}2)$$

The $D^{1/2}$ value was obtained, as in the previous section for NBTMP, as 2.284×10^{-3} cm. sec$^{-1/2}$, so that

$$k_G=0.43_1\times2.284\times10^{-3}=9.83\times10^{-4}\ \text{cm. sec}^{-1}$$

The k_G and α-values of the a. c. first wave of BTMP at various pH values calculated by the above procedure are both shown in Table III and Fig. 8.

In the acidic pH value region, the variation of α and k_G with the pH value in Fig. 8 indicates that the more acidic the medium, the larger the transfer coefficient α, but the k_G-values did not change remarkably.

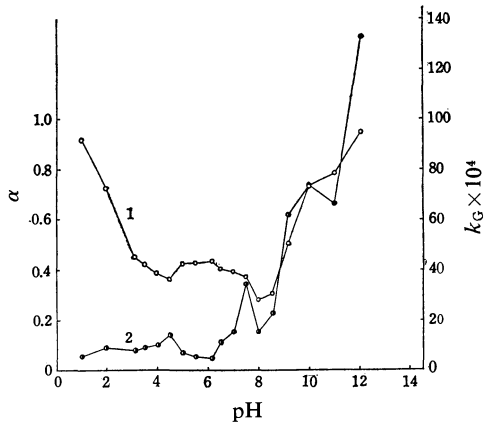

Fig. 8. The relations of pH to α and k_G.
1, α 2, k_G

The Estimation of the Electrode Reaction of BTMP.—The outline of the electrode reaction of BTMP was described in the previous paper[1].

In this paper, the approximation of the D-values of BTMP and the n-values of the electrode reaction at various pH values was carried out, it therefore being thought possible to estimate some of the processes of the electrode reduction.

If the reduction in the acidic solutions take place only at the acyl bond in BTMP and if the reduction at the such other reducible parts of the molecule as the pyrimidine ring is disregarded, the next reactions for the first wave (Fig. 9) may probably be estimated on the basis of the number of electrons, is shown in Table III.

The number of electrons is controlled by the ways in which III split; the alcohol type V is, therefore, produced by a 4-electron discharge, and the pinacol type VI, by a 3-electron discharge.

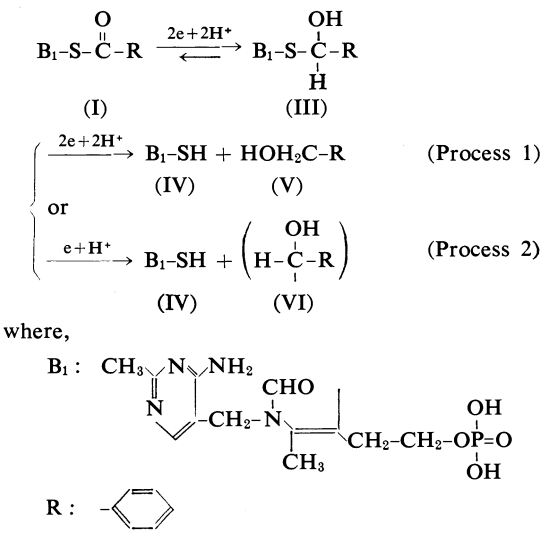

Fig. 9. The reduction processes estimated on BTMP.

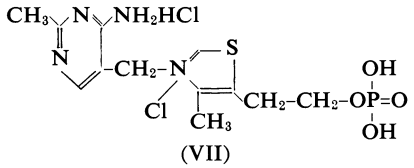
Process 1 seemed to take place in the pH range of about 4.5~5.5, and process 2, in the range of pH<2. These two processes were thought to occur at a pH value of about 3.

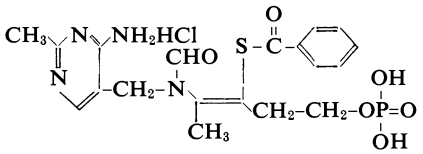
The decrease of n in pH values higher than 5.5 could not be explained by the chemical splitting of the *S*-acyl bond.

The second wave of BTMP seemed to be due to the reduction of the thiamine *O*-monophosphate (TMP) (IV) that was produced by the reduction of BTMP to give the first wave.

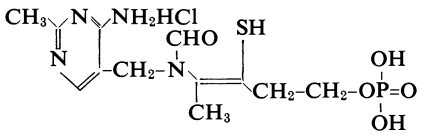
The discontinuous decrease in the wave height was observed for the second wave at pH<4, as is shown in Fig. 2-2, while the first wave of TMP did not show such a decrease[5]. This difference could be explained by a consideration of their species under the same pH value conditions.



(VII)



(VIII)



(IX)

At a pH value of about 3, TMP almost existed as VII, and BTMP as VIII. When VIII was reduced at DME, thiol type TMP (IX) was initially produced. Then IX gradually changed to thiazol type VII.

The second reduction process, therefore, was mainly the reduction of the thiol type IX, because the rate of the thiazol-ring formation seemed to be not so sufficiently rapid as to be comparable to or predominant over the potential sweeping rate.

As has been described in the previous paper[5], the a.c. wave heights of TMP without chlorine at the thiazol ring was about 74% that with chlorine.

The approximate ratio of the wave heights of BTMP and TMP[5] at the pH value of 3.0 was $i_s(\text{BTMP})/i_s(\text{TMP})=60\%$, which was thought not to be different from the result obtained for TMP. The second wave of BTMP, therefore, was considered to be due to the reduction of the thiol type TMP, while the first wave of TMP was that of the thiazol type TMP.

Summary

The polarographic behavior of BTMP was studied using the a.c. polarographic method.

The two peak currents of BTMP in a wide pH value range could be observed definitely. Especially, the observation on the second wave, which was not clearly observed by the d.c. method, could be made.

The variations of the two peak current with the change in pH value were not similar to that of the diffusion currents in that the d.c. first wave height gave the largest value at about the pH value of 5, while the a.c. first wave height was largest at the pH value of 2 and then decreased with the increase in pH value.

The second a.c. wave height showed a maximum value at the pH values between 4 and 5, a minimum at a pH value of about 3, and increased at pH values <3.

The two a.c. waves were recognized to be of the diffusion current, not adsorption or kinetic waves.

The approximation of the diffusion coefficient of BTMP was carried out using the d.c. reduction wave of *S*-*p*-nitrobenzoylthiamine *O*-monophosphate (NBTMP) to give $D=5.22\times10^{-6}$ cm^2 sec^{-1}.

The estimation of the electron number, n, at various pH values on the d.c. first wave of BTMP was made using the value of D, so that it was found that 3 or 4 electrons were discharged in the reduction of BTMP in the acidic solutions.

The calculation of the transfer coefficient, α, and the rate constant, k_G, for the first a.c. wave was undertaken by Matsuda's method, giving, $\alpha=0.91_6$, $k_G=5.7_5\times10^{-4}$ cm. sec^{-1} at a pH value of 1.00, and $\alpha=0.43_0$, $k_G=5.0_2\times10^{-4}$ cm. sec^{-1} at a pH value of 5.5, etc.

The reaction processes of BTMP were estimated again according to the results obtained in this work. For the first wave two splitting mechanisms of the *S*-acyl bond which produced benzyl alcohol and benzpinacol consuming 4 and 3 electrons respectively, were considered. For the second wave, as no definite discussion could be undertaken on account of the ill-defined form of the d.c. wave, it can only be suggested that it is the reduction of the reduction products, TMP. Some of the differences between the second wave of BTMP and the first wave of TMP observed in their pH value $-i_s$ curves can be explained by the difference in the wave heights of the thiazol type and of the thiol type of TMP and also by the rather slow rate of the thiazol-ring formation of the latter.

The author is very much indebted to Director Munetoshi Matsui for affording facilities for this investigation.

Physico-chemical Studies on the Composition of Complex Arsenates of Metals. I. Thermometric and Conductometric Studies on the Composition of Cupric Arsenate

By Mahendra Singh BHADRAVER

(Received September 24, 1962)

The formation and composition of cupric arsenate complexes has been studied by thermometric and conductometric measurements involving theremometric and conductometric titrations between copper sulfate and sodium arsenate at several concentrations of the reactants both by direct and reverse methods. In the direct thermometric titrations, the curves suggest the formation of $CuNaAsO_4$ as a greenish blue precipitate and in the inverse titrations, the formation of $CuNaAsO_4$ is supported. The intersection of the precipitation line and the titrant line in the curves, both for direct and reverse methods, indicated the equivalence point corresponding to the formation of the complex, $CuNaAsO_4$, where the ratio of Cu : AsO_4 is 1 : 1.

Reference in literature about the study of the composition of copper arsenate complexes by applying physico-chemical methods is scarcely available. Hirsch[1] reported a complex salt of copper and sodium arsenates with different values for the ratios Na_2O : CuO : As_2O_5 : H_2O. Thus the ratios 2 : 24 : 9 : 23 or sodium copper hydro-nona-arsenate, Na_2HAsO_4-$4Cu_3(AsO_4)_2 \cdot 11H_2O$, is obtained by mixing a solution of 4 molecules of cupric nitrate with 7 molecules of sodium hydro-arsenate and washing the precipitate during ten days. The ratios 1 : 12 : 5 : 12 or sodium copper dihydro-penta-arsenate, NaH_2AsO_4-$2Cu_3(AsO_4)_2 \cdot 5H_2O$, were obtained by mixing a dilute solution of 2 molecules of sodium hydro-arsenate, with 4 molecules of cupric sulfate, and washing the precipitate for many days. Salkowsky[2] also made this salt. If in preparing the first of the salts, the precipitate be washed for a shorter time, the product has the ratios 2 : 18 : 7 : 20 or sodium copper bishydro-decatetra-arsenate, $2Na_2HAsO_4 \cdot 6Cu_3(AsO_4)_2 \cdot 19H_2O$; and this salt is made by treating a solution of copper nitrate with an excess of sodium hydroarsenate. The ratios 4 : 36 : 15 : 16 or sodium copper hydrobisdihydrodecapenta-arsenate, $Na_2HAsO_4 \cdot 2NaH_2AsO_4 \cdot 6 \cdot Cu_3(AsO_4)_2 \cdot 16H_2O$ was obtained by mixing solutions of 3 molecules of cupric sulfate and 3 molecules of sodium hydroarsenate, and washing the precipitate for three days; if the precipitate is washed until the runnings are free from sulfuric acid a higher hydrate is produced, viz., $331/2H_2O$. There is nothing here to show that these products do not represent arbitrary stages in a process of hydrolysis. Lefevre[3] obtained sodium copper arsenate, green crystalline mass, $CuNaAsO_4$ by dissolving 7~8% of cupric oxide in sodium metaarsenite melted at a low temperature. He obtained sodium copper tetraorthoarsenate, $2Na_3AsO_4 \cdot Cu_3(AsO_4)_2$, by saturating a fused mixture of sodium metaarsenite and chloride of copper oxide.

In view of the difficulties associated with analytical work and in the absence of any decisive views on the composition of cupric arsenate complexes, it was considered worthwhile to undertake the study of these complexes by physico-chemical methods. The results of thermometric and conductometric titrations have been incorporated and discussed in this paper.

Experimental

A. R. B. D. H. $CuSO_4 \cdot 5H_2O$ was used for the preparation of solution and the solution was standardized against sodium thiosulfate solution of known strength. Merck's sample of Na_3AsO_4 was used and the solution was standardized iodometrically against sodium thiosulfate of known strength.

The thermometric titration arrangement was made according to the proccedings laid down by Haldar[4]. Using different concentrations of two salts in solution, the direct and inverse thermometric and conductometric titrations i. e., when copper sulfate or Na_3AsO_4 solution from a micro-burette was added to solution taken in thermos flask or cell, were carried out. Titrations were also carried out upto total concentration of 20% by volume. Curves were plotted between total rise in temperature or corrected conductance and the volume of the titrant added in ml.

4	5	18 cc.	M/5	10	1.02	1.00	$CuNaAsO_4$
4	6	16 cc.	M/5	20	0.99	1.00	$CuNaAsO_4$

The experimental observations of thermometric and conductometric titrations have been given in Table I.

Discussion

The formation of the probable compounds obtained by the interaction of $CuSO_4$ and sodium arsenate can be represented by the following equations:

$$CuSO_4 + Na_3AsO_4 = CuNaAsO_4 + Na_2SO_4 \quad (1)$$

$$2\,CuSO_4 + 3Na_3AsO_4 = Cu_2Na_5(AsO_4)_3 + 2Na_2SO_4 \quad (2)$$

$$3\,CuSO_4 + 2Na_3AsO_4 = Cu_3(AsO_4)_2 + 3Na_2SO_4 \quad (3)$$

$$CuSO_4 + 2Na_3AsO_4 = CuNa_4(AsO_4)_2 + Na_2SO_4 \quad (4)$$

Taking into consideration the strength of solutions of Na_3AsO_4 (pH=8.2) and $CuSO_4$ (pH=4.15), 10 ml. of $CuSO_4$ for the formation of the compounds, $CuNaAsO_4$, $Cu_2Na_5(AsO_4)_3$, $Cu_3(AsO_4)_2$ and $CuNa_4(AsO_4)_2$ will be 2.0, 1.33, 3.0 and 1.0 respectively of Na_3AsO_4 solution. For the inverse titrations and other dilution of reagents, theoretical titer values for the formation of these compounds can be calculated accordingly.

The conductometric titrations curves (Figs. 1 and 2) both in direct and inverse titrations, yield only one point of equivalence at a molecular ratio of reactants $CuSO_4 : Na_3AsO_4$ as 1 : 1, whereas it is much different from the ratios 1 : 2, 2/3 : 1 and 3/2 : 1 as mentioned above (vid. Eqs. 2 to 4) for the formation of probable compounds.

It is observed in direct and inverse titrations that when Na_3AsO_4 solution is added to $CuSO_4$ solution and vice versa, a bluish white precipitate was formed, on adding excess of

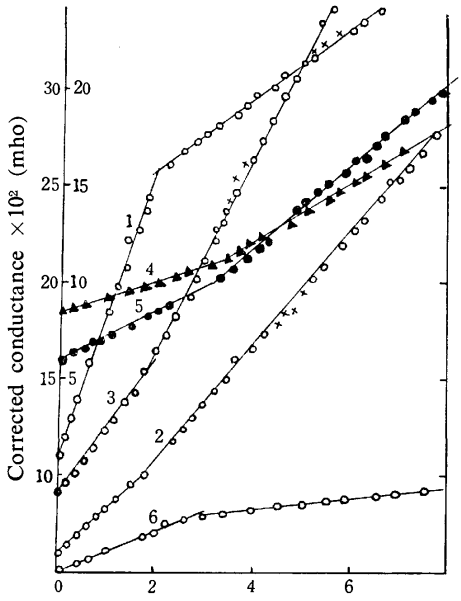

Fig. 1.

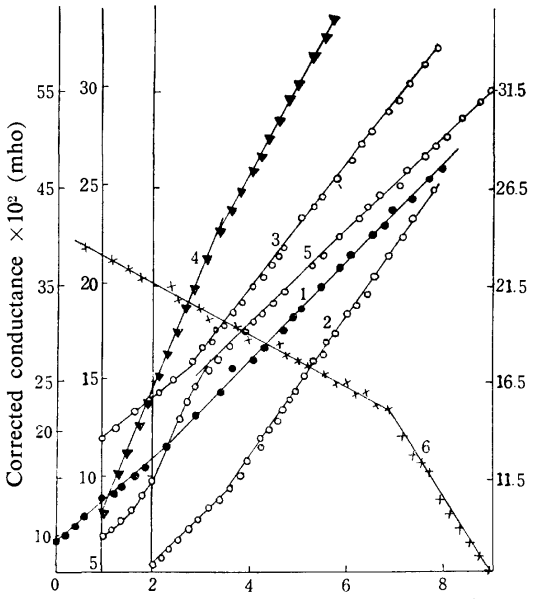

Fig. 2.

either reagent the precipitate in bulk was formed.

The diagrammatic representation of thermometric titrations in Figs. 3—4 reveals that the curves in direct and inverse titrations yield only one point of equivalence corresponding to the formation of the complex, $CuNaAsO_4$, where the ratio of reactants $CuSO_4$: Na_3AsO_4 is 1 : 1. It is evident from the summary of

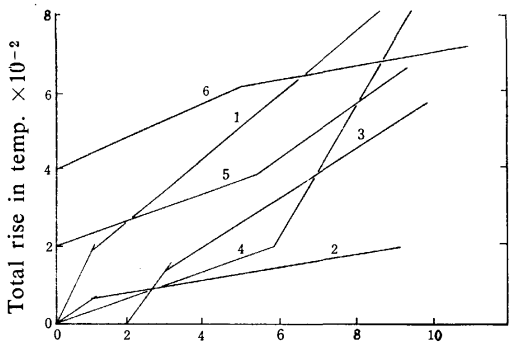

Fig. 3. Direct titrations.

observations of thermometric and conductometric titrations that there is close agreement between the values theoretically calculated and observed. In order to show the discrepancy, which is probably due to slight effect of hydrolysis and adsorption, between theoretically calculated on the basis of strength of solutions used and observed values in aqueous and aqueous alcoholic media, the summary of observations have been given above for comparison. There is coordination in the results obtained by conductometry and Dutoit's thermovolumetry.

Lefevre's[3] observations have been supported by my thermovolumetric and conductometric studies. Views and results reported by Hirsch, and Salkowsky (loc. cit.) have not been supported by my studies.

Grateful thanks are due to Dr. J. N. Gaur, University of Rajasthan, Jaipur, for his kind guidance and keen interest in this piece of investigation.

Spectrophotometric Studies of the Complexes of Phenylazochromotropic Acid Formed with Thorium

By Haruo MIYATA

(Received September 22, 1962)

Various *o*-substituted-*o'*-hydroxyazo compounds having functional groups in the ortho position have been synthetized, and their behaviors as analytical reagents have been studied[1-6]. Among these compounds a series of azo compounds coupled with chromotropic acid are most interesting as the reagents for the spectrophotometric determination of various metals.

The present paper describes the basic studies of the reaction of phenylazochromotropic acid with thorium.

Experimental

Reagents.—*Phenylazochromotropic Acid*[6,7]. — Diazotized aniline was coupled with chromotropic acid, and the pure azo compound was obtained in the form of diacid dihydrate after recrystallization from concentrated hydrochloric acid, followed by that from water. Solutions of 2.5×10^{-4} and 3×10^{-4} mol./l. were prepared and stored in the dark.

Thorium Perchlorate Solution. — Purified thorium nitrate[8] was dissolved in water, the hydroxide was precipitated with sodium hydroxide, and then it was dissolved in perchloric acid. The stock solution was standaridized gravimetrically with oxalate[9]. It contained 17.6 mg. of thorium per milliliter and was diluted to an appropriate concentration for each experiment.

Buffer Solution.—The following buffer solutions were prepared from guaranteed reagents:

5.8~7.0 pH values, acetic acid and sodium acetate.

8.0~9.8 pH values, ammonia and ammonium chloride.

1 M Sodium Perchlorate Solution. — This was prepared from twice recrystallized $NaClO_4\cdot H_2O$.

Apparatus.—The absorbance was measured with a Shimadzu spectrophotometer, QR-50 type, and a Hitachi automatic recording spectrophotometer, EPS-2 type, with 1 cm. cells; the pH value was measured with a Horiba glass electrode pH meter, model M-3.

Results and Discussion

Absorption Spectra of the Reagent and its Thorium Complex. — For the measurement of absorption spectra of the reagents and its thorium complex, the following procedure was used. All solutions were prepared in a dark room, for the absorption of the reagent decreases in daylight, especially at higher pH values. Five milliliter of a 2.5×10^{-4} or a 3×10^{-4} mol./l. reagent solution was placed in a 50 ml. volumetric flask, followed by the addition of an adequate volume of 0.2 M perchloric acid in order to adjust the pH value of the solution to 1~5, of a 0.2 M sodium hydroxide solution in order to adjust the pH value of the solution to 11~13, or of 5 ml. of a buffer solution of the pH 5.8~9.8. The ionic strength was maintained at 0.1 by an appropriate addition of a 1 M sodium perchlorate solution, and then the volume was made up to 50 ml. with water.

Thorium complex solutions were prepared similarly: 5 ml. of a 2.5×10^{-4} mol./l. reagent solution was placed in a 50 ml. volumetric flask, followed by the addition of 0.2 M perchloric acid in order to adjust the pH value of the solution to 1~3.2, of a 1 M sodium perchlorate solution to maintain the ionic strength at 0.1, and of 5 ml. of a 2.5×10^{-2} mol./l. thorium perchlorate solution, then the

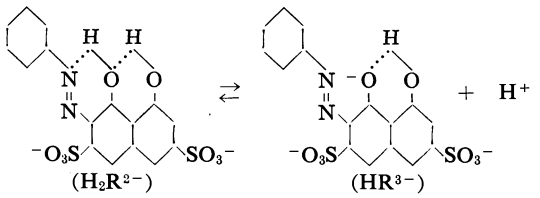
volume was made up to 50 ml. with water. The solutions were allowed to stand for one hour or more at 25°C, after which the absorbance was measured in a 1 cm. cell against water.

In the pH value range higher than 4, thorium hydroxide was precipitated, so absorption measurements were not possible.

In Fig. 1 it is seen that, on the addition of thorium to the reagent solution, the absorption maxima shifted towards the longer wavelengths. Curve VII shows an absorption maximum at 565 mμ.

Dissociation Constant of Phenylazochromotropic Acid. — Judging from the presence of the isosbestic points (348~350, 392~394, 460~462 and 560~562 mμ), two structures (H_2R^{2-} and HR^{3-})[10,11] may be expected to exist (Fig. 1).



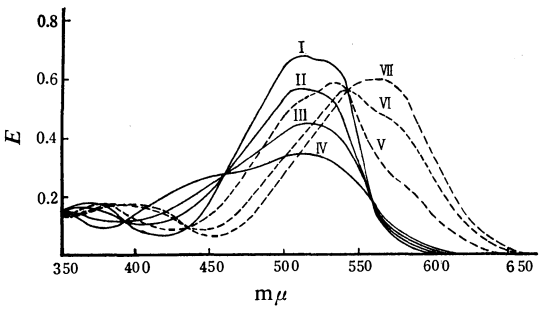


Fig. 1. Absorption spectra of phenylazochromotropic acid (I—IV) and its thorium complex (V—VII).
I 2.5×10^{-5} mol./l., pH 1.8~6, $\mu=0.1$, 25°C; II pH 8.3; III pH 9.3; IV pH 11~12.4; V pH 1.0; VI pH 1.42; VII pH 3.2

The constant of the above dissociation, K_{a_1}, was calculated by the following equation from the absobance vs. the pH value curve at 510 mμ (25°C, $\mu=0.1$) shown in Fig. 2.

In the following equations $[H_2R]$ and $[HR]$ represent the concentrations of H_2R^{2-} and H^{3-} respectively:

$$K_{a_1} = [H][HR]/[H_2R]$$

$$pK_{a_1} = -\log[H] - \log\{[HR]/[H_2R]\}$$

$$= -\log[H] - \log\{(E_{H_2R}-E)/(E-E_{HR})\}$$

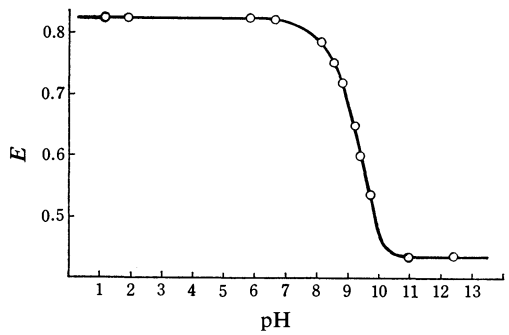

Fig. 2. Absorbance at 510 mμ vs. pH for phenylazochromotropic acid (3×10^{-5} mol./l.).

where E_{H_2R} and E_{HR} represent the absorbance in the 1~6 and 11~12 pH value ranges respectively and E, the absorbance at a pH value of 8~10 (Fig. 2).

In Fig. 3, the values of $\log\{(E_{H_2R}-E)/(E-E_{HR})\}$ were plotted against the pH value, and the value of pK_{a1} was estimated graphically to be 9.30. A value of 9.29 for the same dissociation constant has been reported by Schwarzenbach[12].

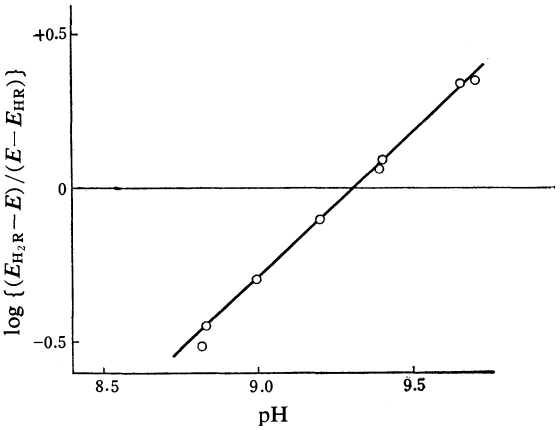

Fig. 3. Relationship between pH and $\log\{(E_{H_2R}-E)/(E-E_{HR})\}$.

Chemical Composition of the Thorium Complex. — *Continuous Variation Method.* — The absorbances at 580 mμ of solutions with various $[Th]/([Th]+[H_2R])$ ratios were measured one hour after the solutions had been prepared; the results indicated the formation of a 1:1 complex of thorium with the reagent (Fig. 4).

Mole Ratio Method. — The results obtained indicate the formation of a 1:1 complex within the range of experimental error. The measurement was made at 580 mμ and at a pH value of 3.1 (Fig. 5).

Thorium concn.=3×10^{-5} mol./l., reagent concn. varied.

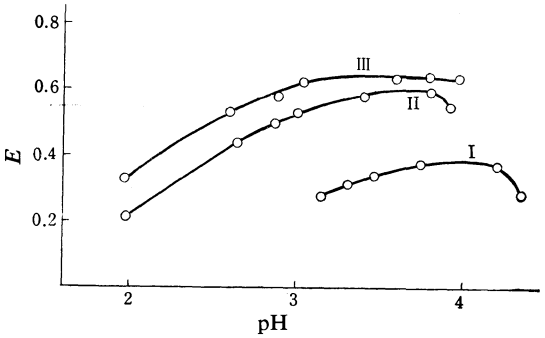

Fig. 6. Effect of pH on absorbance values of the thorium complex.
I H_2R : Th=1 : 1
II H_2R : Th=1 : 5
III H_2R : Th=1 : 10

Both methods show that a 1 : 1 complex is formed between thorium and the reagent in the pH value range studied.

Effect of pH Value on the Color of the Complex.—The pH values of solutions containing thorium and the reagent (3.0×10^{-5} mol./l.) in the molar ratios 1 : 1, 5 : 1 and 10 : 1 were adjusted to 2~4.2 by perchloric acid, and the absorbances were measured (Fig. 6).

The curves in Fig. 6 show that the absorption increases with the increase of the thorium : reagent ratio and that it tends to be constant over a wide pH value range.

Effect of Time. — The relationship between the absorbance at 580 mμ and the lapse of time after the mixing of thorium with the reagent in various pH value ranges is shown in Fig. 7. The color of the thorium complex is fully developed in a few minutes after mixing, and the absorbance remained constant for two hours.

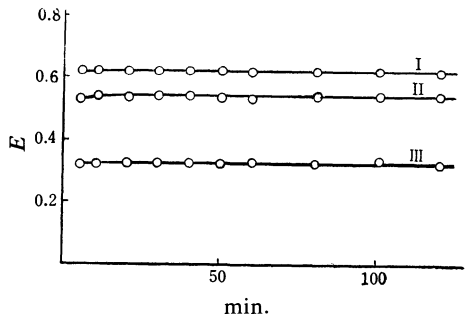

Fig. 7. Effect of reaction time.
I pH 3.5 II 2.59 III 1.95

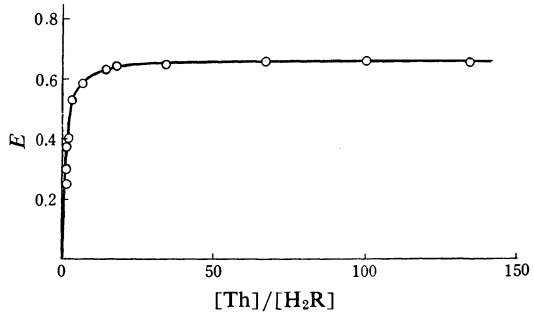

Fig. 8. Effect of excess thorium concentration on the absorbance of the complex.
pH 3.2, μ=0.1, 25°C, 580 mμ
Reagent concn.=3×10^{-5} mol./l.

Effect of an Excess Thorium Concentration. —The effect of an excess thorium concentration on the absorbance is shown in Fig. 8, other experimental conditions being kept constant.

The curve indicates that the absorbance reaches a constant value when the molar ratio of thorium to the reagent exceeds 60.

The Apparent Stability Constant* of the Thorium Complex.—The existence of the isosbestic points (346~347, 436 and 542 mμ) is

* Conditional stability constant suggested by A. Ringbom, *J. Chem. Educ.*, 35, 282 (1958).

TABLE I. APPARENT STABILITY CONSTANT, K', OF THE COMPLEX AT 25°C (μ=0.1)

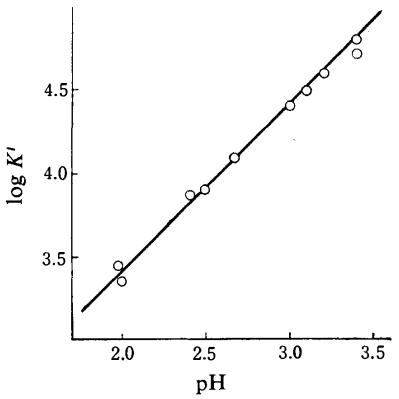

Fig. 9. Relationship between pH and log K'.

excellent evidence that only two structures are present, H_2R and a single complex in the 1.0~3.4 pH value range (Fig. 1).

The value of the apparent stability constant of the thorium complex may be estimated by assuming that the formation of the thorium complex is in accordance with the following equation:

$$Th^{4+} + H_2R^{2-} \rightleftarrows ThHR^{+} + H^{+}$$

The equilibrium constant, K, is given by:

$$K = [ThHR][H]/[Th][H_2R] \quad (1)$$

the ionic charge being neglected for the sake of convenience. The total concentrations of the reagent and thorium are given by:

$$C_R = [H_2R] + [HR] + [R] + [ThHR] \quad (1)$$

$$C_{Th} = [Th] + [ThHR] \quad (2)$$

respectively. At pH values lower than 4, [HR] and [R] can be disregarded. Substitution of Eqs. 2 and 3 into Eq. 1 leads to the following equation:

$$K = [ThHR][H]/(C_{Th} - [ThHR])(C_R - [ThHR]) \quad (4)$$

The absorbance, E, of the thorium complex at 580 mμ may be expressed as:

$$E = \varepsilon_{H_2R}[H_2R] + \varepsilon_{ThHR}[ThHR] \quad (5)$$

The molar absorptivities at 580 mμ, ε_{H_2R} and ε_{ThHR}** were found to be 1.11×10^{3} and 2.33×10^{4} respectively.

From Eqs. 2 and 5.

$$E = \varepsilon_{H_2R}(C_R - [ThHR]) + \varepsilon_{ThHR}[ThHR]$$
$$= \varepsilon_{H_2R}C_R - [ThHR](\varepsilon_{H_2R} - \varepsilon_{ThHR})$$

Hence,

$$[ThHR] = \varepsilon_{H_2R}C_R - E/(\varepsilon_{H_2R} - \varepsilon_{ThHR}) \quad (6)$$

The apparent stability constant, K' (Table I), of the thorium complex was estimated at 2~3.5 pH values using Eqs. 6 and 7:

$$K' = K/[H] = [ThHR]/(C_{Th} - [ThHR])(C_R - [ThHR]) \quad (7)$$

In Fig. 9, the logarithm of the apparent stability constant (log K') is plotted against the pH value. The curve indicates that thorium reacts with the reagent, displacing one hydrogen atom.

Summary

The dissociation constant of phenylazochromotropic acid, pK_a, has been estimated spectrophotometrically to be 9.3_0 (25°C, μ=0.1).

The reagent reacts with thorium in the molar ratio 1:1, displacing one hydrogen atom, and the approximate value of the apparent stability constant of the complex, log K', has been estimated to be 3.4~4.9 in the 2~3.5 pH value range.

The author wishes to express his hearty thanks to Dr. Kyoji Tôei for his guidance in the course of this experiment.

Tsushima, Okayama

** The absorbance has reached a constant value when the molar ratio of thorium to the reagent exceeds 60 (Fig. 8). In this case, the formation of the complex was considered to be complete, and the value of ε_{ThHR} was obtained from the absorbance of the solution containing the reagent and thorium in the molar ratio of 1:100.

*Spectrophotometric Studies of the Complexes of o-Sulfobenzeneazochromotropic Acid Formed with Thorium**

By Haruo MIYATA

(Received November 24, 1962)

Azo compounds having arseno, $-AsO_3H_2$[1], or phosphono, $-PO_3H_2$[2], groups in the ortho position have been applied as reagents for the determination of thorium, zirconium and uranium. These groups are most interesting as functional groups for thorium, and the behavior of sulfo group, $-SO_3H$, for thorium is also attractive to the other.

The present paper describes the preparation of *o*-sulfobenzeneazochromotropic acid, and the determination of the first dissociation constant of the reagent by the spectrophotometric method. The complex of the reagent with thorium is studied spectrophotometrically, and the reaction scheme is presented from the relation between the apparent stability constant and the pH value.

Experimental

Reagents.—*o-Sulfobenzeneazochromotropic Acid***. —Diazotized *o*-aminobenzenesulfonic acid was coupled with chromotropic acid, and a pure azo compound was obtained in the form of reddish brown needles of monosodium salt after recrystallization from concentrated hydrochloric acid. A solution of 3×10^{-4} mol./l. was prepared and stored in the dark.

1 M Thorium Perchlorate Solution.—It was prepared by dissolving thorium hydroxide into perchloric acid.

1 M Sodium Perchlorate Solution.—It was prepared from twice-recrystallized $NaClO_4\cdot H_2O$.

Buffer Solutions.—The following buffer solutions were prepared from guaranteed reagents:

5.8~7.0 pH value acetic acid and sodium acetate.

8.0~10.6 pH value aqueous ammonia and ammonium chloride.

Procedure and Apparatus.—All solutions were made in a dark room, for the absorbance of the reagent tended to be decreased in daylight, especially at higher pH values.

Five milliliter of a 3×10^{-4} mol./l. reagent solution was placed in a 50 ml. volumetric flask, after which an adequate volume of 0.2 M perchloric acid, 0.2 M sodium hydroxide or buffer solution was added in order to adjust the pH value to the desired value. Then a 1 M sodium perchlorate solution was added to maintain the ionic strength at 0.1, and the volume was made up to 50 ml. with water. Each of the solutions was used for the determination of the first dissociation constant of the reagent.

To prepare the complex solution, 5 ml. of a 3×10^{-4} mol./l. reagent solution was placed in a 50 ml. volumetric flask, followed by the addition of 0.2 M perchloric acid to adjust the pH value of the solution to 1~3.4 and of a 1 M sodium perchlorate solution to maintain the ionic strength at 0.1. Five milliliter of a 4×10^{-3} mol./l. thorium perchlorate

2) A. A. Nemodruk et al., *J. Anal. Chem. USSR*, **16**, 296 (1961).

** Anal. Found: C, 36.85; H, 2.23; N, 5.20; Na, 4.4. Calcd. for $C_{16}H_{11}O_{11}N_2S_3Na$: C, 36.50; H, 2.11; N, 5.32; Na, 4.36%.

solution was added, and then the volume was made up to 50 ml. with water. The solutions were allowed to stand for one hour or more at 25°C. The absorbance was then measured with a Shimadzu spectrophotometer QR-50 type and a Hitachi automatic recording spectrophotometer EPS-2 type, with 1 cm. cells, while the pH value was measured with a Tôwa-Denpa glass electrode pH meter model HM-5A. Absorption spectra at various pH values are shown in Figs. 1 and 2.

Results and Discussion

Spectral Properties of the Reagent and its First Dissociation Constant.—Between the pH values of 1 and 8, the reagent gives identical absorption spectra, each with one absorption maximum at 507 mμ (Fig. 1). This indicates that the electrolytic dissociation of the naphtholic group does not occur. Above a pH value of 8, the maximum shifts towards another maximum (527 mμ) with an increase in the pH value, and between the pH values of 11.5 and 13 the reagent again gives identical absorption spectra.

Judging from the presence of the isosbestic points (392～394, 442～444 and 528～530 mμ), two structures (H_2R^{3-} and HR^{4-}) are expected to exist.

$$H_2R^{3-} \rightleftarrows HR^{4-} + H^+$$

The constant of the above dissociation, K_{a_1}, was calculated by the following equation[3]:

$$pK_{a_1} = -\log[H] - \log\{(E_{H_2R} - E)/(E - E_{HR})\}$$

where E_{H_2R} and E_{HR} represent the absorbances at $-\log[H] = 1 \sim 8$ and $11.5 \sim 13$ respectively, and E represents the absorbance at $-\log[H] =$ 8～11.5. These absorbances are measured at 560 mμ, because the difference between E_{H_2R} and E_{HR} is the largest.

In Fig. 3, the values of $\log\{(E_{H_2R} - E)/(E - E_{HR})\}$ are plotted against the pH value, and the value of pK_{a_1} is estimated graphically to be 9.7$_6$.

The Chemical Composition of the Complex.—In order to confirm the mole ratio of the complex, two methods were employed, the continuous variation and the mole ratio methods. In the former method, the measurement of the absorbances of a series of solutions containing a varying mole per cent of 6×10^{-5} M reagent and 6×10^{-5} M thorium was undertaken. As is shown in Fig. 4, the maximum absorbance of the complex was obtained when the mole ratio of thorium to the reagent was 1 : 1.

In the latter method, the absorbances of a series of solutions containing a varying concentration of the reagent to a fixed thorium concentration (4×10^{-5} mol./l.) was measured at 580 mμ. The results obtained indicate the formation of a 1 : 1 complex (Fig. 5). The results of these experiments confirm that the mole ratio of thorium to the reagent in the complex formed is 1 : 1.

The Effet of Time on the Color of the Complex.—The effect of the lapse of time after the mixing of thorium with the reagent at various pH values is shown in Fig. 6. The color of the complex is fully developed in a few minutes after mixing, and the absorbance remained constant for two hours and more.

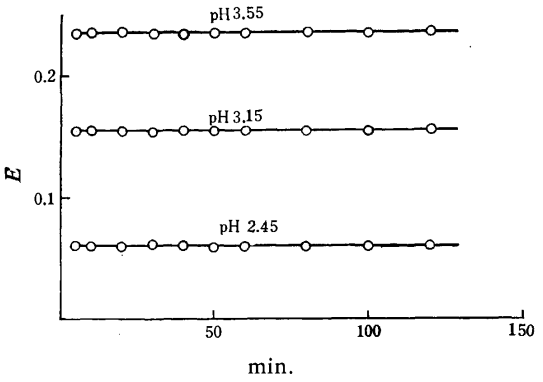

Fig. 6. Effect of reaction time.

The Effect of an Excess Thorium Concentration.—The effect of an excess thorium concentration on the absorbance is shown in Fig. 7, where the curve indicates that the absorbance reaches a constant value when the molar ratio of thorium to the reagent exceeds 110.

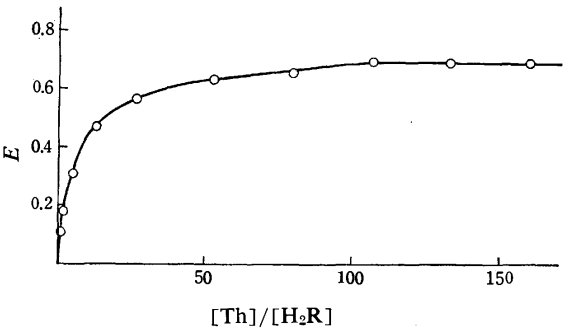

Fig. 7. Effect of excess thorium concentration 580 mμ, pH 2.9, the reagent concentration 3×10^{-5} mol./l.

The Apparent Stability Constant of the Complex. — The existence of the isosbestic points (346～347, 372～374, 435～437 and 540～542 mμ) is excellent evidence that only two structures are present, H_2R^{3-} and a single complex in the pH value range of 2～3.4 (Fig. 2). An approximate value of the apparent stability constant, K', (Table I) of the complex may be obtained by assuming that the formation of the thorium complex is in accordance with the the following equation[3]:

$$Th^{4+}+H_2R^{3-} \rightleftarrows ThHR+H^+$$

The equilibrium constant, K, is given by

$$K=[ThHR][H]/[Th][H_2R]$$

$$K'=K/[H]=[ThHR]/(C_R-[ThHR])\times(C_{Th}-[ThHR])$$

where C_R and C_{Th} represent the total concentration of the reagent and of the thorium respectively, and [ThHR] represents the concentration of the complex.

In Fig. 8, the logarithm of the apparent stability constant ($\log K'$) is plotted against the pH value. The curve indicates that thorium reacts with the reagent, displacing one hydrogen atom.

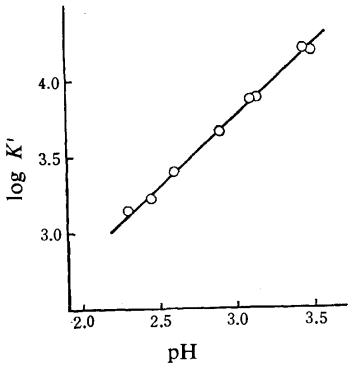

Fig. 8. Relationship between pH and log K'. 580 mμ, 25°C, $\mu=0.1$

Summary

o-Sulfobenzeneazochromotropic acid was prepared in the form of reddish brown needles of monosodium salt, and the value of the first dissociation constant, pK_{a_1}, was estimated spectrophotometrically to be 9.7_6 (25°C, $\mu=0.1$).

The reagent reacts with thorium in the molar ratio 1 : 1, displacing one hydrogen atom, and the approximate value of the apparent stability constant of the complex, $\log K'$, was estimated to be 3.2～4.2 at pH values from 2.5 to 3.5, while the concentration of thorium was about $(4\sim8)\times10^{-5}$.

The author wishes to express his deep thanks to Dr. Kyoji Tôei for his guidance in the course of this experiment.

A Convenient Synthetic Method of Certain Aromatic Polyiodo Compounds

By Hitomi SUZUKI and Ryozo GOTO

(Received October 16, 1962)

Aromatic polyiodo compounds are usually prepared from the corresponding amines by the lengthy, laborious procedures involving acetylation, nitration, diazotization and reduction. Nevertheless, the authors have found it possible to prepare certain types of polyiodo compounds directly from the readily available, simpler iodo compounds.

This method is based on the migration, in the presence of sulfuric acid, of iodine atoms present in the nucleous of aromatic iodo compound (Jacobsen reaction[1]). The procedure is quite simple and needs only to agitate the starting materials with suitable amount of sulfuric acid for some hours followed by chromatographic separation of the products on an alumina column. The products are sufficiently in high state of purity. Although the yields are, in some cases, not so high by the usual standards, the easy availability of starting materials and the simplicity of the procedure recommend this method over any others previously employed.

Present method is expecially attractive to the synthesis of symmetrically substituted or fully iodinated compounds.

Table I presents the compounds prepared by the authors with the aid of this method. Some examples will demonstrate the ease and mode of preparation.

1) L. I. Smith, "Organic Reactions", Vol. I, 370 (1942).

Experimental

2, 5-Diiodo-*p*-xylene.—A mixture of 17.4 g. of 2-iodo-*p*-xylene and 30 g. of sulfuric acid was agitated vigorously with a magnetic stirrer while the temperature of the reaction mixture was held at 50~55°C for 4 hr. After cooling, the reaction mixture was poured into ice water, and the precipitated crystalline solid was filtered off. Recrystallization from petroleum benzine gave 4.2 g. of white needles, m. p. 103~104°C[2]. Mixed melting point with an authentic specimen showed no depression.

2,4-Diiodotoluene and 2,4,5-Triiodotoluene[3,4].—A mixture of 19.1 g. of *p*-iodotoluene and 35 g. of sulfuric acid was magnetically agitated and heated to 50~60°C for 6 hr. The reaction mixture was poured into ice water and the oily material was removed by ether extraction. The ethereal solution was evaporated and the residual oil was chromatographed on an alumina column with petroleum benzine (b. p. 65~70°C). Each 20 ml. fraction was collected and evaporated. 2,4-Diiodotoluene and 2,4,5-triiodotoluene appeared, respectively, in the early and late fractions. 2,4-Diiodotoluene weighed 4.9 g., b. p. 115~117°/1 mmHg. 2,4,5-Triiodotoluene, recrystallized from ethanol to separate as white needles, weighed 3.4 g. and melted at 119~120°C. Admixture with a sepecimen prepared from *m*-toluidine showed no depression.

* Yields based on iodine are not necessarily the best obtainable.
** It is possible to obtain either one of products by proper choice of the experimental conditions.
*** Reaction products in gothic are given as examples in the experimental.

2, 4, 5, 6-Tetraiodo-*m*-xylene[5]. — A mixture of 3.6 g. of 4,6-diiodo-*m*-xylene and 10 g. of sulfuric acid was agitated and heated gradually to 70~80°C. The reaction mixture was kept at this temperature for 4 hr., and then poured over crushed ice. The solid material precipitated was filtered and dissolved in the minimum quantity of cold benzene. Chromatography through a short column packed with alumina gave 2.3 g. of fine, white needles melting at 126~127°C.

2,4-Diiodoanisol[6].—A mixture of 11.7 g. of *p*-iodoanisol and 10 g. of sulfuric acid was stirred at room temperature for 6 hr. The resulting thick mixture was poured into excess water, and the precipitated dark oil was extracted with ether. The ethereal solution was evaporated and the residual oil was chromatographed on alumina. Elution with ether followed by recrystallization from hot petroleum benzine gave colorless large plates of 2,4-diiodoanisol in 70~75% yield, melting point alone or in admixture with an authentic specimen 68~69°C.

Oligomers and Polymers Containing Triple Bonds. I. Derivatives of Ethynylbiphenyl and Ethynylfluorene

By Hisaya TANI, Fumio TODA and Koreyasu MATSUMIYA

(Received October 18, 1962)

Recently, it has been reported that cupric acetate in pyridine[1] and cuprous chloride in pyridine[2] were effective homogeneous reagents for the oxidative coupling of ethynyl compounds. Using these reagents, the authors synthesized a series of conjugated polyacetylenes from the corresponding diethynyl compounds. Lower homologues of these polymers were also prepared in order to study the influence of phenyl, biphenyl and fluorenyl groups on the conjugated systems.

4-Ethynyl and 4, 4′-diethynyl-biphenyl (II and V) were obtained in moderate yields from the corresponding ketones, 4-acetylbiphenyl (I)[3] and 4, 4′-diacetylbiphenyl (IV)[3], using phosphorus pentachloride followed by sodium amide in liquid ammonia. It was wondered why, in the above reaction to prepare II from I, a small amount of di-(*p*-biphenylyl)diacetylene (III) was produced. From acetophenone, however, a similar treatment did not afford the corresponding diacetylenic compound, but instead produced phenylacetylene, in a 30% yield, together with benzoic acid and a small amount of *meso*-2, 3-diphenylbutane[4]. The cause of these curious reactions is not clear.

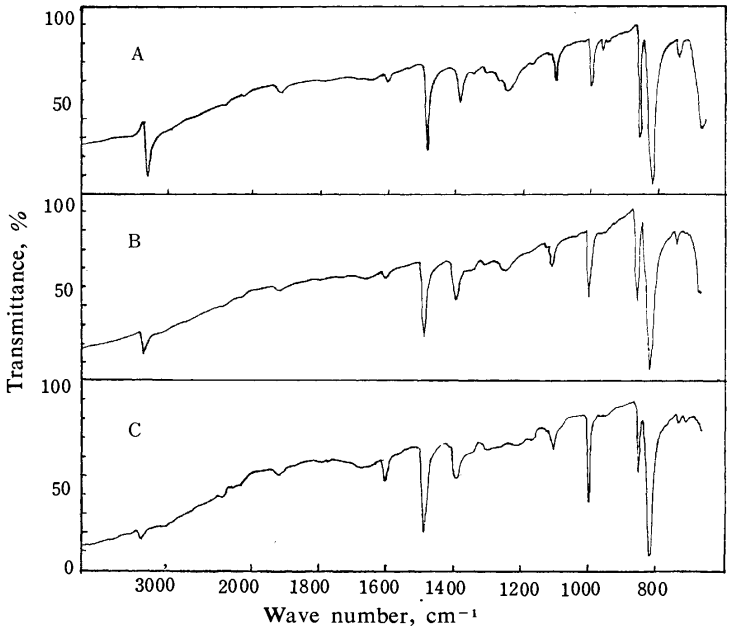

Fig. 1. Infrared absorption spectra.

A, 4,4'-Diethynylbiphenyl (V); B, Di-4-(4'-ethynylbiphenylyl)diacetylene ($VI_{n=2}$); C, Polymer ($VI_{n=4}$); all in KBr disk

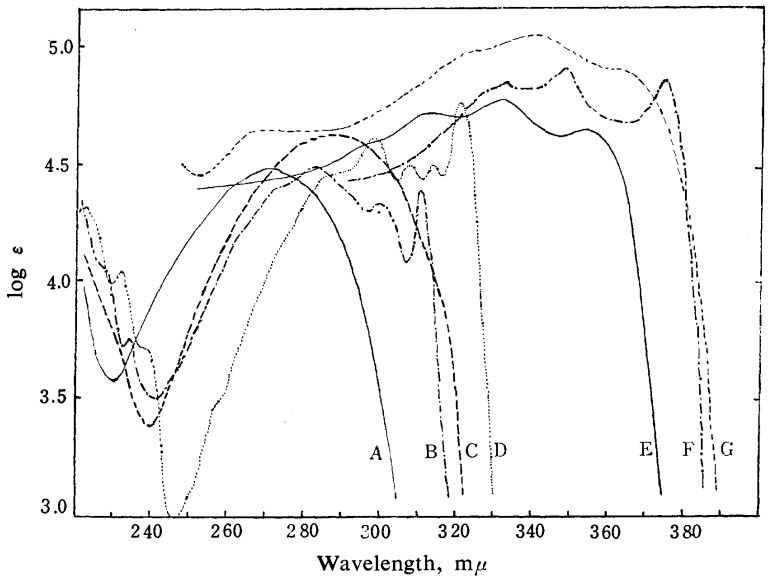

Fig. 2. Ultraviolet absorption spectra.

A, 4-Ethynylbiphenyl (II); B, 2-Ethynylfluorene (XII); C, 4,4'-Diethynylbiphenyl (V); D, 2,7-Diethynylfluorene (XV); all in alcohol, E, Di-(*p*-biphenylyl)diacetylene (III); F, Di-(2-fluorenyl)diacetylene (XIII); G, Di-4-(4'-ethynylbiphenylyl)diacetylene ($VI_{n=2}$); all in dioxane

An attempted synthesis of 4-acetyl-4'-ethynylbiphenyl, a useful compound for the step by step synthesis of conjugated oligomers, failed. Upon the treatment of IV with an equimolecular quantity of phosphorus pentachloride, followed by sodium amide, 4-acetyl-4'-(α-chlorovinyl)biphenyl (VII) and 4,4'-bis-(α-chlorovinyl)biphenyl (VIII) were produced, together with V, but no monoethynylated product was produced.

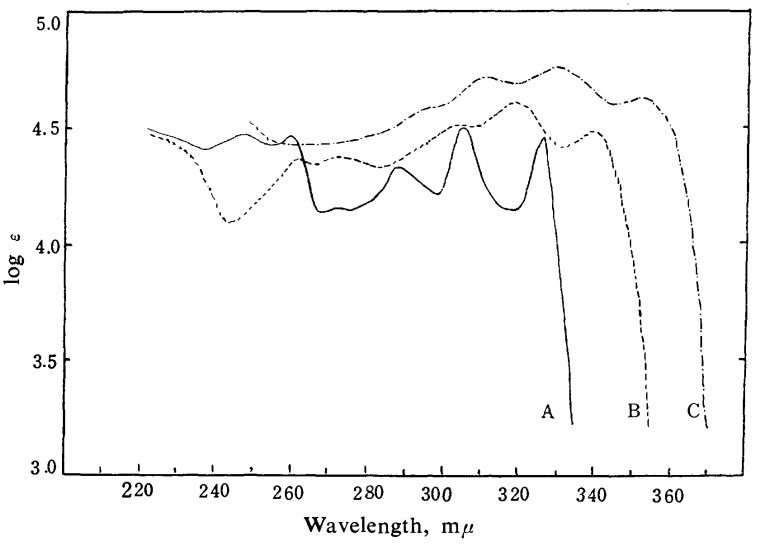

Fig. 3. Ultraviolet absorption spectra.

A, Diphenyldiacetylene (IX); B, 1-Phenyl-4-*p*-biphenylyldiacetylene (X); C, Di-(*p*-biphenylyl)diacetylene (III); all in alcohol

The oxidative coupling of II yielded stable diacetylene III in a quantitative yield. When the oxidative polymerization of V was carried out with cupric acetate in pyridine to which methanol had been added in order to reduce the solubility of the product, the linear dimer of V($VI_{n=2}$) was produced as pale yellow needles in a good yield. The structure of $VI_{n=2}$ was determined by comparing the intensity at the ethynyl maximum in the infrared region of the compound (Fig. 1) with that of V as a standard. This estimation was based on the assumption that the absorbancy of the ethynyl band was not affected by the length of the conjugation system. A comparison of the ultraviolet spectra of $VI_{n=2}$ with that of III, as shown in Fig. 2 and in Table I shows that $VI_{n=2}$ absorbs at ca. 9 mμ longer wavelengths than III. This bathochromic shift may be attributable to the two additional ethynyl substituents.

On the other hand, the shift exhibited when one ethynyl group was introduced into II is 17 mμ (Fig. 2 and Table I). The ultraviolet spectrum of III is similar to that of diphenyldiacetylene (IX), and a bathochromic shift due to two additional phenyl groups is ca. 12 mμ (Fig. 3 and Table I).

In order to study the effects exerted by the addition of one phenyl group on the absorption properties of diphenyldiacetylenes, phenyl-*p*-biphenylyldiacetylene (X) was prepared by the crossed coupling of II and phenylacetylene. As is illustrated in Fig. 3 and in Table I, an increase of one phenyl group in IX and X gave rise to bathochromic shifts of 14 mμ and 12 mμ respectively.

Table I. Ultraviolet absorption spectra at longer wave region

Compound	Solvent*	λ_{max}, mμ ($\varepsilon\times10^{-2}$)	λ_{max}, mμ ($\varepsilon\times10^{-2}$)

$VI_{n=2}$	D	339(1085)	361 (779)
XIII	D	348 (806)	374 (710)

* A, Alcohol D, Dioxane

Further oxidative coupling of $VI_{n=2}$ in boiling pyridine yielded a stable orange solid, the infrared spectrum of which showed that the oxidation of the triple bond to carbonyl had partially occurred during the reaction.

The polymerization of V with the cuprous chloride catalyst in pyridine and in an oxygen atmosphere, as summarized in Table II, resulted in the formation of insoluble and infusible yellow or orange solids. On the basis of the infrared absorption spectra and the elemental analysis, these products were presumed to be linear polymers, the degrees of polymerization of which were about 4~6. The polymers were quite stable, but at a temperature above 300°C they gradually turned to black via brown.

Although all the reactions were carried out

TABLE II. POLYMERIZATION OF 4,4'-DIETHYNYLBIPHENYL (V)

V mg.	Catalyst mg.	Solvent* ml.	Reaction temp., °C	Reaction time, hr.	Atmosphere	Color	Product Degree of polymerization

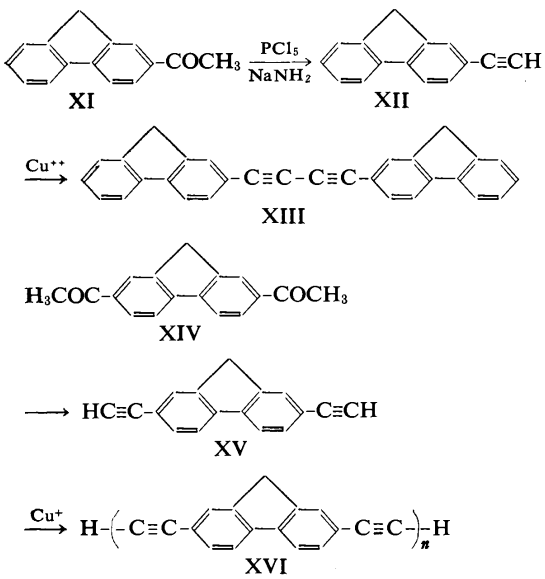
150	CuCl, 10	P+PP 15+10	60	1	O_2	Yellow	4

* P, Pyridine M, Methanol PP, Piperidine

at low temperatures, the products showed weak carbonyl absorptions at about the 1675 cm^{-1} region of their infrared spectra, suggesting the partial oxidation of the triple bond to carbonyl.

In the same fashion as with the preparation of II and V, monoethynyl- (XII) and diethynylfluorene (XV) were synthesized from ketones XI[5] and XIV respectively in poor yields. The bathochromic shift (ca. 11 mμ) attributable to an additional ethynyl in XV is comparable to that exhibited by an additional phenyl and described above in the IX-X-III series, but it



is smaller than that shown in the case of V. The dimerization of XII by oxidative coupling gave XIII as yellow needles quantitatively. The ultraviolet spectra of XIII and related compounds are shown in Fig. 2 and in Table I. The oxidative polymerization of XV resulted in the formation of an orange-brown solid containing a carbonyl group; the intensity at the carbonyl maximum in the infrared spectrum is fairly strong, indicating that the larger the degree of conjugation, the larger the facility of carbonyl formation allowed in the coupling reaction.

Experimental[6]

4-Ethynylbiphenyl (II).—A mixture of 4-acetylbiphenyl (11.8 g., 0.06 mol.), phosphorus pentachloride (16.0 g., 0.078 mol.) and phosphorus oxychloride (25 ml.) was heated at 60°C for 1 hr. After evaporating the phosphorus oxychloride under reduced pressure at a temperature below 30°C, the residue was dissolved in dry tetrahydrofuran (50 ml.) and then stirred drop by drop, over a 20 min. period, into a solution of sodium amide (prepared from sodium 6.5 g., 0.28 g. atom) in liquid ammonia (300 ml.); the stirring was continued for a further 30 min. The residue obtained by the evaporation of ammonia was decomposed with water (100 ml.) and extracted with ether (300 ml.). The ethereal layer was washed with aqueous sodium chloride and dried over anhydrous sodium sulfate. Evaporation of the solvent gave a crude solid which was sublimed at 70°C under 3 mmHg to give II, 7.5 g. (70%) in the form of photo-unstable colorless needles; m. p., 85.5°C (decomp.). IR: KBr disk, 3250 (ethynyl), 2110 (acetylene), 840 (*p*-disubstituted benzene) and 770, 700 cm^{-1} (monosubstituted benzene). UV: λ_{max} in alcohol, 271 mμ (ε, 29300).

Found: C, 93.80; H, 5.52. Calcd. for $C_{14}H_{10}$: C, 93.34; H, 5.66%.

After the sublimation of II, the brownish residue was recrystallized from carbon tetrachloride. Recrystallization of the carbon tetrachloride-insoluble solid from benzene gave pale yellow needles; m. p., 223°C (decomp.). The yield was 200 mg. A mixed melting point with di-(*p*-biphenylyl)-diacetylene (III) showed no depression. The infrared spectrum of this material was identical with that recorded for III.

Di-(*p*-biphenylyl)diacetylene (III).—A mixture of 4-ethynylbiphenyl (II) (2.5 g.), cupric acetate monohydrate (1.5 g.) and pyridine (80 ml.) was stirred for 1.5 hr. at 50°C. After cooling, the crystals formed were collected by filtration, washed with water and alcohol, and then recrystallized from benzene to give III (1.2 g., 48%) as pale yellow needles; m. p., 232° (decomp.). IR: KBr disk, 2150 (acetylene), 840 (*p*-disubstituted benzene) and 766, 700 cm^{-1} (monosubstituted benzene). UV: λ_{max} in alcohol, 294 (shoulder) (ε, 37100), 310.5 (52200), 330 (59200) and 352 mμ (43600).

5) "Organic Syntheses", Coll. Vol. III, 29 (1956).

6) All melting points are uncorrected.

Found: C, 94.73; H, 5.03. Calcd. for $C_{28}H_{18}$: C, 94.88; H, 5.12%.

4, 4'-Diacetylbiphenyl (IV).—Powdered anhydrous aluminum trichloride (2.8 g., 2.1 mol.) was added to a solution of biphenyl (108 g., 0.7 mol.) in carbon disulfide (600 ml.). Acetylchloride (220 g., 2.8 mol.) was stirred into the mixture over a one-hour period at room temperature, and then this stirring was continued for 5 hr. at 55°C. After the removal of the carbon disulfide by distillation, the residue was poured into an ice-cooled, diluted hydrochloric acid to yield a crystalline solid which was then washed with water and alcohol and dried in vacuo. In order to remove both the 4-acetylbiphenyl formed as a by-product and the unchanged biphenyl, the solid thus obtained was washed repeatedly with boiling alcohol. Recrystallization of the alcohol-insoluble solid from benzene yielded IV (60 g., 36%) as pale yellow leaflets; m. p., 189~191°C (lit.[3], 190~191°C). UV: λ_{max} in alcohol, 295 mμ (ε, 32800).

4, 4'-Diethynylbiphenyl (V).—4, 4'-Diacetylbiphenyl (IV) (7.1 g., 0.03 mol.) was treated with phosphorus pentachloride (18.8 g., 0.09 mol.) in phosphorus oxychloride (30 ml.) for 30 min. at 60°C. Evaporation of phosphorus oxychloride under reduced pressure gave chloride as an unstable, bright yellow solid. A solution of the crude chloride in dry tetrahydrofuran (70 ml.) was stirred into a solution of sodium amide (prepared from sodium 7.5 g., 0.32 g. atom) in liquid ammonia (250 ml.) over a 30 min. period, and then this stirring was continued for a further 30 min. The residue obtained by the evaporation of the ammonia was decomposed with water (100 ml.) and extracted with ether (500 ml.). The ethereal layer was washed with aqueous sodium chloride and dried over anhydrous sodium sulfate. After removal of the solvent, the residue was chromatographed on alumina from benzene-carbon tetrachloride (1 : 3) and then crystallized from alcohol to yield V (3.2 g., 53%) as colorless needles; m. p., 165.5~166.5°C. IR: KBr disk, 3260 (ethynyl), 2120 (acetylene) and 860, 825 cm^{-1} (*p*-disubstituted benzene). UV: λ_{max} in alcohol, 288 mμ (41000); dioxane, 290 mμ (ε, 40800).

Found: C, 94.76; H, 5.06. Calcd. for $C_{16}H_{10}$: C, 95.02; H, 4.98%.

***meso*-2, 3-Diphenylbutane.**—The chlorination of acetophenone with phosphorus pentachloride, followed by dehydrochlorination with sodium amide in liquid ammonia, gave an oily product; on distillation this product yielded phenylacetylene (A), (30% b. p. 50°C at 19 mmHg), a high boiling material (B), (b. p. 70~80°C at 19 mmHg) and undistillable resinous material (C). The high boiling material was unstable and solidified after having been left for several weeks. The solid obtained was crystallized from methanol-water to give colorless leaflets (m. p., 114~116°C), which were identified as benzoic acid by mixed melting point determination with the authentic sample and by infrared analysis. The resinous material was chromatographed on alumina from carbon tetrachloride and then crystallized from methanol to afford *meso*-2, 3-diphenylbutane in the form of colorless needles; m. p., 120~122°C (lit[4] m. p. 126°C). IR: KBr disk, 3060, 3010 (aromatic H), 2950 (methyl), 2890 (tertiary H), 1373 (methyl) and 773, 755, 697 cm^{-1} (monosubstituted benzene).

Found: C, 91.31; H, 8.59. Calcd. for $C_{16}H_{18}$: C, 91.37; H, 8.63%.

4, 4'-Bis-(α-chlorovinyl)biphenyl (VIII) and 4-Acetyl-4'-(α-chlorovinyl)biphenyl (VII).—4', 4-Diacetylbiphenyl (IV) (7.1 g., 0.03 mol.) was treated with phosphorus pentachloride (9.4 g., 0.045 mol.) in phosphorus oxychloride (25 ml.) for 30 min. at 80~90°C. The crude chloride obtained in the manner described above was dissolved in dry tetrahydrofuran (50 ml.), and the resulting solution was stirred into a solution of sodium amide (prepared from sodium 3.7 g., 0.16 g. atom) in liquid ammonia (150 ml.) over a one-hour period. After evaporation of the ammonia, water (100 ml.) was added to the residue and then extracted with ether. The ethereal solution was washed with water and dried over anhydrous sodium sulfate. After removal of the solvent, the solid residue was chromatographed on alumina from carbon tetrachloride and benzene. The elute obtained by using carbon tetrachloride gave photosensitive, colorless plates; m. p., 175°C (decomp.). IR: KBr disk, 888 (vinyl) and 825 cm^{-1} (*p*-disubstituted benzene).

Found: C, 69.35; H, 4.34. Calcd. for $C_{16}H_{12}Cl_2$: C, 69.82; H, 4.33%.

The colorless crystals (m. p., 160°C (decomp.)) obtained by elution with benzene were recrystallized from alcohol to yield colorless leaflets; m. p., 160°C (decomp.). IR: KBr disk, 1680 (carbonyl), 890 (vinyl) and 823 cm^{-1} (*p*-disubstituted benzene). UV: λ_{max} in alcohol, 299 mμ (ε, 33500).

Found: C, 74.95; H, 5.12; Cl, 13.54. Calcd. for $C_{16}H_{13}OCl$: C, 74.84; H, 5.06; Cl, 13.84%.

Di-4-(4'-ethynylbiphenyl)diacetylene ($VI_{n=2}$), a Dimer of V.—A mixture of V (1.0 g.), cupric acetate monohydrate (5.0 g.), pyridine (30 ml.) and methanol (20 ml.) was stirred for 1.5 hr. at 50°C. The crude solid obtained in the manner described for III was crystallized twice from dimethylformamide to give pale yellow needles (0.7 g., 70%) showing no clear melting point (>300°C). Upon heating in an air bath, the crystals gradually turned orange, then brown, and finally black. The infrared and ultraviolet spectra showed this compound to be a linear dimer of V. IR: KBr disk, 3260 (ethynyl) and 860, 825 cm^{-1} (*p*-disubstituted benzene). UV: λ_{max} in dioxane, 367 (ε, 43200), 324 (shoulder) (93400), 339 (108500) and 361 mμ (shoulder) (77900).

Found: C, 94.49; H, 4.57. Calcd. for $C_{32}H_{18}$: C, 95.49; H, 4.51%.

1-Phenyl-4-*p*-biphenylyldiacetylene (X).—A mixture of II (0.9 g., 0.005 mol.), phenylacetylene (1.0 g., 0.01 mol.), cupric acetate monohydrate (3.0 g., 0.03 mol.) and pyridine (30 ml.) was stirred for 1 hr. at 50°C. Then alcohol (20 ml.) was added to the reaction mixture to afford pale yellow needles (0.4 g.) after recrystallization from benzene. The crystals (m. p., 230°C (decomp.)) were identified as III by mixed melting point determination with an authentic sample and by the infrared spectrum.

The pyridine-alcohol layer was evaporated to dryness under reduced pressure; the crude material which remained was crystallized from methanol (25 ml.) to give colorless needles (m. p., 85°C, 0.5 g.), which were identified as diphenyldiacetylene by the same methods as have been mentioned above. The methanol-insoluble solid was repeatedly recrystallized from alcohol, resulting in X (0.3 g.) as colorless leaflets; m. p., 148~150°C. IR: Nujol mull, 835 (*p*-disubstituted benzene) and 765, 755, 720 cm^{-1} (monosubstituted benzene). UV: λ_{max} in alcohol, 261 (ε, 23300), 272 (24600), 302.5 (33100), 319 (42000) and 340 mμ (31300).

Found: C, 94.58; H, 5.02. Calcd. for $C_{22}H_{14}$: C, 94.93; H, 5.07%.

2-Ethynylfluorene (XII).—2-Acetylfluorene (XI) (6.42 g., 0.03 mol.) was treated with phosphorus pentachloride (9.37 g., 0.045 mol.) in phosphorus oxychloride (50 ml.) for 3 hr. at 60°C. The mixture was concentrated in vacuo, and the residue was dissolved in dry ether (200 ml.). The ethereal solution was, over a 20 min. period, stirred into a solution of sodium amide (prepared from sodium 3.7 g., 0.16 g. atom) in liquid ammonia (150 ml.); the stirring was then continued for a further 1.5 hr. After the removal of the ammonia, the residue was decomposed with water (150 ml.). Extraction with ether followed by evaporation gave crude crystals, which were chromatographed on alumina from carbon tetrachloride to afford XII (700 mg.) as colorless leaflets; m. p., 85.5°C. IR: KBr disk, 3240 (ethynyl), 2095 (acetylene), 875 (isolated H), 831 (*p*-disubstituted benzene) and 767, 734 cm^{-1} (*o*-disubstituted benzene). UV: λ_{max} in alcohol, 219 (shoulder) (ε, 24600), 228 (shoulder) (10700), 234 (5700), 282 (30100), 299 (20900) and 310 mμ (ε, 24100). λ_{max} in dioxane, 285 (28800), 302 (21800) and 312 mμ (24200).

Found: C, 94.81; H, 5.25. Calcd. for $C_{15}H_{10}$: C, 94.70; H, 5.30%.

Di-(2-fluorenyl)-diacetylene (XIII).—A mixture of 2-ethynylfluorene (XII, 0.5 g.), cupric acetate monohydrate (1.5 g.) and pyridine (15 ml.) was heated at 50°C for 1 hr. while being stirred. The crude crystals deposited were collected by filtration and washed successively with methanol, hot water and methanol. Two recrystallizations of the crystals from benzene gave yellow needles; m. p., 278°C (decomp.) 340 mg. IR: KBr disk, 2120 (acetylene), 870 (isolated H), 326 (*p*-disubstituted benzene) and 764, 733 cm^{-1} (*o*-disubstituted benzene). UV: λ_{max} in dioxane, 832 (67600), 348 (80600) and 374 mμ (ε, 71000).

Found: C, 95.10; H, 4.69. Calcd. for $C_{30}H_{18}$: C, 95.21; H, 4.79%.

2,7-Diacetylfluorene (XIV).—Acetylchloride (19.6 g. 0.25 mol.) was stirred drop by drop into a solution of 2-acetylfluorene (XI) in carbon disulfide over a 30 min. period, and the resulting mixture was then heated under reflux while being stirred for more 3 hr. After the removal of the carbon disulfide under reduced pressure, the residue was decomposed with diluted hydrochloric acid. The crude material collected by filtration was washed with petroleum ether (b. p. 75°C) and alcohol, and recrystallized three times from alcohol to yield XIV 21 g. (33%) as colorless needles; m. p., 178.5~179°C. IR: Nujol mull, 1680, 1359 (ketone), 868 (isolated H) and 841 cm^{-1} (*p*-disubstituted benzene). UV: λ_{max} in alcohol, 320 (ε, 36700) and 326 mμ (36800).

Found: C, 81.13; H, 5.57. Calcd. for $C_{17}H_{14}O_2$: C, 81.58; H, 5.64%.

2,7-Diethynylfluorene (XV).—Crude chloride, obtained by the same treatment of a mixture of 2,7-diacetylfluorene (XIV) (5.5 g., 0.02 mol.), phosphorus pentachloride (12.5 g., 0.06 mol.) and phosphorus oxychloride (60 ml.) as has been described for XII, was treated with sodium amide (sodium 5.5 g., 0.24 g. atom) in liquid ammonia (200 ml.) resulting in crude crystals (800 mg.; m. p., 112~116°C), which were chromatographed on alumina from carbon tetrachloride to give XV (200 mg.) as colorless needles; m. p., 132~132.5°C. IR: Nujol mull, 3290 (ethynyl), 2090 (acetylene), 865 (isolated H) and 845, 825 cm^{-1} (*p*-disubstituted benzene). UV: λ_{max} in alcohol, 222 (ε, 20100), 232 (10200), 240 (shoulder) (4900), 297 (41100), 307 (31600), 314 (31600) and 321 mμ (58700).

Found: C, 95.14; H, 4.73. Calcd. for $C_{17}H_{10}$: C, 95.30; H, 4.70%.

Synthesis of 7-Hydroxy-2', 4', 5'-trimethoxyisoflavone and Related Compounds

By Kenji FUKUI, Mitsuru NAKAYAMA, Masayuki HATANAKA, Tadao OKAMOTO and Yoshiyuki KAWASE

((Received October 22, 1962)

Little has been reported on isoflavones oxygenated at the 2'-, 4'- and 5'-positions. Caviunin[1] (I) and Harper's phenol (" toxicarol isoflavone ")[2] (II) are the only known instances which occur naturally. We have, therefore, been interested in synthesizing 7-hydroxy-2', 4', 5'-trimethoxyisoflavone (III) and the corresponding 2-methyl derivative (IV) because of their structural resemblance to I and II.

Hoesch condensation of resorcinol and 2, 4, 5-trimethoxybenzyl cyanide[3] yielded 2, 4-dihydroxyphenyl 2, 4, 5-trimethoxybenzyl ketone (V) in discouraging yields under a variety of reaction conditions. The ketone V could, however, be prepared in a 46% yield by treating a mixture of resorcinol and homoasaronic acid (2, 4, 5-trimethoxyphenylacetic acid)[4] with polyphosphoric acid. Zinc chloride in either the presence[5] or absence of phosphorous oxychloride gave inferior yields of V. Ethers (VI–VIII) and a diacetate (IX) of V were prepared.

When the ketone V was treated with ethyl orthoformate in pyridine[6], the desired isoflavone III was obtained in a 61% yield. An acetate (X) and a methyl ether (XI) of III were prepared.

Reaction of the ketone V with acetic anhydride in the presence of sodium acetate[7] gave a cyclized acetate XII which could easily be hydrolyzed to 7-hydroxy-2', 4', 5'-trimethoxy-2-methylisoflavone (IV). A methyl ether (XIII) of IV was also obtained.

When the acetylation of the ketone V was carried out with acetyl chloride in pyridine at 0°C, a diketone XIV was produced. The alkaline hydrolysis of XIV was accompanied with a simultaneous ring closure to afford the methylisoflavone (IV), which was identical with the above-mentioned product.

Experimental*

2, 4-Dihydroxyphenyl 2, 4, 5-Trimethoxybenzyl Ketone (V). — *Hoesch Reaction*[8]. — A mixture of resorcinol (1.5 g.) and 2,4,5-trimethoxybenzyl cyanide (m. p., 84~85°C)[3] (1.0 g.) in anhydrous ether (60 ml.) was saturated with dried hydrogen chloride for a 3 hr. period at 0°C and then allowed to stand at room temperature for 4 days. The ethereal solution was decanted from the oily layer of ketimine hydrochloride which had separated. The oily layer was washed twice with dry ether (20 ml.) and then heated on a steam bath with water (30 ml.) for 1 hr. After cooling and standing, the product was collected and recrystallized from ethanol, giving V (m. p., 201~202°C) (reported m. p., 201~202°C[8]) (colorless needles), which showed a reddish-brown ferric chloride reaction in ethanol; yield, 0.2 g. (13%).

Found: C, 64.10; H, 5.82. Calcd. for $C_{17}H_{18}O_6$: C, 64.14; H, 5.70%.

Nencki Reaction. — A mixture of homoasaronic acid (m. p., 102~103°C)[4] (1.0 g.) and freshly fused zinc chloride (0.4 g.) was heated at 130~140°C for 30 min. After resorcinol (1.5 g.) had been added, the mixture was kept at the same temperature for 2 hr. Upon working up the reaction mixture, 0.4 g. (31%) of V was obtained. M. p. and mixed m. p., 199~200°C.

With Phosphorus Oxychloride-Zinc Chloride. — A mixture of resorcinol (2.0 g.), homoasaronic acid (1.5 g.), phosphorus oxychloride (20 ml.) and freshly fused zinc chloride (6.0 g.) was heated at 50~60°C for 2 hr. The product was recrystallized from ethanol, giving V (m. p. and mixed m. p., 197~199°C); yield, 0.6 g. (24%).

With Poly(phosphoric Acid).—A mixture of resorcinol (1.5 g.), homoasaronic acid (1.0 g.) and poly(phosphoric acid) (n=2.5) (10 g.) was warmed on a steam bath for 15 min. The dark red solution was then poured into ice-water. The resulting product was recrystallized from ethanol, giving V (m. p. and mixed m. p., 201~202°C); yield, 0.65 g. (46%).

2-Hydroxy-4-methoxyphenyl 2, 4, 5-Trimethoxybenzyl Ketone (VI). — *With Diazomethane.* — The treatment of V (0.5 g.) in acetone (60 ml.) with an ethereal solution of diazomethane (prepared from 0.5 g. of nitrosomethylurea) gave VI as colorless needles (m. p., 135~136°C (from ethanol)); yield, 0.5 g. (96%).

Found: C, 64.91; H, 6.15. Calcd. for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07%.

With Methyl Iodide.—To a solution of V (1.0 g.) and methyl iodide (0.2 ml.) in acetone (30 ml.) was added potassium carbonate (2.0 g.); the mixture was then refluxed for 70 min. The product was recrystallized from ethanol, giving VI (m. p. and mixed m. p., 135~136°C); yield, 1.0 g. (96%).

2, 4-Dimethoxyphenyl 2, 4, 5-Trimethoxybenzyl Ketone (VII). — To a solution of V (1.0 g.) and dimethyl sulfate (1.0 ml.) in acetone (50 ml.) was added potassium carbonate (5.0 g.); the mixture was then refluxed for 6.5 hr. to provide VII (m. p., 110~111°C) (colorless needles from ethanol); yield, 1.0 g. (91%).

Found: C, 65.89; H, 6.58. Calcd. for $C_{19}H_{22}O_6$: C, 65.88; H, 6.40%.

2-Hydroxy-4-benzyloxyphenyl 2, 4, 5-Trimethoxybenzyl Ketone (VIII).—A mixture of V (1.0 g.), benzyl chloride (1.0 g.) and potassium carbonate (5.0 g.) in acetone (50 ml.) was refluxed for 8 hr. Recrystallization from ethanol gave VIII in the form of colorless needles, (m. p. 149~150°C); yield, 1.2 g. (94%).

Found: C, 70.55; H, 5.99. Calcd. for $C_{24}H_{24}O_6$: C, 70.57; H, 5.92.

2, 4-Diacetoxyphenyl 2, 4, 5-Trimethoxybenzyl Ketone (IX). — The treatment of V (0.1 g.) in pyridine (5.0 ml.) with acetic anhydride (2.0 ml.) at room temperature gave IX as colorless prisms (m. p., 134~135°C (from ethanol)); yield, 0.12 g. (95%).

Found: C, 62.23: H, 5.58. Calcd. for $C_{21}H_{22}O_8$: C, 62.68; H, 5.51.

7-Hydroxy-2', 4', 5'-trimethoxyisoflavone (III).— To a solution of V (0.8 g.) and ethyl orthoformate (2.0 ml.) in pyridine (10 ml.) was added piperidine (0.5 ml.); the mixture was then refluxed for 10 hr. The resulting solution was cooled and acidified with dilute hydrochloric acid. The precipitate was recrystallized from ethanol, giving III (m. p., 244~245°C) (colorless microcrystals), with a negative ferric chloride reaction in ethanol; yield, 0.5 g. (61%). IR: 3320~3200 (broad) (OH), 1640 cm^{-1} (γ-pyrone). UV: λ_{max}^{EtOH} mμ (log ε): 241 (4.35), 249 (4.35), 300 (4.24).

Found: C, 65.62; H, 5.18. Calcd. for $C_{18}H_{16}O_6$: C, 65.85; H, 4.91%.

The acetylation of III with acetic anhydride and pyridine at room temperature gave the acetate (X) (m. p., 156~157°C) (colorless needles from ethanol). IR: 1752 (acetate), 1659 cm^{-1} (γ-pyrone).

Found: C, 64.72; H, 5.11. Calcd. for $C_{20}H_{18}O_7$: C, 64.86; H, 4.90%.

2', 4', 5', 7-Tetramethoxyisoflavone (XI). — This ether XI was prepared from V (0.15 g.) with dimethyl sulfate in acetone. Recrystallization from ethanol yielded colorless plates (m. p., 190~191°C); yield, 0.12 g. (80%). IR: 1639 cm^{-1} (γ-pyrone).

Found: C, 66.62; H, 5.42. Calcd. for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

7-Acetoxy-2', 4', 5'-trimethoxy-2-methylisoflavone (XII).—A mixture of V (1.0 g.) and anhydrous sodium acetate (2.0 g.) in acetic anhydride was refluxed for 18 hr. The cooled mixture was poured into ice-water. An oil separated and solidified on cooling. Recrystallization of the solid from ethyl acetate or ethanol gave XII (m. p., 177~178°C) (colorless needles), with a negative ferric chloride reaction in ethanol; yield, 1.0 g. (83%). IR: 1756 (acetate), 1645 cm^{-1} (γ-pyrone).

Found: C, 65.79; H, 5.31. Calcd. for $C_{21}H_{20}O_7$: C, 65.61; H, 5.24%.

2, 4-Diacetoxyphenyl α-Acetyl-2, 4, 5-trimethoxybenzyl Ketone (XIV).—Into a solution of V (2.0 g.) in pyridine (40 ml.) acetyl chloride (3.0 ml.) was

** All melting points are uncorrected; the infrared spectra were meaured in Nujol.

8) This procedure is based on a private communication from Hiroshi Fukami of the Department of Agricultural Chemistry, Kyoto University.

added with stirring at 0°C. After having been left standing for 24 hr. at 0°C, the reaction mixture was poured into ice-water. The resulting solid mass was collected by filtration and dried. Recrystallization from ethanol gave XIV (m. p., 164~165°C) (colorless prisms), with a negative ferric chloride reaction in ethanol; yield, 2.2 g. (78%).

Found: C, 62.12; H, 5.45. Calcd. for $C_{23}H_{24}O_9$: C, 62.16; H, 5.44%.

2-Hydroxy-2',4',5'-trimethoxy-2-methylisoflavone (IV).—*By Hydrolysis of XII.—i) With Sulfuric Acid:* A solution of XII (0.55 g.) in ethanol (50 ml.) was refluxed with concentrated sulfuric acid (0.3 ml.) for 4 hr. After evaporation of the solvent, the residue was triturated with water. The resulting solid was recrystallized from ethanol giving IV (m. p., 246~247°C) (colorless microcrystals); yield, 0.47 g. (96%). IR: 3248 (OH), 1637 cm^{-1} (γ-pyrone). UV: λ_{max}^{EtOH} mμ (log ε): 242 (4.37), 250 (4.37), 296.5 (4.30).

Found: C, 66.65; H, 5.43. Calcd. for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

The acetylation of IV with acetic anhydride and pyridine gave the acetate (XII) (m. p. and mixed m. p., 177~178°C).

ii) With Sodium Carbonate: A mixture of XII (0.25 g.) and 10% aqueous sodium carbonate (10 ml.) was refluxed for 2 hr. Upon acidification of the hydrolyzate with dilute hydrochloric acid, a precipitate formed. Recrystallization from ethanol gave IV (m. p., 246~248°C, which was identical with that of the above sample); yield, 0.1 g. (48%).

By Hydrolysis of XIV.—XIV (1.0 g.) was treated with sodium carbonate in a manner similar to that described above. Recrystallization from ethanol gave IV (m. p., 246~247°C); yield, 0.5 g. (38%).

2',4',5',7-Tetramethoxy-2-methylisoflavone (XIII).—This ether XIII was prepared from (0.20 g.) with dimethyl sulfate in acetone. Recrystallization from ethanol gave colorless microcrystals (m. p., 189~190°C); yield, 0.20 g. (96%). IR: 1641 cm^{-1} (γ-pyrone).

Found: C, 67.38; H, 5.73. Calcd. for $C_{20}H_{20}O_6$: C, 67.40; H, 5.66%.

The authors are grateful to Professor Minoru Nakajima and Professor Tetsuo Mitsui, Kyoto University, for their measurements of infrared spectra and microanalyses. This work was partially supported by a grant-in-aid for scientific research from the Ministry of Education, which is acknowledged with gratitude.

The Preparation of Stereoisomeric α,ω-Diphenylpolyenes and Related Compounds by Means of the Wittig Reaction

By Soichi MISUMI and Masazumi NAKAGAWA

(Received October 29, 1962)

As reported in a previous paper, the authors have found in the synthesis of polystilbenes that the Wittig reaction gave almost the same amount of cis and trans isomers simultaneously with regard to the ethylenic linkage formed by the particular reaction[1]. The method seemed to be promising for the preparation of geometrical isomers of a wide variety of compounds. It is well-known that the cis isomers of α,ω-diphenylpolyene can be obtained by the semihydrogenation[2] of the corresponding acetylenic compounds on Lindlar's catalyst or by the photoisomerization of the all-trans isomer[2a,3]. The fact that the latter method essentially gives a mixture of several cis isomers reduces the practical value of this process for preparative purpose. On the contrary, the Wittig reaction is advantageous in view of the introduction of cis and trans ethylenic linkages at a definite position in the molecule by the reaction of a carbonyl component with an appropriate yield moiety. The present paper deals with the syntheses of stereoisomeric α,ω-diphenylpolyenes and related compounds according to this procedure.

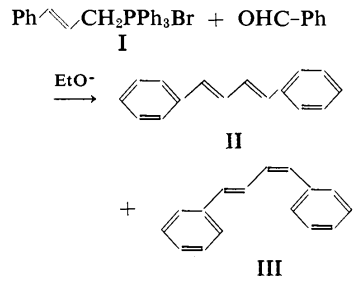
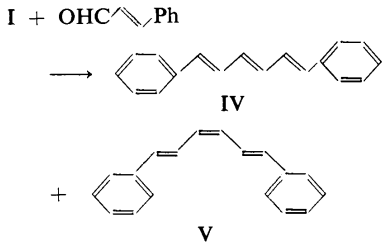
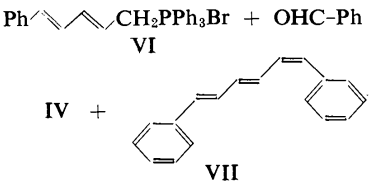
The synthesis of *trans, trans*-1, 4-diphenylbutadiene (II) has been reported recently by Campbell employing triphenylcinnamylphosphonium chloride and benzaldehyde[4]. The present authors have confirmed the simultaneous formation of trans, trans and trans, cis isomers (II and III) by the reaction of triphenylcinnamylphosphonium bromide (I) with the aldehyde. The combined yield was found as high as 77%.



Similarly, the reaction of phosphonium bromide I with cinnamaldehyde afforded two isomers of 1, 6-diphenylhexatriene, trans, trans, trans (IV) and trans, cis, trans (V), in nearly the same yield.

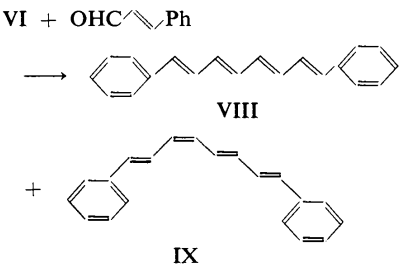


The third isomer, *trans, trans, cis*-diphenylhexatriene (VII) was obtained by the reaction of triphenyl-5-phenyl-2, 4-pentadienylphosphonium bromide (VI) with benzaldehyde and purified by chromatography on alumina. The cis isomer VII, colorless liquid, exhibited the identical electronic spectrum with that of the specimen prepared by Zechmeister and his coworkers[3], and it transformed into an all-trans isomer on exposure to light.



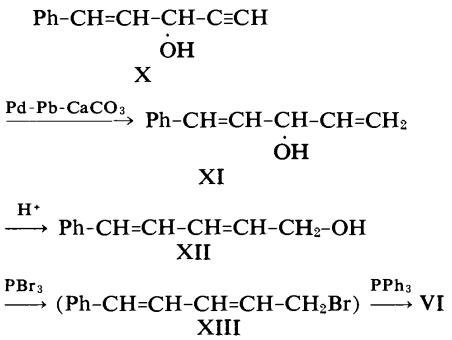
Similarly, the reaction of phosphonium bromide VI with cinnamaldehyde gave two stereoisomers, all-trans (VIII) and trans, cis, trans, trans (IX), of 1,8-diphenyloctatetraene in about the same yield.

4) R. N. McDonald and T. W. Campbell, "Organic Syntheses", **40**, 36 (1960); *J. Org. Chem.*, 24, 1241 (1959).



The melting points and the electronic spectra of all above-mentioned stereoisomeric diphenylpolyenes were found to be identical with those of the reported values[3].

The synthesis of phosphonium salt VI was carried out according to the following scheme. 5-Phenyl-2, 4-pentadienol (XII)[5], obtained by semihydrogenation and anionotropic rearrangement of ethynylstyrylcarbinol (X)[6], was treated successively with phosphorus tribromide and triphenylphosphine yielding the phosphonium bromide VI.



The intermediate, XII and XIII, were used without purification for further reactions owing to their thermal instability. The reduction of ethynylcarbinol X with lithium aluminum hydride afforded unexpectedly 5-phenyl-1-penten-3-ol (XIV) in a 78% yield. The structure of this carbinol XIV was confirmed by elemental analysis, electronic and infrared spectra (Fig. 1). The same type of unusual reduction of $-CH=CH-CH(OH)-C\equiv CH$ grouping by the hydride has been found by Attenburrow in the course of the synthesis of Vitamin A[7].

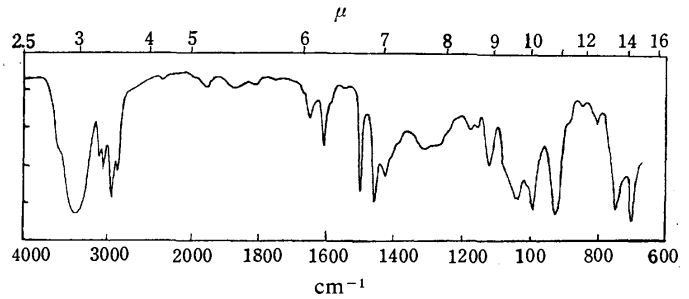

Fig. 1. The infrared spectrum of 5-phenylpent-1-en-3-ol (XIV).

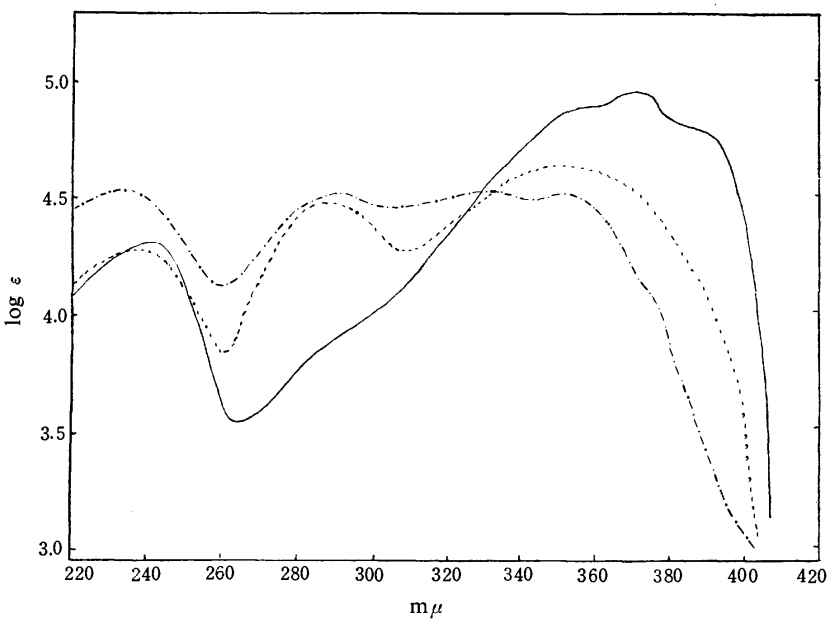

Fig. 2. The electronic spectra of the *p*-styryldiphenylbutadienes (——, all-trans XVI; ------, mono-cis XVII; —·—·—·, Dale's cis compound) (in *n*-hexane).

In addition to the above-mentioned reduction product, a colorless liquid with a lower boiling point was obtained. The formula of an allenic hydrocarbon XV was assigned to this substance on the basis of the absence of hydroxy- and ethynyl-absorptions and the presence of strong peaks of monosubstituted allene in its infrared spectrum.

Dale[8] has obtained a minor amount of a cis isomeric compound by the photoisomerization of *p*-styryldiphenylbutadiene. He suggested the structure of XVII to the minor product by the examination of its electronic spectrum, but there remained an uncertainty on account of its small quantity. We have carried out the synthesis of XVII from stilbenealdehyde in order to ascertain his suggestion. The reaction of phosphonium bromide I with stilbenealdehyde at room temperature resulted in the formation of all-trans (XVI) and mono-cis (XVII) isomers of *p*-styryldiphenylbutadiene in a total yield of 75%. The structure of the cis isomer, pale yellow plates with a green fluorescence, was confirmed by the elemental analysis, the examination of electronic and infrared spectra and the transformation into the all-trans isomer (XVI) on exposure to light.

XVII

8) J. Dale, *Acta Chem. Scand.*, 11, 971 (1957).

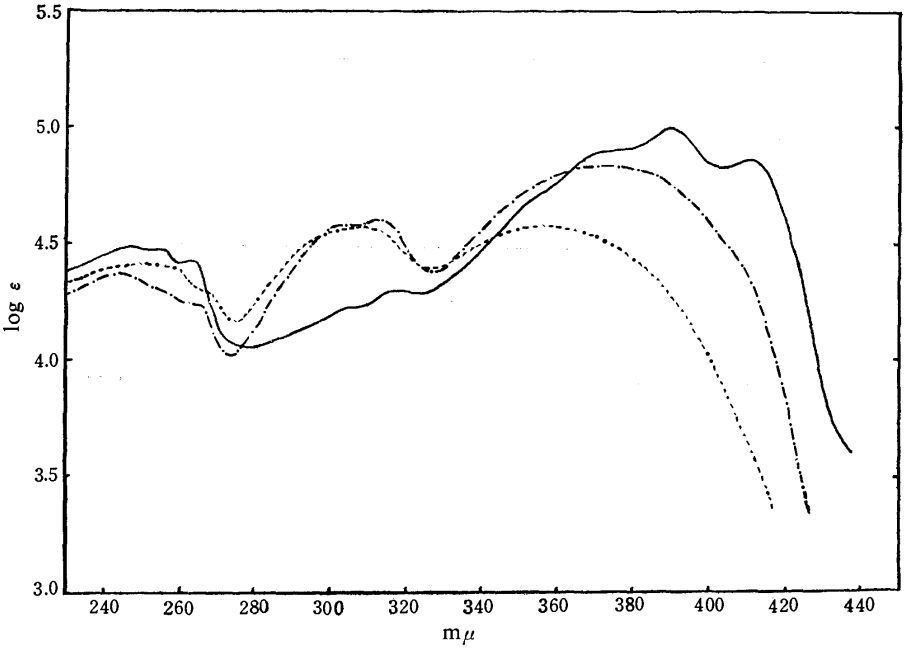

Fig. 3. The electronic spectra of the *p*-bis(phenylbutadienyl)benzenes (——, all-trans XVIII; —·—·, mono-cis XIX; ------, di-cis XX) (in tetrahydrofuran).

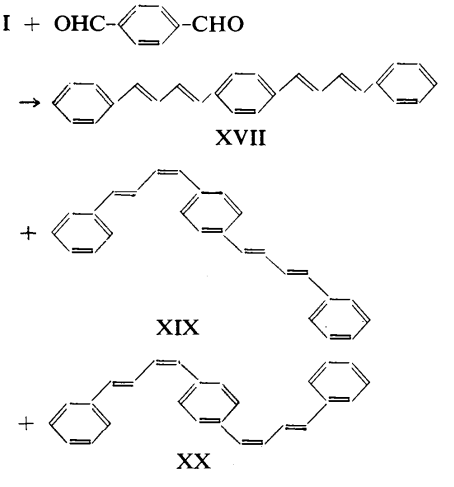
As illustrated in Fig. 2, the distinct fine structure in the main band of all-trans isomer XVI disappears in the spectrum of the mono-cis isomer XVII. As the decrease in fine structure in the main band is a general trend in the spectra of sterically hindered cis compounds, the presence of vibrational structure in the main band of the spectrum of Dale's cis compound seems to indicate the contamination of the all-trans isomer XVI.



The reaction of phosphonium bromide I with terephthalaldehyde in place of stilbenealdehyde resulted in the formation of three stereoisomeric *p*-bis(phenylbutadienyl)benzenes. One of these isomers, all-trans form has already been synthesized by different authors, especially Campbell and McDonald used the Wittig reaction of *p*-xylenebisphosphonium chloride with cinnamaldehyde[9]. Each isomer, isolated by chromatography, gave correct analysis and could be transformed into the all-trans form by the photoisomerization. The assignment of their structure was performed on the bases of the electronic and infrared spectroscopic evidences. Also in the series of *p*-bis(phenylbutadienyl)benzene, only the all-trans isomer[9] exhibits a distinct fine structure in the absorption curve. The introduction of cis ethylenic linkage to the system caused blue-shifts (mono-cis, 16 mμ; di-cis, 33 mμ) of the main absorption maxima accompanied with the decrease of their absorption intensities and the appearance of new absorption peaks at the wavelength region of ca. 300 mμ in which the all-trans form has only a slight inflexion (Fig. 3).

The cis forms of the above-mentioned diphenylpolyenes seem to contain much less or no steric strain as compared with the previously discussed hindered cis polystilbenes and the related compounds[1]. But from the above-stated observation, it was revealed that the spectroscopic behavior of the geometrical isomers in these two series of conjugate system was

9) G. Drefahl and G. Plotner, *Chem. Ber.*, **91**, 1258 (1958); K. Friedlich and H. Henning, ibid., **92**, 2944 (1959); R. N. McDonald and T. W. Campbell, *J. Org. Chem.*, **24**, 1969 (1959); "Organic Syntheses", **40**, 85 (1960).

similar. This fact indicates that the steric strain in *cis*-polystilbenes are insufficient to exert an influence upon spectroscopic properties.

Experimental*

***trans, trans-* and *trans, cis*-1, 4-Diphenylbutadiene (II and III).**—To a stirred suspension of triphenylcinnamylphosphonium bromide (I, 6.9 g., 0.015 mol.) and benzaldehyde (1.8 g., 0.017 mol.) in anhydrous ethanol (40 ml.) was added a solution of a slight excess of lithium ethoxide (from 0.15 g. of lithium) in anhydrous ethanol (75 ml.) in a dark room. After stirring for ca. 10 hr., water (70 ml.) was added precipitating a solid. This was separated by filtration (filtrate A), dried and dissolved in cyclohexane. The solution was filtered to remove unchanged phosphonium salt. Concentration of the solution gave colorless needles, m. p. 147~150°C (1.46 g., 47%), which were recrystallized from cyclohexane yielding trans, trans isomer (II), m. p. 152~153°C (lit.[4] 152~153°C).

Filtrate A was extracted with light petroleum (200 ml.) and the extract was washed, dried and chromatographed on alumina. The column (2×25 cm.) was eluted with light petroleum to give eight 50 ml. fraction. The fractions 3-8 gave the same electronic spectra with that of Zechmeister's trans, cis isomer (UV λ_{max} mμ: 240, 314. $\lambda_{infl.}$ 247 (in *n*-hexane)) and afforded a colorless liquid, 0.918 g. (30%), which transformed into II, when it was exposed to direct sun light.

***trans, trans, trans-* and *trans, cis, trans*-1,6-Diphenylhexatriene (IV and V).**—The phosphonium bromide (I, 4.6 g., 0.01 mol.) and cinnamaldehyde (1.3 g., 0.01 mol.) in anhydrous ethanol (20 ml.) were treated with lithium ethoxide (from 0.1 g. of lithium) in 70 ml. of anhydrous ethanol as described in the case of diphenylbutadiene. The reaction mixture was stirred for 8 hr. precipitating leaflets (1.3 g.), which were collected by filtration and had m. p. 192~194°C. Recrystallization from ethanol-dioxane (1 : 2) gave pure all-trans isomer (IV), 0.7 g. (30%), m. p. 198~199°C (lit.[3] 203°C). UV λ_{max} mμ (log ε): 242 (3.98), 336 (4.80), 351.5 (4.93), 371 (4.80) (in *n*-hexane).

Found: C, 93.01; H, 6.87. Calcd. for $C_{18}H_{16}$: C, 93.06; H, 6.94%.

The above-mentioned mother liquor was diluted with water (100 ml.) precipitating pale yellow crystals. The crude crystals were collected by filtration, dried and chromatographed on alumina (2×30 cm. column) in a dark place. The column was eluted with light petroleum-benzene (19 : 1, 200 ml. followed by 7 : 3, 600 ml.) to afford ten 50 ml. fractions. The fractions 4-10 gave pale yellow needles, m. p. 103~109°C, 650 mg. (28%); these were recrystallized from water-ethanol (2 : 3) to give central cis isomer (V) as pale yellow long needles, m. p. 109~110°C (lit.[3] 107°C). UV λ_{max} mμ (log ε): 260.5 (4.33), 268.5 (4.33), 336 (4.65), 351 (4.73), 369 (4.55) (in *n*-hexane).

Found: C, 93.04; H, 6.89. Calcd. for $C_{18}H_{16}$: C, 93.06; H, 6.94%.

* All melting points are not corrected.

Reduction of Ethynylstyrylcarbinol (X) with Lithium Aluminum Hydride.—Ethynylstyrylcarbinol (X), colorless needles, m. p. 68~69°C (66%), was prepared according to Campbell and his coworker[4].

To a suspension of lithium aluminum hydride (3.8 g., 0.1 mol.) in anhydrous ether (400 ml.), a solution of the carbinol (X, 6 g., 0.038 mol.) in anhydrous ether (60 ml.) was added dropwise under stirring and the mixture was refluxed for 30 min. to afford a greenish solution. After cooling, a small amount of ethyl acetate was added into the solution to decompose an excess of the metal hydride and then water (200 ml.) was added. The organic layer was separated by decantation and the residue was washed with two 20 ml. portions of ether. The combined organic layer and washings were washed with water and dried over magnesium sulfate in the presence of a minor amount of hydroquinone. The residual colorless oil obtained by evaporating the solvent was distilled in vacuo to yield 5-phenyl-1-penten-3-ol (XIV), b. p. 73~74.5°C/0.2 mmHg, 4.8 g. (78%). UV λ_{max} mμ: 254.5, 259, 261.5, 264.5, 268.5 (in *n*-hexane). IR: 3400, 1040 (OH); 1650, 993, 925 (-CH=CH_2); 760, 710 (Ph-) cm^{-1}.

Found: C, 81.12; H, 8.84. Calcd. for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

Triphenyl-5-phenyl-2, 4-pentadienylphosphonium Bromide (VI).—The hydrogenation of the ethynylcarbinol (X, 23.6 g., 0.15 mol.) in anhydrous tetrahydrofuran (200 ml.) over Lindlar's catalyst (1 g.) resulted in the uptake of ca. 1.1 mol. of hydrogen. After removal of the catalyst and the solvent, the residue was distilled in vacuo, yielding styrylvinylcarbinol (XI) as colorless oil, b. p. 91~94°C/0.1 mmHg, 21.8 g. (90.8%). A solution of the vinylcarbinol (XI, 21 g.) in aqueous dioxane (70%, 300 ml.) was treated with concentrated sulfuric acid (5 ml.) at 40~50°C for 2 hr. The reaction mixture was poured into water (1 l.) and extracted with ether. The ethereal extract was washed successively with aqueous potassium carbonate and water and dried over magnesium sulfate. The colorless solid obtained by evaporation of ether was recrystallized three times from light petroleum to give 5-phenyl-2, 4-pentadienol (XII), m. p. 73~78°C, 5 g. (24%).

To a solution of the crude pentadienol (XII, 3.2 g.) in chloroform (100 ml.) was added dropwise a solution of phosphorus tribromide (2 g.) in chloroform (30 ml.), and the crude bromide XIII was isolated according to the usual method. A solution of triphenylphosphine (10 g.) in toluene (80 ml.) was added to a solution of the crude bromide in toluene (20 ml.), precipitaing a white phosphonium salt. The reaction was allowed to proceed overnight without external heating and the reaction mixture was then stirred at 40~50°C for 6 hr. After cooling, the light brown oil deposited was immediately crystallized. The crude crystals were filtered and washed with toluene containing a small amount of ethanol to yield slightly brownish white crystals of phosphonium bromide VI, m. p. ca. 236~240°C, in a yield of 5.8 g.

***trans, trans, trans-* and *trans, trans, cis*-1, 6-Diphenylhexatriene (IV and VII).**—A solution of lithium ethoxide in anhydrous ethanol (from 0.05 g. of lithium in 50 ml. of anhydrous ethanol) was

added dropwise to a stirred suspension of the phosphonium bromide (VI, 3 g., 6.2 mmol.) and benzaldehyde (0.8 g., 7.5 mmol.) in anhydrous ethanol (20 ml.) in a dark place. After stirring for 7 hr. at room temperature, a deposition of brownish plates was observed. The reaction mixture was diluted with water and extracted with a mixture of benzene-light petroleum. The crystals, precipitated on standing the mixture, were collected by filtration (filtrate A) and recrystallized from aqueous dioxane yielding all-trans isomer (IV) as yellow plates, m. p. 194~198°C, in a yield of 0.2 g. (14%).

Filtrate A was chromatographed on alumina from benzene-light petroleum (b. p. 60~70°C) (9 : 1 followed by 4 : 1) to afford six 50 ml. fractions. The fractions 4-6 afforded colorless oil, 241 mg. (17%), which exhibited the same electronic spectra with that of Zechmeister's *trans, trans, cis*-1, 6-diphenylhexatriene (VII). UV λ_{max} mμ: 256, 263, 338 (in *n*-hexane).

All-*trans*- and *trans, cis, trans, trans*-1, 8-Diphenyloctatetraene (VIII and IX).—A stirred suspension of phosphonium bromide (VI, 2.5 g., 5.15 mmol.) and cinnamaldehyde (0.8 g., 16 mmol.) in anhydrous ethanol (20 ml.) was mixed with a solution of a small excess of lithium ethoxide in ethanol and stirred at room temperature for 10 hr. After standing overnight, the mixture was diluted with water precipitating a crystalline solid. This solid was separated, dried and digested with a small amount of chloroform. The insoluble part was recrystallized from the same solvent yielding all-trans isomer (VIII) as brownish yellow plates, m. p. 229~233°C, 0.3 g. (23%). This was recrystallized twice from the same solvent to give an analytical sample, m. p. 235~236.5°C (lit.[3] 235°C). UV λ_{max} mμ (log ε): 242 (4.06), 354 (4.89), 372.5 (5.04), 394.5 (4.95) (in *n*-hexane).

Found: C, 92.66; H, 6.59. Calcd. for $C_{20}H_{18}$: C, 92.98; H, 7.02%.

The soluble part obtained by evaporating chloroform was resolved in benzene-light petroleum (b. p. 60~70°C) (1 : 9) and chromatographed on alumina (2×30 cm.). The column was eluted with benzene-light petroleum (1 : 9, 1 : 4 and 1 : 1, successively) and subsequently with benzene to divide into twenty 50 ml. fractions. The fractions 5-14 gave yellow crystals, m. p. 129~136°C, 292 mg. (22%), which was recrystallized from light petroleum (b. p. 60~70°C) yielding pure *trans, cis, trans, trans*-1. 8-diphenyloctatetraene (IX) as yellow needles, m. p. 132.5~133.5°C (lit.[3] 139~141°C). UV λ_{max} mμ (log ε): 236 (4.09), 246.5 (4.06), 274.5 (4.34), 284 (4.39), 353 (4.65), 371 (4.76), 392 (4.61) (in *n*-hexane).

Found: C, 93.00; H, 6.83. Calcd. for $C_{20}H_{18}$: C, 92.98; H, 7.02%.

All-*trans*- and Mono-*cis*-*p*-styryl-1, 4-diphenylbutadiene (XVI and XVII).—A stirred suspension of *p*-stilbenealdehyde (2.1 g., 0.01 mol.) and the phosphonium bromide (I, 4.6 g., 0.01 mol.) in absolute ethanol (30 ml.) was treated with a solution of lithium ethoxide (from 0.1 g. of lithium) in anhydrous ethanol (70 ml.) and the mixture was stirred at room temperature for 18 hr. After standing overnight, the crystals deposited were separated by filtration and digested with benzene (120 ml.). The insoluble product was combined with the other crop which was obtained by the chromatography described below, and recrystallized from chlorobenzene to give all-trans isomer (XVI), m. p. 258~259°C, 1.42 g. (46.1%).

Found: C, 93.41; H, 6.58. Calcd. for $C_{24}H_{20}$: C, 93.46; H, 6.54%.

The above-mentioned soluble part in benzene was chromatographed on alumina (2×30 cm.) and there was obtained a solid, 0.88 g. (28.6%), m. p. 108~115°C, recrystallization of which from aqueous ethanol (90%) gave mono-cis isomer (XVII), m. p. 115~116°C as light yellow plates with a green fluorescence.

Found: C, 93.07; H, 6.50. Calcd. for $C_{24}H_{20}$: C, 93.46; H, 6.54%.

All-*trans*-, Mono-*cis*- and Di-*cis*-*p*-bisphenylbutadienylbenzene (XVIII, XIX and XX).—To a suspension of the phosphonium bromide (VI, 1.8 g., 0.037 mol.) and terephthalaldehyde (2.4 g., 0.018 mol.) in anhydrous ethanol (70 ml.) was added a solution of lithium ethoxide (from 0.3 g. of lithium) in anhydrous ethanol (75 ml.) under stirring at room temperature. After stirring for 3 hr., the mixture was allowed to stand overnight, and then stirred at 40~50°C for 30 min., cooled and diluted with water (150 ml.). The yellow solid precipitated was collected, dried, digested with benzene and filtered (filtrate A). The insoluble solid was recrystallized from chlorobenzene yielding all-trans isomer (XVIII) as yellow plates, m. p. 278~279.5°C, 1.15 g. (18%).

Found: C, 93.06; H, 6.64. Calcd. for $C_{25}H_{22}$: C, 93.37; H, 6.63%.

Filtrate A was chromatographed on alumina. Elution was carried out with light petroleum (b. p. 60~70°C), benzene-light petroleum (b. p. 60~70°C) and finally with benzene. The crude material obtained from the light petroleum eluate (150 ml.) was recrystallized three times from the same solvent to yield di-cis isomer (XX) as pale yellow fine needles, m. p. 120.5~121°C, 0.5 g. (8%).

Found: C, 93.06; H, 6.65. Calcd. for $C_{26}H_{22}$: C, 93.37; H, 6.63%.

Later fractions gave, on recrystallization from benzene-light petroleum, pure mono-cis isomer (XIX), as light yellow plates, m. p. 153~154°C, 1.2 g. (19%).

Found: C, 93.31; H, 6.83. Calcd. for $C_{26}H_{22}$: C, 93.37; H, 6.63%.

*The Nuclear Magnetic Resonance Spectra of Olefinic Protons and the Substituent Effects. I. Systems of ω-Substituted trans-Styrenes and 1-Substituted trans-Propenes**

By Hazime KASIWAGI and Jun NIWA

(Received October 31, 1962)

Concerning the dependence of the magnetic resonance of olefinic protons on various features of chemical structures, several investigations have been reported, beginning in 1960[1]. Most of them, however, have failed in their attempts to derive some kind of smooth correlation between shifts and the nature of the substituents. The remaining problems center on the point of inquiring how the deviation of the chemical shifts of olefinic protons from values predictable on the basis of Dailey and Shoolery's proposition, which holds generally in the spectra of protons attached to the SP^3 carbon atom[2], can be elaborated and made consistent with the substituent effects by virtue of Hammett's relationship[3].

The present authors confirmed previously, from an inspection of the proton resonance spectra of series of α- and β-substituted methyl cinnamates, that some trends of correlation exist between the shifts of protons situated in the trans-position to the substituents and Hammett's substituent constants**. This finding may indicate that, if an olefinic part of a series of compounds were constructed in such a way that it might conjugate with another resonating group, such as a benzene ring or a hyperconjugative methyl group, the protons of this part of the structure, even though they were essentially of an olefinic nature, would show a similar nuclear magnetic behavior to that of benzene ring protons[3,4]. Therefore, they would be subject to the controlling effect of the series of terminal substituents in the sense of Hammett's relationship. Taking these considerations into account, the authors have attempted to investigate the proton resonance spectra of series of ω-substituted *trans*-styrenes and 1-substituted *trans*-propenes. This paper reports on the correlation between the chemical shifts of the olefinic protons of the two series of compounds mentioned above and the effect of terminal substituents considered from the viewpoint of Hammett's relationship.

Experimental

The nuclear magnetic resonance spectra of ω-substituted-styrenes were obtained with a Varian 4300-B high resolution spectrometer operating at 56.4 Mc., while a spectrometer operating at 60 Mc. was used for obtaining the spectra of 1-substituted propenes. The sample was dissolved in carbon tetrachloride of a 10 mol. per cent concentration, having been sealed in a glass tube, 5 mm. in outside diameter, which was spun in the magnetic field during the measurement. The absorption lines were measured by relating them with the resonance line of 2 mol. per cent cyclohexane added as an internal reference, while the frequencies of the lines were confirmed by the side band technique of controlled frequencies.

All the compounds are of a trans-configuration, but the spectral inspection has shown that some of them are contaminated by a small amount of cis-isomer. The styrene derivatives are as follows: Styrene, ω-chlorostyrene, ω-bromostyrene, ω-nitrostyrene, cinnamonitrile, 1-phenylpropene, cinnamaldehyde, benzilideneacetone, cinnamoyl chloride, styryl acetate, methyl cinnamate, etc. Free cinnamic acid was also included. The synthesized compounds are of the following nature: ω-Nitrostyrene, m. p., 59~60°C; ω-chlorostyrene (cis), b. p., 199~199.5°C; n_D^{25} 1.5735, 1-phenylpropene, b. p., 73~75°C under 14 mmHg; styryl acetate, b. p., 103~104°C under 6 mmHg. The cinnamonitrile prepared through the dry distillation of a mixture of cinnamic acid and lead rhodanide was fractioned into two parts. Of the products distilled, the first became crystalline upon standing for a long time and melted at 10°C, but the second distillate never did crystallize. The rest of the compounds were commercially obtained and purified***. The examined derivatives of propene are as

follows : 1-Bromopropene (b. p., 59~60°C), 1-phenylpropene (already mentioned), crotonyl chloride (b. p., 124~125°C), methyl crotonate (b. p., 119~120°C), crotonaldehyde (b. p., 104~105°C), crotonitrile (b. p., 118~119°C) and 1-nitropropene (b. p., 94~95°C under 8 mmHg).

Results

The spectra of olefinic protons with regard to substituted styrenes belong to the simple AB-type, with the exception of those of styrene and cinnamaldehyde. Substituted propenes give the spectra corresponding to the system of 5 nuclei, ABX_3, and crotonaldehyde has a system of ABX_3Y. The chemical shifts obtained by analysis of the spectra are summarized in Table I. The coupling constants will be discussed later.

Discussion

Whipple et al. investigated the substituent effects on the chemical shifts of olefinic protons. They claim that, although the trends of the vinyl proton shifts in 2-substituted propenes are qualitatively consistent with inductive and mesomeric effects attributable to substituents, no precise correlation exists between the shifts and Hammett's constants for substituents[5].

Meanwhile Taft investigated to secure a correlation between the nuclear magnetic resonance shifts of fluorine atoms in mono- and di-substituted fluorobenzenes and Hammett's σ-constants. Taft found that the σ-value leads to a fairly good correlation with the fluorine nuclear shielding constants, $\delta^{F}{}_{m}$ and $\delta^{F}{}_{p}$[3]. The olefinic part in the system examined by Whipple et al. indeed conjugates with the methyl group, but this conjugation will be somewhat disintegrated by the introduction of a second substituent. Therefore, the direct application of the relationship advanced by Taft would not necessarily be suitable for the results obtained for systems of a poorer stabilization due to such cross-conjugation, and any correlations of σ_p would probably be missed. In the case of the compounds here investigated ($RCH_A=CH_BX$, R : C_6H_5 or CH_3), on the other hand, the olefinic bond conjugates not only with the aromatic ring or the methyl

group, but with substituent X in a uniform direction. Consequently, the olefinic proton, H_A, of these compounds seems to be shielded by substituent X in a sharper and more characteristic way than may be the case in the system of Whipple. It may be reasonable, therefore, to apply Hammett's relationship to the τ-values of H_A. It is true, on the other hand, that the influence of substituents on the resonance absorption may be subject also to the anisotropy of the magnetic susceptibility of bonding axes in substituent groups, the diamagnetic anisotropy arising from a long range shielding exerted by the benzene ring and other substituents. Indeed, Spiesecke and Schneider, who studied the resonance spectra of mono-substituted benzenes, assumed that the shifts due to ortho-protons are controlled by the polar nature of substituents as well as by the disturbing factors of the diamagnetic anisotropy of substituents and other magnetic effects[6]. The disturbing factors, however, may be seen as not very considerable from an inspection of Fig. 1, which illustrates that the shifts for ortho-protons correlate practically with those of para-protons, at least so far as the substituents, OCH_3, H, F, Cl, Br, CHO and NO_2, are concerned. This fact implies that the cis-proton chemical shifts in the ω-styrene and 1-propene systems are governed mainly by the polar substituent effects.

Figure 2 shows the relationship between the τ-values of H_A of these compounds and Hammett's constants, σ_p. The value of the resonance line of H_A in stilbene, adopted from Tiers' table, may be lowered by the long-range shielding effect of the benzene ring. As the lowering of the shift by the benzene ring, situated in the cis-position to H_A, is estimated as about 0.05 p. p. m., the τ-value of H_A may be corrected to 3.51 p. p. m.[7] In Fig. 2 the corrected value is used. The value observed with ω-chlorostyrene is tentatively assumed to be attributable to the cis-isomer, but the value may not differ considerably from that of trans-isomer[1]. As for the cinnamo- and crotonitriles, the cyano group exerts on the neighboring cis-proton, H_A, a positive shielding contribution due to the bond anisotropy around its triple bond axis[8]. In the case of crotonitrile, the magnitude of this diamagnetic shielding of the cis-proton has been calculated by Reddy et al. to be as much as +0.287 p. p. m., and that of the geminal proton, as +1.11 p. p. m.[9] In plotting the value of the H_A of cinnamonitrile, it is assumed that a positive shielding of the cyano group would give an exaggeration of about the same order as in the case of crotonitrile. The groups, $COCH_3$ and possibly CO_2CH_3, may have the same kind of anisotropic shielding effect. That an anisotropic shielding effect of some magnitude should not be ignored in computing the substituent effects

of halogens, may probably be illustrated from the departure of their plots from the correlation line in Fig. 2.

Generally, the decrease of free energy in the reactions of benzene derivatives changes under the influence of a substituent in such a way that the parameters of the inductive and resonance interactions, σ_I and σ_R, which are inherent to the substituent, may act independently of each other. Since the nuclear magnetic shielding is also supposed to be affected by these two parameters independently, as in the reactions of benzene derivatives, the shielding constants may be expressed by the equation of the general form, $\delta=\alpha\sigma_I+\beta\sigma_R$. The coefficients, α and β, are measures of the susceptibility with which the inductive and resonance influences are called upon to function. Taft has suggested that the relation of the proton shielding might best be described by the equation, $\delta_H=0.40\sigma_I+0.70\sigma_R$[3]. As is shown in Fig. 3, this equation is applicable to the data presented here with regard to styrene and l-propene derivatives. The linearity of its correlation with the observed shifts is a little improved compared with that obtained from σ_p alone. The σ_I and σ_R values and their combination according to Taft's equation are listed in Table II.

From the existence of a certain correlation between the cis-proton shifts of these olefinic compounds and Hammett's σ-values, the same kind of correlation may be expected among the shifts of those protons situated at the

corresponding positions of the systems which have a similar conjugation structure,—cis-proton shifts, here investigated, ortho-proton shifts of mono-substituted benzenes[6], and β-proton shifts of 4-substituted pyridine l-oxides[10]. In Fig. 4, the fairly clear correlations among them may be observed. This suggests that, in these systems, the modes of the transmittance of substituent effects are essentially similar. These modes would be not only peculiar to the benzene nucleus, but also inherent in the structures of carbon skeltons, which constitute the expanded conjugation systems with certain restricted conditions. To

the conditions correspond the constancy of the parameters, α and β.

Figures 5 and 6 illustrate the correlations of the chemical shifts of two sets of protons with each other for styrene and 1-propene derivatives. The former relates with those of cis-protons (H_A), and the latter, with those of geminal protons (H_B). It is clear that the correlation for cis-protons is excellent. Any straightforward correlation of geminal proton shifts has been discernible neither with the electronegativity of the first atom of substituents nor with Hammett's constants. The reasons for this will be clear from an observation of the two figures. It is worthy of brief mention, however, that the geminal proton shifts for compounds, the substituent of which is hydrogen itself, are located in the highest region of the field in both series. This probably arises form the lower electronegativity of hydrogen compared with that of the first atoms in other substituents.

Summary

High resolution proton magnetic resonance spectra of ω-substituted *tsans*-styrenes and 1-substituted *trans*-propenes have been observed and discussed from the viewpoint of substituent effects. The chemical shifts of protons located at the cis-position to substituents depend roughly upon Hammett's σ_p constants and presumably correlate better with the combination of potential inductive and resonance parameters, namely $0.40\,\sigma_I + 0.70\,\sigma_R$, proposed by Taft.

These results suggest that the chemical shifts of olefinic cis-proton may be computed from the viewpoint of the polar nature of the substituents, though the diamagnetic anisotropy and the long-range shielding effect of the substituents must be carefully considered side by side.

When the chemical shifts of protons situated at corresponding positions of structure in several systems are compared, a fairly good correlation is observed among them. This fact implies that the modes of the transmittance of substituent effects is similar in these systems.

The nature of the substituent effects on the chemical shifts of geminal protons is, however, very complicated and might be out of consonance with both the electronegativity and the available substituent parameters.

The authors wish to take this opportunity to thank Dr. Naoya Nakagawa of the University of Electro-Communications for his helpful discussions. Thanks are also due to Dr. Yô-ichirô Mashiko of the Government Chemical Industrial Research Institute, Professor Shizuo Fujiwara of The University of Tokyo, Dr. Kenkichi Nukada of the Basic Research Laboratories of Tôyô Rayon Co., Ltd., and Dr. Ichirô Yamaguchi of the Japan Atomic Energy Research Institute for kindly giving permission to use the spectrometers of those institutions.

The Nuclear Magnetic Resonance Spectra of Olefinic Systems and the Substituent Effects. II. Methyl Esters of α- or β-Substituted Cinnamic Acids

By Hazime KASIWAGI, Naoya NAKAGAWA* and Jun NIWA

(Received October 31, 1962)

In the preceding paper**, a study of the possibility of Hammett's relationship being applicable to the chemical shifts of olefinic protons in ω-substituted *trans*-styrenes and in 1-substituted *trans*-propenes was reported on. A tentative plotting of the shifts against Hammett's substituent constants showed that such an application was reasonable. In fact, the correlation between the shifts and a certain combination of the potential inductive and resonance parameters for the substituent, that is, $0.40\ \sigma_I + 0.70\ \sigma_R$[1], has been found to fit the purpose even better.

This paper is concerned with the proton magnetic resonance spectra of a series of methyl cinnamates which carry substituents at the α- or β-position. Its main purpose is to examine whether the trends of olefinic proton shifts with regard to these compounds may be represented by the same relationship applied to substituted styrenes and 1-propenes.

Experimental

A Varian 4300-B spectrometer operating at 56.4 Mc. was used for obtaining the spectra. Glass tubes 5 mm. in outside diameter, containing the sample solution of a 10 mol. per cent concentration in carbon tetrachloride, were spun in the magnetic field. The other conditions of measurement were stated in the preceding paper.

Samples. — *Methyl Cinnamate.* — Dry hydrogen chloride gas was passed through a solution of pure cinnamic acid in anhydrous methanol. The product was rectified under reduced pressure. M. p., 33°C.

Methyl α-Chlorocinnamate and Methyl α-Bromocinnamate. — Prior to esterification, each isomer mixture of free acids, which are synthesized from cinnamic acid, is separated into cis- and trans-acids by means of the poorer solubility of the potasium salt of the latter in a buffered ethanol solution[2]. *trans*-α-Chloroester. M.p., 33~34°C; *trans*-α-bromoester: B. p., 150~152°C under 9 mmHg.

Methyl α-Methylcinnamate.—The free acid was prepared through the condensation of benzaldehyde with methylmalonic acid and esterified[3]. M. p., 37~38°C.

Methyl α-Cyanocinnamate.—The free acid, melting at 180.5°C, was obtained by the condensation of benzaldehyde with sodium cyanoacetate. As the ester, melting at 90~90.5°C, is sparingly soluble in carbon tetrachloride, a solution of about a 2 mol. per cent concentration was used for the measurement.

Methyl β-Chlorocinnamate and Methyl β-Bromocinnamate[4]. — From the isomer mixture of free acids, obtained by means of the addition of hydrogen chloride or hydrogen bromide to phenylpropiolic acid, the trans-isomer was separated by means of its poorer solubility[2] and esterified. Chloroester: M. p., 22~4°C; bromoester: 58°C.

Methyl β-Methylcinnamate. — The corresponding acid was converted into its methyl ester. M. p., 27°C; b. p., 109°C under 4.5 mmHg.

Results and Discussion

The signals of olefinic protons in methyl cinnamates, $C_6H_5CH_A{=}CH_BCO_2CH_3$, and the compounds in which H_A or H_B is substituted for by the other substituent, X, are simple and are easily characterized. The estimated values of each signal are summarized in the Table I.

If styrene is assumed to be the reference compound in considering the substituent effects, the resonance of the olefinic proton will take place under the effects of both substituents, i. e., an invariable methoxycarbonyl and a variable X. The correlation of cis-proton shieldings with substituent effects, discussed in Part I, will hold also in the case of the proton situated at the trans-position to the substituent X. The chemical shifts of the trans-proton may be computed from the same data as were applied to the cis-proton and so are governed by the identical combination of inductive and resonance parameters, namely, $0.40\ \sigma_I + 0.70\ \sigma_R$[5]. In Fig. 1, the individual proton shift with regard to the α-compounds is plotted against the combined substituent constants just mentioned. When the trends

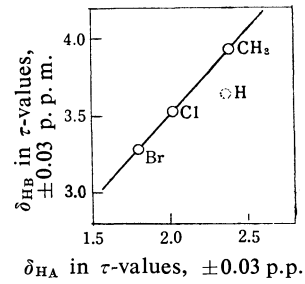

Fig. 2. The correlation of olefinic proton shifts between methyl esters of α- and β-substituted cinnamic acids.

are compared with the correlation line obtained with respect to ω-substituted styrenes, thier regularity, otherwise obscure, may become fairly clear. The introduction of a cyano group causes the proton shifts, here also, to move into a higher region of the field owing to the diamagnetic anisotropy of that group around its triple-bond axis. Reddy et al. have reported that the value of the exaggeration of the trans-proton chemical shift should amount to as much as 0.38 p. p. m. in acrylonitrile[6]. For plotting the proton shift for the cyano substituent, before being used the value is corrected by subtracting this magnitude. From an inspection of Fig. 1, it can be noticed that the plot for H_A in methyl cinnamate keeps a distance from the correlation line. The reason for this can easily be explained. In the case of methyl cinnamates with a substituent at the α-position, the substituent X, interfering with the benzene ring, gives rise to the rotation of the ring. Such a conformation would effectively alter the trends of correlation with substituent parameters originally obtained with the styrene system. Hence, the shift of H_A in methyl cinnamate itself should not be compared directly with proton shifts in other α-derivatives. The δ_{H_A} value for this compound would, then, deviate from the correlation line. This deviation is presumably reflected in Fig. 2, in which the proton chemical shifts for α- and β-substituted cinnamates are shown to correlate with each other, while for the value of hydrogen as the substituent X, the linear correlation does not hold. In β-substituted cinnamates the invariable substituent should be the phenyl group, as

6) G. S. Reddy, J. H. Goldstein and L. Mandell, *J. Am. Chem. Soc.*, **83**, 1300 (1961).

the proton H_B is under the influence of both the phenyl group and the variable substituent X, which are placed in the cis- and the trans-position respectively to the proton under consideration. Here the correlation occurs at a higher part of the figure than that for α-substituted cinnamates, largely because of the diminution of the long-range shielding contribution effected by the benzene ring in β-substituted cinnamates.

Summary

The proton magnetic resonance spectra with regard to methyl esters of α- or β-substituted cinnamic acids have been investigated from the viewpoint of the substituent effect. When the results are compared with the correlation obtained with ω-substituted styrenes, the trends are also explicable as being controlled by the polar nature of the substituents.

*The Distribution Function of Internal Displacement Coordinates in Linear XY_2 Molecules**

By Yonezo MORINO and Takao IIJIMA

(Received November 10, 1962)

Since the motion of atoms in a molecule is dependent on the interatomic force field, it must be of great help for understanding the physical significance of the potential field to consider the probability distribution function of the interatomic displacements. The calculation of the probability function is simple for a diatomic molecule which is treated as a one-dimensional oscillator. In this case the distribution of the interatomic displacements is described by a Gaussian function, if the interatomic potential is assumed to be a simple harmonic one. The effect of the cubic potential constant would be illustrated by resulting asymmetry of the distribution curve. In this work the distribution function is calculated for linear XY_2 molecules, and a schematical interpretation of intramolecular motion is presented by means of a distribution map. Numerical computation of the distribution map is carried out for carbon dioxide and carbon disulfide.

The Probability Distribution Function

The probability distribution function is given in a straight-forward manner by the vibrational wave functions expressed in terms of the normal coordinates,

$$P=\sum_{v} w_v \psi_v^* \psi_v \tag{1}$$

where w_v is the normalized Boltzmann factor of the v-th vibrational state**. The vibrational Hamiltonian of a linear XY_2 molecule consisting of the zeroth- and the first-order terms, is

$$H=H^{(0)}+H^{(1)} \tag{2}$$

where $H^{(0)}$ stands for the terms of the kinetic energy and the harmonic potential energy, while $H^{(1)}$ is given by

$$H^{(1)}=hc\,[k_{111}q_1^3+k_{122}q_1(q_{2a}^2+q_{2b}^2)+k_{133}q_1q_3^2] - \left(\frac{h}{\pi^2 c\omega_1 I}\right)^{1/2}\langle E_{\mathrm{rot}}\rangle q_1 \tag{3}$$

The first term of $H^{(1)}$ is the cubic part of the potential function and the second term is the energy decrease due to the centrifugal stretching, where $\langle E_{\mathrm{rot}}\rangle$ is the mean rotational energy of the molecule[1]. The quartic and higher-order terms of the potential function are ignored in the present treatment. The coordinates q's are dimensionless normal coordinates.

* A preliminary report of this work was presented at the International Conference on Magnetism and Crystallography, Kyoto, 1961.

** A set of quantum numbers designating the vibrational state is symbolically expressed by a single letter v.

1) Y. Morino and E. Hirota, This Bulletin, 31, 423 (1958).

The subscript 1 corresponds to the totally symmetric vibration, $2a$ and $2b$ to the doubly degenerate, and 3 to the antisymmetric vibration, respectively.

The wave function ψ_v is obtained by the first-order perturbation theory according to the equation

$$\psi_v=\psi_v^0-\sum_{v'}{}'\frac{\langle v'|H^{(1)}|v\rangle}{E_{v'}^0-E_v^0}\psi_{v'}^0 \tag{4}$$

as a linear combination of the zeroth-order wave functions ψ_v^0. All non-vanishing coefficients of $\psi_{v'}^0$ are calculated as shown in Appendix I, by substituting Eq. 3 for $H^{(1)}$. By the use of Eq. 4, Eq. 1 is rewritten as

$$P(q_1,q_{2a},q_{2b},q_3)=\sum w_v\psi_v^{0*}\psi_v^0 -\sum_v w_v\sum_{v'}{}'\frac{\langle v'|H^{(1)}|v\rangle}{E_{v'}^0-E_v^0}(\psi_v^{0*}\psi_{v'}^0+\psi_v^0\psi_{v'}^{0*}) \tag{5}$$

Since there hold the relations

$$\psi_v^0=\prod_s\psi_{v_s}^0(q_s), \qquad s=1,\ 2a,\ 2b \text{ and } 3$$

and

$$w_v=\prod_s \chi_s^{v_s}/\sum_{v_s}\chi_s^{v_s}, \left(\chi_s=\exp\left(-\frac{hc\omega_s}{kT}\right)\right)$$

every term of Eq. 5 can be calculated as a product of the summations over single vibrational quantum number. It should be mentioned that this type of calculation was performed by Reitan in his thesis[2], although his method of calculation seems to be a little more tedious than that of the present work. The essential part of the calculation is reported in Appendix II.

As the result of the calculation, we have

$$P(q_1,q_{2a},q_{2b},q_3)=N[1+a_1q_1+a_{111}q_1^3 +a_{122}q_1(q_{2a}^2+q_{2b}^2)+a_{133}q_1q_3^2] \times\exp\left[-\frac{q_1^2}{T_1}-\frac{(q_{2a}^2+q_{2b}^2)}{T_2}-\frac{q_3^2}{T_3}\right] \tag{6}$$

$$T_s=\coth(hc\omega_s/2kT)$$

with the following expressions for the coefficients;

$$a_1=-\frac{2k_{111}}{\omega_1}\left(\frac{1-\chi_1}{1+\chi_1}\right)^2 +\frac{4k_{122}\omega_2\gamma_{122}{}^+}{\omega_1(1+\chi_1)(1-\chi_2)(1+\chi_2)} +\frac{2k_{133}\omega_3\gamma_{133}{}^+}{\omega_1(1+\chi_1)(1-\chi_3)(1+\chi_3)}+\frac{2\langle E_{\rm rot}\rangle}{b_1T_1f_{11}r_e} \tag{7a}$$

$$a_{111}=-\frac{2k_{111}(1-\chi_1)(1+10\chi_1+\chi_1^2)}{3\omega_1(1+\chi_1)^3} \tag{7b}$$

$$a_{122}=-\frac{2k_{122}}{(1+\chi_1)(1+\chi_2)^2}\left\{\frac{2\chi_2(1-\chi_1)}{\omega_1}-\gamma_{122}{}^-\right\} \tag{7c}$$

$$a_{133}=-\frac{2k_{133}}{(1+\chi_1)(1+\chi_3)^2}\left\{\frac{2\chi_3(1-\chi_1)}{\omega_1}-\gamma_{133}{}^-\right\} \tag{7d}$$

and

$$\gamma_{1ss}{}^{\pm}=\left\{\frac{-1+\chi_1\chi_s{}^2}{\omega_1+2\omega_s}\pm\frac{-\chi_1+\chi_s{}^2}{\omega_1-2\omega_s}\right\} \tag{7e}$$

where b_1 is designated by Eq. 9, and f_{11} is the force constant for the symmetric stretching vibration.

Because of the accidental degeneracy of ω_1 and $2\omega_2$, the second term of Eq. 7e would fail to be a good approximation. It will, however, be shown in Appendix III that the same expression can be used without any serious error even in the case of strong degeneracy.

The distribution function in terms of the normal coordinates is converted to the expression in terms of Δz_1, Δz_2 and $\Delta\rho$, the internal Cartesian displacements; Δz denotes the relative displacements of the atom X to Y along the molecular axis and $\Delta\rho$ is the relative displacement perpendicular to the axis. $\Delta\rho^2$ is sometimes written as $\Delta x^2+\Delta y^2$. The displacements of the two X—Y atom-pairs are designated by Δz_1 and Δz_2, respectively.

These internal coordinates are related to the normal coordinates by the following relations,

$$\Delta z_1=b_1q_1+b_3q_3 \tag{8a}$$

$$\Delta z_2=b_1q_1-b_3q_3 \tag{8b}$$

and

$$\Delta\rho^2=b_{22}(q_{2a}{}^2+q_{2b}{}^2) \tag{8c}$$

The coefficients b's are given by

$$b_1=\left(\frac{h\mu_Y}{8\pi^2c\omega_1}\right)^{1/2} \tag{9a}$$

$$b_3=\left[\frac{h}{8\pi^2c\omega_3}(\mu_Y+2\mu_X)\right]^{1/2} \tag{9b}$$

and

$$b_{22}=\frac{h}{8\pi^2c\omega_2}(\mu_Y+2\mu_X) \tag{9c}$$

where μ_X and μ_Y are the reciprocal masses of the atom X and Y, respectively.

By these relations together with the followings,

$$q_{2a}=b_{22}{}^{-1/2}\Delta\rho\cos\varphi \tag{10a}$$

$$q_{2b}=b_{22}{}^{-1/2}\Delta\rho\sin\varphi \tag{10b}$$

where φ is the azimuthal angle, the probability distribution function $P(q_1,q_{2a},q_{2b},q_3)$ is transformed to the expression in terms of Δz_1, Δz_2, $\Delta\rho$ and φ, as

2) A. Reitan, thesis, Institutt for Teoretiske Kjemi, Norges Tekniske Høgskole (1958).

$$P(\Delta z_1, \Delta z_2, \Delta\rho, \varphi) = N\left[1+\frac{a_1}{2b_1}(\Delta z_1+\Delta z_2) + \frac{a_{111}}{(2b_1)^3}(\Delta z_1+\Delta z_2)^3 + \frac{a_{122}}{2b_1b_{22}}\Delta\rho^2(\Delta z_1+\Delta z_2) + \frac{a_{133}}{2b_1(2b_3)^2}(\Delta z_1+\Delta z_2)(\Delta z_1-\Delta z_2)^2\right] \times \Delta\rho \exp\left[-\frac{\Delta\rho^2}{b_{22}T_2}-\frac{(\Delta z_1+\Delta z_2)^2}{(2b_1)^2T_1} - \frac{(\Delta z_1-\Delta z_2)^2}{(2b_3)^2T_3}\right] \quad (11)$$

In order to obtain a two-dimensional probability function $P(\Delta z, \Delta\rho)$, Eq. 11 is integrated over φ and over either one of Δz_1 and Δz_2. The calculation leads to the following result;

$$P(\Delta z, \Delta\rho) = N'\left[1+A_1\Delta z+A_{111}\Delta z^3+A_{122}\Delta z\Delta\rho^2\right] \times \Delta\rho \exp\left[-\frac{\Delta\rho^2}{\langle\Delta\rho^2\rangle}-\frac{\Delta z^2}{2\langle\Delta z^2\rangle}\right] \quad (12)$$

where

$$A_1 = \frac{a_1b_1T_1}{2\langle\Delta z^2\rangle} + \frac{3a_{111}b_1T_1b_3^2T_3}{8\langle\Delta z^2\rangle^2} + \frac{a_{133}b_1T_1T_3(b_1^2T_1-2b_3^2T_3)}{8\langle\Delta z^2\rangle^2} \quad (13a)$$

$$A_{111} = \frac{a_{111}b_1^3T_1^2}{8\langle\Delta z^2\rangle^3} + \frac{a_{133}b_1T_1b_3^2T_3^2}{8\langle\Delta z^2\rangle^3} \quad (13b)$$

$$A_{122} = \frac{a_{122}b_1T_1T_2}{2\langle\Delta z^2\rangle\langle\Delta\rho^2\rangle} \quad (13c)$$

and

$$\langle\Delta z^2\rangle = \frac{b_1^2T_1+b_3^3T_3}{2} \quad (13d)$$

$$\langle\Delta\rho^2\rangle = b_{22}T_2 \quad (13e)$$

It is noted that $P(\Delta z, \Delta\rho)$ describes the relative motion of the end atom Y to the central atom X, the coordinate axes Δz and $\Delta\rho$ being fixed on the rotating plane defined by the triangle Y—X—Y.

The Probability Distribution Function of the Interatomic Distances r_{XY} and r_{YY}

The distribution function $P(\Delta z, \Delta\rho)$ given by Eq. 12 is further transformed to a one-dimensional distribution function in terms of

Δz / $\Delta\rho$

the instantaneous displacement of the interatomic distance δr_{XY}. In this case, the transformation is not linear but it is given by

$$\delta r_{XY} = \Delta z + \Delta\rho^2/2r_e + \cdots\cdots, \quad (\delta r = r - r_e) \qquad (14)$$

to the first-order of approximation. The calculation leads to the result

$$P(r_{XY}) = \frac{1}{(2\pi\langle\delta r^2\rangle)^{1/2}}\left\{1+\left(A_1 + A_{122}\langle\Delta\rho^2\rangle + \frac{\langle\Delta\rho^2\rangle}{2r_e\langle\delta r^2\rangle}\right)\delta r + A_{111}\delta r^3\right\}\exp\left(-\frac{\delta r^2}{2\langle\delta r^2\rangle}\right) \qquad (15)$$

where A's are defined by Eq. 13's.

It is seen that asymmetry is introduced into the Gaussian function by linear and cubic terms of δr. The $P(r)$ function is important in the study of electron diffraction by gaseous molecules, because it is closely connected with the molecular intensity curve and the radial distribution curve obtained by the diffraction study[3]. The empirical asymmetric parameters determined by the analysis of the radial distribution curve will be related to the spectroscopic force constants through this equation. It is accordingly expected that better interpretation of the radial function will be attainable on the basis of intramolecular force field.

The distribution function for the Y—Y distance is calculated more simply, because the transformation is linear as shown below;

$$\delta r_{YY} = \Delta z_1 + \Delta z_2 = 2b_1 q_1 \qquad (16)$$

The $P(r_{YY})$ is therefore obtained from Eq. 6 through integration over q_{2a}, q_{2b} and q_3, as

$$P(r_{YY}) = \frac{1}{(2\pi\langle\delta r^2\rangle)^{1/2}}\{1 + A'_1\delta r + A'_{111}\delta r^3\} \times \exp\left(-\frac{\delta r^2}{2\langle\delta r^2\rangle}\right) \qquad (17)$$

with

cubic potential constants k and the linear and cubic coefficients A of $P(\Delta z, \Delta\rho)$ obtained. The schematic diagrams of $P(\Delta z, \Delta\rho)$ are computed with an arbitrary normalizing-factor and arranged in rows so as to make correspondence to the point specified by the coordinates $(\Delta z, \Delta\rho)$, as seen in Figs. 1a and 1b. The contour lines are drawn on the diagrams, and the distribution maps thus obtained are shown in Fig. 2a for CO_2 and in Fig. 2b for CS_2, respectively.

These maps illustrate the relative motion of the end atom Y to the central atom X. The Δz axis lies on the equilibrium molecular axis. The point specified by $\Delta z=0$ and $\Delta\rho=0$ is the equilibrium position of the Y atom. The location of the atom X is far down out of the figures in the negative direction, specified by $\Delta z=-r_e$ and $\Delta\rho=0$.

It is easily seen in the diagrams of $P(\Delta z, \Delta\rho)$ that in the region of small $\Delta\rho$, the outer region of Δz is more favorable, and the inner region of Δz becomes more favorable as $\Delta\rho$ increases. This is caused by the negative contribution of the coupling term between bending and stretching, or A_{122}, to the distribution function. This general tendency of the probability distribution corresponds to a classical picture of the bending motion that the two X—Y bonds are bent at the central atom and the end atom Y moves along a circular locus which is slightly shifted outwards by the stretching anharmonicity.

It may be accordingly suggested that the intramolecular potential can be described better

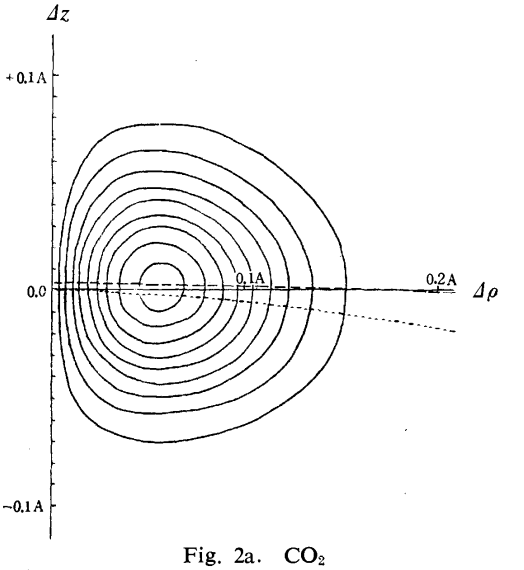

Fig. 2a. CO_2

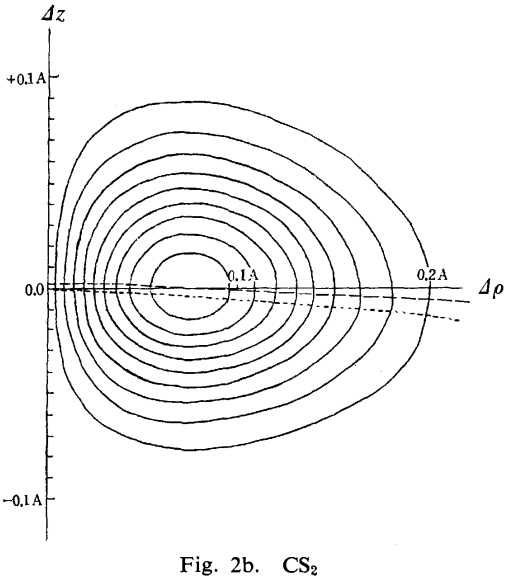

Fig. 2b. CS_2

Fig. 2. Contour map of the probability-distribution.

—— shows the ridge
- - - is the circular locus drawn by keeping the X—Y distance constant

and more simply in terms of internal coordinates, i.e., the bond-stretching δr and the bending angle $\delta\rho$, rather than in terms of Cartesian coordinates. The force constants for the expression of the potential energy in terms of the internal coordinates are expected to have more distinct physical significance and therefore to be transferable among the chemical bonds of the same kind. An extensive study on the anharmonic force constants has been carried out along this line, and it was found that the most part of the constant k_{122} comes from the quadratic stretching force constants through coordinate transformation[4].

A more careful examination of the distribution map reveals that according as $\Delta\rho$ increases, the ridge in the map runs more and more outwards than the circular locus which is drawn by keeping the X—Y distance constant. In other words, it is easier for a bond to stretch when the bending motion takes place. Such an interaction term as $L_3\delta r\delta\alpha^2$ with a negative value of L_3, is therefore expected to improve the description of the intramolecular potential field. As a matter of fact, the predicted value of k_{122} was found to be in complete agreement with the observed value by introducing $L_3=-0.5$ md./A for CO_2, in addition to the main contribution from the quadratic stretching constants; while a smaller value $L_3=-0.1$ md./A is necessary to get the agreement for CS_2[4], corresponding to the fact that the extent of the outward shift is seen to be more appreciable in the case of CO_2 than CS_2.

The authors wish to express their gratitude to Professor Hidetoshi Takahashi and his coworkers, in the Department of Physics, for the use of PC-2 computer. They are indebted to the Ministry of Education of Japan for the research grant.

$v_1-1,\ v_s-2,\ v_{s'}$	$-\dfrac{k_{1ss}}{\omega_1+2\omega_s}\left(\dfrac{v_1}{2}\right)^{1/2}\dfrac{[v_s(v_s-1)]^{1/2}}{2}$

Appendix II. Calculation of the Summation over Vibrational States

It is easily shown that the summations over vibrational states appearing in Eq. 5 can be reduced to the products of some of the following summations:

$$F_0=\sum_v w_v\,|\phi_v^0|^2$$

$$F_1=\sum_v w_v\left(\frac{v+1}{2}\right)^{1/2}\phi_{v+1}^0\phi_v^0$$

$$F_2=\sum_v w_v\left[\frac{(v+1)^3}{8}\right]^{1/2}\phi_{v+1}^0\phi_v^0$$

$$F_3=\sum_v w_v[(v+1)(v+2)]^{1/2}\phi_{v+2}^0\phi_v^0$$

$$F_4=\sum_v w_v\left[\frac{(v+1)(v+2)(v+3)}{8}\right]^{1/2}\phi_{v+3}^0\phi_v^0$$

where ϕ_v^0 is a non-perturbed wave function of a harmonic oscillator with the vibrational quantum number v.

As well known F_0 is given by[5,6],

$$F_0=\pi^{1/2}\left[\tanh\frac{hc\omega}{2kT}\right]^{1/2}\exp\left[-\left(\tanh\frac{hc\omega}{2kT}\right)q^2\right] \qquad \text{(AII-1)}$$

By the use of the recursion formula,

$$\phi_{v+1}^0=\left(\frac{2}{v+1}\right)^{1/2}q\phi_v^0-\left(\frac{v}{v+1}\right)^{1/2}\phi_{v-1}^0$$

F_1 is rewritten as,

4) K. Kuchitsu, T. Iijima and Y. Morino, International Symposium on Molecular Structure and Spectroscopy, Tokyo, Japan, 1962.

5) F. Bloch, *Z. Phys.*, 73, 295 (1932).

6) Series of Modern Physics; "Statistical Mechanics", Iwanami Co., Ltd., Tokyo (1955), p. 212.

$$F_1=q\sum_v w_v\psi_v{}^0\psi_v{}^0-\chi\sum_v w_{v-1}\left(\frac{v}{2}\right)^{1/2}\psi_v{}^0\psi_{v-1}{}^0$$
$$=qF_0-\chi F_1$$

where

$$\chi=\exp\left(-\frac{hc\omega}{kT}\right)$$

Therefore we have,

$$F_1=\frac{1}{1+\chi}qF_0 \qquad \text{(AII-2)}$$

Similarly,

$$F_2=\sum_v w_v\left(\frac{v+1}{2}\right)q\psi_v{}^0\psi_v{}^0-\sum_v w_v\left(\frac{v+1}{2}\right)\left(\frac{v}{2}\right)^{1/2}$$
$$\times\psi_v{}^0\psi_{v-1}{}^0=\frac{q}{2}G+\frac{q}{2}F_0-\chi F_2-\frac{1}{2}\chi F_1$$

Therefore,

$$F_2=\frac{1}{1+\chi}\left(\frac{1}{2}qG+\frac{1}{2}qF_0-\frac{1}{2}\chi F_1\right) \qquad \text{(AII-3)}$$

where

$$G=\sum_v w_v v\psi_v{}^0\psi_v{}^0$$
$$=-\frac{1}{\sum_v\chi^v}\frac{\partial}{\partial\left(\frac{hc\omega}{kT}\right)}[F_0\cdot\sum_v\chi^v]$$
$$=\left\{\frac{\chi^2}{1-\chi^2}+\frac{2\chi}{(1+\chi)^2}q^2\right\}F_0 \qquad \text{(AII-4)}$$

Inserting Eqs. AII-2 and AII-4 into AII-3, we have,

$$F_2=\frac{1}{1+\chi}\left[\frac{1-\chi+\chi^2}{2(1-\chi^2)}q+\frac{\chi}{(1+\chi)^2}q^3\right]F_0$$

and

$$F_3=2qF_1-G-F_0=\left\{-\frac{1}{1-\chi^2}+\frac{2}{(1+\chi)^2}q^2\right\}F_0$$

$$F_4=\frac{1}{2}qF_3-F_2-\frac{1}{2}F_1$$
$$=\frac{1}{1+\chi}\left\{-\frac{3}{2(1-\chi^2)}q+\frac{1}{(1+\chi)^2}q^3\right\}F_0$$

Appendix III. The Effect of Fermi Resonance on the Probability Distribution Function

In order to simplify the discussion, let us consider a resonance between state I ($v_1=1$, $v_2=0$) and state II ($v_1=0$, $v_2=2$), connected by a coupling term $hck_{122}q_1q_2^2$, and calculate the probability distribution function $P=w_1|\psi_I|^2+w_2|\psi_{II}|^2$, both by an ordinary first-order perturbation treatment and more rigorously by solving the secular determinant.

As the result of the first-order treatment, we have the perturbed wave functions as

$$\psi_I=\psi_{10}{}^0-a_{20}\psi_{20}{}^0-a_{22}\psi_{22}{}^0-a_{00}\psi_{00}{}^0-a_{02}\psi_{02}{}^0$$

and

$$\psi_{II}=\psi_{02}{}^0-a_{12}\psi_{12}{}^0-a_{14}\psi_{14}{}^0-a_{10}\psi_{10}{}^0$$

where

$$a_{20}=\frac{k_{122}}{2\omega_1},\qquad a_{12}=\frac{3k_{122}}{2\sqrt{2}\,\omega_1}$$

$$a_{22}=\frac{k_{122}}{\sqrt{2}\,(\omega_1+2\omega_2)},\qquad a_{14}=\frac{\sqrt{3}\,k_{122}}{\sqrt{2}\,(\omega_1+2\omega_2)}$$

$$a_{00}=-\frac{k_{122}}{2\sqrt{2}\,\omega_1},\qquad a_{10}=\frac{k_{122}}{2(\omega_1-2\omega_2)}$$

$$a_{02}=-\frac{k_{122}}{2(\omega_1-2\omega_2)}$$

These wave functions are expressed more simply as

$$\psi_I=\psi_{10}{}^{(1)}-a_{02}\psi_{02}{}^0$$

and

$$\psi_{II}=\psi_{02}{}^{(1)}-a_{10}\psi_{10}{}^0$$

where $\psi^{(1)}$ includes all terms except for the term having a resonance denominator.

Accordingly we have,

$$P=w_1{}^0|\psi_{10}{}^{(1)}|^2+w_2{}^0|\psi_{02}{}^{(1)}|^2+\frac{w_1{}^0-w_2{}^0}{\omega_1-2\omega_2}k_{122}\psi_{10}{}^0\psi_{02}{}^0 \qquad \text{(AIII-1)}$$

$$w_1{}^0=\exp\left(-\frac{hc\omega_1}{kT}\right),\qquad w_2{}^0=\exp\left(-\frac{2hc\omega_2}{kT}\right)$$

On the other hand, in a rigorous treatment, we consider the wave functions ψ_I and ψ_{II} to be expressed as

$$\psi_I=a\psi_{10}{}^{(1)}+b\psi_{02}{}^{(1)}$$
$$\psi_{II}=b\psi_{10}{}^{(1)}-a\psi_{02}{}^{(1)}$$

by the linear combinations of $\psi_{10}{}^{(1)}$ and $\psi_{02}{}^{(1)}$ which include contributions from non-resonant states as defined above. The secular determinant is established as*,

$$\begin{vmatrix}\omega_1-E & k_{122}/2\\ k_{122}/2 & 2\omega_2-E\end{vmatrix}=0$$

As a solution of the determinant, we have,

---

* This secular determinant is not correct for the case of linear XY_2 type molecules, because the ω_2 normal vibration is doubly degenerate. By denoting two degenerate modes as ω_{2a} and ω_{2b}, we have to diagonalyse the energy matrix consisting of the elements among three states, ($v_1=1$, $v_{2a}=0$, $v_{2b}=0$), ($v_1=0$, $v_{2a}=2$, $v_{2b}=0$) and ($v_1=0$, $v_{2a}=0$, $v_{2b}=2$), where the perturbation term is $hck_{122}q_1(q_{2a}{}^2+q_{2b}{}^2)$.

The secular determinant is,

$$\begin{vmatrix}2\omega_2-E, & k_{122}/2, & 0\\ k_{122}/2, & \omega_1-E, & k_{122}/2\\ 0 & k_{122}/2, & 2\omega_2-E\end{vmatrix}=0$$

Therefore we have,

$$E_1=\omega_1+\varepsilon$$
$$E_2=2\omega_2-\varepsilon$$
$$E_3=2\omega_2$$

where

$$\varepsilon=\frac{1}{2}\{-\delta+(\delta^2+2k_{122}{}^2)^{1/2}\}$$

and

$$\psi_1=a\psi_{100}+b\left(\frac{1}{\sqrt{2}}\psi_{020}+\frac{1}{\sqrt{2}}\psi_{002}\right)$$
$$\psi_2=b\psi_{100}-a\left(\frac{1}{\sqrt{2}}\psi_{020}+\frac{1}{\sqrt{2}}\psi_{002}\right)$$
$$\psi_3=\frac{1}{\sqrt{2}}\psi_{020}-\frac{1}{\sqrt{2}}\psi_{002}$$

with

$$a=\frac{k_{122}}{(2\varepsilon^2+k_{122}{}^2)^{1/2}},\qquad b=\frac{\sqrt{2}\,\varepsilon}{(2\varepsilon^2+k_{122}{}^2)^{1/2}}$$

$$E_{\mathrm{I}}=\omega_1+\varepsilon$$

$$E_{\mathrm{II}}=2\omega_2-\varepsilon$$

where

$$\varepsilon=\frac{1}{2}\{-\delta+(\delta^2+k_{122}{}^2)^{1/2}\}$$

and

$$\delta=\omega_1-2\omega_2$$

$$a=\frac{k_{122}}{(4\varepsilon^2+k_{122}{}^2)^{1/2}},\qquad b=\frac{2\varepsilon}{(4\varepsilon^2+k_{122}{}^2)^{1/2}}$$

The probability distribution function is rewritten as

$$P=w_1|\psi_{\mathrm{I}}|^2+w_2|\psi_{\mathrm{II}}|^2$$
$$=(w_1a^2+w_2b^2)\,|\psi_{10}{}^{(1)}|^2+(w_1b^2+w_2a^2)\,|\psi_{02}{}^{(1)}|^2$$
$$+2(w_1-w_2)ab\psi_{10}{}^{(1)}\psi_{02}{}^{(1)}$$

The term $w_1a^2+w_2b^2$ can be replaced by $w_1{}^0$, since $w_1\cong w_2\cong w_1{}^0$ and $a^2+b^2=1$. Similarly we have $w_1b^2+w_2a^2=w_2{}^0$. In the third term, $\psi_{10}{}^{(1)}\psi_{02}{}^{(1)}$ can be approximated by $\psi_{10}{}^0\psi_{02}{}^0$. Thus we have

$$P=w_1{}^0|\psi_{10}{}^{(1)}|^2+w_2{}^0|\psi_{02}{}^{(1)}|^2+2(w_1-w_2)ab\psi_{10}{}^0\psi_{02}{}^0 \qquad \text{(AIII-2)}$$

The zeroth-order term $w_1{}^0|\psi_{10}{}^{(1)}|^2+w_2{}^0|\psi_{02}{}^{(1)}|^2$ is just equal to the corresponding expression in Eq. AIII-1.

In the case of weak resonance, i.e., $|\delta|\gg k_{122}$, we have

$$2(w_1-w_2)ab\cong(w_1{}^0-w_2{}^0)k_{122}/\delta$$

which is equivalent to the resonance-term of Eq. AIII-1.

In the case of strong degeneracy, i.e., $|\delta|\ll k_{122}$,

$$2(w_1-w_2)ab\cong-\frac{hck_{122}}{\boldsymbol{kT}}\exp\left(-\frac{hc\omega_1}{\boldsymbol{kT}}\right) \qquad \text{(AIII-3)}$$

because,

$$2ab=1$$

and

$$w_1-w_2=-\frac{2hc\varepsilon}{\boldsymbol{kT}}\exp\left(-\frac{hc\omega_1}{\boldsymbol{kT}}\right)$$

where $\varepsilon=k_{122}/2$. On the other hand, the resonance term of Eq. AIII-1 yields in the limit of $\delta\to0$,

$$\lim_{\delta\to0}\frac{w_1{}^0-w_2{}^0}{\delta}k_{122}=-\frac{hck_{122}}{\boldsymbol{kT}}\exp\left(-\frac{hc\omega_1}{\boldsymbol{kT}}\right)$$

which is equal to Eq. AIII-3. This result seems to make sure the validity of Eq. AIII-1 even in the case of strong degeneracy.

The ratio of the resonance-term of Eq. AIII-1 to that of Eq. AIII-2 is evaluated at several values of δ, in the case of $k_{122}=50\,\mathrm{cm}^{-1}$. As shown in Table II, no appreciable discrepancy is found between the numerical values of the two expressions throughout the whole region of δ. Therefore, it seems most likely that the probability distribution function obtained in this article holds to a good approximation even in the case of an accidental degeneracy, although complicated manipulation of the summation over upper vibrational states have not been performed in this supplementary note.

Kinetics of the Acid-Catalyzed Decomposition of Trimeric Acetone Peroxide

By Yoshiaki FURUYA and Yoshiro OGATA

(Received November 24, 1962)

Both dimeric and trimeric acetone peroxides explode violently on shock, but they are considerably stable in a solution of organic solvents. In the presence of strong acids, however, these peroxides decompose comparatively fast. Thus far the kinetics of the decomposition of acetone peroxide in solutions have not yet been studied. The present report summarizes our investigation on the kinetics of the sulfuric acid-catalyzed decomposition of trimeric acetone peroxide in acetic acid.

Experimental

Materials. — Trimeric acetone peroxide (abbreviated as TAPO) was prepared by Wolffenstein's method[1] by the reaction of acetone with aqueous hydrogen peroxide containing a small amount of phosphoric acid as catalyst for two or three weeks, and the obtained product was recrystallized from methanol and then from ether, m. p. 97°C, the yield was 80.4%.

1) K. Wolffenstein, *Ber.*, **28**, 2265 (1895).

The Criterion of the Reaction Products.—Trimeric acetone peroxide was dissolved in acetic acid containing a known amount of sulfuric acid. The solution was kept standing at 30°C for 30 min.; the solution of the reaction mixture was developed with a mixture of diethyl ether and ethyl acetate (1 : 4 $^{v}/_{v}$) on Toyo Filter Paper No. 54 which was preliminarily treated with a mixture of acetic acid (300 g.), acetic anhydride (80 g.) and zinc chloride (20 g.)[2]. A pink spot was observed by spraying with methanolic solution of 3% *p*-dimethylaminoaniline dihydrochloride. The value of R_f was found to be 0.77, which corresponded to that of peroxyacetic acid.

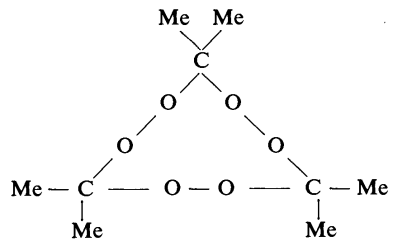
Produced peroxyacetic acid liberated iodine from potassium iodide instantaneously, while the acetone peroxide and acetyl peroxide reacted with aqueous potassium iodide very slowly as shown in Table I; hence peroxyacetic acid could be estimated by iodometry. Aliquots (each 5 ml.) of the reaction solution were poured into 100 ml. of an ice-cooled aqueous solution containing ca. 0.1% potassium iodide, iodine liberated by the reaction with peroxyacetic acid being titrated with 0.01 N sodium thiosulfate.

A solution of 0.005 M TAPO in acetic acid containing 0.18 N sulfuric acid was kept standing for one hour and it was confirmed that the reaction was complete after one hour. Acetone formed by decomposition of TAPO was detected and estimated by gas chromatography. The blank test showed that the concentration of acetone in acetic acid was proportional to the corresponding chromatogram area.

TABLE I. THE RATE OF REACTION OF TAPO (5 ml. OF 0.005 M SOLUTION) WITH AQUEOUS POTASSIUM IODIDE EXPRESSED AS THE CONSUMPTION OF 0.01 N SODIUM THIOSULFATE SOLUTION

Time, min.	2	3	7	13	∞
Consumed 0.01 N $Na_2S_2O_3$, ml.	0.03	0.03	0.13	0.20	14.96

The concentrations of peroxyacetic acid and acetone in two samples taken out from a reaction solution at the same time were found to be 0.0138 and 0.0132 M, respectively; hence it is reasonable that the decomposition of TAPO gives the same molar concentrations of peroxyacetic acid and acetone. Therefore, the stoichiometric equation of this acid-catalyzed decomposition may be written as follows:



$$+3CH_3CO_2H \xrightarrow{H_2SO_4} 3CH_3COCH_3+3CH_3CO_3H$$

2) J. Janoušek, *Faserforsch. u. Textiltech.*, 8, 339 (1957).

A Typical Run for the Rate Measurements.—After a solution of 49 ml. of 0.0051 M TAPO in acetic acid in a stoppered flask had attained the temperature equilibrium at 20°C, the reaction was started by the addition of 1 ml. of 9 N sulfuric acid in acetic acid. Aliquots (each 5 ml.) were taken out at appropriate time intervals and each aliquot was poured into an ice-cooled 100 ml. solution of ca. 0.1% potassium iodide. Iodine liberated by peroxyacetic acid was quickly titrated with 0.01 N sodium thiosulfate solution to estimate the concentration of peroxyacetic acid.

Results and Discussion

The rate followed the first-order equation with TAPO, although a short induction period was observed, especially when the reaction was slow. The first-order rate constants were shown in Table II. The plot of log k vs. acidity function H_0 gave a straight line with a slope of −1.12 as shown in Fig. 1. The energy of activation was calculated to be 19.14

TABLE II. THE RATE CONSTANTS FOR THE DECOMPOSITION OF TAPO TO PEROXYACETIC ACID IN ACETIC ACID WITH VARYING INITIAL CONCN. OF TAPO AT 20°C WITH ACIDITY FUNCTION OF −1.55

Initial concn. of TAPO, M	3×10^{-3}	5×10^{-3}	7×10^{-3}	10×10^{-3}
$k\times10^4$ sec^{-1}	3.99	3.93	4.05	4.07

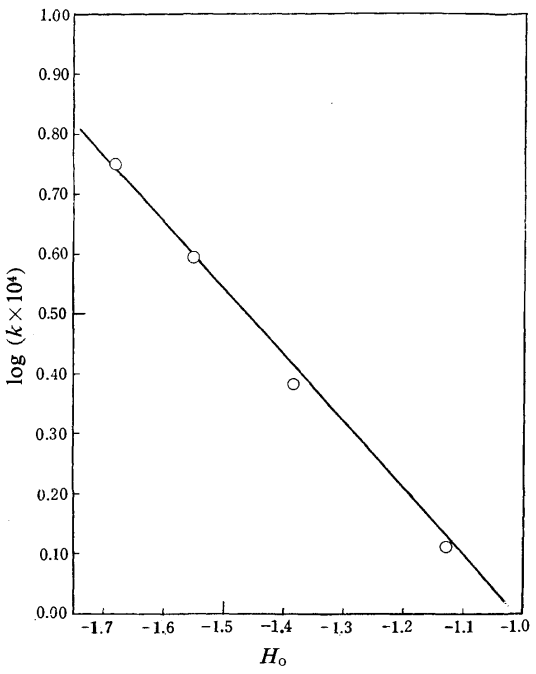


Fig. 1. The plots of log k *vs.* H_0 for the decomposition of TAPO in acetic acid at 20°C.
Initial concn. of TAPO: 5×10^{-3} M

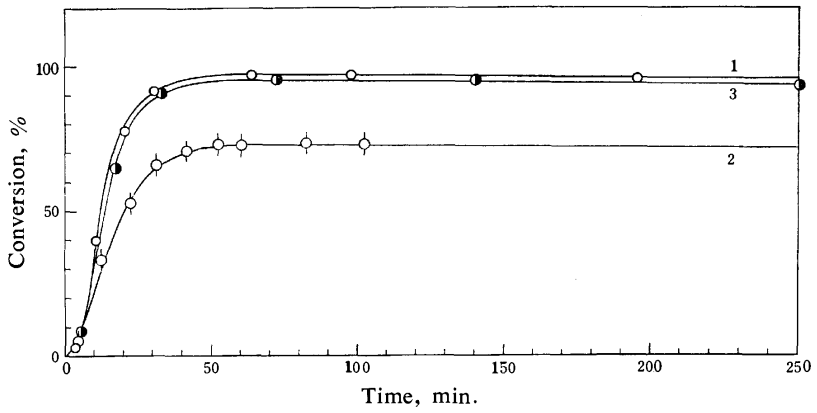

Fig. 2. A typical run for the reaction of TAPO in acetic acid at 30°C.

	Initial concn. of TAPO, M	Concn. of H_2SO_4, N	Concn. of added acetone, M
1	0.005	0.18	—
2	0.05	0.18	—
3	0.005	0.18	0.015

kcal./mol. from the average values of $k\times10^4$ sec^{-1} at 20°C, 1.29; at 25°C, 2.53; at 30°C, 3.88 and at 35°C, 6.99 in a solution with acidity function of −1.13.

Since the reaction has an induction period, it may be autocatalytic or consecutive. If the reaction were autocatalytic, the reaction would be accelerated on addition of the decomposition products or reaction mixture, but this was not observed; i. e., peroxyacetic acid, acetone or reaction mixture did not promote the reaction. Furthermore, the induction period was not affected by the addition of either trinitrobenzene, *p*-benzoquinone or Fenton's reagent. Therefore, these radical sources or radical-trapping agents do not seem to play an important role at least in the early stages of this decomposition reaction, but it is propable that the reaction is consecutive and it may go by way of any metastable intermediate.

It is of interest to note that an increase of the initial concentration of TAPO resulted in a decrease of the ultimate yield of peroxyacetic acid. For example, two solutions with initial concentrations of 0.005 M and 0.05 M TAPO, each containing 0.18 N sulfuric acid, were kept standing for 60~100 min. at 30°C until no production of peroxyacetic acid was observed. The amount of acetone in this resulting solution was estimated by gas chromatography, which showed that the reaction, irrespective of the concentration of TAPO, was 100% complete. But the amount of peroxyacetic acid measured iodometrically was only 74.0% of the theoretical with a solution of 0.05 M TAPO, while a solution of 0.005 M TAPO gave 97.0%. This phenomenon is not due to the reversibility of the reaction, since the "apparent equilibrium constants" calculated varied considerably with the change of the concentration of TAPO and added acetone, as shown in Table III, and the addition of acetone had no effect on the rate as obvious in Fig. 2.

TABLE III. THE VARIATION OF "APPARENT EQUILIBRIUM CONSTANTS" WITH THE CHANGE OF INITIAL CONCENTRATION OF TAPO IN ACETIC ACID SOLUTION WITH 0.18 N H_2SO_4

Concn. of TAPO, M	Concn. of acetone added, M	Equilibrium const.
0.005	None	6.32×10^{-8}
0.05	None	1.43×10^{-9}
0.005	0.015	2.58×10^{-5}

As reported previously[3], the phenomenon may be explained by the transformation of the produced peroxyacetic acid into acetyl peroxide, the extent of the transformation being increased with increasing concentration of peroxyacetic acid.

$$CH_3CO_3H + CH_3CO_2H \rightleftharpoons CH_3CO\text{-}O_2\text{-}COCH_3 + H_2O$$

As shown in Fig. 2, the plot of conversion vs. time gives a slight maximum which suggests the transformation of peroxyacetic acid. Moreover, the paper chromatography of the reaction mixture afforded a spot corresponding to peroxyacetic acid $R_f=0.77$, at 30 min. as stated above, while it gave spots with the R_f values of 0.75 and 0.85, corresponding to peroxyacetic

3) Y. Ogata, Y. Furuya, J. Maekawa and K. Okano, *J. Am. Chem. Soc.*, in press.

acid and acetyl peroxide, respectively[3] at 300 min. The spot corresponding to acetyl peroxide was more remarkable as the concentration of peroxyacetic acid was increased.

Summary

It was confirmed by the iodometry and gas chromatography that one mole of TAPO in acetic acid was decomposed to three moles of acetone and peroxyacetic acid in the presence of sulfuric acid. The rate of the reaction satisfied the first-order equation with a short induction period. The plot of $\log k$ vs. H_0 gave a straight line with a slope of -1.12. When the concentration of TAPO was high, the amount of peroxyacetic acid was not quantitative, probably because of the transformation of peroxyacetic acid into acetyl peroxide.

The Crystal Structures of Metal 8-Hydroxyquinolinate. I. Copper 8-Hydroxyquinolinate[*1]

By Fumikazu KANAMARU[*2], Kazuhide OGAWA[*3] and Isamu NITTA

(Received December 1, 1962)

In the course of recent developments in the valency theory and streochemistry of copper, it has been reported by Orgel and Dunitz[1] that there are three types of environment about the cupric ion: (1) distorted octahedral with four short and two long bonds, (2) square coplanar, and (3) tetrahedral. The tetrahedral compounds, such as Cu_2CsCl_4[2], are few in number, but, in the case of the cuprous ion, copper usually makes sp^3 (tetrahedral) bonds with surrounding ligands. A greater number of cupric compounds are of type 1 or 2. These types may be considered together as a single class, since we regard the planar compounds as a limiting case of 1, with the two opposite ligands with long bonds removed completely.

The crystal structure of copper 8-hydroxyquinolinate dihydrate has been determined by Kruh and Dwiggins[3]. It is isomorphous with the corresponding zinc salt, the crystal structure of which has been determined by Meritt et al.[4] Moreover, since Liu and Bailar[5] have found that, in zinc salt of 8-hydroxyquinoline-5-sulfonic acid, the coordination of the zinc is tetrahedral, it may be assumed that the same arrangement of the ligands will be found in the anhydrous zinc 8-hydroxyquinolinate. According to the results of the X-ray analysis of the corresponding anhydrous copper compound by Mundy[6], the copper atoms are not arranged at the centers of symmetry, but in the general positions of the unit cell of the space group $P2_1/a$. Thus, he inferred that there is no reason why the copper complex should not be tetrahedral.

Since copper(II) shows a strong tendency toward a square planar coordination and since Mundy's analysis is not complete, it will be interesting to see which of the two possible structures is the actual arrangement in the anhydrous salt. The present paper deals with the structure analysis of copper 8-hydroxyquinolinate in more detail than Mundy provides. In connection with this substance, it has been determined by Ogawa that the anhydrous zinc 8-hydroxyquinolinate is triclinic, with two formula units in a cell of the dimensions $a=11.1, b=9.20, c=11.1$ Å, $\alpha=114.9°$, $\beta=75.1°$, $\gamma=90.8°$; the details of his research will be published elsewhere.

Experimental

The anhydrous copper 8-hydroxyquinolinate was prepared by heating, on the water bath, the hydrated precipitate obtained by mixing a solution of copper in acetic acid with an alcoholic solution of 8-hydroxyquinoline (oxine). Crystals of anhydrous copper 8-hydroxyquinolinate were grown by slow evaporation at about 45°C from a pyridine solution of the anhydrous compound. The crystals in the shape of rods or of hexagonal plates are colored dark brown. They were not always obtained in the form of rods however, and the axis of the rod was not always parallel to the direction of the b axis. In the present experiment, we used a rod crystal the axis of which was parallel to b, thus obtaining the Weissenberg *h0l* reflections, otherwise we used specimens cut along the b or c direction out of hexagonal tabular crystals with developed (100).

When anhydrous copper 8-hydroxyquinolinate is recrystallized from a pyridine solution, a green pyridine addition compound is also obtained at the same time[7]. In order to ascertain that the specimen is the desired anhydrous salt, we determined the nitrogen content of the specimen and took an X-ray diffraction powder pattern for comparison with the results reported by Sekido[8]. The analysis showed that the chemical formula of the specimen corresponded to $CuC_{18}H_{12}O_2N_2$, while the phase corresponded to the β-form of $Cu(oxine)_2$ designated by Sekido.

Using Ni-filtered Cu-K_α radiation, Weissenberg, Sauter, and oscillation photographs were taken about the b and c axes using the multiple-film technique. These photographs showed that the unit cell was monoclinic and that the cell dimensions were $a=23.66\pm0.04$, $b=8.72\pm0.01$, $c=15.30\pm0.02$Å, $\beta=117.5\pm0.5°$. The systematic absences of *hkl* reflections when $h+l$ is odd, of *h0l* reflections when both h and l are odd, and of $0k0$ reflections when k is odd show that the space group is C_{2h}^5–$B2_1/a$. This space group expression is different from that given by Mundy, but this difference may be due to the difference in the selection of axes between our method and Moundy's. If we adopt the following lattice constants: $a=10.72$, $b=8.72$, $c=15.30$Å, and $\beta=98.0°$, the space group of this crystal becomes $P2_1/c$, but our present investigation is based on the space group $B2_1/a$.

The approximate density measured with a picnometer is 1.5 g. cm^{-3}, so that there are eight molecules in the unit cell (the calculated density 1.66 g. cm^{-3}). The intensities of integrated Weissenberg photographs of *hk*0 and *h0l* layers were estimated visually by comparison with a calibrated scale of time exposures. Corrections for Lorentz and polarization factors were made in the usual way. No absorption corrections were made, since small crystals were used ($\mu=26.1$ cm^{-1} for Cu-K_α).

By the use of Wilson's method, the relative structure amplitudes were converted to the absolute scale by a comparison of the calculated average intensities $\sum f_j^2$ with those observed for five zones of the appropriate reciprocal lattice section; at the same time the values of the temperature factors were calculated to be 4.9Å^2 for (*h0l*) and 3.2Å^2 for (*hk*0).

Determination of Structure

As has been shown by Howells, Phillips and Rogers[9], there are remarkable differences among centric, acentric and hypercentric crystals as regards the distribution of the magnitudes of the structure factors. It is the necessary condition for the application of this method that there should be a sufficiently large number of equal atoms in general positions in the unit cell. In our case, however, there are eight heavy copper atoms in the cell, thus greatly influencing the structure factors, so the statistical method is not strictly applicable. Nevertheless, we applied this method to our crystal and guessed the structure to be a hypercentric one. From this we further inferred that there would be centers of symmetry in the unit cell besides the one in the molecule itself, so that the $Cu(oxine)_2$ molecule will not have a tetrahedral configuration, but a planar one (Fig. 1).

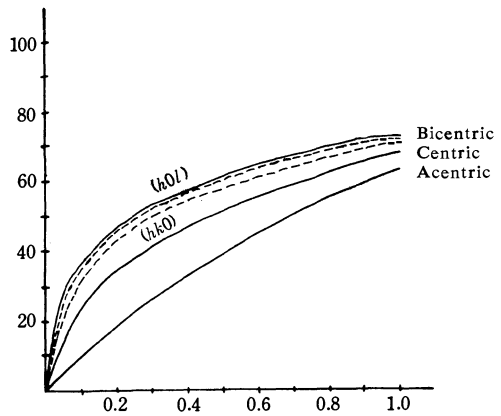

Fig. 1. Comparison of the experimental distribution N(z) for $Cu(oxine)_2$ (marked by dotted lines) with the theoretical distribution curves.

The sharpened Patterson synthesis of (*h0l*) and (*hk*0) projections showed that copper atoms were located at the positions with $x=0.061$, $y=0.118$, and $z=0.010$. In view of the short b axis, this synthesis was considered to proceed first with a projection on (010). On the basis of the above copper parameters, the values of the $F(h0l)$ for the copper atoms only were calculated. From a comparison of

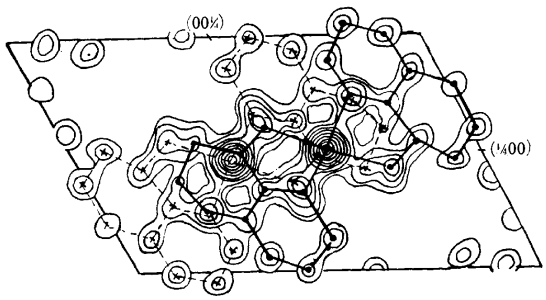

Fig. 2. Electron-density projection along the b axis.

them with the observed structure amplitudes of this compounds, it was possible to deduce the signs of about one-tenth of all the possible reflections $F(h0l)$ within the limiting sphere. In the following calculations, the atomic scattering factors of carbon, nitrogen, and oxygen given by McWeeny and that of copper listed in the Internationale Tabellen were adopted. The expressions for $F(h0l)$ and $F(hk0)$ of the space group $B2_1/a$ are given by:

$$F(h0l) = 8\sum f_j \cos 2\pi(hx_j + lz_j)$$

$$F(hk0) = 8\sum f_j \cos 2\pi hx_j \cdot \cos 2\pi ky_j$$

when k is even,

$$F(hk0) = -8\sum f_j \sin 2\pi hx_j \cdot \sin 2\pi ky_j$$

when k is odd.

Parameters were assigned to all the atoms in the initial projection on (010), using an assumed model of the 8-hydroxyquinoline molecule; these were refined as far as possible by successive Fourier syntheses of electron density. The x parameters finally obtained were incorporated into projections along the c axis. From the information derived from the preceding Patterson projection on (010), and from the fact that the intensity of the (420) reflection is strongest, we could determine the orientation of the 8-hydroxyquinoline molecule in the following way: The calculated copper contribution to the (420) reflection is almost zero, so that the structure factor (420) contributed from 8-hydroxyquinoline molecules must be large. This means that the plane of the oxine molecule must be nearly parallel to (420) or ($\bar{4}$20) through the positions of the copper atoms determined from Patterson projections. In this case, one cannot distinguish between the two-fold axes and the centers of symmetry in the (010) projection, so it was also not possible to decide the two alternatives in the (010) projection. Setting up two kinds of structure models projected on the (00l) plane, in each of which the origin of a unit cell was the two-fold screw axis or the center of symmetry, we found an approximate arrangement of the molecules by spacing the molecules so that they would not be too close together and so that the calculated intensity of the reflection of (420) would be very large in conformity with the obtained one. Then, calculating the three-dimensional structure factors $F(h1l)$, we ascertained that the crystal structure thus obtained gave a satisfactory agreement between the observed and calculated structure factors.

The refinement of the structure was accomplished by using the error synthesis method proposed by Bunn et al.[10] Also we partly adopted Booth's back-shift method as a correction for termination-of-series errors. In order to find the diffraction ripples in a Fourier summation due to copper atoms, which might overlap the positions of light atoms in projection, a Fourier synthesis was carried out using the calculated values of $F(h0l)$ for the copper atoms alone for the reflections included in the original summation; this was then compared with the original Fourier projection. In determining the exact positions of the peaks representing the light atoms, we allowed for these diffraction effects.

The coordinates that gave the best agreement between calculated and observed structure factors were chosen. The results are given in

10) D. Crowfoot, C. W. Bunn, B. W. Rogers-Low and A. Turner-Jones, "The X-Ray Crystallographic Investigation of the Structure of Penicillin" Princeton Univ. Press, Princeton, N. J. (1949), p. 310.

Table I, where x, y, and z are expressed in fractional coordinates, all referred to the monoclinic axial directions. They are also expressed in orthogonal coordinates x', y', and z' referred to the a, b and c' axes, where c' is an axis perpendicular to the b and a axes. These orthogonal coordinates, not shown here, were used in calculating the interatomic distances and valency angles. They are derived from the monoclinic crystal coordinates by the relations $x'=x+z\cos\beta$, $y'=y$, and $z'=z\sin\beta$.

In electron-density projections on both (*hk*0) and (*h*0*l*), calculations of standard errors by Cruickshank's method were rendered impossible by the overlapping of the maxima which were present in this structure. Therefore, we adopted Luzzati's method as an indication of the accuracy of the given coordinates. The mean errors for *hk*0 and *h*0*l* reflections are 0.07 and 0.06Å respectively. The fact that the values of *R* for *hk*0 reflections do not precisely follow the curve shown by Luzzati may be due to the absorption effect of the crystal. The mean disagreement factors, *R*, were as follows: $R(h0l)=0.18$, $R(hk0)=0.195$

Description and Discussion of the Structure

The interatomic distances and the bond angles calculated on the basis of the above parameter values are shown in Fig. 3. Each copper atom in the lattice is surrounded by two oxygen and two nitrogen atoms in a square configuration. These four atoms are coplanar with the copper atom, and in the direction perpendicular to the plane of this square there are no atoms within a distance of 3.0Å from the copper atom, so that the electronic structure of the copper atom is a typical dsp^2 type.

Each 8-hydroxyquinoline radical is almost flat. Two plane equations for the two crystallographically different radicals coordinated with the same copper atom were determined.

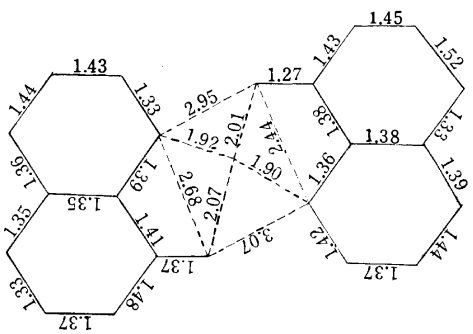

Fig. 3-a. Diagrammatic representation of the Cu(oxine)$_2$, showing bond lengths (in Ångstrom units).

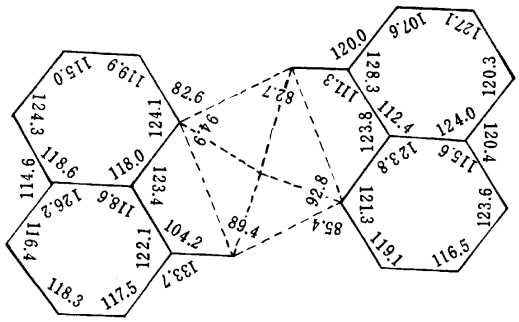

Fig. 3-b. Diagrammatic representation of the Cu(oxine)$_2$, showing bond angles (in degrees).

Within the range of experimental error, they are coplanar with a central copper atom and almost parallel to each other. The mean plane, containing two 8-hydroxyquinoline molecules with a copper atom, was found by the least-squares method to have the following equation:

$$0.268x'+0.465y'+0.256z'=1$$

The orientation of the molecule in the crystal can be expressed by the angles χ, ψ, and ω, which the molecular axes, L, M and their normal, make with the a, b and c axes. Axes L and M are taken to lie in the mean plane of the molecule and to be directed parallel to the C(8)—C(9) line and its normal respectively. The mean values of these angles are listed in Table II. These show also that the inclination of the molecular plane to the (010) plane is about 51.5°. The arrangement of the

molecules in the crystal will be clear from the projection in Fig. 4. The perpendicular distances between successive mean molecular planes are 3.36, 3.48 and 3.32Å. These values are to be compared with the interplane spacing in graphite 3.41Å, coronene 3.40Å, or phthalocyanine 3.38Å. The shortest Cu–Cu distance of 3.45Å implies that the Cu–Cu bonds contribute to a union of the two chelate molecules, but not so strongly as in copper acetate dihydrate $Cu_2(CH_3COO)_4 \cdot 2H_2O$[11]. The possibility of the type of metal-metal interaction suggested here has also been shown in nickel dimethylglyoxime[12], in which the metal-metal interaction has been reported to have some relation with the solubility. In the copper 8-hydroxyquinolinate crystal, such dimeric molecules as $Cu_2(oxine)_4$ with the Cu–Cu distance of 3.45Å, are juxtaposed to form layers in the direction of the b and [101] axes like brick walls. The binding forces between these layers may be due to the van der Waals interaction, while within the layers π-bond overlapping will contribute somewhat to the layer formation, as will the metal-metal bond and the van der Waals forces. Such a layer structure, with π-bond overlapping, has been found in quinhydrone[13], phenoquinone[14] and chloranil-hexamethylbenzene complexes[15], while the results of the measurement of the electric conductivity of $Cu(oxine)_2$ powder crystals seems to prove the partial overlap of molecular π-orbitals.

Summary

The crystal structure of anhydrous copper 8-hydroxyquinolinate has been determined by the two-dimensional Fourier method. It is monoclinic and has been shown to belong to the $B2_1/a$ space group, with eight molecules in a cell of the dimensions: $a=23.66$, $b=8.72$, $c=15.30$Å and $\beta=117.5°$. A copper atom is surrounded by four atoms with Cu–N distances of 1.92 and 1.90Å, and Cu–O distances of 2.01 and 2.07Å. Two nitrogen and two oxygen atoms form a square and are coplanar with the copper atom. The closest approach of adjacent chelate molecules occurs along the b axis and in the [101] direction, where the interplanar distances are 3.36, 3.47, and 3.32Å. These chelate molecules are grouped in pairs around the symmetry center at the point of origin with a Cu–Cu bond of 3.45Å. The perpendicular distances between successive dimeric molecules given above are almost the same

within the range of experimental error. A π-bond overlapping of molecules is considered to be a part of the binding forces between such layers. The metal-metal bond is presumably the same as that in nickel dimethylglyoxime.

The Normal Vibrations of trans-trans Diacetamide

By Toyozo UNO and Katsunosuke MACHIDA

(Received December 3, 1962)

In a previous report on the infrared spectra and structure of acyclic imides[1], it was concluded that diacetamide takes the trans-cis and the trans-trans configuration in the crystal in A and B forms respectively. With respect to form A, X-ray diffraction study was carried out and the trans-cis configuration was proven to be approximately valid[2]. Such a support from X-ray analysis, however, has not yet been given to form B, for which it is therefore of interest to determine the type of its hydrogen bond in connection with the molecular symmetry in the crystal[3].

The present work has been undertaken to see whether or not the observed infrared frequencies of diacetamide crystals in form B can be reproduced by a reasonable set of force constants based on the assumed trans-trans structure. For this purpose, we have carried out normal vibration calculations for the in-plane vibrations of diacetamide and diacetamide-d in the trans-trans configuration and have obtained satisfactory results, particularly for imide characteristic frequencies.

Calculation

The methyl group was treated as a point mass, and the resulting eight-body problem was treated by Wilson's ***GF*** matrix method[4]. A molecule of diacetamide in the trans-trans configuration has the C_{2v} symmetry. Besides the vibrations arising from the methyl group, there are thirteen inplane vibrations, which are classified into seven A_1 and six B_2 vibrations according to their symmetry[5]. The N–H stretching vibration belonging to the A_1 species was separated from the other A_1 vibrations[4,6], and secular equations of the sixth order were set up for both species A_1 and species B_2. The internal coordinates were defined as shown in Fig. 1, and the symmetry coordinates were constructed as shown in Table I. The bond lengths used in the present calculations are: $r(\mathrm{C{-}N}) = 1.32$ Å, $r(\mathrm{C{=}O}) = 1.21$ Å and $r(\mathrm{CH_3{-}C}) = 1.54$ Å. All the bond angles were assumed to be 120°. These bond lengths and bond angles are the same as those used in the calculations for *N*-methylacetamide by Miyazawa et al.[7]

TABLE I. SYMMETRY COORDINATES

Symmetry species	Symmetry coordinates	Description
A_1	$S_1=(1/2)^{1/2}\Delta(r_1+r_2)$	C-N stretching
	$S_2=(1/2)^{1/2}\Delta(r_3+r_4)$	C-C stretching
	$S_3=(1/2)^{1/2}\Delta(r_6+r_7)$	C=O stretching
	$S_4=(1/6)^{1/2}\Delta(2\alpha_{12}-\alpha_{15}-\alpha_{25})$	C-N-C bending
	$S_5=(1/12)^{1/2}\Delta(2\alpha_{36}-\alpha_{13}-\alpha_{16}+2\alpha_{47}-\alpha_{24}-\alpha_{27})$	CH_3-C=O bending
	$S_6=(1/2)\Delta(\alpha_{13}-\alpha_{16}+\alpha_{24}-\alpha_{27})$	CH_3-C=O rocking
B_2	$S_7=(1/2)^{1/2}\Delta(r_1-r_2)$	C-N stretching
	$S_8=(1/2)^{1/2}\Delta(r_3-r_4)$	C-C stretching
	$S_9=(1/2)^{1/2}\Delta(r_6-r_7)$	C=O stretching
	$S_{10}=(1/2)^{1/2}\Delta(\alpha_{15}-\alpha_{25})$	N-H(N-D) in-plane deformation
	$S_{11}=(1/12)^{1/2}\Delta(2\alpha_{36}-\alpha_{13}-\alpha_{16}-2\alpha_{47}+\alpha_{24}+\alpha_{27})$	CH_3-C=O bending
	$S_{12}=(1/2)\Delta(\alpha_{13}-\alpha_{16}-\alpha_{24}+\alpha_{27})$	CH_3-C=O rocking

Force Constants. — The Urey-Bradley type potential function[8].

$$2V=\sum_i K_i(\Delta r_i)^2+\sum_{i\neq j}\{H_{ij}r_i^0r_j^0(\Delta\alpha_{ij})^2+F_{ij}(\Delta q_{ij})^2\}+\text{linear terms}$$

was assumed. Here, three bond-stretching (K_i), five bond-angle-deformation (H_{ij}), and five non-bonded repulsion (F_{ij}) force constants are necessary. These force constants may be transferred from *N*-methylacetamide[7], which includes all the five pairs of adjacent bonds (H-N-C, C-N-C, C-C-N, O=C-N and C-C=O) included in diacetamide. Diacetamide differs from *N*-methylacetamide, however, in containing a carbonyl carbon atom instead of the methyl carbon atom attached to the nitrogen atom in the latter. This may leave a question about the transferability of the force constants related to the C-N-C linkage. There has been no report, however, on the C-N-C bond angle deformation and the C···C repulsion force constants for the O=C-N-C=O linkage. The calculations were, therefore, started with the initial set of the force constants transferred from *N*-methylacetamide[7,9]. They are listed in the first column of Table II. The refinement of the force constants was made by a comparison of the observed and the calculated frequencies with reference to the Jacobian matrix[10]. Since there are two A_1 and one B_2

TABLE II. FORCE CONSTANTS (md./Å)

	Initial set	Final set
K_{C-N}	5.50	4.00
$K_{C=O}$	8.50	9.80
K_{C-CH_3}	3.40	3.20
H_{H-N-C}	0.35	0.31
H_{C-N-C}	0.20	0.50
H_{N-C-CH_3}	0.30	0.30
$H_{N-C=O}$	0.35	0.20
$H_{CH_3-C=O}$	0.30	0.25
$F_{H\cdots C}$	0.50	0.35
$F_{C\cdots C}$	0.40	1.70

$F_{N\cdots O}$	1.50	1.20
$F_{CH_3\cdots O}$	0.50	0.50

skeletal deformation frequencies which have not yet been observed, it was impossible to adjust the related force constant directly from these frequencies. On the other hand, except for the imide I, II and III frequencies[11], the observed frequencies were found to be not far from the frequencies calculated on the basis of the initial set of the force constants. Considering these facts, adjustment was made particularly with respect to the force constants related mainly to the imide I, II and III frequencies. In the course of this procedure it was found that the difference in the bond orders of C=O and C-N bonds between amides and imides should be taken into account in the refinement of $K_{C=O}$, K_{C-N} and H_{H-N-C}. The conceivable canonical forms in the resonance hybridization of an imide molecule are shown in Fig. 2, from which it may

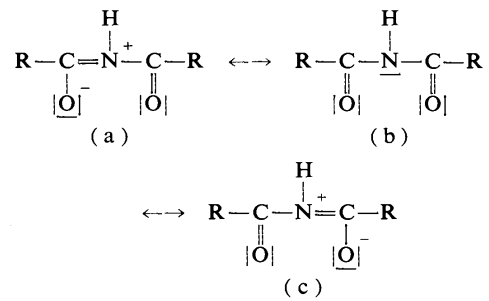

Fig. 2. Resonance structures of imides.

easily be understood that the C=O bond order increases but the C-N bond order decreases with an increase in the contribution of the non-polar form b. The trans-trans configuration may be advantageous for form b since the other two forms should give rise to a strong repulsion between the adjacent oxygen atoms. Thus, it is quite reasonable that

8) T. Shimanouchi, ibid., 17, 245, 734, 848 (1949).
9) The only exception was $F_{C\cdots C}$, which has been chosen to be 0.30 md./Å for *N*-methylacetamide[7].

imides should exceed amides with respect to $K_{C=O}$ and vice versa with respect to K_{C-N} and H_{H-N-C}. In order to compensate for the decrease in the value of K_{C-N}, a marked increase in the value of $F_{C...C}$ was necessary for the frequency fit in the A_1 C-N-C symmetric stretching frequency. As may be seen from Fig. 2, imides have non-localized electrons around the C-N-C linkage. Therefore, a resonance cross term[12] may be implicitly included in the effective value of $F_{C...C}$. In this respect, it is reasonable that the $F_{C...C}$ of diacetamide is comparable to the $F_{O...N}$ rather than to the $F_{C...C}$ of *N*-methylacetamide[7]. The repulsion between the oxygen atoms may also be expected to contribute to the effective value of the $F_{C...C}$ of trans-trans diacetamide. The quantitative treatment of these contributions could not be undertaken without the determination of the lowest three skeletal deformation frequencies. The final set of the force constants obtained in the present calculation is shown in the second column of Table II. They reproduce the observed frequencies with deviations of less than 6%.

Numerical Calculation.—Most of the present calculations were carried out on the KDC-1 digital computer at Kyoto University. A program for the normal vibration calculation was constructed with reference to those of the previous investigators[13,14]. The library subroutines were used for the matrix multiplications and for the solution of the secular equations. These library subroutines were connected to the additional subroutines designed to calculate the $\boldsymbol{F}$ matrix[4], the Jacobian matrix[10], the potential energy distribution[15,16], and the $\boldsymbol{LL'}$ matrix[13]. The $\boldsymbol{F}$ matrix was calculated from the $\boldsymbol{A}_h$ matrices and the force constants, K_h, according to the formula[10]:

$$\boldsymbol{F} = \sum_h \boldsymbol{A}_h K_h$$

The program was designed to be appropriate to such a matrix, including many zero elements as $\boldsymbol{A}_h$. The construction of the $\boldsymbol{F}$ matrix requires the following input for a given matrix $\boldsymbol{A}_h$: (1) the values of the non-zero elements, (2) the indices denoting the locations of the non-zero elements, and (3) the number of the non-zero elements. The same input, together with the $\boldsymbol{L}$ matrix, was used to construct the Jacobian matrix. This method was quite effective in utilizing the memory of the computer and in reducing the computing time. The present calculations, which included four secular equations of the sixth order, the input, and output procedures, could be performed within fifty minutes.

Results and Discussion

In Table III, the final set of the calculated frequencies are listed, together with the potential energy distributions, and are compared with the observed frequencies. The previous assignments[1,11] of the characteristic frequencies are in good agreement with the results of the present calculations.

The calculated values for the imide I frequencies elucidate well the facts that the A_1 frequency (ν_1) is about 40 cm^{-1} higher than the B_2 frequency (ν_7) and that it does not shift on deuteration, while the B_2 frequency undergoes a low-frequency shift by about 15 cm^{-1}. The vibrations responsible for these frequencies are almost all localized at the C=O stretching coordinates (S_3 and S_9). The imide II and III frequencies (ν_8 and ν_9) belonging to the B_2 species are contributed mainly from the C-N stretching and the N-H in-plane deformation vibrations, as was suggested in a previous paper[11]. It may be seen from the present calculations, however, that the energetic contribution of the C-C stretching vibration is also important for the imide III frequency. In contrast with the imide I and II frequencies, the imide III frequency seems to vary with the change of one or both of the frameworks attached to the -CONHCO- group from the methyl to the higher alkyl groups[11]. This fact may reasonably be expected from the present calculations, which show that interaction between the -CONHCO- group and the alkyl framework vibrations is involved in the imide III frequency.

With respect to the imide II' frequency (ν_8'), the contribution of the C-N stretching vibration is three times as energetically important as that of the N-D in-plane deformation vibration. The smallness of the contribution of the C-C stretching vibration seems to be related to the slight dependence of this frequency upon the change of the alkyl group[11]. The imide II, III and II' frequencies of trans-trans diacetamide are quite analogous to, respectively, the amide II, III and II' frequencies of *N*-methylacetamide in the trans configuration[7] in their potential energy distributions. It is of interest that the appreciable difference in the corresponding force constants

between these compounds does not produce any difference in the energetic natures of the corresponding characteristic vibrations. Besides the N–D in-plane deformation vibration, the contribution of the C–C stretching vibration is important for the imide III' frequency (ν_9'), on which it has been revealed that the influence of the alkyl group is also appreciable[11]. The difference between the observed and the calculated values (56 cm^{-1}) for the imide III' frequency may be attributed to the disregard of the interaction with the B_2 CH_3 rocking vibration in the present calculations. This is suggested by the facts that the intensity of the 1035 cm^{-1} band of diacetamide in form B is appreciably reduced on deuteration and that a weak band appears at 1100 cm^{-1} for diacetamide-d in form B[1]. For the undeuterated species, it seems that the absorption due to the B_2 CH_3 rocking vibration is overlapped by the 1035 cm^{-1} band due to the A_1 skeletal vibration. For the deuterated species, however, the B_2 CH_3 rocking vibration seems to couple with the N–D in-plane deformation vibration, thus giving rise to the 1100 cm^{-1} band and pushing the imide III' frequency down from the uncoupled value near the calculated frequency (1007 cm^{-1}) to the observed frequency (951 cm^{-1}). This interpretation may be confirmed by the application of the product rule[4] to the B_2 frequencies. As is shown in Table IV, we have obtained a good agreement between the observed and the theoretical ratios by employing the frequencies ν_i and ν_i' ($i=7$, 8, 9 and 10) which are shown in Table III, together with two additional frequencies: 1035 cm^{-1} for the undeuterated species and 1100 cm^{-1} for the deuterated species.

The present calculations show that the two imide IV frequencies assigned previously to the two C=O in-plane deformation vibrations[1] are essentially different from each other in their vibrational modes. The B_2 frequency (ν_{11}) arises from the almost pure CH_3–C=O bending vibration, while the A_1 frequency (ν_4) has a complicated vibrational mode to which

TABLE IV. PRODUCT RULE RATIOS

B_2	1.41	1.40

* ν_i : 1690, 1505, 1236, 1035 and 920
ν_i' : 1675, 1348, 1100, 951 and 901

the C–C stretching, CH_3–C=O bending, and CH_3–C=O rocking vibrations contribute. Such a mixing of vibrational modes is also seen for the A_1 skeletal frequency (ν_3). Further discussion of the vibrational modes of ν_3 and ν_4, however, will not be undertaken here since these mixed vibrational modes are probably affected by those force constants related mainly to the unobserved frequencies below 450 cm^{-1}.

Summary

A normal coordinate analysis of the in-plane vibrations of diacetamide and of diacetamide-d taking the trans-trans configuration has been undertaken. The calculated frequencies agree well with the observed frequencies for the crystals in form B. The Urey-Bradley force field has been adopted, and the force constants obtained have been interpreted in terms of the difference in resonance structures between amides and imides. It has been shown that the vibrational modes of the characteristic imide frequencies are closely related to the behavior of the corresponding characteristic bands upon the change in the alkyl frameworks attached to the imide group.

The authors wish to express their thanks to Dr. Kiyoshi Nakamura of the Research Laboratory, Dainippon Pharmaceutical Co., Ltd., and to Dr. Tatsuo Miyazawa of the Institute of Protein Research, Osaka University, for their helpful advice throughout this work.

*Kinetics of Hydrolytic Reaction Catalyzed by Crystalline Bacterial α-Amylase. II. The Influence of Solvent**

By Sôzaburo ONO, Keitaro HIROMI and Yoshiki SANO**

(Received September 17, 1962)

The electrostatic nature of a chemical reaction in solution can be inferred from the dependence of the reaction rate on the dielectric constant and on the ionic strength of the medium[1-3]. As for enzyme reactions, however, the study of the ionic strength effect is not so useful, because various ions often exert specific effects on enzyme reactions; moreover, the theoretical treatment of this effect is extremely difficult with such large complex ions as protein[4,5]. Thus the study of the dielectric constant effect becomes important in elucidating the electrostatic nature of enzyme reactions, for it would provide information concerning the reaction mechanisms.

There are, however, two difficulties in the study of the dielectric constant effect on enzyme reactions. The first, which is a theoretical one, is that the conventional theories that have been developed for simple ions or molecules[1-3] may no longer be applicable to enzyme reactions because of the complex charge structure of the molecule; the second is that the organic additives used to control the dielectric constant of the medium may possibly influence, directly or indirectly, the reaction rates from various causes other than the electrostatic one.

The effects of solvent on the rates of various enzyme reactions have been studied by several

authors[6-16], some of whom have interpreted[6-10] the results in terms of simple electrostatic theories developed for simple ions or dipolar molecules. Recently one of us developed a theory of the influence of the dielectric constant of solvent on equilibria and reaction rates[17,18], using the Kirkwood model of a spherical solute molecule having an arbitrary charge distribution[4], which is most probably an appropriate model for a protein molecule in solution[5]. The theory is essentially applicable to the dielectric constant effect on reactions in solution, including enzyme reactions, in which any rearrangement of charges occurs within the spherical solute molecules involved. The applicability of the theory was tested for certain enzyme reactions[18], as well as for some simple organic reactions[17], and the results were considered satisfactory. Hosoya has also applied the theory to the interpretation of his data on the peroxidase reaction[15].

As for the second difficulty, we have tried in this paper to find some general kinetic procedures by which we can distinguish the true dielectric constant effect from the other non-electrostatic effects caused by the organic additives.

In Part I of this paper[19], the influence of pH upon the α-amylase-catalyzed hydrolysis of amylose was investigated, and the properties of the ionizable groups essential for the reaction were elucidated. In this paper, the influence of solvent upon the reaction rates will be studied kinetically, and the results will be interpreted on the basis of the theory developed by one of us[17,18]. The possible effects of the addition of the organic solvent will also be examined.

Experimental

Enzyme.—Six times-recrystallized bacterial amyloclastic α-amylase of *Bac. amyloliquefaciens* Fukumoto was kindly provided by Prof. J. Fukumoto and Dr. T. Yamamoto of Osaka City University. An aqueous solution of the crystalline enzyme was used as a stock solution. The enzyme activity of the stock solution was checked before each experiment.

Substrate.—Since amylose is precipitated from an aqueous solution by the addition of even a small volume of such an organic solvent as methanol, it can not be used as the substrate for the present purpose. Therefore, potato soluble starch, washed with cold water and with methanol and dried, was used as the substrate.

Solvent.—Water or a methanol-water mixture was used as the solvent. The methanol was purified with alkaline silver nitrate and twice redistilled.

Reaction Mixture.—The composition of the reaction mixture was as follows: Aqueous solution of soluble starch, 20 ml.; methanol, x ml,; water, $(8-x)$ ml.; diluted-enzyme stock solution, 2 ml. The final concentration of the substrate varied from 0.075% to 0.5%. The methanol concentration ranged from zero to 22.3 per cent by weight. In order to minimize the ionic strength of the medium[17,18] no buffer solution was used. The pH value of the reaction mixture, however, was maintained at 6.0 $\pm$ 0.1, sufficiently close to the optimum pH value of 5.85[19]. The reaction was carried out at 25.0°C throughout the experiments.

Procedure.—Two milliliters of the reaction mixture was pipetted into 1 ml. of 0.5 N sodium hydroxide to stop the reaction every minute during the first five minutes; 1 ml. of a 3, 5-dinitrosalicylate reagent[20] was then added, and the mixture was heated at 65°C for one hour and diluted to 20 ml., and the red color which developed was measured photometrically, using maltose as the standard. Methanol slightly increases the color density, and this effect was calibrated.

Relative Rate-pH Curves. — In the investigation of the effect of methanol on the relative rate-pH curve, a Britton-Robinson buffer was used in its 1/30 concentration to adjust the pH values.

Even at the maximum methanol concentration used, no irreversible inactivation of the enzyme was detected during the reaction period at 25°C and pH 6.0.

Results

The Michaelis constant, K_m, and the first order rate constant for the breakdown of the ES complex, k_3, obtained from the Lineweaver-Burk plot[21] for nine different substrate concentrations at various methanol contents, are listed in Table I. Since the substrate soluble starch contains α-1, 6 linkages, which are not hydrolyzed by this enzyme, the intrinsic substrate concentration cannot be

a) Dielectric constant of the solvent. Interpolated from the values of Davis and Jones[22].

defined accurately. The Michaelis constants, therefore, is conveniently expressed in per cent units.

It is clearly indicated that K_m is constant over the range studied, while k_3 decreases with an increase in the methanol concentration, or with a decrease in the dielectric constant of the medium.

The relationship between pH and the relative rate, v/v_{max}, the ratio of the initial rate at a given pH value to that at the optimum pH value, is influenced by the addition of methanol, as is shown in Fig. 1. The curve is shifted towards the alkaline side by the addition of methanol (22.3 per cent by weight), which is probably due in part to the fact that the pK values of the essential ionizable groups of the enzyme have been influenced by the addition of methanol. It may be seen from Fig. 1 that the velocity is remarkably influenced by the addition of methanol at pH's remote from the optimum pH while the rate at the optimum pH is changed only insignificantly. In order to study the dielectric constant effect on the reaction rates, therefore, the reaction should be observed in the vicinity of the optimum pH. In the present case, in which the reactions were carried out at pH 6.0, the discrepancy between the curves is so small that the observed decreases in k_3 cannot be attributed to the shift of the pH optimum.

Analysis of the Results

In the interpretation of the effect of a solvent upon the rate of enzyme reaction special caution is required, since the addition of an organic solvent may give rise to changes in reaction rates for various reasons. Six factors which may influence the rate on the addition of organic solvents and which are considered to be important in the present case are as follows: 1) a change in the dielectric constant of the solvent, which may directly influence the rate; 2) a decrease in the water concentration; 3) an inhibitory action of the organic additive; 4) an irreversible or reversible denaturation of the enzyme; 5) an aggregation of the substrate, and 6) a shift in the relative rate-pH curve. The first factor is the electrostatic one at which the present study is aimed. However, there may possibly exist influences from the other factors. In fact, for the enolase reaction[23] it was observed that the rate is the same function of the water concentration, irrespective of the nature of the organic additives used. In the myosine- and α-chymotrypsin-catalyzed reactions, it has been reported that methanol acts as a "water analogue" to yield methanolysis products, and the existence of the specific water site in these enzymes has been suggested [24,25]. The hydroxylaminolysis of methyl hyppurate catalyzed by α-chymotrypsin has also been observed[26]. On the other hand, by using a variety of organic substances as solvent additives, Castañeda-Agulló and Del Castillo [13,14] have shown that in α-chymotrypsin- and trypsin-catalyzed hydrolyses there is an obvious relationship between the rates and the dielectric constant. Thus, how to distinguish these possible factors is a general and important problem in the interpretation of solvent effects on enzyme reactions. The kinetic procedure for it will be worked out below.

Kinetic Treatment Considering the Participation of the Water Molecule.—With respect to the role of water in enzyme-catalyzed hydrolytic reactions, two cases may be considered, based on the usual Michaelis-Menten-Briggs-Haldane mechanism, which includes a single intermediate enzyme-substrate complex[27].

Case 1. Water reacts with the ES complex directly from the bulk of the solvent.

The reaction scheme should be written as follows:

$$E+S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \tag{1}$$

$$ES+H_2O \xrightarrow{k_3'} E+P \tag{2}$$

instead of the ordinary scheme:

$$E+S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E+P \tag{3}$$

Obviously the apparent rate constant, k_3, is proportional to the water concentration $[H_2O]$:

$$k_3=k_3'\,[H_2O] \tag{4}$$

The k_3 values obtained are tentatively plotted against the water concentration in Fig. 2. It is apparent that the observed change in k_3 is too large to be accounted for by Eq. 4.

Case 2. The case in which there is competition between the water molecule and the organic solvent molecule for the water site on the enzyme.

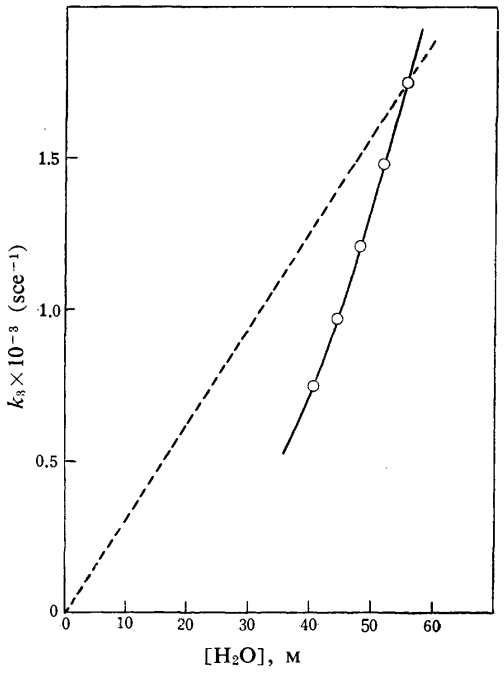

Fig. 2. Plot of k_3 vs. molar concentration of water. The dotted line represents the proportionality between them.

Since evidence has been obtained for the existence of a specific water site in some hydrolytic enzymes[24,26], it is possible that there is a specific water site on this enzyme for which the water molecule competes with the organic solvent molecule. The reaction scheme may then be written as follows:

$$\begin{array}{ccccc} & & \overset{K_M}{\rightleftharpoons} & \overset{K_W}{\rightleftharpoons} & \\ EM & & E & & EW \\ {\scriptstyle K_S''}\downarrow\uparrow & & {\scriptstyle K_S}\downarrow\uparrow & {\scriptstyle K_S'}\downarrow\uparrow & \\ & & \underset{K_M'}{\rightleftharpoons} & \underset{K_W'}{\rightleftharpoons} & \\ EMS & & ES & & EWS \end{array} \xrightarrow{k_o} E+P \tag{5}$$

where W and M represent water molecule and organic solvent molecule, respectively, and where only the ternary complex EWS is assumed to break down into the hydrolytic product P with the rate constant k_o. The K_S' are the association constants for the binding of S, W and M to E, as is indicated in the scheme; five of these are independent. A quasi-equilibrium treatment leads to the equation:

$$v=\frac{k_oK_S'K_wswe}{(1+K_ww+K_Mm)+(K_S+K_S'K_ww+K_S''K_Mm)s} \tag{6}$$

where w, m, s and e are the molar concentration of water, the organic solvent, the substrate and the total enzyme, respectively. The K_m and k_3 obtained from the Lineweaver-Burk plot are now represented by:

$$K_m=\frac{1+K_ww+K_Mm}{K_S+K_S'K_ww+K_S''K_Mm} \tag{7}$$

$$k_3=\frac{k_oK_S'K_ww}{K_S+K_S'K_ww+K_S''K_Mm} \tag{8}$$

If the substrate binding is not affected by the binding of water and that of the organic solvent molecule (it may be true with water and an organic solvent molecule of a small size, such as methanol), i.e., if $K_S=K_S'=K_S''$, K_m reduces to $1/K_S$, which is independent of the solvent composition. The density of a mixed aqueous solvent relative to pure water, ρ, is approximately expressed by $\rho=1+bm$, where b is a constant characteristic of the organic solvent for not so large an organic solvent content (e.g., up to ca. 30% by volume for methanol and ethanol). Using this relation we have:

$$w+pm=55.5 \tag{9}$$

26) S. A. Bernhard, W. C. Coles and J. F. Nowell, ibid., 82, 3043 (1960).

27) Similar treatments have been worked out by Inagami and Sturtevant[15] in the case of two intermediate complexes; according to them, the ratio of the apparent k_3 value to the apparent K_m value should be independent of the water concentration, although each of them is dependent on it. These features are obviously inconsistent with our results.

p is a constant expressed by $p=(M_M-1000b)/M_W$, where M_M and M_W are the molecular weights of the organic solvent and water respectively. (For a methanol-water mixture, $b=-0.0059$ and $p=2.10$.)

From Eqs. 8 and 9 we derive the following equation:

$$\frac{1}{k_3}=\left(\frac{K_S+55.5K_S''K_M/p}{k_OK_S'K_W}\right)\frac{1}{w}+\left(\frac{K_S'K_W-K_S''K_M/p}{k_OK_S'K_W}\right) \quad (10)$$

which predicts a linear relationship between $1/k_3$ and $1/w$. As may clearly be seen from Fig. 3, however, the linearity does not hold for the present case. Thus, this mechanism is not consistent with the observed results.

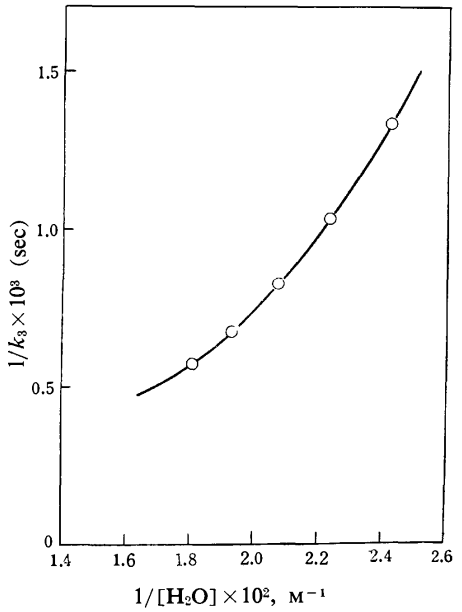

Fig. 3. Plot of $1/k_3$ vs. $1/[H_2O]$.

The Inhibitory Action of the Organic Additive.—Apart from the inhibitory action of the organic additive as a water analogue discussed above, there is a possibility that the organic additive may act as a simple inhibitor, either competitive, or non-competitive. At least qualitatively, the results obtained in this study are not inconsistent with a possible interpretation that methanol acts as a non-competitive inhibitor. If this is the case, k_3 may be written as:

$$k_3=\left(\frac{K_I}{K_I+m^n}\right)\cdot k_3^\circ \quad (11)$$

where m and K_I denote the methanol concentration and the dissociation constant of the inactive complex EM_n (or ESM_n) according to the scheme:

$$E\ (\text{or } ES)+nM \overset{K_I}{\rightleftharpoons} EM_n\ (\text{or } ESM_n) \quad (12)$$

where n is the number of methanol molecules combined with the enzyme molecule to form the inactive enzyme-methanol complex, and k_3° is k_3 at $m=0$. If we define α as the ratio k_3/k_3°, we have:

$$\frac{1-\alpha}{\alpha}=\frac{m^n}{K_I} \quad (13)$$

Thus, a plot of $\log\left(\frac{1-\alpha}{\alpha}\right)$ versus $\log m$ should give a straight line of slope n. This plot is shown in Fig. 4, which does not give a straight line of an integral number of slope, but does give a concave curve with an average slope of ca. 1.4. Thus, the results are not consistent with a typical non-competitive inhibitory mechanism involving the stoichiometric binding of the organic solvent molecule to the enzyme molecule.

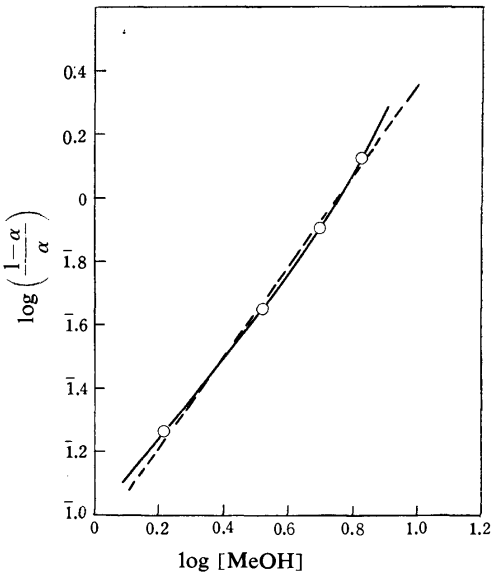

Fig. 4. Plot of $\log\left(\frac{1-\alpha}{\alpha}\right)$ vs. log [MeOH].
The dotted line represents a straight line whose slope is equal to 1.42.

Denaturation of the Enzyme.—Although an irreversible denaturation of the enzyme caused by the addition of the organic solvent could easily be found out experimentally, a rapid, reversible denaturation would be difficult to detect. If the enzyme undergoes a reversible denaturation in the presence of the organic solvent, the scheme may be written as follows:

$$\left.\begin{aligned} &E+S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \overset{k_3}{\rightarrow} E+P \\ &E \overset{K}{\rightleftharpoons} E' \\ &E'+S \overset{K_m'}{\rightleftharpoons} E'S \end{aligned}\right\} \quad (14)$$

where E' denotes the reversibly denatured form of the enzyme, which may (or may not) combine with the substrate to form an inactive complex E'S, where K_m' is the dissociation constant of this complex, and where K represents the equilibrium constant for the denaturation of the enzyme, which, in general, may increase with an increase in the concentration of the organic solvent. Then the initial rate v becomes

$$v=\frac{k_3es}{K_m(K+1)+(K_mK/K_m'+1)s} \quad (15)$$

where $K_m=(k_2+k_3)/k_1$. The apparent Michaelis constant, K_{ma}, and the apparent breakdown rate constant, k_{3a} which are obtained from the Lineweaver-Burk plot, are expressed as follows:

$$K_{ma}=\frac{K_mK_m'(K+1)}{K_mK+K_m'} \quad (16)$$

$$k_{3a}=\frac{k_3K_m'}{K_mK+K_m'} \quad (17)$$

K_{ma} will be independent of the solvent composition if $K_m=K_m'$. Assuming that k_{3a} and K_{ma} in water (or in the absence of the organic additive) are equal to k_3 and K_m, respectively, at a given concentration of organic solvent can be calculated from k_{3a}/K_{ma} (or directly from k_{3a} if $K_m=K_m'$). The K' values were tentatively calculated from the data on the assumption of this mechanism. There is, however, no linear relationship between K and the methanol concentration nor between $\log K$ and $1/D$, as may be seen from Figs. 5 and 6. Thus, the experimental results are inconsistent with this assumption.

Aggregation of the Substrate.—If the addition of the organic solvent gives rise to aggregation of the substrate, the effective concentration of the substrate will be reduced from s to γs, where γ is a positive number less than unity. The initial rate, v, becomes

$$v=\frac{k_3es}{K_m/\gamma+s} \quad (18)$$

Thus, in the presence of the organic solvent, the apparent Michaelis constant will be increased by a factor of $1/\gamma$, while k_3 will remain constant. Obviously this is not consistent with our results.

As was mentioned earlier, it was experimentally confirmed that neither the irreversible inactivation of the enzyme (one of factor 4) nor the shift of pH curve (factor 6) can be the cause of the present results.

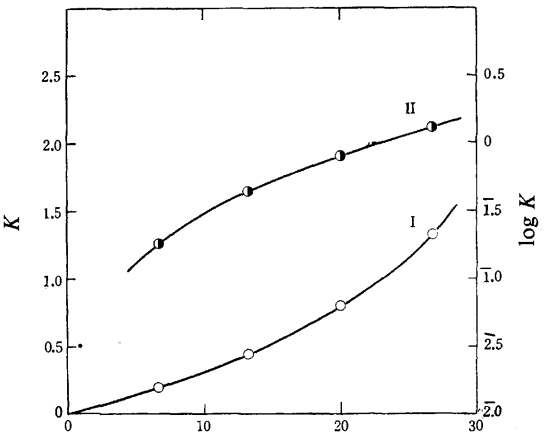

Fig. 5. Plots of K (Curve I) and $\log K$ (Curve II) vs. methanol concentration.

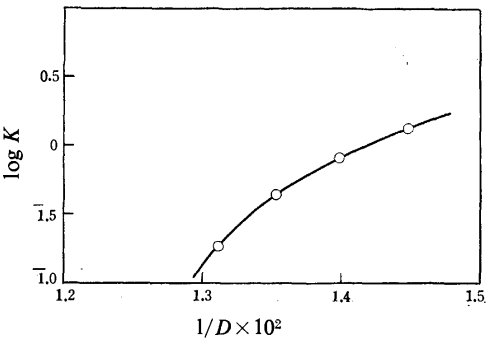

Fig. 6. Plot of $\log K$ vs. $1/D$.

Analysis of the Results by the Electrostatic Theory.—The above arguments have shown that no reasonable interpretation of the results can be obtained on the basis of factors 2 to 6 mentioned above. We will next, examine the possibility of the factor 1, i. e., the electrostatic influence of the dielectric constant of the medium. According to the theory of the dielectric constant effect on enzyme reactions which has been developed by one of the present authors [17,18], the variation of the rate parameters, K_m and k_3, with the dielectric constant, D, of the solvent can be expressed in the following equations:

$$-\frac{d\log K_m}{d(1/D)}=\frac{\varepsilon^2}{2.303(2kT)}\left[\frac{L_S}{b_S}+\frac{1}{b_E}(L_E-L_{ES})\right] \quad (19)$$

$$=\frac{\varepsilon^2}{2.303(2kT)}\left[\frac{L_S}{b_S}+\frac{1}{b_E}(L^o_E-L^o_{ES})\right] \quad (20)$$

$$\frac{d \log k_3}{d(1/D)} = \frac{\varepsilon^2}{2.303(2kT)} \cdot \frac{1}{b_{ES}}(L_{ES} - L_{ES^{\neq}}) \quad (21)$$

$$= \frac{\varepsilon^2}{2.303(2kT)} \cdot \frac{1}{b_{ES}}(L^{o}_{ES} - L^{o}_{ES^{\neq}}) \quad (22)$$

where ε is the protonic charge, k the Boltzmann constant, T, the absolute temperature, b's are the radii of the species denoted by the suffixes, and L's are their "charge configuration functions" as defined elsewhere[17]. L is a dimensionless quantity which is determined by the radius and the charge state of the molecule; it is calculated by the aid of Tables I and II of Ref. 17, provided the charge configuration within the molecule is given. Although the spatial distribution of every charge in E, ES or $ES^{\neq}$ is not yet known, and the exact evaluation of the L values of these species is impossible, it can be shown that under certain conditions we may use the "effective charge configuration function"[18] denoted by L^o instead of the complete charge configuration function, L. L^o is the charge configuration function constructed with respect only to the small number of charges within the local region of the enzyme or the enzyme-substrate complex in which the catalytic reaction is considered to occur, neglecting all the other charges, which are considered to be unimportant for the reaction and to be fixed during the course of the reaction. The radii of E, ES and $ES^{\neq}$ may be equated for small substrates. Thus, Eqs. 20 and 22 are the approximate equations to be used in treating enzyme reactions. These equations predict that the plot of $\log K_m$ or $\log k_3$ against $1/D$ will give a straight line, the slope of which will be determined by the radii and the effective charge configuration functions of the species involved. In Fig. 7 are shown the plots of $\log K_m$ and $\log k_3$ versus $1/D$. The linearity of the plots is in accordance with the theory.

Since L is usually small for a neutral molecule unless it is largely polarized, the contribution of the L_S/b_S term in Eq. 20 to the slope may be no more than the experimental error of the slope. (For example, this contribution has been found to be negligibly small for several uncharged organic acids[17]). Thus, the fact that the slope $d \log K_m/d(1/D)$ is zero implies that L^o_{ES} is equal to L^o_E (or $L_{ES}=L_E$); i. e., there is no appreciable change in charge state during the formation of the ES complex because a change in the charge state would be reflected in a change in L^o. The force operating in the ES complex formation, therefore, is supposed to be non-electrostatic in origin, i. e., van der Waals force or hydrogen bonding, or both.

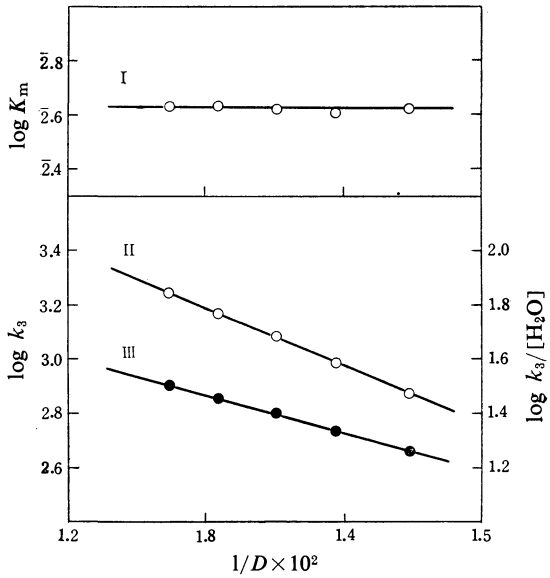

Fig. 7. Plots of log K_m (Curve I), log k_3 (Curve II) and log $k_3/[H_2O]$ (Curve III) vs. $1/D$.

On the other hand, the plot of log k_3 versus $1/D$ gives a straight line of negative slope, indicating that the effective charge configuration function of the activated state of the ES complex ($L^o_{ES^{\neq}}$) is larger than that of the normal ES complex (L^o_{ES}). If we calculate L^o_{ES} and $L^o_{ES^{\neq}}$, assuming certain charge configurations of ES and $ES^{\neq}$, and compare the slope $d \log k_3/d(1/D)$ thus calculated with that observed experimentally, we can pick up some of the charge configurations as plausible; this may give information about the reaction mechanism.

The theoretical estimation of the slope, $d \log k_3/d(1/D)$, will be made on the basis of the following assumptions, all of which are considered plausible: 1) In the activated state of ES, designated by $ES^{\neq}$, the C_1 atom and the glucosidic oxygen atom of the substrate molecule are located near the surface of the sphere of $ES^{\neq}$, with their centers situated d Å below the surface (d was taken to be 0.3 Å to 1.0 Å). The bond length between these atoms is assumed to be ca. 50% stretched over the normal value. (For convenience of calculation, the angle between the lines adjoining the center of the sphere to the C_1 atom and the oxygen atom was kept constant at 5°26'40''. This angle corresponds to the bond length of 2.15 Å when d is 0.5 Å. The bond length ranges form 2.10 Å to 2.17 Å depending on the value of d[28].) As a consequence of the

28) This minor change in the bond length scarely affects the value of the slope.

charge separation in ES‡, two charges of equal magnitude but of opposite signs are produced on the C_1 atom and the glucosidic oxygen atom between which the linkage is to be split. In the ground state of ES, however, no such charge separation is assumed to occur. 2) The essential dissociable groups of the enzyme, the carboxylate and the imidazolium (or ammonium) group, which are considered essential in the breakdown process of ES[19], are assumed to be located below the glucosidic bond and to attack the bond simultaneously as a base and as an acid, respectively[19]. The water molecule is considered to be situated between the carboxylate group and the C_1 atom. The positions of these essential groups are assumed to be kept fixed in ES and ES‡. The geometrical disposition of the atoms assumed in the calculation is shown in Fig. 8. The C_1

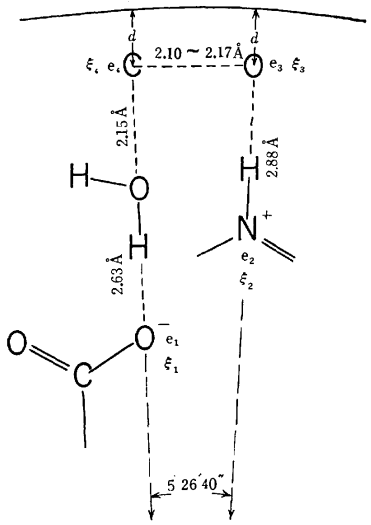

Fig. 8. Model of ES‡.
e_1 and e_2 represent the charges of the essential ionizable groups of the enzyme, and e_3 and e_4 represent the charges produced in the glucosidic linkage in the activated state.

atom, the O–H bond of the water molecule and the carboxylate oxygen atom are assumed to lie on one radius, and the glucosidic oxygen and the N–H bond of the imidazolium group on another radius. The hydrogen-bonded distances of O–H···O and N–H···O are taken as 2.63 Å and 2.88 Å respectively[29]. The charges to be considered (or to be involved in the effective charge configuration functions) are those on carboxylate oxygen, imidazolium nitrogen, glucosidic oxygen, and the C_1 atom; they are designated by $e_1, e_2, \ldots, e_4$, respectively, as is shown in Fig. 8. ξ's are the valences of the charges. In ES, it was assumed that $\xi_1=-1$ and $\xi_2=+1$ and $\xi_3=\xi_4=0$. In ES‡, calculations were carried out for several cases, i.e., $\xi_3=-\xi_4=\pm 1$ and $\pm 1/2$; $-\xi_1=+\xi_2=1$, 1/2 or 0, and $d=0.3$, 0.5, 0.7 and 1.0 Å.

The expressions for L°_{ES} and $L^{\circ}_{ES^{\ddagger}}$ are as follows[18,19]:

$$L^{\circ}_{ES}=\xi_1^2 f_{11}+\xi_2^2 f_{22}+2\xi_1\xi_2 g_{12} \tag{23}$$

$$L^{\circ}_{ES^{\ddagger}}=\sum_{k=1}^{4}\xi_k^2 f_{kk}+\sum_{k=1,l\neq k}^{4}\sum\xi_k\xi_l g_{kl}=\xi_1^2 f_{11}+\xi_2^2 f_{22}+\xi_3^2 f_{33}+\xi_4^3 f_{44}+2\xi_1\xi_2 g_{12}+2\xi_1\xi_3 g_{13}+2\xi_1\xi_4 g_{14}+2\xi_2\xi_3 g_{23}+2\xi_2\xi_4 g_{24}+2\xi_3\xi_4 g_{34} \tag{24}$$

f_{kk} is a function of $(r_k/b)^2$, where r_k is the distance of the charge, e_k, from the center of the molecule. g_{kl} is a function of $(r_k r_l/b^2)$ and $\cos\theta_{kl}$, where θ_{kl} is the angle between r_k and r_l. The values of f_{kk} and g_{kl} may be readily obtained from the tables[17] if r_k's and θ_{kl}'s are calculated from Fig. 8.

The results of the calculation are summarized in Table II, in which the slopes theoretically predicted for various cases are presented. The theoretical slopes are negative in all the cases considered, the magnitude depending primarily upon the valences of the charges produced on the glucosidic linkage (ξ_3 and ξ_4) and on the depth of the charges, d, and being relatively insensitive to the situation of the neighboring charges, e_1 and e_2. The experimentally observed magnitude of the slope, -210, may reasonably be accounted for if $d=0.6$ Å and $-\xi_3=+\xi_4=\pm 1$, i.e., if a considerably large separation of charges occurs in the glucosidic linkage in the activated state, ES‡. The value of d is not of an unreasonable order of magnitude, although it appears to be somewhat smaller than that of the carboxylic oxygen atom (ca. 1.0 Å)[17], calculated from the dependence of the pK values of carboxylic acids on the dielectric constant of the medium.

Discussion

The above calculations have revealed that the observed results can reasonably be explained in terms of the electrostatic effect of the dielectric constant of the solvent on the reaction rates only, although slightly smaller values had to be assigned for d. However, it may also be possible that, in addition to the dielectric constant effect, some non-electrostatic effects, e.g., a decrease in the water concentration or an inhibitory effect of the organic solvent, might have been involved in the observed results. Although it is not a simple matter to determine the magnitude of the effect which is really due to the dielectric

29) G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond", Freeman & Co., San Francisco (1960), pp. 284, 289. These are the average values for carboxylic acids and for ammonium, respectively. A minor change in these values does not affect the resultant slopes seriously.

a) The large white or black circle represents a positive or a negative unit charge, and the small white or black circle a positive or a negative half unit charge, respectively.

constant of the solvent itself, we may be able to take the non-electrostatic effect to some extent into consideration by plotting the logarithms of $k_3/[H_2O]$ instead of k_3 versus $1/D$. This case corresponds to case 1 considered above, where water reacts with the ES complex directly from the bulk of solvent (see Eq. 4), or to a special case of case 2 (the case in which $K_W=K_M/p$ in Eq. 8), where methanol competes for the water site with the water molecule. This plot is shown in curve III of Fig. 7, where a straight line with a slope of -124 is obtained. Table II shows that this order of magnitude of the slope is reasonably accounted for if $-\xi_3=+\xi_4=\pm1$ and $d=0.75\sim0.8$ Å.

Although there is a little ambiguity in the value of d to be assigned, it may be reasonable to conclude that the main effect operating in the present case is the electrostatic one, i. e., the effect of the dielectric constant on the rate, and the results of calculation are consistent with the hypothesis that the charge separation occurs at the glucosidic linkage of the substrate molecule to be hydrolyzed in the activated state of the ES complex.

Electrostatic Entropy.—Electrostatic entropy is often discussed in relation to the dielectric constant effect on reaction rates[1-3,9,10]. As will be shown in the Appendix, we can estimate the electrostatic part of the entropy change involved in the formation of the ES complex, $\Delta S_{e.s.}$, and of the entropy of activation involved in the breakdown of the ES complex, $\Delta S_{e.s.\neq}$, if we assume that the temperature dependence of the internal dielectric constant of the cavity is much smaller than that of the solvent. From Eqs. A-13 and A-14 in the Appendix, with water as the solvent and at 25°C, we obtain:

$$\Delta S_{e.s.} \fallingdotseq -0.159 \times \frac{d \log K_m}{d(1/D)} \tag{25}$$

$$\Delta S_{e.s.\neq} \fallingdotseq 0.159 \times \frac{d \log k_3}{d(1/D)} \tag{26}$$

Since $d \log K_m/d(1/D)=0$, and $d \log k_3/d(1/D)=-210$ or -124 according as the non-electrostatic effect of the solvent is disregarded or not, we can estimate the electrostatic entropies to be:

$\Delta S_{e.s.} \fallingdotseq 0$

$\Delta S_{e.s.\neq} \fallingdotseq -33$ or -20 cal. deg^{-1} mol^{-1}

The negative entropy of activation suggests that the electrostriction of the solvent is caused by the charge separation in ES$_{\neq}$.

Summary

The influence of methanol on the rate of the hydrolytic reaction of soluble starch catalyzed by crystalline bacterial amyloclastic α-amylase has been studied at 25°C and pH 6.0, over the methanol concentration of 0～22.6% by weight.

The apparent Michaelis constant, K_m, is independent of the methanol concentration,

while the breakdown rate constant of the ES complex, k_3, decreases with an increase in the methanol concentration.

The plot of log k_3 versus the reciprocal dielectric constant of the solvent gives a straight line with a negative slope.

Various possible effects on the reaction rates caused by the addition of methanol have been examind, and it has been concluded that the dielectric constant effect is predominantly operative.

The results have been interpreted quantitatively on the basis of the electrostatic theory previously developed by one of the present authors. The results of calculation have been found to be consistent with the hypothesis that charge separation occurs in the glucosidic linkage to be hydrolyzed in the activated state of the ES complex.

The electrostatic entropy of activation in the breakdown of the ES complex has also been estimated.

The authors wish to express their appreciation to Professor Juichiro Fukumoto and Dr. Takehiko Yamamoto of Osaka City University for their gift of the crystalline enzyme.

Appendix

The Evaluation of the Electrostatic Entropy.— The electrostatic part of the entropy of reaction and that of the entropy of activation may be estimated from the variation of the equilibrium constant and of the rate constant with the dielectric constant of the medium respectively, in the following manner. For example, consider an equilibrium:

$$A+B=C+D \tag{A-1}$$

with an equilibrium constant of K. We have:

$$\Delta G=-\boldsymbol{R}T\ln K \tag{A-2}$$

where ΔG is the standard free energy change, which is divided into the non-electrostatic part, $\Delta G_{n.e.s.}$, and the electrostatic part, $\Delta G_{e.s.}$. Thus

$$\Delta G=\Delta G_{n.e.s.}+\Delta G_{e.s.} \tag{A-3}$$

The electrostatic free energy, $\Delta G_{e.s.}$, is expressed in terms of the work of the charging, W, of each species, in the following equation:

$$\Delta G_{e.s.}=\boldsymbol{N}\Delta W=\boldsymbol{N}(W_C+W_D-W_A-W_B) \tag{A-4}$$

where $\boldsymbol{N}$ is the Avogadro number. ΔW of a species for zero ionic strength, designated as W_0, is expressed in the form:

$$W_0=\frac{\varepsilon^2}{2b}\left(\frac{L'}{D_1}+\frac{L}{D}\right) \tag{A-5}$$

where ε is the protonic charge, b, the radius of the species, L, the charge configuration function, and L', a parameter also dependent on the charge configuration of the species. (The full expressions of L and L' will be found in Eq. 3 of Ref. 17.) D_1, the internal dielectric constant of the spherical cavity formed by the solute species, was taken by Kirkwood to be 2 for all the molecules or ions. D is the dielectric constant of the solvent.

The electrostatic part of the entropy change, $\Delta S_{e.s.}$, is obtained by differentiating $\Delta G_{e.s.}$ with respect to the absolute temperature, T. Thus we have:

$$\Delta S_{e.s.}=-\frac{\partial(\Delta G_{e.s.})}{\partial T}=-N\cdot\frac{\partial(\Delta W)}{\partial T}$$
$$=-\frac{N\varepsilon^2}{2}\left[\frac{\partial(1/D_1)}{\partial T}\cdot\Delta\left(\frac{L'}{b}\right)+\frac{\partial(1/D)}{\partial T}\cdot\Delta\left(\frac{L}{b}\right)\right] \tag{A-6}$$

where $\Delta(L'/b)$ and $\Delta(L/b)$ stand for:

$$\Delta\left(\frac{L'}{b}\right)=\frac{L'_C}{b_C}+\frac{L'_D}{b_D}-\frac{L'_A}{b_A}-\frac{L'_B}{b_B} \tag{A-7}$$

$$\Delta\left(\frac{L}{b}\right)=\frac{L_C}{b_C}+\frac{L_D}{b_D}-\frac{L_A}{b_A}-\frac{L_B}{b_B} \tag{A-8}$$

The dielectric constant of a liquid can be expressed as a function of temperature by the empirical formula[30]:

$$D=D^0e^{-T/\theta} \tag{A-9}$$

where D^0 and θ are the constants characteristic of the liquid. Since L and L' are considered to be independent of temperature, if we assume that $\partial(1/D_1)/\partial T$ is much smaller than $\partial(1/D)/\partial T$, i.e., the temperature coefficient of the reciprocal dielectric constant of the cavity is negligibly smaller than that of the solvent, Eq. A-6 becomes:

$$\Delta S_{e.s.}=-\frac{\varepsilon^2\boldsymbol{N}}{D\theta}\cdot\Delta\left(\frac{L}{b}\right)$$
$$=\frac{\varepsilon^2\boldsymbol{N}}{D\theta}\left(\frac{L_A}{b_A}+\frac{L_B}{b_B}-\frac{L_C}{b_C}-\frac{L_D}{b_D}\right)$$
$$=\frac{4.606\,\boldsymbol{R}T}{D\theta}\cdot\frac{\mathrm{d}\log K}{\mathrm{d}(1/D)} \tag{A-10}$$

since

$$\frac{\mathrm{d}\log K}{\mathrm{d}(1/D)}=\frac{\varepsilon}{4.606\,kT}\left(\frac{L_A}{b_A}+\frac{L_B}{b_B}-\frac{L_C}{b_C}-\frac{L_D}{b_D}\right) \tag{A-11}$$

Thus, the electrostatic entropy, $\Delta S_{e.s.}$, is expressed in terms of the slope, $\mathrm{d}\log K/\mathrm{d}(1/D)$, which can be obtained experimentally. Quite similarly, for a rate process, we have:

$$\Delta S_{e.s.\neq}=\frac{4.606\,\boldsymbol{R}T}{D\theta}\cdot\frac{\mathrm{d}\log k}{\mathrm{d}(1/D)} \tag{A-12}$$

where $\Delta S_{e.s.\neq}$ and k are the electrostatic entropy of activation and the rate constant, respectively.

With water as solvent and at 25°C, $\theta=219$[30], $D=78.5$ and $T=298$; therefore, we have

$$\Delta S_{e.s.}\fallingdotseq 0.159\times\frac{\mathrm{d}\log K}{\mathrm{d}(1/D)} \tag{A-13}$$

$$\Delta S_{e.s.\neq}\fallingdotseq 0.159\times\frac{\mathrm{d}\log k}{\mathrm{d}(/1D)} \tag{A-14}$$

Syntheses of Some Derivatives of 7-Hydroxydecahydroisoquinoline

By Tatsuo TOMIOKA, Toshio NAKAMURA and Yasuo HOSHIDE

(Received December 4, 1962)

The syntheses described in this paper were undertaken to prepare some compounds related to reserpine, an important alkaloid found in *Rauwolfia* species. Sastry and Lasslo[1] and Miller and Weinberg[2] have reported syntheses and significant reserpine-like activities of the 3-(*N*, *N*-diethylaminopropyl) and 4-(*N*, *N*-diethylaminobutyl) esters of 3, 4, 5-trimethoxybenzoic acid, and a considerable number of compounds in which the alcohol moiety of the carboxylic ester and the acyl moiety of the trimethoxybenzoic acid ester functions vary have been reported in the patent literature. However, little information is available regarding the related derivatives of decahydroisoquinoline. Of special interest were decahydroisoquinoline derivatives, which contain a peripheral *N*-alkyl group simulating the cut-away indole portion of reserpine. Such a derivative corresponds to that part of reserpine shown by solid line in Formula 1. The present paper is concerned with the synthesis of methyl quaternary bromides of 7-methoxybenzoyloxy-2-methyldecahydroisoquinolines and of 7-methoxybenzoyloxy-2-ethyldecahydroisoquinolines[3].

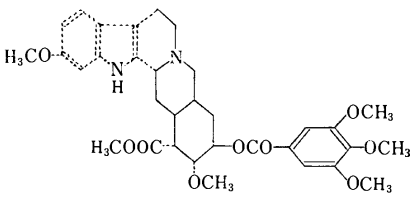

Chart 1

7-Hydroxy-2-methyl- and 7-hydroxy-2-ethyl decahydroisoquinoline and their derivatives were prepared by the general scheme outlined in Chart 2:

Methiodide (I) of 7-hydroxyisoquinoline was reduced with sodium borohydride to yield 7-hydroxy-2-methyl-1, 2, 3, 4-tetrahydroisoquinoline (II) in a 76.5% yield. The catalytic hydrogenation of II with Raney nickel proceeded smoothly, affording an 84.2% yield of 7-hydroxy-2-methyldecahydroisoquinoline (III), an oily product with a b. p. of 110~115°C (2 mmHg). The structure of III was confirmed by elemental analysis and by the formation of a methiodide derivative. Ochiai and Nakagome[4] reported a b. p. of 105~115°C (3 mmHg, bath temperature) for the material obtained on the catalytic hydrogenation of 2-methyl-7-oxo-Δ^8-octahydroisoquinoline with platinum oxide; moreover, they reported a m. p. of 257~258°C for its methiodide. It was found that the melting point of our sample varied with the nature of the solvent used for recrystallization. Repeated recrystallization from alcohol gave a m. p. of 277.5~278.5°C, and recrystallization from alcohol-petroleum ether gave a m. p. of 253~257°C, substantially the same melting point as that described by Ochiai and Nakagome. Although stereoisomeric separation was not attempted, III can be assumed to be a mixture of stereoisomers.

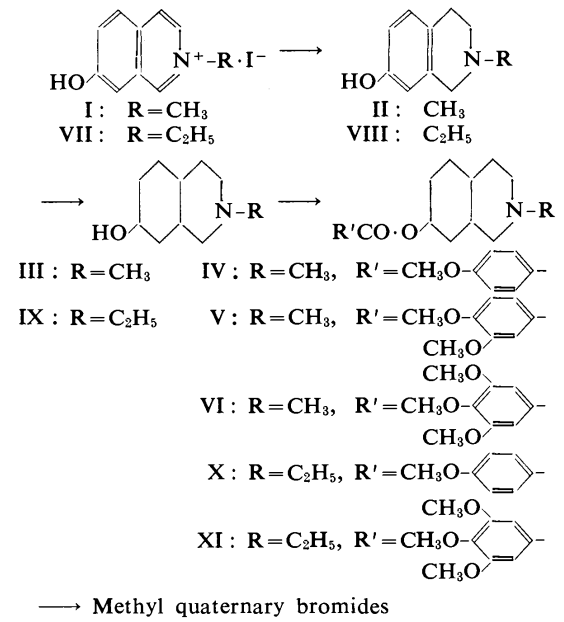

Chart 2

Compounds of Formulas IV, V and VI were prepared by the treatment of 7-hydroxy-2-methyldecahydroisoquinoline (III) with anisoyl

3) Recently, syntheses of 5-hydroxy-2-methyldecahydroisoquinoline and 6-hydroxy-2-methyldecahydroisoquinoline have been reported by S. Kimoto and M. Okamoto, *Chem. & Pharm. Bull.*, **9**, 480 (1961); **10**, 368 (1962).

4) E. Ochiai and T. Nakagome, *J. Pharm. Soc. Japan*, **78**, 1438 (1958).

chloride, veratroyl chloride and tri-*O*-methylgalloyl chloride respectively in benzene at 45°C for 6 hr. After removal of the solvent, each of the reaction mixtures was treated with water, each giving an insoluble part which was confirmed to be anisic anhydride, veratric anhydride or tri-*O*-methylgallic anhydride respectively. The water-layers were evaporated under reduced pressure, and the viscous products were treated with silver carbonate in acetone-methanol. Each of the resulting free bases was chromatographed on alumina and eluted with ether to give two fractions, namely, the first and second fractions. The second fractions were 7-hydroxy-2-methyldecahydroisoquinoline, unchanged and converted to its crystalline methiodide, which was identified by comparison with the methiodide of III. After removal of ether from the first fractions, each of the resulting syrups was treated with an excess of methyl bromide to yield a crystalline mixture of stereoisomers of methyl 7-aroyloxy-2-methyldecahydroisoquinolinium bromide. Extraction of each of the stereoisomeric mixtures with a large quantity of acetone left a relatively insoluble isomer (A), while evaporation of the acetone-extract gave a soluble isomer (B). Thus, each of the methiodides of 7-anisoyloxy-2-methyldecahydroisoquinoline, 7-veratroyloxy-2-methyldecahydroisoquinoline and 7-tri-*O*-methylgalloyloxydecahydroisoquinoline was separated into two corresponding isomers, A and B.

The synthesis of 7-hydroxy-2-ethyldecahydroisoquinoline (IX) was carried out by procedures analogous to those used for the preparation of the 2-methyl derivative III. The condensation products of 7-hydroxy-2-ethyldecahydroisoquinoline (IX) with anisoyl chloride and tri-*O*-methylgalloyl chloride were treated with water, giving again anisic anhydride and tri-*O*-methylgallic anhydride respectively. The viscous products obtained from the water-layers by evaporation were treated with silver carbonate in acetone, and the resulting free bases were subjected to alumina chromatography to yield again two fractions, the second fraction being unchanged IX. Evaporation of each of the first fractions gave an oily mixture of stereoisomers of 7-aroyloxy-2-ethyldecahydroisoquinoline. The oily product of 7-anisoyloxy-2-ethyldecahydroisoquinoline was treated with an excess of methyl bromide to yield a crystalline product of methyl 7-anisoyloxy-2-ethyldecahydroisoquinolinium bromide (XV). The treatment of this product with acetone again gave two fractions, one soluble and one relatively insoluble; however, only one isomer could be obtained from the soluble fraction.

The oily product of 7-(tri-*O*-methylgalloyloxy)-2-ethyldecahydroisoquinoline was also treated with an excess of methyl bromide, producing a crystalline product of methyl 7-(tri-*O*-methylgalloyloxy)-2-ethyldecahydroisoquinolinium bromide (XVI). Treatment of the product with acetone also gave two fractions, one soluble and one relatively insoluble, from which one isomer could be obtained.

Although stereochemical assignments for the above-mentioned isomers have not yet been made, material differences have been discerned between the biological properties of the stereoisomeric derivatives of methyl quaternary bromide, and some of them look promising for clinical use. Details of the studies of the hypotensive activity and toxicity of the above-mentioned stereoisomeric derivatives will be published elsewhere in the near future.

Experimental

7-Hydroxy-2-methyl-1, 2, 3, 4-tetrahydroisoquinoline (II).—A solution of 1.19 g. of 7-hydroxyisoquinoline methiodide (I) in 25 ml. of 10% aqueous methanol was added to 0.66 g. of sodium borohydride and refluxed for 5 min. After the addition of 10 ml. of acetone, the reaction mixture was allowed to cool to room temperature. After removal of the solvent, the residue was mixed with 15 ml. of a 3.5% sodium carbonate solution to give colorless crystals of the title compound; m. p., 169~170°C, 0.52 g. (76.5%). Repeated recrystallizations from acetone raised the m. p. to 171~172°C (reported[5]: 171~172°C).

7-Hydroxy-2-methyldecahydroisoquinoline (III).—A solution of 2.99 g. of 7-hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline (II) in 330 ml. of absolute ethanol was hydrogenated with 3.5 g. of Raney nickel at 155~160°C for 16 hr. at a pressure of 200~202 kg./cm^2. After removal of the catalyst by filtration, the reaction mixture was evaporated to give an oily residue, which was then distilled under reduced pressure to give 2.61 g. (84.2%) of 7-hydroxy-2-methyldecahydroisoquinoline; b. p., 110~115°C (2 mmHg). The b. p. reported by Ochiai and Nakagome[4] is 105~115°C (3 mmHg, bath temperature).

Methiodide of III.—A mixture of 7-hydroxy-2-methyldecahydroisoquinoline and of an excess of methyl iodide in ethyl acetate, when warmed for a while and then allowed to cool to room temperature, gave colorless crystals of methyl iodide; m. p., 229~253°C. Repeated recrystallizations from ethanol raised the m. p. to 277.5~278.5°C.

Found: C, 42.28; H, 7.23; N, 4.76. Calcd. for $C_{11}H_{22}ONI$: C, 42.44; H, 7.07; N, 4.50%.

Recrystallizations of the crude methiodide from ethanol-petroleum ether gave a m. p. of 253~257°C (reported[4] 257~258°C).

Found: C, 42.17; H, 7.15%.

7-Anisoyloxy-2-methyldecahydroisoquinoline (IV).—A solution of 1.29 g. of anisoyl chloride in 15 ml.

5) F. L. Pyman and F. G. P. Remfry, *J. Chem. Soc.*, 101, 1595 (1912).

of dried benzene was stirred drop by drop into a solution of 1.28 g. of 7-hydroxy-2-methyldecahydroisoquinoline (III) in dried benzene. This solution was warmed at 45°C for 6 hr. and then distilled under reduced pressure to give 2.80 g. of a viscous residue. This residue was triturated with 50 ml. of water, and the aqueous layer was separated from the insoluble part by filtration. Recrystallization of the insoluble part (0.66 g.) from ethanol-water gave colorless crystals of anisic anhydride; m. p., 98~99°C (reported m. p., 99°C)[6].

Found: C, 67.12; H, 4.69. Calcd. for $C_{16}H_{14}O_5$: C, 67.13; H, 4.93%.

The above-mentioned aqueous layer was treated with a small quantity of active charcoal and evaporated under reduced pressure. The viscous residue was then dissolved in a mixture of 50 ml. of acetone and 20 ml. of methanol and mixed thoroughly with 3.0 g. of silver carbonate. After removal of the precipitate by filtration, the solution was evaporated under reduced pressure, and the residue was taken up in a small quantity of ether. The ether solution was evaporated to give an oily product (1.56 g.). This product was chromatographed on alumina and then developed and eluted with ether to give two fractions. The second fraction was treated with methyl iodide to yield a methiodide with a m. p. of 266~269°C, which was identical with the methiodide of 7-hydroxy-2-methyldecahydroisoquinoline.

The first fraction was evaporated to give an oily product of 7-anisoyloxy-2-methyldecahydroisoquinoline (IV) (0.75 g.) (32.8%).

Stereoisomers (XII-A, XII-B) of Methyl 7-Anisoyloxy-2-methyldecahydroisoquinolinium Bromide.—A mixture of 0.75 g. of the crude product of 7-anisoyloxy-2-methyldecahydroisoquinoline (IV) and an excess of methyl bromide in 20 ml. of ether was sealed in a test tube and allowed to stand at room temperature for 2 days. Removal of the solvent from the reaction mixture gave 0.97 g. of crude crystals of quaternary ammonium salt. This crude product was thoroughly triturated with 110 ml. of acetone, and the acetone-layer was separated from the insoluble part by filtration. The insoluble part weighed 0.32 g. (33.0%) and melted at 262.5~265.5°C. Repeated recrystallizations from ethanol-petroleum ether gave colorless needles with a m. p. of 281~282°C. Elemental analysis indicated the product to be a stereoisomer (XII-A) of methyl 7-anisoyloxy-2-methyldecahydroisoquinolinium bromide.

Found: C, 57.60; H, 7.32; N, 3.67. Calcd. for $C_{19}H_{28}O_3NBr$: C, 57.29; H, 7.08; N, 3.52%.

The above-mentioned acetone-layer was evaporated, and the residue was again dissolved in 60 ml. of acetone, leaving a small insoluble part. The acetone solution was concentrated to 20 ml., and the separated crystals were collected; 0.25 g. (25.8%); m. p., 216~221°C. Recrystallizations from acetone-ethyl acetate gave colorless needles with a m. p. of 220~223°C. Elemental analysis indicated the product to be another isomer (XII-B) of methyl 7-anisoyloxy-2-methyldecahydroisoquinolinium bromide.

Found: C, 57.63; H, 7.28; N, 3.79. Calcd. for $C_{19}H_{28}O_3NBr$: C, 57.29; H, 7.08; N, 3.52%.

The mixed melting point of the two above-mentioned isomers showed considerable depression and a wide range.

Evaporation of the mother-liquor from the isomer (XII-B) left 0.33 g. of a viscous residue.

7-Veratroyloxy-2-methyldecahydroisoquinoline (V). — In a manner similar to that used for the preparation of IV, 1.47 g. of 7-hydroxy-2-methyldecahydroisoquinoline (III) was treated with 1.78 g. of veratroyl chloride in benzene to give 3.49 g. of a viscous product. Trituration of the product with 250 ml. of water left an insoluble part (0.60 g.), which was recrystallized from ethanol to give colorless needles of veratric anhydride; m. p., 118~120°C (reported m. p., 124~125°C)[7]. The aqueous layer was treated with active charcoal and evaporated. The viscous residue was dissolved in a mixture of 50 ml. of acetone and 20 ml. of methanol and mixed thoroughly with 3.8 g. of silver carbonate. After removal of the precipitate, the solution was evaporated and the residue was taken up in a small quantity of ether. The oily product obtained by the evaporation of the ether solution was chromatographed on alumina and then developed and eluted with ether to give two fractions. The first fraction was evaporated to give 1.05 g. (36.2%) of an oily product of 7-veratroyloxy-2-methyldecahydroisoquinoline (V).

The Stereoisomers (XIII-A, XIII-B) of Methyl 7-Veratroyloxy-2-methyldecahydroisoquinolinium Bromide. — In a manner similar to that used for the preparation of XII-A and XII-B, 1.05 g. of the crude product of 7-veratroyl-2-methyldecahydroisoquinoline was treated with an excess of methyl bromide to give 1.31 g. of crude crystals of quaternary ammonium salt. The crude product was thoroughly triturated with 350 ml. of acetone, and the acetone-layer was separated from the insoluble part. The insoluble part weighed 0.30 g. (22.0%) and melted at 252~255°C. Repeated recrystallizations from ethanol-petroleum ether gave colorless needles; m. p., 263~264°C. Elemental analysis indicated the product to be a stereoisomer (XIII-A) of methyl 7-veratroyloxy-2-methyldecahydroisoquinolinium bromide.

Found: C, 56.08; H, 7.03; N, 3.32. Calcd. for $C_{20}H_{30}O_4NBr$: C, 56.08; H, 7.06; N, 3.27%.

The acetone-layer was evaporated, and the residue was again dissolved in 130 ml. of acetone, leaving a small insoluble part. Concentration of the acetone solution to 17 ml. separated 0.58 g. (43.0%) of crystals; m. p., 157~162°C. Recrystallizations from acetone gave colorless hygroscopic needles with a m. p. of 169~170°C. Elemental analysis indicated the product to be another stereoisomer (XIII-B) of methyl 7-veratroyloxy-2-methyldecahydroisoquinolinium bromide.

Found: C, 55.14; H, 6.93; N, 2.93. Calcd. for $C_{20}H_{30}O_4NBr \cdot 1/2H_2O$: C, 54.93; H, 7.14; N, 3.20%.

The mixed melting point of the two above-mentioned isomers showed considerable depression and

7) J. Shinoda and S. Sato, *J. Pharm. Soc. Japan* (*Yakugaku Zasshi*), No. 540, 24 (1927).

wide range.

7-(Tri-*O*-methylgalloyloxy)-2-methyldecahydroisoquinoline (VI). — In a manner similar to that used for the preparation of IV, 1.50 g. of 7-hydroxy-2-methyldecahydroisoquinoline (III) was treated with 2.06 g. of tri-*O*-methylgalloyl chloride in benzene to give 3.56 g. of a viscous product. Trituration of the product with 320 ml. of water left an insoluble part (0.93 g.), which was then recrystallized from acetone to give colorless needles of tri-*O*-methylgallic anhydride with a m. p. of 159~160°C (reported m. p., 159~160°C)[8].

Found: C, 59.32; H, 5.53. Calcd. for $C_{20}H_{22}O_9$: C, 59.11; H, 5.46%.

After the aqueous layer had been processed, an oily product (1.86 g.) was chromatographed on alumina by a similar procedure to give two fractions. The oily product from the second fraction gave methiodide (m. p., 261~266°C) which was identical with the methiodide of the starting substance III. The first fraction gave 1.04 g. (32.2%) of an oily product of 7-(tri-*O*-methylgalloyloxy)-2-methyldecahydroisoquinoline.

The Stereoisomers (XIV-A, XIV-B) of Methyl 7-(Tri-*O*-methylgalloyloxy)-2-methyldecahydroisoquinolinium Bromide.—In a manner similar to that used for the preparation of XII-A and XII-B, 1.04 g. of 7-(tri-*O*-methylgalloyloxy)-2-methyldecahydroisoquinoline was reacted with an excess of methyl bromide to give 1.29 g. of crude crystals of quaternary ammonium salt. Fractionation of the product with acetone gave two fractions. The more insoluble fraction weighed 0.29 g. (21.9%) and melted at 260~263°C. Recrystallizations from ethanol-petroleum ether gave colorless needles with a m. p. of 262.5~264.0°C. Elemental analysis indicated the product to be a stereoisomer (XIV-A) of methyl 7-(tri-*O*-methylgalloyloxy)-2-methyldecahydroisoquinolinium bromide.

Found: C, 54.58; H, 7.37; N, 3.36. Calcd. for $C_{21}H_{32}O_5NBr$: C, 55.02; H, 7.04; N, 3.06%.

The soluble fraction weighed 0.47 g. (36.3%) and melted at 192~198°C. Recrystallizations from acetone gave colorless hygroscopic plates with a m. p. of 201.5~203.5°C. Elemental analysis indicated the product to be another isomer (XIV-B) of methyl 7-(tri-*O*-methylgalloyloxy)-2-methyldecahydroisoquinolinium bromide.

Found: C, 55.01; H, 7.04; N, 3.27. Calcd. for $C_{21}H_{32}O_5NBr$: C, 55.02; H, 7.04; N, 3.06%.

7-Hydroxy-2-ethyl-1,2,3,4-tetrahydroisoquinoline (VIII).—The reduction of 7.08 g. of 7-hydroxyisoquinoline methiodide with 3.57 g. of sodium borohydride in 10% aqueous methanol gave 4.08 g. (97.8%) of crude crystals. Recrystallization from acetone-petroleum ether gave colorless needles with a m. p. of 144~147°C.

Found: C, 74.13; H, 8.48. Calcd. for $C_{11}H_{15}ON$: C, 74.53; H, 8.53%.

7-Hydroxy-2-ethyldecahydroisoquinoline (IX).—A sample of 3.22 g. of 7-hydroxy-2-ethyl-1,2,3,4-tetrahydroisoquinoline was hydrogenated with 4.0 g. of Raney nickel in absolute ethanol at about 165°C for 16 hr. at a pressure of 191 kg./cm^2. After processing, the colorless oil of 7-hydroxy-2-ethyldecahydroisoquinoline with a b. p. of 122.5~126.5°C (3 mmHg) was obtained; 2.59 g. (77.8%). The product gave methiodide with a m. p. of 214~219°C.

Found: C, 44.61; H, 7.31; N, 4.64. Calcd. for $C_{12}H_{24}ONI$: C, 44.31; H, 7.44; N, 4.31%.

7-Anisoyloxy-2-ethyldecahydroisoquinoline (X).—The reaction of 1.20 g. of 7-hydroxy-2-ethyldecahydroisoquinoline (IX) with 1.12 g. of anisoyl chloride in dried benzene gave 2.04 g. of a viscous product. The trituration of the product with 100 ml. of water left an insoluble part (0.48 g.) which, after recrystallization from ethanol-water, melted at 98~99°C and which was identical with anisic anhydride. The aqueous layer was processed in a manner similar to that described for the preparation of IV, and the viscous product was chromatographed on alumina to give two fractions. The second fraction gave methiodide (m. p., 216~218°C) which was identical with the methiodide of 7-hydroxy-2-ethyldecahydroisoquinoline. The first fraction gave an oily product (0.68 g., 32.9%) of 7-anisoyloxy-2-ethyldecahydroisoquinoline.

Methyl 7-Anisoyloxy-2-ethyldecahydroisoquinolinium Bromide (XV). — In a manner similar to that used for preparation of XII-A and XII-B, 0.68 g. of 7-anisoyloxy-2-ethyldecahydroisoquinoline was reacted with an excess of methyl bromide to give 0.87 g. of crude crystals of quaternary ammonium salt. Fractionation of the product with 150 ml. of acetone gave two fractions. The more insoluble fraction weighed 0.054 g. (6.1%) and melted at 243.5~245°C. The soluble fraction was concentrated to 12 ml. to give 0.26 g. (29.1%) of colorless crystals with a m. p. of 224.5~228°C. Recrystallization from acetone raised the m. p. to 234~237.5°C.

Found: C, 58.33; H, 7.42; N, 3.25. Calcd. for $C_{20}H_{30}O_3NBr$: C, 58.25; H, 7.33; N, 3.40%.

7-(Tri-*O*-methylgalloyloxy)-2-ethyldecahydroisoquinoline (XI). — The treatment of 1.21 g. of 7-hydroxy-2-ethyldecahydroisoquinoline with 1.52 g. of tri-*O*-methylgalloyl chloride in dried benzene gave 2.94 g. of a viscous product. The trituration of the product with 250 ml. of water left an insoluble part (1.21 g.) which, after recrystallization from ethanol, melted at 159~160°C and was identical with tri-*O*-methylgallic anhydride. The aqueous extract was processed to give a viscous product, which was then chromatographed on alumina to give two fractions. The first fraction gave 0.50 g. (20.0%) of an oily product of 7-(tri-*O*-methylgalloyloxy)-2-ethyldecahydroisoquinoline.

Methyl 7-(Tri-*O*-methylgalloyloxy)-2-ethyldecahydroisoquinolinium Bromide (XVI). — The treatment of 0.50 g. of 7-(tri-*O*-methylgalloyloxy)-2-ethyldecahydroisoquinoline with an excess of methyl bromide gave 0.61 g. of crude crystals of quaternary ammonium salt. Trituration with 16 ml. of acetone left 0.087 g. (14.0%) of an insoluble solid with a m. p. of 241~243.5°C. Recrystallization from ethanol-petroleum ether gave colorless needles with a m. p. of 244.5~245.0°C.

Found: C, 55.89; H, 7.37. Calcd. for $C_{22}H_{34}O_5NBr$: C, 55.93; H, 7.25%.

Evaporation of the acetone solution gave 0.52 g.

The Wetting of Paraffin by Aqueous Solutions of Fatty Alcohol Homologues

By Teruo TSUNODA*

(Received December 12, 1962)

The relation between the wetting of a solid by solutions and the adsorption of the solute has been studied by various authors. Rehbinder[1] and Cook[2] have proposed formulas expressing the relation between contact angle and adsorption, but these are largely empirical in nature and lack theoretical foundation. On the other hand, Doss[3] and Wada[4] have derived theoretical formulas, but these are not always applicable to all of the practical cases. Recently, Bartell[5] has given a wetting isotherm which predicted fairly well the relation between the solute adsorption and the adhesion tension in the case of the wetting of platinum by water. His formula, however, concerns hydrophilic surfaces and is not applicable to hydrophobic surfaces such as paraffin, which, according to his formula, should have a portion of the surface free from any adsorption, at least in the case of wetting by pure water, which is different from the adsorption model he assumed.

We have also attempted to derive an equation based on the molecular structure of the adsorbed layer which was valid both for the wetting and the anti-wetting of a solid surface by aqueous ethyl alcohol and xanthate solutions respectively[6]. The present investigation was undertaken further to check our wetting isotherm for the case of the wetting of paraffin by aqueous solutions of alcohol homologues and to obtain further knowledge concerning adsorbed films on solid surfaces.

Experimental

The alcohols used were *n*-propyl, *n*-butyl, *n*-amyl and *n*-octyl alcohols, which had been refluxed over calcium oxide for several hours and then distilled twice before use. Their boiling points were within the range of 1°C of the published data. The paraffin used was purified by treating it with concentrated sulfuric acid, then with sodium hydroxide, and finally by vacuum distillation. For the wettability measurement, the paraffin surface was prepared by dipping a glass rod of a uniform diameter into molten paraffin, withdrawing it, and then solidifying the paraffin film on the rod in air. The surface thus obtained was sufficiently smooth for the measurement of contact angle not to obscure the conclusion obtained. The contact angle and surface tension were measured using the Wilhelmy balance. The temperature was controlled to 25 ± 0.3°C throughout the experiments.

Results and Discussion

Contact Angles.—The changes in contact angle with time of immersion in an alcohol solution are shown in Table I, which shows a nearly constant value of the angle after an hour. As the time dependence of the surface tension of aqueous alcohol solutions was not perceptible in this experiment, the observed change in the contact angle may be ascribed mainly to a slow change in the solid/solution interfacial tension with time. In the present experiment, contact angles were measured for paraffin soon after it had been immersed in solution for one hour. The advancing and receding contact angles thus obtained were

A, advancing B, receding

plotted against the concentration of solutions, as is shown in Figs. 1, 2, 3 and 4. It was found that the hysteresis of the contact angles was at most about 10 degrees throughout the experiments.

Wetting Isotherm.—As for the wetting isotherms, Doss[3] proposed an equation which gave the relation between the contact angle and the liquid adsorption as:

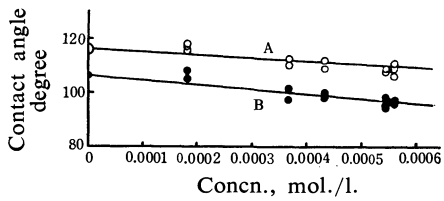

Fig. 4. Contact angle vs. concentration of *n*-octyl alcohol.
A, advancing B, receding

$$\cos\theta = 2\phi - 1 \qquad (1)$$

where θ denotes the contact angles of pure liquid and ϕ, the fractional area of liquid adsorption. By a similar reasoning we derived a more general isotherm[6] for the wetting of a solid by solution:

$$\cos\theta_r = \frac{\sigma_1 + \sigma_w}{\sigma_1}(\phi + aX) - 1 \qquad (2)$$

where θ_r denotes a receding contact angle, σ_1 and σ_w the surface tension of the wetting solution and solvent (water) respectively, ϕ and a, constants depending on the nature of the wetting solution (namely solvent and solute), and X, the fraction of the surface covered with the solute molecules. In deriving Eq. 2 we used θ_r for the contact angles which corresponded to the work of adhesion, $W_a = \sigma_1(\cos\theta_r + 1)$, instead of $W'_a = \pi + \sigma_1(\cos\theta_a + 1)$ for the advancing contact angle, θ_a, where π denotes the spreading pressure of the adsorbed film on the

solid. Equation 2 can be reduced to the Doss Eq. 1 in the case of a pure liquid where $X=0$, $\sigma_1=\sigma_w$. Now in Eq. 2, we can put $X=\Gamma\lambda$, where Γ denotes the amount of adsorption in mol./cm^2, and λ the area occupied by a mole of an adsorbed substance in a closely packed state in cm^2/mol. Equation 2 then takes the form:

$$\cos\theta_r=\frac{\sigma_1+\sigma_w}{\sigma_1}(\phi+K\Gamma)-1 \qquad (3)$$

where K is a new constant equal to $a\lambda$. We checked our wetting isotherm Eq. 3 using the experimental values of σ_r, σ_w, σ_1 and Γ. Γ is calculated from the Gibbs' adsorption isotherm:

$$\Gamma=\frac{d(\sigma_1\cos\sigma_a)}{RT\,d\ln c} \qquad (4)$$

where c expresses the concentration in mol./l. of alcohol in the wetting solution. We used the advancing contact angle, θ_a, for the calculation of Γ, because in the advancing liquid state the solid surface is considered to be practically free from adsorbed solute, which is also assumed to be the case in the derivation of Eq. 4. The adsorption isotherms thus obtained for the paraffin/aqueous solution interface, together with those for the aqueous solution surface, are shown in Figs. 5 and 6. We can see in these figures that the amount of adsorption is somewhat larger for the paraffin/solution interface than for the aqueous surface, while it is nealy equal for both surfaces in the case of butyl and amyl alcohols and is a little larger for the paraffin/solution interface in the case of octyl alcohol. Davies[7] reported that the proportionality between Γ and the concentration of solute is better for the oil/solution interface than for the aqueous surface. However, we can observe no such differences.

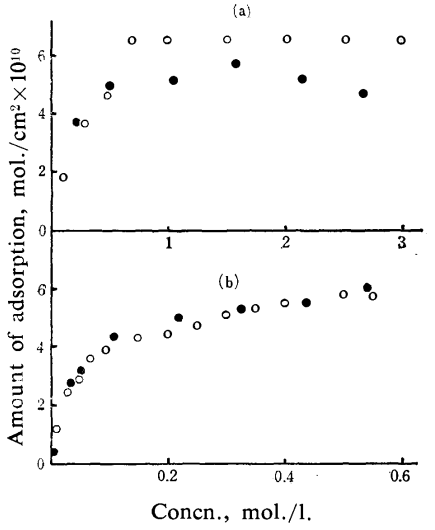

Fig. 5. Adsorption isotherms of (a) *n*-propyl and (b) *n*-butyl alcohol on paraffin/solution (○) and air/solution (●) interfaces.

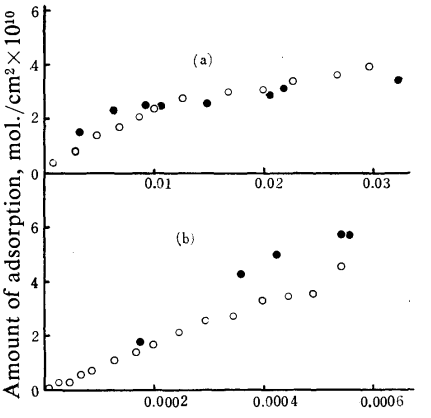

Fig. 6. Adsorption isotherms of (a) *n*-amyl and (b) *n*-octyl alcohol on paraffin/solution (○) and air/solution (●) interfaces.

In order to check Eq. 3, it was transformed into

$$\frac{\sigma_1(\cos\theta_r+1)}{\sigma_1+\sigma_w}=\phi+k\Gamma \qquad (5)$$

and $\sigma_1(\cos\theta_r+1)/(\sigma_1+\sigma_w)$ was plotted against Γ. The results are shown in Fig. 7. The

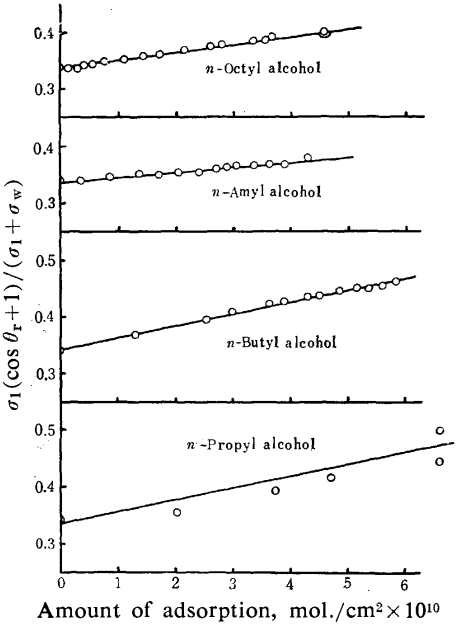

Fig. 7. Validity of Eq. 3.

7) J. T. Davies, *Proc. Roy. Soc.*, **A245**, 415 (1958).

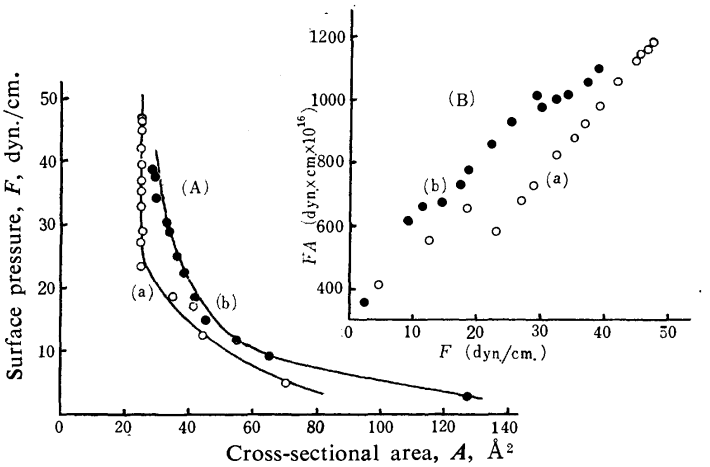

Fig. 8. (A) Pressure~area and (B) $FA \sim F$ relations for adsorbed films of (a) *n*-propyl and (b) *n*-butyl alcohol on paraffin surface.

linearity obtained in these figures lends support to the validity of Eqs. 2 and 3. From the linearity, we calculated the ϕ and K constants which are shown in Table II. We can see in Table II that the calculated value of ϕ is constant, regardless of the alcohol used, while the values of K decrease with an increase in molecular weight with the exception of the irregular value for amyl alcohol. The value of ϕ, which is the proportion of polar part to the total area of the solid surface, should be practically independent of the nature of alcohol used. That the value of ϕ is 0.34 means that the polar part of the surface is about one-third of the total area of the solid surface. The K value, on the other hand, may be expected to decrease with an increase in the molecular weight of the solute, since it depends on the relative polarity of solute and is expected to decrease with an increase in the molecular weight. This requirement is also satisfied as a whole. Using the adsorption isotherm of the Langmuir type, c was substituted for Γ in Eq. 3. We thus obtained, for *n*-propyl alcohol:

$$\cos\theta_r = \frac{\sigma_l + \sigma_w}{\sigma_l}\left(0.346 + \frac{c}{1+6.82c}\right) - 1$$

for *n*-butyl alcohol

$$\cos\theta_r = \frac{\sigma_l + \sigma_w}{\sigma_l}\left(0.347 + \frac{c}{0.536+8.11c}\right) - 1$$

for *n*-amyl alcohol

$$\cos\theta_r = \frac{\sigma_l + \sigma_w}{\sigma_l}\left(0.339 + \frac{c}{0.34+19.6c}\right) - 1 \qquad (6)$$

for *n*-octyl alcohol

$$\cos\theta_r = \frac{\sigma_l + \sigma_w}{\sigma_l}\left(0.342 + \frac{c}{7.88\times10^{-3}+5.58c}\right) - 1$$

TABLE II. CONSTANTS ϕ AND K IN WETTING ISOTHERM 3

Alcohol	ϕ	K, cm²/mol.
n-Propyl alc.	0.346	2.2×10^{8}
n-Butyl alc.	0.347	1.9×10^{8}
n-Amyl alc.	0.339	0.8×10^{8}
n-Octyl alc.	0.342	1.2×10^{8}

The Eqs. 6 are shown as solid lines in Figs. 1—4. We can further express the surface tension, σ_l of the Eqs. 6 in terms of the concentration, c, using an equation, for instance, of the Szyzkowski type, and express the contact angle as a function of the solute concentration alone, but we did not attempt to do so. It should be noted that the wetting phenomena is characterized both by the wetting power (K) of the liquid and the wettability (ϕ) of the solid surface, besides the surface tension of the liquid and the amount of solute adsorption.

The Equation of State for the Film at the Solid/Solution Interface.—Although a number of studies have been undertaken concerning the equation of the state of the film at the liquid/air interface[8], only a few have been reported on the solid/liquid interface[9]. The surface pressure, F, of the adsorbed film at the aqueous solution/solid interface can be expressed by:

$$F \equiv \sigma_{l_0} - \sigma_l = \sigma\cos\theta_a - \sigma_0\cos\theta_{a_0} \qquad (7)$$

where σ_{l_0} and σ_l denote the solid/water and solid/solution interfacial tensions, σ_0 and σ, the surface tensions of water and the aqueous solution, and θ_{a_0} and θ_a, the advancing contact angles of water and the aqueous solution on

n-Amyl alc.	24.0 (Å²/mol.)	26.6 (Å²/mol.)
n-Octyl alc.	—	11.6 (Å²/mol.)

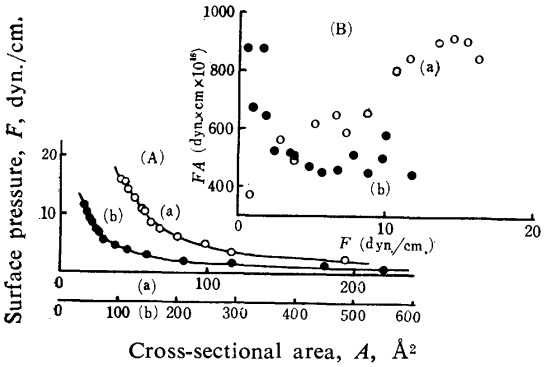

Fig. 9. (A) Pressure~area and (B) $FA \sim F$ relations for adsorbed films of (a) *n*-amyl and (b) *n*-octyl alcohol on paraffin surface.

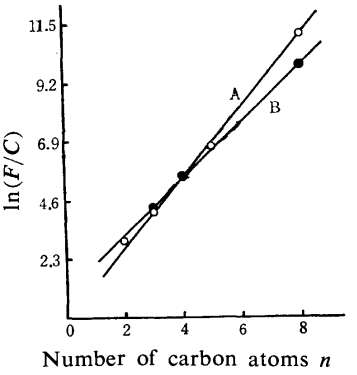

Fig. 10. $\ln(F/c)_n$ vs. number of carbon atoms of fatty alcohol homologues.
A, Paraffin/solution interface
B, Air/solution interface

the solid respectively. Thus, we can calculate the surface pressure of the film at the solid/liquid interface from the measurement of the surface tension and contact angle. Further, the area occupied by a molecule in the film is given by

$$A = 1/\Gamma N \qquad (8)$$

where N denotes the Avogadro number. The $F \sim A$ diagrams were then constructed as shown in Figs. 8 and 9, with $FA \sim F$ curves inserted. The $FA \sim F$ curves of *n*-propyl, *n*-butyl and *n*-amyl alcohols can then be expressed by Volmer's equation as:

$$FA = ikT + A_0F \quad \text{or} \quad F(A - A_0) = ikT \qquad (9)$$

where i and the co-area A_0 are constants. The slope of the straight line of $FA \sim F$ gives the co-area of the adsorbed molecule which corresponds to the saturation amount of adsorption obtained from Langmuir's formula. These values are shown in Table III. The two values coincide and are also equal to the corresponding values of the air/water interface.

Traube's Rule for the Solid Solution Interface.—Traube's rule[10] predicts that

$$\ln(F/c)_n = E + \frac{\Delta W}{RT}n \qquad (10)$$

where $(F/c)_n$ denotes the slope of $F \sim c$ curve at its origin for aqueous C_n-alcohol, ΔW, the work per mol. of CH_2 chain of the alcohol molecules required to bring it from the adsorbed layer to the interior of the solution, and E, a constant. To check Eq. 10, the value of $(F/c)_n$ was calculated from the slope of the $F \sim c$ curve (not shown) at the origin for each solution of alcohol homologues. The diagram of $\ln(F/c)_n$ thus obtained against n is shown in Fig. 10, together with the diagram for an aqueous solution for purposes of comparison. In this figure the plot for ethanol was taken from a preceding report[6]. As is shown in Fig. 10, the linear relation of Eq. 10 holds for both paraffin/solution and air/solution interfaces. We evaluated ΔW from this slope, obtaining the values of 824 cal./mol. CH_2 for the paraffin/solution interface and 656 cal./mol. CH_2 for the aqueous solution surface respectively. As for the ΔW of the paraffin/solution interface, we obtained 774 cal./mol. CH_2 for saturated fatty acid adsorbed on paraffin[11], 1000 cal./mol. CH_2 from the experiment of monolayer penetration[12], 800 cal./mol. CH_2 from the adsorption of benzylamine on the α-bromopalmitic acid monolayer[13], and 810 cal./mol. CH_2 for the oil/solution interface[14], while for the ΔW of the air/solution interface, values of 630 cal./mol.[14] and 640 cal./mol.[12] are given. Our ΔW values may be considered to be of the right order of magnitude as compared with these published

10) J. T. Davies and E. K. Rideal, "Interfacial Phenomena", Academic Press, New York (1961), p. 155.

11) H. Gastalla, *Compt. rend.*, 235, 941 (1952).

14) J. T. Davies, *Trans. Faraday Soc.*, 48, 1052 (1952).

data. As is seen, the value of ΔW for the paraffin/solution interface is somewhat larger than that for the air/solution interface. This is consistent with the view of a larger affinity of the hydrocarbon chain of the alcohol molecule for the paraffin/solution interface than for the air/solution interface[14].

Here we may add that, in the present case, Eq. 4 or its integrated form,

$$\sigma_1 \cos\theta_a = RT\int_0^c \Gamma \, d\ln c$$

can also be considered as a wetting isotherm which, if we put Γ as a Langmuir-type adsorption isotherm, can be integrated to give an adsorption isotherm similar to that of Eq. 3. However, we should like to emphasize that Eq. 3 is more useful than Eq. 4 because (i) Eq. 3 is an integrated formula with respect to Γ, while the integration of Eq. 4 is not always possible, (ii) Eq. 4 is limited only to cases of physical adsorption, as in the present case, while Eq. 3 fits the wetting data even when Eq. 4 fails to explain the adsorption, as in the case of the chemisorption of xanthate on a mineral surface[6] or the surface attack of polystyrene by sulfuric acid[15], and (iii) Eq. 3 offers the more distinct molecular explanation of the effect of surface film on wetting. It should also be added that Eqs. 3 and 4 cannot be applied to the cases of polymolecular adsorption or deep surface chemical attack where the wetting property cannot be considered as a simple function of the adsorption amount.

Summary

The wettability of paraffin towards aqueous solutions of *n*-propyl, *n*-butyl, *n*-amyl and *n*-octyl alcohols has been studied. It has been found that the wetting isotherm which had been proposed by the present author and had been valid for the wetting of paraffin by an aqueous ethyl alcohol solution, could also be applied successfully to the present systems. The equations of state for the adsorbed films of these alcohols at the paraffin/aqueous solution interface were obtained. It was further shown that Traube's rule holds for the paraffin/aqueous alcohol solution interface as well as for the air/solution interface. The adsorption energies found were 824 cal./mol.·CH_2 for the paraffin/solution interface and 656 cal./mol. CH_2 for the aqueous surface.

The author wishes to express his hearty thanks to Professor Tsunetaka Sasaki for his helpful guidance throughout this experiment. The cost of this research has been defrayed by a Scientific Research Grant of the Ministry of Education given to Professor Sasaki.

The Wetting of Paraffin by Aqueous Solutions of Sodium Decyl, Dodecyl and Tetradecyl Sulfates

By Teruo TSUNODA* and Tsunetaka SASAKI

(Received December 12, 1962)

The wetting of the surface of such solids as metals, plastics, and fibers by wetting agents and detergent solutions has offered many fundamental problems[1]. However, studies upon the theory underlying the phenomena have hitherto been rather unsatisfactory, especially regarding the relation between the wetting and the solute adsorption[2].

In a previous paper we reported on the relation between the wetting of paraffin by aqueous solutions of fatty alcohol homologues and the solute adsorption[3]. In the present paper we will attempt to study further the relation between the wetting of the paraffin surface by aqueous solutions of sodium decyl, dodecyl and tetradecyl sulfates, and their adsorption.

Experimental

The detergents used were sodium decyl (SDeS), dodecyl (SDoS) and tetradecyl (STS) sulfates. They were prepared by the reaction of corresponding alcohols with chlorosulfonic acid in ether. In order to purify them, the alkyl sulfates obtained were dissolved in ethyl alcohol, treated with charcoal, and then recrystallized. The disappearance of the minimum in surface tension concentration curves, as is shown in Fig. 1, proved their purity. The paraffin used was purified by treating it with concentrated sulfuric acid, then with sodium hydroxide, and finally by vacuum distillation. For the wettability measurement, the paraffin surface was

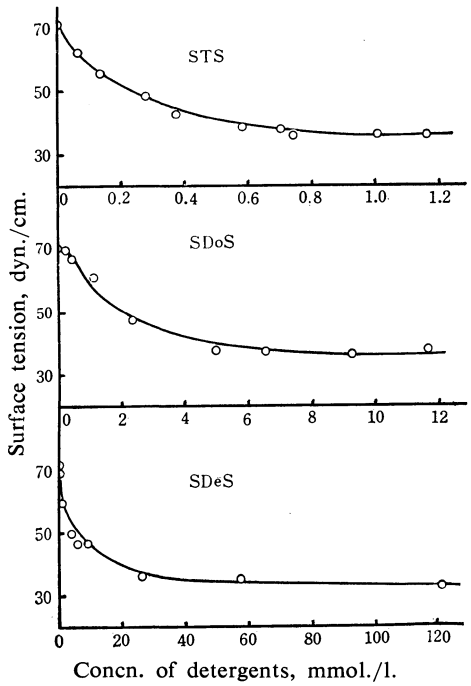

Fig. 1. Surface tension vs. concentration of detergents.

prepared as a thin layer on a glass rod of a uniform diameter. The measurements of wettability and surface tension were made in the same manner as was reported in a preceding paper[3]. The temperature was controlled at 30±0.3°C throughout the experiments. No particular control of the pH was made for the solution used. It was about 6.

Results and Discussion

The changes in the wetting tension of paraffin towards aqueous solutions of detergents with the time of immersion in those solutions are shown in Fig. 2, for instance, for SDoS solution, where $\sigma_1 \cos\theta_r$ is the wetting tensinon, σ_1, the surface tension of the solution, and θ_r, the receding contact angle of the solution on paraffin. The equilibrium values of the wettability were attained within 60 min. after the immersion of the paraffin into the detergent solutions. The equilibrium advancing and receding contact angles thus obtained were plotted against the concentration of detergent solutions as shown in Figs. 3, 4 and 5. The hysteresis of the contact angles was at

most 10 degrees in these experiments. Figure 6 shows the relation between the cosine of the receding contact angles and the surface tension of the detergent solutions. We can observe in this figure that the curves tend to show a discontinuity in slope at about 40 dyn./cm. A similar phenomenon was observed for the wetting of teflon and polyethylene by several detergent solutions[4]. We calculated the Zisman critical surface tension, γ_c[5], by the extrapolation of the σ_l vs. $\cos\theta_r$ plot to $\cos\theta_r=1$ and thus found γ_c to be 26 dyn./cm.

Now we shall refer to the wetting isotherm. As in a preceding paper[6] we used the following wetting isotherm;

$$\cos\theta_r=\frac{\sigma_l+\sigma_w}{\sigma_l}(\phi+K\Gamma)-1 \qquad (1)$$

where θ_r denotes the receding contact angles, σ_l and σ_w, the surface tension of the solution and solvent (water) respectively, Γ, the amounts of solute adsorption in mol./cm^2, and ϕ and K constants. In order to check our wetting isotherm 1, we calculated Γ using Gibbs' adsorption isotherm:

$$\Gamma=\frac{d(\sigma_l\cos\theta_a)}{RT\,d\ln c} \qquad (2)$$

and made plots between the Γ thus obtained and $\sigma_l(\cos\theta_r+1)/(\sigma_l+\sigma_w)$, as in the preceding paper[3]. Figures 7, 8 and 9 show the adsorption isotherm $\Gamma\sim c$. In the region of concentration lower than the CMC of the detergents, the apparent maximum in the adsorption isotherm is observed in these curves. It is, however, hard to interpret these maxima in the adsorption isotherm, since the $\sigma_l\cos\theta_a\sim\ln c$ plot is not generally so accurate in the concentrated region of saturated adsorption. Figure 10 shows the $\sigma_l(\cos\theta_r+1)/(\sigma_l+\sigma_w))\sim\Gamma$ plots. The plots indicate a linear relation in the

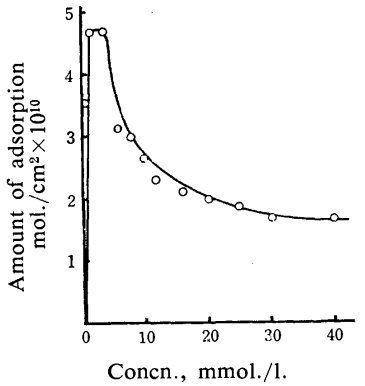

Fig. 7. Adsorption isotherm of SDeS for paraffin/solution interface.

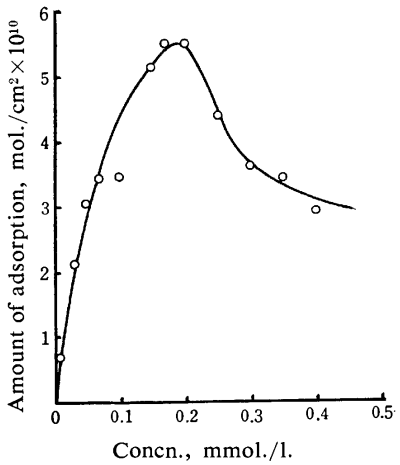

Fig. 9. Adsorption isotherm of STS for paraffin/solution interface.

region of concentration less than that of the maximum adsorption. From this linearity we calculated the constants ϕ and K, which are shown in Table I. In this table we may notice, that the calculated values of ϕ are constant, regardless of the detergents used, while the K values decrease with the increasing molecular weight. These results are similar with the values of ϕ and K obtained for fatty alcohols on paraffin[3]. Inserting the values of ϕ and K into Eq. 1, we obtained:

for SDeS

$$\cos\theta_r=\frac{\sigma_1+\sigma_w}{\sigma_1}(0.353+0.026\times10^{10}\Gamma)-1$$

for SDoS

$$\cos\theta_r=\frac{\sigma_1+\sigma_w}{\sigma_1}(0.347+0.025\times10^{10}\Gamma)-1 \qquad (3)$$

for STS

$$\cos\theta_r=\frac{\sigma_1+\sigma_w}{\sigma_1}(0.347+0.016\times10^{10}\Gamma)-1$$

Figure 11 shows the comparison between the values obtained from Eq. 3 (solid line) and the observed values (circles). Beyond the concentration of maximum adsorption of detergents, the discrepancies between the calculated and observed contact angle values are marked in all cases, partly because of the inevitable inacuracy in observation already mentioned.

TABLE I. CONSTANTS ϕ AND K IN WETTING ISOTHERM 1

Detergent	ϕ	K, cm²/mol.
Sodium decyl sulfate	0.353	2.6×10^5
Sodium dodecyl sulfate	0.347	2.5×10^8
Sodium tetradecyl sulfate	0.347	1.6×10^8

In Figs. 12, 13 and 14, we show $F\sim A$ diagram, together with the $FA\sim A$ curves inserted. The surface pressure of the adsorbed film on the solid/solution interface, F, and the area occupied by molecules in the film, A, is obtained in a manner similar to that used in a preceding paper[6]. Applying Volmer's equation, $FA=ikT+A_0F$ to the $FA\sim F$ curves, as shown by solid lines in Figs. 12, 13 and 14, the co-area A_0's are obtained as 30, 23, 30Å²/molec. for SDeS, SDoS and STS respectively.

We further examined the validity of Traube's rule, which is expressed by:

$$\ln(F/c)_n=\ln(F/c)_1+\Delta w(n-1)/RT \qquad (4)$$

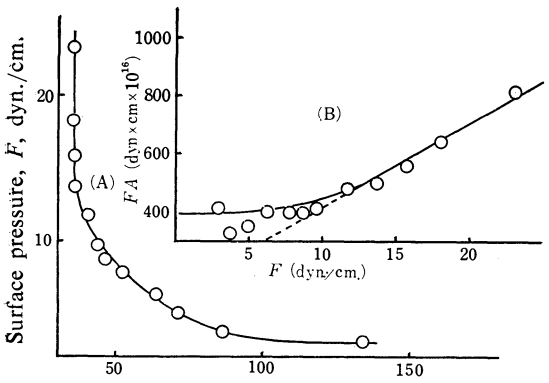

Fig. 12. (A) Pressure~area and (B) $FA \sim F$ relations for adsorbed film of SDeS for paraffin/solution interface.

where F/c denotes the slope of the $F \sim c$ curve at $c=0$, n, the number of carbon atoms in the alkyl sulfate molecules, and Δw, the work per CH_2 of adsorbed solute molecule required to bring it from the paraffin surface back into the interior of the solution. Figure 15 shows the lineality between $\ln(F/c)$ and n. From these figures, we obtained 588.9 cal./mol. CH_2 as the Δw for the paraffin/solution interface. This figure is smaller than 824 cal./mol. CH_2 obtained for the fatty alcohol at the solution/paraffin interface[3]. For the air/solution interface, we obtained 534.7 cal./mol. CH_2 as the Δw value. This value is also smaller than that of 656 cal./mol. CH_2 for fatty alcohols at the aqueous alcohol solution surface[3].

Summary

The wettability of the paraffin by aqueous solutions of sodium decyl, dodecyl and tetradecyl sulfate have been studied. A slight but distinct discontinuity of the slope in the curve of the cosine of the receding contact angle vs. the surface tension of the solution was observed for the solution of sodium decyl, dodecyl and tetradecyl sulfate. The discontinuity of the slope appeared at the surface tension of about 40 dyn./cm. It was found that the wetting isotherm which had been proposed by the present author, and which had been found valid for the wetting of paraffin by the aqueous solution of fatty alcohol homologues, was also valid for this experiment in the dilute aqueous solution of sodium alkyl sulfates. The adsorption energy was 588.9 cal./mol. CH_2 and 534.7 cal./mol. for the paraffin/solution and air/solution interfaces respectively.

The cost of this research has been defrayed by a Scientific Research Grant of the Ministry of Education given to Tsunetaka Sasaki.

The Stereoregularity-Fractionation of Polyvinyl Alcohol by Foaming

By Kiyokazu IMAI and Masakazu MATSUMOTO

(Received December 17, 1962)

It has been found that several properties of polyvinyl alcohol (PVA), probably related to its stereoregularity, vary with the polymerization conditions of the polyvinyl acetate from which PVA is derived[1]. Therefore, one method to obtain PVA differing in regularity is to control the conditions of the polymerization. As a complementary method, we have evolved a method for separating PVA into fractions differing in regularity. Besides being interesting for its own sake, such a fractionation procedure should give a method for determining the stereoregularity distribution of PVA. We found that PVA can be separated into fractions of different stereoregularity by foaming an aqueous solution of the polymer. Although it is well known that foams can serve to separate substances of different chemical structures[2], the foam method seems not yet to have been applied in the stereoregularity fractionation of polymers. The present report may, therefore, be the first communication about it.

Experimental

Three samples of PVA of differing stereoregularity were used. These samples are listed in Table I.

The fractionation procedure was as follows: a 1~2% aqueous solution of fully hydrolyzed PVA derived from polyvinyl acetate was placed in a 1~5 l. wide-mouthed bottle. The bottle was then shaken at a frequency of 100 cycl. per minute with an amplitude of 6.7 or 10.8 cm. on a horizontal shaker; a foam layer was thus created. After being shaken for a certain time, the solution was allowed to stand for more than 15 hr. In the course of this standing, part of the foam usually disintegrated and drained down, but the remaining layer was separated and the PVA contained in the foam was collected. The residual solution usually became cloudy, and a slight amount of gel precipitated at the bottom of the bottle. To obtain successive fractions, the cloudy solution was heated until it became a completely clear and uniform solution

and then the procedure involving shaking, standing, separation and heating was repeated.

We have found that the color reaction of PVA with iodine-iodide in an aqueous solution can be used as a measure of the stereoregularity of PVA[3]. An absorption peak is produced at 620 mμ by the iodine-PVA complex when it is prepared under specified conditions, and the absorbance at this wavelength, D_{620}, is used as a quantitative index of the color reaction. According to some unpublished data of the authors and of K. Fujii, the color reaction does not occur for isotactic PVA, but since it appears to depend on the degree of syndiotacticity of PVA, the D_{620} value may be used as a parameter of the syndiotacticity for PVA samples having the same degree of polymerization. Strictly speaking, it is not certain whether the color reaction is due simply to the existence of the fraction of syndiotactic linkage or to their regular sequence length.

Results and Discussion

The D_{620} values of PVA contained in the foam layers are illustrated in Table II in comparison with that of the original PVA. The degree of the polymerization of the PVA contained in the foam layers is approximately the same as that of the original PVA, but the D_{620} value of the former is quite different from that of the original. In general, the values of the former exceed that of the latter.

Since the D_{620} value depends on the degree of polymerization, a difference in molecular weight distribution between the original PVA and the sample obtained from the foam layer could theoretically explain the observed color-test difference. However, the dependence of the D_{620} value upon the degree of polymerization is not strong enough to make this likely. For example, if the PVA sample is fractionated by a precipitation method from a solvent (water)-non-solvent (*n*-propyl alcohol)-mixture, the D_{620} values range from 0.08 for DP=639 up to only 0.31 for DP=3960. Even at this latter value, the sample lies well below the 0.5 to 1.0 range found in the foam layer in Table II.

The 1,2-glycol content of the PVA from the foam layer is slightly less than that of the original, this also might be a cause of the different D_{620} value. However, since the difference in content of the 1,2-glycol structure is quite small, the predominant cause of the different D_{620} value was considered to be the tacticity of the sample. From the results of Table II, it may be concluded that the stereoregularity, probably the syndiotacticity, of the PVA obtained from the foam layer is larger than that of the original PVA.

a) Original unfractionated PVA, DM32-2,3

Tables III, IV and V show the results of three successive fractionations of PVA by foaming. From the properties and polymerization conditions, the stereoregularity order of the PVA used is as follows:

L-O-43 (Table III) > W-6 (Table IV) > DM32-2,3 (Table V)

Polyvinyl alcohol W-6 is an ordinary one and the same as the original PVA in Table II.

As may be seen in every table, the degree of the polymerization of PVA in each fraction is not constant, but increases slightly with an increase in the fraction number and then decreases again. On the other hand, as the fractionation progresses, the D_{620} value decreases and the swelling degree and solubility increase, suggesting that the sample is being separated according to regularity, i. e., syndiotacticity.

It is well-established that the lower the polymerization temperature of vinyl acetate, the more stereoregular the PVA obtained. Therefore, when PVA prepared by a low temperature polymerization is fractionated by the foam method, it is to be expected that the first fraction will furnish an extremely stereoregular PVA. Such a result is illustrated in Table III. The D_{620} value for PVA F1 in this table is 3.05, much larger than the 0.23 of an ordinary PVA W-6. This indicates that the F1 fraction is highly regular.

According to unpublished data collected by the present authors, the regularity of PVA is responsible for the foaminess of its aqueous solution; the foaminess of the solution increases with an increase in the regularity. This behavior seems to relate more closely to foam stability than to foaming capacity because the foam volume formed by a blowing method remains nearly constant, independent of the polymerization conditions of the parent ester polymer of PVA[4]. On the other hand, it is known that the aging of a concentrated aqueous solution of PVA depends upon such polymerization conditions as the temperature[5] and the solvent[4] used; it has also been observed that the regular polymer shows greater aging.

Furthermore, aqueous solutions of PVA have a tendency to gel at an air-water interface[6]. It is, therefore, believed that foam stabilization due to aging is a basic factor in the performance of fractionation according to regularity. When a blowing method is applied in the foam formation, PVA is not separated in regularity[4]. This is considered to be due to the fact that foam formation occurs more easily in the blowing method than in the shaking method, but foam rupture occurs more easily in the latter than in the former. To fractionate effectively, foaming alone is not sufficient; a proper breaking of the foam seems also to be required.

Studies on Antibiotics and Related Substances. XVII. Syntheses of trans-2-Aminocyclohexyl-D-glucosaminides

By Tetsuo SUAMI, Seiichiro OGAWA and Sumio UMEZAWA

(Received December 25, 1962)

As a model compound of simpler structure of kanamycin[1], 2-aminocyclohexyl-D-glucosaminides has been studied in our laboratory[2]. In the present report a further investigation has been accomplished to characterize *l*- and *d-trans*-2-aminocyclohexyl-D-glucosaminides.

d,l-trans-2-Aminocyclohexanol was prepared by the method of Osterberg and Kendal[3]. A literature method[4] for a resolution of *d,l-trans*-2-aminocyclohexanol with L-(+)-tartaric acid by a fractional recrystallization in 80% ethanol proved to be good for the preparation of *l-trans* isomer. Then, by applying 95% aqueous methanol for a fractional recrystallization, a better result for isolating *d-trans* isomer was obtained.

By treatments of L-(+)-tartrates of *l*- and *d-trans*-2-aminocyclohexanol with alkali, *l*- and *d-trans*-2-aminocyclohexanol were obtained respectively in the optically active forms.

N-Carbobenzoxy-*l-trans*-2-aminocyclohexanol (I) and *N*-carbobenzoxy-*d-trans*-2-aminocyclohexanol (V) were prepared directly by carbobenzoxylation of L-(+)-tartrate of *l*- and *d-trans*-2-aminocyclohexanol respectively in good yields.

The condensation of I with α-1-bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine[5] in the presence of mercuric cyanide gave β-(*N*-carbobenzoxy-*l-trans*-2-aminocyclohexyl)-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosaminide (II) melting at 217~217.5°C in 37% yield. Also it was noticed that a considerable amount of 4, 5-(3, 4, 6-triacetyl-D-glucopyranosyl)oxazolone-2[10] was formed which was recovered from the mother liquor of II as a by-product.

Deacetylation of II with methanol saturated with ammonia gave β-(*N*-carbobenzoxy-*l-trans*-2-aminocyclohexyl)-*N*-carbobenzoxy-D-glucosaminide (III) melting at 224~225.5°C in 81% yield.

A catalytic hydrogenolysis of III yielde β-(*l- trans*-2-aminocyclohexyl)-D-glucosaminide (IV) melting at 159~161°C (decomp.) in 60% yield.

The reaction sequences employed in the synthesis of β-(*d-trans*-2-aminocyclohexyl)-D-glucosaminide (VIII) were similar to those of IV.

The optical rotations of the products were listed on Table I.

TABLE I. SPECIFIC ROTATION OF *trans*-2-AMINOCYCLOHEXANOLS AND THEIR DERIVATIVES

Derivative	$[\alpha]_D$ *l*	$[\alpha]_D$ *d*
trans-2-Aminocyclohexanol	−37.6°	+38.4°
N-Benzoyl-*trans*-2-aminocyclohexanol	−39.8°	+41.1°
N-Carbobenzoxy-*trans*-2-aminocyclohexanol	−20.1°	+20.3°
β-(*N*-Carbobenzoxy-*trans*-2-aminocyclohexyl)-3, 4, 6-triacety-*N*-carbobenzoxy-D-glucosaminide	+5.6°	+22.9°
β-(*N*-Carbobenzoxy-*trans*-2-aminocyclohexyl)-*N*-carbobenzoxy-D-glucosaminide	−28.1°	+10.3°
β-(*trans*-2-Aminocyclohexyl)-D-glucosaminide	−72.6°	+4.6°

Designation of IV and VIII as β-anomers was based on their optical rotations and infrared spectra. The optical rotations of IV and VIII were less dextrorotatory, compared with that of (α-D-6-amino-6-deoxyglucopyranosyl)deoxystreptamine[6] and paromamine[7]. The infrared spectra of IV and VIII showed characteristic absorption bands for derivatives of β-glucopyranose at 895 cm^{-1} (type 2b)[8], and for cyclohexane ring deformation at 975 and 1044 cm^{-1} [9] in agreement with the assigned structures.

Considering from the optical rotation of *trans*-2-aminocyclohexyl-D-glucosaminides in Table I, β-(d, *l-trans*-2-aminocyclohexyl)-D-glucosaminide in the previous paper[2] had to be corrected to β-(*l-trans*-2-aminocyclohexyl)-D-glucosaminide and *d,l-tsans*-2-aminocyclohexyl-D-glucosaminide must be a crude product of β-(*d-trans*-2-aminocyclohexyl)-D-glucosaminide.

In addition to the above mentioned syntheses of *l-* and *d-trans*-2-aminocyclohexyl-D-glucosaminides, the attempt to prepare glucosaminides via trityl derivative of aminocyclohexanol was made. *N*-Carbobenzoxy-*d,l-trans*-2-aminocyclohexanol was tritylated with trityl chloride in anhydrous pyridine to give *N*-carbobenzoxy-*O*-trityl-*d, l-trans*-2-aminocyclohexanol (IX) melting at 126.5~128°C in 37% yield. Then, IX was condensed with α-l-bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine in the presence of silver perchlorate to obtain a mixture of II and VI. The recrystallization of the mixture resulted in obtaining II in a considerably pure state, but VI was not obtained in a pure state.

Experimental

***l-trans*-2-Aminocyclohexanol.**—According to the procedure of Godchot and Mousseron[4], *l-trans*-2-aminocyclohexanol L-(+)-tartrate melting at 175~176°C, $[\alpha]_D^{22}$ −4.8° (*c* 3.2, water) [lit.[4] m. p. 177~178°C, $[\alpha]_D$ −2.73°] was obtained in 10% yield from *d, l-trans*-2-aminocyclohexanol L-(+)-tartrate. A mixture of *l-trans*-2-aminocyclohexanol L-(+)-tartrate and 10% potassium hydroxide solution was extracted with ether. The ethereal solution was dried over anhydrous sodium sulfate and the solvent was removed under reduced pressure to yield *l-trans*-2-aminocyclohexanol melting at 84~86°C, $[\alpha]_D^{22}$ −37.6° (*c* 1.30, water) [lit.[4] m. p. 83~84°C, $[\alpha]_D$ −40.2°].

N-Benzoyl derivative was prepared by shaking 1.0 g. of *l-trans*-2-aminocyclohexanol L-(+)-tartrate with 0.8 g. of benzoyl chloride in 11 ml. of 6.5% sodium hydroxide solution. The amide separating from the reaction mixture was collected by filtration. After three recrystallizations from benzene, the product melted at 168~169°C, $[\alpha]_D^{11}$ −39.8° (*c* 2.9, ethanol).

Fonud: C, 71.33; H, 7.61; N, 6.24. Calcd. for $C_{13}H_{17}NO_2$ (219.3): C, 71.20; H, 7.82; N, 6.39%.

***N*-Carbobenzoxy-*l-trans*-2-aminocyclohexanol (I).**—A solution of 4.3 g. of *l-trans*-2-aminocyclohexanol L-(+)-tartrate and 5.5 g. of sodium bicarbonate in 30 ml. of water was vigorously agitated and 5.3 g. of carbobenzoxy chloride was added to it in toluene (78% solution) in twenty minutes at room temperature. After agitation for two hours, the mixture was kept in a refrigerator overnight. The crystalline precipitate was collected and washed with cold water. The crude product weighed 4.3 g. (98%). The product was recrystallized repeatedly from a water-methanol mixture (3 : 2) to yield 2.8 g. (66%) of *N*-carbobenzoxy-*l-trans*-2-aminocyclohexanol melting at 115.5~116.5°C, $[\alpha]_D^{15}$ −20.1° (*c* 1.2, ethanol).

Found: C, 67.44; H, 7.75; N, 5.66. Calcd. for $C_{14}H_{19}NO_3$ (249.3): C, 67.44; H, 7.68; N, 5.62%.

β-(*N*-Carbobenzoxy-*l-trans*-2-aminocyclohexyl)-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosaminide (II).—A mixture of 1.9 g. of α-l-bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine and 1.0 g. of I in 22 ml. of dry benzene was heated under reflux for 2 hr. with 1.7 g. of mercuric cyanide. The mixture was cooled and filtered to remove an insoluble substance. The filtrate was diluted with 70 ml. of chloroform and then washed twice with 10% sodium chloride solution and three times with cold water. After drying over anhydrous sodium sulfate, the solvent was removed under reduced pressure to give a crystalline residue. The residue was washed with anhydrous ether to obtain 1.75 g. of the product. The crude product was recrystallized from absolute ethanol to yield 0.95 g. (37%) of crystals melting at 217~217.5°C, $[\alpha]_D^{25}$ +5.6° (*c* 2, chloroform). A further recrystallization did not raise its melting point.

Found: C, 61.25; H, 6.44; N, 4.06. Calcd. for $C_{34}H_{42}N_2O_{12}$ (670.7): C, 60.88; H, 6.31; N, 4.18%.

The infrared spectrum (KBr) of the product showed absorption at 1751 (ester carbonyl); 1708, 1542, 1294 (amide); 975, 1049 (cyclohexane); 902 (type 2b of β-D-glucopyranose) and 752, 695 cm^{-1} (monosubstituted benzene).

The mother liquor of the above product was evaporated under reduced pressure to half the volume and placed in a refrigerator to yield 0.28 g. of a crystalline product. The product was recrystallized from ethyl acetate to obtain fine crystals melting at 170~170.5°C.

Mixed with an authentic sample of 4, 5-(3,4,6-triacetyl-D-glucopyranosyl)oxazolone-2[10], this product did not show a depression of the melting point. The infrared spectrum of the product was superimposable with that of an authentic sample.

4, 5-(3, 4, 6-Triacetyl-D-glucopyranosyl)oxazolone-2.—According to the procedure of Konstas et al.[10], 1, 3, 4, 6-tetraacetyl-*N*-carbobenzoxy-D-glucosamine, m. p. 148.5~149°C, $[\alpha]_D^{12}$ +20.4° (*c* 1.2, pyridine) [lit.[11] m.p. 150~151°C, $[\alpha]_D$ +21.5°], was treated with aluminum chloride and phosphorus pentachloride in dry chloroform to obtain 4, 5-(3, 4, 6-triacetyl-D-glucopyranosyl)oxazolone-2 melting at 170.5~171°C, $[\alpha]_D^{24}$ +23.7° (*c* 2, chloroform) in 36% yield. [lit.[10] m. p. 174~176°C, $[\alpha]_D$ +50.3° (*c* 2, chloroform)].

Found: C, 47.53; H, 5.21; N, 4.17. Calcd. for $C_{13}H_{17}O_9$ (331.3): C. 47.11; H, 5.18; N, 4.23%.

β-(*N*-Carbobenzoxy-*l-trans*-2-aminocyclohexyl)-*N*-carbobenzoxy-D-glucosaminide (III).—A mixture of 1.31 g. of II and 50 ml. of methanol saturated with ammonia was kept below 5°C for 3 hr. to obtain a clear solution. After it was placed in a refrigerator overnight, the solution was evaporated under reduced pressure to dryness. The residue was washed with 20 ml. of ethyl aceteate and

10) S. Konstas, I. Photaki and L. Zervas, *Chem. Ber.*, **92**, 1288 (1959): see also S. Umezawa, Y. Ito and S. Koto, This Bulletin, **36**, 186 (1963).

11) A. Neuberger and R. P. Rivers, *J. Chem. Soc.*, **1939**, 122.

recrystallized from isopropanol to yield 0.87 g. (81%) of the product melting at 224~225.5°C. A further recrystallization did not show any change in the melting point. $[\alpha]_D^{27}$ −28.1° (*c* 1.8, pyridine).

Found: C, 61.60; H, 6.58; N, 5.28. Calcd. for $C_{28}H_{36}N_2O_9$ (544.6): C, 61.75; H, 6.66; N, 5.14%.

The infrared spectrum (KBr) of the product showed absorption at 3400 broad (OH); 1690, 1553, 1260 (amide); 975, 1049 (cyclohexane); 896 (type 2b of β-D-glucopyranose) and 775, 696 cm^{-1} (mono-substituted benzene).

β-(*l-trans*-2-aminocyclohexyl)-D-glucosaminide (IV).—A suspension of 0.72 g. of III in 30 ml. of dioxane- water mixture (1 : 1) was added to a prehydrogenated suspension of 0.2 g. of palladium black in 10 ml. of the same solvent. The mixture was hydrogenated for 3 hr. at room temperature (31~32°C) with mechanical shaking. At the end of the reaction, 53 ml. of hydrogen was absorbed. The mixture was filtered to remove the catalyzer and the filtrate was evaporated under reduced pressure to dryness. The residue was dissolved in 7 ml. of hot absolute methanol and added with 5 ml. of anhydrous ether. The solution was placed in a refrigerator for a few days to obtain crystals. The crystals were collected by filtration and dried in a vacuum desiccator to yield 0.22 g. (60%) of the product melting at 159~161°C (decomp.). $[\alpha]_D^{30}$ −72.6° (*c* 1.3, water).

Found: C, 51.90; H, 8.77: N, 10.27. Calcd. for $C_{12}H_{24}N_2O_5$ (276.3): C, 52.16; H, 8.75; N, 10.14%.

The infrared spectrum (KBr) of the product showed absoption at 3590 (OH); 3355, 3300, 1593 (amine); 975, 1044 (cyclohexane) and 895 cm^{-1} (type 2b of β-D-glucopyranose).

***d-trans*-2-Aminocyclohexanol.**—From the mother liquor of *l-trans*-2-aminocyclohexanol L-(+)-tartrate, an attempt to isolate *d-trans*-2-aminocyclohexanol L-(+)-tartrate with 80% ethanol was not successful. The suitable solvent for separating *d-trans*-2-amino-cyclohexanol L-(+)-tartrate was found to be 95% methanol. The mother liquor of *l-trans*-2-amino-cyclohexanol L-(+)-tartrate was evaporated under reduced pressure to dryness. The residue was recrystallized repeatedly from 95% methanol to obtain the crystals melting at 169.5~170°C in 30% yield. $[\alpha]_D^{28}$ +36.5° (*c* 2.3, water). (Found: C, 45.33; H, 7.23, N, 5.26%). [lit.[4] m. p. 170~171°C, $[\alpha]_D$ +31.2°].

A further recrystallization did not show any change in the melting point and the specific rotation.

d-trans-2-Aminocyclohexanol was obtained by the same procedue of *l-trans* aminoalcohol from the corresponding tartrate. The *d-trans* aminoalcohol melted at 84~86°C. $[\alpha]_D^{10}$ +38.4° (*c* 1.8, water). [lit[4]. m. p. 83~84°C, $[\alpha]_D$ +40.2°].

N-Benzoyl derivative melting at 168~169°C was obtained by the Schotten-Baumann technique. $[\alpha]_D^{12}$ +43.5° (*c* 2.0, ethanol). Found: C, 71.33; H, 7.61; N, 6.25. Calcd. for $C_{13}H_{17}NO_2$ (219.3): C, 71.20; H, 7.82; N, 6.39%.

***N*-Carbobenzoxy-*d-trans*-2-aminocyclohexanol (V).**—To 5.3 g. portion of *d-trans*-2-aminocyclo-hexanol L-(+)-tartrate in 30 ml. of water was added 6.7 g. of sodium bicarbonate. To the mixture 6.6 g. of carbobenzoxy chloride (80% toluene solution) was added under mechanical agitation. The precipitate was treated similarly as I to obtain 3.3 g. (66%) of the crystals melting at 115.5~116.5°C. $[\alpha]_D^{14}$ +20.3° (*c* 1.1, ethanol).

Found: C, 67.30; H, 7.68; N, 5.68. Calcd. for $C_{14}H_{19}NO_3$ (249.3): C, 67.44; H, 7.68; N, 5.62%.

β-(*N*-Carbobenzoxy-*d-trans*-2-aminocyclohexyl)-3, 4, 6, -triacetyl-*N*-carbobenzoxy-D-glucosaminide (VI).—A mixture of 2.2 g. of α-l-bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine and 1.1 g. of V in 25 ml. of anhydrous benzene was refluxed for 2 hr. with 1.9 g. of mercuric cyanide. Then the mixture was treated similarly to a corresponding derivative of *l*-form, II, to obtain 1.1 g. (38%) of the crystalline product melting at 191~192°C. $[\alpha]_D^{17}$ +22.9° (*c* 1.4, chloroform).

Found: C, 60.94; H, 6.19; N, 4.30. Calcd. for $C_{34}H_{42}N_2O_{12}$ (670.7): C, 60.88; H, 6.31; N, 4.18%.

The infrared spectrum of the product showed the same pattern as that of II.

β-(*N*-Carbobenzoxy-*d-trans*-2-aminocyclohexyl)-*N*-carbobenzoxy-D-glucosaminide (VII).—Upon treatment of 2.7 g. of VI with 130 ml. of methanol saturated with ammonia in a refrigerator overnight, the clear solution was obtained. The solution was treated similarly to III to yield 1.6 g. (76%) of crystals melting at 199~200°C. $[\alpha]_D^{11}$ +10.30 (*c* 3.1, pyridine).

Found: C, 61.42; H, 6.66; N, 4.91. Calcd. for $C_{28}H_{36}N_2O_9$ (544.6): C, 61.75; H, 6.66; N, 5.14%.

The infrared spectrum of the product was superimposable with that of III.

β-(*d-trans*-2-Aminocyclohexyl)-D-glucosaminide (VIII).—A 1.39 g. portion of VII was hydrogenated with 0.4 g. of palladium black in 65 ml. of dioxane-water mixture (1 : 1). The mixture was treated similarly to IV to yield 0.35 g. (57%) of the crystalline product melting at 195.5~196.5°C (decomp.). $[\alpha]_D^{11}$ +4.9° (*c* 1.4, water).

Found: C, 52.21; N, 8.57; N, 10.12. Calcd. for $C_{12}H_{24}N_2O_5$ (276.3): C, 52.16; H, 8.75; N, 10.14%.

The infrared spectrum of the product was superimposable with that of IV.

***N*-Carbobenzoxy-*O*-trityl-*d, l-trans*-2-amino-cyclohexanol (IX).**—To a solution of 6.0 g. of *N*-carbobenzoxy-*d, l-trans*-2-aminocyclohexanol in 43 ml. of dry pyridine was added 7.4 g. of trityl chloride. The mixture was heated on a boiling water bath for 20 hr. After placed overnight at room temperature, the mixture was filtered to remove a precipitate.

The filtrate was poured into 180 ml. of ice cold water to give an oily product, which began to crystallize by scratching a wall of the vessel with a glass rod under ice cooling.

The crystals were collected by filtration and then dissolved in ether. The ethereal solution was dried over anhydrous sodium sulfate and evaporated under reduced pressure to yield a crystalline residue. The residue was recrystallized from methanol to yield 6.29 g. (53%) of the product melting at 111~115°C. The crude product was recystallized again

from absolute ethanol to yield 4.36 g. (37%) of crystals melting at 126.5~128°C.

Found: C, 80.52; H, 6.56; N, 2.68. Calcd. for $C_{33}H_{33}NO_3$ (491.6): C, 80.62; H, 6.77; N, 2.85%.

The second crop of the product (0.15 g.) melting at 126~128°C was recovered from the mother liquor.

β-(*N*-Carbobenzoxy-*l-trans*-2-aminocyclohexyl)-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosaminide.—A solution of 1.1 g. of silver perchlorate and 18 ml. of anhydrous nitromethane was added with 1.5 g. of anhydrous calcium sulfate. Then, 2.4 g. of IX and 2.9 g. of α-l-bromo-3, 4, 6-triacetyl-*N*-carbobenzoxy-D-glucosamine were added to the mixture under ice cooling. The mixture was vigorously shaken at room temperature for 2 hr. After standing overnigth at room temperature, the mixture was filtered to remove a precipitate. The filtrate was washed twice with saturated sodium bicarbonate solution and five times with cold water. The organic solvent layer was filtered again to remove triphenylcarbinol and then diluted with 50 ml. of chloroform. The solution was dried over anhydrous sodium sulfate and evaporated under reduced pressure to yield 5.1 g. of a crystalline residue. The residue was washed with anhydrous ether to obtain 2.6 g. of a crude mixture of II and VI melting at 107~167°C. The crude product was repeatedly recrystallized from absolute ethanol to yield 230 mg. (7.0%) of the product melting at 215~216°C. The mixed melting point with II did not show any depression.

From the mother liquor, VI was not obtained in a pure state.

Bioassays.—IV and VIII showed almost no antimicrobial activity against *E. coli* in a paper disk method.

The authors were indebted to Mr. Saburo Nakada for microanalyses and to Mrs. Setsuko Iriyama for bioassays. A part of this research was supported by the Asahi Glass Foundation for the Contribution to Industrial Technology.

*The Electronic Spectrum of Cumene Adsorbed on the Silica-Alumina Catalyst Surface during the Cracking Reaction**

By Taro TACHIBANA and Michio OKUDA

(Received December 11, 1962)

It is generally assumed that cumene dealkylation over silica-alumina catalyst involves, as an intermediate, the protonated cumene formed by the addition of a proton to cumene[1]. However, the existence of this intermediate has not yet been proven, although it is considered to form on the surface of catalyst during cracking. Since chemical species such as hydrocarbon ions or radicals often show a characteristic electronic spectrum, it is interesting, in studying the cracking mechanism, to investigate those species adsorbed on the catalyst by measuring their electronic spectra. Recently such studies have been reported by Leftin and Hall[2a-c], who have demonstrated the formation of dimethylphenyl-carbonium ions in the chemisorption of cumene. However, these ions are inconsistent with the generally accepted mechanism for the dealkylation reaction. It should be noted that Leftin's spectral measurement was carried out at room temperature. In order to detect an unstable intermediate on a catalyst, the spectra should be measured on the catalyst during cracking. Such a study, which will be reported on here, should contribute substantially to establishing the reaction mechanism.

Experimental

Cumene was washed with concentrated sulfuric acid and then dried and distilled. The distillate was percolated through columns of silica gel to remove the peroxide.

The silica-alumina catalyst, which had been prepared by the coprecipitation method and which had been calcinated at 500°C in air for 2 hr., was kindly supplied by Prof. Shiba of the Tokyo Institute of Technology and was said to contain approximately 10% alumina. This catalyst was prepared for optical measurement in the form of a semitransparent thin disk (0.1 mm. thick) by pressing its powder at a pressure of 8 ton./cm^2. This disk was placed in an optical cell similar to that described

* Presented at the 14th Annual Meeting of the Chemical Sosiety of Japan, Tokyo, April, 1961.

previously[3]. Heating was provided by a winding of nichrom wire around the outside of the cell; thus the spectrum during reaction at an elevated temperature was obtained. This cell was connected directly to the vacuum system, evacuated for one hour at 300°C, and then sealed off under vacuum. The pure cumene sample to be adsorbed was sealed in a separate compartment, one separated from the cell by a break-off seal. Exposure of the catalyst disk to cumene vapor was carried out by rupturing this break off seal. Exposure times of several hours were allowed to make an equilibrium condition at room temperature. The optical spectra were measured with a Hitachi EPS-2 recording spectrophotometer and were determined by measuring the transmission through this disk. Another disk, pretreated identically in a separate cell, was used as a blank in the reference beam.

Results and Consideration

At first, the absorption spectrum of the material adsorbed on the catalyst disk was measured at room temperature. As is shown by curve A of Fig. 1, the spectrum obtained is characterized by a double peak absorption band in the 258~265 mμ region and is almost identical with the spectrum of an alcoholic solution of cumene, indicating that cumene is physically adsorbed on the catalyst.

The cell was then heated to 150°C, and the absorption spectra at this temperature were taken at various intervals of time. The results are shown by curves B–E of Fig. 1. On heating at 150°C for 30 min., a new band appeared at 335 mμ. With further heating, another band appeared at 430 mμ; this finally proved to be the most intense band.

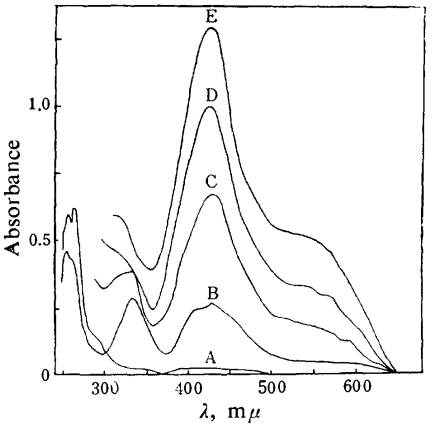

Fig. 1. Spectra of cumene on silica-alumina.
A : Room temperature
B : Heated 150°C for 1 hr.
C : Heated 150°C for 3 hr.

E : Heated 150°C for 17 hr.

3) M. Okuda, *J. Chem. Soc. Japan, Pure Chem Sec.* (*Nippon Kagaku Zasshi*), **82**, 1115 (1961).

After heating for 17 hr., the gases in the cell were spectrophotometrically analyzed. The liquid product was mainly benzene, with a small amount of di-isopropylbenzene. This shows that the cracking dealkylation reaction took place mainly in the cell, though the reaction was followed at a lower temperature than that for catalytic cracking in usual (350~450°C). The 430 and 335 mμ bands were not found with the reaction product. Therefore, the bands at both 430 and 335 mμ are ascribed to chemisorbed molecules formed on the catalyst during the cracking reaction.

Recently, Leftin and Hall[2a] have shown, by spectrophotometric studies, that when triphenylmethane and related compounds, including cumene, are adsorbed on the surface of thoroughly dried silica-alumina catalysts, carbonium ions are formed which have an absorption band at about 400 mμ. With reference to their results, the 430 mμ band indicated by curves B–E of Fig. 1 can be assigned to a stable dimethylphenylcarbonium ion produced between cumene and the Lewis acid site on the silica-alumina surface. After the catalyst had been heated at 150°C for 17 hr., it was exposed to air at room temperature. In this case, the 430 mμ band was still observed, and the catalyst developed a brown color. When the catalyst was treated with an aqueous solution of ammonia, the brown color was lost and the 430 mμ band completely disappeared. This indicates that the carbonium ion is displaced from the acid center by the ammonia molecule, which forms a stronger base.

On the other hand, when the 335 mμ band was superimposed on the absorption in the ultraviolet region, which developed gradually with time, it became quite obscure after 6 hr. By reducing the effect of the absorption of the background at the ultraviolet region, it was found that the absorbance at 355 mμ after one hour is almost the same as that after three hours. In order to investigate in more detail the behavior of this band in relation to the time, measurements were made in an earlier stage of reaction. The results are shown by curves A and B of Fig. 2. It may be seen that, immediately after the temperature of cell reached 150°C, an absorption band appeared 327 mμ and that, thereafter, it increased in absorbance with a shift to 335 mμ. In this period the 430 mμ band had not yet appeared. After 13 min., heating was stopped and the spectrum was measured at room temperature. As is shown by curve C of Fig. 2, the 335 mμ absorption was considerably decreased, though absorbance around this peak increased. This fact indicates that the surface

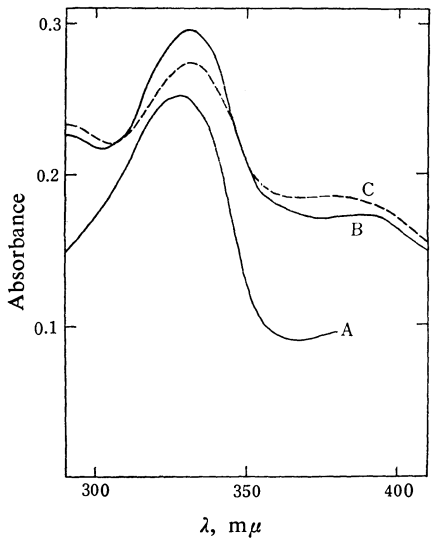

Fig. 2. Spectra of cumene on silica-alumina.
A : Immediately after heating at 150°C
B : Heated 150°C for 13 min.
C : At room temperature after heating for 13 min.

species contributing to the formation of this band ceased to be formed at room temperature.

On the basis of these results, it is suggested that the 335 mμ band could be due to an intermediate in the cracking reaction. A similar spectrum, with a peak at 327.5 mμ, was obtained from a solution of cumene in concentrated sulfuric acid. This absorption disappeared after 20 hr.; therefore, it is due to an unstable chemical species, probably protonated cumene, since it is well known that such hydrocarbon acts as a base in concentrated sulfuric acid and forms a proton adduct[4]. It seems probable that the unstable intermediate on the catalyst is also a protonated cumene produced by the reaction of cumene with the Brönsted acid site of the catalyst.

In summary, under the experimental conditions used, there exist both a Lewis acid site and a Brönsted acid site on the surface of the silica-alumina catalyst; the latter contributes to the cracking reaction through the formation of a chemisorbed intermediate.

This work was made possible by a grant from the Ministry of Education of Japan. The authors wish to thank Professor Tadao Shiba and Professor Tominaga Keii of the Tokyo Institute of Technology for their kind advice throughout the course of this work. Thanks are also due to Miss Fumie Hashimoto and Miss Yaeko Ide for their technical assistance.

The Infrared Spectra of O-Deuterated and O-Methylated Derivatives of Diacetyl Monoxime and Isonitrosoacetone

By Yoko KURODA and Masao KIMURA

(Received December 4, 1962)

In a previous study the assignement of the absorption bands of diacetyl monoxime and isonitrosoacetone was carried out to determine the characteristic frequencies of the O=C–C=N system and also those of the functional group of oximes, –C=N–OH[1]. We have found that (1) these oximes take not a nitroso form but an oxime form in solutions; (2) the C=N stretching vibration appears in a lower frequency range than that of unconjugated oximes; (3) the oximes in solutions make intermolecular hydrogen bonds of an –O–H···O=C*1 type, while unconjugated oximes in solutions or in the solid state make intermolecular hydrogen bonds of an –O–H···N=C type, and (4) the bond character of an O=C–C=N–OH system changes with the hydrogen bonding so that molecules in the free and in the associated state have two sets of frequencies corresponding to these states. The characteristic frequencies of C=N bonds have been observed for some kinds of compounds, such as unconjugated imines[2], unconjugated

oximes[3-7], conjugated imines[8], conjugated oximes containing phenyl groups[9,10], azines[11], glyoximes[12] and so on[13]. It is worth noting that the frequencies of the bands scatter over a very wide range of wave numbers, 1520~1680 cm^{-1}, depending on the kinds of compounds or the existence of hydrogen bonding. Moreover, absorption intensity is affected to a considerable extent by the environment around a C=N bond[13,14]. Now that the assignment of bands has been made for diacetyl monoxime and isonitrosoacetone, it is quite interesting to observe the effect of environments on the infrared spectra of the O=C-C=N-OH system. Therefore, the *O*-deuterated and *O*-methylated derivatives of diacetyl monoxime and isonitrosoacetone have been dealt with in the present study in order to investigate the effect of substituents on the positions and intensities of bands of the O=C-C=N-O system. This study will also serve to confirm the previous assignment. When the Raman and infrared spectra of these oximes were reported on by Kahovec and Kohlrausch[15], Matsui[16] and Milone and Borello[17], they were not completely analyzed.

Experimental

Deuterated samples were prepared from the same purified samples as used in the previous study[1] by exchanging the hydrogen in OH groups with deuterium in heavy water. These samples were dried before use.

Commercial preparations of diacetyl monoxime-*O*-methyl ether and isonitrosoacetone-*O*-methyl ether were purified by distillation under atmospheric and reduced pressure respectively.

The spectra were taken with the optical system of a Hilger H-800 spectrophotometer equipped with interchangeable fluorite and rock-salt prisms. Solutions of various concentrations in carbon tetrachloride, carbon disulfide and chloroform were

used in order to observe changes in the absorption intensity with changes in the concentration. Isonitrosoacetone-*d* was used only in dilute solutions, since it has only a limited solubility in the solvents used. The deuterated oximes in the solid state were examined as mulls in Nujol and hexachlorobutadiene. The methylated oximes in the liquid state were also examined. However, no additional data were obtained.

The observed frequencies of absorption bands are listed in Tables I, II and III. For the sake of comparison, the observed frequencies of the original oximes are also included in Tables I and II. These values are reproduced from the previous paper[1]. However, the C-H stretching frequencies are omitted from the tables, because they are not necessary for later discussion. Some portions of the spectra are shown in Figs. 1 to 9.

Assignment and Discussion

The Stretching Frequencies of O=C-C=N.— The bands previously assigned to the C=O stretching vibrations, $\nu(C=O)$, of diacetyl monoxime and isonitrosoacetone show no appreciable change in their positions and intensities on deuteration. The general behavior of the concentration dependence of the intensity is also unaltered by replacing hydrogen with deuterium. However, the $\nu(C=O)$ bands of associated molecules at 1686 cm^{-1} for diacetyl monoxime and at 1674 cm^{-1} for isonitrosoacetone not only become weak on dilution but also disappear on methylation (Figs. 1 and 2). These facts confirm the previous assignment. The vibrational mode in the solid state absorbs at a frequency lower by about 20 cm^{-1} than that in solution. The low-frequency shift is a quite general phenomenon observed in condensed phases.

For the C=N stretching vibration, $\nu(C=N)$, distinct variations in intensity and position are observed on deuteration and methylation.

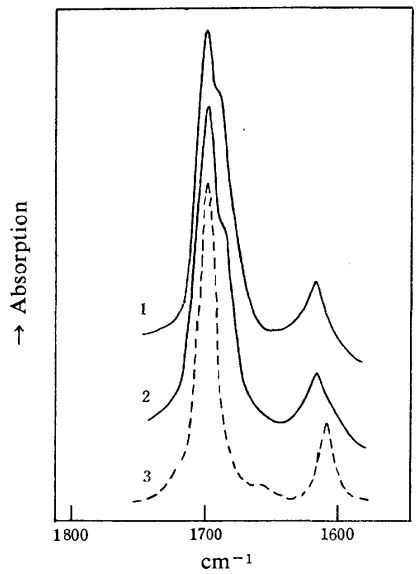

Fig. 1. Infrared spectra of diacetyl monoxime-*d* in CCl_4 solutions: (1) 0.148 mol./l., 0.2 mm. cell; (2) 0.059 mol./l., 0.5 mm. cell, and (3) diacetyl monoxime-*O*-methyl ether (liq.).

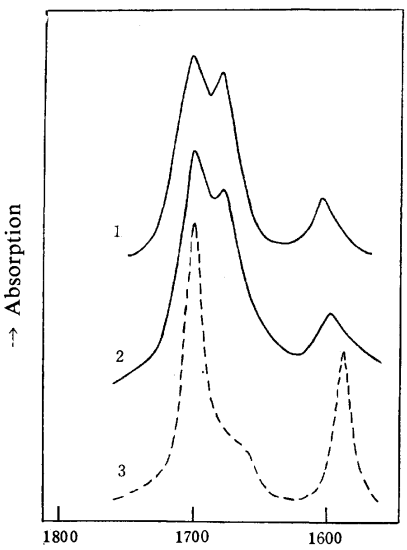

Fig. 2. Infrared spectra of isonitrosoacetone-*d* in $CHCl_3$ solutions: (1) 0.515 mol./l., 0.05 mm. cell; (2) 0.130 mol./l., 0.2 mm. cell, and (3) isonitrosoacetone-*O*-methyl ether (liq.).

Deuteration gives rise to a lowering in frequency along with a slight but perceptible increase in intensity. Methylation causes a similar frequency shift and an intensity change, the magnitude of which is, however, much greater than that on deuteration (Figs. 1 and 2). As a result, the methylated oximes have rather strong and sharp ν(C=N) bands, unlike the original oximes. The doubling of the ν(C=N) bands attributable to free and associated molecules could not be detected for either the deuterated compounds or the original compounds. This fact suggests that the influence of association does not practically extend to the C=N bonds. The ν(C=N) band of diacetyl monoxime in the solid state is masked by the strong band of ν(C=O).

For all compounds treated in the present study, the C=O stretching vibrations appear in a region of lower frequency than that of unconjugated ketones (1705～1725 cm^{-1})[13], while the frequencies of the C=N stretching vibrations are lower than those of unconjugated oximes or imines (1660～1680 cm^{-1}). Conjugation in an O=C-C=N system is considered to be the cause of the lowering in the ν(C=O) and ν(C=N) frequencies. We can find the following absorption ranges for ν(C=O)[13,18]: α-diketones, 1710～1730 cm^{-1}; α,β-unsaturated ketones, 1665～1685 cm^{-1}; and for ν(C=N): azines[11], about 1660 cm^{-1}; benzaldoximes[8,13], 1620～1660 cm^{-1}. Thus, ν(C=O) in an O=C-C=N system can be considered to absorb in a wave number range between those of saturated ketones and of α,β-unsaturated ketones. The ν(C=N) is in a wave number range still lower than that of a C=N group conjugated with a phenyl group*2. *vic*-Dioximes appear to have very weak absorptions near 1620 cm^{-1} originating from an N=C-C=N system[19]*3. This value is very close to the ν(C=N) wave number in an O=C-C=N system.

Deuteration and methylation result in an increase in absorption intensity and a decrease in frequency for ν(C=N), but not for ν(C=O). The frequency shift of ν(C=N) is probably a natural consequence of substitution. The fact that there is no significant change in ν(C=O) implies that the substitution does not affect the C=O bond.

As Cross and Rolfe have pointed out[5], the C=N absorption intensities of oximes are generally weak, while those of other kinds of compounds are not necessarily so. Once the hydrogen atom of an OH group is replaced by another atom or group, the C=N absorption band is intensified. Matsui also made a similar

18) See also M. L. Josien, J. Lascombe, J. Lecomte and J. P. Mathieu, *Compt. rend.*, 240, 1982 (1955).

*2 Palm and Werbin reported the value of about 1620 cm^{-1} for the ν(C=N) of α-benzaldoxime[9]. As the value was observed in the solid state, the frequency for a free state is possibly higher than this.

*3 The frequency was estimated from the spectra given by Voter et al. in their paper[19].

19) R. C. Voter, C. V. Banks, V. A. Fassel and P. W. Kehres, *Anal. Chem.*, 23, 1730 (1951).

finding in his studies of oximes[16]. This seems to be characteristic of the spectra of oximes.

Hydrogen bonding gives rise to a shift towards a frequency lower by about 10 cm^{-1} for the ν(C=O) of diacetyl monoxime and by about 25 cm^{-1} for that of isonitrosoacetone. In general, a frequency shift caused by hydrogen bonding does not exceed 10 cm^{-1} in unconjugated ketones[20,21]. The frequency shift in diacetyl monoxime is of the same order as that in unconjugated ketones. On the other hand, the frequency shift in isonitrosoacetone is greater than that in unconjugated ketones.

In the previous paper, the bands due to the C–C stretching vibrations, $\nu(C-C)_{central}$, in the system discussed here were placed near 1300 cm^{-1} for diacetyl monoxime and at 1320 cm^{-1} for isonitrosoacetone. The corresponding bands of deuterated oximes are at 1306 and 1321 cm^{-1}, while those of methylated oximes are at 1311 and 1318 cm^{-1}. The bands of these oximes become intense on deuteration and more intense on methylation (Figs. 3—6). This property of $\nu(C-C)_{central}$ is analogous to that of ν(C=N). The bands of the deuterated oximes look like single bands rather than composite ones. Reexamination of diacetyl monoxime revealed that two well-defined bands and their concentration dependence could not always be observed. Accordingly, only one frequency is shown in Table I for the $\nu(C-C)_{central}$ of diacetyl monoxime.

The Stretching Frequencies of N–O and N–O–C.—In the previous study, the bands of diacetyl monoxime at 970 and 963 cm^{-1} and of isonitrosoacetone at 990 and 972 cm^{-1} were assigned to the N–O stretching vibrations, ν(N–O).

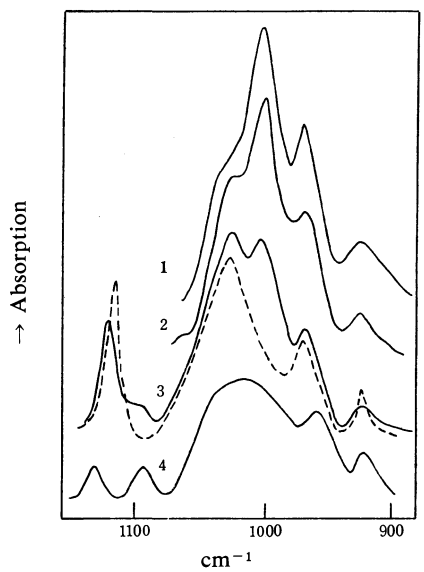

Fig. 7. Infrared spectra of diacetyl monoxime-*d* (1) in CS_2, 0.02 mol./l., 1.5 mm. cell; (2) in CS_2, 0.059 mol./l., 0.5 mm. cell; (3) in CCl_4, 0.345 mol./l., 0.085 mm. cell, and (4) in hexachlorobutadiene mull. The dotted line indicates the spectrum of diacetyl monoxime in CCl_4 at the same concentration as (3).

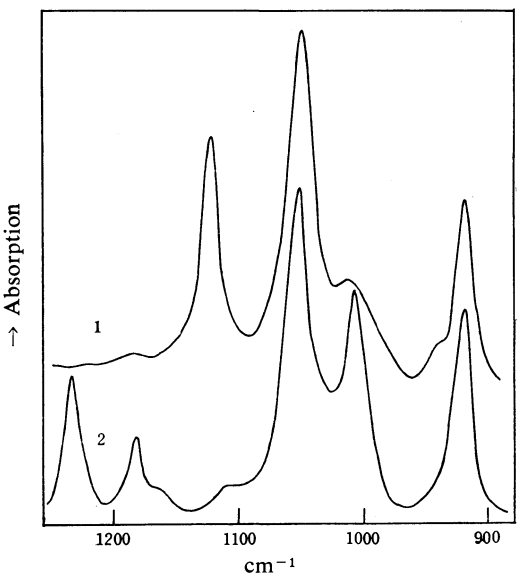

Fig. 9. Infrared spectra of (1) diacetyl monoxime-*O*-methyl ether (liq.), and (2) isonitrosoacetone-*O*-methyl ether (liq.).

On deuteration, no appreciable changes can be observed in the absorption frequencies and in the concentration dependence of the intensity (Figs. 7 and 8). The N–O stretching frequencies of this type of oximes are higher than those of unconjugated oximes[3,7-9] or

benzaldoxime[22], but lower than that of benzoquinone monoxime[10]. This difference in characteristic frequencies is possibly due to the double-bond characters of N–O bonds in conjugation with adjacent bonds or groups as has been stated above.

The bands mentioned above, however, must be turned into an entirely different pattern by methylation, because an N–O system is replaced by a system of three atoms, N–O–C. As expected, all the N–O stretching bands of oximes are missing in the spectra of methyl ethers. Instead, new bands appear at 1190, 1049 and 917 cm^{-1} for diacetyl monoxime-*O*-methyl ether and 1180 and 1052 cm^{-1} for isonitrosoacetone-*O*-methyl ether (Fig. 9). Strong bands are to be assigned to the N–O–C stretching vibration, ν(N–O–C), while weak bands are to be assigned to the CH_3 rocking vibration, as is described below. The stretching vibration of a C–O–C system in alkyl ethers[13] absorbs in the 1060~1150 cm^{-1} range. Analyzing the spectra of dimethyl ether, Kanazawa and Nukada assigned a band at 928 cm^{-1} to the symmetric stretching vibration and a band at 1102 cm^{-1} to the antisymmetric vibration of C–O–C[23]. Accordingly, two strong bands at 1049 and 917 cm^{-1} for diacetyl monoxime-*O*-methyl ether can be assigned to ν(N–O–C). The corresponding bands of isonitrosoacetone-*O*-methyl ether are a band at 1052 cm^{-1} and perhaps a band at 918 cm^{-1} (Figs. 8 and 9). Although the band at 918 cm^{-1} is not a band appearing only in the case of *O*-methylated isonitrosoacetone, it is strengthened by substituting a methyl group for hydrogen. Therefore, it seems to be much more reasonable to assign the band at 918 cm^{-1} rather than a weak band at 1180 cm^{-1} to ν(N–O–C). A value of 918 cm^{-1} for *O*-methylated isonitrosoacetone is practically equal to the value of 917 cm^{-1} for *O*-methylated diacetyl monoxime. The bands near 1050 cm^{-1} are stronger than those near 918 cm^{-1}. The formers belong to the antisymmetric vibration, and the latters, to the symmetric vibration of the N–O–C.

The Stretching and Bending Frequencies of OH and OD.—The bands representing the OD stretching vibration, ν(OD), are evidently those at 2630 and 2420 cm^{-1} for diacetyl monoxime-*d* and those at 2620 and 2440 cm^{-1} for isonitrosoacetone-*d*. In the solid state only bands near 2400 cm^{-1} appear. The observed frequencies of these bands were roughly estimated because of the disturbance caused by the absorption of carbon dioxide. The ν(OD) bands completely disappear from the spectra of the methylated oximes. The bands near 2600 cm^{-1} should be assigned to the ν(OD) of free molecules, and the bands near 2400 cm^{-1}, to that of associated molecules. The values of the ν(OH) : ν(OD) frequency ratio are 1.36 and 1.38 for the free and the associated state of diacetyl monoxime and 1.36 for both states of isonitrosoacetone.

In the previous study, the band of diacetyl monoxime at 1355 cm^{-1} and that of isonitrosoacetone at 1398 cm^{-1} were assigned to the OH in-plane bending vibration, $\delta(OH)_{in\text{-}plane}$, of free molecules. These bands disappear on deuteration (Figs. 3—6). Therefore, the assignment made in the previous study is justified. New bands of free molecules attributable to the OD in-plane bending vibration, $\delta(OD)_{in\text{-}plane}$, appear at 995 cm^{-1} for diacetyl monoxime-*d* and near 1015 cm^{-1} for isonitrosoacetone-*d* in solution. The former band becomes strong with a decrease in the concentration. The concentration dependence of the latter is not simple (Figs. 7 and 8). Judging from the complicated appearance of the band, it can hardly be regarded as a single absorption band. The band changes into a sharp band on methylation (Fig. 9). Therefore, it can be considered to be a composite band of $\delta(OD)_{in\text{-}plane}$ and the rocking vibration of CH_3 attached to the C=O group of isonitrosoacetone-*d*. The values of the δ(OH) : δ(OD) frequency ratio are 1.36 and 1.38 for diacetyl monoxime and isonitrosoacetone respectively.

The $\delta(OH)_{in\text{-}plane}$ band of diacetyl monoxime in the associated state could not be determined definitely in the previous study owing to an overlap with a band at 1424 cm^{-1}. The present study revealed that in solutions a band in this region becomes relatively sharp on deuteration and even sharper on methylation. The corresponding band in the solid state is a broad one at 1450 cm^{-1} which disappears on deuteration (Fig. 3). From these facts, the band at 1450 cm^{-1} can be considered to represent the $\delta(OH)_{in\text{-}plane}$ of diacetyl monoxime in the associated state. Even in solutions, the band should be considered to be present near 1450 cm^{-1}, although it cannot be located precisely because of the presence of a band at 1424 cm^{-1}.

For isonitrosoacetone, no definite conclusion could be drawn in the present study about the exact position of the $\delta(OH)_{in\text{-}plane}$ in the associated state. Nevertheless, it is most likely that the band near 1450 cm^{-1} arises from the δ(OH) of isonitrosoacetone in the associated state and that the CH_3 degenerate deformation band overlaps the band (Fig. 4).

22) A. Palm and H. Werbin, *Can. J. Chem.*, **32**, 858 (1954).
23) Y. Kanazawa and K. Nukada, This Bulletin, **35**, 612 (1962). See also Y. Masiko, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zassi*), **79**, 470 (1958).

A very weak band at about 1080 cm^{-1} can be assigned to the $\delta(OD)_{in\text{-}plane}$ of associated diacetyl monoxime-*d*, since it becomes more intense at higher concentrations. In the solid state, two bands appear at 1090 and 1134 cm^{-1} in place of a very weak band at about 1080 cm^{-1} and a strong band at 1124 cm^{-1} in solution (Fig. 7). A band at 1124 cm^{-1} is assigned to the CH_3 rocking vibration in N=C-CH_3, ρ(N=C-CH_3), below. The two bands in the spectrum of the solid have nearly equal intensities and are only half as intense as the band at 1124 cm^{-1} in solution. The frequency shifts and the intensity changes arise probably from a coupling between δ(OD) and ρ(N=C-CH_3) in the associated state. In solution it seems that the band at 1134 cm^{-1}, due to relatively few associated molecules, is poorly defined because of the existence of the strong band at 1124 cm^{-1} due to free molecules (Fig. 7).

The band of solid isonitrosoacetone-*d* at 1062 cm^{-1} can be assigned to the δ(OD) in association, although no distinct band was detected near 1062 cm^{-1} in the spectra of solutions since concentrated solutions could not be prepared. The values of the δ(OH) : δ(OD) frequency ratio are 1.33 for diacetyl monoxime and 1.36 for isonitrosoacetone.

The Bending and Rocking Vibrations of CH_3 and CH.—The bands at 1424 and 1365 cm^{-1} and those at 1450 and 1366 cm^{-1} were assigned previously to the CH_3 deformation vibrations of diacetyl monoxime and isonitrosoacetone respectively[1]. The assignment of the 1450 cm^{-1} band, however, was somewhat ambiguous. The corresponding bands of the deuterated oximes are the bands at 1424 and 1362 cm^{-1} for diacetyl monoxime-*d* and those at about 1465 and 1372 cm^{-1} for isonitrosoacetone-*d*.

Their methyl ethers show bands at 1463, 1442, 1428 and 1361 cm^{-1} for diacetyl monoxime-*O*-methyl ether and bands at 1465, 1446, 1427 and 1367 cm^{-1} for isonitrosoacetone-*O*-methyl ether (Fig. 6). Two new bands observed in the spectra of the methyl ethers do not show the concentration dependence of the intensity. Among the four bands of diacetyl monoxime-*O*-methyl ether, the bands at 1424 and 1365 cm^{-1} can readily be assigned to the CH_3 deformation vibrations of C-CH_3, δ(C-CH_3), because they are present in the spectra of both the original and deuterated oximes. Therefore, the bands at 1463 and 1442 cm^{-1} should be attributed to the CH_3 deformation vibrations of O-CH_3, δ(O-CH_3). The band at 1463 cm^{-1} is stronger than that at 1442 cm^{-1}. The former represents the antisymmetric vibration, and the latter, the symmetric one.

For diacetyl monoxime no substantial change in the positions and intensities of the CH_3 deformation bands is produced by *O*-methylation. A band at about 1365 cm^{-1} is characteristic of all the compounds under investigation. Therefore, it is a natural inference that the CH_3 degenerate deformation vibrations of isonitrosoacetone and its deuterated compound will also give rise to bands at about 1427 cm^{-1}, corresponding to the band observed for the methyl ether, although the band was not identified on the spectrum of the oxime itself because of a broad band due to the $\delta(OH)_{in\text{-}plane}$. The remaining bands of isonitrosoacetone-*O*-methyl ether, at 1465 and 1446 cm^{-1}, should be assigned to $\delta(O\text{-}CH_3)_{degenerate}$ and $\delta(O\text{-}CH_3)_{symmetric}$ respectively. Thus, a consistent interpretation can be achieved for the CH_3 deformation bands. The values of 1465 and 1446 cm^{-1} for δ(O-CH_3) lie in the same range as that observed for dimethyl ether by Kanazawa and Nukada[23], these values being higher than those of δ(C-CH_3) in alkanes.

The band of isonitrosoacetone at 1226 cm^{-1} was assigned previously to the CH in-plane bending vibration, $\delta(CH)_{in\text{-}plane}$. The corresponding bands are present at 1223 cm^{-1} for its deuterated oxime and at 1236 cm^{-1} for its methyl ether. A band at 831 cm^{-1} for the deuterated and methylated isonitrosoacetone can be attributed to the CH out-of-plane bending vibration, $\delta(CH)_{out\text{-}of\text{-}plane}$. None of the bands discussed in this paragraph appear in the spectra of diacetyl monoxime and its derivatives.

There are bands at 1017 and at 1011 cm^{-1} for deuterated and methylated diacetyl monoxime respectively. Similarly, there are bands at 1015 and at 1007 cm^{-1} for deuterated and methylated isonitrosoacetone respectively. These bands are unequivocally due to the CH_3 in-plane rocking vibrations, ρ(O=C-CH_3), of O=C-CH_3, which have bands at 1022 and 1016 cm^{-1} for the original oximes.

In addition, diacetyl monoxime and its derivatives have bands at exactly the same frequency, 1124 cm^{-1}. These bands must be due to the CH_3 in-plane rocking vibrations, ρ(N=C-CH_3), of N=C-CH_3. These facts convince us of the correctness of the assignments made in the previous study. For the solid of diacetyl monoxime-*d*, the band at 1134 cm^{-1} may be interpreted as ρ(N=C-CH_3). The position can be considered to shift in the solid state through a coupling with δ(OD), as has already been mentioned.

In methyl ethers, the CH_3 rocking vibration, ρ(O-CH_3), of O-CH_3 should appear in the rock-salt region. With a methyl group in place of hydrogen, a new additional weak band

appeared at 1190 cm^{-1} for diacetyl monoxime-*O*-methyl ether and at 1180 cm^{-1} for isonitrosoacetone-*O*-methyl ether. The weak band near 1190 cm^{-1} is assigned to $\rho(O-CH_3)$.

The bands of the deuterated diacetyl monoxime at 930 cm^{-1} and of the methylated one at 945 cm^{-1} correspond to the weak band of the original oxime at 933 cm^{-1} which was previously assigned to $\nu(C-CH_3)$. However, the band of the methyl ether at 945 cm^{-1} is detectable merely as a shoulder on the higher frequency side of a strong band at 917 cm^{-1}. Consequently, the observed frequency can only roughly be estimated. For isonitrosoacetone and its derivatives, the corresponding bands are weak ones at 920 cm^{-1} in the oxime and at 918 cm^{-1} in the deuterated and methylated oximes. It is most probable that these bands are due to the stretching vibrations of $C-CH_3$ bonds, $\nu(C-CH_3)$, because the C–C stretching bands cannot be considered to shift substantially on deuteration and methylation and also because no other bands could be found in the spectra of isonitrosoacetone.

Summary

The infrared absorption bands due to the O=C–C=N–OH system have been investigated by the use of diacetyl monoxime, isonitrosoacetone, and their *O*-deuterated and *O*-methylated derivatives. All the bands observed have been reasonably assigned. So far as the infrared spectra are concerned, the degree of conjugation in the C=O bonds is between those of saturated ketones and α,β-unsaturated ketones. The degree of conjugation in the C=N bonds is greater than those of conjugated imines and of aldoximes containing a C=C–C=N group and is approximately equal to those of *vic*-dioximes containing an N=C–C=N group. Under the influence of conjugation, the N–O bonds have a greater double-bond character than those of unconjugated oximes. The bond character varies with the hydrogen bonding, the type of which is not –O–H···N=C, but –O–H···O=C. In general, the bands due to the C=N bonds of oximes are weak. However, they are intensified by deuteration and are intensified remarkably by methylation.

The authors wish to express their gratitude to Professor Masaji Kubo of the Department of Chemistry, Nagoya University, for his helpful advice.

NOTES

Molecular Rotations of Glucides in Relation to their Structures. XI[1]. *β-D-Allomethylose*

By Shukichi YAMANA

(Received October 29, 1962)

Micheel observed the mutarotation of β-D-allomethylose and obtained the following data[2]: $[M]_D^{18}(W) = -19.7°$ (30 sec. after the time of resolution) $\rightarrow -1.6°$ (85 min. after the time of resolution)

Therefore, it can be expected that the initial $[M]_D^{20}(W)$ of β-D-allomethylose is more laevorotatory than $-19.7°$. However, by using his own method of calculation, Whiffen obtained 2° as the $[M]_D(W)$ of β-D-allomethylose[3]. It is apparent that Whiffen's calculated value is incompatible with the values observed by Micheel. The present author will try to apply the PM-method in this case. The names of the carbohydrates to which the calculations are applied, with the unit groups in their molecules, are given in Table I.

TABLE I

Name	Unit group	$[M]_D(W)$	Ref.
β-D-Allomethylose	$[(OH)^{1\beta}, (OH)^{2\alpha}, (OH)^{3\alpha}, (OH)^{4\alpha}, (CH_3)^{5\beta}$, Ring]		
β-D-Gulomethylose	$[(OH)^{1\beta}, (OH)^{2\alpha}, (OH)^{3\alpha}, (OH)^{4\beta}, (CH_3)^{5\beta}$, Ring]	−69.4°[4]	5

Referring to Table I, if the orientation of $(OH)^4$ changes from β to α in β-D-gulomethylose, β-D-allomethylose is obtained. By using the PM-method, $\sum [\mu]_{D\,obs}^{20}$, caused by this orientation change of $(OH)^4$ (that is to say, $[\mu]_{D\,obs}^{20}$ of Yo. Diff. <β-D-allomethylose − β-D-gulomethylose>[6]), is calculated as below:

$$\{(4\alpha)-(4\beta)\}\chi\{(1\beta)+(2\alpha)+(3\alpha)+(CH_3)^{5\beta}+R\}^{7)}=(4\alpha)\chi(1\beta)+(4\alpha)\chi(2\alpha)+(4\alpha)\chi(3\alpha)+(4\alpha)\chi(CH_3)^{5\beta}+(4\alpha)\chi R-\{(4\beta)\chi(1\beta)+(4\beta)\chi(2\alpha)+(4\beta)\chi(3\alpha)+(4\beta)\chi(CH_3)^{5\beta}+(4\beta)\chi R\}=0.0-0.5+45.4+37.9+(4\alpha)\chi R-\{-0.6+7.1+0.6-37.6+(4\beta)\chi R\}^{8)}=113.3+(4\alpha)\chi R-(4\beta)\chi R=43.8^{9)}$$

The corresponding observed value in given by: $\{[M]_D^{20}(W)$ of β-D-allomethylose$\}$ minus $\{[M]_D^{20}(W)$ of β-D-gulomethylose$\}$. Therefore, if the $[M]_D^{20}(W)$ of β-D-allomethylose is x, the observed value of Yo. Diff. <β-D-allomethylose − β-D-gulomethylose> is $(x-(-69.4))$. This observed value should be equal to the above calculated $[\mu]_{D\,obs}^{20}$.
Therefore,

$$x-(-69.4)\equiv 43.8$$
$$\therefore \quad x=-25.6$$

This expected value of $[M]_D^{20}(W)$ of β-D-allomethylose, −25.6, is compatible with Micheel's data already mentioned. This fact may indicate the suitability of the PM-method in this case.

Some Observations on the Calcination Process of Precipitated Magnesium Hydroxide

By Tatsuo SAITO and Yoshihide KOTERA

(Received November 22, 1962)

It has previously been reported[1] that the particle size of magnesium oxide crystals prepared by the thermal decomposition of pure precipitated magnesium hydroxide and of native brucite increases with the calcination temperature and the duration of heating at a fixed temperature according to the equation: $d=Kt^n \exp(-E/RT)$, where d is the average crystal diameter determined from the broadening of the X-ray diffraction line, t is time, E is the activation energy, R is the gas constant, T is the absolute temperature, and K and n are constants. The present paper presents microscopic and atomic observations on the calcination process of precipitated magnesium hydroxide.

Experimental

The materials used were the same as those described in a previous paper[1]. Their NMR spectra were obtained by means of a Varian DP 60 spectrometer equipped with an RF unit of 40 Mc., the modulation frequency and width on operation being 40 c. p. s. and 1.1 gauss respectively. The electron microscopic photographs were taken by means of a Nippon Denshi electron microscope TEM-5G.

Experimental Results and Discussion

NMR spectra were obtained for samples which had been dehydrated in a vacuum from precipitated magnesium hydroxide and brucite for 3 hr. at 100, 200, 280, 300, 310, 330, 400 and 500°C. The results are shown in Fig. 1, where the (a)'s are the spectra of precipitated magnesium hydroxide and the (b)'s, those of brucite. It may be seen in Fig. 1 that there is a great difference between (a) and (b) below 280°C. The spectra of precipitated magnesium hydroxide are rather complex, having the central peak, while those of brucite have the typical two-proton shape. Figure 2 shows the variations in line width of the NMR spectra with the change in calcination temperature. The decrease in line width began at a lower temperature (at about 200°C) for precipitated magnesium hydroxide than for

brucite. To clarify the effect of water vapor on dehydrated samples, these samples were prepared from brucite by means of calcination in a vacuum for 3 hr. at 200, 300, 330, 360, 400 and 500°C, and then reacted with water vapor by succesive exposure to an atmosphere saturated with this vapor at room temperature. After the exposure, rehydrated samples were evacuated at room temperature for 12 hr. in order to remove any excess adsorbed water. In Fig. 3 NMR spectra are shown for dehydrated (a) and rehydrated (b) samples. The central peaks seen in Fig. 3 (b) may be a result of the presence of a trace of movable water adsorbed by the samples and not re-

1) Y. Kotera, T. Saito and M. Terada, This Bulletin, 36, 195 (1963).

moved by evacuating the samples at room temperature. It was possible to remove it, however, by heating the samples to 110°C and by then evacuating them at this temperature. It is interesting that the spectra of (b) are similar to those of precipitated magnesium hydroxide (Fig. 1 (a)).

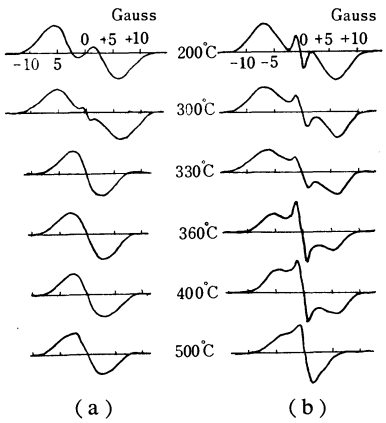

Fig. 3. NMR spectra of proton in the thermally dehydrated products of brucite in vacuo and their rehydrated products.
(a) Samples of dehydration series
(b) Samples of rehydration series

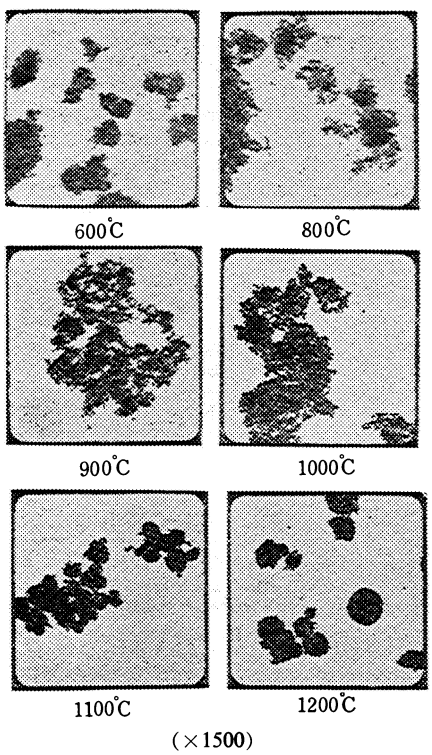

Fig. 4. Electron micrographs of MgO prepared from precipitated $Mg(OH)_2$.

The samples for the electron micrograph were prepared by the calcination of precipitated magnesium hydroxide at 600, 700, 800, 900, 1000, 1100 and 1200°C for durations ranging from 30 min. to 24 hr. The duration had a smaller effect upon the crystal size and the crystal form than the temperature. The effect of the calcination temperature upon the crystal figure is shown in Fig. 4, the rate of magnification being ×1500. From Fig. 4 it may be seen how crystals aggregate with each other until the temperature of 900°C is reached and how they grow to sphere-like particles, the particle size being about 0.1, 1 and 3 μ for the products at 1000, 1100 and 1200°C respectively.

From the results obtained it may be concluded that the precipitated magnesium hydroxide holds the movable water in the interstices between crystal lattice layers or between fine particles and that the structure water is removed only partially from the precipitated magnesium hydroxide by calcination below 280°C. It may also be concluded that the rehydration process is not the reverse reaction of dehydration but proceeds according to the thermal history of the samples. Such a tendency was seen in our experiment, where the water contents of the samples rehydrated by saturated water vapor were measured gravimetrically with the change of storage time; it has also been reported in adsorption experiments carried out for magnesium oxide[2]. The crystal growth of magnesium oxide shown in Fig. 4 would support the conclusion of the preceding paper[1]. A detalied study of these and other aspects will be published elsewhere in due course.

The authors are indebted to Dr. Matsuo Terada for his helpful discussions.

New Addition Reactions. V. Dimerization of Diketene

By Ryohei ODA, Shunichi TAKASHIMA and Masaya OKANO

(Received December 8, 1962)

It is well known that diketene easily dimerizes to give dehydroacetic acid in the presence of a basic catalyst such as sodium ethoxide, sodium phenolate, triethylamine, or pyridine[1]. We now wish to report the formation of two isomeric diketene dimers by the use of aluminum tribromide as a catalyst. This result is in contrast to other Lewis acid-catalyzed reactions, where polymerizations of diketene to a polyketone[2] (by boron trifluoride and aluminum trichloride) or a polyester[3] (by mercuric chloride) were achieved.

When diketene was treated with 5~10 mol. % of aluminum tribromide in ethylene dichloride at 10~20°C for about thirty hours, a mixture of two dimers, 2,6-dimethyl-γ-pyrone-3-carboxylic acid (I) and dehydroacetic acid (II), was obtained in a fair yield without any formation of a polymeric byproduct. Compound I was separated from II by fractional crystallization using a ligroin-chloroform mixture, and their yields were 20 and 35% respectively. Both structures were confirmed by mixed melting point determinations with respective authentic samples. Here, the authentic material of I was prepared from II by the method of Feist[4]. It is interesting to note that the exclusive formation of II was observed (in ca. 20~25% yields) when chloroform or carbon disulfide was used as a solvent, but no plausible explanation for this solvent effect can be offered.

Collie and Hilditch[5] reported that II could be converted to I in hot 85% sulfuric acid. However, when II was treated with aluminum tribromide in cold ethylene dichloride, no isomeric I was found, rather a small amount of an unidentified product (m. p. 230°C) resulted. Therefore, both dimers would be directly produced from diketene as shown in the following scheme. The formation of the anion III (or its protonated form) as a common intermediate seems probable in view of the fact that, in the presence of aluminum trichloride, a similar acylation of benzene with diketene has been achieved with ease[1a].

Experimental

Dimerization of Diketene.—To a stirred mixture of 30 g. (0.11 mol.) of aluminum tribromide and 300 ml. of dry ethylene dichloride, 100 g. (1.20 mol.) of diketene was added dropwise at the rate of 30 g./hr. The temperature was maintained below 10°C by means of an ice-bath. On the completion of the addition, the mixture was held at that temperature for 5 hr., and allowed to stand at room temperature for additional ca. 20 hr. (until the odor of diketene almost disappeared). Then 250~300 ml. of ca. 5 N hydrochloric acid was gradually added to the reaction mixture to destroy the catalyst. The organic layer separated was washed with water, dried over anhydrous sodium sulfate, and the solvent was removed in vacuo. The residue which solidified on cooling was washed with cold ethanol, dried, and weighed 62 g. By recrystallization from ca. 500 ml. of ligroin-chloroform (3 : 2), 20 g. (20%) of light-brown crystals separated. Concentration of the

filtrate gave 35 g. (35%) of other crystals. The first compound, after two recrystallizations from chloroform or ethanol, showed m. p. 96~98°C. Based on its analytical data, spectral (infrared and ultraviolet) data and chemical reactivities (neutralization with aqueous alkaline, decarboxylation, reaction with amine etc.), formula I was proposed for this compound. The structure was further confirmed by a mixed melting point determination with an authentic material, which was prepared from II, by chlorination with phosphorus pentachloride, and by treatment with concentrated sulfuric acid[4]. The second substance melted at 108~109°C after recrystallization from aqueous ethanol. This compound showed an infrared spectrum identical with that of authentic II, and no mixed melting point depression was observed.

The authors wish to thank Mr. Masahiko Miyanoki for his helpful and stimulating discussions, and Dainippon Celluloid Co., Ltd., for the gift of diketene.

The Quantitative Determinations of High-boiling Divalent Organo Sulfur Compounds by Copper —Determinations of Divalent Sulfur Compounds Formed in the Reaction between Benzene and Sulfur—*

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received December 27, 1962)

Determinations of aromatic mercaptans, sulfides and disulfides dissolved in hydrocarbon are of considerable importance both in industrial and fundamental investigations. Separation of these high-boiling aromatic sulfur compounds into individual components[1,2] is usually difficult because of the similar chemical behaviors toward many reagents. Especially analysis is more difficult when sulfur is present in samples that are to be distilled.

Heavy metals, such as copper, silver and mercury[3-6], are known to form complexes with divalent sulfur compounds and could be used for the analysis of these sulfur compounds. Such a procedure would have an advantage of great rapidity and simplicity in handling at room temperature over other methods. In this investigation, we have chosen metallic copper and studied in detail the behaviors of copper metal toward various divalent sulfur groups and the scope of application of this procedure for the analysis of various divalent sulfur compounds.

Preparation of spongy active copper powder has been reported by Blumer[7]. Actually, we found that we could make two kinds of copper powders, i. e., red-brown and black copper powders depending upon two different procedures we used. These two different copper powders showed different affinities toward various divalent sulfur compounds. Therefore, these different affinities could be utilized for the separation of divalent sulfur compounds. Divalent sulfur compounds used for this work were benzenethiol, diphenyl sulfide, diphenyl disulfide and thianthrene, which are considered to be present in the products mixture of the reaction between benzene and sulfur. Our results indicate that elemental sulfur and benzenethiol can be eliminated from benzene solution of divalent sulfur compounds by precipitation with red-copper, whereas diphenyl sulfide, disulfide, and thianthrene remained in the solution. When the remaining solution was treated with black copper, the disulfide was found to be eliminated leaving other components in the solution.

Experimental

Preparation of Spongy Active Copper Powder. — *Red-brown Copper.*—Copper sulfate, 45 g., was dissolved into 500 ml. of distilled water containing 50 ml. of 2 N hydrochloric acid and slowly stirred. Fifteen grams of thick slurry zinc was added to this solution at once. Stirring was continued until copper which precipitate turns from black to red-brown color. This copper was washed with distilled water, which was replaced with acetone and then with ether. Red-brown copper was kept in vacuum in dried condition. Completely dried copper

powder are quite stable in air. But in the presence of even a trace amount of water, copper reacts with oxygen and carbon dioxide in air to form black copper oxide and green $CuCO_3Cu(OH)_2$.

Black Copper.—When about 20 g. of zinc was added to the copper sulfate solution at several time intervals and the mixture was continued to stir, black colored copper precipitated. It was washed with distilled water and was kept in cold.

Preparation of Copper Column.—In this work, a column with bed volume of 20 ml. of copper powder in a glass tube having the diameter of 2 cm. and length of 25 cm. was used. The size of the column could be adjusted depending on the amounts of sulfur compounds. The copper column was soaked with benzene before a benzene solution containing sulfur compounds were passed through.

Preparation of Standard Sulfur Compounds.—Benzenethiol was purchased from Maruwaka Kagaku, Osaka, and diphenyl sulfide was K and K Lab. Inc., Long Island, N. Y., respectively, and both were used after careful distillations. Diphenyl disulfide was prepared by oxidizing benzenethiol with hydrogen peroxide and recrystallized from ethanol.

Results

The divalent sulfur compounds in benzene were characterized by measuring the intensities of ultraviolet absorption at 280 mμ against benzene blank. Benzenethiol, diphenyl disulfide, diphenyl sulfide, thianthrene, thiophene and elemental sulfur, all have the absorption at around 280 mμ. At this absorption spectra, Beer's law was obeyed at concentration around 5×10^{-5} mol./l. for diphenyl disulfide and thianthrene, 2×10^{-5} mol./l. for diphenyl sulfide, 2×10^{-4} mol./l. for benzenethiol and 0.2 mol./l. for thiophene. Molar extinction coefficients of these compounds at 280 mμ was shown in Table I.

Table I. Molar extinction coefficients of organo sulfur compounds

Compound	Molar extinction coefficient
Benzenethiol	593
Diphenyl disulfide	2500
Diphenyl sulfide	5700
Thianthrene	2400
Thiophene	0.79

Benzene solution containing benzenethiol or diphenyl disulfide was slowly passed through the red-brown copper column. By this procedure, benzenethiol was removed as can be observed from Table II, but diphenyl disulfide was not effected at room temperature. Benzenethiol apparently reacted with copper to form cuprous phenyl mercaptide, which has yellow

$$C_6H_5SH+Cu \rightarrow Cu_2(C_6H_5S)_2$$

brown color and is not soluble in benzene, water, dilute hydrochloric acid or in ammonia. These chemical properties of this compound suggest a formation of cuprous mercaptide[8].

Table II. Removal of benzenethiol from benzene

Initial amount of thiol mM	Residual thiol in elute mM
0.80	0.09
1.06	0.14
2.11	0.15

Meanwhile diphenyl disulfide did not form any compound with copper in this condition. Therefore, when both the mercaptan and the disulfide are present in the solution, at first the total absorbancy of the solution at 280 mμ was measured, and then the solution was passed through the red-brown copper column and the absorbancy of the filtrate was measured again. The absorbancy of the filtrate corresponds to the amount of the disulfide. The amount of benzenethiol can be calculated by subtracting the absorbancy of the disulfide from the total absorbancy of the original solution at 280 mμ. Table III shows their analytical data.

Table III. Determination of benzenethiol and diphenyl disulfide in benzene

1.34	0.14	1.22	0.16

Detection of the disulfide and the sulfide in the presence of elemental sulfur in benzene solution was also tried by the same procedure. Elemental sulfur often presented in these organic sulfur compounds is a serious hazzard in the analysis of these sulfur compounds. To remove elemental sulfur from these divalent sulfur compounds, red-brown copper column was used. Elemental sulfur, the disulfide and the sulfide were dissolved in benzene and this solution was passed through the red-brown copper column. By this procedure only elemental sulfur was removed from the original solution.

In order to determine the amount of the sulfide, the filtrate solution was passed once

more through the black copper column. By this procedure the disulfide was removed, and the filtrate solution contained only the sulfide. The amount of each sulfur compound was determined by ultraviolet absorption at 280 mμ. Analytical results for the determination of their sulfur compounds were shown in Table IV. Agreement was quite satisfactory. The mechanism of the separation of the disulfide by black copper and the disulfide may produce a similar compound which was obtained by the reaction between the mercaptan and red-brown copper.

A benzene solution containing thianthrene was treated through these copper columns to see how these sulfur compounds behave toward active copper. We found that thianthrene was a little effected by these copper columns. Therefore, active copper is not applicable for quantitative separation of diphenyl disulfide and thianthrene. They were determined by the reaction with concentrate sulfuric acid[9].

These results indicated that the affinities of these divalent sulfur compounds toward active copper depends on the nature of sulfur group. Experimentally determined order of affinities of these sulfur compounds to copper are elemental sulfur>benzenethiol>diphenyl disulfide>thianthrene>diphenyl sulfide.

SHORT COMMUNICATIONS

Photoconductivity in an Organic Liquid Solution

By Mizuka SANO and Hideo AKAMATU

(Received December 17, 1962)

Semi- and photo-conductivity in organic substances have been studied for several years, but most of the experiments have been concerned with the crystalline state[1]. Recently, however, the electronic conduction has been investigated in liquid benzene[2], pyrene[3] and *n*-hexane[4]. The electronic mobility in the liquid was samller by three orders of magnitude than that in the solid[3]. However, the conductivity itself rose sharply at the melting point[5,6]. The rise in the conductivity could not be attributed to the increase in the mobility at the melting point, but it might be due to the enormous increase in the number of charge carriers. In the present experiment the photoconductivity of solutions was investigated preliminarily in relation to the intermolecular energy transfer.

Measurement was made with benzene solutions of pyranthrene (3.3×10^{-5} mol./l.), tetracene (2.0×10^{-5} mol./l.), and pyrene (1.3×10^{-1} mol./l.), all of which show intense absorption spectra in the range of 370~500 mμ. A photocell was made of Teflon, with two parallel Nesa-glass electrodes (1.3 cm^2 in area), forming a sandwich-type cell. The distance between the electrodes was fixed at 3 mm. Through one of the electrodes the solution was illuminated by monochromatized light. The currents were measured by a d.c. method.

The dark currents through the solutions, as well as the benzene, followed Ohm's law below the electric field of 10^2 V./cm. The specific conductivity of benzene was $6.4\times10^{-14}\Omega^{-1}\cdot cm^{-1}$, judging from the observed current in this ohmic range. Beyond the electric field of the above value, the current increased non-

linearly and showed a tendency to saturate in accordance with an applied voltage. Similar behavior was found in the photocurrent in the solutions, as is shown in Fig. 1.

Benzene itself did not show any response to illumination in the visible spectral region. However, when benzene dissolved pyranthrene, for instance, the solution was found to be

photosensitive in the spectral region. As is shown in Fig. 2, the benzene solution of pyranthrene exhibited a remarkable photocurrent in the spectral region between 400 and 500 mμ. The spectral response of photocurrent is located in the absorption region of the pyranthrene molecule. Therefore, the result indicates the contribution of the solute molecules in the first singlet excited state to the photoconduction. The photocurrent depended linearly on the light intensity below 3×10^{17} photons/sec. cm^2. The linearity was independent of the wavelength of the illumination and of the applied voltage, even if the measurement was made outside the ohmic range.

It is uncertain whether the solute molecules facilitate an injection of charge carriers from the electrode, or whether charge carriers are produced by the interaction between the excited solute molecules and the solvent. The presence of solute molecules at the surface of electrode may, however, reduce the work of emitting electrons from the elecrode. This reduction of the work function is probably induced by the excited molecules. It must also be considered that the conducting state of the solvent is located below the first singlet excited state of the solute, and that the excitation energy is transferred from the excited solute molecule to the solvent by interaction, generating the charge carriers. These different patterns of behavior could not, however, be separated in this preliminary experiment.

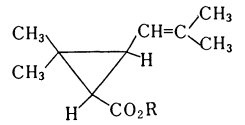
The Stereoselective Synthesis of trans-Chrysanthemum Monocarboxylic Acid

By Takeshi MATSUMOTO, Akira NAGAI and Yutaro TAKAHASHI

(Received December 28, 1962)

Chrysanthemum monocarboxylic acid ethyl ester (I) has been synthesized from ethyl diazoacetate and 2, 5-dimethyl-2, 4-hexadiene[1]. However, the product was a mixture of cis and trans esters in a ratio of about 1 : 1[2].



I R=C_2H_5
II R=*t*-C_4H_9
III R=H

The present authors wish to report a stereoselective formation of *trans*-chrysanthemum monocarboxylic acid *t*-butyl ester (II) achieved by treatment of the diene with *t*-butyl diazoacetate.

t-Butyl diazoacetate (1.42 g., 0.010 mol.)[3] was added slowly to a mixture of the diene 2.5 g., 0.022 mol.) and copper powder (0.05 g.) at 120~130°C. The reaction product was distilled to yield 0.95 g. of II (b. p., 120~125°C/14 mmHg; Found: C, 74.82; H, 10.81. Calcd. for $C_{14}H_{24}O_2$: C, 74.95; H, 10.78%; ν_{max} 1720 cm^{-1}; δ (c. p. s.)'s are shown in Table I), the infrared spectrum of which was identical with that of the ester prepared form the silver salt of authentic trans acid III and *t*-butyl iodide. Complete hydrolysis of the ester II was effected in a 1 N hydrochloric acid solution at 100°C, affording a single crystalline acid whose infrared spectrum and m. p. (53~54°C) were identical with those of *trans*-III.

Data of the NMR spectra of I, II and III are summarized in Table I. A quantitative analysis of the cis and trans ratio is especially possible by drawing a comparison between the intensity of the signals due to the olefin proton of each isomer. The fact that the synthetic II exhibited only one detectable

The Importance of NMR in Determining Structure and Electrical Effects in Substituted Ferrocenes[1)]

By Robert A. BENKESER, Yoichiro NAGAI and John HOOZ

(Received December 24, 1962)

The determination of the structure of polysubstituted ferrocenes has proved to be a vexing problem. Classic methods of structure proof based upon unequivocal syntheses or degradations are not often feasible in the case of substituted ferrocenes. The ferrocene moiety is quite stable, and, while degradation of the molecule is possible, generally rather drastic conditions must be employed[2)]. The result is usually a mixture of products which contains substituted cyclopentadienes and cyclopentanes, the structures of which are also frequently in doubt. Likewise the unequivocal synthesis

of a polysubstituted ferrocene is not easily accomplished. Isomeric mixtures are almost invariably encountered which are difficult and tedious to separate[3].

As a result of the synthetic problems associated with structure proofs in this field, considerable reliance has been placed upon infrared spectroscopy[4] for determining the structure of substituted ferrocenes. While infrared is extremely useful in determining the structure of certain ferrocene compounds, there is considerable need for a more unequivocal and universal structural probe. It is the purpose of this paper to report that NMR spectroscopy will provide such a probe in many instances.

Table I lists the chemical shifts and relative intensities for the ring protons of seventeen substituted ferrocene compounds. It is immediately apparent from this table that the structure of the mono-, as well as the disubstituted ferrocenes (1, 1'- as well as 1, 2- and 1, 3-) are clearly pinpointed by the chemical shifts of the ring protons. In addition to establishing the ferrocene structures, the values in Table I can be used also as a measure of the electrical effects of substituent groups at various positions in the ferrocene ring system, a topic of considerable current interest[5].

TABLE II. CHEMICAL SHIFTS FOR α-PROTONS[1] OF ALKYL GROUPS ON FERROCENE RINGS[2-4]

Substituent	α-H(Me)	α-H(Et)	α-H(*i*-Pr)
R(alkyl)	8.04	7.71	7.41
1-Ac-1'-R	8.09	7.73	7.43
1-Ac-2-R	7.67	7.28	6.59
1-Ac-3-R	7.97	7.62	7.34

1) The α-protons referred to in this Table are those located on the carbon atom of the alkyl group which is attached to the ferrocene ring.
2) The data listed are "tau" values using tetramethylsilane as an internal standard. A Varian A-60 analytical spectrometer was used for all the measurements.
3) Ac in the Table refers to the acetyl group.
4) The spectra of all the compounds listed in this table as well as in Table I were obtained in a solvent of carbon tetrachloride.

The structural assignments for the acetylalkylferrocenes listed in Table I are further supported by the trend of the chemical shifts for the α-protons of the various alkyl groups attached to the ferrocene ring (see Table II).

Thus the α-protons in 1-acetyl-1'-alkylferrocenes are at higher field than the 1, 3-isomers. The latter, in turn, are at higher field than the 1, 2-isomers. This trend can be rationalized in terms of the shielding effect on the α-protons induced by their proximity to the electron withdrawing acetyl group.

Palladium(II)- and Platinum(II)-complexes of Schiff Bases Derived from Salicylaldehyde and Alkylamines

By Shoichiro YAMADA, Hiroaki NISHIKAWA and Kayo YAMASAKI*

(Received February 7, 1963)

Previous studies of metallic complexes with Schiff bases of a type shown in Fig 1 have

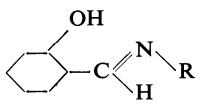

Fig. 1. *N*-Alkylsalicylideneimine.

revealed that it depends much upon the nature of the metal ion as well as upon that of the ligand whether the quadri-co-ordinate complex of a transition element takes a squareplanar configuration or a configuration distorted from it. Thus, the stability of the tetrahedral co-ordination around the metal ion, as compared with that of the square-planar one, is higher for cobalt(II)[1], a little lower for nickel(II)[2], and much lower for copper(II)[3].

3) S. Yamada and H. Nishikawa, unpublished.

A similar study has now been extended to palladium(II) and platinum(II) in order to examine the stereochemistry of these compounds and to explore the possibility of obtaining complexes of palladium(II) and platinum(II) with a configuration distorted from the square-plane, a configuration which is quite rare for these metal ions. For example, in the complexes with R=*t*-butyl the square-planar configuration of the complex is impossible because of serious steric hindrance, so that these complexes, if prepared at all, are expected to have a configuration distorted from the square-plane. Platinum(II) complexes with neither *N-n-* nor isoalkyl-salicylideneimines have been reported previously, nor has the preparation of the corresponding *N*-isopropyl or *t*-butyl derivative been described, although *N-n*-alkylsalicylideneimines of palladium(II) were reported[4]. The present communication reports on the successful preparation of palladium(II)- and platinum(II)-complexes of these Schiff bases, including those complexes with a configuration distorted from the square-plane.

The platinum(II)-complexes were prepared by the following two methods: (1) To an aqueous solution of potassium tetrachloroplatinate(II) were added solutions of potassium hydroxide in water, salicylaldehyde in ethanol, and one of the alkylamines in ethanol, the molar ratio being 1 : 2 : 2 : 2. After the solution had been left at room temperature for a few days, a black mass containing a small orange-colored part was precipitated. By treating the mass with a suitable solvent, such as chloroform, benzene, ethanol and ether, the platinum(II)-complex with the Schiff base was obtained as orange crystals. (2) To a solution of [Pt(*salal*)$_2$] in ethanol was added a solution of an alkylamine in ethanol in the molar ratio of 1 : 4; the solution was then warmed gently[5]. In a few hours, the platinum(II)-complex with the Schiff base separated out.

The second method was adopted in the preparation of the *t*-butyl and the isopropyl derivative. The platinum(II)-compounds with R=methyl, ethyl, *n*-propyl and *n*-butyl were obtained in either way, while the palladium-complexes with R=methyl, ethyl, *n*- and isopropyl, and *n*- and *t*-butyl were prepaerd by the first method. The elemental analyses for carbon, hydrogen and nitrogen agree with the calculated values for the bis(*N*-alkylsalicylideneimine) complexes.

Since palladium(II) and platinum(II) strongly demand the square-planar co-ordination, the configuration of $Pt(N)_2(O)_2$ or $Pd(N)_2(O)_2$ in the *n*-alkyl complexes is most likely to be planar. The co-ordination around the palladium(II) was reported to be trans-planar with the methyl derivative[6]. In general, the cis configuration is very difficult sterically with complexes of this series, and it is usually regarded as unlikely for the modification obtained under ordinary conditions.

When *t*-butyl groups are substituted for the *n*-alkyl groups in the complex, the square-planar co-ordination around the metal ion is completely prevented by the serious steric hindrance, so that the configuration around the metal ion is distorted from the plane. The ultraviolet spectra of the *t*-butyl complex of palladium(II) and platinum(II) differ significantly from the spectra of the corresponding *n*-alkyl complexes of the same central ion, whereas the spectra of the Schiff bases of the type examined in the present work are quite similar to one another both in the frequency of maxima and minima and in band intensity. This is in agreement with the conclusion based on the steric condition that the co-ordination around the palladium(II) or the platinum(II) in the *t*-butyl complex is distorted from the square-plane.

In the case of the isopropyl group, the steric hindrance seems to be considerable, but it may not be as serious as in the case of the *t*-butyl group. The present measurements indicate that the ultraviolet spectra of the isopropyl derivatives of palladium(II) and platinum(II) are nearly identical with the spectra of the corresponding compounds of the *n*-alkyl groups. This fact is taken as showing that the co-ordination around the palladium(II) or platinum(II) in the isopropyl derivative is similar to that of the corresponding complexes of the *n*-alkyl groups, which are most probably planar. In this connection, it is worth noting that bis(*N*-isopropylsalicylidene)-nickel(II)[2], cobalt(II)[1] and copper(II)[3] were found to be distorted from the square-planar co-ordination. The comparison clearly indicates that the stability of the square-planar co-ordination, as compared with that of the tetrahedral one, is higher for palladium(II) and platinum(II) than for cobalt(II), nickel(II) and copper(II).

The present measurements also indicate that the spectra of these complexes of palladium(II) and platinum(II) in pyridine show very little difference from the spectra of the same complexes in chloroform, ethanol or benzene.

4) L. Sacconi, M. Ciampolini, F. Maggio and G. Del Re, *J. Am. Chem. Soc.*, 82, 815 (1960).

5) The notation, *salal*, represents an anion derived when a molecule of salicylaldehyde loses a proton. The preparation of the complex will be reported shortly by the present authors.

6) B. Meuthen and M. V. Stackelberg, *Z. anorg. u. allgem. Chem.*, 305, 279 (1960).

This shows that the pyridine molecules are not co-ordinated with the palladium(II) or platinum(II), whereas it is well-known that the nickel(II) ions in all these complexes except the *t*-butyl complex[2] do take up pyridine molecules to form a sexa-co-ordinate complex. This is also in agreement with the current view that it is much more difficult for the palladium(II) and platinum(II) ions to take sexa-co-ordination than for the nickel(II) ions, for which sexa-co-ordination is quite common.

*The Partial Resolution of Racemic α-Alanine through the Cobalt(III) Complex of L-Aspartic Acid**

By Muraji SHIBATA, Yoshiho FUJITA, Miho NAITO and Kuniko HORI

(Received February 9, 1963)

Studies of the resolution of racemic organic acids and amine have been reported by Bailar and his co-workers[1-3]. As far as alanine is concerned, the percentages of resolutions attained through the L-tartratocopper(II) complex and copper(II) L-glutamate were 3.8 and 3.3 respectively[3]. Attempting to resolve the same racemic mixture by using a cobalt(III) complex of L-aspartic acid, we have succeeded in effecting a much higher resolution.

The reaction path which we adopted for the resolution was as follows:

$$[Co(CO_3)_3]^{-3} \xrightarrow{2\,asp} [Co(asp)_2]^- \xrightarrow{6\,ala} [Co(ala)_3]$$

where "asp" stands for an aspartate ion, and "ala" for an alaninate ion. The starting material, a green solution of potassium tricarbonatocobaltate(III), was prepared by our method[4]. An exactly equivalent amount of L-aspartic acid was introduced into the green solution, and the mixture was stirred in the presence of active charcoal at temperatures not exceeding 15°C. The color of the solution gradually changed to violet with the formation of the asparato-complex. A hundred per cent excess of racemic alanine was added to the above solution, and the resulting mixture was adjusted to pH 9.5~10 with potassium hydroxide and warmed to 30~40°C. When the stirring was continued, *cis-cis-tris*-alaninatocobalt(III), $[Co(ala)_3]\cdot H_2O$ separated out. This was filtered and washed thoroughly with hot water and then with ethanol and ether.

The dried *tris*-alaninatocobalt(III) was suspended in hot dilute aqueous ammonia, and hydrogen sulfide was passed into the suspension. After the removal of the cobalt sulfide by filtration with charcoal, the filtrate was concentrated to a small volume on a water-bath. The solution was once more treated with charcoal for purification, and then acetone was added to precipitate the alanine. A 5% solution of this alanine in 1N hydrochloric acid was prepared, and its optical rotation was measured. The percentage of resolution was calculated by dividing the measured specific rotation with the specific rotation of pure L-alanine, $[\alpha]_D = +14.47°$[5].

In the course of the above experiments, we have discovered the very interesting fact that the co-existence of the cellulose powder

intended for chromatography in the reaction system of $[Co(asp)_2]^-$ and racemic alaninate ion effectively increases the resolution of alanine. Some of the data for these experiments are given in Table I. In the absence of the cellulose powder, the resolution was about 13%, while in its presence a resolution over 30% was achieved. In the reaction system used here, the D-form of alanine was preferentially coordinated.

We are continuing our investigations in our attempt to find the conditions giving the highest yield of the alaninatocomplex and to discover some material more effective than the cellulose for a higher resolution.

An Explosive Synthesis of Titanium Carbide

By Yoshikazu HORIGUCHI and
Yōkan NOMURA

(Received February 9, 1963)

Titanium carbides were explosively synthesized from a mixture of titanium metal powder and carbon black by using the arrangement illustrated in Fig. 1. The eight grams of a stoichiometric mixture of titanium metal powder (Osaka Titanium Co., Ltd.) and acetylene black (Denki Kagaku Kogyo Kabushiki Kaisha) to be compacted were put in a mild steel container; this container was then sealed at its open end by a mild steel plug. The arrangement was completed by filling an annulus between the neck of the container and a plastic tube with about 65 g. of a high explosive, tetryl, and by setting up an electric detonator along a prolongation of the central axis of the container. Upon the detonation of the explosive charge, the original mixture, black in color, could be satisfactorily compacted into a grayish white, very hard, cylindrical shape. The X-ray diffraction pattern for the compact agreed well with that of titanium carbide. No additional lines could be observed.

In the same way, direct carburizations of aluminum and tungsten by carbon black have been achieved by the explosive compaction.

Studies of the Absorption Spectra of Azo Dyes and their Metal-complexes. I[*1]. *The Absorption Spectra of Phenylazo-acetoacetanilide and its Related Compounds*

By Yoshiharu YAGI

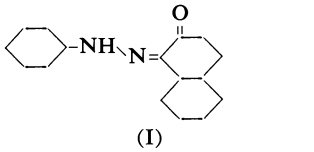
(Received June 12, 1962)

Although the recent development of neutral-dyeing metal-complex azo dyes has been remarkable[1], the chemical properties of the metal complexes of azo dyes, particularly of *o*, *o'*-disubstituted monoazo dyes, have not been fully investigated. It has, therefore, been considered important for the further progress of these complex dyes to study the structures of ligand azo dyes and their metal-complexes.

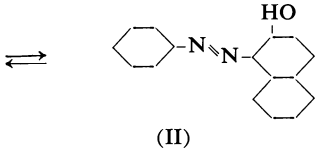
In this connection, the author tried to make clear the structure of phenolazoacetoacetanilides, which form yellow-dyeing metal-complexes. As the first step, the electronic and infrared absorption spectra of α-phenylazoacetoacetanilide[*2] and its related compounds were studied.

Results and Discussion

The Electronic Absorption Spectra of Phenylazoacetoacetanilide in Various Solvents.—It had long been studied whether *o*- and *p*-hydroxy azo compounds have the azo form or the hydrazone form[2]. For example, 1-phenylazo-2-naphthol in solution was found[3] to be in a



(I)



(II)

tautomeric equilibrium between azo- and quinonehydrazone-forms, as is shown in I and II.

An electronic absorption spectrum of phenylazoacetoacetanilide in *n*-hexane shows three bands in the region of 200~400 mμ (Fig. 1).

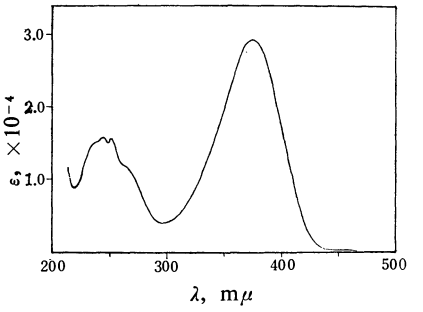


Fig. 1. Phenylazoacetoacetanilide in *n*-hexane.

These bands are referred to as A, B and C—D from the longer wavelength side. Band A is considered to arise from a transition involving electron migration along the whole conjugate system of the molecule. In Table I are shown the absorption spectra of this compound in various solvents. The absorption maxima of band A shift toward a shorter wavelength in the following order: pyridine>chloroform>acetic acid>*n*-hexane>standard solvent[*3]. The relatively small differences in λ_{max} suggest that the displacement of band A is due to the polarity change of the absorbing system caused by solute-solvent interaction; that is, it is due to the general solvent effect.

Burawoy[3] investigated the absorption spectra of 1-phenylazo-2-naphthol in the above-mentioned solvents and concluded that the tautomeric equilibrium of azo ⇌ quinonehydrazone depends upon the polarity of the solvent.

With respect to phenylazoacetoacetanilide, however, the locations of each absorption band in *n*-hexane and in the standard solvent almost coincide. This indicates that the compound is not in a tautomeric equilibrium but may

TABLE II. THE CARBONYL STRETCHING VIBRATIONS (cm^{-1})

Compound	Ketone	Ester	Amide I
a	1623(1633)*	—	1667(1665)
b	—	—	1652(1655)
c	—	1750(1757)	—
e	1620(1630)	1718(1720)	—
f	—	1653(1676) 1728(1733)	—
g	—	1675(1678) 1723(1733)	—
h	1649(1670)	—	—

Values in paraffin-oil and in CCl_4 (in parenthesis) were tabulated.

TABLE III. THE NH STRETCHING VIBRATIONS (cm^{-1})

Compound	Nujol mull	CCl_4
c	3250	3320
d	3240	3333
h	3310	3390
e	not detected	3200
f	3115	3210
g	3160	3195
i	3280	3370

Compounds, a—i, exhibit strong bands in the region of 1590~1600 cm^{-1} (in paraffin-oil) or 1585~1600 cm^{-1} (in a carbon tetrachloride solution). These are considered to be due to C=C skeletal in-plane vibrations of phenyl rings. Although it is generally known that the NH deformation vibration of the secondary amine shows a weak band in the 1550~1650 cm^{-1} region[4], compounds d and i have no band in this region. This suggests that bands due to the NH vibration of the hydrazone group do not appear at frequencies higher than 1600 cm^{-1}. In the region of 1640~1690 cm^{-1} also, the C=N stretching vibration may be expected to appear[5], but, as will be seen in d and i, this band seems to be too weak to detect. Consequently, the bands in the 1620~1760 cm^{-1} region in this study are ascribed to the carbonyl stretching vibration.

5) Ibid., p. 263.

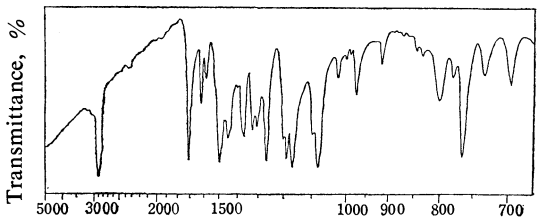

Fig. 2. Infrared spectrum of e (Nujol mull).

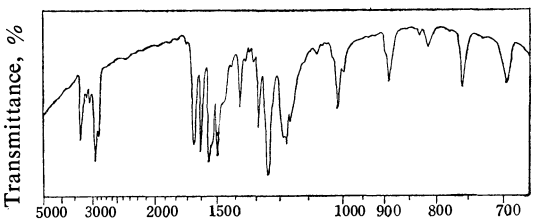

Fig. 3. Infrared spectrum of h (Nujol mull).

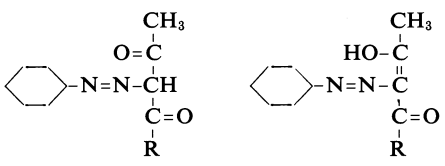
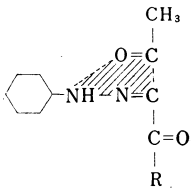
Solid 2-hydroxyazobenzene[6] and 3-methyl-1-phenyl-4-phenylazo-5-pyrazolone[7] were found to exhibit $\nu_{C=O}$ at 1610 and 1650 cm^{-1} respectively. The azo compounds in this study also exhibit the C=O absorption in the same region.

As to the acetyl derivatives in Table II, h shows $\nu_{C=O}$ at 1649 cm^{-1}, and a and e, at lower frequencies of about 1620 cm^{-1}. In these cases, a band at about 1665 cm^{-1} in the spectrum of a is assigned to the amide I band, while a strong absorption at 1720 cm^{-1} in the spectrum of e is attributed to the ester carbonyl. The derivatives of alkylmalonates, f and g, have two absorption bands in this region. It is evident that either of these two bands arises from the C=O stretchings of ester carbonyls.

The C=O stretching vibration of the acetyl derivative and that of one ester group in the alkylmalonate derivative are markedly lower in frequency than those of ordinary α,β-unsaturated carbonyl systems. This indicates that the compounds, a, e, f and g, form intramolecular hydrogen bonds in the solid state and in a non-polar solvent, as is shown in V.





(V)
(R=$-OC_2H_5$, -NHPh, etc.)

In Table III are illustrated the NH stretching vibrations of the hydrazone group belonging to the group of compounds having no acid amide group. Compounds i and d have a sharp absorption at 3370 and 3333 cm^{-1} respectively. These agree with Ramirez and Kirby's value reported[8] for the NH stretching vibrations of hydrazone groups.

The compounds in Table III are classified into two groups, one showing relatively broad bands in the 3195~3210 cm^{-1} region, such as e, f and g (Fig. 4) and the other having sharp bands at higher frequencies in the 3320~3390 cm^{-1} region such as c, d and i. The former group consists of the compounds which have been deduced from the $\nu_{C=O}$ values to have an intramolecular hydrogen bond. It is considered that the ν_{NH} and $\nu_{C=O}$ markedly decrease, owing to the chelate ring formation between a carbonyl oxygen and a hydrazone hydrogen atom. Randall[9] investigated the infrared absorption bands of e and found the ketone and ester carbonyls (1706 cm^{-1}), the azo group (1626 cm^{-1}) and the C=C stretching (1511 cm^{-1}) in an enolized form, as is shown in IV. However, α,α-dimethyl ethylacetoacetate, which is not enolizable, was reported to have a ketonic carbonyl band (1718 cm^{-1}) and an ester carbonyl band (1742 cm^{-1})[10]. The azo

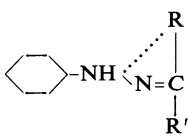
S, Standard solvent; H, *n*-Hexane

group usually does not exhibit distinct absorption[11]. Further, the author was unable to detect the OH stretching vibration in this study. Consequently, it can not be considered that e has such a structure as III or IV.

In the latter group, the ν_{NH} values do not differ from that of i. It is conceivable that the intramolecular hydrogen bond between the cyano nitrogen and the hydrazone hydrogen atom is almost negligible or does not exist at all. This is supported by the fact that the proton-accepting power of the cyano group is generally weak[12].

The Electronic Absorption Spectra of Phenylazoacetoacetanilide and its Related Compounds. —The electronic absorption spectra of the series of compounds in *n*-hexane and the standard solvent are tabulated in Table IV. The three groups of characteristic bands in the 200~400 mμ region are abbreviated as A, B and C—D.



(R, R′ : Substituents)

(VI)

Generally a >C=N linkage was reported[13] to have properties spectrally analogous to an ethylenic linkage. Hence, an electronic effect of R or R′ in VI will be transmitted to the whole conjugate system through the π-p conjugation between a nitrogen atom and a phenyl nucleus in Ph–NH–N=, exerting a considerable influence upon band A. As will be seen in Table IV, every substituent, such as $-COCH_3$, $-CONH_2$, etc., when introduced as R or R′, has a bathochromic effect on the bands A.

The intensity and the maximum wavelength of band A in the spectra of a are the most notable in Table IV, and a comparison of b with phenylazocyanoacetamide (j) indicates that the introduction of a phenyl ring into the carboxylic acid amide group causes a marked red-shift of band A. This suggests that the π-p conjugation at a carboxylic acid anilide group contributes much to the transition along the whole conjugate system.

In the compounds a, e, f and g, the absorption maxima of the bands A are almost equal in *n*-hexane and in the standard solvent. On the other hand, in the compounds b, c, d and h, the bands A in *n*-hexane are at appreciably shorter wavelengths. The former are the compounds having the internal hydrogen bond in the solid state and in non-polar solvents.

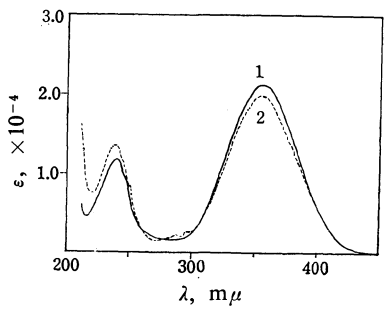


Fig. 5. Absorption spectra of e in the standard solvent (1) and in *n*-hexane (2).

12) S. Seki et al., "Hydrogen-bond" (Suiso-Ketsugo), Iwanami-Shoten, Tokyo (1956), p. 24.
13) E. A. Braude and E. R. H. Jones *J. Chem. Soc.*, **1945**, 498; **1946**, 948; **1949**, 1898; **1952**, 1068.

It is considered that the six-membered chelate ring in *n*-hexane, as shown in V, stabilizes the excited state and decreases the electronic transition energy[3,8,14].

In the ultraviolet region, the bands B are usually situated in the region of 270~300 mμ, and their intensities are generally small. In some cases, these consist of three peaks in *n*-hexane, but they are apt to disappear in polar solvents. Undoubtedly, the bands B are thought to originate from the carbonyl group, since d and i exhibit no absorption in this region. The true molar extinction coefficients of the B bands seem rather small (10^2~10^3), taking into account the fact that these are superposed by the slopes of the bands A or C-D. These B bands are tentatively ascribed to the $n \rightarrow \pi$ transition (R-band)[15] of carbonyl. However, the band B of a alone absorbs at a shorter wavelength and has a relatively high intensity. This may be a conjugation band (K-band)[16] of another origin.

The bands C-D are located in the 230~250 mμ region. Some of them show fine structures. It is not possible, however, to make a full examination of these bands on the basis of the present knowledge alone.

Experimental

Preparation of Azo Compounds.—*Phenylazoacetoacetanilide (a).*—This was prepared from diazotized aniline and acetoacetanilide. Recrystallization from ethanol gave green-yellow needles; m. p., 107~108°C. (reported 107~108°C)[17].

Phenylazocyanoacetanilide (b).—Cyanoacetanilide was prepared according to the method described in the literature[18]. Compound b was obtained by the treatment of cyanoacetanilide with diazotized aniline. Recrystallization from ethanol gave rectangular yellow plates; m. p., 199~200°C.

Found: C, 68.35; H, 4.18; N, 21.01. Calcd. for $C_{15}H_{12}ON_4$: C, 68.18; H, 4.58; N, 21.19%.

Phenylazocyanoacetic Acid Ethylester (c).—An aqueous alcoholic solution containing ethyl cyanoacetate and an excess of sodium acetate was treated with diazotized aniline to yield yellow needles. This was recrystallized from ligroin, giving yellow needles with an m. p. of 126°C (reported 125°C)[19].

Phenylazomalonic Dinitrile (d).—This was obtained in the same manner as c and was recrystallized from ethanol, giving orange-yellow plates; m. p., 145°C (decomp.) (reported 146~147°C (decomp.))[19].

Phenylazoacetoacetic Acid Ethylester (e).—This was obtained in the manner described in c. Recrystallization from ligroin gave pale-yellow rectangular plates; m. p., 82~83.5°C (reported 82~83°C)[20].

Phenylazomalonic Acid Dimethylester (f).—This was obtained in the same manner as c. Recrystallization from ligroin gave yellow prisms; m. p., 62~63°C (reported 63.5°C)[19].

p-Chlorophenylazomalonic Acid Diethylester (g).—This was obtained in a manner similar to that above. Recrystallization from ligroin yielded pale-yellow rectangular plates; m. p., 59~61°C.

Found: C, 52.39; H, 4.85; N, 9.09. Calcd. for $C_{13}H_{15}O_4N_2Cl$: C, 52.36; H, 5.06; N, 9.37%.

α-Ketopropionaldehydephenylhydrazone (h).—Acetoacetic acid prepared by the method of Schechter et al.[21] was treated with diazotized aniline. An orange precipitate was recrystallized from benzene, affording pale-yellow rectangular plates; m.p., 151~152°C (reported 149~150°C)[22].

Propionaldehyde-p-nitrophenylhydrazone (i).—This was prepared by the treatment of *p*-nitrophenylhydrazine with propionaldehyde in ethanol. Recrystallization from 50% ethanol gave orange-yellow needles; m. p., 124°C (reported 124°C)[23].

Phenylazocyanoacetamide (j)—Cyanoacetamide was prepared by the method described in the literature[24]. Compound j was obtained in the same manner as c and was recrystallized from ethylacetoacetate, giving rectangular yellow plates; m. p., 249~251°C (decomp.).

Found: C, 57.88; H, 4.23; N, 29.46. Calcd. for $C_9H_8ON_4$: C, 57.44; H, 4.30; N, 29.76%.

Measurements of the Spectra.—The infrared spectra were measured by two infrared spectrophotometers, a Perkin-Elmer model 21 and a Shimadzu model IR-27, equipped with NaCl optics. In the case of the solution measurements, the spectra were determined at concentration of 10^{-3}~10^{-4} M.

Visible and ultraviolet absorptions were carried out using two recording spectrophotometers, a Beckman model DK-2 and a Shimadzu model RS-27. The concentration of samples was 2.5×10^{-5} M.

Summary

Phenylazoacetoacetanilide and its related compounds have the hydrazone structure. The phenylazoacetoacetic acid ethylester, for example, forms an intramolecular hydrogen bond between a ketone group and a hydrazone group in the solid state and in non-polar solvents.

The electronic absorption spectra exhibit three groups of bands—A, B and C-D. The effects upon the spectra of the intramolecular hydrogen bond and of the π-p conjugation at

Studies of the Absorption Spectra of Azo Dyes and their Metal-complexes. II. The Absorption Spectra of Phenolazoacetoacetamide and its Derivatives[*1]

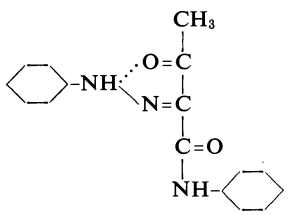
By Yoshiharu YAGI

(Received June 20, 1962)

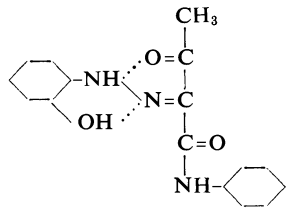
Phenolazoacetoacetamides[*2] can be used as yellow-dyeing metal-complex dyes and have valuable dyeing properties[1]. The relationships between the chemical structure and the absorption spectra of phenolazoacetoacetamides were investigated in this paper.

Results and Discussion

The Chemical Structure of Phenolazoacetoacetanilides and the Assignments of the A and C Bands.—It was concluded in the preceding paper[2] that phenylazoacetoacetanilide (I) and its related compounds have the hydrazone structure and from a hydrogen bond between a carbonyl oxygen and a hydrazone nitrogen atom in the solid state and in non-polar solvents.



(I)



(II)

The infrared spectra of phenylazoacetoacetanilide (I), its 2-hydroxy derivative (II) and 2-methoxy derivative in liquid paraffin are given in Table I. The C=O stretching vibrations of the three compounds are at lower frequencies than those of the strong amide I bands, indicating a marked decrease in frequency compared with ordinary α,β-unsaturated carbonyl systems[3]. Since these frequencies agree with those of phenylazoacetoacetanilide cited in the previous paper, the azo compounds in this paper are also considered to have the hydrazone form. The three compounds show a broad band in the 3000~3500 cm^{-1} region. It is difficult to investigate the exact nature of this band, owing to the superposition of other band systems. In the 2-hydroxy derivative, however, the band is very broad and intense, as is shown in Fig. 1. This band can possibly be attributed to the stretching vibration of the hydroxyl, which forms an intramolecular hydrogen bond

*1 Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

*2 The compounds in this study are named as azo compounds; α-(2-hydroxyphenylazo)-acetoacetanilide, for example, is abbreviated as phenolazoacetoacetanilide.

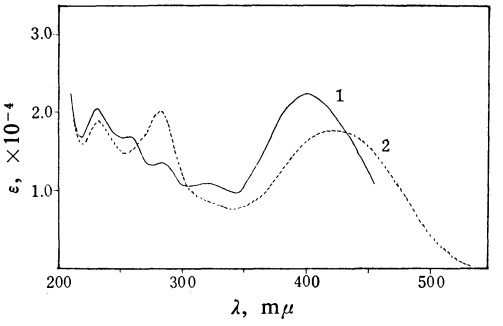

Fig. 2. Absorption spectra of III in anhydrous methanol (1) and 95% methanol (2).

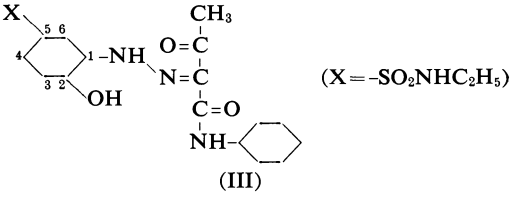
with a hydrazone nitrogen atom, as is shown in II.

The electronic absorption spectra of II in the 200~500 mμ region show four groups of bands, which will subsequently be referred to as A, B, C and D counting from the longer wavelength side. The absorption spectrum of 2-hydroxy-5-(*N*-ethylsulfamoyl)-phenylazoacetoacetanilide (III) in anhydrous methanol (Fig. 2) shows five bands: D, 232; C, 258 and 281: B, 320; A, 400 mμ. In 95% methanol, however, only four bands (D, 231; C, 282; B, 325 as an inflection; A, 426 mμ) are observed; the band at 258 mμ disappears.



The latter spectrum resembles that in an aqueous 0.01 N sodium hydroxide solution (Table II, Fig. 3). In the standard solvent*3, there is no band at about 280 mμ, and the band C appears distinctly at 258.3 mμ.

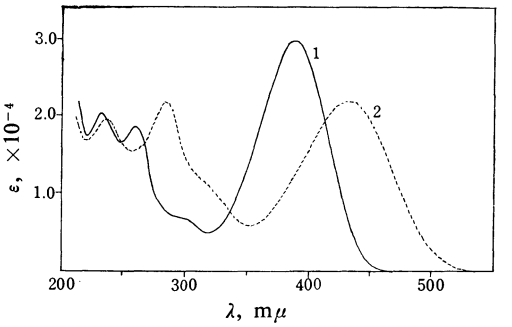


Fig. 3. Absorption spectra of III in the standard solvent (1) and in aqueous 0.01 N NaOH (2).

The above results may be interpreted as follows: The phenolic hydroxyl group is released from the hydrogen-bonded state in polar solvents. This hydroxyl, retaining an equilibrium between a dissociated and an undissociated states in anhydrous methanol (probably due to the absorption of a trace of water while being measured), dissociates in aqueous methanol.

*3 The term "standard solvent" denotes 80% aqueous methanol containing 0.1 g. of acetic acid per liter.

TABLE III. ELECTRONIC ABSORPTION SPECTRA OF II AND ITS METHOXY-ANALOGUE

Compound	Solvent	A	B	C	D
II	S	396.0 (2.81)	(279.0)*(1.00)	258.0 (1.14)	234.0 (1.36)
	H	395.0 (2.59)	319.0* (0.57)	271.0 (1.60) 263.8*(1.48)	243.0*(0.98) 235.7*(1.14) 224.0 (1.20)
Methoxy-analogue of II	S	392.0 (2.88)	277.4* (0.97)	258.5*(1.24)	247.8 (1.33) 237.0 (1.39)
	H	387.4 (2.83)	273.8* (0.95)	253.3 (1.49)	242.5 (1.50) 233.5*(1.43)

Wavelength in parenthesis denotes an indistinct location.
S, Standard solvent; H, *n*-Hexane

The C bands are assigned to a conjugation band (K band)[4] arising from an electronic transition within a partial chromophore[5] consisting of a phenolic nucleus and a hydrazone group. Benzene derivatives usually show B band[6], this band would, however, be submerged by such high intensity K bands as the C bands. Consequently, the absorbing positions and intensities of the C bands alter in accordance with the electronic state of the hydroxyl group. In the standard solvent, the hydroxyl group is fixed in an undissociated state, resulting in a clear-cut formation of the C band.

The A bands are considered to be the absorptions due to a transition involving electron migration along the whole conjugate system of the respective molecule. There also undergo band-shifts according to the polarity of the phenolic hydroxyl, parallel with the shifts of the C bands.

The absorption spectra of II and the 2-methoxy derivative of phenylazoacetoacetamide in the standard solvent and *n*-hexane are shown in Table III. Each band of the 2-methoxy compound in *n*-hexane undergoes a hypsochromic displacement compared with that in the standard solvent. In compound II, λ_{max} of the A band is almost equal in both solvents. However the C band in *n*-hexane is longer in wavelength and higher in intensity than that in the standard solvent, as is shown in Fig. 4. This indicates that the formation of a hydrogen bond ring raises the polar character of the O–H linkage and stabilizes the excited state[7]. Thus, the formation of two internal hydrogen bond rings in a non-polar solvent as shown in II, displaces

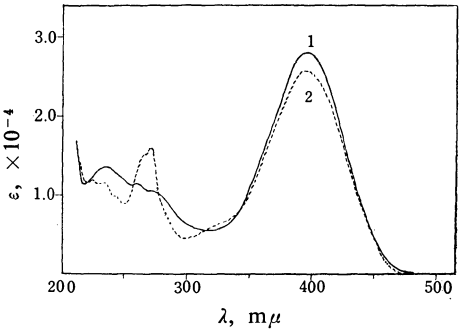

Fig. 4. Absorption spectra of 2-hydroxyphenylazoacetoacetanilide (II) in the standard solvent (1) and in *n*-hexane (2).

the A band towards the longer wavelength region.

It has generally been found[8] that the methylation of a hydroxyl group attached to the conjugate systems causes a small red-shift of the K band. In Table III, however, the A band in both the solvents blue-shifts rather upon methylation. This confirms the view that the hydroxyl group forms the internal or external hydrogen bond in *n*-hexane or in the standard solvent respectively.

The Effects of Substituents in Phenolic Nuclei upon the A and C Bands. — Table IV illustrates the variation of four characteristic bands caused by the introduction of substituents into the phenolic nucleus of II.

The displacements of the C bands by substitution in the 5-position are the most notable and exhibit this decreasing order of λ_{max}: $CH_3 > Cl > H$, $SO_2NH_2 > NO_2$. Such shifts of the C bands suggest that an absorption band due to the electronic transition expected for a partial chromophore is generally very susceptible to the effects of substituents in its chromophore, as has been pointed out by Braude[9]. The maxima of the A bands run

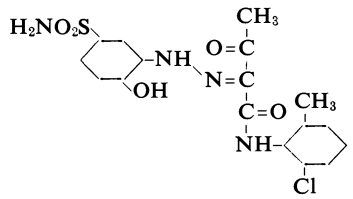
almost parallel with the C bands, though the degrees of displacement are smaller. With regard to sulfamoyl and nitro derivatives in the 4-position, the A bands of both the derivatives are higher in intensity and longer in wavelength than those of corresponding 5-substituted derivatives. However, the λ_{max} values of the C bands are almost equal to that to the non-substituted compound II.

It is interesting that the absorption intensity of the C band in a 5-nitro or 5-sulfamoyl derivative, particularly in the latter, is markedly high.

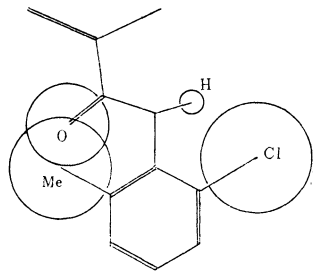
From the results outlined above, it is considered that the substituent in the 5-position—meta to the hydrazone group; i. e., para to the hydroxyl—affects the auxochromic property of the hydroxyl group; e. g., a substitution by methyl emphasizes the auxochromic nature of the hydroxyl group, resulting in the red-shifts of the C and A bands.

On the other hand, the substituent in the 4-position—para to the hydrazone group; i. e., meta to the hydroxyl—is considered to have a mesomeric effect upon the whole absorbing system[10]. However this has little effect upon the auxochromic property of the hydroxyl, because the C band undergoes almost no shift upon the introduction of this substituent.

The Steric Inhibition of the π-p Conjugation and the Assignment of the D Bands.—It seems probable that the amide group participates in the origin of the D bands. In 2-hydroxy-5-sulfamoylphenylazoacetoacet-2-chloro-6-methylanilide (IV-a), a steric conformation of the amide-moiety is shown in a projection (IV-b), exhibiting a steric repulsion between the substituent and the carbonyl oxygen. In the above projection, the covalent radius is conveniently taken for the dimension of the methyl and carbonyl radii. Since the covalent radius represents a minimum measure of the interference radii between non-bonded atoms[11], a true overlap would be larger than that in IV-b.



(IV-a)



(IV-b)

N.B. Dimensions used: Bond lengths are Pauling's values[12]. H, covalent bond radius 0.31 Å; Me, covalent bond radius 1.39 Å; =O, covalent bond radius 1.10 Å[13]; Cl, radius 1.50 Å.

In Table V (Fig. 5), the A, B and C bands blue-shifts with substitution in the 2- and 6-positions are shown. On the other hand, the D

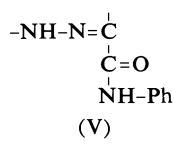
band undergoes a reverse shift and a marked intensity-decrease. Consequently, the effect caused by the di-substitution is considered to correspond to Braude's type (2)[14] steric hindrance to uniplanarity; i. e., a phenyl ring within the amide-moiety of the molecule is distorted out of a plane containing -NHCO- and a hydrazone group in the ground state and can not become coplanar or nearly coplanar, even in the excited state. Thus, the A band shows a hypsochromic and a hypochromic displacement, accompanying identical behaviors of the B and C bands.

From the peculiar change of the D band, the following assignment is possible: The D bands are conjugation bands arising from an electronic transition along a partial chromophore V. A phenyl ring within the amide-moiety predominates over a conjugate system involving -NHCO- and the hydrazone group by the π-p conjugation between the phenyl ring and the amide nitrogen atom. When the electronic interaction of the phenyl ring is completely inhibited, these D bands occur in the region of about 240 mμ.



(V)

With regard to 2, 5-disubstituted derivatives, e. g., the 5-chloro-2-methoxy compound, it is considered that such disubstitution in the 2- and 5-positions strengthens the π-p conjugation and causes the small hyper- and bathochromic shifts of the D band, resulting in the same displacements of the A band.

The Effects of Substituents (in the Phenyl Ring of the Amide-moiety) upon the A Bands. —On 2-hydroxy-5-sulfamoylphenylazoacetoacetanilide, a variety of substituents was introduced into the phenyl ring of the amide group. The A bands in the standard solvent are shown in Table VI.

As to each substituent, the absorption maxima of *o*- and *p*-derivatives are larger than those of *m*-derivatives. It may be concluded that the substituent exerts a weak mesomeric effect upon the whole absorbing system by the π-p conjugation between the amide nitrogen atom and the phenyl nucleus, resulting in a decrease in the energy of a transition along the system, i. e., λ_{max} increase in the A bands.

Effects of Substituents Adjacent to the Hydroxyl Group upon the Spectra.—The substitution in the 3- or 3, 5-positions in the phenolic nucleus of II is expected to have a marked effect upon the electronic state of the hydroxyl. In Table VII, the A bands mostly split into two peaks. In the case of the (X, Y = NO_2) compound a single A band is located at a fairly long wavelength in the standard solvent and in an aqueous alkaline solution (Fig. 6).

It is considered that the substituent in the 3-position exerts an inductive effect upon the adjacent hydroxyl rather than upon the whole conjugate system; e. g., the introduction of an electron-withdrawing group causes a polarization of the O-H linkage. This is emphasized by the further introduction of such a group in the 5-position. Consequently, the longer wavelength maxima or inflections of the A bands is considered to be due to an electronic transition along the whole conjugate system of the molecule in which the hydroxyl is dissociated. The complete or almost complete disappearance of this band in the

N, Aqueous 0.01 N NaOH; A, Aqueous 80% methanol containing 0.002 mol. of HCl per liter.

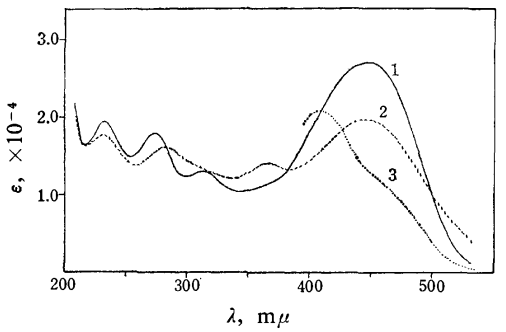

Fig. 6. Absorption spectra of 2-hydroxy-3,5-dinitrophenylazoacetoacetanilide in the standard solvent (1), in aqueous 0.01 N NaOH (2) and in aqueous 80% methanol containing 0.002 mol. of hydrochloric acid per liter (3).

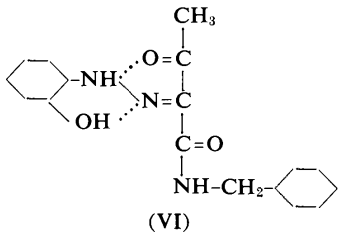
hydrochloric acid-methanol solvent system confirms the above view.

When the splitting of the A band occurs, the C band is located at a longer wavelength than that in the hydrochloric acid-methanol medium and becomes a broad inflection, as is shown in the (X=Cl, Y=NO_2) compound. This is possibly because the molecules of the monoazo compound are in an equilibrium between a dissociated and an undissociated state in this medium.

The Absorption Characteristics of Phenolazoacetoacetbenzylamides and the Assignment of the B Bands. — It has been found[15] that phenolazoacetoacetbenzylamides (VI) form fast-dyeing cobalt(III)-complexes which dye proteinic fibers in clear-yellow shades. It seems reasonable that the four absorption bands in the spectra of phenolazoacetoacetanilides also appear in the series of VI.

15) Y. Yagi and K. Kimura, Japanese Pat., Announced No. 36-11975.



(VI)

Further, the C and D bands are expected to approach to and overlap each other, since the π-p conjugation is intercepted by a methylene bridge. In Table VIII, the spectra of phenylazoacetoacetbenzylamide, its 2-hydroxy derivative VI and related compounds are illustrated. The C bands of the former are superposed upon the D band and appear to be a single band. A similar band system is also observed in the spectra of the derivatives of VI (Table IX, Figs. 7 and 8). The spectroscopic behavior of the C band of VI in *n*-hexane is similar to that of II.

The absorption spectra of the 5-substituted derivatives of VI are illustrated in Table IX. The B bands appear more distinctly than those of the II series. The maximum wavelengths of the C bands, as well as those of the A

5-SO_2NH_2	380.0 (2.60)	296.0 (0.56)	251.7 (1.43)	239.0 (1.43)
5-NO_2	376.0 (2.46)	302.0 (1.18)	246.0 (1.38)	(232.3)*(1.21)

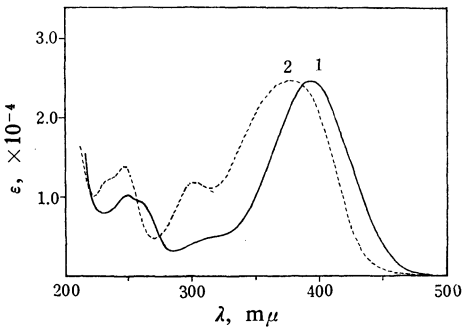

Fig. 8. Absorption spectra of 2-hydroxy-5-methyl- (1) and 2-hydroxy-5-nitrophenylazoacetoacetbenzylamide (2) in the standard solvent.

bands, are displaced towards shorter wavelengths in the order: $CH_3>Cl>H>SO_2NH_2>NO_2$. The range of such wavelength variation of the A bands is wider than that in the II series, so suggesting that the electronic transitions along the whole conjugate systems are liable to suffer the effect of the substituent, because the conjugate systems are shorter in this series.

The origin of the B bands has not yet been explored. When X=H in Table VIII, the benzyl derivative shows a very weak B band, one which splits into two peaks in *n*-hexane. This resembles those of such azo compounds as phenylazoacetoacetic acid ethylester in Part I. It has been considered that these bands are due to the $n\rightarrow\pi$ transition (R band)[4] of a ketonic carbonyl or of an amide carbonyl, because saturated ketones and α,β-unsaturated ketones usually absorb in the region near 300 mμ[16].

On the other hand, those of the hydroxy derivatives have higher intensities. In Table IX, the more electronegative the substituent in the phenolic nucleus, the higher the intensity of the B band. A similar intensity change was observed in the II series. Table IX also indicates that a compound showing the A band at a relatively longer wavelength similarly exhibits the B band at a longer wavelength position. When measured in an aqueous alkaline solution, both the A and B bands of 2-hydroxy-5-sulfamoylphenylazoacetoacetbenzylamide undergo bathochromic displacement, about 45 and 20 mμ respectively, as compared with those in the standard solvent in Table IX.

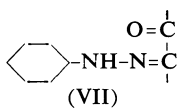
If the B bands in the hydroxy derivatives are R bands, they should undergo hypsochromic displacement[4] upon any alteration of the electronic configuration of the system, which

16) Cf. Ref. 4, pp. 48 and 95.

would cause a bathochromic shift of the K band. Therefore, these bands can not be attributed to the intensified R bands, nor can they be considered to be B bands, because of the high absorption intensities.

1-Phenylazo-2-naphthol[17], 4-phenylazo-1-naphthol[18] and other hydroxyazo compounds[19] are known to exist in a solvent-dependent tautomeric equilibrium between a hydroxyazo- and a *o*-quinonephenylhydrazone form. In such cases, the introduction of an electronegative group into the phenyl ring has been reported to cause an increased contribution of the hydrazone form in equilibrium[17]. It has also been found in 3-methyl-1-phenyl-4-phenylazo-5-pyrazolone as well as in its 2-hydroxyphenylazo-analogue[20], both of which have the hydrazone form, that the greater the Hammett[21] substituent-constant of a substituent in the phenyl ring attached to the hydrazone group, the weaker the hydrogen bond between a carbonyl oxygen and a hydrazone hydrogen atom and, thus, the higher the frequency of the C=O stretching vibration.

Consequently, the B bands are assigned to a conjugation band, which arises from a conjugative transition within a partial chromophore consisting of the acetyl carbonyl and the hydrazone group. The electronegative substituent in the phenyl ring of VII stabilizes the hydrazone form; i. e., it



(VII)

increases the double-bond character of >C=N– and >C=O, resulting in the intensity-increase of the B bands. Thus, both 2-hydroxy-5-nitrophenylazoacetoacetanilide and its benzyl analogue exhibit high-intensity B bands in the 302~303 mμ region.

Experimental

Preparations of 2-Aminophenols.—*2-Amino-4-(N-ethylsulfamoyl)phenol.* — This was obtained in the same manner as were the 4-sulfamoyl derivatives[22], pale gray plates; m. p., 128°C.

Found: C, 44.25; H, 5.38; N, 12.85. Calcd. for $C_8H_{12}O_3N_2S$: C, 44.43; H, 5.59; N, 12.94%.

The other 2-aminophenol derivatives were prepared according to the methods in the literature. Their melting points agree with those in the literature.

Preparation of Acetoacetamides.—*1-Acetoacetylamino-2-methoxy-5-methylbenzene.*—Treatment of *p*-cresidine (m. p. 50.5°C) with diketene in solvent naphtha gave cubic crystals. They were recrystallized from ethanol, giving colorless plates; m. p., 82°C.

Found: C, 65.05; H, 6.69; N, 6.28. Calcd. for $C_{12}H_{15}O_3N$: C, 65.14; H, 6.83; N, 6.33%.

1-Acetoacetylamino-2-chloro-6-methylbenzene.—This was obtained from 2-chloro-6-methylaniline (b. p. 120~121°C) and diketene. Recrystallization from 50% ethanol gave colorless needles; m. p., 123~124°C.

Found: C, 58.35; H, 5.05; N, 6.28. Calcd. for $C_{11}H_{12}O_2NCl$: C, 58.53; H, 5.36; N, 6.20%.

Acetoacetbenzylamide. — Colorless plates. Recrystallization from 50% ethanol gave rectangular plates; m. p., 102~103°C.

Found: C, 68.88; H, 6.72; N, 7.47. Calcd. for $C_{11}H_{13}O_2N$: C, 69.09; H, 6.85; N, 7.35%.

Acetoacet-n-hexylamide. — This was obtained as paraffin-like flakes; m. p., 52.0°C.

Found: C, 64.58; H, 10.25; N, 7.25. Calcd. for $C_{10}H_{19}O_2N$: C, 64.90; H, 10.30; N, 7.56%.

The other acetoacetylamino derivatives were obtained in the same manner. The purities were checked by elemental analysis.

Preparations of Phenolazoacetoacetamides. — *2-Methoxyphenylazoacetoacetanilide.* — This was obtained by the treatment of acetoacetanilide with diazotized *o*-anisidine in an aqueous solution. It was recrystallized from ethanol, giving yellow needles.

Found: C, 63.37; H, 5.83; N, 13.65. Calcd. for $C_{17}H_{17}O_3N_3$: C, 65.58; H, 5.50; N, 13.50%.

2-Hydroxy-5-sulfamoylphenylazoacetoacet-2-methoxy-5-methylanilide.—An aqueous solution of diazotized 2-amino-4-sulfamoylphenol was added to a solution containing 1-acetoacetylamino-2-methoxy-5-methylbenzene, sodium carbonate and sodium hydroxide. An orange precipitate was obtained. After an aqueous suspension of this was treated with hydrochloric acid, the precipitate was recrystallized from *n*-butanol, giving yellow needles.

Found: C, 51.49; H, 5.41; N, 13.21. Calcd. for $C_{18}H_{20}O_6N_4S$: C, 51.42; H, 4.80; N, 13.33%.

The Other Phenolazoacetoacetamides.—All of these were synthesized in the above manner. They were recrystallized from ethanol, dioxane, acetoacetic ester, ethylcellosolve or higher alcohols. The purities were checked by elemental analysis.

Measurments of the Absorption Spectra. — Infrared measurements were made by a Shimadzu model IR-27 infrared spectrophotometer equipped with NaCl optics. The Nujol mull method was employed for the preparation of samples. The visible and ultraviolet spectra were measured using a Beckman model DK-2 and a Shimadzu model RS-27 recording spectrophotometers. The spectra were determined at a sufficient dilution, (0.5~2.5) $\times 10^{-5}$ M, Beer's law being valid within these limits except in hydrous methanol. The solvents used were of spectral grades.

Summary

Phenolazoacetoacetamides take the hydrazone form. The phenolic hydroxyl group forms an intramolecular hydrogen bond with a hydrazone nitrogen atom in the solid state and in non-polar solvents.
