The electronic absorption spectra of these compounds exhibit four groups of characteristic bands: The A bands arise from a transition involving electron migration along the whole conjugate system of the respective compound; the C bands originate in a conjugative electronic transition between a phenolic nucleus and a hydrazone group, and the D bands, in a conjugative electronic transition between a carboxylic acid anilide group and a hydrazone group.

From the investigation of the series of spectra in phenolazoacetoacetbenzylamides, the B bands have been assigned to the conjugation band; they arise from a conjugative electronic transition within a partial chromophore consisting of an acetyl carbonyl and a hydrazone group.

The author owes gratitude to the late Professor Ryutaro Tsuchida of Osaka University for his encouragement and kindness in participating in discussions throughout this work. The author also wishes to express his gratitude to Sumitomo Chemical Co., Ltd., for its permission to publish this work, and to Mr. Kikuo Kimura for his assistance in this study. The reading of the manuscript by Professor Shoichiro Yamada is also gratefully acknowledged.

Studies of the Absorption Spectra of Azo Dyes and their Metal-complexes. III. The Electronic Absorption Spectra of Metal-complexes Derived from Phenolazoacetoacetanilides[*1]

By Yoshiharu YAGI

(Received July 5, 1962)

Metal-complex dyes, having two molecules of such ligand dyes as *o,o'*-dihydroxymonoazo dyes per atom of chromium(III) or cobalt(III), are recognized to have superior dyeing-properties[1] and are expected to develop progressively. The absorption spectra of such ligand dyes generally undego marked changes by coordination with metal atoms[2].

In previous papers[3] the author investigated the electronic absorption spectra of phenolazoacetoacetamides[*2] in order to assign the four characteristic groups of bands. With respect to the metal-complexes of these azo compounds, there are many problems deserving of further study; e.g., the cobalt(III)-complexes ordinarily have a higher fastness to light than the chromium(III)-complexes[4]. The author supposed that an investigation of the spectral variations of the four characteristic bands with the complex formation would give useful information about the metal-ligand linkage. This paper deals with the absorption spectra of the metal-complexed phenolazoacetoacetanilides.

Results and Discussion

A General Survey of the Electronic Absorption Spectra of the Metal-containing Phenolazoacetoacetanilides and the Assignments of the Four Groups of Bands.—The structure of 2 : 1-metal-complexes of phenolazoacetoacetanilides has up to the present been represented as in I[5]. Two molecules of such terdentate ligand-dyes are known to have a octahedral

groups of bands are generally observed in the visible and ultraviolet region. These bands will hereafter be referred to as A, B, C and D counting from the longer wavelength side. The absorption spectra of the chromium(III)-complex*4 of II in a variety of solvents are illustrated in Table I. A slight intensity decrease and a small hypsochromic displacement of each band in an aqueous sodium hydroxide solution are probably due to the electrostatic interaction between inorganic ions and solvent molecules around the absorbing system, as was discussed by Klotz[9]. However, the relative positions of the four bands in each solvent are almost invariable. Provided that an anionic charge, which is generated with the ionization of the free complex-acid in a polar solvent, as in an aqueous alkaline solution, is localized in the complex-molecule, there should be appreciable band-shifts in the ultraviolet region, as has been reported in the case of ligand-dyes in Part II. Consequently, the anionic charge is considered to have a non-localized character.

In Part II, the four characteristic groups of bands in the spectra of the ligand-dyes were assigned: the ligand-band A arises from a transition involving electron migration along the whole conjugate system. The ligand-band

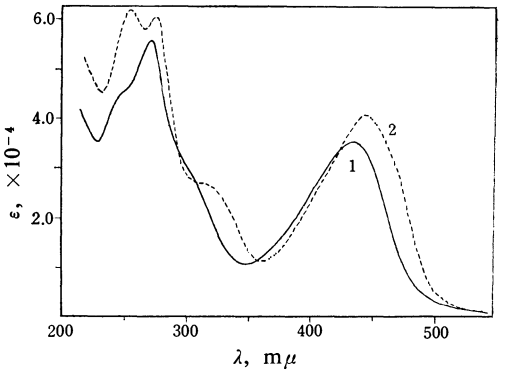

Fig. 3. The cobalt-complexes of 2-hydroxy-5-sulfamoylphenylazoacetoacet-2-chloro-6-methylanilide (1) and 2-hydroxy-5-sulfamoylphenylazoacetoacet-5-chloro-2-methoxyanilide (2) in the standard solvent.

B originates in a conjugative electronic transition between the acetyl carbonyl and the hydrazone group; the ligand-band C, in a conjugative electronic transition between the phenolic nucleus and the hydrazone group, and the ligand-band D, in a conjugative electronic transition between the carboxylic acid anilide group and the hydrazone group.

From the investigation of the wavelength variations and the intensity changes as a result of substitutions, the four groups of bands in the spectra of the metal-complexes are considered to originate in the four bands of the respective ligand-molecule. For example, a marked intensity decrease of the D band in the spectrum of the 2-chloro-6-methyl derivative (Fig. 3) is similar to that of the ligand-dye itself, as has been reported in Part II. The first and the second bands[10] are thought to be submerged in these four bands. That is, these bands are the special bands[11].

The Electronic Absorption Spectra of the Chromium(III)-, Cobalt(III)-, Iron(III)- and Aluminum-complexes.—Metal-complexes of four ligand-dyes were prepared: II, 2-hydroxy-5-sulfamoylphenylazoacetoacet-2-methylanilide (III), 2-hydroxy-5-(*N*-methylsulfamoyl)-phenylazoacetoacet-2-chloranilide (IV), and 5-chloro-2-hydroxyphenylazoacetoacetanilide (V). The electronic absorption spectra of these azo compounds and their metal-complexes are illustrated in Table II.

Wavelengths in parenthesis denotes an indistinct location.
The letters, l and δ, are the half-value widths and the inclination parameters of the A bands (in $cm^{-1} \times 10^{-3}$) respectively.

indicating that these are essentially ionic complexes, as was reported by Freeman and White[12].

Shifts of the C ligand-bands with complex-formation are characteristic of the central metal atom used. Generally, red-shifts of the ligand-bands C ($\Delta\lambda_C$) with complex-formation are in the order: Cr> Al> Fe> Co.

Chromium(III)-complexes.—In the series of phenolazoacetoacetamides, it was found that the polarity increase of the phenolic O–H linkage, as in the case of the dissociation or formation of the intramolecular hydrogen bond, causes a red-shift and an intensity increase of the C band. Generally the bond formed between the phenolic oxygen and the tervalent metal is considered to be based on ion-dipole interaction, because the hydroxyl group has a strong dissociative ability[3]. The M–O (M, tervalent metal; O, phenolic oxygen) bond, therefore, is considered to have an essentially polar character. This presumably causes a displacement of the C band towards a longer wavelength. Indeed, such red-shifts of the C bands ($\Delta\lambda_C$) are the largest in the chromium(III)-complexes, indicating that the Cr–O bonds are the most ionic among the four sorts of metal-complexes.

The maintenance of the B ligand-bands, even in the coordinated state, suggests that the double bond character of >C=O in the acetyl group is not eliminated with the complex-formation. The lone pair electrons of the carbonyl oxygen will coordinate with the metal atom to form a σ bond. When the same ligand is used, the B bands of the four metal-complexes are almost equal in intensity and show only small displacements. The shifted order of the B bands as shown in Fig. 6 is probably due to the effect of an electronic transition along the whole conjugate system of the respective ligand-molecule.

12) D. C. Freeman, Jr., and C. E. White, *J. Am. Chem. Soc.*, 78, 2678 (1956).

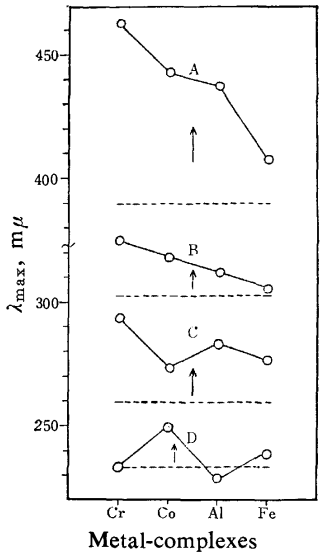

Fig. 6. Absorption maxima of the four bands in the spectra of metallized IV; dotted lines show absorption maxima of the four ligand-bands.

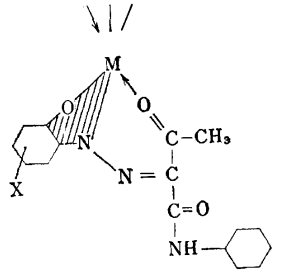
Therefore, the nature of the M–O (O, carbonyl oxygen) bonds are thought to be independent of the central metal used.



(VI)

(X, Substituent)

The above explanations lead to the conclusion that the structure shown in VI contributes much to the matal-ligand linkage. An imino group in the hydrazone group will coordinate with a metal atom, with a splitting off of a proton. Craig and his co-workers[13] suggested that the nitrogen lone pair has the ability to enter the π-electron orbital and that, therefore, the π-electrons of the system will be distributed over the whole conjugate system of the ligand. Thus, the overlap of the dπ-orbitals[13] of the metal with the nitrogen π-orbital will form the dπ-pπ bonding.

Cobalt(III)-complexes.—The maximum wavelengths of the A bands are always about 20 mμ shorter than those of the chromium(III)-complexes. Generally the values of $\Delta\lambda_C$ are the smallest among the four kinds of the metal-complexes, indicating the highly covalent character of the Co–O (O, phenolic oxygen) bonds.

Since the chromium(III)- and the cobalt(III)-complexes in this study are formed by d^2sp^3 hybridized orbitals, their electronic configurations are:

	3d				4s	4p
Cr:	d^1	d^1	d^1	D^2	S	P^3
Co:	d^2	d^2	d^2	D^2	S	P^3

Such completely filled or half-filled dπ-orbitals are known to be the most stable electronic configurations[14]. Consequently, the dπ-pπ bonds are considered to be almost equally operative in the chromium(III)- and the cobalt(III)-complexes. In such a case, the bathochromic shifts of the A bands with complex-formation are ascribed mainly to two causes: (i) the polarity of the M–O (O, phenolic oxygen) bond, and (ii) the perturbation of the π-electron system by the dπ-pπ interaction, serving to increase the electronic polarizability of the system. The shorter wavelength positions of the A bands in the cobalt(III)-complexes are attributed to the highly covalent character of the Co–O bonds. Thus, a chelate ring (the shaded portion in VI) is stabilized, resulting in a facilitation of an electronic transition which will increase the intensity of the C band.

In the ligand-dye V, $\Delta\lambda_C$ decreases in the order: Cr≫Co> Fe> Al. An electronegative subsutituent in the para position with regard to the hydroxyl will increase the polarity of the M–O (O, phenolic oxygen) bond. Thus, the polarity order of the bond may be somewhat different from those of the metallized II, III and IV.

Iron Compexes.—The absorption spectra of the iron(III)-complexes have some peculiarity. If the penetration complexes (a) are formed, the contribution of the dπ-pπ interaction upon the metal-ligand linkage will be small.

	3d				4s	4p	4d
(a)	d^2	d^2	d^1	D^2	S	P^3	
(b)	d^1	d^1	d^1	d^1d^1	D^2	S	P^3

If the iron(III)-complexes formed are the normal complexes (b), the distribution of the bonding electrons will be biased in the direction of the ligand in order to increase the metal-ligand

13) D. P. Craig et al., *J. Chem. Soc.*, **1954**, 332.

14) Cf. Ref. 11b, p. 185.

distance.[15] The relatively small shifts of the C bands with the complex-formation may indicate the covalent charactr of the Fe–O (O, phenolic oxygen) bonds. However, the A bands are broader than those of the chromium(III)- and cobalt(III)-complexes, in which the $d\pi$-$p\pi$ bondings are effectively operative. Moreover, the C bands of the iron(III)-complexes are also broadened, mostly as shoulders. It may consequently be postulated that the iron(III)-cmplexes are a mixture of different bond types, as is shown in a and b.

The weak shoulders are located in the 535~545 mμ region. Their true absorption intensities are about $(2\sim3)\times10^3$, since these shoulders are superposed by the slopes of the A bands. These may probably be ascribed to the first absorption bands[16] due to the iron(III)-ion, because similar weak bands in the spectra of copper- and nickel-chelates of salicylaldoxime were reported[17] to be due to the metal ions.

Aluminum-complexes. — Aluminum-complexes are ordinarily recognized to be essentially ion-dipole aggregates, as was pointed out by Craig et al.[13]

As is shown in Fig. 6, the values of $\Delta\lambda_C$ are next larger to those of the chromium(III)-complexes, indicating the high polarity of the Al–O (O, phenolic oxygen) bonds. The A bands are sharp and symmetrical; i. e., both the half-value widths (l) and the inclination parameters (δ) are smaller than those of the respective ligand-dye. This indicates that the aluminum-complexes are ionic complexes. The shifts of the A ligand-bands with complex-formation are mainly to be attributed to the polarity of the Al–O (O, phenolic oxygen) bonds.

Experimental

Syntheses of the Metal-complexes of Phenolazoacetoacetanilides.—*Metal-complexes of 2-Hydroxy-5-(N-ethylsulfamoyl)-phenylazoacetoacetanilide (II).*—(*i*) *Chromium(III)-complex.*—The ligand-dye (0.02 mol.) in formamide was treated with chromium(III) formate (0.01 mol.) at 120°C for 10 hr. The reaction mixture was poured into a dilute solution of hydrochloric acid to yield a yellow-brown precipitate of the complex-acid. A small portion of the crude product was dissolved in 95% ethanol, added to a column of activated alumina, and developed with 95% ethanol. A yellow-brown zone was separated and eluted with the same solvent.

After evaporation of the eluted solution to dryness under reduced pressure, a residue was dissolved in dry acetone, filtered, and diluted with hot benzene. Orange-brown needles were obtained.

Found: C, 50.15; H, 4.56; N, 13.33. Calcd. for $C_{36}H_{37}O_{10}N_8S_2Cr$: C, 50.04; H, 4.34; N, 13.06%.

(*ii*) *Cobalt(III)-complex.*—The ligand-dye (0.02 mol.) was suspended in a dilute solution of sodium hydroxide and treated at 80°C with cobalt(II) sulfate (0.01 mol.) to yield a brown precipitate. This precipitate was dissolved in aqueous ethanol containing sodium hydroxide, and the solution was then acidified with hydrochloric acid to precipitate the complex-acid. Purification was performed in the same manner as the chromium(III)-complex. A yellow-brown precipitate was obtained.

Found: C, 49.36; H, 4.51; N, 12.68. Calcd. for $C_{36}H_{37}O_{10}N_8S_2Co$: C, 49.90; H, 4.30; N, 12.98%.

(*iii*) *Iron(III)-complex.*—The ligand was treated with iron(III) chloride in formamide. The reaction mixture was poured into a dilute aqueous solution of acetic acid to yield a brown precipitate. After an aqueous ethanolic solution of the precipitate had been acidified with acetic acid, the complex-acid obtained was purified by chromatographic adsorption, as has been shown above. After removal of the solvent from an eluted solution, a residue was dissolved in dry ethanol and diluted with hot benzene to crystallize brown needles.

Found: C, 49.83; H, 4.45; N, 12.93. Calcd. for $C_{36}H_{37}O_{10}N_8S_2Fe$: C, 50.19; H, 4.30; N, 13.01%.

(*iv*) *Aluminum-complex.*—Reaction was carried out in the same manner as with the iron(III)-complex, except that aluminum sulfate was used instead of iron(III) chloride. The purification procedures were the same as that for the iron(III)-complex. Yellow needles were obtained.

Found: C, 51.38; H, 4.39; N,13.28. Calcd. for $C_{36}H_{37}O_{10}N_8S_2Al$: C, 51.91; H, 4.38; N, 13.46%.

Metal-complexes of 5-Chloro-2-hydroxyphenylazoacetoacetanilide(V). — (*i*) *Chromium(III)-complex.*—The reaction and the chromatographic separation procedures were the same as have been shown for the *N*-ethylsulfamoyl derivative. A residue obtained by the evaporation of an eluted solution was dissolved in aqueous ethanol containing sodium hydroxide. Neutralization of the solution with hydrochloric acid and the addition of sodium chloride to this gave red-brown prisms.

Found: C, 54.09; H, 3.63; N, 11.74. Calcd. for $C_{32}H_{25}O_6N_6Cl_2Cr$: C, 53.94; H, 3.54; N, 11.78%.

(*ii*) *Cobalt(III)-complex.*—Purification was carried out in the same way as with the above-mentioned chromium(III)-complex.

Found: C, 52.92; H, 3.73; N, 11.39. Calcd. for $C_{32}H_{25}O_6N_6Cl_2Co$: C, 53.42; H, 3.50; N, 11.68%.

(*iii*) *Iron(III)-complex.*—A mixture of 95% ethanol and pyridine was used as a developer liquid in chromatographic adsorption. The dilution of a dry-ethanolic solution of the separated complex-acid with hot *n*-hexane gave red-brown needles.

Found: C, 53.24; H, 3.38; 11.58. Calcd. for $C_{32}H_{25}O_6N_6Cl_2Fe$: C, 53.65; H, 3.52; N, 11.73%.

(*iv*) *Aluminum-complex.*—Yellow needles were obtained in the same manner as has been described

in the case of *N*-ethylsulfamoyl derivative.

Found: C, 55.38; H, 3.81; N, 12.49. Calcd. for $C_{32}H_{25}O_6N_6Cl_2Al$: C, 55.90; H, 3.67; N, 12.22%.

Metal-complexes of the Other Ligand-dyes.—These were also prepared in the manner described above. The purities were checked by elemental analysis.

Measurements of the Electronic Absorption Spectra.—The absorption spectra were measured by two recording spectrophotometers, a Beckman model DK-2 and a Shimadzu model RS-27. All the spectra were determined at a concentration of 1.6×10^{-5} M. The solvents used had the qualities of spectral grades.

Summary

1) The electronic absorption spectra of metallized phenolazoacetoacetanilides exhibit four characteristic groups of bands—A, B, C and D. These groups of bands originate in the band of the respective ligand-dye.

2) The metal-complexes have the structure shown in formula VI.

3) The bathochromic shifts of the A ligand-bands with complex-formation are ascribed to two causes: (i) the polarity of the M–O (M, tervalent metal; O, phenolic oxygen) bond, and (ii) the perturbation of the π-electron system by the $d\pi$-$p\pi$ interaction. The shifts of the C ligand bands with the complex-formation are closely related to the polarity of the above-mentioned M–O bond. The cobalt(III)-complex has the covalent M–O bond with which to form a stable chelate ring, whereas the chromium(III)-complex has the ionic M–O bond.

4) The absorption characteristics of the iron(III)- and the aluminum-complexes have been discussed.

The author owes his deep gratitude to the late Professor Ryutaro Tsuchida of Osaka University for his encouragement and kindess in participating in discussions throughout this work. The author is also indebted to Sumitomo Chemical Co., Ltd., for its permission to publish this work, and to Mr. Kikuo Kimura for his assistance in this study.

Studies of the Absorption Spectra of Azo Dyes and their Metal-complexes. IV. The Effects of Substituents on the Absorption Spectra of Chromium(III)- and Cobalt(III)-complexes of Phenolazoacetoacetanilides[*1]

By Yoshiharu YAGI

(Received July 9, 1962)

Studies of the relationships between substituents and electronic absorption spectra or stabilities have been reported[1] on metal-complex azo-dyes containing functional groups ortho and ortho' to the azo linkage. Little is known, however, with respect to the 2 : 1-metal-complex monoazo dyes, for example, the chromium(III)- or cobalt(III)-complexes of phenolazoacetoacetamides[*2].

Since the chelate ring involving a phenolic oxygen, a central metal, and a hydrazone nitrogen contributes much toward the metal-ligand linkage, as has been shown in Part III[2], the influence of substituents in the phenolic nucleus upon the electronic absorption spectra will be characteristic of the central metal used. Therefore, the author has investigated the metal-complexes[*3] of substituted phenolazoacetoacetanilides.

Results and Discussion

The Effects of Substituents in the Phenolic Nuclei upon the Electronic Absorption Spectra of Metallized Phenolazoacetoacetanilides.—It has been reported in this series of studies[3]

[*1] Presented at the 15th Annual Meeting of the Chemical Society of Japan, Kyoto, April, 1962.

[*2] The compounds in this paper have hydrazone forms but are, for convenience, named as azo forms. α-(2-Hydroxyphenylazo)-acetoacetanilide, for example, is abbreviated as phenolazoacetoacetanilide.

that the electronic absorption spectra of phenolazoacetoacetanilides exhibit four groups of conjugation bands (K bands)[4] and that these bands undergo characteristic changes with complex-formation. The A ligand-band arises from a transition involving electron migration along the whole conjugate system of the ligand. The B ligand-band originates in a conjugative electronic transition between the acetyl carbonyl and the hydrazone group, the C ligand-band in a conjugative electronic transition between the phenolic nucleus and the hydrazone group and, the D ligand-band, in a conjugative electronic transition between the carboxylic acid anilide group and the hydrazone group.

Since the degree of modification of the bands expected for the partial chromophores is regarded as an indication of the extent of the electronic interaction therein[5], an investigation of the four characteristic bands of the metal-complexes will reveal useful information about the metal-ligand linkage.

N. B. a) Absorotion maxima (λ_{max}) in mμ, molar extinction coefficients (ε_{max}) in 10^{-4}, red-shifts of the ligand-bands with complex-formation ($\Delta\nu$) in $10^{-3}\times cm^{-1}$, half-value widths (l) and inclination parameters (δ) of the A bands in $10^{-3}\times cm^{-1}$.

b) * Inflection.

c) Absorption maximum in parenthesis denotes an indistinct location.

d) In the chromium-complexes of the 3-nitro and 5-nitro derivatives, the C band is superposed by the B band.

e) Inflections near the four main bands are shown under the respective main band.

arranged in the generally accepted order[6] of electronegativity at regular intervals.

Cobalt(III)-complexes.—Band-shifts with substitution are the most notable in the C bands. The degree of the shifts ($\Delta\nu_C$ in cm^{-1}) with complex-formation varies according to the substituent, as is shown in Fig. 4b. Generally an electronegative substituent in para to the M–O (M, tervalent metal; O, phenolic oxygen) bond increases the red-shift of the C band in the chromium(III)- and the cobalt(III)-complexes.

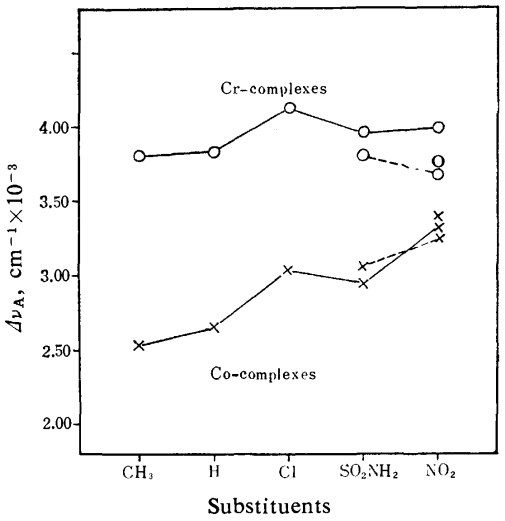

Fig. 4a. Relation between the substituents and the shifts of the A ligand-bands with complex-formation ($\Delta\nu_A$) (full lines, 5-substituted derivatives; dotted lines, 4-substituted derivatives; single marks, 3-substituted derivatives.)

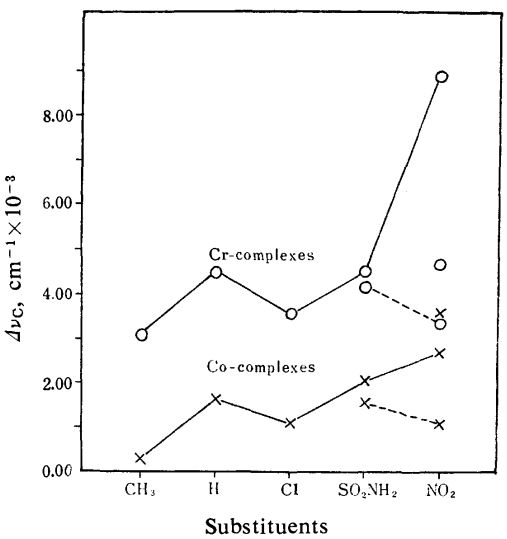

Fig. 4b. Relation between the substituents and the shifts of the C ligand-bands with complex-formation ($\Delta\nu_C$).

In Part II it was noticed how, in the spectra of phenolazoacetoacetamides, the C ligand bands are sensitive to any alteration of the electronic configuration of the system. In the metal-complexes also, the values of $\Delta\nu_C$ are considered to indicate the polarity of the M–O (O, phenolic oxygen) bond. The relatively small $\Delta\nu_C$ value of the cobalt(III)-complexes as compared with those of the chromium(III)-complexes indicate the covalent character of the Co–O (O, phenolic oxygen) bond.

Since the chromium(III)- and the cobalt(III)-complexes in this study are formed by d^2sp^3 hybridized orbitals and since their $d\pi$-orbitals[7a] have stable electronic configurations[2,7b], the $d\pi$-$p\pi$ bondings in both the complexes are considered to contribute equally to the ligand-metal linkage. A five-membered chelate ring (the shaded portions in II) is stabilized in the cobalt(III)-complexes to facilitate the transition expected for a partial chromophore involving the phenolic nucleus, i. e., to increase the intensities of the C bands. Both the half-value widths (l) and the inclination parameters (δ) of the cobalt(III)-complexes are somewhat larger than those of the corresponding chromium(III)-complex, indicating that the stable chelate ring emphasizes the perturbation of the π-electron system.

The bathochromic shift of the A ligand-bands with the complex-formation may be ascribed mainly to two factors; (i) the polarity of the M–O (O, phenolic oxygen) bond, and (ii) the perturbation of the π-electron system by the $d\pi$-$p\pi$ interaction. Generally, influences increasing the polarity of the absorbing system displace the K band to longer wavelengths[8]. Therefore, a substituent increasing the polarity of the above mentioned M–O bond displaces the A band as well as the C band towards longer wavelengths, as is shown in Fig. 4 (i. e., factor i). That is, the more electronegative the substitutent in the 5-position, the larger the values of $\Delta\lambda_A$ and $\Delta\nu_C$. In the metal-complexes, which have larger $\Delta\lambda_A$ and $\Delta\nu_C$ values, the A bands are generally higher in intensity and smaller in l and δ (except those of the 5-nitro derivative). This suggests shat the contribution of the five-membered chelate ring slightly decreases because of the polarity increase of the M–O bond.

		Co	448.9	4.49	3.90	6.52	1.51
			412.7*	3.78			

All the spectra were measured in the standard solvent. But those of the ligand-dyes, except the dye ($X=NO_2$, $Y=CH_3$), were determined in aqueous 80% methanol containing 0.002 mol. of hydrochloric acid per liter.

In case of the 4-nitro and 4-sulfamoyl derivatives, the polarization of the M–O bond is not so large as those of the 5-substituted derivatives (Fig. 4b). However, the values of $\Delta\nu_A$ are almost equal to those of the 5-substituted derivatives (Fig. 4a). It is considered that an elongation[9] and a planarity increase[10] of the conjugate system upon the introduction of the substituent in the 4-position, i. e., para to the hydrazone group, result in an enhancement of the $d\pi-p\pi$ bonding (i. e., factor ii).

With regard to the 3-nitro derivative, the nitro-group in the 3-position fairly polarizes the M–O bond, resulting in the increase of both $\Delta\nu_A$ and $\Delta\nu_C$ values.

The relatively large $\Delta\nu_D$ values in the cobalt(III)-complexes indicate that the stable chelate ring emphasizes the planarity of the ligand-molecule to reduce the energy of the transition expected for the partial chromophore involving the amide group.

Since most of the B bands are superposed by the C bands and present themselves as inflections, exact evaluations of them are difficult. However, the intensities of the B bands in the spectra of 3-nitro and 5-nitro derivatives are higher than those of the other derivatives. Such intensity increases agree with the finding, reported in Part II, that the electron-withdrawing group stabilizes the hydrazone structure[3,11], resulting in an enhancement of the conjugation B band.

Chromium(III)-complexes.—In the chromium(III)-complexes, the $\Delta\nu_C$ values are larger than that of the corresponding cobalt(III)-complex. That is, the Cr–O (O, phenolic oxygen) bonds have a highly ionic character. The larger shifts of the A bands as compared with those of the coblt(III)-complexes are mainly to be attributed to the ionic Cr–O bond.

In the series of 5-substituted derivatives, the $\Delta\nu_C$ values in Fig. 4b show that an electronegative group increases the polarity of the Cr–O bond. On the other hand, a variation of $\Delta\nu_A$ in Fig. 4a exhibits a gentler slope than that of the chromium(III)-complexes. Consequently, it is concluded that the influence of the i factor on the A bands is not so effectively operative as in the case of the cobalt(III)-complexes, because the Cr–O bonds originally have a highly ionic character.

In the series of 4-substituted derivatives, both $\Delta\nu_A$ and $\Delta\nu_C$ values are smaller than those of the corresponding 5-substituted derivative.

9) H. P. Koch, ibid., **1949**, 408; H. H. Szmant and H. J. Planinsek, *J. Am. Chem. Soc.*, **72**, 4042 (1950).
10) W. R. Brode, "The Roger Adams Symposium", John Wiley & Sons, Inc., New York (1955), p. 29.
11) A. Burawoy, A. G. Salem and A. R. Thompson, *J. Chem. Soc.*, **1952**, 4793; H. Shingu, *J. Chem. Soc. Japan, (Nippon Kwagaku Kwaishi)*, **60**, 542 (1939).

It is considered that the substituent in the 4-position, i. e., meta to the M–O bond, scarcely participates in the polarization of the M–O bond (smaller $\Delta\nu_C$) and that the $d\pi$-$p\pi$ interaction also is not effectively operative, because the five-membered chelate ring is weaker than that of the 4-substitued cobalt(III)-complex (smaller $\Delta\nu_A$).

A small $\Delta\nu_A$ value in the spectrum of the 3-nitro derivative also is attributed to the same reason.

Further Observation of 3, 5-Disubstituted Derivatives.—The bathochromic displacements of the A bands due to the polarization of the M–O (O, phenolic oxygen) bond are pronounced in the cobalt(III)-complexes. As will seen in the series of 5-substituted derivatives in Table I, the A band of the cobalt(III)-complex approaches that of the corresponding chromium(III)-complex in accordance with the polarization of the Co–O bond.

In Table II are shown the visible absorption bands of the chromium(III)- and cobalt(III)-complexes of 3, 5-disubstituted phenolazoacetoacetanilides. Remarkable proximities of the absorption maxima in the two complexes produced by the introduction of electron-withdrawing groups in the 3- and 5-positions are to be seen. That is, the polarization of the Co–O bonds results in the displacement of the A bands to longer wavelengths.

In Table II, the A bands of those metal-complexes having a nitro group in the 5-position are broader than those of the other derivatives. Moreover, the cobalt(III)-complex of the 3-chloro-5-nitro derivative, as well as of the 5-nitro derivative in Table I, exhibits a weak inflection at a shorter wavelength than that of the A band. An assignment of this band will be made in the next paper.

Experimental

Syntheses and Purifications of Metal-complexes Derived from Phenolazoacetoacetanilides.—*Metal-complexes of Phenolazoacetoacetanilide.*—*(i) Chromium(III)-complex.*—The ligand-dye (0.02 mol.) was treated with chromium(III) formate (0.01 mol.) in formamide at 120°C for 12 hr. The reaction mixture was poured into a dilute aqueous solution of hydrochloric acid to yield a precipitate of the complex-acid. This complex-acid was then filtered off, washed with water, and dried in vacuo. Purification was carried out by column-chromatography. The crude complex-acid (200 mg.) was dissolved in 95% ethanol, added to an adsorption-column of activated alumina, and developed with 95% ethanol. A brown zone of the metal-complex was extruded, separated, and eluted with 95% ethanol. The eluted solution was evaporated to dryness under reduced pressure. The residue obtained was dissolved in aqueous ethanol containing sodium hydroxide. The neutralization of the solution with dilute hydrochloric acid at 50°C and the successive addition of sodium chloride to this gave a brown-yellow precipitate. The precipitate was filtered off, washed with water, and dried in vacuo, yielding 140 mg. of the pure chromium(III)-complex.

Found: C, 59.56; H, 4.26; N, 13.09. Calcd. for $C_{32}H_{27}O_6N_6Cr$: C, 59.71; H, 4.23; N, 13.05%.

(ii) Cobalt(III)-complex.—A suspension of the ligand-dye (0.02 mol.) in a dilute aqueous solution of sodium hydroxide was treated at 80°C with cobalt(II) sulfate (0.01 mol.). The sodium-salt of the cobalt-complex crystallized out as fine flakes in the reaction mixture. The reaction mixture was made into a solution by adding ethanol and then acidified (pH 2.40) by the addition of hydrochloric acid. The precipitated complex-acid was filtered off, washed with water, and dried in vacuo. Chromatographic purification of the crude product (200 mg.) was performed in the same manner as with the chromium(III)-complex to yield 150 mg. of a brown-yellow precipitate.

Found: C, 58.86; H, 4.32; N, 12.62. Calcd. for $C_{32}H_{27}O_6N_6Co$: C, 59.08; H, 4.18; N, 12.91%.

Metal-complexes of 2-Hydroxy-5-methylphenylazoacetoacetanilide.—*(i) Chromium(III)-complex.*—The pure chromium-complex was obtained as yellow-brown precipitate.

Found: C, 60.94; H, 4.83; N, 12.49. Calcd. for $C_{34}H_{31}O_6N_6Cr$: C, 60.80; H, 4.65; N, 12.51%.

(ii) Cobalt(III)-complex.—The purified product was in the form of yellow-brown needles.

Found: C, 59.85; H, 4.59; N, 12.25. Calcd. for $C_{34}H_{31}O_6N_6Co$: C, 60.19; H, 4.60; N, 12.38%.

Metal-complexes of the Other Phenolazoacetoacetanilides.—These also wese prepared in the manner described above. Their purities were checked by elemental analysis.

Measurements of the Electronic Absorption Spectra.—The absorption spectra were measured by two recording spectrophotometers, a Beckman model DK-2 and a Shimadzu model RS-27. All the spectra were determined at a concentration of 1.6×10^{-5} M. Beer's law is valid in this dilution. The qualities of the solvents were of spectral grades.

Summary

The electronic absorption spectra of the series of metallized phenolazoacetoacetanilides have been investigated.

The substituent, in the *o*- or *p*- position to the M–O (M, central metal; O, phenolic oxygen) bond, generally alters the polarity of the M–O bond. On the other hand, the substituent, in the *m*-position to the M–O bond, i. e., the *p*-position to the hydrazone group, mainly contributes to the $d\pi$-$p\pi$ interaction between the hydrazone group and the central metal atom.

The effects of such substituents upon the shifts of the A bands are more pronounced in the cobalt(III)-complexes than in the chromium-(III)-complexes, because the former complexes have the stable five-membered chelate rings

involving the highly covalent Co–O (O, phenolic oxygen) bonds.

The author owes his gratitude to the late Professor Ryutaro Tsuchida of Osaka University for his valuable discussions and criticism. Thanks are also to be accorded to Sumitomo Chemical Co., Ltd., for permission to publish this work and to Mr. Kikuo Kimura for his assistance throughout this study.

Studies of the Absorption Spectra of Azo Dyes and their Metal-complexes. V. The Electronic Absorption Spectra of Metal-complexed Phenolazoacetoacetbenzylamides

By Yoshiharu YAGI

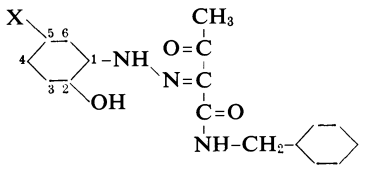
(Received July 16, 1962)

Previous studies[1] of the electronic absorption spectra of phenolazoacetoacetanilides*1 have shown that four groups of bands are to be expected for partial or total chromophoric systems[2] of the respective molecules and that the interception of the π-p conjugation between the amide nitrogen and the amide aryl group, as in case of phenolazoacetoacetbenzylamide (I), causes the hypsochromic displacement of the A, B and C bands. The author has also investigated the metal-ligand linkage of the 2 : 1-complexes consisting of two molecules of phenolazoacetoacetanilides (II)[3a] and a tervalent metal atom. The work described in the present paper was first undertaken to study the absorption characteristics and the metal-ligand linkage with respect to the metallized phenolazoacetoacetbenzylamides[3b].

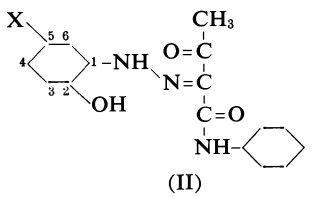
In the series of metallized phenolazoacetoacetanilides, the A band of the cobalt(III)-complex*2 having a nitro group in the para-position to the Co–O (O, phenolic oxygen) bond has been observed to split into two peaks. The cause of such anomalous band-splitting will be investigated, together with the above-mentioned problems.

Results and Discussion

The Electronic Absorption Spectra of Chromium(III)- and Cobalt(III)-complexes Derived from Phenolazoacetoacetbenzylamides. — The electronic absorption spectra of chromium(III)- and cobalt(III)-complexes derived from 5-sulfamoyl- and 5-chloro derivatives of I in the standard solvent*3 are illustrated in Table I (Figs. 1–3), together with the corresponding derivatives of II.



(I)



(II)

(X, Substituent)

The spectra of the metal-complexed I in the near ultraviolet and visible regions show four groups of bands, which will be identified as A, B, C and D counting from the longer

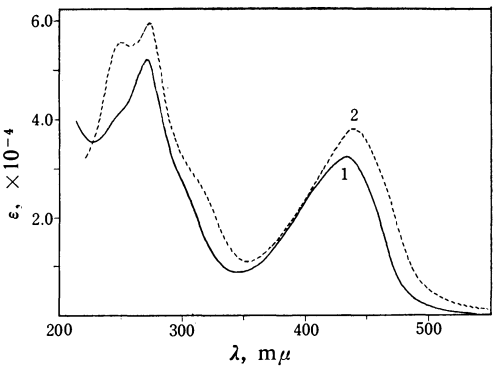

Fig. 2. Absorption spectra of cobalt-complexes derived from the ligand-dyes shown in Fig. 1 in the standard solvent; the numbering of the curves corresponds to those in Fig. 1.

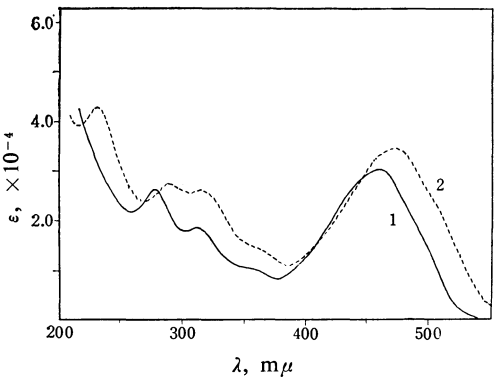

Fig. 3. Absorption spectra of chromium-complexes derived from 5-chloro-2-hydroxyphenylazoacetoacetbenzylamide (1) and 5-chloro-2-hydroxyphenylazoacetoacetanilide (2) in the standard solvent.

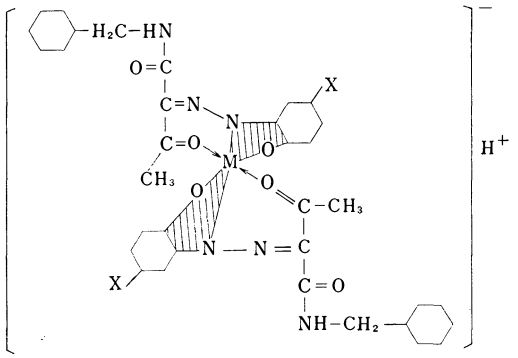
wavelength side. As was pointed out in Part III, these bands originate in the four conjugation bands (K bands)[4] of the respective ligand-dye. The A ligand-band arises from a transition involving electron migration along the whole conjugate system of the ligand-molecule. The B ligand-band originates in a conjugative electronic transition between the acetyl carbonyl and the hydrazone group, the C ligand-band, in one between the phenolic nucleus and the hydrazone group, and the D ligand-band, in one between the carboxylic acid amide group and the hydrazone group.

With regard to absorption spectra of the ligand-dye I, the interception of the π-p conjugation by the insertion of a methylene bridge caused a decrease in the intensity and the red-shift of the D band, resulting in the hypsochromic and hypochromic displacement of the A, B and C bands. In the spectra of metal-complexed II also, the D bands markedly decrease in intensity, as is shown in Figs. 2 and 3. For example, the D band in the chromium(III)-complex of the 5-chloro derivative is completely submerged in the other band-system and can not be detected. An absorption band due to a forbidden transition within the phenyl or the phenol nucleus (B-band)[5] should appear near the D bands, but this is considered to be submerged in such conjugation bands as the D or C bands.



(III)

A comparison of the A bands between the I and II series indicates that the elimination of the π-p conjugation causes a hypsochromic displacement of about 7 mμ in the cobalt(III)-complexes and one of 10~14 mμ in the chromium(III)-complexes, In Table I, the $\Delta\nu_A$ values (the red-shifts of A ligand-bands with complex-formation, i. e., the absorption maximum of the ligand-band A−absorption maximum of the corresponding complex-band, in cm^{-1}) of the chromium(III)-complexes are almost equal in the two series. However, the $\Delta\nu_A$ values of the cobalt(III)-complexes are larger in the I series.

		Cr	473.3	3.43	4.12	4.77	0.55
		Co	450.2	3.19	3.04	5.85	1.10

N.B. a) Absorption maxima (λ_{max}) in mμ, molar extinction coefficients (ε_{max}) in 10^{-4}, red-shifts of the ligand-bands with complex-formation ($\Delta\nu$) in $10^{-3}\times cm^{-1}$, half-value widths (l) and inclination parameters (δ) of the A bands in $10^{-3}\times cm^{-1}$.

The bathochromic shifts of the A ligand-bands with the complex-formation are ascribed mainly to two factors: (i) the polarity of the M–O (M, tervalent metal; O, phenolic oxygen) bond; i.e., any alteration of the electronic configuration, which polarizes the bond, causes a red-shift of the A band, and (ii) the perturbation of the π-electron system by the $d\pi$-$p\pi$ interaction between the hydrazone group and the central metal. The $d\pi$-$p\pi$ interaction in the chromium(III)- and the cobalt(III)-complexes are considered to be equally effectively operative, because the $d\pi$-orbitals in both the complexes by d^2sp^3 hybridization have stable electronic configurations[6]. Consequently, the different degrees of the bathochromic shifts of the A ligand-bands with the cobalt-complex formation are considered to depend mainly upon the polarities of the M–O bonds. The larger values of $\Delta\nu_A$ in the cobalt(III)-complexs of the I series indicate that the Co–O (O, phenolic oxygen) bond increases its ionic character. This is probably due to the stronger basicity of the phenolic hydroxyl in the I series. Further, since the substituents in the phenolic nuclei of the I series have more pronounced effects upon the absorbing systems, as was pointed out in Part II, the electronegative substituent, such as the 5-chloro or 5-sulfamoyl group, will emphasize the polarity-increase of the Co–O bond.

Since the Cr–O (O, phenolic oxygen) bond originally has a highly ionic character, the values of $\Delta\nu_A$ in the I and II series do not differ from each other.

The half-value widths (l) and the inclination parameters (δ) are generally larger in the cobalt(III)-complexes than in the chromium-(III)-complexes. This suggests that the stable five-membered chelate-ring in the cobalt(III)-complexes, as shown in III (the shaded portions), emphasizes the perturbation of the π-electron system by the $d\pi$-$p\pi$ interaction.

The C bands are closely related to the polarities of the M–O (O, phenolic oxygen) bonds, as was reported in Parts III and IV. That is, the highly ionic character of the Cr–O (O, phenolic oxygen) bond resulted in the appearance of the C bands at markedly longer wavelengths, while the highly covalent character of the Co–O (O, phenolic oxygen) bond caused the slight red-shift and the intensity increase of the C band. Such characteristic band-shifts are also observed in the I series. It is noteworthy that the $\Delta\nu_C$ values of the cobalt(III)-complexes in the I series are relatively larger than those of the corresponding chromium(III)-complexes. This confirms that the Co–O bond increases its ionic character in the I series.

The B bands run parallel to the shifts of the A bands, indicating that this group of bands is influenced by an electronic transition involving electron migration along the whole conjugate system of the molecule. The absorption intensities are almost equal in the chromium(III)- and the cobalt(III)-complexes.

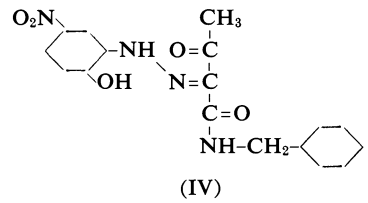
b) * Inflection
c) Absorption maximum in parenthesis denotes an indistinct location.
d) Inflections near the four main bands are shown under the corresponding main band.

However, exact evaluation is difficult, because most of these bands appear as inflection.

The D bands in the I series also often appear as inflection, because their intensities are generally low because of the interception of the π-p conjugation. Relatively longer wavelength positions and higher intensities of the D bands in the spectra of the cobalt(III)-complexes are observed than in those of the chromium(III)-complexes. This is in accord with the explanation given in the previous paper that the stable chelate ring emphasizes the planarity of the coordinated ligand-molecule, facilitating the electronic transition expected for a partial chromophore involving the amide group and resulting in an approach of the D band to the high-intensity C band.

The Splitting of the A Bands in the Spectra of Metallized 2-Hydroxy-5-nitrophenylazoacetoacetbenzylamide.—The absorption spectra of chromium(III)-, cobalt(III)-, iron(III)- and aluminum-complex of 2-hydroxy-5-nitrophenylazoacetoacetbenzylamide (IV) in a variety of solvents are shown in Table II (Figs. 4 and 5).



(IV)

Two peaks of the split A band are, for convenience, named as A_1 and A_2 counting from the longer wavelength side.

The splitting of the A bands is observed in every solvents. The D bands of these complexes decrease their intensities in a manner similar to those in Table I. For example, the D band of the cobalt(III)-complex can not be detected, as is shown in Fig. 4. Weak inflections at about 550 mμ in the spectra of the iron(III)-complex are considered to be the first absorption band[7], that due to the iron(III)-ion, as was reported in Part III. The results in Part III also showed that the aluminum-complex generally shows a sharp and symmetric A band. However, all the metal-complexes of IV have broadly split A bands.

It has been reported that the absorption band of salicylaldoxime tends to split with the Ni-chelate formation[8] and that such band-splitting probably arises from different bond-types, such as dsp^2 and sp^3 hybridizations. It can not, however, be thought that the A_1 and A_2 bands originate in two different bond-types, for the 2:1-chromium(III)- or cobalt(III)-complexes, such as the metal-complexes in this studies, are known to be stable penetration complexes by d^2sp^3 hybridization[9]; the results in the preceding papers[1] also confirm the above view. Nor can it be considered that the band-splitting is due to the vibrational

c) In the chromium-complex, the B band is superposed by the C band.

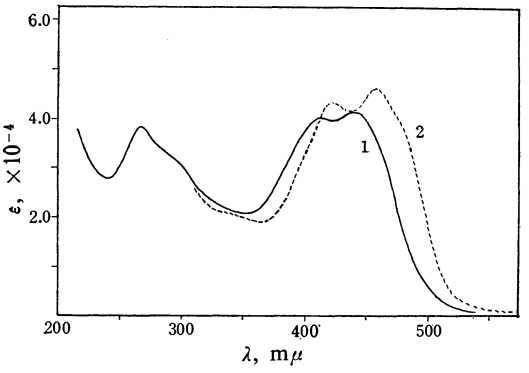

Fig. 4. Cobalt-complex of IV in the standard solvent (1) and in pyridine (2).

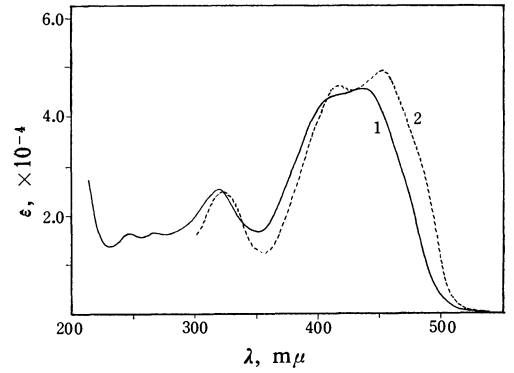

Fig. 5. Aluminum-complex of IV in the standard solvent (1) and in pyridine (2).

structure, as has been reported on metal-chelates of α, α'-dipyridyl[10].

In the cobalt(III)-complex of IV, a comparison of the absorption maxima of the A_1 and A_2 bands in pyridine with those in the standard solvent shows that the A_1 and A_2 bands undergo bathochromic shifts of 0.89×10^3 and 0.42×10^3 (in cm^{-1}) respectively when measured in pyridine. The batho- and hyperchromic displacement is more pronounced in the A_1 band (Fig. 4). Such a tendency is also observed in the other metal-complexes of IV, as is shown in Fig. 5. Generally, the increase in the polarity due to the solute-solvent interaction, and thus the magnitude of the solvent effect, is enhanced with the polar character of the absorbing molecules[11]. Although various causes are conceivable for such band-splitting, the following explanation is thought to be the most reasonable; one of the two M–O (O, phenolic oxygen) bonds which form the chelate-rings of the 2 : 1-metal-complex III is markedly polarized by the *p*-substituted nitro group, and thus an electronic transition along the conjugate system of the coordinated ligand-molecule involving the polarized M–O bond exhibits the A_1 band.

10) K. Sone, P. Krumholz and H. Stammreich, *J. Am. Chem. Soc.*, **77**, 777 (1955).
11) A. Burawoy, M. Cais., J. T. Chamberlain, F. Liversedge and A. R. Thompson, *J. Chem., Soc.*, **1955**, 3721.

Though an anionic charge of the 2:1-complex is generally considered to have a non-localized character, as has been pointed out in Part III, this will be localized at the polarized M–O bond in the metal-complexed IV. To confirm this explanation on other metal-complex systems, further studies are now in progress.

If the metal-complex molecule of IV involves the two M–O bonds of different polarities as explained above, the C bands expected for the partial chromophore involving the phenolic nucleus will split to two peaks. In fact, the C band of the chromium(III)-complex in an alkaline solution splits and forms an inflection near 267 mμ. No such band-splitting, however, can be detected in the other complexes of IV.

That the A_2 band of the cobalt(III)-complex has a relatively higher intensity as compared with that of the A_1 band, as is shown in Table II, agrees with the finding in Parts III and IV that the metal-ligand linkage is the most stable in the cobalt(III)-complexes. Since the M–O bonds of the chromium(III)-, iron(III), and aluminum-complexes are essentially ionic, the A_2 bands of these complexes are low in intensity. A fine structure of the A_2 band in the spectrum of the iron(III)-complex in pyridine may support the deduction in Part III that the iron(III)-complex is a mixture of different bond types.

Experimental

The Preparation of Metal-complexes of Phenolazoacetoacetbenzylamides.—*Metal-complexes of 5-Chloro-2-hydroxyphenylazoacetoacetbenzylamide.* — *(i) Chromium(III)-complex.*—The ligand-dye (0.02 mol.) was treated with chromium(III) formate (0.01 mol.) in formamide at 120°C for 10 hr. The reaction mixture was poured into a dilute aqueous solution of hydrochloric acid to yield a yellow-brown precipitate. This complex-acid was filtered off, washed with water, and dried in vacuo. The crude complex-acid (300 mg.) was dissolved in 95% ethanol, added to an adsorption-column of activated alumina, and developed with 95% ethanol. The brown zone of the complex was separated and eluted with ethanol. The eluted solution was evaporated to dryness under reduced pressure. The residue obtained was dissolved in aqueous ethanol containing sodium hydroxide. The neutralization of the solution with dilute hydrochloric acid and the successive addition of sodium chloride to this gave reddish brown prisms. This product was filtered off, washed with water, and dried in vacuo, yielding 230 mg. of the pure chromium(III)-complex.

Found: C, 54.70; H, 4.02; N, 11.41. Calcd. for $C_{34}H_{29}O_6N_6Cl_2Cr$: C, 55.14; H, 3.94; N, 11.34%.

(ii) Cobalt(III)-complex. — The ligand-dye (0.02 mol.) was suspended in an aqueous alkaline solution containing sodium hydroxide (0.05 mol.) and tartaric acid (0.005 mol.) and treated with cobalt(II) sulfate (0.01 mol.) at 60°C for 1 hr. The reaction mixture was made into a solution by the addition of ethanol and was acidified (pH 2.70) with hydrochloric acid. The precipitated complex-acid was filtered off, washed with water, and dried in vacuo. The chromatographic purification of the product (200 mg.) was carried out in the same manner as with the chromium(III)-complex, giving yellow-brown needles (150 mg.).

Found: C, 54.23; H, 4.18; N, 10.98. Calcd. for $C_{34}H_{29}O_6N_6Cl_2Co$: C, 54.64; H, 3.91; N, 11.24%.

Metal-complexes of the Other Phenolazoacetoacetbenzylamides.—These complexes were also prepared in the manner described above. The iron(III)- and aluminum-complexes of IV were prepared in a method similar to that described in Part III. The purities were checked by elemental analysis.

Measurements of the Electronic Absorption Spectra.—The absorption spectra were measured by two recording spectrophotometers, a Beckman model DK-2 and a Shimadzu model RS-27. All the spectra were determined at concentrations of 1.6×10^{-5} M (metal-complexes) and 2.5×10^{-5} M (ligand-dyes).

Summary

The absorption spectra of metallized phenolazoacetoacetbenzylamides were investigated.

The isolation of the electronic effect of the amide phenyl ring by the insertion of the methylene bridge decreases the intensity of the D band, resulting in the hypso- and hypochromic displacement of the A, B and C bands.

The red-shifts of the A and C ligand-bands with the complex-formation indicate that the Co–O (O, phenolic oxygen) bonds increase their ionic character as compared with those of the metallized phenolazoacetoacetanilides.

The splitting of the A band in the spectra of metallized 2-hydroxy-5-nitrophenylazoacetoacetbenzylamide is possibly to be attributed to the polarization of the M–O (O, phenolic oxygen) bond by the electron-withdrawing nitro group.

The author owes thanks to the late Professor Ryutaro Tsuchida of Osaka University for his valuable discussions and encouragement. Thanks are also to be accorded to Sumitomo Chemical Co., Ltd., for permission to publish this work and to Mr. Kikuo Kimura for his assistance throughout this study.

The Selective Titrations of Calcium in the Presence of Magnesium

By Yoshiko DATE and Kyoji TÔEI

(Received August 18, 1962)

The chelometric determination of calcium in the presence of magnesium is carried out by using ethylenediaminetetraacetic acid (EDTA) as a titrant at pH 12~13. Magnesium is precipitated as the hydroxide, and murexide, thymolphthalein complexone (TPC), Calcon or Patton-Reeder's reagent[1] (NN) is used as an indicator. However, the presence of precipitated magnesium hydroxide causes a coprecipitation of calcium and an adsorption of the metal indicator on the precipitate, and these behaviors interfere to find an end-point of reaction accurately. Some attempts to overcome them have been reported. For example, to prevent the precipitation, tartrate[2] or sucrose[3,4] was added. Although the precipitate was thereby avoided, the end-point was indefinite. This is because of the small difference in the stability constants of calcium- and magnesium-EDTA complexes ($\log K_{CaZ}=10.70$, $\log K_{MgZ}=8.69$).

Instead of using EDTA as a titrant for calcium in the presence of magnesium, glycoletherdiaminetetraacetic acid (GEDTA) could be introduced; the difference between the stability constants of calcium- and magnesium-GEDTA complexes is 5.8 in $\log K$ units ($\log K_{CaZ}=11.0$, $\log K_{MgZ}=5.2$), and therefore the selective titration of calcium in the presence of magnesium would be possible at pH 10 where magnesium remains in the solution. However, a selective indicator for calcium at pH 10 has not yet been found. A potentiometric end-point detection by the mercury electrode[5], and an indirect end-point indication using the zinc-zincon system[6] have been proposed. Unfortunately both methods somewhat restrict the use of certain important masking agents which are often employed in practical analyses.

Burg and Conaghan[7] achieved the selective titration of calcium in the presence of magnesium with GEDTA, using tartrate as a masking agent for magnesium and Calcon as an indicator at pH 13 and at about 40°C.

In this paper, the work of masking agents and indicators on the chelometric determination of calcium in the presence of magnesium is reported. Some applications for limestone, dromite and magnesite will be presented.

Experimental and Results

Reagents.—A 0.01 M EDTA solution was prepared by dissolving 3.73 g. of EDTA (disodium salt) in 1 l. of distilled water. A 0.01 M GEDTA solution was prepared by dissolving 3.8 g. of glycoletherdiaminetetraacetic acid in 20 ml. of 1 N sodium hydroxide and then by diluting this solution with redistilled water to 1 l. A 0.01 M calcium solution; dissolve 1.0009 g. of calcium carbonate in hydrochloric acid, add distilled water, and heat to remove the carbon dioxide. After cooling, dilute with distilled water to 1 l. The 0.01 M EDTA and GEDTA solutions were standardized with this solution. The 0.1 M magnesium solution was prepared by dissolving 24.65 g. of magnesium sulfate heptahydrate in a small volume of distilled water and by diluting this solution. to 1 l.

The BT solution was prepared by dissolving 0.5 g. of Eriochrome Black T and 4.5 g. of hydroxylamine hydrochloride in 100 ml. of methanol. The Dotite NN solution was prepared by dissolving 2-hydroxy-1-(2-hydroxy-4-sulfo-1-naphthylazo)-3-naphthoic acid (Patton-Reeder's reagent) in methanol. For the buffer solution, 7 g. of ammonium chloride and 57 ml. of concentrated aqueous ammonia were dissolved in 100 ml. of distilled water. The tartrate solution was prepared by dissolving 10 g. of potassium sodium tartrate in 100 ml. of distilled water.

Indicators.—The optimum pH ranges for several indicators were studied. Various pH solutions were prepared using aqueous ammonia or potassium and sodium hydroxide. A small amount of an indicator was added to each of them, and the stability of the color was examined. Further, the color of the free indicator was compared with that of the calcium complex. The indicators, their optimum pH ranges, and the methods of preparation are shown in Table I.

It was tested whether or not, in the calcium titration, these indicators indicated the accurate quantitative value, with sharp color changes. These tests were carried out in the following

TABLE I

Indicator	Optimum pH range	Preparation
Calcein (Fluorescein complexone)	12.9~13.1	Diluted 1 : 100 with KNO_3
MTB (Methylthymolblue)	11.9~12.5	Diluted 1 : 100 with KNO_3
TPC (Thymolphthalein complexone)	10.4~12.0	Diluted 1 : 100 with K_2SO_4
PC (*o*-Cresolphthalein complexone)	10.5~11.0	0.1% PC in methanol
Calcon (1-(2-Hydroxy-1-naphthylazo)-2-naphthol-4-sulfonic acid)	11.8~12.2	0.5% Calcon in methanol
NN	13.3~13.5	Dotite NN solution

way: Take 10 ml. of a 0.01 M calcium solution and dilute to about 50 ml. with distilled water. Adjust pH and add a small amount of an indicator. Titrate with 0.01 M GEDTA.

The results of these analyses are given in Table II.

TABLE II

Indicator	ca. 0.01 M GEDTA required (ml.)	Nature of end-point
Calcein	10.66±0.01	Sharp
MTB	10.67±0.01	Very sharp
TPC	10.64±0.01	Sharp
PC	10.65±0.06	Fairly sharp*
Calcon	—	Indefinite**
NN	10.67±0.01	Sharp

* Influenced by the amount of the indicator.
** Needs the presence of magnesium.

In the presence of tartrate to prevent the precipitation of magnesium hydroxide, it was investigated whether or not these indicators changed their colors at the end-point and also whether the color changes indicated the accurate quantitative value by this method: Take 10 ml. of a 0.01 M calcium solution and dilute to about 50 ml. with distilled water. Add 2 ml. of a 0.1 M magnesium solution and 2 ml. of a tartrate solution. Adjust pH and add a small amount of an indicator. Titrate with 0.01 M GEDTA.

For Calcein, MTB, TPC and PC, these color changes at the end-point were indefinite. These indicators could, therefore, not be used for this titration.

Calcon was tested according to the procedure proposed by Burg and Conaghan. It changed the color sharply at the end-point. However, because of warming the sample up to about 40°C before the titration, magnesium tended to precipitate. NN was also used in this titration at room temperature, but it took some time for the color to change completely. Both Calcon and NN indicated the correct end-point by MTB in the absence of magnesium.

Masking Agents.—Because many magnesium complexes are the O, O co-ordinated chelates, the suitable masking agents for magnesium at pH 12~13 would be expected to be found among organic substances having oxygen atoms capable of co-ordinating with magnesium. Several masking agents for magnesium were tested; the results were shown in Table III. The test solution was prepared by diluting 10 ml. of 0.01 M calcium and 5 ml. of a 0.01 M magnesium solution to 50 ml. with distilled water and by adding one of the masking agents. The pH value of the solution was adjusted to 13 and 13.5 by potassium and sodium hydroxide. Then we investigated to see whether or not the precipitate was formed at pH 13 and 13.5.

Among the masking agents shown in Table III, tartrate and gluconic acid were found to be the most suitable masking agents for magnesium at pH 13.5.

TABLE III. MASKING AGENTS FOR MAGNESIUM

Masking agent		Precipitation*	
Name	Amount	pH 13	pH 13.5
Glycolic acid (70%)	0.5 ml.	×	×
Lactic acid (75%)	0.5 ml.	○	×
Maleic acid	0.1~0.5 g.	×	×

2 ml. of a tartrate solution or 2.5 ml. of 5% gluconic acid, 2 ml. of 8 N potassium hydroxide, and a few drops of NN solution were added, and the solution was titrated with 0.01 M GEDTA.

In the presence of gluconic acid, the color change from red to blue at the end-point was proceeding slowly, and the amount of 0.01 M GEDTA was 0.2 ml. smaller than that of the correct end-point as indicated by MTB in the absence of magnesium. On using tartrate, there was a clearer difference than with gluconic acid between the color just before and after the end-point, and the amount of 0.01 M GEDTA consumed was the same as the correct equivalent value.

Magnesium Amount and Tartrate Amount. — With an increase in the concentration of magnesium, the concentration of tartrate should also be increased. The relation between the amounts of magnesium and of tartrate is shown in Fig. 1 and Table IV.

It was found that the maximum concentrations of magnesium and tartrate were 7 ml. of a 0.1 M magnesium solution (about 7×10^{-4} mol.) and 5 ml. of a tartrate solution (about 1.7×10^{-3} mol.).

The color at the end-point upon using the NN solution is light blue and somewhat differs from that of the calcium titration in the absence of tartrate and magnesium.

small amount of dilute hydrochloric acid by heating. If the solution is turbid, leave it to stand for about 12 hours, filter and wash the precipitate with water. Dilute the filtrate in a 250 ml. measuring flask with distilled water. The solution is used as a test solution.

Determination of the Total Amount of Calcium and Magnesium.—Take 5 ml. of the test solution and dilute to about 50 ml. with distilled water. Add 1 ml. of 0.1 M Mg-EDTA, 1 ml. of a buffer solution, 3 drops of a 10% potassium cyanide solution (and triethanolamine, if necessary), and a few drops of a BT solution. Titrate with 0.01 M EDTA.

Determination of Calcium.—For limestone and dromite, take 5 ml. of the test solution and dilute to about 50 ml. with distilled water. Add 2 ml. of a 0.1 M Mg solution, 2 ml. of a tartrate solution, 2 ml. of 8 N potassium hydroxide, 3 drops of 10% potassium cyanide (and triethanolamine, if necessary), and a few drops of an NN solution, and titrate with 0.01 M GEDTA. For magnesite, take 10 ml. of the test solution and dilute to about 50 ml. with distilled water. Add 5 ml. of a tartrate solution and titrate with the procedure mentioned above, or titrate it after adding a known amount of calcium to the aliquot. Calculate by deducting the known amount of calcium. In this paper, the amount of calcium in magnesite was analysed by both two procedures and the two values were averaged.

Determination of Magnesium.—Magnesium is calculated by deducing the calcium from the calcium and the magnesium. The results of the analyses of limestone, dromite and magnesite are given in Table V.

Studies of Organic Peroxides. VII. The Decomposition of Symmetrically Substituted Benzoyl Peroxides by Iron(II)

By Shigeo HASEGAWA, Norio NISHIMURA, Seiichi MITSUMOTO and Ken'ichi YOKOYAMA

(Received October 10, 1962)

In previous papers[1,2], the rate of the decomposition of benzoyl peroxide catalysed by ferrous ion has been followed by means of analytical and thermal analysis methods. A mechanism involving free radicals has been proposed for the reaction, and the effect of the solvent on the reaction rate has been discussed.

The next step of the study, which seems to be of special interest from the point of view of chemical kinetics, is to investigate the effect of substituents on the peroxide concerning the reaction rate. In this field, some investigators[3,4] have studied the thermal decomposition of many symmetrically-substituted benzoyl peroxides. On the other hand, Orr and Williams[5] and Imoto and Suckon[6] have studied the catalysed decomposition of substituted benzoyl peroxides.

In this report, the rates of decomposition of symmetrically-parasubstituted benzoyl peroxides by ferrous ions will be followed by means of the thermal analysis method. It is confirmed that all the reaction are apparently of the first order, as was the case for the unsubstituted peroxide.

Experimental

All the experiments were carried out in ethanol. In preliminary studies, the presence of water in the reaction system was found to retard the reaction rate to a great extent. One percent of water decreases the reaction rate about half and ten percent of it decreases the rate by a factor of ten. Hence, ethanol was refluxed with calcium oxide for a day, and the water in it was removed with great care.

Ferrous chloride crystals ($FeCl_2 \cdot 4H_2O$) were prepared by the method reported previously[7].

All peroxides were prepared according to the method of Pechmann and Vanino[8] or that of Price and Krebs[9].

Table I lists the peroxides studied, together with pertinent data.

The experimental details were the same as in the previous report[2].

Owing to the poor solubilities of the peroxides in ethanol, the concentration ranges of the peroxides were limited between 0.15 and 0.6 mmol. per liter. The concentrations of ferrous ions in each experiment were taken to be larger than those of the peroxides by a factor of about ten.

Results and Discussion

In the case when a reaction is of the first order, the fundamental equation of the thermal analysis may be given by:

$$\log\left(\frac{dT}{dt}+K\Delta T\right)=\log\frac{Q}{W}\cdot ka-\frac{kt}{2.303} \qquad (1)$$

where dT/dt is the rate of temperature change in the solution, $K\Delta T$ is a correction term for Newtonian cooling, Q and W denote the heat of reaction and the water equivalent of the

* Average value in 1. mol^{-1} sec^{-1}

reaction vessel respectively, and a denotes the initial concentration of a reactant concerned.

For the reaction of benzoyl peroxide with ferrous ions, the apparent first order rate constant, k, in Eq. 1 was found to be proportional to the initial concentration of ferrous ions:

$$k = k' [Fe^{2+}]_0 \qquad (2)$$

in which k' is, as was discussed in the previous paper[2], the rate constant of the bimolecular reaction between ferrous ions and benzoyl peroxide. It has also been proposed that the reaction consists of several steps; that is, the primary radical-producing step is followed by radical-induced reactions.

In Table II the values of k' are listed for the reactions between symmetrically parasubstituted benzoyl peroxides and ferrous ions at three temperatures. Using the data in Table II, $\log k'$ was plotted against $1/T$, as is shown in Fig. 1. Straight lines were drawn by means of the least squares method.

The estimated values of the energy and entropy of activation are listed in Table III, together with the values of Hammett's substituent constants[10].

An inspection of Tables II and III will show that there are some relationships between these substituents and the rate of reaction.

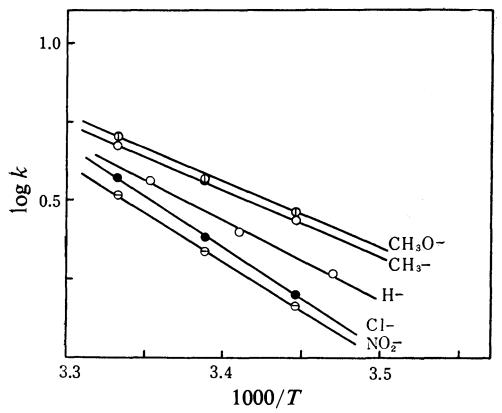

Fig. 1. Arrhenius plot of $\log k'$ against $1/T$.

TABLE III. ENERGY AND ENTROPY OF ACTIVATION OF THE FERROUS ION-CATALYSED DECOMPOSITION OF SUBSTITUTED BENZOYL PEROXIDE IN ETHANOL

Substituent	E, kcal./mol.	ΔS^*, e. u. (300°K)	σ
CH_3O-	9.66	−25.2	−0.268
CH_3-	9.70	−25.1	−0.170
H-	11.58	−19.2	0
Cl-	14.77	− 8.7	0.227
NO_2-	14.09	−11.3	0.778

It may be seen that the introduction of an electropositive group at the para position in the benzene nucleus increased the reaction rate, and that an electronegative group caused it to decrease over the range of experimental temperatures. However, it seems more reasonable to discuss the problem in relation to the energy and entropy of activation rather than the reaction rate.

In view of the fact that the activation energies for the spontaneous decomposition of benzoyl peroxides are around 30 kcal. per mole, whereas those for the ferrous ion-catalysed decomposition are around 12 kcal. per mole, there must be a strong interaction between a ferrous ion and the peroxides.

As a ferrous ion approaches a peroxide molecule, there should be interconversion of the translational into vibrational energy, resulting in an activated complex.

Regarding the activated complex, which consists of a ferrous ion and a hydroperoxide, Orr and Williams[5] suggested that the formation of the activated complex would be by coördination and that it would be analogous to an addition reaction.

In our case, a similar formation of an activated complex would be expected to occur. It is quite natural to consider that an electron-attracting group will decrease the availability of the coördinating electrons to which a ferrous ion bonds. Conversely, an electron-repelling group will shift the electrons to the central oxygen atoms, permitting an O-Fe(II) bond to be formed easily; this would lower the activation energy.

According to Rollefson[11], the formation of

11) G. K. Rollefson, *J. Phys. Chem.*, **56**, 976 (1952).

a new normal bond is accompanied by an entropy loss of 30 e. u. in an addition reaction, but if there is only a simple collision process without bond formation, then the entropy loss in activation is 10 e. u. which corresponds to a loss of only one degree of translational freedom.

Therefore, it may reasonably be expected that there would be a range of the entropy of activation between -10 and -30 e. u. in the present reaction series, corresponding to bonds of varying strength formed in the activated complexes. This is in accordance with our data.

For *p*-methyl- and *p*-methoxy-substituted benzoyl peroxide, the entropies of activation have large negative values, indicating the formation of rigid complexes. On the other hand, the small values of the loss in the entropy of activation for *p*-chloro- and *p*-nitro-substituted benzoyl peroxide may indicate weak bond formation in these complexes.

As may be seen in Table III, there also exists a correlation between the entropy of activation and the energy of activation. In Fig. 2, the values for the reaction between benzoyl peroxide and iron(II) are chosen as the standard, and the difference, $\Delta\Delta S^{\neq}$, in the entropy of activation is plotted against the difference, ΔE, in the energy of activation. It may be seen in Fig. 2 that those two quantities are linearly related to each other. From the slope of the best linear line, the isokinetic temperature, β, where all the reaction rates should become identical, is calculated to be 313°K.

In a previous paper[2], the linear enthalpy-entropy relationship has already been discussed, especially in relation to the solvent effect.

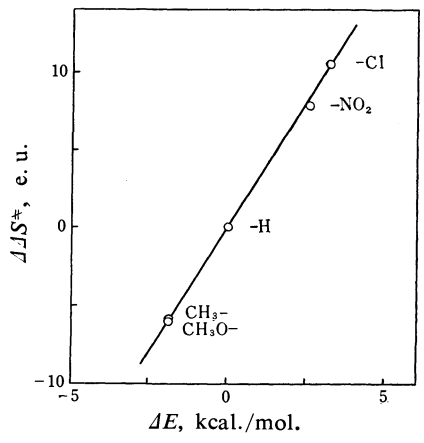

Fig. 2. Relationship between ΔE and $\Delta\Delta S^{\neq}$.

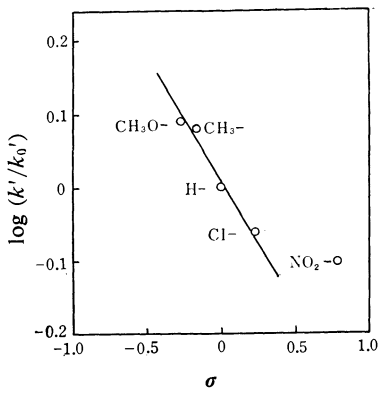

Fig. 3. Hammett's plot of log (k/k_0) against σ.

In Fig. 3, log (k'/k_0') at 27°C is experimentally plotted against σ, where k_0' is the rate constant for the reaction between unsubstituted benzoyl peroxide and iron(II), and the values of k' are those which were estimated from Fig. 1. Allowing for experimental errors, each value seems to fall on a straight line. However, for nitrosubstituted benzoyl peroxide, the deviation is too great to be ascribed to experimental errors.

Blomquist and Ruselli[3], reporting similar results, suggested the possibilities of induced decomposition and a change in the dipole direction. However, further experimental and theoretical information is needed in this field.

Summary

An investigation of the reactions between symmetrically-parasubstituted benzoyl peroxides and iron(II) has been made. From the apparent first order specific reaction rates, which were obtained from the data of the thermal analysis method, the energy and entropy of activation have been estimated. In this reaction series, the linear enthalpy-entropy relationship was observed.

Williams' concept of the coördination of iron(II) to the peroxide molecule was assumed, and the effects of substituents on both the enthalpy of activation and the entropy of activation were discussed. It was also found that the Hammett's equation is approximately applicable, except for nitrosubstituted benzoyl peroxide.

The Activation of Platinum Electrodes by Preoxidation

By Shigeo SHIBATA

(Received October 15, 1962)

It is well-known[1-11] that the activity of a bright platinum electrode is markedly increased by anodic polarization followed by cathodic polarization. To account for the mechanism of this phenomenon, two theories, the impurity theory[4-7] and the oxidation theory[3,8-12], have been proposed. According to the former theory, the activation is due to the removal of the impurities which have been poisoning the electrode. Indeed, some kinds of impurities, even in very small amounts, poison the platinum electrode considerably[13]. On the other hand, the latter theory attributes the increase in activity to the change of nature of the surface itself caused by the successive formation and reduction of superficial oxide layers.

The present work attemps to elucidate this phenomenon by studying the effects of the conditions of the preoxidation on the decay of the activity.

Experimental

As the test electrodes, a number of square-shaped pieces having an apparent area of 1 cm^2 were cut out of one large plate of bright platinum. Each piece was welded to one end of a fine platinum wire, and the other end of this wire was sealed into a glass tube. The electrodes were cleaned successively with hot concentrated hydrochloric acid, hot concentrated nitric acid, and hot chromic acid and washed with distilled water. Then, after being reduced by cathodic polarization in a sulfuric acid solution, they were aged in a hydrogen atomosphere at room temperature for two weeks.

The electrolyte was 1 N hydrochloric acid for the measurement of the hydrogen overpotential and 1 N sulfuric acid for that of the anodic activation. These electrolytes were prepared from, respectively, water and hydrochloric acid, each distilled carefully several times with a quartz still, and from sulfuric acid distilled twice under reduced pressure. Hydrogen gas was prepared by the electrolysis of a sodium hydroxide solution, and it was freed from oxygen by passage through a column of palladium asbestos. The electrodes were activated by either of the two methods, i. e, the anodic polarization with a 0.1 amp./cm^2 current for 0.25, 1 or 28 hr. or soaking in a chromic acid solution at 80±2°C for 1, 15 or 60 min. The electrodes thus oxidized were washed repeatedly with conductivity water, reduced by cathodic polarization with a 20 mamp./cm^2 current for 200 sec., and then introduced into the cell containing the electrolyte saturated with the hydrogen. After the electrode had thus been let alone for a definite time at open circuit, the hydrogen overpotential was measured in the usual manner against the c. d. in order to determine the activity.

The amount of platinum oxide formed by the anodic polarization or by the soaking in the chromic acid was determined by means of chronopotentiometry with another cell with the electrolyte which was freed from oxyen by passing nitrogen gas of 99.99% purity.

The cells for the measurement of the overpotential and for the chronopotentiometry were of all-glass construction, with anode and cathode compartments separated by a fritted-glass disk, and each was equipped with a gas inlet tube. The reference electrode was a saturated calomel electrode in both cases.

All measurements were carried out in a thermostat of 15±0.1°C. All potentials quoted are on the hydrogen scale.

Results and Discussion

The relation between the c. d., i, and the hydrogen overpotential, η, may be expressed as follows[8,13]:

$$i = i_k - i_a = k' e^{-b'\eta} - k' e^{+b''\eta}$$

where i_k is the cathodic c. d. and i_a, the anodic c. d.

When the value of η is sufficiently small,

$$i = -k'(b' + b'')\eta$$

Since k', b' and b'' are constants for a given electrode, a linear relation should then hold between η and i. The slope, $di/d\eta$, of this straight line is proportional to k' and may be

taken as a measure of the activity of the electrode[8,13]. Typical overpotential-c. d. curves for the electrode activated by means of the anodic polarization are shown in Fig. 1. It may be seen in this figure that the activity decreases with an increase in the aging time. The electrodes have almost identical activity immediately after the activation, irrespective of the pretreatment. However the rate of decay of the activity differed according to the method of pretreatment. Furthermore, in both cases the longer the pretreatment, the slower the decay, as is seen in Fig. 2. If the deactivation or the activation was caused only by either the adsorption or the desorption of the trace of impurities contained in the electrolyte, the rate of decay of the activity would be the same, irrespective of the method of activation. At any rate, it may be inferred from the above experimental facts that the surface texture, depending on the condition of preoxidation, is one of the most important factors determining the behavior of the electrode with regard to the activity. It would be reasonable to postulate that the surface texture of the electrode should be changed by the preoxidation, since the electrode surface is visibly "coarsened" when it is repeatedly oxidized and subsequently reduced, as in the case of the alternating current electrolysis[14,15].

When the electrodes were treated with the chromic acid solution, the amount of platinum oxide formed on the surfaces increased with an increase in the periods of soaking in the solution, as may be seen in Fig. 3. The electrode pretreated anoidically reveals, on the other hand, two rests on the chronopotentiogram (Fig. 4.). The amount of oxide reduced at the potential of the first rest is slightly more than that on the electrode pretreated with the chromic acid. The second rest did not appear until the electrode had beeen preliminarily anodically polarized for a sufficiently long time,

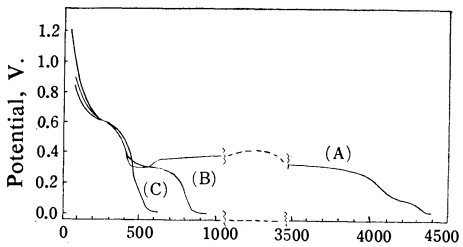

Fig. 4. Cathodic chronopotentiograms for the electrode anodically polarized with 0.1 amp./cm² current in 1 N H_2SO_4 for (A) 28, (B) 1 and (C) 0.25 hr. respectively, $i=10$ μamp./cm².

and the amount of oxide reduced at the potential increased steeply with an increase in the time of the anodic polarization.

The above experimental facts lead the present author to the following hypothesis: as the electrode is oxidized and then reduced, there is formed a very thin layer of unstable atoms, such as a freshly electrodeposited platinum, a layer which has high activity associated with a small crystallization rate[12,16]. The activity decays as the unstable active structure gradually settles down into a more stable state or as, in other words, a sort of recovery takes place in the superficial portion. It would take a long time for a thick activated layer resulting from a thick oxidized layer to recover. It is possible that the electrode is turned so as to be scarcely poisoned at all by the structure change resulting from the preoxidation. In any case, however, it is a reasonable to assume that the structural change itself plays an important part in the activation process.

Summary

The decay of the activity of bright platinum electrodes activated by means both of electrolytic and chemical preoxidations have been studied under a hydrogen atmosphere.

The life of the activity has been shown to depend upon the extent of the oxidation of the surface in the pretreatment. The structural change of surfare caused by the preoxidation appears to be responsibe for the enhanced activity.

Redox Reaction of Tetrahydrofuran Hydroperoxide

By Shinji MURAI, Noboru SONODA and Shigeru TSUTSUMI

(Received November 24, 1962)

The hydroperoxides of various ethers have been synthesized and their decomposition reactions have been reported by several workers[1]. There have been little reports, however, on the redox reaction of the ether hydroperoxide[2,3]. This investigation was carried out to clarify the nature of the reaction of an ether hydroperoxide, and tetrahydrofuran hydroperoxide (THF-HPO) was used as a starting material since it is readily available by the autoxidation of tetrahydrofuran[4] and can be handled without any explosion. The decomposition reaction of THF-HPO was carried out by using some metal ions such as ferrous or cuprous ion.

Results

THF-HPO was decomposed in the presence of ferrous sulfate at $-2\sim3$°C, and hexane-1,6-diol-diformate (I) and γ-butyrolactone (II) were obtained as the main products, and a small amount of 4-hydroxybutanal (III) was isolated as its 2,4-dinitrophenylhydrazone derivative. Hexane-1,6-diol-diformate (I) might be formed by the dimerization of 3-formoxypropyl radical (IV) produced through the β-fission of the carbon-carbon bond of 2-tetrahydrofuranoxy radical (V).

a) The yields were calculated from the gas chromatographic analysis of crude products[9].
b) The yields of this product was estimated as less than 1.0 wt. % by the gravimetric determination of its 2, 4-dinitrophenylhydrazone derivative.

In the presence of metal halide, the dimerization of 3-formoxypropyl radical (IV) was not observed, and halogen derivative, trapped by halogen, was obtained as the main product instead of the dimer. For example, when THF-HPO was added to the suspension mixture of cuprous chloride and cupric chloride in water at 0~5°C, 3-formoxypropyl chloride (VI) was produced in a yield of 42.3% being accompanied by γ-butyrolactone (II) (16.9%) and a trace amount of 4-hydroxybutanal (III). The results obtained are summerized in Tables I and II.

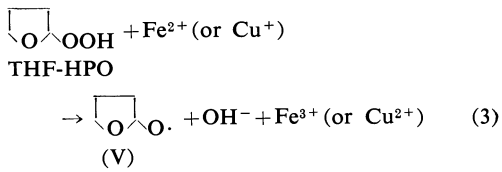
Discussion

A hydroperoxide may decompose in a number of different ways when treated with metal ions having variable oxidation numbers. Equations 1 and 2 would be possible in the reaction of hydroperoxide with ferrous (or cuprous) and ferric (or cupric) ions respectively as the first step of the redox reaction.

$$ROOH + Fe^{2+}(\text{or } Cu^{+}) \rightarrow RO\cdot + OH^{-} + Fe^{3+}(\text{or } Cu^{2+}) \quad (1)$$

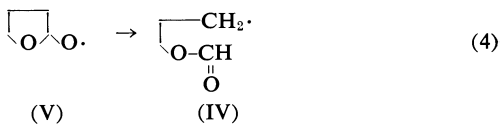
$$ROOH + Fe^{3+}(\text{or } Cu^{2+}) \rightarrow ROO\cdot + H^{+} + Fe^{2+}(\text{or } Cu^{+}) \quad (2)$$

Equation 1 shows a reaction of a hydroperoxide with a metal ion in its lower oxidation state, such as ferrous (or cuprous) ion, and Eq. 2 shows the reaction with a metal ion in its higher oxidation state. At the reaction temperature of −3~5°C, used in these experiments, the reaction 1 may be preferable from the fact that no reaction was observed between THF-HPO and cupric chloride in water solution below 5°C. Thus, 2-tetrahydrofuranoxy radical (V) seems to be produced as the first step of these reactions.

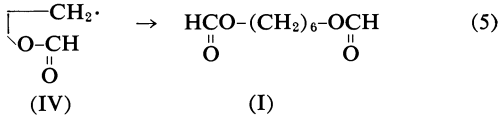


(3)

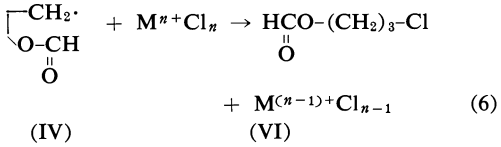
Several reactions of the radical V would be probable as shown below.



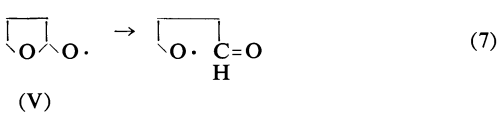
(4)



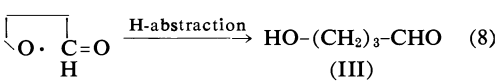
(5)



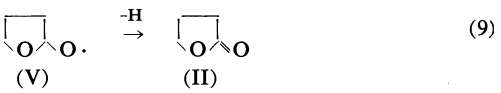
(6)



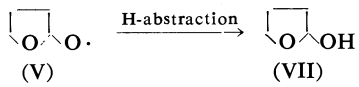
(7)



(8)



(9)



(10)

Equations 4, 7 and 9 show the β-fission of the carbon-carbon, carbon-oxygen and carbon-hydrogen bonds of the 2-tetrahydrofuranoxy radical (V) respectively. Equation 10 is the hydrogen abstraction of the 2-tetrahydrofuranoxy radical (V), giving 2-tetrahydrofuranol (VII).

The 3-formoxypropyl radical (IV) produced in the reaction 4 would dimerize to hexane-1, 6-diol-diformate (I) as shown by Eq. 5. On the other hand, in the presence of additives such as copper chloride, the 3-formoxypropyl radical (IV) gave 3-formoxypropyl chloride (VI) through the path of Eq. 6.

There may be some plausible explanations for such chlorination process. Kumamoto and his coworkers[2] have suggested that the chlorination process is best explicable by chlorine-bridged transition state in which chlorine is transferred to an alkyl radical.

$$R\cdot + M^{n+}Cl_n \rightarrow [R\cdots Cl\cdots M^{n+}Cl_{n-1}]$$
$$\rightarrow RCl + M^{(n-1)+}Cl_{n-1}$$

Recently Minisci[5] has reported the reaction of carbon free radical with some metallic salts and pointed out that such a process may be interpreted by the analogous to that of Sandmeyer's reaction presented by Waters[6]. Kochi[7] has postulated that such a transition state for redox reaction can be well represented as a resonance hybrid between ligand transfer and electron transfer contribution.

$$[R{-}ClM^{+(n-1)} \leftrightarrow R\cdot Cl{-}M^{+n}$$
$$\leftrightarrow R^{\oplus}Cl{-}M^{+(n-1)}]$$

It is considered that the reaction of 3-formoxypropyl radical (IV) would also proceed via the reaction process described above, and dimerization would be inhibited by the more favorable chlorine transfer process.

The reaction 9 gave γ-butyrolactone (II). It might be possible, however, that II was produced through a rather ionic process.

As shown in Eqs. 7 and 8, the product obtained by carbon-oxygen bond fission of 2-tetrahydrofuranoxy radical (V) is 4-hydroxybutanal (III) which is under equilibrium with 2-tetrahydrofuranol (VII). As mentioned above 2-tetrahydrofuranol is also obtained by Eq. 10. The yield of this product is very low and estimated to be less than 1.0 wt. % by 2, 4-dinitrophenylhydrazone gravimetric method. It seems to us from these results that carbon-oxygen bond fission or hydrogen abstraction is more difficult to occur than carbon-carbon or carbon-hydrogen bond fission under these experimental conditions.

From the results of experiments 3 and 4, it is inferred that the addition of chlorine anion has no apparent effect on the yield of 3-formoxypropyl chloride (VI).

Experimental

Material.—THF-HPO[4] used was synthesized by autoxydation of THF at 45°C according to Rein's method. About 20 g. of THF-HPO was obtained from 400 ml. of THF and was purified by distillation, b. p. 40°C/0.2 mmHg. The amount of active oxygen was determined by iodometry, 15.3~15.4% (Calcd. for $C_4H_8O_3$: 15.4%).

Reaction of THF-HPO with Ferrous Sulfate (Exp.1).—To a solution of 27.8 g. of ferrous sulfate heptahydrate in 100 ml. of water was added 10.4 g. of THF-HPO dropwise over the period of 30 min. at −2~3°C under vigorous stirring. The reaction mixture was extracted with ether, and then the extract was dried over anhydrous magnesium sulfate. After the ether was evaporated, the residue was devided into the following two fractions, fraction 1, 2.7 g. of colorless oily liquid: b. p. 102~105°C/27 mmHg, fraction 2, 1.2 g. of colorless oily liquid: b. p. 137~139°C/27 mmHg.

The infrared spectrum of the fraction 1 showed strong bands at 1771 (C=O of lactone) and 1169 cm^{-1} (C-O-C), and was identical with that of γ-butyrolactone (II). This fraction 1 was also identified as II by gas chromatography: column, Silicone DC-550, DNP and PEG; column temperature, 140°C; carrier gas, H_2. The fraction 1 contained 3.7 wt. % of 4-hydroxybutanal (III) identified and determined as its 2, 4-dinitrophenylhydrazone derivative: m. p. 114~115°C (lit.[8] m. p. 116~117°C).

Found: C, 45.44; H, 4.86. Calcd. for $C_{10}H_{12}O_5N_4$: C, 44.78; H, 4.51%.

The fraction 2, b. p. 137~139°C/27 mmHg, was purified by redistillation and showed an identical infrared spectrum with that of an authentic sample of hexane-1, 6-diol-diformate (I): 1720 (C=O) and 1180 cm^{-1} (C-O-C).

Found: C, 55.10; H, 8.12. Calcd. for $C_8H_{14}O_4$: C, 55.16; H, 8.10%.

Reaction of THF-HPO with Cuprous Chloride and Cupric Chloride (Exp. 2).—To the suspension mixture of 12.9 g. of cuprous chloride and 22.1 g. of cupric chloride dihydrate in 100 ml. of water was added dropwise 13.6 g. of THF-HPO over the period of 30 min. under vigorous stirring at 0~5°C. After the reaction mixture was extracted with ether, the ether extract was dried over anhydrous magnesium sulfate, and the ether was removed, and then the residue was separated into two components by the preparative gas chromatography: type, Yanagimoto G. C. G-2, No. 214; column, Silicone DC-550; column temperature, 141.5°C; carrier gas, N_2. The two components were redistilled respectively, fraction 3 of b. p. 65~66°C/27 mmHg and fraction

5) F. Minisci, R. Galli, *Tetrahedron Letters*, p. 533 (1962).
6) D. C. Nonhebel and W. A. Waters, *Proc. Roy. Soc.*, **A242**, 16 (1957).
7) J. K. Kochi, *Tetrahedron*, **18**, 483 (1962).
8) C. L. Wilson, *J. Chem. Soc.*, **1945**, 52.

4 of b. p. 100~105°C/27 mmHg. The fraction 4 was identified as II by gas chromatographic analysis[9]. The infrared spectrum of fraction 3 showed strong absorption bands at 1718 (C=O) and 1180 cm^{-1} (C-O-C) and was identical with that of an authentic sample of 3-formoxypropyl chloride (VI). It shows the same retention time as that of an authentic sample in the gas chromatographic analysis[9]. α-Naphthylurethan derivative of its hydrolysis product, 3-hydroxypropyl chloride, was prepared and mixed melting point with an authentic sample was not depressed, m. p. 76.2~77.2°C.

Found : C, 63.46; H, 5.28. Calcd. for $C_{14}H_{14}O_2 \cdot NCl$: C, 63.76; H, 5.35%.

From the gas chromatographic analysis[9], 8.4 g. of the crude distillate of b. p. 65~102°C/27 mmHg was estimated to contain 6.7 g. of VI and 1.9 g. of II. Compound III was identified and estimated as less than 1.0 wt. % of the crude fraction in the same manner as used in Exp. 1.

Reaction of THF-HPO with Cuprous Chloride and Sodium Chloride (Exp. 3).—To the suspension mixture of 5.7 g. of cuprous chloride and 3.4 g. of sodium chloride in 50 ml. of water was added 6.0 g of THF-HPO at 3~5°C over the period of 25 min. The reaction mixture was treated in the same manner as used above and 3.5 g. of a fraction of b. p. 65~120°C/23 mmHg was obtained. This fraction was estimated to contain 1.7 g. of VI and 1.8 g. of II from the gas chromatographic analysis[9], and also contained a trace of III estimated as less than 1.0 wt. % of this fraction.

Reaction of THF-HPO with Cuprous Chloride (Exp. 4).—To the 8.6 g. of cuprous chloride in 70 ml. of water was added 9.0 g. of THF-HPO at 0~5°C. From the reaction mixture, 3.0 g. of a fraction of b. p. 59~95°C/19 mmHg was obtained. From the gas chromatographic analysis[9], this fraction included 2.3 g. of VI and 0.7 g. of II, and also contained a trace of III identified as its 2, 4-dinitrophenylhydrazone (less than 1.0 wt. % of this fraction).

9) The qualitative and quantative estimations were carried out under the following condition; column, Silicon DC-550; column temperature, 140°C; carrier gas, H_2.

Summary

1) Reaction of tetrahydrofuran hydroperoxide with ferrous sulfate produced hexane-1, 6-diol-diformate (13.8%), which was formed by the dimerization of 3-formoxypropyl radical generated from 2-tetrahydrofuranoxy radical, and γ-butyrolactone (31.4%) and 4-hydroxybutanal (trace).

2) In the presence of metal halide, the dimerization of the 3-formoxypropyl radical did not occur and halogenation of the 3-formoxypropyl radical was observed. For example, when tetrahydrofuran hydroperoxide was reacted with cuprous chloride and cupric chloride, 3-formoxypropyl chloride was obtained in a yield of 42.3%.

3) It is worth nothing that under suitable experimental condition the chloro compound was obtained in a good yield.

4) Probable reaction process was discussed.

The authors wish to thank Dr. Yoshinobu Odaira for his helpful suggestion and encouragement.

The Kinetics of Substitution Reactions Involving Metal Complexes. VIII. Reaction between Copper(II) and Ethylenediaminetetraacetatocobaltate(II) Complexes in Aqueous Solutions

By Nobuyuki TANAKA, Hisao OSAWA* and Minoru KAMADA

(Received November 29, 1962)

In the previous paper[1] the kinetics of the substitution reaction of lead(II) ions and ethylenediaminetetraacetatocobaltate(II) complexes (cabalt(II)-EDTA) was dealt with. The reaction was found to proceed through four simultaneous reaction paths including the reaction paths in which the dissociation of cobalt(II)-EDTA complexes is rate-determining. This kind of rate-determining step was not observed in other substitution reactions[2-8] except the

substitution reaction involving nickel(II)-EDTA complexes[9].

In this paper, the kinetic study of the reaction between copper(II) ions and cobalt(II)-EDTA complexes

$$Cu^{2+}+CoY^{2-} \rightleftarrows CuY^{2-}+Co^{2+} \quad (1)$$

is presented.

Derivation of the Rate Equation

In the preliminary experiments that were carried out in the presence of large excess of cobalt(II) ions and cobalt(II)-EDTA complexes over copper(II) ions, the following facts were found out.

(1) In the solutions of the given pH and the given concentrations of $[Co^{2+}]_{0,app}$, $[Cu^{2+}]_{0,app}$ and $[OAc^-]$, the apparent reaction rate of the forward reaction is proportional to the initial concentration of Co(II)-EDTA ($[CoY^{2-}]_0$), and $k^+/[CoY^{2-}]_0$ is independent of $[CoY^{2-}]_0$, where k^+ means the apparent rate constant of the forward reaction, the subscript 0 means zero time, and $[Cu^{2+}]_{app}$ and $[Co^{2+}]_{app}$ represent the apparent concentrations that can be determined polarographically[10]. In the solutions that contain less than 0.2 M of acetate ions, $[Cu^{2+}]_{app}$ and $[Co^{2+}]_{app}$ are given by

$$[Cu^{2+}]_{app}=[Cu^{2+}]+[CuOAc^+]+[Cu(OAc)_2]$$
$$[Co^{2+}]_{app}=[Co^{2+}]+[CoOAc^+] \quad (2)$$

(2) In the solutions of the given pH and the given concentrations of $[Co^{2+}]_{0,app}$, $[CoY^{2-}]_0$ and $[OAc^-]$, the apparent reaction rate is proportional to $[Cu^{2+}]_{0,app}$, and $k^+/[CoY^{2-}]_0$ is independent of $[Cu^{2+}]_{0,app}$.

(3) In the solutions of the given concentrations of $[Co^{2+}]_{0,app}$, $[CoY^{2-}]_0$, $[Cu^{2+}]_{0,app}$ and $[OAc^-]$, $k^+/[CoY^{2-}]_0$ is a linear function of the hydrogen ion concentration, and given by the equation

$$k^+/[CoY^{2-}]_0=k_\xi+k_\eta[H^+] \quad (3)$$

where k_η is dependent on the value of $[Co^{2+}]_{0,app}$.

(4) In the solutions of the given pH and the given concentrations of $[CoY^{2-}]_0$, $[Cu^{2+}]_{0,app}$ and $[OAc^-]$, $k^+/[CoY^{2-}]_0$ is a linear function of the reciprocal of $[Co^{2+}]_{0,app}$ and given by the equation,

$$k^+/[CoY^{2-}]_0=k_\varepsilon+k_\gamma/[Co^{2+}]_{0,app} \quad (4)$$

These observed facts clearly indicate that the mechanism of the reaction between copper(II) ions and cobalt(II)-EDTA complexes would be the same as the reaction between copper(II) ions and lead(II)-EDTA complexes[5] but not the reaction between lead(II) ions and cobalt(II)-EDTA complexes[1].

After the analogy of the reaction between copper(II) ions and lead(II)-EDTA complexes, the present reaction is considered to proceed through three simultaneous reaction paths.

$$\text{(i)}\quad Cu^{2+}+CoY^{2-} \underset{k_1^-}{\overset{k_1^+}{\rightleftharpoons}} CuY^{2-}+Co^{2+} \quad (5)$$

$$\text{(ii)}\quad CoY^{2-}+H^+ \rightleftharpoons CoHY^- \quad (6a)$$

$$Cu^{2+}+CoHY^- \underset{k_{II}^-}{\overset{k_{II}^+}{\rightleftharpoons}} CuHY^-+Co^{2+} \quad (6b)$$

$$CuHY^- \rightleftharpoons CuY^{2-}+H^+ \quad (6c)$$

$$\text{(iii)}\quad CoY^{2-}+H^+ \underset{k_a^-}{\overset{k_a^+}{\rightleftharpoons}} Co^{2+}+HY^{3-} \quad (7a)$$

$$Cu^{2+}+HY^{3-} \underset{k_{III}^-}{\overset{k_{III}^+}{\rightleftharpoons}} CuY^{2-}+H^+ \quad (7b)$$

Assuming that the reaction proceeds through the hydrated ions, the apparent rate of the forward reaction v^+ is expressed as Eq. 8.

$$v^+=k^+[Cu^{2+}]_{app}=\left\{\frac{k_1^++k_2^+[H^+]+k_3^+[H^+]\dfrac{1+K_{CoOAc}[OAc^-]}{[Co^{2+}]_{app}}}{1+\sum_{n=1}^{2}K_{Cu(OAc)_n}[OAc^-]^n}\right\}\times[Cu^{2+}]_{app}[CoY^{2-}] \quad (8)$$

where

$$k_2^+=k_{II}^+K_{CoHY}^H,\quad k_3^+=k_{III}^+/(K_{CoY}K_{HY}) \quad (9)$$

$K_{Cu(OAc)_n}$, K_{CoOAc} and K_{CoY} represent the formation constants of acetatocopper(II), acetatocobalt(II) and cobalt(II)-EDTA complexes, respectively, K_{HY}, the fourth dissociation constant of ethylenediaminetetraacetic acid, and K_{CoHY}^H, the equilibrium constant of Eq. 6a.

Experimental

The preparation of the solutions of copper(II) nitrate, cobalt(II) nitrate, disodium ethylenediaminetetraacetate and sodium acetate-acetic acid buffers was described in the previous paper[10]. Sodium carbonate, acetic acid and other reagents used for the supporting electrolyte were of guaranteed reagent grade and used without further purification.

The rate of the reaction between copper(II) ions and cobalt(II)-EDTA complexes was followed by measuring the change of the polarographic diffusion current of copper(II) ions with time in acetate buffer solutions at 5 and 15°C. The apparatus used was the same as described in the previous

9) N. Tanaka, Y. Sakuma and G. Satô, presented at the 12th Annual Meeting of the Chemical Society of Japan, Kyoto (1959), Lecture No. 1032.

10) N. Tanaka, M. Kamada, H. Osawa and G. Satô, This Bulletin, 33, 1412 (1960).

paper[1]. The experimental procedure was also given previously[4,6,8].

Results

Since the kinetic measurements are carried out in the solutions that contain cobalt(II) ions and cobalt(II)-EDTA complexes in excess over copper(II) ions, the substitution reaction can be treated as a pseudo first-order reaction, and the apparent reaction rate is expressed as

$$-\frac{d[Cu^{2+}]_{app}}{dt}=k^{+}[Cu^{2+}]_{app}-k^{-}[CuY^{2-}] \tag{10}$$

where k^{+} and k^{-} are the apparent rate constants for the forward and the reverse reaction, respectively.

Comparing Eq. 8 with Eq. 10, Eq. 11 is obtained

$$\frac{k^{+}}{[CoY^{2-}]_0}=\left\{\frac{k_1^{+}+k_2^{+}[H^{+}]+k_3^{+}[H^{+}]\dfrac{1+K_{CoOAc}[OAc^{-}]}{[Co^{2+}]_{0,app}}}{1+\sum_{n=1}^{2}K_{Cu(OAc)_n}[OAc^{-}]^{n}}\right\} \tag{11}$$

where the initial concentrations, $[Co^{2+}]_{0,app}$ and $[CoY^{2-}]_0$, are substituted for $[Co^{2+}]_{app}$ and $[CoY^{2-}]$, respectively.

The values of $k^{+}/[CoY^{2-}]_0$ were obtained at various pH's at two different concentrations of cobalt(II) ions but at the same concentrations of other species, and plotted against the hydrogen ion concentration. The plots for 15°C are given in Fig. 1, which indicate linear relations existing between $k^{+}/[CoY^{2-}]_0$ and $[H^{+}]$. Similar relations were observed also at 5°C.

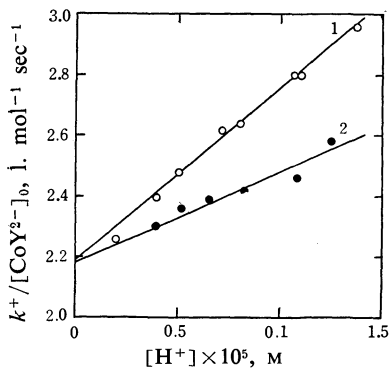

Fig. 1. $k^{+}/[CoY^{2-}]_0$ as a function of the hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 15°C. Initial concentrations are: $[Cu^{2+}]_{0,app}=2.0\times10^{-4}$ M; $[CoY^{2-}]_0=5.00\times10^{-3}$ M; $[Co^{2+}]_{0,app}=5.00\times10^{-3}$ M (curve 1) and 15.00×10^{-3} M (curve 2). Concentration of free acetate is 0.10 M.

The rate constants in Eq. 8 were calculated from the plots in Fig. 1, when $K_{Cu(OAc)_n}$ and K_{CoOAc} that were reported in the previous papers[10,11] were employed. With these constants, the rate constants for both elementary reactions 6b and 7b were calculated using Eqs. 9 and the values of K^{H}_{CoHY}, K_{CoY} and K_{HY} which were evaluated with the same procedure as described previously[4,6]. The results were given in Table I.

TABLE I. RATE CONSTANTS FOR REACTIONS 5, 6b AND 7b AT IONIC STRENGTH 0.2

Temp. °C	Rate constant, l. mol^{-1} sec^{-1}		
	k_1^{+}	k_{II}^{+}	k_{III}^{+}
5	7.0	(1.2×10^{2}) a)	(3.1×10^{8}) a)
15	15.3	(1.5×10^{2}) a)	(6.2×10^{8}) a)

a) Values in parentheses are less accurate.

Discussion

The rate constant k_{III}^{+} for the reaction

$$Cu^{2+}+HY^{3-}\xrightarrow{k_{III}^{+}}CuY^{2-}+H^{+}$$

has been determined in the studies of other substitution reactions. These are given in Table II with the value obtained in this study, where it is seen that the value obtained with the substitution reaction between copper(II) ions and cobalt(II)-EDTA complexes is considerably smaller than those obtained with other substitution reactions.

In reaction path iii, the concentration of HY^{3-} is given by

$$[HY^{3-}]=\frac{k_a^{+}[CoY^{2-}]+k_{III}^{-}[CuY^{2-}]}{k_a^{-}[Co^{2+}]+K_{III}^{+}[Cu^{2+}]}[H^{+}] \tag{12}$$

The rate of reaction path iii, therefore, is expressed as Eq. 13, where v_3^{+} and v_3^{-} are the rates of the forward and the reverse reaction of path iii, respectively. When the condition

$$k_{III}^{+}[Cu^{2+}]\ll k_a^{-}[Co^{2+}] \tag{14}$$

is assumed, Eq. 13 can be reduced to a simpler

$$v_3=v_3^{+}-v_3^{-}=\frac{k_a^{+}k_{III}^{+}[CoY^{2-}][Cu^{2+}]-k_a^{-}k_{III}^{-}[CuY^{2-}][Co^{2+}]}{k_a^{-}[Co^{2+}]+k_{III}^{+}[Cu^{2+}]}[H^{+}] \tag{13}$$

form and the apparent rate of the forward reaction v_3^{+} is given by

$$v_3^{+}=k_3^{+}\frac{[H^{+}]}{[Co^{2+}]}[Cu^{2+}][CoY^{2-}]$$
$$=k_3^{+}\frac{1+K_{CoOAc}[OAc^{-}]}{1+\sum_{n=1}^{2}K_{Cu(OAc)_n}[OAc^{-}]^{n}}\frac{[H^{+}]}{[Co^{2+}]_{app}}\times[Cu^{2+}]_{app}[CoY^{2-}] \quad (15)$$

In the substitution reaction between copper(II) ions and cobalt(II)-EDTA complexes, the condition given in Eq. 14 was found not to be satisfied. The ratio of $k_a^{-}[Co^{2+}]$ to $k_{III}^{+}[Cu^{2+}]$ $(=(k_a^{-}[Co^{2+}])/(k_{III}^{+}[Cu^{2+}]))$ that was calculated with k_{III}^{+} and k_a^{-} obtained in this and the previous[1] studies respectively ranged from 0.7 to 4 under the experimental condition. When Ep. 14 is not fulfilled, $k^{+}/[CoY^{2-}]_0$ can not be a linear function of $1/[Co^{2+}]_{0,app}$.

The experimental results, however, showed that $k^{+}/[CoY^{2-}]_0$ was proportional to the reciprocal of $[Co^{2+}]_{0,app}$ and independent of $[Cu^{2+}]_{0,app}$. This discrepancy may arise from a small contribution of reaction path iii to the overall reaction. Percentage of the contribution of each reaction path to the overall reaction is given in Table III, which clearly shows that the reaction proceeding through reaction path iii gives only minor contribution to the whole reaction. This fact supports the linearity between $k^{+}/[CoY^{2-}]_0$ vs. $1/[Co^{2+}]_{0,app}$ obtained in the experiments. Consequently, it seems reasonable to consider that the rate constant of reaction path i, k_1^{+}, obtained in this study is acceptable.

It is interesting to compare the substitution reaction between copper(II) ions and cobalt(II)-EDTA complexes with that between lead(II) ions and cobalt(II)-EDTA complexes. In the former the contribution of the reaction path i to the whole reaction is approximately 90%, whereas in the latter it is only several per cents. In reaction path iii, the dissociation of cobalt(II)-EDTA complexes is rate-determining in the reaction between lead (II) ions and cobalt(II)-EDTA complexes but not in the reaction between copper(II) ions and cobalt(II)-EDTA complexes. This suggests that the dissociation of cobalt(II)-EDTA complex is not so slow.

Summary

The kinetic study of the substitution reaction of copper(II) ions and cobalt(II)-EDTA complexes in acetate buffer solutions has been carried out with the same procedure as that reported previously. The reaction was found to proceed, under the experimental conditions, through three simultaneous reaction paths similar to those found in the substitution

reaction of copper(II) ions and lead(II)-EDTA complexes. The rate constants for three elementary reactions of those reaction paths were determined at ionic strength 0.2 at 5 and 15°C. A reaction path in which the dissociation of cobalt(II)-EDTA complex is rate-determining was not observed in this substitution reaction.

The Angular Dependency of the ESR Proton Hyperfine Coupling Constant of the CH_2 Group

By Keiji MOROKUMA and Kenichi FUKUI

(Received November 29, 1962)

Recent ESR studies of organic radicals in the solid state have revealed several interesting facts on the structures of these radicals. One of these facts is that, in some radicals, the β protons--the protons in the methyl or methylene groups adjacent to the carbon atom which brings an odd electron—are chemically distinct from each other.

Heller and McConnell[1] have studied the ESR spectra of a γ irradiated single crystal of succinic acid, analyzing them to show that the radical produced was identified as in Fig. 1a and that the coupling constants (nearly isotropic) of the two protons, H_1 and H_2, were

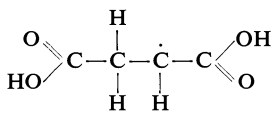

Fig. 1a

not equal. They concluded that the distinction was caused by a kind of deformation of the CH_2 group: the H-C-H angle was no longer bisected by the molecular plane. They assumed the following equation for the angular dependency of the coupling constant of β-protons:

$$a_H(\theta) = \rho_\alpha{}^0 K\cos^2\theta \qquad (1)$$

In the equation, $a_H(\theta)$ is the isotropic hyperfine coupling constant of β protons, $\rho_\alpha{}^0$ is the spin density on the carbon (α carbon) adjacent to the methylene group, and θ is the angle between the carbon pπ orbital on the α carbon and each of the C-H bonds, both

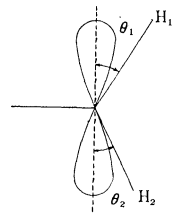

Fig. 2. Projection angles θ_1 and θ_2.

projected to a plane perpendicular to the $C_\alpha-C_\beta$ bond, as is shown in Fig. 2. In this equation they seem to have assumed that the type of deformation would be the rotation of the alkyl group around the $C_\alpha-C_\beta$ axis.

Kurita and Gordy[2] then found a similar distinction between the two protons in a CH_2 group in studying the ESR of the γ irradiated single crystal of L-glycine hydrochloride. In this case the radical was identified as that shown in Fig. 1b, and the coupling constants

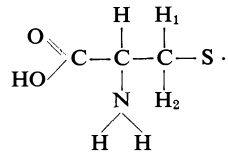

Fig. 1b

were $a_{H_1}=9$ gauss and $a_{H_2}=2$ gauss. If we simply applied Eq. 1 to the discussion of the a_{H_1}/a_{H_2} ratio, the deformation would have to be very large. Pooley and Whiffen[3] have also observed different coupling constants of β protons in the $HOOCCH_2\dot{C}HCOOH$ radical

1) C. Heller and H. M. McConnell, *J. Chem. Phys.*, **32**, 1535 (1960).

2) Y. Kurita and W. Gordy, ibid., **34**, 282 (1961).

3) D. Pooley and D. H. Whiffen, *Mol. Phys.*, **4**, 81 (1961).

from succinic acid (100 Mc and 80 Mc). Jasejà and Anderson[4] have obtained a different pair of unequal coupling constants (115 Mc and 18 Mc) in the same $HOOCCH_2\dot{C}HCOOH$ radical from aspartic acid, attributing the cause of the deformation to intermolecular forces. In both of the papers the deformation angle was discussed by the $\cos^2\theta$ rule.

Recently Ohnishi, Sugimoto and Nitta[5] have carefully studied the temperature dependency of the ESR spectra of the radical in γ-irradiated stretched polyethylene which had been assigned to the allyl-type radical shown in Fig. 1c; they have found that, at a low temperature ($-180°C$), the protons in CH_2 groups adjacent to the allyl group, H_1 and H_2 in the figure, give different isotropic hyperfine coupling constants, that is, 30 and 11 gauss respectively, while at a high temperature

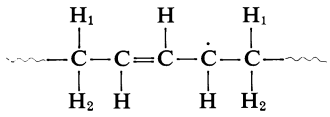

Fig. 1c

($+142°C$) the distinction disappears and the both constants become 21.3 gauss. By using Eq. 1, the calculated θ values of H_1 and H_2 are obtained as 55°02′ and 18°52′. The deviation from the normal angle, 30°, seems irrationally large.

As the mechanism of deformation, the rotation would be more difficult in the case of a methylene group, CH_2R, than in the case of a methyl group, CH_3, because of the bulky group—COOH, alkyl and so forth—attached to the former. Especially in polymeric solids like stretched polyethylene, the R group being a very long chain, the rotation around the $C_\alpha-C_\beta$ axis would be almost entirely hindered. In this case the deformation would be performed by rocking, twisting, or in other ways.

In the present paper considering two typical mechanisms of deformation: one is the rotation around the $C_\alpha-C_\beta$ axis, and the other is the rocking of the CH_2 group on a plane on which normally the two C–H bonds of the CH_2 group exist, we make a valence bond calculation on the spin density on CH_2 protons for their various conformations caused by the rotation and the rocking, in order to see what angular dependency proton hyperfine coupling constants on CH_2 groups obey.

The fact that we assumed rotation and rocking as a source of non-equivalent coupling constants does not necessarily mean that the energy minimum is accomplished by these kinds of deformation. The possibility that one hydrogen is attracted to the odd p orbital, making a bent bond, might be considered, as well as a possibility of twisting. It would be very interesting to study theoretically what is the most stable conformation and why such a deformed conformation could be stable, but the calculation needed in order to explain such a slight difference in conformational energy seems to be excessively complicated, and hence this problem will not be discussed in this paper.

Method of Calculation

In calculating the ground state wave function and the spin density in the state we employed the hypothetical system, consisting of five valence electrons on the five atomic orbitals, as is shown in Fig. 3: the $2p\pi$ orbital (designated by P) on the carbon α in which an odd electron is situated, the two hybridized

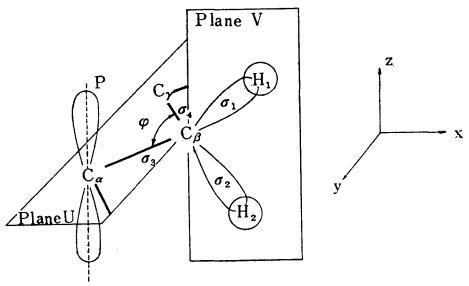

Fig. 3. The model of calculation and the notation used.

orbitals (σ_1 and σ_2) on the carbon β, and the two 1s orbitals (H_1 and H_2) on the two hydrogens which are bonding with the hybridized orbitals, σ_1 and σ_2 respectively. In their normal conformation, the $C_\alpha C_\beta C_\gamma$ chain is situated on the U plane and the two CH bonds are on the V plane, which is perpendicular to the U plane and which bisects the $C_\alpha C_\beta C_\gamma$ angle.

All canonical structures that have the maximum bondings, that is, five structures, are taken as the bases of the valence bond calculation, but all ionic structures were disregarded. This disregard would result in a larger spin density on hydrogen atoms, but we are going to discuss only the relative change of the spin distribution caused by the variation in conformation because of an uncertainty involved in evaluating atomic integrals that will be mentioned later, and in this the disregard does not affect the conclusion.

4) T. S. Jasejà and R. S. Anderson, *J. Chem. Phys.*, **36**, 2727 (1962).
5) S. Ohnishi, S. Sugimoto and I. Nitta, ibid., **37**, 1283 (1962).

Throughout the calculations the deformation is considered to cause the corresponding change in the hybridization of the carbon orbitals making the deformed bonds, and the hydrogen atoms are always regarded as in the direction of the hybridized orbitals, with a CH bond length which is not changed by the deformation.

In treating rotating conformations, the four hybridized orbitals, σ_1, σ_2, σ_3 and σ_4, remain sp^3 hybridized. The calculation of the spin density was made for various rotated angles around the $C_\alpha-C_\beta$ axis.

In treating the rocking conformation, the hybridized orbitals on the carbon β are written with the two parameters a and b. Parameter a corresponds to the variation in the $C_\alpha C_\beta C_\gamma$ angle. The reason why we considered this kind of deformation is that, for instance, regarding the allyl type radical in oriented polyethylene mentioned above, the polyethylene main chain would be fixed, and in order to decrease the strain the allyl radical might change the angle, φ, of $C_\alpha C_\beta C_\gamma$. In our calculations the angle φ is expressed in terms of parameter a, which designates the hybrization of the orbitals, σ_3 and σ_4; a^2 is the s nature of the orbitals σ_3 and σ_4, as can be seen in the following:

$$\varphi=\cos^{-1}[a^2/(a^2-1)] \tag{2}$$

$$\left.\begin{aligned}\sigma_3&=a\psi_{\beta 2s}-\sqrt{(1-2a^2)/2}\ \psi_{\beta 2px}\\&\quad+(\sqrt{2})\ \psi_{\beta 2py}\\\sigma_4&=a\psi_{\beta 2s}-\sqrt{(1-2a^2)/2}\ \psi_{\beta 2px}\\&\quad-(1\sqrt{2})\ \psi_{\beta 2py}\end{aligned}\right\} \tag{3}$$

where $\psi_{\beta 2s}$, $\psi_{\beta 2px}$ and $\psi_{\beta 2py}$ are 2s, 2px and 2py orbitals respectively on the β carbon, the coordinates being taken as in Fig. 3.

In any conformation with a varied a value and with various magnitudes of rocking of the two CH bonds, it is assumed that the $C_\alpha C_\beta C_\gamma$ chain and, consequently, the σ_3 and σ_4 orbitals are always on the U plane, which is perpendicular to the odd p orbital, P, and that the σ_1, σ_2, H_1 and H_2 orbitals are on the V plane, parallel to P and bisecting angle φ. The other parameter, b, is utilized to stand for the hybridization of the σ_1 orbital: b^2 being the s nature of the orbital σ_1, the s nature of the orbital σ_2 is $1-2a^2-b^2$. The exact form of the σ_1 and σ_2 orbitals is written as follows:

$$\left.\begin{aligned}\sigma_1&=b\psi_{\beta 2s}+(\sqrt{2}\,ab/\sqrt{1-2a^2})\psi_{\beta 2px}\\&\quad+(\sqrt{1-2a^2-b^2}/\sqrt{1-2a^2})\psi_{\beta 2pz}\\\sigma_2&=\sqrt{1-2a^2-b^2}\ \psi_{\beta 2s}+(\sqrt{2}a\sqrt{1-2a^2-b^2}\\&\quad/\sqrt{1-2a^2})\ \psi_{\beta 2px}-(b/\sqrt{1-2a^2})\psi_{\beta 2pz}\end{aligned}\right\} \tag{4}$$

Calculations were carried out for the following three values of a:

Series 1: $a=1/2$, i.e., σ_3 and σ_4 are both sp^3 hybridized (s nature: 25%), and, consequently, the $C_\alpha C_\beta C_\gamma$ angle is 109°28′ (normal). The hybridization of σ_1 is varied from sp^3 to p, at the same time as that of σ_2 is varied from sp^3 to sp.

Series 2: $a=1/\sqrt{5}$: σ_3 and σ_4 are both sp^4 hybridized (s nature: 20%), and, consequently, the $C_\alpha C_\beta C_\gamma$ angle is 104°29′, narrower than normal.

Series 3: $a=\sqrt{3/10}$: σ_3 and σ_4 are both s^3p^7 hybridized (s nature: 30%), and the $C_\alpha C_\beta C_\gamma$ angle is 114°23′, more obtuse than normal.

The angles, θ_1 and θ_2, defined in Fig. 2 are easily connected with the parameters, a and b, as follows:

$$\left.\begin{aligned}\tan\theta_1&=ab/\sqrt{1-2a^2-b^2}\sqrt{1-a^2}\\\tan\theta_2&=a\sqrt{1-2a^2-b^2}/b\sqrt{1-a^2}\end{aligned}\right\} \tag{5}$$

The following relationship between the θ_1 and θ_2 angles as a function of parameter a but independent of parameter b will be used in the following section in checking the calculated results:

$$\tan\theta_1\tan\theta_2=a^2/(1-a^2) \tag{6}$$

Matrix elements between the canonical structures are reduced to those between hybridized orbitals by the usual method; they are also reduced to those between atomic orbitals by Eqs. 3 and 4.

The atomic exchange integrals requisite to the calculation are evaluated according to the methods proposed by van Vleck[6] and by

TABLE I. VALUES OF EXCHANGE INTEGRALS EMPLOYED (in unit of eV.)

Exchange integrals between C_β and H

$N_{\pi\pi'\pi'\pi}$	0.026

6) J. H. van Vleck, ibid., 1, 219 (1933); 2, 20 (1934).

Karplus et al.[7] The values of the integrals employed are collected in Table I. The N_{rs}'s in the Table are the following exchange integrals between C_β and H_1 or H_2:

$$N_{rs}=-\int\psi_{\beta r}(1)\psi_{H1s}(2)\cdots H\psi_{H1s}(1)\psi_{\beta s}(2)\cdots d\tau \quad (7)$$

H: Total Hamiltonian

and are evaluated from the dissociation energy of methane and the heat of the sublimation of graphite. All N_{rs}'s between C_α and H_1 are neglected because they are small. The F_0's and F_2 and G_1 are the usual one-center atomic integrals of C_β, whose values are deduced from the spectroscopic data of a carbon atom. The exchange integral $[H_1, H_2]$ between H_1 and H_2 is calculated on the Morse function as a function of their interatomic distance. There seems no reliable method available for evaluating the exchange integrals N_{rstu} between C_α and C_β:

$$N_{rstu}=\int\psi_{\alpha r}(1)\psi_{\beta s}(2)\cdots H\psi_{\beta t}(1)\psi_{\alpha u}(2)\cdots d\tau \quad (8)$$

In this paper, except for $N_{\pi\pi\pi\pi}$, the effective two-electron Hamiltonian approximation by Karplus[7] is used, giving the following results:

$$N_{rstu}=\int\psi_{\alpha r}(1)\psi_{\beta s}(2)e^2/r_{12}\psi_{\beta t}(1)\psi_{\alpha u}(2)d\tau_1 d\tau_2 \quad (9)$$

$$\left(\begin{array}{l}\text{for } (r,u)=(2p\pi,\ 2p\pi)\\ \quad\ s,t=2s,\ 2p\sigma,\ 2p\pi'\end{array}\right)$$

As to $N_{\pi\pi\pi\pi}$, Altman's result[8] is adopted.

The overlap integrals between atomic orbitals are entirely disregarded in order to simplify the calculations.

Results and Discussion

The calculated spin densities on protons for rotating conformations of various angles are tabulated in Table II, together with the spin densities on β carbon hybridized orbitals. From the spin density, ρ_H, on the proton, one can calculate the coupling constant, a_H, by the following equation:

$$a_H=Q\rho_H \quad (10)$$

Q being the coupling constant of the proton when ρ_H is unity. In the normal conformation, both θ_1 and θ_2 are 30°. The spin density on a proton does not seem to be dependent only on its own projection angle, θ_1 for instance, but also on the angle of the other proton, for instance θ_2, which one can see by comparing Calculation Nos. 1 and 4, where ρ_H is different for the same θ, 30°. The situation is the same in Calculation Nos. 3 and 5. Roughly speaking, however, it varies in accord with $\cos^2\theta$, as one may see in Fig. 4. In Fig. 4 the $\rho_H=\text{const}\times\cos^2\theta$ curve is drawn so as to fit the calculated result (Calcd. No. 1) at $\theta=30°$. Accordingly, it may be said that the $\cos^2\theta$ rule may be utilized for the hyperfine coupling of CH_2 protons in the rotating conformation.

The spin density on the hybridized orbitals increases with the increased spin density on the proton of the CH bond, as is seen in Table II. Thus, as the isotropic coupling constant of the methylenic proton (deformed by rotation) becomes large, the anisotropy of the coupling will also grow large, though the magnitude of anisotropy seems to be negligibly small.

conformations are collected in Tables III, IV and V, together with the spin densities on β carbon hybridized orbitals and the s nature of the latter. The angular dependency of proton spin densities in the case of rocking conformations is entirely different from that in the case of rotating conformations, as is illustrated in Fig. 5. It should be stressed that the $\cos^2\theta$ rule by no means applies to the proton coupling of the methylene group in the rocking conformation; the proton coupling constant varies more rapidly with the projection angle, θ. If one tries to use the $\cos^2\theta$ rule for the rocking methylene group, one will be led to a larger deformation from the normal sites than is really the case. Actually, the rotation,

* Observation temperature

the rocking and other kinds of deformation would take place in the methylene group, which gives unequal proton coupling constants for the two protons. Therefore, minute care should be taken in discussing the deformation angle of the methylene group on the basis of its proton coupling constants.

The proton spin density in the case of this deformation is not simply a function of θ. For instance, the negative spin density on the proton nearly on plane U (for example, −0.0459 in Calcd. No. 7 in Table III) does not seem to originate from the direct interaction of the CH bond with the odd orbital, P, but from the mixing of the interaction of the CH bond with the other CH bond and of the interaction of the latter with orbital P. This is shown by a valence bond calculation of the system consisting of the three atomic orbitals (P, σ and H orbitals of the bond in plane U): the proton spin density in this case is calculated to be −0.0036, which is ten times smaller in magnitude than the spin density shown above.

Actually, there may occur other kinds of deformation than rotation and rocking. So far as the spin density is concerned, other deformations, twisting for instance, might be derived as a mixing of rotation and rocking in the first approximation.

The effect of the $C_\alpha C_\beta C_\gamma$ angle, φ, on the proton spin density may be seen by comparing Table III with Tables IV and V, or in Fig. 5. Generally speaking, the larger value of φ results in the larger (in absolute value) proton spin density for the same hybridization or the same b value, though the difference is relatively small. In a minute discussion this difference should be taken into consideration, but for a rough estimation of the rocking angle, the calculated spin density and its interpolation for the normal φ value (Table III) may safely be used.

The spin density on β carbon hybridized orbitals varies almost in parallel with that on the proton in the bond, as can also be seen in Tables III, IV and V. Thus, the anisotropy of the proton coupling constant becomes important for protons whose projection angle is smaller than 20°.

Application to the Allyl-Type Radical in Oriented Polyethylene

We would like to apply the results of the preceding section to the coupling constants of the two non-equivalent protons in the methylene group adjacent to the allyl-type radical in oriented polyethylene, which were observed by Ohnishi et al.[5] Application to this problem would be appropriate and rational because, as has been mentioned previously, the allyl radical, which is produced midway in an oriented polyethylene molecule, would not be able to rotate because of the long main chain of the molecule, but it would be able to rock, because rocking needs no motion of the main chain.

The coupling constants they observed are given in Table VI, where −180°C is the temperature at which the deformation of the methylene group seems to be entirely frozen to the minima of the potential energy (probably double minima on either side of the normal conformation) and +142°C is the one at which the transformation from one minimum to the other is perfectly free.

At first, for comparison, the $\cos^2\theta$ rule is employed to estimate the projection angle. If 21.3 gauss at +142°C is assumed to correspond to $\theta=30°$, 30 gauss at −182°C cannot be achieved by any θ value (Table VI). On the other hand, if an empirically deduced $K=58$ gauss and the SCF π spin density on the α carbon of allyl radical $\rho_\alpha^0=0.622$ are used for Eq. 1, an unexpectedly large deformation from the normal angle (30°) is obtained (Table VI).

In our valence bond calculation, an odd electron on the π carbon orbital (P) interacting with β CH bonds is treated. However,

in the allyl radical, which is a conjugated system, the number of odd electrons on P is not unity but ρ_α^0. Therefore, instead of Eq. 10, Eq. 11 may be used in the first approximation:

$$a_H = \rho_\alpha^0 \rho_H Q \tag{11}$$

Q is theoretically given as 507 gauss and $\rho_\alpha^0 = 0.622$, as stated above, while a_H is observed, ρ_H can then be calculated, and, consequently, the θ angle will be deduced. However, as the numerical value of the calculated proton spin density, ρ_H, may include some error caused by the approximations employed, e. g., disregard of overlap integrals or of ionic structures, it seems more rational to take ρ_H as compared in its relative value. That is to say, regarding the product, $\rho_\alpha^0 Q$, as a parameter to be decided experimentally, we connect the observed a_H to ρ_H and θ and use one more relation, Eq. 6, to check the consistency of the assignment.

First we assume that the radical has the conformation where $a^2 = 0.250$, that is, $\varphi = 109°28'$. Then the coupling 21.3 gauss at +142°C will correspond to the normal site, $b^2 = 1/4$ and $\theta_1 = \theta_2 = 30°00'$, and from the calculated $\rho_H = +0.0817$ of this case, $Q\rho_\alpha^0$ is obtained as 261 gauss.* Using this, and interpolating the calculated spin density in Series 1 (Table III), the values of θ in Table VI, 24°20' and 39°10', are obtained. This set of θ_1 and θ_2 comes to the relation $\tan\theta_1 \tan\theta_2 = 0.368$ and, with the aid of Eq. 6, $a^2 = 0.269$, which is larger than the assumed value, $a^2 = 0.250$.

Secondly, if the conformation of the radical is assumed to be the case, $a^2 = 0.333$, i. e., $\varphi = 114°23'$; hence we obtain the results in the last line of Table VI and $a^2 = 0.317$, which is smaller than the assumed value.

Thus, the value of a^2 in the allyl radical obtained is between 1/4 and 1/3, and therefore φ lies between 109°28' and 114°23'; a widening of the $C_\alpha C_\beta C_\gamma$ angle from the tetrahedral angle seems to take place in this allyl-type radical. The deformation from the equivalent sites derived by our rocking model is 6° to 9°, which is much smaller and more probable than 18° or more obtained by the $\cos^2\theta$ rule.

By considering the difference of the bond length between the CC single bond and the allyl CC bond, the widening of the $C_\alpha C C_\gamma$ angle is proved to be probable for the radical as a means of reducing the strain[5].

In the present paper we applied our calculations based on the rocking conformations only to the allyl-type radical in polyethylene, but the unequal couplings of some organic radicals in single crystals and in rigid glass also seem to have to be partly reexamined in the light of this finding.

Summary

Valence-bond calculations of the angular dependency of the proton coupling constants of the methylene group in the ESR spectra have been carried out. If the rotation of the group is the only type of deformation, the $\cos^2\theta$ rule by McConnell seems to be valid. If the rocking of the group takes place, however, the angular dependency is entirely different from the $\cos^2\theta$ rule, and the deformation angle based on the rocking model is much smaller than that derived by the $\cos^2\theta$ rule. This finding has been applied to the unequal coupling constants of the two methylene protons of the allyl-type radical in polyethylene.

The authors are much indebted to Dr. Shun-ichi Ohnishi for his showing them his experimental results on the allyl-type radical in polyethylene before publication. Numerical calculations were carried out by means of the KDC-I Digital Computer of Kyoto University.

* Here if $\rho_\alpha^0 = 0.622$ is applied, $Q = 420$ gauss is obtained. When we compare this with the theoretical value, 507 gauss, we recognize some effect of disregarding ionic structures, like $C^- H^+$, which makes the calculated spin density on protons larger than it is.

The Electronic Structures and Antioxidizing Activities of Substituted Phenols

By Keiji Morokuma, Hiroshi Kato and Kenichi Fukui

(Received January 7, 1963)

The autooxidation of several organic substance-for instance, petroleum hydrocarbons, rubber and oil-has long been studied by many authors and has been well recognized as a radical chain reaction. Such antioxidants as substituted phenols and anilines work as chain-breaking inhibitors of the peroxy radical:

$$RO_2\cdot + IH \rightarrow ROOH + I\cdot \qquad (1)$$

while the radical I· from the inhibitor is less reactive and can initiate a new chain reaction only with difficulty, as was first discovered by Bolland and ten Haave[1].

From the theoretical point of view, Fueno et al.[2] studied, in the simple LCAO MO approximation of π electronic systems, the relation between the highest occupied π electronic level and the oxidation potential of various hydroxy derivatives of aromatic hydrocarbons, and also the relation between the highest occupied level or the stabilization energy of the transition complex and the antioxidizing efficiency.

In the present paper the antioxidizing activity of substituted phenols is discussed in connection with their σ electronic structure as well as with their π electronic structure.

The π Electronic Structure and Antioxidizing Activity of Substituted Phenols

According to Boozer, Hammond et al.[3-5], the overall inhibition reaction, Eq. 1, does not necessarily mean that the rate determining step of the inhibition is the hydrogen abstraction reaction, for *N*-methylaniline-*N*-*d* and diphenylamine-*N*-*d* showed the same efficiency as the undeuterated compounds. They therefore proposed the following mechanism:

$$\left.\begin{aligned} &RO_2\cdot + IH \rightarrow [RO_2\cdot \leftarrow IH] \\ &\qquad\text{(rate-determining)} \\ &RO_2\cdot + [RO_2\cdot \leftarrow IH] \rightarrow \\ &\qquad\text{inactive product} \end{aligned}\right\} \qquad (2)$$

$[RO_2\cdot \leftarrow HI]$ is a molecular complex between the inhibitor and the radical, and the first complex-formation step is rate-determining. On the nature or structure of the complex no decisive fact seems to have been revealed.

In this section π molecular orbital calculations will be given, and the complex will be discussed. The parameters of the Coulomb and the resonance integrals are as follows: $\alpha_O = \alpha + 0.51\beta$, $\beta_{O-C'} = 0.57\beta$, $\alpha_{C'} = \alpha + 0.05\beta$[6]; $\alpha_{CH_3} = \alpha + 3\beta$, $\beta_{C''-CH_3} = 0.7\beta$, $\alpha_{C''} = \alpha - 0.1\beta$; and $\alpha_{C(adj.\ to\ t\text{-butyl})} = \alpha - 0.2\beta$.

The *t*-butyl group is taken as a purely inductive group, while the methyl group as partly inductive and partly hyperconjugative, hyperconjugation being treated by the well-known one-atom model[7].

The Highest Occupied π Level.—It has often been thought that, no matter what the structure of a molecular complex, the ionization potential of the electron donor and the electron affinity of the acceptor decide the ease of complex formation[8-10]. Some comparisons[11] of the oxidation potential and the antioxidizing efficiency (induction period) have supported this probability. In the molecular orbital sense, the ionization potential is the absolute value of the energy of the highest occupied π orbital. We compared the calculated energy of the highest occupied π level with the relative value of the molecular antioxidizing potency of the 2, 4, 6-substituted phenols measured by Rossenwald et al.[12], as is shown in the third and the

fourth columns of Table I. In the table, the methyl and/or *t*-butyl substituted phenols are divided into three classes—one consisting of 2, 2-di-*t*-butyl phenols (class A), another of 2-*t*-butyl phenols (class B), and the third consisting of phenols with no *t*-butyl group at the 2 and 6 positions (class C). A parallelism between the potency and the energy of the highest occupied π level is observed within each class of compounds, suggesting that the smaller ionization potential will result in an easier formation of the complex and, therefore, in a larger potency. Fueno et al.[2] also compared the highest occupied level and antioxidizing efficiency of some hydroxy derivatives of aromatic hydrocarbons, but they interpreted a similar parallelism in a little different sense. Assuming that the efficiency is fully controlled by the dissociation reaction, ROH$\rightarrow$ RO$\cdot$ + $\cdot$H, and dividing the heat of dissociation into the constant σ electronic contribution and the variable π electronic contribution, ΔH_π(RO–H), they found that, in a simple approximation, ΔH_π(RO–H) is nothing but the energy of the highest occupied level. In this connection, the σ electronic structure and the antioxidizing efficiency will be discussed in the next section. Pederson's ionic model[13] also seems to be certified by this parallelism:

$$RO_2\cdot + IH \rightarrow RO_2^- + IH^+ \qquad (3)$$

13) C. J. Pederson, *Ind. Eng. Chem.*, **48**, 1881 (1956).

but a complete one-electron transfer would be more difficult than a partial electron transfer, which is accomplished in the molecular complex.

The Delocalization Energy of the Complex.— In a more concrete model of the complex proposed by Russel[14,15] and by Walling and Mayahi[16], it is assumed that the peroxy radical will probably approach the inhibitor from the direction perpendicular to the aromatic ring in order to interact with the π electrons on it. If this is true, the delocalization calculation of the molecular complexes[9,10] will be appropriate. Assuming that the radical stays on the axis which stands from the center of the benzene ring and which is perpendicular to the ring and that it interacts with the six π atomic orbitals on it to the same extent (cf. the assumed model of the complex shown in Fig. 1), we obtain the following stabilization energy, ΔE_1, of this model by the perturbation treatment:

$$\Delta E_1=\left(\sum_i^{occ}-\sum_i^{unocc}\right)\frac{(\sum_r C_{ir})^2}{\lambda_i}\gamma^2\beta \qquad (4)$$

where $\gamma\beta$ is the resonance integral between the half-occupied orbital of peroxide and a π AO

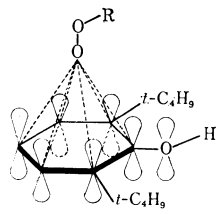

Fig. 1

on the ring, and $\sum_r$ should cover all the AO's on the benzene ring of the compound. The results shown in the fifth column of Table I seem to allow this possibility, too. The charge is transferred from the inhibitor to the peroxy radical in this model.

Another model of the complex would be such as is illustrated in Fig. 2, in which the peroxy

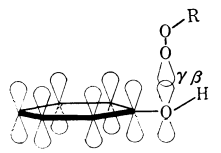

Fig. 2

radical approaches the phenol oxygen so as to interact with the pπ orbital on it. If the peroxy radical is assumed to have one atomic orbital and one electron available to conjugation with the inhibitor, the stabilization energy of the interaction by the second order perturbation treatment is nothing but the superdelocalizability of the oxygen for the radical reaction, $S_O^{(R)}$ *,[17]:

$$S_O^{(R)} = \left(\sum_i^{occ} - \sum_i^{unocc}\right) \frac{(C_{iO})^2}{\lambda_i} \qquad (5)$$

Setting this model, Fueno et al.[2] found a good linear relationship between the logarithm of relative antioxidizing efficiency proposed by Bolland and ten Haave[1] and the superdelocalizability for several unsubstituted phenols**.

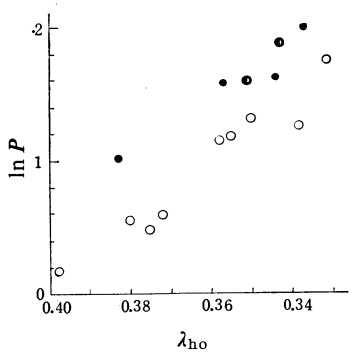
We calculated the superdelocalizability, $S_O^{(R)}$, for this series of compounds, obtaining a good parallelism with the potency in each class, as is shown in the sixth column of Table I. Thus, the model in Fig. 2 may be one of the possible structures of the complex in Eq. 2.

Some inhibitor radicals produced by the reaction, Eq. 1 or 2, may sometimes initiate a new chain reaction as follows[19,20]:

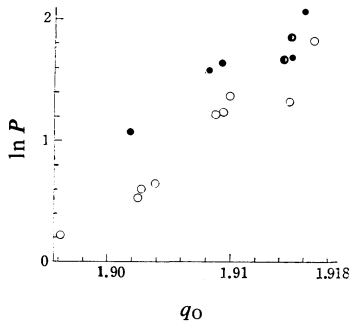
$$I\cdot + RH \rightarrow IH + R\cdot \qquad (6)$$

or

$$IO_2\cdot + RH \rightarrow IOOH + R\cdot \qquad (7)$$



a) The highest occupied level



b) Total π electron density on oxygen atom

17) K. Fukui, T. Yonezawa and C. Nagata, This Bulletin, **27**, 423 (1954).

* As the interacting orbital is not the pseudo-π orbital but the half-occupied orbital of the peroxy radical, the quantity should be rather named "delocalizability" instead of "superdelocalizability".

** In their paper the formula for the transferred charge includes a part of the fourth-order terms mixed with the following correct second order term[18]:

$$\Delta q(\text{second order}) = \left(\sum_i^{occ} - \sum_i^{unocc}\right) \frac{(C_{iO})^2}{(\lambda_i)^2} \gamma^2$$

18) K. Fukui, T. Yonezawa and C. Nagata, *J. Chem. Phys.*, **27**, 1247 (1957).

19) A. F. Bickel and E. C. Kooyman, *J. Chem. Soc.*, **1956**, 2215; **1957**, 2415.

20) W. A. Waters and C. Wickham-Jones, ibid., **1951**, 812.

Ingold[21] has recently proposed to classify the inhibitors into two groups: one, "strong" inhibitors which react very rapidly with the peroxy radical to break the chain reaction, and the other, "efficient" inhibitors each of whose phenoxy radical produced by the reaction (Eq. 1 or 2) is stable enough not to initiate any new chain reaction. Sterically hindered inhibitors are "efficient" inhibitors, for their phenoxy radical is protected from the reactions to follow.

It would be interesting here to discuss the difference in potency among the classes. In Fig. 3 are plotted the calculated indexes against the logarithm of potency. With regard to each index the plots of class A and of class B fall on one line, while those of class C fall on another line. Compounds of classes A and B are both restricted with the bulky *t*-butyl group. The linear relationship found in both these two classes seems to suggest that the restriction would be enough by one *t*-butyl substitution. Judging from the models, the calculated indexes seem to represent only the "strength" of the inhibitors; therefore, the difference, which is estimated from Fig. 3 to be of the order of $\Delta \log P = 0.4$, should probably be attributed to the difference in the "efficiency".

The Total π Electron Density on the Oxygen Atom. — The total π electron density on the oxygen atom, q_O, has also been calculated; as given in the last column of Table I and in Fig. 3b, it is found to possess a good parallelism with the antioxidizing potency. Since, in a radical reaction such as the attack of the peroxy radical, the total π electron density can no longer be the reactivity index, this parallelism would have to be interpreted as indicating that the electron density may affect some other quantity which in turn, has a direct influence upon the reaction. In the next section the total electron density will be taken as affecting the σ electronic structure of the O-H bond.

The σ Electronic Structure and Antioxidizing Activity of Phenols

In this section σ molecular orbital calculations on phenol will first be presented, and then the antioxidizing activity will be discussed in connection with the σ electronic structure.

LCAO MO calculations of the σ electronic structure of conjugated molecules have been carried out with respect to hydrocarbons[22], halides[23] and aldehydes[24], while the parameters of the Coulomb and the resonance integrals of hydrogen and carbon atoms had been determined already[22]. The parameters for phenolic oxygen have been determined to be as follows*: the Coulomb integral of oxygen is settled to be $\alpha_\sigma + 0.3\beta_\sigma$ in accord with that of aldehyde oxygen, β_{O-O} (one center) $= 0.29\beta_\sigma$ from the σ MO treatment of alcohols and peroxides[25], $\beta_{C-O} = 0.6\beta_\sigma$, in accord with the small overlap integral $S(C_{sp^2} - O_p,\ 1.43\text{Å}) = 0.37$, in comparison with $S(C_{sp^2} - C_{sp^2},\ 1.34\text{Å}) = 0.77$ and $\beta_{OH} = 0.7\beta_\sigma$, also with reference to $S(O_p - H_s,\ 0.96\text{Å}) = 0.35$. To make the results more reliable, a calculation with another parameter, $\beta_{OH} = 1.1\beta_\sigma$, has also been made.

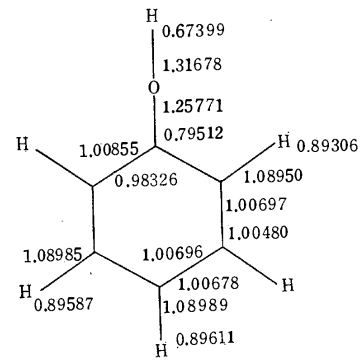

Fig. 4. Total σ electron density of phenol ($\alpha_O = \alpha_\sigma + 0.3\beta_\sigma$, $\beta_{OH} = 0.7\beta_\sigma$).

Figure 4 gives the calculated total σ electron density of phenol, where we can see a clear inductive effect of the oxygen atom. The small σ electron density and, accordingly, the large net positive charge on phenolic hydrogen seem to correspond to its strong acidity. In Table II are gathered the reactivity indexes—delocalizabilities, $D_H^{(N)}$, $D_H^{(E)}$ and $D_H^{(R)}$, for

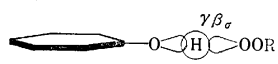

Fig. 5

nucleophilic, electrophilic and radical abstractions of phenolic and para hydrogens, corresponding to the model in Fig. 5. The definition of D_H is as follows[29]:

$$D_H = \sum_i^{\text{all}} (\nu_i - k) \frac{(C_{iH}^\sigma)^2}{\lambda_i^\sigma} \qquad (8)$$

a) In unit of $\gamma^2\beta_\sigma$

where ν_i is the number of electrons on the ith σ MO, λ_i^σ is the coefficient of the energy, ε_i^σ, of the ith σ MO, $\varepsilon_i^\sigma=\alpha_\sigma+\lambda_i^\sigma\beta_\sigma$ and $k=0, 1, 2$, according to electrophilic, radical, nucleophilic reactions respectively, and the energy of the reagent X is assumed to be equal to α_σ. If we assume that the change in the reactivity index will be proportional to the square of β_{OH}, as in Fig. 6, $(\beta_{OH})^2$ must be smaller than $0.9(\beta_\sigma)^2$ in order to agree with the experimental findings that phenolic hydrogen is more liable than *p*-hydrogen to radical abstraction reactions. Our choice, $\beta_{OH}=0.7\beta_\sigma$, is supported by this finding.

Now we are going to discuss the relation between the σ electronic structure and antioxidizing activity. Experimentally, either no isotope effect or only a small one on activities have been observed between substituted phenols and their *O*-deuterated species[21] more than between aromatic amines and their *N*-deuterated derivatives[3-5]. Therefore, the molecular complex formation has been considered to be rate-determining. However, there are also some reports which have reported some isotope effects[26,27]. Furthermore, if the earlier stage of the hydrogen abstruction reaction is the transition state of antioxidation, there would naturally be little isotope effect. It would be worth while to study the possibility of such a mechanism. The delocalizability would be capable of being a measure of this mechanism, since this index is derived from a model in Fig. 5 composed of a molecule and a reagent weakly interacting with each other, upon perturbation treatment.

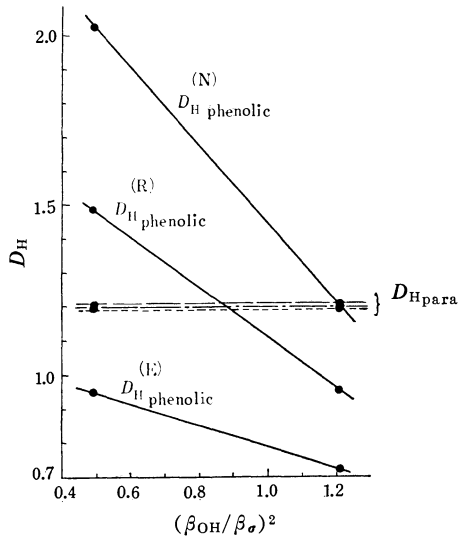

Fig. 6. Crossing of delocalizability of phenolic and para hydrogens.

For an attack of the peroxy radical, a quantity named $D_H^{(R)}(0.3)$ would be more appropriate than $D_H^{(R)}$;

$$D_H^{(R)}(0.3)=\left(\sum_i^{occ}-\sum_i^{unocc}\right)\frac{(C_{iH}^\sigma)^2}{\lambda_i^\sigma-0.3} \qquad (9)$$

This index fits the model in Fig. 5 if the Coulomb integral of the orbital X is equal not to α_σ (in the case of $D_H^{(R)}$) but to $\alpha_\sigma+0.3\beta_\sigma$, the Coulomb integral of the oxygen atom. As is shown in Table III, the high reactivity of phenolic oxygen is indicated also by $D_H^{(R)}(0.3)$. Although all ring hydrogens have almost the same reactivities, the relative reactivity of each position seems to show a slight

26) J. R. Shelton and E. T. McDonel, *J. Polymer Sci.*, 32, 75 (1958).
27) J. R. Shelton, E. T. McDonel and J. C. Crano, ibid., 42, 289 (1960).

difference according to the index, $D_H^{(R)}$ or $D_H^{(R)}$ (0.3).

The parallelism between the total π electron density on oxygen and the antioxidizing activity, which we demonstrated in the previous section, might be interpreted as follows: the total π electron density on the oxygen atom, increased by methyl and *t*-butyl substitutions, will necessarily decrease the electronegativity of the oxygen and make the Coulomb integral of the σ orbitals on oxygen more positive. This change in the Coulomb integral then causes the changes in the σ electronic structure of phenol, especially at the O–H bond. Tentatively putting the Coulomb integral of the oxygen σ orbital as equal to $\alpha_\sigma+0.25\beta_\sigma$, instead of its normal value $\alpha_\sigma + 0.3\beta_\sigma$, we obtain the values of the indexes $D_H^{(R)}$ and $D_H^{(R)}$ (0.3) shown in Table III. As one can clearly see in the table, for an ordinary radical attack, in which $D_H^{(R)}$ would be the index, the reactivity of phenolic hydrogen would hardly be influenced by the change in the total π electron density of oxygen, while for an electronegative radical (such as the peroxy radical) attack, in which $D_H^{(R)}(0.3)$ would be the index, the reactivity is much elevated by an increased π electron density on oxygen.

In order to discuss the change in reactivity, the difference in the calculated total π electron density in Table I should be translated into the difference in $D_H^{(R)}(0.3)$. The change in the Coulomb integral $\Delta\alpha$ caused by the change in the electron density, Δq, on the atom is often estimated by the equation:

$$\Delta\alpha=\omega\Delta q \qquad (10)$$

where ω is a proportionality constant and would have a value ranging from $0.2\beta_\sigma\sim2\beta_\sigma$*. The difference in the total π electron density between the largest and the smallest (phenol) ones in Table I, 0.02, would make the change in the Coulomb integral $\Delta\alpha=0.004\beta_\sigma\sim0.04\beta_\sigma$. Since the change in $D_H^{(R)}$ (0.3) would be proportional to the change in the Coulomb integral, the difference in $D_H^{(R)}$ (0.3), 0.1037, for $\Delta\alpha_0=0.05\beta_\sigma$ (in Table III) would make $\Delta D_H^{(R)}(0.3)=0.0083\sim0.0830$ between the most reactive and the least reactive compounds. These magnitudes of the difference seem to be almost sufficient to explain the experimental differences in antioxidizing activity.

Summary

We have tested several models and their molecular orbital indexes of the rate-determining step of antioxidization by substituted phenols. Some molecular complex models have been found to be rational, though the problem of which of them is actually the true mechanism of the chain-breaking inhibition of autooxidation cannot yet be settled. Another possibility, that the earlier stage of the hydrogen abstraction reaction may be the rate-determining step, cannot yet be abandoned.

The numerical calculations have been carried out on the KDC-I digital computer of Kyoto University.

* ω is the difference in the Coulomb integral between the two states, one of which has one more electron than the other. The difference, which is interpreted as being that between the ionization potential and the electron affinity of oxygen in its valence state, would be about 15 eV.[28] As the unit $\beta\sigma$ is estimated to be ca. -7 eV.[23], ω would be ca. $2\beta\sigma$. On the other hand, the ω value, which is often used in π electronic calculations is $0.5\beta\pi\sim2\beta\pi$, and, referring to the ratio $\beta\pi/\beta\sigma\sim1/3$[23], $\omega=0.2\beta\sigma\sim0.7\beta\sigma$ seems to be rational.

Magnetic Study of the Amino Group

By S. SRIRAMAN and D. SHANMUGASUNDARAM

(Received November 29, 1962)

The theoretical evaluation of the magnetic susceptibility may be done in two different ways (1) either by considering the atomic contribution of the constituent atoms of the molecule together with suitable constitutive correction or (2) by taking the compound as ionic and adding the contribution of ions. The former one has had wider applications than the latter. In the additive method the process suggested by Ingold[1] seems to be preferable due to the fact that it allows for the calculation, the contribution of atoms and multiple bonds as if there were no interactions. The difference between such calculated value and the experimental value is attributed as due to the interaction or conjugation involved in the system. The method suggested by Yang[2] on the other hand treats the shared electron in the covalent bond as ionic and the structures of molecules of covalent compounds are explained accordingly. But the method has got its own limitations as Yang himself pointed out that it requires, for example, different sets of paramagnetic susceptibilities for carbon ion. Still the method enables one to evaluate the contribution of different ions to the magnetic susceptibility.

In the present investigation, an attempt is made to evaluate the contribution due to NH_2^{1+}. Using this data, the χ_M of different compounds are calculated and compared with the experimental values and with theoretical values calculated by using the atomic and bond values suggested by Ingold. Any difference found from the experimental value has been explained as arising due to conjugation and interaction involved in the system. The contribution due to NH_2^{1+} can be found either from primary amines or from amino acids. In this investigation primary amines both aliphatic and aromatic have been studied.

Experimental

The substances used were mostly Merck G. R. or B. D. H.; A. R. The liquids were all distilled and collected exactly at the corresponding boiling

point. The solids were all purified by standard methods and the purification was continued till specimens of constant susceptibility were obtained. Great care was taken to prevent absorption of atmospheric moisture.

Measurement of susceptibilities of the liquids were made with a Guoy[9] balance. A correction has been applied for the residual air above the liquid surface. Since uniformity of packing is difficult to achieve in the case of solids the Curie[10] retorsion method was preferred. A.R. benzene dried over sodium wire and distilled over phosphorus pentoxide was used as standard and its specific susceptibility was taken as -0.702×10^{-6} units.

Results

The results obtained for the amines are recorded in Table I, the observed values were the mean of six very closely agreeing values. The theoretical values (column 4) were calculated by taking atomic and bond values as given by Ingold[1].

Evaluation of $(NH_2)^{1+}$ Contribution.—It is well known that in the aliphatic primary amines, the unshared electrons are in the tetrahedral orbital of non-interacting type. Hence the contribution of the $(NH_2)^{1+}$ has been derived from the experimental values of five such amines. In this evaluation the modified ionic values of Angus[11] has been used wherever necessary. It has been further assumed that the removal of a proton does not affect the ionic susceptibilities. This evaluation from these amines gives fairly consistent values for the $(NH_2)^{1+}$ ion, and the values thus obtained are recorded in Table II. The average value of $(NH_2)^{1+}$ works out to be 8.50.

Discussion

The $(NH_2)^{1+}$ value thus obtained has been utilized to calculate χ_M by Yang's method for aromatic compounds. The values are given in Table III.

The last column gives the exaltations observed in the aromatic amines and these can be explained on the basis of molecular orbital theory. The exaltations that are observed is the result of two interactions arising due to the transfer of tetrahedral orbital of the 'N' atom to the p orbital which results in a negative exaltation and the intermingling of the p orbital of the substituting NH_2 group with the π orbital of the benzene ring which yields a positive exaltation. The NH_2^{1+} value was obtained from the aliphatic amines in which the 'N' atom is in the tetrahydral orbital and so the $\Delta\chi_M$ observed is due to the above mentioned interactions. The $\Delta\chi_M$ is negative in all the cases except in *o*-chloroaniline where it is +2.00. In ortho chloroaniline the intramolecular hydrogen bond keeps the molecule in plane and so the full effect of the p orbital with the aromatic π orbital results in a rather positive exaltation.

9) S. R. Rao and A. S. Narayanasamy, *Proc. Ind. Acad. Sci.*, **9**, 35 (1939).
10) S. R. Rao, ibid., **A1**, 123 (1934).
11) W. R. Angus, *Proc. Roy. Soc.*, **A136**, 569 (1932).

Paramagnetic Contribution of N^{3+} Ion.—The close agreement among the calculated values by Yang's method and that of Ingold's additive method shows that the derived value of $(NH_2)^{1+}$ from aliphatic amines is consistent. Hence this value can be conveniently used for the derivation of the ionic susceptibility of the nitrogen ion N^{3+}.

$$(NH_2)^{1+} = -8.50$$

$$\chi_{N^{3+}} + 2\chi_{\theta} + 2\chi_{H^{1+}} = -8.50$$

Using the value of χ_{θ} as -4.88

$$\therefore \chi_{N^{3+}} = +1.26$$

Thus we are led to the conclusion that the ion N^{3+} posseses a paramagnetic susceptibility value. But Angus[11] gives a value of -2.09. The paramagnetic value that is obtained by Yang's method for the ion N^{3+} has been utilized and calculated for triethylamine.

$$\chi_{(C_2H_5)_3N} = \chi_{N^{3+}} + 3\chi_{M_2{}^{1-}} = -84.54$$

The additive method based on Ingold's value gives χ_M as 85.1 which is in fair agreement with that of the value obtained by Yang's method.

Summary

The diamagnetic susceptibilities of several aliphatic and aromatic amines have been determined. The susceptibility contribution, of $NH_2{}^{1+}$ is evaluated from the noninteracting aliphatic amines, and this value is used for calculation of χ_M of aromatic amines. The exaltations are attributed to the interactions in the system. An anomalous value for N^{3+} ion is obtained.

The Dissolution and Anion Exchange Behavior of Rare Earth and Other Metallic Elements in Potassium Bicarbonate, Potassium Carbonate and Ammonium Carbonate Solutions

By Tomitsugu TAKETATSU

(Received December 8, 1962)

In a previous paper[1] the present author reported that rare earth ions dissolved in potassium and ammonium carbonate solutions were adsorbed on an anion exchange resin and that the amounts both dissolved and adsorbed increase with the increase in atomic number, except for cerium and yttrium.

In this paper, the state of the dissolution and anion exchange behavior of rare earth ions in a potassium bicarbonate solution, as well as that of other metallic ions (thorim, zirconium, aluminum, gallium, indium, uranyl, beryllium, zinc, cadmium, copper, nickel, cobalt and lead ions) in potassium bicarbonate, potassium carbonate and ammonium carbonate solutions, will be studied. By using the results, the application for analytical separations will be discussed.

Experimental

Standard solutions of the metallic ions investigated were prepared by dissolving the reagent grade oxides (lanthanum, prasodymium, neodymium, samarium, gadolinium, dysprosium, erbium, yttrium and gallium), the chlorides (indium, zinc, cadmium, copper, nickel and cobalt) and the nitrates (zirconium, thorium, aluminum, cerium(III), beryllium and uranium(VI)) in dilute chloric or nitric acid. The concentrations of these ions, except for beryllium, were volumetrically determined with EDTA by using xylenol orange (XO), pyrocatechol violet (PV), eriochrome black T (EBT), PAN and murexide (MX) as indicators[2]. The concentration of beryllium was determined gravimetrically as the oxide.

As the anion exchange resins, Dowex 1, X-8 in carbonate and bicarbonate forms, of 50~100 mesh, were used.

All the other chemicals used were of a analytical reagent grade.

The measurement of the amounts of metallic ions dissolved in potassium bicarbonate, potassium carbonate and ammonium carbonate solutions, and of the distribution coefficient, K_d, of the metallic ions between an anion exchange resin and their solutions were carried out by a previously reported procedure[1]. All the experiments were

2) K. Ueno, "Chelate Titration", Nankodo, Tokyo (1960), pp. 205-330.

carried out at room temperature, which was about 20°C.

Results and Discussion

The determination methods and the quantities of metallic ions used in this experiments are shown in Table I.

The Relation between the Concentration of Potassium Bicarbonate Added and the Amount of Rare Earth Bicarbonate Dissolved. — When an excessive amount of potassium bicarbonate in a solution was added to the rare earth chloride or nitrate, first the rare earth bicarbonate was precipitated, and then the precipitate was dissolved partially or completely by shaking. Figure 1 plots the amounts of the rare earth ions dissolved against various concentrations of potassium bicarbonate. It can be seen that the amounts of rare earth ions dissolved increase with the increase in the concentration of bicarbonate, and also with the increase in atomic number, except for cerium and yttrium. Since cerium is partially oxidized to the tetrapositive state in the bicarbonate solution, its behavior differs from that of other rare earth elements. This finding is similar to that

-○- Potassium bicarbonate -×- Potassium carbonate

obtained by using potassium carbonate. However, the precipitates of the light lanthanons (lanthanum, praseodymium and neodymium) can scarcely be dissolved, even in 1.8 M. On the other hand, the heavy lanthanons (dysprosium, erbium and yttrium) can easily be dissolved in a bicarbonate solution of even lower concentrations. For example, the precipitates of samarium, gadolinum, dysprosium, erbium and yttrium bicarbonates are dissolved completely in a bicarbonate solution more concentrated than about 1.95, 1.20, 0.60, 0.40 and 0.25 M respectively. For comparison, the results for several rare earth ions obtained by using potassium carbonate are also plotted in Fig. 1. The variation in the amounts of rare earth ions dissolved in a potassium bicarbonate solution of a certain concentration is more remarkable than in a potassium carbonate solution. Therefore, it is expected that the separation of rare earth elements from each other can be carried out by a fractional separation using the distinct difference.

The Relation between the Adsorbabilities of the Rare Earth Ions and the Concentration of Potassium Bicarbonate.—When the precipitates of rare earth ions were dissolved completely, the anion exchange behavior of these rare earth ions was studied by the batch operation. The distribution coefficient, K_d, is given by

$$K_d = [M_r] / [M_s] \quad (\text{ml./g.})$$

where M_r and M_s are the amount of rare earth ions in one gram of the resin and in one milliliter of the solution respectively. The plot of the distribution coefficient of rare earth ions against various concentrations of potassium bicarbonate is shown in Fig. 2. It can there be seen that the adsorbability of rare earth ions decreases as the concentration of the potassium bicarbonate increases and that the order of the K_d values is yttrium > erbium > dysprosium. However, the differences in these values are very small. Although gadolinium and samarium are dissolved completely in the bicarbonate solution, these ions can only with difficulty be adsorbed on the resin because of the high concentration of the bicarbonate.

When the logarithmic diagram of the K_d value of the rare earth ions against the concentrations of potassium bicarbonate is plotted, the slope of the $\log K_d$ vs. $\log(HCO_3^-)$ curve shows linearity and the lines are parallel to one another with a negative slope. Therefore, it may be concluded, according to a method developed by Kraus et al.[3], that each rare earth ion dissolved in a bicarbonate solution is in a state of identical negative charge.

The Dissolution and Anion Exchange Behavior of the Various Metallic Ions in a Potassium Bicarbonate Solution. — The relation between the amounts of the various metallic ions dissolved and the concentration of potassium bicarbonate was investigated. The results are shown in Fig. 3. The precipitates of thorium, zirconium, gallium and uranyl ions were dissolved at once, while those of beryllium, copper, nickel and cobalt ions were dissolved gradually in those bicarbonate solutions more concentrated than about 0.2 M.

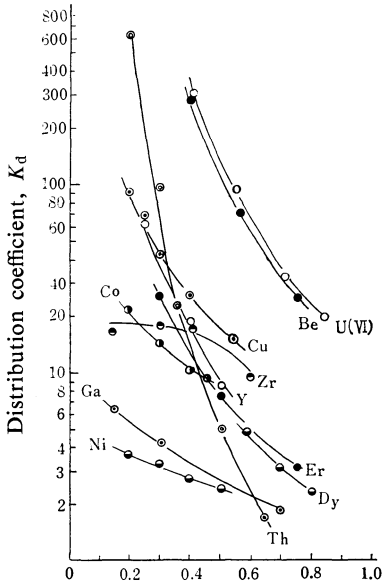

Fig. 2. Distribution coefficient of rare earth and other metallic ions between Dowex 1 and potassium bicarbonate solution.

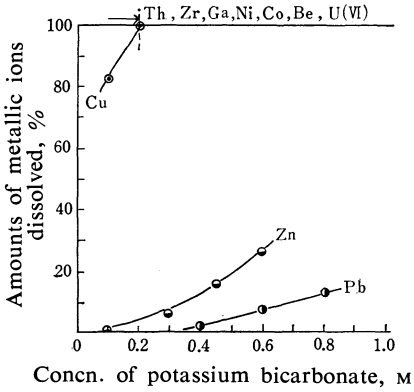

Fig. 3. Relation between the concentration of potassium bicarbonate and the amounts of various metallic ions dissolved.

3) K. A. Kraus and F. Nelson, "Anion Exchange Studies of the Fission Products", in "Peaceful Uses of Atomic Energy", Vol. VII, Proceedings of the International Conference in Geneva (United Nations) (1955), p. 113.

However, the precipitates of lead, zinc and indium could not be dissolved completely, even in 1.0 M.

The plot of the K_d values of the metallic ions dissolved completely in the bicarbonate solution against the concentration of potassium bicarbonate is given in Fig. 2. The K_d values of these metallic ions decrease with the increase in the concentration of potassium bicarbonate. Uranyl and beryllium ions are adsorbed firmly on an anion exchange resin, while copper and cobalt ions are adsorbed less firmly. On the other hand, gallium and nickel ions are adsorbed weakly. The K_d value of zirconium ions is different at different time intervals in the measurement, and so it is difficult to obtain a constant value. This fact is also found in the case of using a potassium carbonate solution, as is described below. It seems that this behavior is a result of the complicated state of the soluble zirconium ion. From the distinct differences in the K_d values, it is expected that uranyl and beryllium ions can be effectively separated from other metallic ions, as well as can copper ions from cobalt and nickel ions, by an anion exchange resin, with the potassium bicarbonate solution as the eluting agent.

The Dissolution and Anion Exchange Behavior of the Various Metallic Ions in a Potassium Carbonate Solution.—The plot of the amounts of the various metallic ions dissolved against the concentration of potassium carbonate is in Fig. 4. It can be seen that uranyl, thorium, zirconium and aluminum ions are dissolved completely in a potassium carbonate solution more concentrated than about 0.2 M, while beryllium, zinc, copper and indium ions can not be dissolved completely, even in 1.0 M.

The relation between the K_d values of the metallic ions dissolved completely in a potassium carbonate solution and the concentration of the carbonate is shown in Fig. 5. Figure 5 shows that the K_d values of uranyl, rare earth and thorium ions depend upon the concentration of potassium carbonate to a remarkable extent, while, on the other hand, those of gallium and aluminum ions are scarcely affected. It is thought that the dissolution and anion exchange behavior of gallium and aluminum ions are related to the amphoteric property rather than to the formation of their carbonate complex ions. Zirconium ion did not give a constant value under these experimental conditions. Although lead ions were dissolved completely in a potassium carbonate solution more concentrated than 0.8 M, their adsorbability for an anion exchange resin is weakly. The distinct difference in K_d values between uranyl and other metallic ions will be applied to their analytical separation by a column operation.

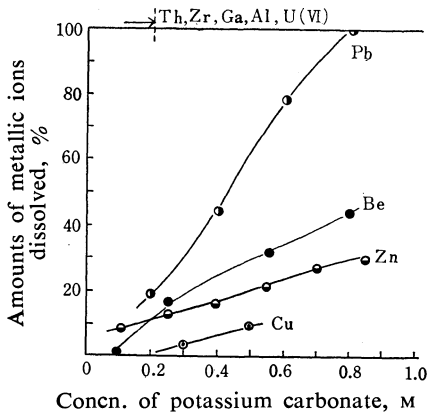

Fig. 4. Relation between the concentration of potassium carbonate and the amounts of various metallic ions dissolved.

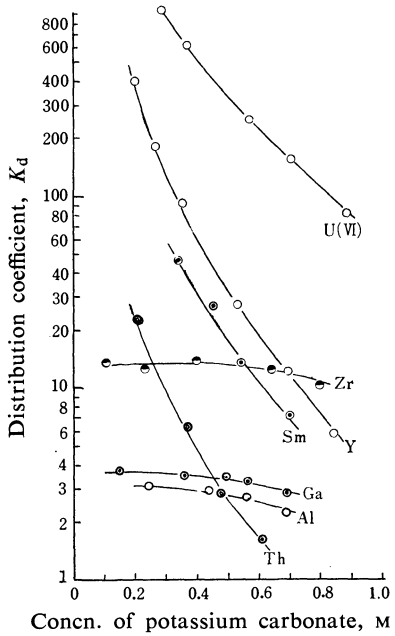

Fig. 5. Distribution coefficient of various metallic ions between Dowex 1 and potassium carbonate solution.

The Dissolution and Anion Exchange Behavior of Various Metallic Ions in an Ammonium Carbonate Solution.—The molar concentration of ammonium carbonate may be represented by a molar formula of $NH_4CO_2NH_2 \cdot NH_4HCO_3$, but this formula is not accurate because of the unstable property of ammonium carbonate. The plot of the amounts of the various metallic ions dissolved against the concentration of ammonium carbonate is given in Fig. 6. Figure 6 shows that uranyl, thorium, gallium, berylliun, zinc, cadmium,

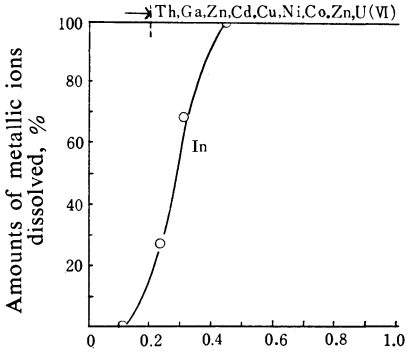

Fig. 6. Relation between the concentration of ammonium carbonate and the amounts of various metallic ions dissolved.

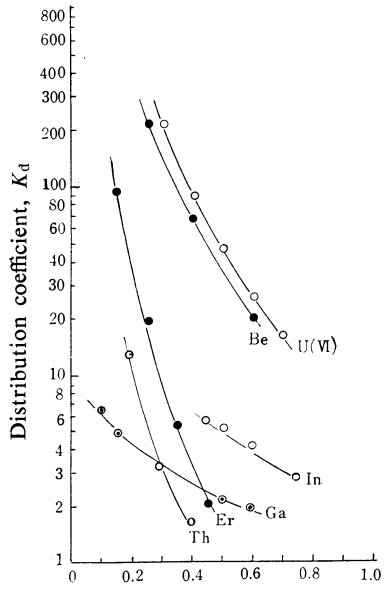

Fig. 7. Distribution coefficient of various metallic ions between Dowex 1 and ammonium carbonate.

copper, nickel and cobalt ions are dissolved completely in an ammonium carbonate solution more concentrated than about 0.2 M. Because of the formation of the ammine complexes, the macro amounts of zinc, cadmium, copper, nickel and cobalt ions are easily dissolved in an ammonium carbonate solution. Indium ions are dissolved completely in a carbonate solution more concentrated than about 0.45 M.

The relation between the K_d values of these metallic ions dissolved completely and the concentration of ammonium carbonate is shown in Fig. 7. The K_d values decrease with the increase in the concentration of ammonium carbonate. Uranyl and beryllium ions are adsorbed firmly on an anion exchange resin, while gallium, indium, thorium and rare earth ions are adsorbed less firmly. On the other hand, zinc, nickel, cobalt, cadmium and copper ions are scarcely adsorbed at all. The differences in K_d values among the metallic ions will be applied to an analytical separation; it is especially expected that the micro amounts of uranyl and beryllium ions may be separated from the macro amounts of nickel, cobalt, zinc, cadmium and copper ions.

Summary

The amounts of rare earth ions dissolved in a potassium bicarbonate solution, as well as those of other metallic ions dissolved in potassium bicarbonate, potassium carbonate and ammonium carbonate solutions, have been measured. Moreover, the minimum concentrations of potassium bicarbonate, potassium carbonate and ammonium carbonate required to dissolve the precipitates of the metallic bicarbonate and carbonate completely has been determined, and the distribution coefficients, K_d, of the completely dissolved metallic ions between an anion exchange resin and a potassium bicarbonate, potassium carbonate or ammonium carbonate solution had been measured. On the basis of those findings, the dissolution and anion exchange behavior of the metallic ions has been discussed, and the applicability to an analytical separation has been described.

The author wishes to express his gratitude to Professor Shozo Misumi for his valuable discussions and encouragement.

*Formation of Ion-pair Cr^{3+}—SO_4^{2-} in Aqueous Solution**

By Ryokichi TSUCHIYA and Akira UMAYAHARA

(Received December 20, 1962)

The measurement of coagulation value has, in general, been used for a long time to determine the charge of electrolytes in aqueous solutions. This method has also been applied to complexes. However, it is a rough method. A much more definite and exact methods for determining the charge of salt depends on electrical conductivity.

The molecular conductivity of a solution decreases, as a rule, as its concentration increases. The rate of decrease of the molecular conductivity with the increase in concentration is relatively small in the case of such chlorides as potassium and magnesium chloride and such nitrates as silver nitrate. In such cases, it is comparatively easy to determine the proper charge of the electrolytes, even in a relatively high concentration, by measuring the electrical conductivity.

On the other hand, the decrease in molecular conductivity accompanying an increase in concentration is much greater in the case of the sulfates of such bivalent metals as magnesium, copper and cadmium. The same relation is expected for the sulfate of tervalent chromium. In these cases, the proper charge of the electrolytes can not always be determined from the conductivity as easily as in the former cases.

However, the ionic state of the solution can be inferred from the conductivity.

The formation constants of the ion-pairs of tervalent cobalt, iron or chromium ions and its counter-anions have already been reported for $[Co(NH_3)_6]Cl^{2+}$ [1], $[Co(NH_3)_6]SO_4^+$ [2], $[Co(NH_3)_5H_2O]SO_4^+$ [2], $[Fe(H_2O)_6]Cl^{2+}$ [3], $[Cr(H_2O)_6]SCN^{2+}$ [4], $[Cr(H_2O)_6]Cl^{2+}$ [4] and so on, but not for $[Cr(H_2O)_6]SO_4^+$. It is known that chrome alum, which is often used as the raw material for chromium complexes, has the ion, $[Cr(H_2O)_6]^{3+}$ [5], and the formation of $[Cr(H_2O)_6]SO_4^+$ in its solution is thought to be a matter of course. The formation constant of the ion-pair, $[Cr(H_2O)_6]SO_4^+$, must be known when the properties of chromium(III) ions in the presence of sulfate ions in an aqueous solution are to be investigated. In this study the formation constant concerning chromium sulfate and chrome alum in solution will be determined through the electrical conductivity measurement.

Experimental

Hexa-aquochromium(III) Sulfate. $[Cr(H_2O)_6]_2(SO_4)_3 \cdot nH_2O$ (Violet form).—The salt was crystallized by cooling a mixture of a solution of potassium chrome alum and concentrated sulfuric acid [6]. The value of n was found to be 3.19 by chemical analysis.

Potassium Chrome Alum.—The salt of the "special" commercial grade was further purified by recrystallization. The dehydration curve of the alum was obtained with a Shimadzu thermobalance of the torsion type.

The measurement of the electrical conductivity of the solution was made with a Yokokawa Universal Bridge BV-Z-13A, and its pH was obtained with a Horiba HRL Model M-3 pH meter, both at 25°C.

Two resins, Amberlite IR-120 and Dowex 1×8, were used for the ion exchange.

Calculation and Results

Calculation of the Formation Constant of the Ion-pair in a Hexa-aquochromium(III) Sulfate Solution.—The cation $[Cr(H_2O)_6]^{3+}$ contained in the solution is presumed to produce the hydroxopenta-aquochromium(III) ion, $[Cr(H_2O)_5OH]^{2+}$, by hydrolysis, because the pH of the solution is found to be in the acid range. The experimental finding that the molecular conductivity exceedingly decreases as the concentration of the solution increases indicated the formation of the ion-pair, $[Cr(H_2O)_6]SO_4^+$, between hexa-aquochromium(III) and sulfate ions.

Consequently, the following equilibria are thought to be established in an aqueous solution:

$$[Cr(H_2O)_6]^{3+} + SO_4^{2-} \overset{K}{\rightleftharpoons} [Cr(H_2O)_6]SO_4^{+} \quad (1)$$

$$[Cr(H_2O)_6]^{3+} \overset{K_h}{\rightleftharpoons} [Cr(H_2O)_5OH]^{2+} + H^{+} \quad (2)$$

$$[Cr(H_2O)_6]SO_4^{+} \overset{K_h}{\rightleftharpoons} [Cr(H_2O)_5OH]SO_4 + H^{+} \quad (3)$$

where the hydrolysis constants of reactions 2 and 3 are assumed to be equal.

When the total concentration of chromium(III) contained in the aqueous solution of hexa-aquochromium(III) sulfate is expressed by a, the total concentration of sulfate is $3/2\ a$. If, in the state of equilibrium, the concentration of sulfate ions spent for the formation of the ion-pairs is expressed by x, that of $[Cr(H_2O)_5OH]^{2+}$ produced by the hydrolysis 2, by y, and that of $[Cr(H_2O)_5OH]SO_4$ produced by the hydrolysis 3 by z, the concentrations of the ionic species are:

$$\left.\begin{array}{ll} [Cr(H_2O)_6]^{3+} & a-x-y \\ SO_4^{2-} & 3/2\,a-x \\ [Cr(H_2O)_6]SO_4^{+} & x-z \\ [Cr(H_2O)_5OH]^{2+} & y \\ [Cr(H_2O)_5OH]SO_4 & z \\ H^{+} & y+z \end{array}\right\} \quad (4)$$

The equilibrium constants of reactions 1, 2 and 3 are given by the equations:

$$K=(x-z)/(a-x-y)(3/2\,a-x) \quad (5)$$

$$K_h=y(y+z)/(a-x-y)=z(y+z)(x-z) \quad (6)$$

By eliminating y and z from Eqs. 5 and 6, the formation constant of the ion-pair $[Cr(H_2O)_6]SO^{+4}$ is obtained as:

$$K=2x/(a-x)(3a-2x) \quad (7)$$

When the molecular conductivities of $[Cr(H_2O)_6]^{3+}$, sulfate, $[Cr(H_2O)_6]SO_4^{+}$, $[Cr(H_2O)_5OH]^{2+}$ and hydrogen ions are expressed by Λ_1, Λ_2, Λ_3, Λ_4 and Λ_H respectively, and the observed conductivity of hexa-aquochromium(III) sulfate in solution, by Λ_0, we have

$$1/2\ a\Lambda_0=\{(a-x-y)\Lambda_1+(3/2\,a-x)\Lambda_2+(x-z)\Lambda_3+y\Lambda_4+(y+z)\Lambda_H\}/\eta \quad (8)$$

where η is the specific viscosity of the solution. This equation was deduced on the basis of Walden's law $\eta\Lambda=$const., which has been established between η and the electrical conductivity Λ.

Since the ionic radii of hexa-aquochromium(III) and sulfate ions are 2.33 Å and 2.30 Å respectively, the ionic volume of $[Cr(H_2O)_6]SO_4^{+}$ is assumed to be approximately twice the size of the hexa-aquochromium(III) ion; therefore, the molecular conductivity of $[Cr(H_2O)_6]SO_4^{+}$ is a half of that of the hexa-aquochromium(III) ion if only the ratio of the ionic radius is considered. On the basis of the ratio of the charges, 1 to, 3 for $[Cr(H_2O)_6]SO_4^{+}$ and the hexa-aquochromium(III) ion, the molecular conductivity of the former is assumed to be one-third of that of the latter. By taking both the ratios of the ionic radii and of the charges into consideration, the molecular conductivity of $[Cr(H_2O)_6]SO_4^{+}$ is reduced to one-sixth of that of the hexa-aquochromium(III) ion. The ionic radius of $[Cr(H_2O)_5OH]^{2+}$ is assumed to be approximately equal to that of the hexa-aquochromium(III) ion, and, therefore, the molecular conductivity of the former is assumed to be two-thirds of that of the latter, allowance being made only for the ratio of their charges.

Solving Eqs. 6, 7 and 8 for x, we get

$$x=\{2a(3a-C_H)\Lambda_1+9a^2\Lambda_2+6aC_H\Lambda_H-3a^2\Lambda_0\eta\}/(5a-C_H)\Lambda_1+6a\Lambda_2 \quad (9)$$

where C_H is the hydrogen ion concentration. By substituting the value calculated by Eq. 9 into 7, the formation constant of the ion-pair, $[Cr(H_2O)_6]SO_4^{+}$, can be obtained.

The ionic strength μ is calculated by the following:

$$\mu=15/2\,a-6x-2y \quad (10)$$

Results of Calculation.—The observed values of electrical conductivity and pH of the solution of hexa-aquochromium(III) sulfate at 25°C are shown in Table I, together with the values of the formation constants of the ion-pair and the ionic strengths calculated from them.

In these calculations, the ionic conductivities of the chromium(III), sulfate and hydrogen ions were taken as $\Lambda_1=201$[7], $\Lambda_2=161.98$[8] and $\Lambda_H=348$[9] respectively. The plot of the measured conductivity against the square root of the concentration is given in Fig. 1.

The observed value of pH is not the hydrogen ion concentration itself, but its activity. Therefore, x was at first calculated by putting the activity, instead of C_H, in Eq. 9, and then the ionic strength was calculated by 10. The activity coefficient of the hydrogen ion corresponding to the ionic strength was then obtained from Kielland's table[10] and employed for finding the hydrogen ion concentration,

C_H, which, substituted in 9 and 10, gave the corrected values of x and μ.

The formation constant of the ion-pair was computed by Eq. 7. The logarithm of the constant is plotted against the square root of the corresponding ionic strength in Fig. 2. By extrapolating the smoothed curve formed by the observed points up to zero ionic strength, the thermodynamic formation constant of the ion-pair, $[Cr(H_2O)_6]SO_4^+$, at 25°C was obtained as $K=6.2\times10^4$.

In addition, the hydrolysis constant of $[Cr(H_2O)_6]^{3+}$ at 25°C was obtained as p$K=3.95$ at $\mu=0$ by Eq. 6.

Calculation of the Formation Constant of the Ion-pair $Cr^{3+}-SO^{2-}$ in Potassium-Chrome Alum in an Aqueous Solution.—An aqueous solution of potassium-chrome alum contains hexa-aquochromium(III), $[Cr(H_2O]_5OH]^{2+}$, $[Cr(H_2O)_6]SO_4^+$, potassium, sulfate and $K\text{-}SO_4^-$ ions. In addition to Eqs. 1, 2 and 3, the following equilibrium is thought to be present in the solution:

$$K^+ + SO_4^{2-} \overset{K'}{\rightleftharpoons} K\text{-}SO_4^- \qquad (11)$$

In this case, if the total molar concentration of chromium(III) is expressed by a, that of the sulfate ion is given by $2a$. When the concentration of the sulfate ion contributing to the formation of the ion-pair $K\text{-}SO_4^-$ in 11 is expressed by x', the concentration of potassium, sulfate and $K\text{-}SO_4^-$ ions at equilibrium are given by $a-x'$, $2a-x-x'$ and x' respectively. The concentrations of the other ionic species are the same as have been given in 4. By considering Eq. 6 at the same time, the formation constant of the ion-pair $[Cr(H_2O)_6]SO_4^+$ in the aqueous solution of chrome alum is obtained as:

$$K=x/(a-x)(2a-x-x') \qquad (12)$$

Since the ionic radii of potassium and sulfate ions are 1.33Å and 2.30Å respectively, the

ionic volume of $K\text{-}SO_4^-$ is assumed to be approximately one-and-a-half times that of the sulfate ion. In addition, by considering that the charge of $K\text{-}SO_4^-$ is a half of that of the sulfate ion, the molecular conductivity of $K\text{-}SO_4^-$ is presumed to be one-third of that of the sulfate ion. By a procedure similar to that used in the case of hexa-aquochromium-(III) salt, the equation corresponding to 9 is introduced as:

$$(5a\Lambda_1+C_H\Lambda_1+6a\Lambda_2)x+(6a\Lambda_5+4a\Lambda_2)x' = 6a^2(\Lambda_5+\Lambda_1+2\Lambda_2)-2aC_H\Lambda_1 + 6aC_H\Lambda_H-3a^2\Lambda_0\eta \quad (13)$$

where Λ_5 is the molecular conductivity of the potassium ion and Λ_0 is the observed conductivity of the potassium-chrome alum in solution.

In order to obtain the x' value, the conductivity of pure potassium sulfate in an aqueous solution was measured. Where the total molar concentration of the potassium ion and that of the ion-pair $K\text{-}SO_4^-$ formed at equilibrium are expressed by a and x' respectively, the concentration of potassium and sulfate ions at equilibrium are given by $a-x'$ and $a/2-x'$. The equilibrium constant for Eq. 11 is given by:

$$K'=2x'/(a-x')(a-2x') \quad (14)$$

When the observed conductivity is expressed by Λ_0' in a solution of potassium sulfate, by using the assumption concerning the ionic conductivity of $K\text{-}SO_4^-$ mentioned above, the equation corresponding to 9 is given by:

$$x'=3a(2\Lambda_5+\Lambda_2-\Lambda_0'\eta)/(6\Lambda_5+4\Lambda_2) \quad (15)$$

The value of x' was obtained by inserting the observed conductivity of potassium sulfate in various concentrations and the ionic conductivities of each species concerned, $\Lambda_5=75.63$[11] and $\Lambda_2=161.98$[8], into Eq. 15, while the value of K' was calculated by Eq. 14. The logarithm of K' by Eq. 14 was plotted against the ionic strengths. The value of K' at each ionic strength where the conductivity of chrome alum had been measured was obtained by interpolation or extrapolation of the above plots.

On the other hand, the formation constant of the ion-pair of $K\text{-}SO_4^-$ in the solution of chrome alum is given by:

$$K'=x'/(a-x')(2a-x-x') \quad (16)$$

By inserting the value of K' obtained above into Eq. 16 and combining it with Eq. 13, the values of x and x' were obtained. By introducing these values of x and x' into Eq. 12, the formation constant of the ion-pair $[Cr(H_2O)_6]SO_4^+$ was calculated. The results of this calculation are listed in Table II. The measured conductivity of chrome alum in the solution at 25°C against the square root of the concentration is given in Fig. 1, while the formation constant is plotted against the ionic strength in Fig 2, together with the case of hexa-aquochromium(III) salt. By extrapolating the latter plot to zero ionic strength, the thermodynamic formation constant at 25°C was obtained as $K=6.4\times10^4$, which is in good agreement with the corresponding constant in the case of hexa-aquochromium(III) sulfate. The mean value is log $K=6.3\times10^4$.

Electrical Conductivity and the Result of the Ion Exchange of the Solution of Heated Potassium-Chrome Alum and That of Chromium-(III) Sulfate in the Green Form.—The loss in weight of solid potassium-chrome alum due to heating is shown in Fig. 3. One-half of the water of crystallization, i. e., 12 H_2O, was lost at 80°C. The product is a violet powder, and the conductivity of its aqueous solution was found to be identical with that of the original alum, as is shown in Fig. 1. At 150°C another eight moles of water of the crystallization of the solid alum are lost. Under this condition

the salt has lost four of the six moles of water combined with chromium. The conductivity of its solution is remarkably larger than that of the original alum, as is shown in Fig. 1.

The solution of chrome alum was warmed at 55°C for three hours, and the electrical conductivity was measured at the same temperature. By using the equation: $\kappa_t = \kappa_{18}\{1 + 235\times10^{-4}(t-18) + 95\times10^{-6}(t-18)^2\}$[12] where κ_t and κ_{18} are the specific conductivity of salt at t°C and 18°C respectively, the observed conductivity at 55°C was converted into that at 25°C, as is shown in Fig. 1. The molecular conductivity of the chromium(III) sulfate $Cr_2(SO_4)_3\cdot6.35H_2O$ in the green form was also measured; its value is shown in Fig. 1 together with those of hexa-aquochromium(III) sulfate (chromium(III) sulfate in the violet form) and potassium-chrome alum.

The pH values and the percentages of the quantities of cation, anion and non-electrolytes expected to be contained from the ion exchange using Amberlite IR-120 and Dowex 1×8 in the following solutions are listed in Table III:

(a) An M/100 aqueous solution of potassium-chrome alum.

(b) An M/100 solution of the violet form of chromium sulfate (hexa-aquochromium(III) sulfate).

(c) An M/100 solution of chrome alum heated at 55°C for about 3 hr.

(d) An M/100 solution of chrome alum heated at 80°C for 10 min.

(e) An M/100 solution of chrome alum deprived of 20 H_2O in the solid state.

(f) An M/100 solution of the green form of chromium(III) sulfate.

Discussion

On the Formation Constant of the Ion-pair between the Hexa-aquochromium(III) Ion and the Sulfate Ion.—The formation constant of the ion-pair between hexa-aquochromium(III) and sulfate ions is shown in Table IV. The formation constants of the ion-pairs in an aqueous solution of chromium(III) chloride and thiocyanate, iron(III) chloride and several cobalt(III) salts are also listed in this table for comparison.

The power of the sulfate ion to form an ion-pair was found to be exceedingly larger than that of the chloride ion in chromium(III), iron(III) and cobalt(III) salts. This is attributable to the fact that, in the solution, the sulfate ion combines more easily with the hydrogen in H_2O or NH_3 coordinated to the metal than the chloride ion does. It was also found that the hexa-aquochromium(III) ion had a little stronger tendency to form the ion-pair with the sulfate ion than did the hexa-amminecobalt(III) ion. This may be attributed to the fact that the O–H–O bond in the chromium-hexa-aquo ion-pair is stronger than the N–H–O bond in the cobalt-hexa-ammine ion-pair. This result is in good agreement with the study presented at the symposium[13] showing that the force constant between chromium and oxygen in the hexa-aquochromium(III) ion is larger than that between cobalt and nitrogen in the hexa-amminecobalt(III) ion.

Change of the Ionic Species of Chrome-Alum upon Heating in the Solid State and in the Aqueous Solution.—When the aqueous solution of chrome alum was heated, it was found that its color changed from violet to green, that

* Present study by authors

Data of K are those at zero ionic strength except for that at $\mu = 1.0$ from Ref. 3.

the value of pH fell, that anionic species appeared and that the electrical conductivity of the solution decreased a little. There have been reports[14] that the conductivities of the green solution of chromium(III) sulfate and potassium-chrome alum are greater than those of the respective violet solutions, but the results of the present study are quite the opposite. This suggests that hydrolysis and sulfation take place and that a binuclear complex which contains hydroxy and sulfate ions in the coordination sphere is formed.

In the aqueous solution of chrome alum deprived of $20H_2O$ in the solid state, the quantity of anionic species was larger and the conductivity higher than in the heated solution. It may be inferred from these facts that there are among the complex ions, some species with a higher negative charge due to the possession of more than one sulfate ion group in the coordination sphere.

It may be presumed from the pH values and ion exchange that the composition of species in the aqueous solution of chromium(III) sulfate in the green form is almost the same as that in the solution of chrome alum dehydrated in the solid state mentioned above.

Summary

1) By measuring the conductivity of the solution of hexa-aquochromium(III) sulfate and potassium-chrome alum, the formation constant of the ion-pair $[Cr(H_2O)_6]SO_4^+$ has been calculated.

2) By measuring the pH, ion exchange separation and electrical conductivity of the heated solution of potassium-chrome alum and of the solution of the alum heated in the solid state, their ion compositions have been deduced.

Appreciation is expressed to Messrs. Teruyoshi Fujishima and Tosuke Imamura for their help in the determination of the electrical conductivity.

Electron Spin Resonance Hyperfine Spectra of Di-p-anisyl Nitric Oxide

By Kisaburo UMEMOTO, Yasuo DEGUCHI and Hideo TAKAKI

(Received December 20, 1962)

One of the present authors has previously reported the ESR study of diphenyl nitric oxide (DPNO) in the solid state[1] and in a liquid solution[2]. Similarly, the ESR study of di-*p*-anisyl nitric oxide, one of the derivatives of DPNO, has been reported by some authors[3-7]. Bijl and Rose-Innes[5], for instance, observed the ^{14}N hyperfine structure in a liquid solution for the first time. Roggen et al.[6] also observed the triplet hyperfine structure due to the ^{14}N nucleus; they interpreted it by assuming that the odd electron is associated mainly with the NO group. However, they did not find any evidence for the splitting or significant broadening of the lines by the proton moments. We have now observed the proton hyperfine spectra of di-*p*-anisyl nitric oxide in liquid solutions and have studied the effect of solvents on the spectra and on the width of nitrogen and proton hyperfine splittings.

Experimental

Following the method of Meyer et al.[8,9], we synthesized di-*p*-anisyl nitric oxide. This radical is very stable; it remains unchanged even six months after preparation. Solutions of di-*p*-anisyl nitric oxide were made in various kinds of solvent, i. e., benzene, toluene, cyclohexane, carbon tetrachloride, carbon disulfide, dimethoxyethane, tetrahydrofuran, acetone, acetonitrile, *n*-butyl alcohol, isopropyl alcohol, ethyl alcohol, methyl alcohol and water. These samples were contained in vacuum-sealed glass tubes. The solvents were completely dehydrated, degassed[2] and purified just before the preparation of the sample solutions. In order to determine the nitrogen and proton hyperfine coupling constants, an aqueous solution of peroxylamine disulfonate was used as a reference in the same manner as in the case of DPNO[2]. The ESR spectrometer employed was a JES-3B-type instrument of the Japan Electron Optics Co. This spectrometer is an X-band apparatus employing a cylindrical reflection cavity operated in the TE_{001} mode. The static magnetic field was generated by a JES electro-magnet with 300 mmϕ pole pieces, with a homogeneity of 10^{-6} gauss/sample volume. The magnetic field was modulated in 100 kilocycle/sec.

Results and Discussion

We observed the ESR spectra of di-*p*-anisyl nitric oxide in various kinds of solvent, thus determining a suitable concentration for obtaining a well-resolved hyperfine spectrum. In a properly diluted solution, a well-resolved hyperfine spectrum was obtained. Figure 1a* shows the ESR hyperfine spectrum of di-*p*-anisyl nitric oxide in the carbon tetrachloride solution. There are three large groups in the spectrum, and each of them splits further into many, about 160, fine absorption lines. These three groups arise from the interaction of the unpaired electron spin with the nuclear spin of ^{14}N, as has been suggested by Bijl and Rose-Innes[5] and by others[6,7], while the further splittings may be caused by the interaction with the proton moments. In Fig. 1a, the absorption lines show the effect of the anisotropy of molecular motion in solution, which results in a different line width for each line[10,11], as in the case of DPNO[2].

The measured *g*-value is 2.0054, and the ^{14}N hyperfine coupling constant is 10.20 gauss for the tetrahydrofuran (THF) solution. This coupling constant is a little larger than that of DPNO. This is perhaps because the electron-repelling effect of methoxy groups at the para position in the molecule of di-*p*-anisyl nitric oxide may enhance the unpaired-electron spin density at the nitrogen nucleus more than in the case of DPNO.

The structure of di-*p*-anisyl nitric oxide is shown in Fig. 1c. As the unpaired-electron spin density in this molecule has not yet been calculated, we can not compare the obtained spin density with the theoretically-calculated spin density. In order to explain the obtained

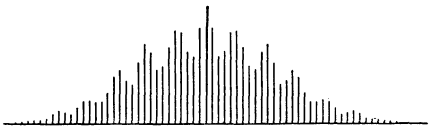
(a)



(b)

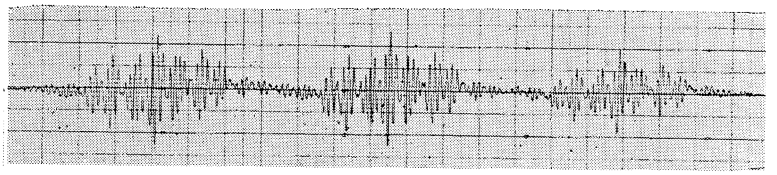
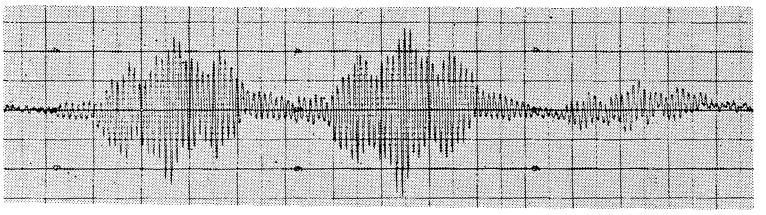
Fig. 2. (a) The ESR spectrum of di-*p*-anisyl nitric oxide in *n*-butanol.
(b) The one in water solution.

ESR spectrum in Fig. 1a, however, one can assume that the ratios of the unpaired-electron spin densities at the α, β and γ positions of the molecule shown in Fig. 1c are 10 : 4 : 1; according to this assumption one can then construct such a spectrum as is shown in Fig. 1b. In this figure only one of the three groups is shown. Although, in Fig. 1a, the groups overlap with each other at the tails and although the outermost absorption lines are too weak to be distinguished from the noise level, it can be seen that the calculated spectrum in Fig. 1b shows a very good agreement with the observed ESR spectrum in Fig. 1a.

Spectra of a type similar to that obtained in the carbon tetrachloride solution were observed in relatively non-polar solvents, such as benzene, cyclohexane, dimethoxyethane and tetrahydrofuran. The resolution of the proton hyperfine splittings slightly changed from one solvent to another. However, in relatively strong polar solvents, such as acetone, acetonitrile, alcohols and water, a broadening of the line width is clearly observed and the number of proton hyperfine splittings decreases as compared with those in the cases of non-polar solvents. The spectra of the *n*-butanol solution and the aqueous solution are illustrated in Figs. 2a and 2b. In the case of alcohols and water, both of which have a hydroxyl group, the ESR spectra showed another remarkable change in that the absorption lines of the higher magnetic field group are strongly broadened compared with those of the lower one. This phenomenon can be considered to be a result of the strong anisotropic effect[2,11]; it may be illustrated qualitatively as follows. The alcoholic hydroxyl group has a very large affinity to the lone pair electrons of oxygen atoms in the molecule of di-*p*-anisyl nitric oxide, so that alcohol molecules will strongly solvate to the molecule of di-*p*-anisyl nitric oxide in solution.



(a)



(b)

Fig. 3. (a) The ESR spectrum of di-*p*-anisyl nitric oxide in THF solution at room temperature 20°C.
(b) The one at −55°C.

Therefore, the motion of the solute radical will be reduced, and, consequently, the anisotropic effect will appear, causing a different set of relaxation times, T_2 and T_1, for each hyperfine line[2,10,11]. Thus we may explain this phenomenon, taking into account both the line-width calculation for DPNO[2], which revealed that the absorption lines of the higher magnetic field group were broader than those of the lower one, and the molecular similarity between DPNO and di-*p*-anisyl nitric oxide. For the quantitative varification of the above explanation, an experiment is expected to determine the *g*-tensor of di-*p*-anisyl nitric oxide.

To check the above explanation further, measurements were performed at low temperatures, since the viscosity of a solvent would increase at low temperatures. As an example, the ESR spectra of the THF solution are shown in Figs. 3a and 3b, where the former was measured at room temperature and the latter at −55°C. The latter spectrum is very similar to those shown in Fig. 2a and 2b. At a low temperature the free motion of the solute molecule is reduced and may be hindered as the viscosity of the solvent increases. The anisotropic effect, as a result, becomes appreciably large; it will broaden the width of each absorption line, especially those in the higher magnetic field group as compared with those in the lower magnetic field group, as is shown in Fig. 3b. This effect was not so remarkable in the case of DPNO. This is perhaps because DPNO has no methoxy group and because the free motion of the molecule of DPNO is not so strongly hindered by strong solvation or by the high viscosity of the solvent at a low temperature, as in the case of di-*p*-anisyl nitric oxide.

The effect of solvents on the widths of nitrogen and proton hyperfine splittings, which was first found in DPNO[2], was also found in di-*p*-anisyl nitric oxide. The results obtained are shown in Fig. 4 where the magnitudes of the dielectric constants of the solvents are conveniently taken as an abscissa scale. In this figure the alcoholic and aqueous solutions exhibit remarkably greater values than the others. This solvent effect will be explained qualitatively if one will consider

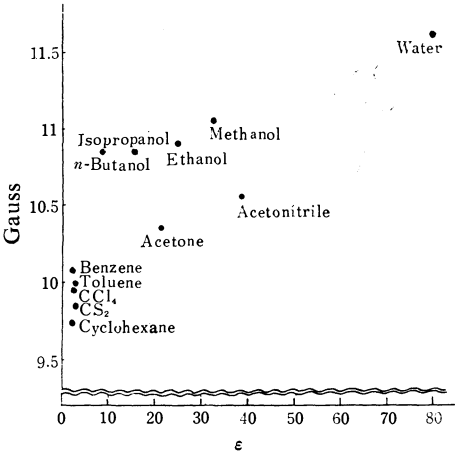


Fig. 4. Solvent effect on the nitrogen isotropic hyperfine coupling constant.

that the ionic structures of the radical molecule in the valence bond theory will be favored by the presence of polar solvents, as in the case of DPNO[2], so that the spin densities at the nitrogen and the ring carbons will be enhanced. Especially in the case of the alcoholic solution, these ionic structures may be much more favored by the effect of strong solvation. However, this explanation is not conclusive and further investigation is required to provide a rigorous theoretical basis.

*Kinetics of Hydrolytic Reaction Catalyzed by Crystalline Bacterial α-Amylase. III. The Influence of Temperature**

By Keitaro HIROMI, Yoshiyuki TAKASAKI** and Sôzaburo ONO

(Received December 22, 1962)

In previous publications[1,2] we have studied the influence of pH[1] and of solvent[2] upon the rates of hydrolytic reactions catalyzed by α-amylase of *Bacillus subtilis*, and obtained information about the nature of the essential ionizable groups of the enzyme and the electrostatic character of the reaction processes. The present paper deals with the influence of temperature upon the kinetic constants of this enzyme reaction; this study will provide information about the reaction mechanism, especially in connection with the results obtained in the previous studies[1,2].

Experimental

Enzyme.—The six times-recrystallyzed bacterial amyloclastic α-amylase of *Bacillus subtilis* (*Bac. amyloliquefacience* Fukumoto), furnished by Prof. J. Fukumoto and Dr. T. Yamamoto of Osaka City University, was dissolved in 1/50 M calcium acetate and was then kept in a refrigerator as a stock solution. This solution was diluted with a 1/300 M calcium acetate solution before use to avoid the inactivation of the enzyme, the enzymic activity of which was checked before each experiment.

Substrate.—Thrice-recrystallized potato amylose provided by the Nagase Sangyo Co., Ltd., was dissolved with a small amount of 1 N sodium hydroxide (to give a ca. 5% solution), kept overnight in a refrigerator, diluted with water and finally neutralized with 1 N acetic acid to pH 5.85 to give a 0.25% amylose solution in a 0.05 M acetate buffer. Substrate solutions of various concentrations were prepared by diluting this solution with a 0.05 M acetate buffer of the same pH.

Procedure.—Reaction was commenced by introducing 1 ml. of the diluted enzyme solution into 25 ml. of the substrate solution placed in a reaction vessel equipped with a glass stirrer. At certain time intervals (usually one minute) 2 ml. of the reaction mixture was pipetted out and poured into 2 ml. of Somogyi's reagent (see below), and the reaction was stopped. The number of reducing ends produced was determined by means of Somogyi-Nelson's photometrical method[3,4] with this slight modification: the amount of anhydrous sodium bisulfate in Somogyi's reagent[3] was reduced to 1/10 of its original amount (18 g. instead of 180 g. per l.), and nitrogen gas was passed through the solution containing Somogyi's reagent and the reaction mixture for 10 min. before boiling it to remove the dissolved oxygen. This latter procedure is especially important in determining a small number of reducing ends, because without this procedure reducing ends less than ca. 30 μmol./l. (or equivalently 5 μg./ml. of glucose) cannot be detected, probably due to the oxidation of the reducing material. The mixture was heated for 30 min. in a boiling water bath and cooled in ice water, into which 2 ml. of Nelson's reagent[4] was added. After 30 min. the colored solution was diluted to 10 ml., and the optical density was measured at 600 mμ with a Shimadzu QB 50 spectrophotometer using glucose as the reference reducing substance.

The reaction conditions were as follows: pH: 5.85 (optimum[1]) with a 0.05 M acetate buffer; substrate concentration: 0.24~0.0096%; enzyme

concentration: 3.0×10^{-9} M unless otherwise described (the molecular weight of this enzyme is 48200[5]); calcium acetate: 1.3×10^{-4} M, and the temperature was in the range from 6 to 40°C.

The concentration of the substrate or product was usually expressed in units of "mole of bond per l." (per cent unit multiplied by 10/162), which means the number of mole of glucosidic linkage per l. present or hydrolyzed.

Results

Typical examples of the reaction time curve are shown in Fig. 1. Each curve was found to have a small break in the earliest phase of the reaction (about 30 seconds after commencement). As is shown in Fig. 2, except for the initial break, the reaction follows an apparent first order kinetics until about 30% hydrolysis is attained (or until 15% of the total linkages is broken). Such a break had not been observed in previous studies[1,2], in which the determination of the reducing ends had been carried out using 3, 5-dinitrosalicylate (DNS)[6]. In Fig. 3, the reaction time curve followed by the DNS method (curve I) is compared with that of the Somogyi-Nelson (SN) method (curve II), glucose being used as the reference in both cases. The discrepancy between the two curves is quite serious, and besides the initial break, the velocity (which is represented by the slope

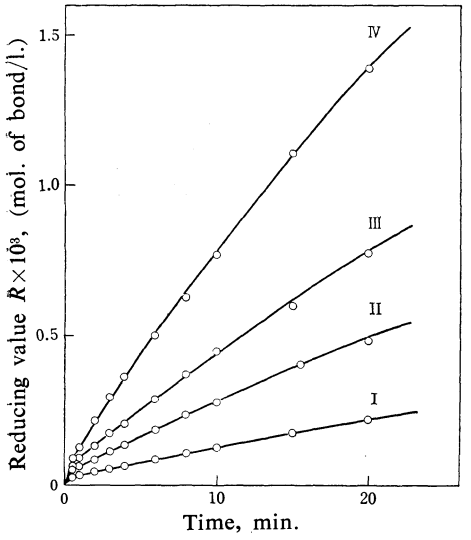

Fig. 1. Reaction time curves. Substrate concentration: 1.50×10^{-2} mol. of bond/l., 12.0°C. Enzyme concentration ($\times10^9$ M): I 0.94, II 2.82, III 4.70, IV 9.40.

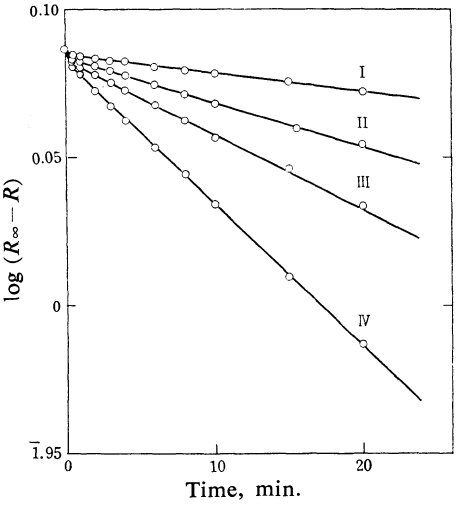

Fig. 2. The first-order plots. The numbers correspond to those in Fig. 1.

of the apparently linear part of the curve) in the SN method is about 1/14 as large as that of the DNS method. This phenomenon, though not yet fully understood, is presumed to be due to the different sensitivity of these two methods for reducing ends of different chain lengths. In fact, it has been found that the ratio of the reducing value (per mole) of maltose to that of glucose is 0.85 in the DNS method, while the ratio in the SN method is 0.50. The latter value is exactly equal to the reciprocal ratio of their molecular weights[7].

The initial velocity, v, was estimated according to the following equation, disregarding the initial break:

$$v=k_a(R_\infty-R_0) \qquad (1)$$

where R_0 and R_∞ are the reducing values at zero time and at complete hydrolysis (the theoretical limit at which 50% of the total linkage is broken) respectively, and where k_a is the apparent first order rate constant determined from the slope of the plot of log $(R_\infty-R)$ versus time (see Fig. 2). The initial velocity, v, thus obtained is in good proportionality with the enzyme concentration, [E], as is shown in Fig. 4.

The Michaelis constant, K_m, and the maximal velocity, V, were obtained from the plot of s/v versus s according to the equation:

7) According to our unpublished data, it has been proved for the SN method that the reduing value (per mole) of malto-oligosaccharide is independent of its chain length, at least up to maltopentaose. Since this relationship has not been proved to hold for amylose, it might be possible that the observed velocity does not reflect the true magnitude of the hydrolysis rate. However, the relative magnitude of rate obtained is correct, as far as initial rates are concerned.

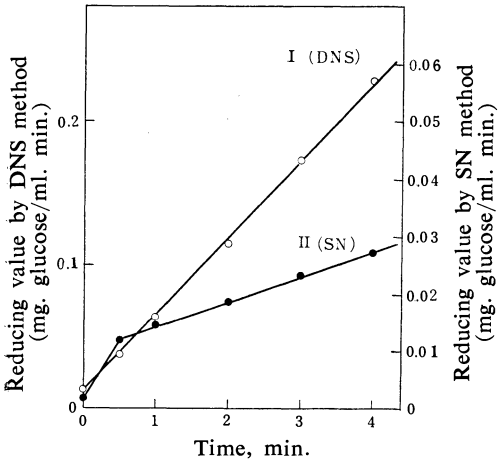

Fig. 3. Comparison of reducing values obtained by DNS and SN methods. Substrate concentration: 1.48×10^{-2} mol. of bond/l., 12.0°C.

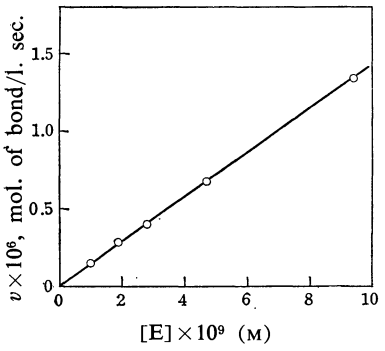

Fig. 4. Relationship between v and [E]. Substrate concentration: 1.50×10^{-2} mol. of bond/l. 12.0°C.

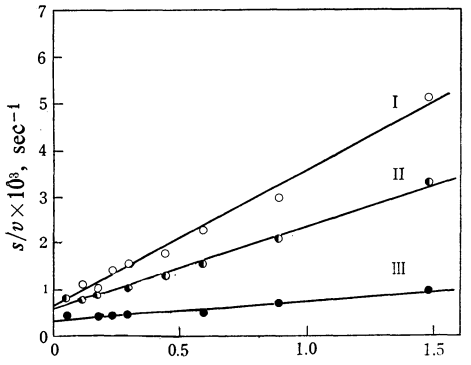

Fig. 5. Plots of s/v versus s. Temperature: I 6°C, II 12°C, III 40°C. [E]= 3.0×10^{-9} M.

$$s/v=K_m/V+s/V \qquad (2)$$

where v is the initial velocity at substrate concentration s. Fig. 5 shows some typical plots of s/v versus s. Let k_3 be a rate constant obtained by dividing V by the enzyme concentration [E]:

$$k_3=V/[E] \qquad (3)$$

According to the Michaelis-Menten-Briggs-Haldane mechanism[8]:

$$E+S \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \xrightarrow{k_3} E+P \qquad (4)$$

from which Eq. 2 is derived, k_3 corresponding to the breakdown rate constant of the ES complex. K_m is expressed as

$$K_m=(k_2+k_3)/k_1 \qquad (5)$$

where k_1, k_2 and k_3 are the rate constants designated in Eq. 4.

TABLE I. VALUES OF THE RATE PARAMETERS AT VARIOUS TEMPERATURES

Temp. °C	K_m (mol. of bond/l.)×10³	k_3 sec⁻¹	k_3/K_m (sec⁻¹/mol. of bond/l.)×10⁻⁴
6.0	2.13±0.32	114.5± 4.6	5.38±0.78
12.0	3.22±0.29	187.3± 7.4	5.82±0.48
18.0	4.33±0.49	293.2±17.9	6.77±0.64
25.0	6.15±0.70	460.8±32.1[a]	7.50±0.67
32.0	7.11±0.90	656.8±60.5	9.23±0.80
40.0	8.01±1.13	818.5±88.6	10.21±0.93

a) This value is 1/8.5 as large as the previous value[1], which was obtained by DNS method using maltose as reference. This discrepancy is due to the difference in the analytical method employed and to that in the reference sugar. (See text)

The values of K_m, k_3 and k_3/K_m obtained from Eqs. 2 and 3 using the least square method are listed in Table I, along with their standard deviations[9]. In Fig. 6, the logarithms of K_m, k_3 and k_3/K_m are plotted against the reciprocal of the absolute temperature, T, in which standard deviations are also indicated. It was found that the plots of $\log K_m$ and $\log k_3$ are almost linear below 25°C, but above that point they tend to flatten out. On the other hand, the $\log k_3/K_m$ versus $1/T$ plot was found to give a straight line over the whole temperature range studied.

Apparent Thermodynamic Quantities. — The non-linearity of $\log k_3$ vs. $1/T$ plot suggests that the reaction may be more complicated than is represented by Eq. 4. In this case, the rate parameters, K_m and k_3, should be regarded as empirical and apparent ones. Leaving their meanings to later consideration, however, we will define several apparent

8) L. Michaelis and M. L. Menten, *Biochem. Z.*, **49**, 333 (1913); G. E. Briggs and J. B. S. Haldane, *Biochem. J.*, **19**, 383 (1925).

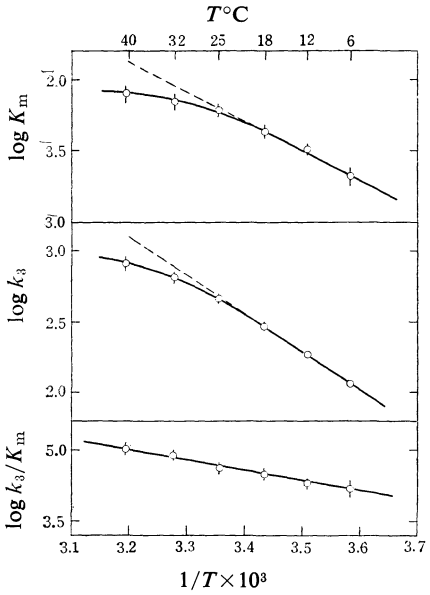

Fig. 6. Plots of $\log K_m$, $\log k_3$ and $\log k_3/K_m$ versus $1/T$.

thermodynamic quantities which are derived from K_m and k_3.

First, we define Δg_m, Δh_m and Δs_m as follows[10]:

$$\Delta g_m = \boldsymbol{R}T \ln K_m \quad (6)$$

$$\Delta h_m = \boldsymbol{R}\mathrm{d}\ln K_m/\mathrm{d}(1/T) \quad (7)$$

$$= \boldsymbol{R}\Delta \ln K_m/(1/T_1 - 1/T_2) \quad (8)$$

$$\Delta s_m = (\Delta h_m - \Delta g_m)/T \quad (9)$$

where $\boldsymbol{R}$ is the gas constant, and $\Delta \ln K_m$ designates the difference between $\ln K_m$ at temperature T_1 and that at temperature T_2.

Similarly, let $\Delta g_3^{\ddagger}$, $\Delta h_3^{\ddagger}$ and $\Delta s_3^{\ddagger}$ be defined by:

$$\Delta g_3^{\ddagger} = \boldsymbol{R}T(\ln \boldsymbol{k}T/\boldsymbol{h} - \ln k_3) \quad (10)$$

$$\Delta h_3^{\ddagger} = E - \boldsymbol{R}T \quad (11)$$

$$E = -\boldsymbol{R}\mathrm{d}\ln k_3/\mathrm{d}(1/T) \quad (12)$$

$$= -\boldsymbol{R}\Delta \ln k_3/(1/T_1 - 1/T_2) \quad (13)$$

$$\Delta s_3^{\ddagger} = (\Delta h_3^{\ddagger} - \Delta g_3^{\ddagger})/T \quad (14)$$

where $\boldsymbol{k}$, $\boldsymbol{h}$ and E are the Boltzmann constant, the Planck constant and the Arrhenius activation energy obtained from k_3, respectively, and where $\Delta \ln k_3$ represents the difference between $\ln k_3$ at T_1 and that at T_2.

Moreover, let the thermodynamic quantities, $\Delta g^{\ddagger}$, $\Delta h^{\ddagger}$ and $\Delta s^{\ddagger}$, be defined as follows:

$$\Delta g^{\ddagger} = \Delta g_m + \Delta g_3^{\ddagger}$$

$$= \boldsymbol{R}T(\ln \boldsymbol{k}T/\boldsymbol{h} - \ln k_3/K_m) \quad (15)$$

$$\Delta h^{\ddagger} = \Delta h_m + \Delta h_3^{\ddagger} = E' - \boldsymbol{R}T \quad (16)$$

$$E' = -\boldsymbol{R}\mathrm{d}\ln (k_3/K_m)/\mathrm{d}(1/T) \quad (17)$$

$$\Delta s^{\ddagger} = \Delta s_m + \Delta s_3^{\ddagger} \quad (18)$$

If the simple Michaelis-Menten scheme is valid, and, further, if K_m is a dissociation constant of ES complex (i.e., $k_2 \gg k_3$), Δg_m, Δh_m and Δs_m would be the standard free energy, enthalpy and entropy change accompanied by the ES complex formation, respectively, and $\Delta g_3^{\ddagger}$, $\Delta h_3^{\ddagger}$ and $\Delta s_3^{\ddagger}$ would stand for the free energy, enthalpy and entropy of activation for the breakdown process of ES complex, respectively.

The values of the apparent thermodynamic quantities calculated by means of least square method, are listed in Table II, which also includes their standard deviations. $\Delta h^{\ddagger}$ was obtained for the whole temperature range studied by using Eqs. 16 and 17. The values of Δh_m and $\Delta h_3^{\ddagger}$ below 25°C were obtained from the linear part of the log plots in Fig. 6, while those values above 25°C, where linearity fails, were obtained by using Eqs. 8, 11 and 13.

Discussion

The non-linearity of $\log K_m$ and $\log k_3$ versus $1/T$ plots, which is often encountered in enzyme reactions, may be attributed to several factors[11]. Possibilities relevant to the present case include: first, the reaction may consist of three steps, including two types of ES complex[12-16], and, second, the reaction may be accompanied by the rapid and reversible denaturation of the enzyme molecule[17-19].

If it is a three-step mechanism, the reaction scheme may be written as follows:

$$E + S \underset{\tilde{k}_2}{\overset{\tilde{k}_1}{\rightleftharpoons}} ES_1 \overset{\tilde{k}_3}{\rightarrow} ES_2 \overset{\tilde{k}_4}{\rightarrow} E + P \quad (19)$$

where ES_1 and ES_2 represent the two types of intermediate complex[20]. The rate parameters, k_3 and K_m, obtained experimentally using Eqs. 2 and 3 are given by:

10) The apparent thermodynamic quantities are designated by small letters in order to distinguish them from the true thermodynamic quantities, which will be designated by large letters (see below).

TABLE III. PHYSICAL MEANINGS OF THE APPARENT THERMODYNAMIC QUANTITIES AT THE LOWER TEMPERATURE RANGE BELOW 25°C

Apparent thermodynamic quantities	Physical meanings: Case a $\tilde{k}_4 \gg \tilde{k}_3$	Physical meanings: Case b $\tilde{k}_3 \gg \tilde{k}_4$	Numerical values at 18°C
Δg_m	ΔG_1	$\Delta G_1+\Delta G_1^*-\Delta G_2^*$	− 3.2 kcal. mol^{-1}
Δh_m	ΔH_1	$\Delta H_1+\Delta H_1^*-\Delta H_2^*$	− 9.3 kcal. mol^{-1}
Δs_m	ΔS_1	$\Delta S_1+\Delta S_1^*-\Delta S_2^*$	−21.0 cal. deg^{-1} mol^{-1}
Δg_3^*	ΔG_1^*	ΔG_2^*	13.7 kcal. mol^{-1}
Δh_3^*	ΔH_1^*	ΔH_2^*	12.0 kcal. mol^{-1}
Δs_3^*	ΔS_1^*	ΔS_2^*	− 5.8 cal. deg^{-1} mol^{-1}
Δg^*	$\Delta G_1+\Delta G_1^*$	$\Delta G_1+\Delta G_1^*$	10.6 kcal. mol^{-1}
Δh^*	$\Delta H_1+\Delta H_1^*$	$\Delta H_1+\Delta H_1^*$	2.7 kcal. mol^{-1}
Δs^*	$\Delta S_1+\Delta S_1^*$	$\Delta S_1+\Delta S_1^*$	−27.1 cal. deg^{-1} mol^{-1}

$$k_3=\tilde{k}_3\tilde{k}_4/(\tilde{k}_3+\tilde{k}_4) \quad (20)$$

$$K_m=\tilde{k}_4(\tilde{k}_2+\tilde{k}_3)/\tilde{k}_1(\tilde{k}_3+\tilde{k}_4) \quad (21)$$

$$k_3/K_m=\tilde{k}_3\tilde{k}_1/(\tilde{k}_2+\tilde{k}_3) \quad (22)$$

where the $\tilde{k}$'s are the rate constants indicated in Eq. 19. Previous study of the pH effect[1] has suggested that $\tilde{k}_2 \gg \tilde{k}_3$ in the present case. Eqs. 21 and 22, therefore, reduce to:

$$K_m=\tilde{k}_4/K_s(\tilde{k}_3+\tilde{k}_4) \quad (23)$$

$$k_3/K_m=\tilde{k}_3K_s \quad (24)$$

where K_s is the equilibrium constant for the process $E+S \rightleftarrows ES_1$ and is given by $K_s=\tilde{k}_1/\tilde{k}_2$.

Eq. 24 suggests that the $\log k_3/K_m$ versus $1/T$ plot should be linear. Eqs. 20 and 23 predict that the $\log k_3$ and $\log K_m$ versus $1/T$ plots will be linear at lower temperatures, where $\tilde{k}_3 \ll \tilde{k}_4$ (case a) or $\tilde{k}_4 \ll \tilde{k}_3$ (case b), but they will be concave in a higher temperature range, where $\tilde{k}_3$ and $\tilde{k}_4$ become comparable. Thus, the present findings may most reasonably be accounted for by considering that the $\tilde{k}_3$ step and the $\tilde{k}_4$ step have different activation energies and that either one of them becomes rate-limiting in the lower temperature range (below 25°C). In the lower temperature range, the rate parameters become as follows:

$$k_3=\tilde{k}_3 \text{ (case a)} \qquad k_3=\tilde{k}_4 \text{ (case b)} \quad (25)$$

$$K_m=1/K_s \text{ (case a)} \qquad K_m=\tilde{k}_4/\tilde{k}_3K_s \text{ (case b)} \quad (26)$$

$$k_3/K_m=\tilde{k}_3K_s \text{ (in both cases)} \quad (27)$$

Accepting this mechanism, we can express the apparent thermodynamic quantities in terms of the true thermodynamic quantities concerned with each step in Eq. 19. Let the true thermodynamic quantities be defined as follows: ΔG_1, ΔH_1 and ΔS_1 represent the standard free energy, enthalpy and entropy change, respectively, accompanied by the K_s step, $E+S \rightleftarrows ES_1$; let ΔG_1^*, ΔH_1^* and ΔS_1^*

represent the free energy, enthalpy and entropy of activation, respectively, of the $\tilde{k}_3$ step, $ES_1 \rightarrow ES_2$, and let $\Delta G_2^{\neq}$, $\Delta H_2^{\neq}$ and $\Delta S_2^{\neq}$ represent the free energy, enthalpy and entropy of activation, respectively, of the $\tilde{k}_4$ step, $ES_2 \rightarrow E+P$. The physical meanings of the apparent thermodynamic quantities in the lower temperature range are given in Table III in terms of these true thermodynamic quantities.

Although at present we have no other evidence which strongly supports the three-step mechanism of this enzyme reaction, the kinetic features which have been observed hitherto are by no means inconsistent with this mechanism. For instance, the fact that pH and solvent both affect k_3 but do not affect K_m[1,2] may reasonably be expected in case a; it may also reasonably be expected in case b if these extrinsic factors influence both the $\tilde{k}_3$ and the $\tilde{k}_4$ steps in the same manner.

The second possibility, that the reaction is accompanied by the reversible denaturation of the enzyme molecule, was also examined kinetically. It was found that, in order to interpret the results in terms of this mechanism, we are forced to assume that the substrate binding greatly facilitates the reversible denaturation. This is obviously contrary to what is expected from the well-known phenomenon that substrates protect enzymes from their thermal denaturation. Thus, this mechanism is poorly consistent with the experimental results.

Entropy change, ΔS, of a reaction in general, as well as other thermodynamic quantities, can be expressed as a sum of the electrostatic part, $\Delta S_{e.s.}$, and the non-electrostatic part, $\Delta S_{n.e.s.}$, the former of which may be estimated from the study of the dielectric constant effect[2,21] The entropy values obtained in the present study being the total entropy change, ΔS, the non-electrostatic entropy, $\Delta S_{n.e.s.}$, can be obtained by subtracting $\Delta S_{e.s.}$ previously obtained from the solvent effect[2] from ΔS. Using the values at 25°C, $\Delta s_m = -21$ cal. deg^{-1} mol^{-1} and $\Delta s_3^{\neq} = -6$ cal. deg^{-1} mol^{-1}, which were obtained in this study and $\Delta s_{m_{e.s.}} = 0$ and $\Delta s_{3\,e.s.}^{\neq} = -33$ (or -20)[22] cal. deg^{-1} mol^{-1}, which were obtained in the previous study[2], we have:

$$\Delta s_{m_{n.e.s.}} = \Delta s_m - \Delta s_{m_{e.s.}} = -21 - 0 = -21 \text{ cal. deg}^{-1} \text{ mol}^{-1}$$

$$\Delta s_{3\,n.e.s.}^{\neq} = \Delta s_3^{\neq} - \Delta s_{3\,e.s.}^{\neq} = -6 - (-33) = 27 \text{ cal. deg}^{-1} \text{ mol}^{-1}$$

$$(\text{or } -6 - (-20) = 14 \text{ cal. deg}^{-1} \text{ mol}^{-1})^{22}$$

The negative value of $\Delta s_{m_{n.e.s.}}$ may be due in part to the loss of freedom by the complex formation. The loss of the electrostatic entropy of activation, $\Delta s_{3\,e.s.}^{\neq}$, which may probably be due to charge separation in the activated complex[2], seems to be compensated for by the gain in the non-electrostatic entropy of activation, $\Delta s_{3\,n.e.s.}^{\neq}$, which may be due to a loosening of the linkage to be broken and/or to some conformation change in the enzyme protein[23].

It may be of interest to note that the value of Δh_m (-9.3 kcal. mol^{-1} in the present case) is of the same sign as, and of a magnitude similar to, those reported with other α-amylases, i. e., the swine pancreatic α-amylase-maxy maize starch system[24] (-7.1 kcal. mol^{-1}) and the Taka-amylase A-phenyl-α-maltoside system[25] ($-12 \sim -13$ kcal. mol^{-1}). The value of Δh_m, together with that of Δs_m, suggests that the binding force between substrate and enzyme may be hydrogen bonding and/or van der Waals force[26]. The results of solvent effect are also consistent with this view[2].

Summary

The influence of temperature upon the Michaelis constant, K_m, and on the breakdown rate constant, k_3, has been investigated for the hydrolytic reaction of amylose catalyzed by crystalline *Bacillus subtilis* α-amylase at pH 5.85 (the optimum pH) over the temperature range from 6 to 40°C.

It has been found that $\log K_m$ and $\log k_3$ increase linearly with a decreasing reciprocal absolute temperature $1/T$ in the lower temperature range below 25°C, while above that point they tend to flatten out. On the other hand, the plot of $\log k_3/K_m$ versus $1/T$ has been found to be linear over the whole temperature range studied. Apparent thermodynamic quantities have been calculated from K_m, k_3 and k_3/K_m and their temperature dependences.

The results have been examined kinetically in terms of two different mechanisms, the first assuming a three-step mechanism, and the

second assuming the reversible denaturation of the enzyme molecule. It has been found that the former is reasonably consistent, but the latter is poorly consistent with the results.

By combining these findings with the previous data of solvent effect, the non-electrostatic part of the entropies for the reaction processes has been estimated.

The meanings of thermodynamic quantities obtained have been discussed.

The authors are very grateful to Professor Juichiro Fukumoto and Dr. Takehiko Yamamoto of Osaka City University for their gift of the crystalline enzyme, and to Nagase Sangyo Co., Ltd., for supplying the crystalline amylose.

The Diffusion of Barium in a Rutile Single Crystal

By Takashi NAKAYAMA* and Tsunetaka SASAKI

(Received December 22, 1962)

There have been many studies of diffusion in such solids as metals[1], metal halides[2,3] and metal oxides[4]. Little attention has, however, been paid, except in a few cases[5], to mutual diffusion between two metal oxides at higher temperature; this neglect has partly been due to the experimental difficulties and partly due to the chemical and/or crystallographic change taking place. We have studied the diffusion phenomena in the system of titanium dioxide and barium oxide in order to obtain some information concerning the chemical reaction of barium titanate formation and its sintering at higher temperatures. Our investigation is rather microscopic in nature, compared with the published reports of macroscopic observation[6,7]. In the present report, the change of state of the system is first observed qualitatively by means of an optical microscope. The diffusion of barium into a rutile single crystal is then measured by the radiotracer technique.

Experimental

Materials. — A rutile single crystal was obtained from the Tokyo Hoseki Co. The crystal was prepared by the flame fusion method[8] and was then annealed in oxygen gas at 1000°C[9]. Spectroscopic analysis revealed traces of silicon and iron as impurities. It seemed very likely that a minute amount of silicon would contaminate the rutile crystal, as it was ground in a mortar in the preparation of the spectroscopic specimens. Since the rutile crystal is optically anisotropic, the c-axis of the crystal was readily determined by a polarizing microscope. We obtained two kinds of rutile single-crystal plates by cutting, the one having a normal of the plate parallel to, and the other, one perpendicular to the c-axis. The direction of a normal of the crystal plate used for diffusion measurements was determined by X-ray Laue patterns. In most cases, the deviations of the X-ray resulting from the optical determination of the crystal axis were less than 2°. The barium carbonate powder for microscopic observations was of a Merk's reagent, the impurities being listed as calcium and alkali<0.1%, iron<0.001%, lead< 0.001% and barium hydroxide<0.03%. It was used without further purification. The barium carbonate used for the diffusion measurement was of a Johnson-Mathy's "specqure" grade, the impurities being listed as calcium 2 p. p. m., magnesium 1 p. p. m., and copper and sodium 1 p. p. m. Radioisotope ^{133}Ba was obtained as barium chloride in 1 N hydrochloric acid. It was mixed with the non-radioactive barium carbonate dissolved in hydrochloric acid. Sodium carbonate was then added to this mixture, and the labeled barium carbonate was obtained as a precipitate. The specific activity of the barium carbonate thus obtained was 4500 c.p.m./mg.

Microscopic Observations. — As it was difficult to observe a cross-section of the contact plane between the rutile single crystal and the barium carbonate powder, the barium carbonate powder was placed

on the rutile crystal and the changes of the state were observed from above at a high reaction temperature, as is shown in Fig. 1. The temperature of the system was measured by inserting a Pt/Pt-Rh hot-junction (C in Fig. 1) into the rutile single crystal. It was reported that rutile is reduced when it is heated in vacuo (10^{-5}~10^{-4} mmHg) at a high temperature[10]. Therefore, the phenomenon we observed was the phase change of the system consisting of a single crystal of rutile with small oxygen vacancies and the powder of barium carbonate at a high temperature. However, as we kept the system at a high temperature for rather a short time (30 to 60 min.), such a reduction of rutile, if any, seemed not to influence the results obtained. After allowing the diffusion to take place at a high temperature (1100~1400°C) for two hours in oxygen gas to avoid reduction, it was cooled; the cross-section of the diffusion layer was then observed at room temperature. To enlarge the cross-section of the reaction layer, the sample plate was cut out obliquely, as may be seen in Fig. 2.

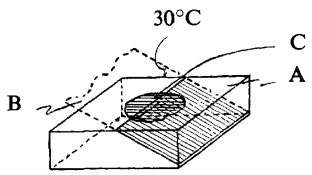

Fig. 2. Cross section of diffusion layer for microscopic observation.

C Reacted area

Measurement of the Diffusion Coefficient of Barium. — For the diffusion experiment at a high temperature, oxygen gas was led into the furnace at the rate of 2~3 l./hr. under 1 atm. to avoid the back reaction of the carbon dioxide and barium oxide produced by the decomposition of barium carbonate forming barium carbonate again, and to prevent the reduction of rutile at the high temperature. Prior to the introduction of oxygen, the furnace was evacuated by a vacuum pump. The rate-controlled oxygen gas was then passed through a heated platinum black to change the hydrogen impurity into water, which was then cooled and removed by a potassium hydroxide solution and silica gel. The carbon dioxide in the oxygen was also removed by means of an alkaline solution. As is shown in detail in Fig. 3, the oxygen current was preheated before it reached the diffusion system. The rutile crystal sample was cut to about 10×10×1 mm., and a few milligrams of ^{133}Ba-labeled barium carbonate powder were put on the crystal. The whole system was mounted on the ceramic boat, A, and was heated to a desired temperature under the oxygen current. The Pt/Pt-Rh thermocouple was set outside the alumina sheath, C, close to the sample. The actual temperature of the sample inside the alumina sheath was 5°C lower than the value indicated by the thermocouple.

Arrow shows the direction of gas flow.

After the radioactive material had been heated, utmost care was taken of the waste gas, which was passed through concentrated sulfuric acid and through glass fiber filters to catch the radioactive barium oxide. Actually, however, the radioactivity was not detectable in either the sulfuric acid or in the filters. After the barium had diffused into a single crystal of rutile at a high temperature, the surface of the specimen was abraded successively with powder of carborundum, keeping it flat; the decrement of the thickness was measured by an electromicrometer, the precision of which was checked with a block-gauge to be 0.2 μ/div. The residual radioactivity of the abraded surface due to ^{133}Ba diffusion was measured by a G-M counter. The G-M tube used was equipped with a mica window 27 mm. in diameter and 3.4 mg./cm^2 thick. The specimen was placed 32 mm. below the window. To avoid the edge effect of the diffusion area, we masked the surface of the specimen with a lead plate (12 mm. thick) which had a circular hole 3 mm. in diameter in its center, through which the γ-radiation of ^{133}Ba (half life: 7.2 years) free from self-absorption was measured.

Results and Discussion

Microscopic Observations.—Two processes of diffusion can occur when a single crystal of rutile is in contact with barium oxide at a high temperature, namely: the diffusion of barium into the rutile crystal, the diffusion layer being formed inside the rutile crystal, and the

10) M. E. Straumanis et al., *Acta Cryst.*, **14**, 493 (1961).

diffusion of titanium into barium oxide, the diffusion layer being formed outside the single crystal of rutile. The two processes are illustrated in Figs. 4 (a) and (b) respectively, assuming that the volume does not change on diffusion. To confirm which process really happened, the diffusion layer was cut as shown in Fig. 2 after diffusion had taken place at a high temperature (1300°C, 1 hr.) and was then observed by a microscope (Fig. 5). In this specimen, the c-axis of the rutile crystal was at right angles to the diffusion layer. In Fig. 6, the diffusion front, F, was seen to advance across the reference plane, B, into the rutile crystal region. Therefore, it is clear that barium diffused into the rutile crystal and that the diffusion phenomenon observed was the case of Fig. 5 (a). The diffusion layer was seen to be polycrystalline, and observation by a polarization microscope showed that the optical anisotropy of the crystal grains was random in its direction. This suggests that the crystal grains of the diffusion product did not grow epitaxially. It is likely for the diffusion mechanism that barium diffuses into the rutile single crystal, destroys the crystal structure of rutile, and creates a new crystal structure consisting of titanium, barium and oxygen. A sufficient number of new crystal nuclei are created to result in the polycrystalline diffusion layer.

Since the diffusion of an atom is considered to take place more rapidly in the liquid state than in the solid state, the rate of reaction is expected to be affected profoundly by the liquefaction of the diffusion layer. Microscopic observation of the diffusion system of Fig. 1 at a high temperature revealed two kinds of liquid state. The first liquefaction occurred at 900~1050°C. At the lower temperature of 650°C, the barium carbonate in the single crystal of rutile seemed to remain in a solid state, as is shown in Fig. 6 (a). It was liquefied at 950°C, as is shown in Fig. 6 (b). The fluidity was seemingly increased at 1000°C, as is indicated in Fig. 6 (c). The accuracy of the temperature measurement depended on the position of the hot-junction placed beneath the rutile crystal, as may be understood from Fig. 1. The accuracy of the temperature measurement was ±25°C. Accordingly, the liquid state is considered to be a eutectic mixture of $2BaCO_3 \cdot BaO$, the eutectic point of which is 1030±3°C[11]. This liquid

state can also be identified with the one observed by Hirota et al.[12], who studied the thermal decomposition of barium carbonate with an electron microscope. Therefore, the liquefaction in the temperature range of 900~1050°C may be considered to be related to barium carbonate and oxide, which may affect the diffusion of barium into a rutile crystal very little.

The second liquefaction occurs at about 1300°C. This is shown in Fig. 7(c). As will be mentioned later, this liquefaction is exclusively concerned with barium oxide and titanium dioxide, not with barium carbonate. To confirm this, barium oxide film was made by evaporation in vacuo on a single crystal of rutile, and barium was diffused into the rutile crystal at a high temperature in vacuo ($5\sim7\times10^{-5}$ mmHg). At 1200°C (Fig. 7 (a)) no liquid state was observed, but at 1290°C (Fig. 7 (b)) the liquefaction was recognized from the interference fringes caused by a relatively uniform liquid film. According to the phase diagram of barium oxide~titanium dioxide proposed by Rose and Rey[6], a eutectic mixture exists at the mole ratio of $BaO : TiO_2$ 68 : 32 (eutectic point 1317°C). Therefore, the liquid phase observed is considered to be the eutectic mixture of this composition produced by the diffusion of barium. This liquefaction explains the marked change in reaction velocity, namely, above 1317°C barium diffusion is rapid, since it takes place in the liquid state, while below 1317°C it is rather slow, owing to the solid state diffusion. This is confirmed further by the following quantitative experiment.

Radiotracer Observation.—After the diffusion was allowed to take place at high temperatures,

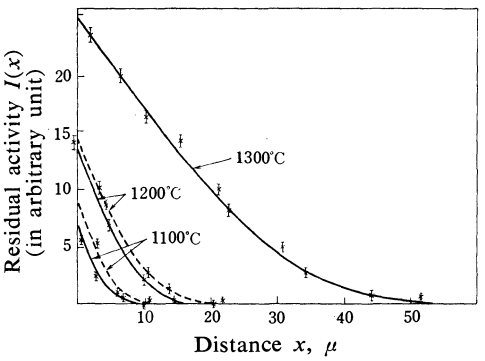

Fig. 8. Relation between diffusion distance and residual activity $I(x)$.
—— Diffusion parallel to c-axis of rutile single crystal
---- Diffusion perpendicular to c-axis of rutile single crystal

the reacted surface was abraded by successive thin layers. After each abrasion the residual radioactivity of the surface was measured. Figure 8 shows the residual radioactivity curve $I(x)$, denoting, in an arbitrary unit, the concentration of barium remaining after the abrasion to the depth x, measured from the plane of contact between the rutile single crystal and ^{133}Ba carbonate. Then, we obtain:

$$I(x)=\int_x^\infty c(x')\cdot A(x'-x)\,dx' \qquad (1)$$

where $A(x'-x)$ is the factor due to the self-absorption of radioactivity through the reacted rutile crystal of the thickness of $x'-x$, and $c(x')$ is the barium concentration per unit thickness at x' for $x'\geqq x$. Differentiating with respect to x, we get

$$dI(x)/dx=[-c(x')\cdot A(x'-x)]_{x'=x}$$
$$=-c(x)\cdot A(0) \qquad (2)$$

12) S. Hirota et al., *J. Phys. Soc. (Japan)*, **15**, 137 (1960).

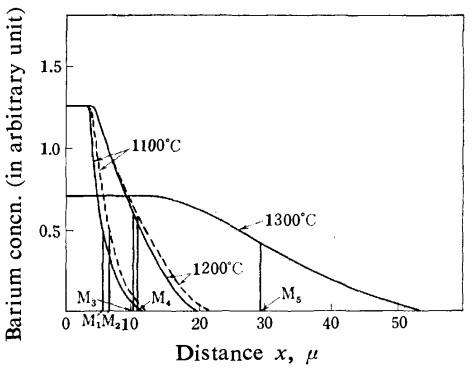

Fig. 9. Relation between diffusion distance and barium concentration $c(x)$.
—— Diffusion parallel to c-axis of rutile single crystal
---- Diffusion perpendicular to c-axis of rutile single crystal

However, since

$$A(0)=1$$

Equation 2 becomes

$$dI(x)/dx=-c(x) \qquad (3)$$

That is, the barium concentration $c(x)$ is given by the negative of the tangent of $I(x)$.

Figure 8 shows the diffusion systems of barium carbonate on the rutile single crystal, systems which were heated to 1100, 1200 and 1300°C under the oxygen current for two hours. As the ionic configuration along the c-axis of the rutile is quite different from that perpendicular to the c-axis[9], the $I(x)$'s along both directions were determined. We can see in Fig. 8 that barium diffuses more rapidly at 1300°C than at 1100 and 1200°C, which may be explained by the formation of liquefied eutectic mixture at 1300°C mentioned above. The $c(x)$ curves in Fig. 9 were obtained by the differentiations of the curves of Fig. 8. Small differences are seen between the $c(x)$ curves parallel to and those perpendicular to the c-axis, but the anisotropic diffusion of barium is not conclusive from these data alone. Above 1300°C, liquefaction occurred and the volume of the diffusion layer slightly decreased, so that the accuracy of $I(x)$ beyond 1300°C is rather low. Actually, no quantitative result could be obtained at 1400°C.

For the calculation of the diffusion coefficient from the concentrations distribution curve, initial and boundary conditions should be given; in our experiments these were:

$$\begin{aligned} &c(x)=\text{const.} \quad \text{for } x<0, \quad t=0 \\ &c(x)=0, \quad \text{for } x>0, \quad t=0 \end{aligned} \qquad (4)$$

where t denotes time.

As a diffusion coefficient is assumed to be dependent on the concentration, the diffusion equation takes the form:

$$\frac{\partial c}{\partial t}=\frac{\partial}{\partial x}\left(D(c)\cdot\frac{\partial c}{\partial x}\right) \qquad (5)$$

Using the Matano interface[14], $D(c)$ can be calculated readily under the conditions of 4. Let c_M be the concentration on the Matano interface, then the diffusion coefficient at c_M is[13]:

$$D(c_M)=-\frac{1}{2t}\left(\frac{dx}{dc}\right)_{c=c_M}\cdot\int_0^{c_M}x\,dc \qquad (6)$$

The Matano interfaces M_1, M_2, M_3,..., M_5 are shown in Fig. 9 for each concentration curve. $D(c_M)$ was calculated using Eq. 6.

The values of $D(c_M)$ obtained were 3.6×10^{-14} (1100°C) and 1×10^{-13} (1200°C) (both parallel to the c-axis), 5×10^{-14} (1100°C) and 2.4×10^{-13} (1200°C) (both perpendicular to the c-axis), and 2.5×10^{-12} (1300°C), expressed in cm^2/sec. As for the self-diffusion coefficient of barium in barium titanate, Verduch and Linder[14] gave about 10^{-14} cm^2/sec. at 1150°C, which is in reasonable agreement with our result of about 3×10^{-14} cm^2/sec. at 1100°C.

Assuming that the activation energy, E, for diffusion is independent of the temperature, T, it can be calculated from:

$$D(c_M)=D_0(c_M)\cdot\exp(-E/RT)$$

by plotting $D(c_M)$ against $1/T$. The rough estimation of E in the of 1100~1200°C range gives 59 kcal./mol. (perpendicular to the c-axis) and 43 kcal./mol. (parallel to the c-axis).

With regard to the state of barium during diffusion, no conclusive statement can be made from our results. However, the experimental results of barium self-diffusion in barium oxide by Redington[15] show, that both charged and neutral barium constituents diffuse in the temperature range from 1077 to 1227°C, whereas only the neutral barium diffuses in the lower temperature range (327~1027°C). Thus we may expect that the barium diffusing in our experiments (1100°C and above) is partly charged and partly neutral.

In these experiments, the average concentration was determined over a circular area 3 mm. in diameter, assuming that the diffusion proceeds vertically to the rutile surface and that the diffusion front is flat. Actually, however, as is shown in Fig. 5, the photomicrograph reveals, that the diffusion front is not completely flat over the area observed. In addition,

barium is considered to diffuse rather rapidly along such imperfections of the rutile single crystal as the subgrain boundaries. It may be possible to obtain a more exact concentration curve without being disturbed by crystal imperfections if the diffusion is studied by the X-ray microanalyzer. The chemical composition and the crystal structure may also be identified by the X-ray microanalyzer and microdiffraction methods. The details, however, require further study.

Summary

1) Microscopic and radiotracer studies have been made upon the diffusion of barium into a rutile single crystal.

2) In the microscopic observation, the diffusion layer of barium oxide in the rutile single crystal was confirmed to liquefy above 1300°C due to the formation of a eutectic mixture between both constituents. Below 1300°C solid phase diffusion prevails, and the diffusion layer consists of polycrystalline of a random orientation.

3) The diffusion coefficients of barium oxide in a rutile single crystal were measured by means of the radiotracer method using ^{133}Ba. The diffusion coefficients obtained were $3.5\times10^{-14}\sim2.4\times10^{-13}$ cm^2/sec. in the range of 1100~1200°C and 1.1×10^{-12} cm^2/sec. at 1300°C. Between 1100°C and 1200°C, small differences seemed to be observed for the values obtained according to the direction of the diffusion in the crystal, but this is not conclusive. The large value of the diffusion coefficient at 1300°C was considered to be due to the liquefaction of the diffusion layer. The energy of activation was calculated to be 43 kcal./mol. (parallel to the c-axis) and 59 kcal./mol. (perpendicular to the c-axis).

Nuclear Magnetic Resonance Study of Acetaldehyde Aqueous Solution

By Yuzuru FUJIWARA and Shizuo FUJIWARA

(Received December 28, 1962)

Acetaldehyde in aqueous solution has been the subject of spectroscopic and calorimetric investigations in regards to the equilibrium with hydrated molecules.

$$CH_3CHO + H_2O \rightleftarrows CH_3CH(OH)_2 \qquad (1)$$

In spectroscopic studies, the absorption band due to C=O double bond is the measure of concentration of aldehyde and its disappearance by formation of hydrated molecules has been investigated. Nuclear magnetic resonance (NMR) technique has the merit to measure all kinds of protons in both sides of Eq. 1 and enables us to investigate it more precisely than the spectroscopic method. From the view point of NMR, acetaldehyde shows characteristic features, for instance, aldehyde hydrogen gives the NMR signal in a very low field, and the spin coupling constant between methyl and aldehyde hydrogens is very small. These features of NMR spectra may be interpreted in correlation with the chemical activity of aldehyde hydrogen. Since NMR data such as chemical shift, spin coupling constant, and relaxation time can be interpreted in terms of electronic and structural configurations, and of motion of molecules, we planned to make an NMR investigation of acetaldehyde in aqueous solution.

Experimental

NMR spectra were obtained at 56.445 Mc./sec., using a Varian Associates spectrometer. Chemical shifts were measured by the side band method from the methyl proton signal of free acetaldehyde. Concentrations of various species of hydrogen were measured as the areas of the spectra obtained. This was actually practised by setting the condition that line width was so large that the transverse

relaxation times, T_2's, were predominated by the inhomogeneity of the external magnetic field. This method to determine the concentration is helpful to avoid the change of concentration on sealing the sample in the tubes, since acetaldehyde with boiling point 20.8°C volatilizes easily at room temperature. Acetaldehyde was prepared by the decomposition of commercial paraaldehyde using sulfuric acid as catalyst and was redistilled.

Results and Discussion

NMR spectra of acetaldehyde are shown in Fig. 1. Each component of the spectra is easily assigned unambiguously as shown in Fig. 1 with the consideration of the line shape and the intensity[3]. The hydrogens of water and OH radicals of hydrated aldehyde form a single broad line, and its position depends upon concentration (cf. Fig. 2). The width of this line increases as the temperature is lowered or as the concentration of acetaldehyde is increased. This suggests the existence of proton exchange between water and hydrated aldehyde and that of the rate of exchange is rather rapid. The magnitudes of chemical shift and spin-spin coupling constant, J, of all components except water coincide well with those in the literatures[2,3].

The methyl proton signal for the hydrated molecule shows smaller value of chemical

shift and a larger coupling constant as compared with that for the free molecule. Moreover, the difference between the two J's as well as that between the two shift is conspicuous; $J=5.2$ and 2.8 c. p. s. and $\delta=2.96$ and 7.53 p. p. m. for hydrated and free molecules, respectively. Resonance positions of all hydrogens other than that in OH are almost constant and independent of the concentration. The spectra are temperature dependent as shown in Fig. 3. The line width of hydrated acetaldehyde increases as the solution becomes viscous in a lower temperature range, while that of free molecules does not vary so much. The intensity of the latter is much reduced at lower temperatures as the result of drift of the chemical equilibrium. Saturation curves for methyl protons in both hydrated and free molecules at two temperatures, 27°C and −14°C, are shown in Figs. 4 and 5, respectively. As seen in Fig. 4, the behaviors of the two lines are almost the same for both species of molecules at 27°C, whereas very different from each other at −14°C. In Table I, the relative relaxation times are shown, where T_1

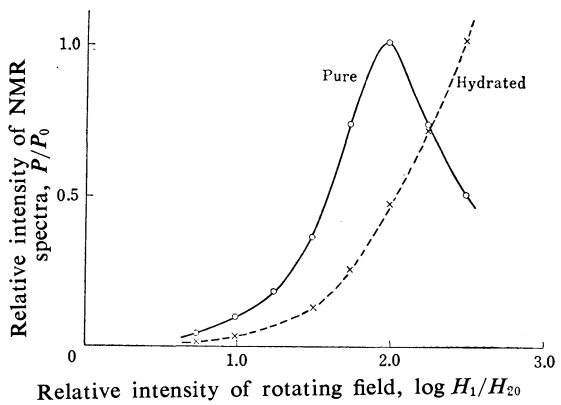

Fig. 5. Saturation curves of CH_3CHO at −14°C.

TABLE I. RELATIVE RELAXATION TIME

Temp., °C		CH_3CHO	$CH_3CH(OH)_2$
27	T_1/T_{20}	1.00	0.771
	T_1/T_{10}	1.0	0.91
−14	T_1/T_{10}	0.724	0.115
	T_2/T_{10}	0.715	0.22

for free molecule at room temperature was taken as unit. The T_1's obtained from saturation curves with the assumption that T_1 is equal to T_2, coincide fairly well with the T_2's which were obtained from the line width. Small discrepancies between the two sets of relaxation times may have been caused by the neglect of field inhomogeneity. T_1 diffrence between the two kinds of molecules at −14°C is due to the difference in correlation times for the Brownian motion of molecules. It is interesting that the correlation times are different between the free and the hydrated acetaldehyde molecules, namely, the molecules of similar size in homogeneous medium of liquid. T_1's of free molecules are almost equal to each other at 27°C and at −14°C inspite of a large difference in viscosity of the solution. This fact suggests that translational motion of the molecule does not effectively contribute to relaxation. On the other hand, T_1 of the hydrated molecule is much smaller than that of free molecule at the lower temperature and this may be attributed to the difference of rotational motions, since hydrated molecules are strongly hydrogen-bonded with surrounding water, receiving hindrance in both translational and rotational motions, whereas unhydrated ones are comparatively speaking, free and rotational motion remains. Measurements of T_1 values in two different temperature ranges made it possible to calculate the apparent activation energy as 7.1 and 1.3 kcal./mol. for the rotational motions of hydrated and unhydrated molecules, respectively. The strength of the hydrogen bond ranges around 5 kcal./mol. for water or ethanol. The fact that the value obtained here (3.5 kcal./mol.) is a little smaller than this value may be due to its structure which has two adjacent OH's, unfavorable to form hydrogen bonds.

Configurations of hydrated and free acetaldehyde will be discussed in regard to the large difference of J's. The value of J, 5.2 c. p. s., for the hydrated molecule may be interpreted by simple application of the electronegativity $-J$ rule which was empirically obtained by Glick et al. for isopropyl derivatives[4]. Equation 2 correlates the coupling constants with

4) R. E. Glick and A. A. Bothner-By, *J. Chem. Phys.*, 25, 362 (1956).

the Huggins' electronegativity scale, E[5], of the substituent, X for $(CH_3)_2CHX$.

$$J(\text{c. p. s.}) = 8.0 - 0.55 \times E \qquad (2)$$

If we modify this relation to replace the methyl radical in isopropyl by OH, Eq. 2 leads to 5.6 c. p. s. as J value for hydrated acetaldehyde, which is a fairly good approximation. This result suggests that the electron density around protons is reduced by this replacement. Provided that this substitution only affects the electron density in such a way that it is reduced homogeneously throughout the molecule, the electron density of aldehyde hydrogen is reduced by 16% from that of propane, by using Karplus calculation of J by the valence bond method[6] and by comparing the J, 5.2 c. p. s. with the J for propane which has been reported as 7.26 c. p. s.[7] If we assume that the electron densities around C–H protons in pure and hydrated molecules are mainly determined by the polarization of C–O bonds, then the electron densities of C–H protons should be very different between the two molecules, since J's are different. Pure aldehyde has one C=O bond and the hydrated molecule has two C–OH bonds. The ionicity of C–O single bond has been reported as about 22%[8] and that of C=O double bond of acetaldehyde as 47%[9] by the measurement of the electric dipole moment[10]. In so far as the polarization is concerned the aldehyde hydrogen can not make any sizable difference between the two molecules. This result contradicts the observed difference of J's for pure and hydrated acetaldehyde, since Glick's rule stands for linear relationship between J and electron density which is determined by the electronegativity of the substituent. The observed difference may be attributed partly to that of hybridization of carbon orbitals; sp^3 and sp^2 structures for hydrated and pure aldehyde, respectively. Comparing propane (J=7.26) with propylene (J=6.4)[7] the orbital effect can be estimated and the expected value for pure acetaldehyde should be 4.6 c. p. s. which is still larger than the experimental value of 2.8 c. p. s. In order to analyze the results more precisely, further investigations would be necessary for many other factors such as difference of excitation energy, bond length[11], and angle[11,12], and electronic configurations. The low value of aldehyde-hydrogen shift could be interpreted in terms of (1) the effect of electric field due to the dipole moment of C=O, (2) the anisotropic magnetic screening of C=O double bond and (3) the reduction of electronic screening associated with the decrease of electron density. The magnetic effect 2 will be of the order of 4.57 p. p. m. which was obtained as the difference between the hydrated and the unhydrated aldehyde. The electronic effect is calculated as 2.8 p. p. m. by using the Lamb's screening constant for hydrogen atom[15] and the electron density obtained from the discussion of J. The electric field effect was estimated to be 4.4 p. p. m. comparing the shifts of ethane and acetaldehyde[2]. The sum of these effects is 11.77 p. p. m. which is reasonable and proves that the above estimations are correct.

The equilibrium constant K for 1, defined as

$$K = (H)/(A-H)(W-H)$$

where W, A and H refer to concentrations of water, free, and hydrated acetaldehyde, respectively. K is plotted against the concentration of acetaldehyde in Fig. 6. The equilibrium constant decreases with the increase of concentration. This may be attributed partly to the experimental error in the measurements of concentration where we neglected effects of relaxation times and activities. For dilute solutions, however, the errors mentioned above are small and K approaches to 0.021 l./mol. This value coincides well with the UV and NMR results by other authors[1,3]. The temperature dependence of the equilibrium constant is also shown in Fig. 7 and the heat of hydration was calculeted as 4.9 kcal./mol., which also agrees well with the data already reported[1], within the experimental errors.

Conclusion

In aqueous solution of acetaldehyde the hydrated and unhydrated molecules have different relaxation times, since the interaction with the solvent, mainly the formation of hydrogen bonding, is different. Relaxation is dominated mainly by rotational motion of the molecule. The hydrogen bond between the hydrated acetaldehyde and water has the energy about 3.6 kcal./mol. and these hydrogens exchange with each other rapidly.

Small J of acetaldehyde may be attributed to the smallness of electron density around protons and also to the bond angle, the bond length, and the cxcitation energy. The NMR signal of aldehyde hydrogen locates in a low field because of the electron density, the anisotropic magnetic screening of the C=O and the electric field produced by the dipole moment of the C=O and these effects were estimated to be 2.8, 4.6 and 4.4 p. p. m., respectively.

The equilibrim constant and the heat of hydration are determined by the NMR method more accurately than by other conventional methods and the obtained values are in good agreement with the values in the literatures.

The authors thank Mr. Naohiro Hayakawa of the Japan Atomic Energy Research Institute for the help to obtain the NMR spectra. They are grateful to Dr. Hiroshi Shimizu of Chiba University for valuable discussions.

*Nuclear Magnetic Resonance Spectra of Amino Acids and their Derivatives. II. Analyses of NMR Spectra of Amino Acids**

By Shizuo FUJIWARA and Yoji ARATA

(Receied January 19, 1963)

Investigations of proton resonance in amino acids have so far been restricted to those of the over-all features of the spectra[1-3]. This situation led us to make more detailed study of the spectra.

We will summarize here the results of precise analyses of the spectra of methylene and methine protons of amino acids of the type,

$$R-CH_2-\underset{\displaystyle NH_2}{\underset{|}{CH}}-COOH$$

where R has no protons interacting with those under invesitigation.

* Presented at the International Symposium on Molecular Spectroscopy, Tokyo, 1962.

3) F. A. Bovey and G. V. D. Tiers, *J. Am. Chem. Soc.*, **81**, 2870 (1959).

Experimental

Materials.—The amino acids studied were all commercial materials (Ajinomoto Co.). They were dissolved in heavy water, 2N HCl, and 2N NaOD at the concentration of 1 mol.%. 2N HCl was prepared by diluting concentrated hydrochloric acid with heavy water. 2N NaOD was prepared by adding sodium peroxide powder to heavy water under cooling.

Spectrometer.—A Varian Associates model V4301C NMR spectrometer operating at 60.00 Mc./sec. was employed for all measurements.

Results

Cysteine dissolved in diluted hydrochloric acid gives a simple spectrum as shown in Fig. 1d. The spectrum tells that the two protons attached to the beta-carbon atom are equivalent to each other. Serine and aspartic acid also

TABLE I. RESULTS OF ANALYSES IN C. P. S. FOR THE SPECTRA MEASURED AT 60.00 Mc./sec.

		$\nu_A-\nu_C$	$\nu_B-\nu_C$	J_{AC}	J_{BC}	J_{CA}
(B) (A)

	Cysteine { D_2O	55.5	0	4.9	—	4.9

give the spectra of three protons, two of which are equivalent.

Chemical shifts between alpha and beta protons vary from one amino acid to others. When the chemical shift is large compared to the spin coupling constant between these protons, the spectrum can easily be analyzed by means of the first-order perturbation theory. Cysteine in an acid medium shows a spectrum of this type.

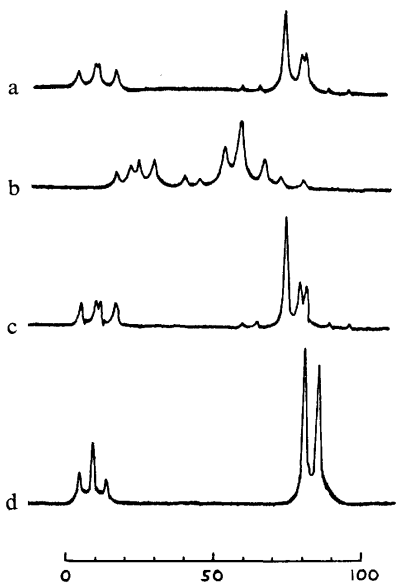

Fig. 1. NMR Spectra of amino acids measured at 60.00 Mc./sec.
(a) Phenylalanine in 2N HCl
(b) Phenylalanine in 2N NaOD
(c) Cystine in 2N HCl
(d) Cysteine in 2N HCl
In these spectra magnetic field increases from left to right.

When cysteine is dissolved in diluted NaOD solution, the spectrum changes to a complex one of a non-equivalent three spin system.

When R is bulky as in the cases of phenylalanine, tryptophane, tyrosine, hystidine and cystine, the spectra take the features of a nonequivalent three spin system even in acid media as well as in basic media.

For the analyses of these spectra we used the method of the least-squares reported by Shimizu and the present authors[4]. This method is useful in the present case, where we have relatively fewer than those theoretically expected. Some examples of the spectra are shown in Fig. 1a—1c and the results of the analyses are summarized in Table I.

The molecular constants shown in the table may be considered to be the weighted averages of chemical shifts and of spin-coupling constants over rotational isomers[5]. The relative population of each rotational isomer depends upon the acidity of the solution. This situation is more clearly seen in the spectra of valine for several kinds of solutions with different pH. The results are summarized in Table II.

TABLE II. CHEMICAL SHIFTS AND SPIN SPIN COUPLING CONSTANTS IN C. P. S. OBTAINED FROM THE SPECTRA OF VALINE AT A SERIES OF pH VALUES

	pH	J_{23}	$\lvert \nu_4-\nu_{4'} \rvert$

Formaldehyde Resins. LXXV. Novolak Resin from p-Chlorophenol and Formaldehyde*

By Minoru IMOTO and Shin-ichi NAKADE

(Received January 5, 1963)

In 1956, Burke et al. obtained some novolak resins of a high molecular weight by the reaction of *p*- or *o*-chlorophenol with *s*-trioxane at 150°C in a sealed tube[1]. They reported that, after fractionation and acetylation of the resin, a fraction of a lower molecular weight showed the molecular weight of 2090, which was determined by the cryoscopic method using benzil as the solvent. This result attracted our attention, as it had previously been believed that the molecular weight of novolak was below 1000. In a foregoing paper of this series, Imoto and Tanigaki[2] repeated Burke's experiments, using *p*-chlorophenol and *α*-polyoxymethylene, but the molecular weight of the resin obtained was below 1000.

In the present study, we followed Burke's experiment accurately and determined the molecular weight distribution of the resin. The molecular weight of the resin obtained here was 400 to 1000. No novolak resin of a high molecular weight, such as those described by Burke, could be obtained. The molecular weight distribution of the resins obtained at the early stage of the reaction showed rather a good agreement with the theoretical equation submitted by one of the present authors (M. I.)[3], but as a general rule, they did not agree. This lack of agreement was due to a reaction of the "reformation" of the novolak-molecules[4]. Therefore, it was considered that the distribution should be ruled by Poisson's distribution equation, as was proved to be true.

Experimental

Materials.—*p*-Chlorophenol was of a commercial grade and was used after distillation (b. p., 79~80°C/5 mmHg). *p*-Toluenesulfonic acid was refined by recrystallization from water; m. p., 103~104°C. *s*-Trioxane was of a purity of over 99%. The solvent, bis(2-ethoxyethyl) ether, was synthesized according to the method given in the literature[5]; b. p., 77~80°C/11 mmHg.

The Formation of the Resin.—A solution composed of 12.86 g. (0.1 mol.) of *p*-chlorophenol, 3.03 g. (corresponding to 0.101 mol. of formaldehyde) of *s*-trioxane, 0.200 g. of *p*-toluenesulfonic acid and 15 ml. of bis(2-ethoxyethyl) ether was placed in a sealed tube and heated at 150°C for 2~24 hr. in an oil bath. After cooling the reaction mixture, it was added slowly with vigorous stirring into about 500 ml. of water containing a small amount of hydrochloric acid. The resin precipitated here was dissolved in about 50 ml. of acetone to purify it. When the reaction was carried out at 150°C over for 11 hr., a small amount of the insoluble resin in acetone was obtained. The acetone solution was poured into one liter of water to precipitate the novolak resin. After the resin had been filtered, it was dried at about 60°C under reduced pressure (1 mmHg).

The Acetylation of the Resin.—After 1 g. of the resin had been dissolved in 10 ml. of pyridine, 2~3 ml. of acetic anhydride was added and left standing for several days at room temperature. The reaction mixture was poured into water to yield an acetylated resin. The purification was carried out by the reprecipitation method, using acetone and water. The completion of the acetylation was comfirmed by the disappearance of the OH bands in the infrared absorption spectra.

The Saponification of the Acetylated Resin.—One gram of caustic potassium was dissolved in 15 ml. of methanol, and the solution was maintained at 5°C, Then, 1 g. of acetylated resin was dissolved in 25 ml. of acetone, and the afore-mentioned solution was added and cooled at 5°C for 24 hr. The reaction mixture was poured into water to yield a saponified resin. The completion of the saponification reaction was comfirmed by the disappearance of the CO absorption bands in the infrared spectra.

The Fractionation of the Resin.—Fractionational precipitation was carried out by the successive addition of a poor solvent to the resin solution or by removing the solvent from the resin solution. Acetone, tetrahydrofuran or dimethylformamide was used as the solvent, and water or 33% ethanol-water as the poor solvent. Five to seven fractions were obtained from an about 5% resin solution by the successive addition of the poor solvent at 30.0 ±0.1°C and by removing the solvent.

The Molecular Weight Determination of the Resin.—The molecular weight of the resin was determined by the cryoscopic method, using camphor as solvents. It was shown by Imoto and Tanigaki[2] in the previous paper that camphor was suitable for the molecular weight determination of the novolak resin. When the molecular weight reached over 1000, however, the determination of molecular weight became difficult, because of the coloring of the camphor solution. Moreover, the acetylated resin is only with difficulty soluble in camphor. Therefore, we used benzil for the resin which could not be determined with camphor, as was described in Burke's papers.

Results

The Yield and Molecular Weight of the Resin. — The yield of the resin reached about 90% at 150°C for 2 hr. The maximum of the yield was seen at 8 hr. With the reduction in yield after that time, a small quantity of the insoluble resin was observed. The molecular weight of the soluble resin became larger with an increase in the yield at the initial stage, but it had the tendency to drop once when the formation of the insoluble resin had taken place and then to increase again (Fig. 1).

△ Yield of resin ○ Mol. wt. of resin
● Mol. wt. calculated from mol. wt. of acetate

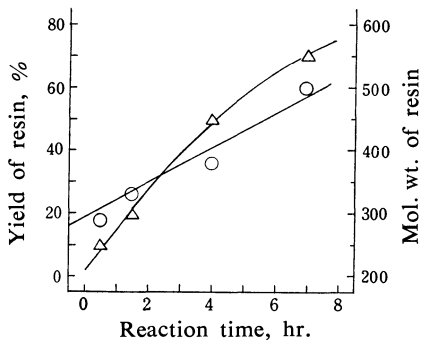

Fig. 2. The process of the formation of resin at 120°C.
△ Yield of resin ○ Mol. wt. of resin

The yields and the molecular weights of the resins obtained at 120°C increased with the reaction time (Fig. 2).

The Viscosity of the Resin. — The viscosity of the resin was determined at 25°C in a solution of 10 ml. of *N*, *N*-dimethylformamide containing 0.05 g. of the sample. Changes of the solution viscosity with reaction time showed the same tendency as that of the molecular weight (Fig. 3). No definite relationship between the molecular weight and the viscosity could be obtained.

8	150	870	10	150	770*
11	150	700	3	150	930*

* The insoluble product was obtained in a small yield.

The distribution curves are shown in Figs. 4 and 5.

The Reformation of the Resin.—1.3 g. of the resin and 0.020 g. of *p*-toluenesulfonic acid were dissolved in 1.5 ml. of bis(2-ethoxyethyl) ether and then heated in a sealed tube for 3 hr. at 150°C. The reaction product was purified by reprecipitation from acetone with water. The results obtained may be seen in Table II. The yields in all runs were about 75%.

Discussion

A Comparison of Burke's and the Present Author's Results. — The results obtained by Burke and by us are shown in Tables III and IV.

As can be seen from these tables, our results agreed well with Burke's results with regard to the viscosity and elementary analysis. Also, the infrared spectra of the resins show a good agreement (Fig. 6). Consequently, it is believed that the resins obtained by both are the same; only the molecular weights are quite different.

The Molecular Weight Distribution of the Resin.—While the distribution curves of the resins obtained at 150°C did not agree at all with Imoto's equation, a tendency for agreement in Poisson's distribution was observed for the resin obtained by reaction for 8 hr. at 150°C (Fig. 7). It is believed that this was because the reaction was so violent that the yield reached 90% in only 2 hr. and that "a reformation reaction" had already occurred. We, therefore, carried out the reaction under milder conditions, at 120°C, and thus obtained a distribution curve of the resin at the early

stage of the reaction. This curve, which agreed with Imoto's equation, is shown in Fig. 8.

Elementary Analysis of the Resin.—From the elementary analysis of the resins, it was made clear that another reaction, one differing from the usual novolak formation, took place. The results obtained are shown in Table V. The determined value of C% was larger than the calculated value, and the difference became lagrer as the reaction proceeded. Moreover, not only was the observed value of Cl% smaller than the calculated value, but the difference became larger with the reaction time and with the increase in the molecular weight, as is shown in Fig. 9. The values of Cl% of the acetylated resin, however, approached the theoretical values (Table VI).

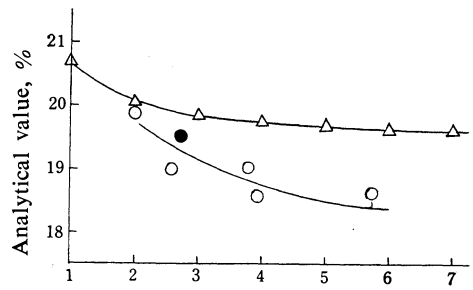

Fig. 9. Analytical values of Cl observed in the resin before and after fractionation. Acetate of the resin (150°C, 2 hr.) was used as sample.
△ Calculated values for acetate
● Observed value of acetate of resin
○ Observed values after fractionation on the acetate

From these facts it may be considered that the reaction of dehydrochlorination occurred, yielding the structure shown in Table VII.

Summary

A novolak resin of a higher molecular weight, as described by Burke et al., was not obtained. It was considered that the reaction of *p*-chlorophenol with *s*-trioxane proceeded as follows: (1) At first, a normal reaction of novolak formation proceeded. The molecular weight distribution was explained by Imoto's theoretical equation (120°C, 4 hr.). The analytical value of Cl% was rather close to the calculated value. (2) Then "reformation reaction" started (120°C, 7 hr. and 150°C, 2 hr.). (3) Reformation took place rather vigorously, and the molecular weight distribution became close to Poisson's distribution (150°C, 8 hr.). (4) A three-dimensional compound was formed, and the molecular weight of the soluble part was lowered (150°C, 11 hr.). (5)

The molecular weight of the soluble part increased by the decomposition of the three-dimensional compound and by the dehydrochlorination reaction (150°C, 24 hr.).

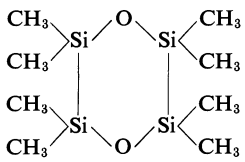
The Crystal Structure of Bistetramethyldisilanilenedioxide $((CH_3)_4Si_2O)_2$

By Tsunehiro TAKANO, Nobutami KASAI and Masao KAKUDO

(Received January 5, 1963)

There have been many structural investigations of the bond angle and bond length of the Si–O–Si skeleton in various types of inorganic silicates. It would be of interest to extend these investigations in the field of organic silicon compounds. The crystal structures of various types of siloxanes have been studied by Frevel and Hunter[1], Roth and Harker[2], Peyronel[3] and Steinfink, Post and Fankuchen[4]. These structure analyses have shown that cyclic siloxanes have two configurations in the Si–O–Si rings, one planar and one puckered.

There has, however, been no study of the crystal structure of an organic silicon compound containing the Si–Si bond. It would be interesting, for instance, to determine the crystal structure of bistetramethyldisilanilenedioxide, which has a cyclic member which includes the Si–Si bond. From the results of chemical analysis, it was supposed that the molecule had following constitutional formula:



Experimental

Crystals recrystallized several times from petroleum ether at 10°C are colorless, plate-like, and have no cleavage. The crystals very quickly sublime at room temperature, and are soluble in most organic solvents.

To prevent such sublimation of the specimen, the crystal was sealed in a thin-walled glass capillary. The quick sublimation and the low melting point made it impossible cut the crystal into a cylindrical specimen suitable for a X-ray photograph.

Oscillation and Weissenberg photographs were taken using Cu-K_α radiation filtered by nickel foil.

The cell dimensions and physical constants were determined to be as follows;

$a=7.67\pm0.02$ Å	$D_{obs}=1.04$ g. cm^{-3}
$b=6.64\pm0.02$ Å	$D_{calcd}=1.05$ g. cm^{-3}
$c=17.39\pm0.03$ Å	m. p. $=42$°C
$\beta=111.0\pm0.2$°	mol. wt. $=264$
$V=826.8$ Å^3	$Z=2$

The reflections $(0\,k\,0)$ with k odd and $(h\,0\,l)$ with l odd were absent, the $(h\,k\,l)$ reflections showed no extinction rule. These extinction rules show that the corresponding space group is $C_{2h}^5-P2_1/c$. The oscillation photographs taken at -50°C did not show any transition within the temperature range, unlike that taken at room temperature. The exposure time was limited by the sublimation of the crystal, so it was very difficult to obtain three-dimentional intensity data. The equatorial Weissenberg photographs around the a and b axes were taken by using the multiple-film technique. The relative intensities of the observed reflections were estimated in terms of an arbitrary scale by visual comparison with an intensity scale. The observed structure factors were brought to an absolute scale by means of Wilson's method[5].

Determination of the Configuration

The intensities of $(0\,k\,l)$ and $(h\,0\,l)$ reflections were corrected with the Lorentz and polarization factors. For the space group $P2_1/c$, two molecules in a unit cell have to be placed on the center of symmetry. This means that the molecule has a center of symmetry in itself. Therefore the asymmetric unit is a half of the molecule; two silicon atoms, one oxygen atom and four methyl groups. Consequently, twenty-one parameters, except for those of hydrogen atoms, should be determined in this structure analysis.

5) A. J. C. Wilson, *Nature*, **150**, 152 (1942).

First, an attempt was made to locate the silicon atoms by the Patterson function $P(xz)$ projection of the $(0\,l\,0)$ plane, because it is considered that overlapping of atoms were minimized in this projection (Fig. 1). All $(h\,0\,l)$ reflections which formed about two-thirds of the total number of unique $(h\,0\,l)$ reflections, were used to calculate the Patterson function. In the Patterson projection $P(xz)$, the silicon-silicon and silicon-oxygen vectors of adjacent molecules were fairly distinguishable. Thus, the coordinates of silicon and oxygen atoms could be approximately determined. The carbon atoms were not fixed by this Patterson projection. A probable structure model was made from the positions of the silicon and oxygen atoms derived from the Patterson projection and was corrected by structure factor refinements, referring to the covalent radii and tetrahedral angles about the silicon atoms[6].

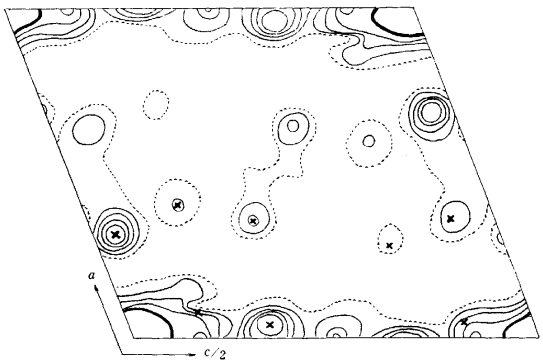

Fig. 1. Patterson function P(xz) projected on the $(0\,l\,0)$ plane. Contours show equal intervals in an arbitrary scale. The intermolecular vectors between ring members are marked with crosses.

Although the results of the calculation of structure factors on the first model did not show a good agreement with the observed structure factors $F(h\,0\,l)$, even for the reflections with low indices, a two-dimensional Fourier synthesis on the $(h\,0\,l)$ plane was tried, using lower order reflections. The electron density map obtained here, however, indicated not only the outline of the molecule but also two silicon atoms, an oxygen atom and two carbon atoms. The structure factors were calculated, and several Fourier syntheses were made. After these procedures, the (F_o-F_c) syntheses were applied for correcting the coordinates and temperature factors. The isotropic temperature factors for carbon atoms, oxygen atom and silicon atoms were $B_C=3.5$, $B_O=3.5$ and $B_{SI}=2.5$ Å^2 respectively at this step of the refinement.

6) L. C. Pauling, "The Nature of the Chemical Bond", Cornell University Rress, Ithaca, N. Y. (1960), p. 246.

On the other hand, an attempt to locate the y parameters was calculating the Patterson function, $P(yz)$. The intensities of the $(0\,k\,l)$ reflections were generally weak because of the limitation of exposure time. The intensities of about one-third of the $(0\,k\,l)$ reflections observed were too weak to be measured. As has been mentioned before, no peaks corresponding to the intramolecular vectors could be resolved in this Patterson projection. Therefore, a special type of modified Patterson function[7] was calculated:

$$P'(yz)=\sum\sum|F(0\,k\,l)|^2(1-\exp(-\xi^2))\times\cos 2\pi ky\cos 2\pi lz$$

where $\xi=2\sin\theta$. This modified Patterson map was particularly effective in distinguishing the intramolecular vectors, as is shown in Fig. 2.

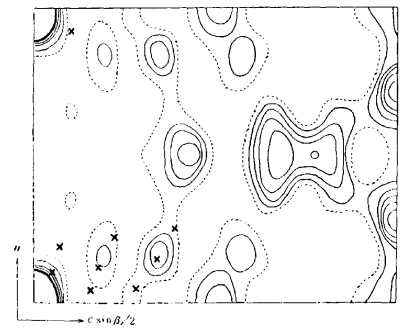

Fig. 2. A modified Patterson function projected on the $(l\,0\,0)$ plane. Contours are at equal intervals in an arbitrary scale. The intermolecular vectors between ring members are marked by crosses.

Using the y parameters derived from this modified Patterson projection and the z parameters obtained from the (0 1 0) projection, the structure factors of $(0\,k\,l)$ reflections were calculated. The usual successive refinements of atomic parameters were carried out. The isotropic temperature factors $B_C=9.0$ for carbon, $B_O=9.0$ for oxygen and $B_{SI}=5.0$ Å^2 were used in the calculations of $F(0\,k\,l)$. At this step of refinement, including the (F_o-F_c) syntheses, the reliability factors, $R=\sum||F_o|-|F_c||/\sum|F_o|$, were 24.6% for $(0\,k\,l)$ and 21.2% for $(h\,0\,l)$.

The least square method was used in the next step of the refinement. Ten cycles of the refinement of positional and isotropic temperature factor parameters reduced the R factor from 24.6% to 20.1% for $(0\,k\,l)$ and from 21.2% to 13.5% for $(h\,0\,l)$, non-observed reflections being excluded.

The calculations of the structure factors and the least square refinements were carried

out with a NEAC-2203 electronic computer, and the Fourier and Patterson functions, with a NEAC-2101 electronic computer. The least square calculations were performed using the program of Osaki[8]. The Hartree-Fock atomic scattering curves for carbon and oxygen atoms and Slater's for silicon atoms were employed throughout the calculations of the structure factors. In the computations of the structure factors, the contribution of hydrogen atoms was disregarded. The final atomic coordinates and isotropic temperature factors of each atom as obtained by the least square method are listed in Table I. The final electron density projections upon (1 0 0) and (0 1 0) are shown in Fig. 3 and Fig. 4 respectively. The observed and calculated structure factors are tabulated in Table II.

Diallylsilanediol	—	1.63	1.90	—	110	110	—

intermolecular bond lengths and angles as well as the intramolecular distances, are illustrated in Figs. 5 and 6.

The equation of a plane including the Si-O-Si triangle the ring member is:

$$6.63x-3.06y+z-62.5=0$$

and that including the four silicon atoms is:

$$3.06x-2.93y+z=0.$$

These two planes form an angle of 170°. Thus, the skeleton of the ring has a chair form. This shows that the configuration of the skeleton compensates for the energy of strain which may exist in the ring if it has a planar form.

The Si-Si bond distance, 2.35 Å, in the molecule is almost the same as that found in metallic silicon (2.34 Å). The Si-O bond length, 1.61 Å, is considerably shorter than the value (1.83 Å) which is the sum of the covalent radii of the silicon and oxygen atoms. This shrinkage of the bond length as known in silicates has already been reported also in organic silicon compounds[9-14]. The bond angle of Si-O-Si (143°) is greater than either the covalent p orbital bond angle or the sp^2 and sp^3 hybrid orbital bond angle. This finding and the shrinkage of the Si-O bond length may indicate the presence of an ionic character in the Si-O-Si configuration, as was been suggested by Pauling[15]. The average bond length of the Si-C bond (1.88 Å) is almost in agreement with those of spirosiloxane, diethylsilanediol and diallylsilanediol. However, the deviations of the Si-C bond lengths from the average bond length are not small in this case. This may be caused by the overlapping of carbon atoms in the two-dimensional projections. The bond angles around the silicon atoms are almost regularly tetrahedral; their values agree with those of spirosiloxane, octamethylcyclotetrasiloxane and hexamethylcyclotrisiloxane, as is shown in Table IV. The intermolecular interaction seems to be somewhat weaker than the ordinary methyl-methyl interaction, because the crystal has an extremely large sublimation nature and a low melting point. In fact, the intermolecular distances of the crystal obtained in this study (Figs. 5 and 6) are longer than the ordinary van der Waals distance (4.0 Å) between methyl groups.

The authors wish to express their gratitude to Professor Makoto Kumada* of Osaka City

The Radiolysis and Photolysis of Cycloheptatriene

By Shigeyoshi ARAI, Michio MAEMORI, Kenji YAMAGUCHI and Shoji SHIDA

(Received January 5, 1963)

Previously we reported[1] that cyclooctatetraene is one of the most radiation-stable organic liquids. Henglein's experiment[2], in which the *G* value of the radical formation was determined by the addition of sulfur dioxide as the radical scavenger, also supports this conclusion. Although cyclooctatetraene resembles benzene in chemical structure, its chemical properties rather belong to the cycloolefins. Therefore, it would be interesting to investigate the radiolysis of cycloheptatriene C_7H_8, which is a cycloolefin with three alternant double bonds and one methylene group. There has been, to the author's knowledge, only one paper dealing with the radiolysis of cycloheptatriene. Juppe and Wolf[3] carried out the irradiation of carbon-14 labeled cycloheptatriene and found that randomly-labeled bitropyl is produced from specifically-labeled cycloheptatriene. They therefore suggested that a symmetrical intermediate is formed as a precursor of the dimer.

It is known that in many cases reactions in the radiation chemistry are similar to those involved in the photochemistry. The photochemical study of cycloheptatriene in the vapor phase is of considerable value for understanding the mechanism in the radiolysis. Recently Srinivasan[4] has found that toluene is mainly formed in its direct photolysis.

A more detailed study of the radiolysis and electron resonace study are presented here. Moreover, the mercury-photosensitized reaction of cycloheptatriene has been investigated in the expectation of elucidating the mechanism of the radiolysis.

Experimental

Material.—Cycloheptatriene was prepared by the thermal isomerization of bicycloheptadiene in the method described by Woods[5]. Repeated distillations were carried out to remove the by-products, especially toluene, from the raw material. However, the sample used here was shown to be 95 to 97% cycloheptatriene and 3 to 5% toluene by gas chromatography.

Irradiation.—The radiation employed in the radiolysis of liquid cycloheptatriene utilized γ rays from 200C ^{60}Co. The sample was degassed on a vacuum line by freezing and pumping, and then sealed off in a glass cell. Irradiations were made at room temperature for 3 to 14 days. The dose rate was about 3.9×10^3 r/min.

Analysis.—After irradiation the non-condensables at -196°C (a mixture of hydrogen and methane) were transferred to a gas-buret by the use of a Toepler pump. Then the hydrogen and methane were analyzed by using a copper oxide furnace. The condensables were divided at -120°C into two fractions, (a) $C_2\sim C_4$ hydrocarbons, and (b) C_7 hydrocarbons. Quantitative analysis of each fraction was accomplished by gas chromatography. The columns, consisting of benzyl ether and silicon oil on crushed firebrick support, enabled the complete separation of the compounds for fractions a and b respectively. After distillation of the volatile products in vacuo at 100°C, a viscous yellow residue was found on the wall of the glass cell. This substance was determined gravimetrically as the polymer.

ESR Experiments.—In the ESR experiments the radiation used was the electron beam from a 1.5MeV. Van de Graaff generator. The sample in an open vessel, which was kept at the temperature of liquid nitrogen, was irradiated with a dose of 1×10^8 rad. The spectra were observed also at -196°C using a Nihon Denshikogaku ESR spectrometer.

Photochemical Experiments.—Cycloheptatriene vapor in a cylindrical quartz cell (diameter, 50 mm., length, 50 mm.), which contained a drop of

mercury, was irradiated by a neon-gas-filled mercury lamp. The light shorter than 2200A was cut off with a filter. The analytical procedures were the same as in the radiolysis.

Results and Discussion

Mercury Photosensitized Reaction in the Vapor Phase.—Owing to the presence of impurities it was not possible to obtain the absorption intensity of cycloheptatriene at the wavelength of 2537A. However, the large absorption coefficient of mercury vapor for the radiation of 2537A led the authors to assume that it is predominantly the mercury photosensitized reaction which takes place.

Figure 1 shows the changes in total pressure as a function of the reaction time. Curves A and B are obtained for the initial pressures

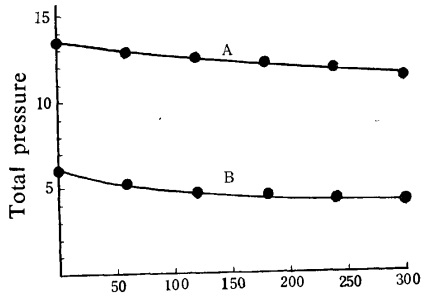

Fig. 1. Variation of total pressure as reaction time proceeds.
A Initial pressure, 13.5 mmHg
B Initial pressure, 6 mmHg

of 13.5 mmHg and 6 mmHg respectively. In run A a decrease in pressure of 2.2 mmHg was observed after the irradiation time of 300 sec., at which time the gas compositions were 30% toluene and 70% cyclcheptatriene. In run B a decrease of 2.0 mmHg was observed after 300 sec. The gas compositions were 75% toluene and 25% cycloheptatriene. In both cases the decomposition products were scarcely detectable. These results indicate that the major reaction is the isomerization of cycloheptatriene into toluene. The small decrease in total pressure may be attributed to the polymerization initiated by some radical decomposition of the cycloheptatriene.

Figure 2 shows the amounts of toluene formed as the irradiation time proceeds. The initial pressure of cycloheptatriene is 7 mmHg. The amount of toluene increases as a linear function of the irradiation time.

In Fig. 3 the amounts of toluene for the irradiation time of a half minute are plotted for the various initial pressures of cycloheptatriene. It may be clearly seen that the rates

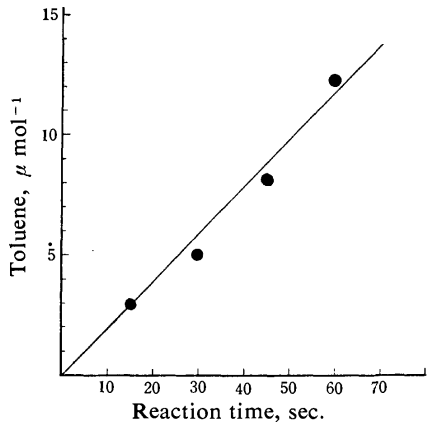

Fig. 2. Amounts of toluene formation as reaction time proceeds. The initial pressure of cycloheptatriene, 7 mmHg.

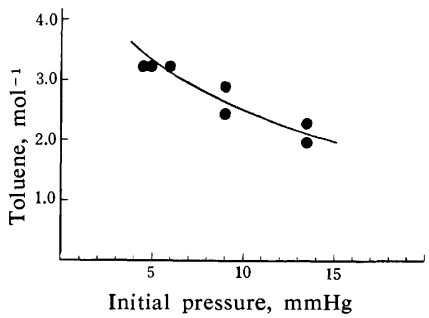

Fig. 3. Variation of toluene formation as a function of the initial pressure of cycloheptatriene. Irradiation time, 30 sec.

of toluene formation are strongly pressure-dependent. Thus, the present authors have concluded that, in the same manner as in cyclooctatetraene[6,7], an excited molecule of cycloheptatriene, which may either isomerize into toluene or be collisionally deactivated, is formed at the initial step. The experimental results may be explained by the following reaction mechanism:

$$C_7H_8 + Hg^* \rightarrow C_7H_8^* + Hg \quad (1)$$

$$C_7H_8^* \rightarrow CH_3C_6H_5 \quad (2)$$

$$C_7H_8^* + C_7H_8 \rightarrow 2C_7H_8 \quad (3)$$

$$C_7H_8 + Hg^* \rightarrow \text{Polymerization initiated by radicals} \quad (4)$$

The steady-state treatment leads to Eq. A:

$$\frac{I_o}{R_t} = 1 + \frac{k_3}{k_2}[C_7H_8] \quad (A)$$

where R_t is the rate of toluene formation, I_o

6) H. Yamazaki and S. Shida, *J. Chem. Phys.*, **24**, 1278 (1956).
7) H. Yamazaki, This Bulletin, **31**, 677 (1958).

is the absorbed intensity of the 2537A resonance line, $[C_7H_8]$ is the pressure of cycloheptatriene, and k_2 and k_3 are the rate constants of reactions 2 and 3 respectively. Thus, there has to be a linear relationship between $1/R_t$ and $[C_7H_8]$. As may be seen in Fig. 4, a satisfactory straight line is given. A slope-to-intercept ratio corresponds to k_3/k_2 in Eq. A. The numerical value is 0.11 $mmHg^{-1}$.

Srinivasan[4] has recently studied the direct photolysis of cycloheptatriene in the vapor phase and has found that the formation of toluene decreases with the total pressure. He suggested that isomerization to toluene occurs not from an electronically-excited molecule of cycloheptatriene but from a vibrationally-excited ground state molecule that is formed

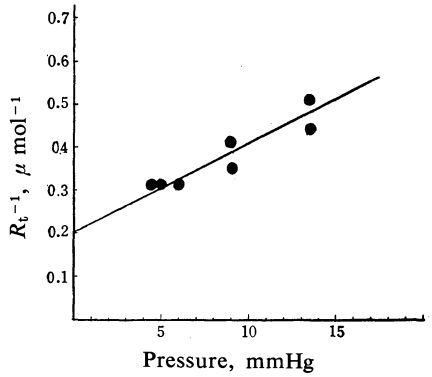

Fig. 4 Relationship between R_t^{-1} and $[C_7H_8]$. R_t is amount of toluene formation for the irradiation time of 30 sec. $[C_7H_8]$ is the pressure of cycloheptatriene.

by the internal conversion of the electronic energy. Generally speaking, however, a triplet state lies at a lower energy than a singlet state formd from the same orbital, and such large molecules as cycloheptatriene and cyclooctatetraene may easily undergo transitions from the initially-excited singlet to the lower triplet level. Further, in the present case, when an excited mercury atom (^3P) reacts with cycloheptatriene, the triplet-excited molecule is considered to be produced according to the spin conservation rule[8]. Hence, in both cases the isomerization reaction to toluene is likely to arise from the triplet excited molecule. The results in the present experiments are very similar to those obtained by Srinivasan from the direct photolysis at 2600A. Moreover, the value of k_3/k_2 nearly agrees with that calculated from his data[9].

Srinivasan pointed out that the formation of toluene was not totally quenched by the addition of even considerable amounts of oxygen or nitric oxide. However, it has been reported[10,11] that in the mercury photosensitized reaction of ethylene nitric oxide has no effect on the decomposition reaction of the triplet-excited ethylene. Therefore, the above experimental finding does not necessarily lead to the exclusion of the triplet-excited molecule.

The Electron Spin Resonance of Irradiated Cycloheptatriene[12].—It has been known that when frozen hydrocarbons are irradiated by ionizing radiations, the free radicals produced can be stabilized. A survey of the their ESR spectra gives valuable information concerning the primary act of ionizing radiations. Therefore, we carried out the ESR measurements of electron-irradiated cycloheptatriene frozen at −196°C.

As is shown in Fig. 5, eight equally-spaced

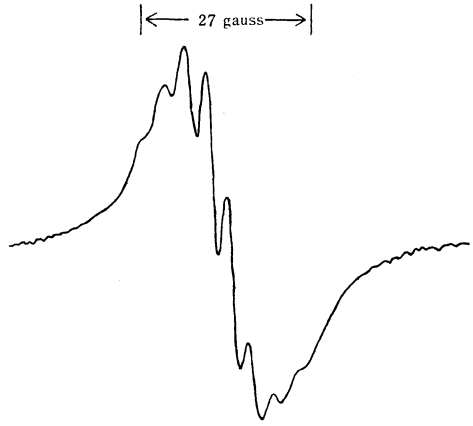

Fig. 5. First derivative ESR spectra of electron irradiated cycloheptatriene. Dose 1×10^8 rad, temperature of irradiation and ESR measurement is −196°C.

lines are observed in the spectrum. This fact clearly indicates that the seven equivalent protons interact on the unpaired electron. That is, the cycloheptatrienyl radical C_7H_7, which has a symmetric conjugated plane frame, is produced by the electron irradiation. On the basis of the simple LCAO MO method, it is to be expected that cycloheptatrienyl radical will have a large delocalization energy, as a

8) K. J. Laidler, "The Chemical Kinetics of Excited States", Oxford University Press, London (1955).

9) He also observed that the formation of toluene at 3130A shows a different pressure dependency from that at 2600A. However, this may be explained as follows. At a shorter wavelength the more vibrationally-excited molecule in the triplet state would be produced as the result of internal conversion. This results in the increase of the rate constant of reaction 2. Consequently, k_3/k_2 at 2600A gets larger than k_2/k_3 at 3130A in Eq. A.

120	5.975	7.0	1.2	—	—	3.4
	C_8H_8	2.0				0.66

result of which the bond dissociation energy of the parent molecule, $H\text{-}C_7H_7$, will be much smaller than the other C–H bonds. Lossing et al.[13] reported 74±7 kcal./mol. for this bond. Generally speaking, in the reaction of radiation chemistry the C–H bonds with lower bond energies are preferentially fractured. This principle leads to the conclusion that the formation of the cycloheptatrienyl radical is one of the major reactions in the radiolysis. In order to obtain a rough estimate of the relative yield of the radical formation, the ESR signal intensity of irradiated cycloheptatriene was compared with that of irradiated benzene under the same experimental conditions. The near equality of the signals shows that cycloheptatriene is as stable as benzene with respect to the radical formation by ionizing radiations. During irradiation and the procedures which followed the sample was open to the air. However, the result with a degassed cycloheptatriene sample was the same as that obtained in air. Therefore, oxygen has no effect on the cycloheptatrienyl radical at −196°C.

The Radiolysis of Liquid Cycloheptatriene.— The *G* value of the products in the radiolysis of liquid cycloheptatriene at room temperature are shown in Table I; they are there also compared with the corresponding values for cyclooctatetraene.

The cycloheptatriene used contained 3 to 5% of toluene as an impurity. Judging from the findings about the irradiation of pure toluene[14], however, the direct effect of radiation on toluene is entirely negligible, even when a maximum is present.

The *G* values of the gaseous products found here are very small. Since cycloheptatriene itself is a reactive scavenger for free radical, those products appear to be produced by a molecular process, a hot atom process being included, or by an ion-molecule reaction. In discussing the radiolytic process, electron impact studies of cycloheptatriene will provide interesting information. In the mass spectra of cycloheptatriene obtained by Meyerson and Rylander[15] the most abundant ion ocurrs at mass 91, and the second most abundant ion, at 92. Other peaks of relative intensity greater than 10% occur at 65 and 39. Accordingly, the following reactions may take place:

$$C_7H_8 + e = C_7H_8^+ + 2e$$

$$C_7H_8 + e = C_7H_7^+ + H + 2e$$

$$C_7H_7^+ = C_5H_5^+ + C_2H_2$$

It is very interesting that the $C_7H_7^+$ ion is produced in a large amount. The results of the ESR experiments show that cycloheptatrienyl radicals are formed by electron irradiation. Juppe et al. suggested a cycloheptatrienyl radical as a precursor of the dimer which was isolated in their experiments. This radical may arise from the recombination of $C_7H_7^+$ with the electron, along with the split of a hydrogen atom from a highly-excited neutral molecule of cycloheptatriene. The formation of the hydrogen molecule may be explained by the abstraction reaction of a hot hydrogen atom, which comes from the energetic fragmentation in these processes. According to Meyerson and Rylander, the cyclic $C_7H_7^+$ ion decomposes into the $C_5H_5^+$ ion and acetylene. Thus, the formation of acetylene may be attributed to this reaction. However, the formation of ethylene can not be explained from the mass spectra of cycloheptatriene, because the ions corresponding to the loss of ethylene from $C_7H_7^+$ and $C_7H_8^+$ are relatively small. Probably in this case more complex reactions take place.

The polymer in Table I contains the C_{14} products, of course, together with the heavier hydrocarbons. Cycloheptatriene has a remarkable reactivity to the radicals, and the polymerization reaction gradually takes place even in the presence of air. Judging from this fact, the *G* value found here may be said

13) A. G. Harrison, L. R. Honnen, H. J. Dauben and F. P. Lossing, *J. Am. Chem. Soc.*, **82**, 5593 (1960).
14) J. P. Manion and M. Burton, *J. Phys. Chem.*, **56**, 560 (1952).
15) S. Meyerson and P. N. Rylander, *J. Chem. Phys.*, **27**, 901 (1957).

to be rather small. That is, the yield of the radical formation in the initial step may be low.

Owing to the presence of toluene in the sample used, the precise G value of the toluene formation was not obtained. However, there was no difference between the gas chromatographic check of toluene before and after irradiation. If the experimental error is taken into account, the G value of toluene will be small, not larger than 0.5.

From these experimental results we concluded that, in the radiation chemistry of liquid cycloheptatriene the major part of the absorbed energy results in the formation of the excited molecule, the electronic energy of which is readily converted to thermal energy. In the case of cyclooctatetraene, its high stability against ionizing radiations was attributed to the collisional deactivation of the excited molecule. The life time of 2×10^{-8} sec. is obtained for the excited cycloheptatriene molecule from the above-mentioned photochemical experiment, assuming that k_3 is about 1×10^{11} l./mol. sec.; that is, every collision leads to deactivation. Consequently, it may be considered that in the liquid phase the excited molecule is deactivated prior to its decomposition or its isomerization.

The over-all reaction mechanism of the radiolysis of cycloheptatriene is:

$$C_7H_8 \rightsquigarrow C_7H_8^*$$

$$C_7H_8^* + C_7H_8 \longrightarrow 2C_7H_8$$

The latter process plays a leading role. In addition,

$$C_7H_8 \rightsquigarrow C_7H_7 + H$$

$$C_7H_8 \rightsquigarrow H(\text{hot}), C_2H_2, C_7H_7, \text{ etc.}$$

$$H(\text{hot}) + C_7H_8 \longrightarrow H_2 + C_7H_7$$

$$2C_7H_7 \longrightarrow C_{14}H_{14}$$

$$H \text{ (or the other radicals)} \xrightarrow{C_7H_8} \text{Polymer}$$

As has been stated above, Juppe et al. found ditropyl as the product in the radiolysis of cycloheptatriene. The other reactions have not been considered here because there is no definite evidence for their occurrences.

Summary

1) In the photosensitized reaction of cycloheptatriene vapor, toluene was produced as the result of isomerization. The amount of toluene formation decreases as the pressure of cycloheptatriene increases. Isomerization to toluene proceeds through the excited molecule, which may be collisionally deactivated.

2) The ESR experiments at low temperatures show that cycloheptatrienyl radicals are formed by electron irradiation. However, the yield of the radical formation is low, nearly equal to that of benzene.

3) In the radiolysis of liquid cycloheptatriene the G values of the gaseous products and toluene are very small. The G value of the polymer seems to suggest the low yield of the radical formation at the initial step. We concluded that the major part of the absorbed energy results in the formation of the excited molecule, the electronic energy of which is readily converted to thermal energy.

The anthors wish to thank Professor Zenichiro Kuri and Dr. Shin Sato for their helpful discussions. The bicycloheptadiene was kindly given by Dr. Katsundo Matsuzawa.

The Polymerization Reaction of Sodium Phosphate

By Masayuki NAKAGAKI, Hiroshi INOUE, Tadao FUJIE and Shigeru OHASHI*

(Received January 5, 1963)

The amorphous polymer of sodium phosphate is called by several names, such as Graham's salt, glassy phosphate, sodium metaphosphate glass, sodium polymetaphosphate, and sodium hexametaphosphate[1]. Although the chemical formula of this substance is the same as that of a metaphosphate $(NaPO_3)_n$, it is not a ring-phosphate but a kind of chain polymer[2-4] and so may be called a sodium polyphosphate. The polyphosphate usually prepared is, however, a branched polymer, and it is partly depolymerized within several hours after dissolution in water or in an aqueous sodium bromide solution[5-7]. It has been concluded that the depolymerization is mainly due to the hydrolysis at the point of branching[5,6]. Therefore, it is interesting to polymer chemists[5] that the solution obtained at the end of the hydrolysis contains unbranched molecules only, and that the distribution function of the molecular weight has been determined both theoretically and experimentally[8].

In the present paper, polymerization reaction of sodium phosphate will be studied. Generally speaking, polymerization reactions are classified into two types: (1) condensation polymerization, and (2) addition polymerization, the latter including ring-opening polymerization. In the case of the preparation of amorphous sodium polyphosphate, a reaction starting from sodium hydrogen orthophosphate:

$$n\mathrm{NaH_2PO_4} = (\mathrm{NaPO_3})_n + n\mathrm{H_2O} \qquad (1)$$

is a kind of condensation polymerization, while a reaction starting from sodium trimetaphosphate (a ring-phosphate):

$$(n/3)(\mathrm{NaPO_3})_3 = (\mathrm{NaPO_3})_n \qquad (2)$$

is a kind of ring-opening (addition) polymerization. In this paper, these two reactions will be compared on the basis of viscometry of the products.

Experimental

Material. — The sodium dihydrogen orthophosphate dihydrate ($NaH_2PO_4 \cdot 2H_2O$) used was the same specimen as was used in a previous study[7]. The dihydrate was changed into an anhydrate by heating it at 110°C under a reduced pressure for about 15 hr.; thus it reached a constant weight and could be used for further experiments.

Sodium trimetaphosphate $(NaPO_3)_3$ was prepared by heating the above-described sodium dihydrogen orthophosphate anhydrate in a platinum crucible at 530°C for 5 hr.[1,3] and was then kept in a desiccator.

Polymerization Reaction. — The polymerization reaction was effected by heating about 7 g. of the starting material in a platinum crucible about 35 mm. in diameter, 37 mm. in height and about 30 ml. in capacity. For the heating, a Siliconit electric furnace BH-1020, equipped with a thermoelectric automatic regulator P-400 with a platinum platinum-rhodium thermocouple, was used. It took the furnace about 1.2, 1.8 and 3.5 hr. to reach 530, 700 and 900°C respectively from room temperature. At the end of the polymerization reaction, the content of the crucible was poured on a copper plate and pressed with another copper plate in order to cool the product rapidly.

Viscometry.—The product of the polymerization reaction was dissolved in a 0.07 N sodium bromide solution at the polymer concentration of 1 g./100 ml. It took about 1 hr. to dissolve. Solutions of other concentrations were prepared by the dilution of the above-prepared solution. Viscosity was measured by an Ostwald viscometer, while density was measured by an Ostwald pycnometer in a thermostat at 25.5°C.

Results and Discussion

Polymerization Equilibrium.—As the theory of reorganization[9] suggests, the polymerization reaction of phosphate will reach an equilibrium state if the reaction time is sufficiently long. The state of the equilibrium, however, may depend on the temperature. For a relatively long reaction time, therefore, the average molecular weight of the reaction product will

depend more on the temperature than on the reaction time[10].

Setting the reaction time at 5 hr., the polymerization reaction was effected at various temperatures, and the average degree of polymerization, $\bar{n}$, of the product was determined by end-group titration. On the basis of the results shown in Fig. 1, it may be concluded that the degree of polymerization increases with the reaction temperature, and that the degrees of polymerization are equal for the products both by condensation polymerization and by ring-opening polymerization[11].

○ Condensation polymerization of orthophosphate
● Ring opening polymerization of trimetaphosphate

Time Dependence of Solution Viscosity.—The viscosity of solutions of the polymerization products decreases with time because of the depolymerization of the polyphosphate, and it has already been shown in a previous paper[7] that the reaction is of the first order. As the examples in Fig. 2 show, the viscosity, η, of the solution relative to that of the solvent (a 0.07 N sodium bromide solution) changes with time, τ, according to the following empirical equation:

$$\log(\eta-\eta_\infty)=\log(\eta_0-\eta_\infty)-K\tau \qquad (3)$$

where the constants, η_0, η_∞ and K, are the relative viscosities at $\tau=0$, $\tau=\infty$, and the rate constant respectively. As for the value of η_∞, the relative viscosity at $\tau=24$ hr. was used,

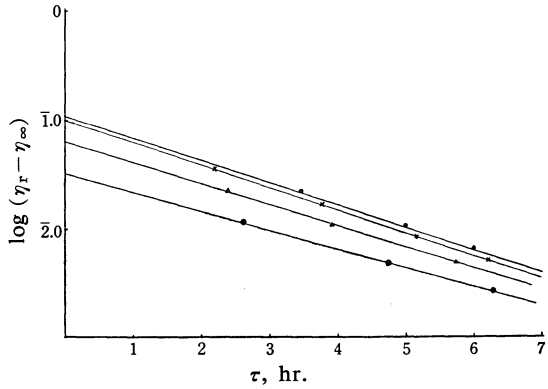

Fig. 2. Examples of decrease of solution viscosity with time in 0.07 N NaBr solution at 25.5°C for the product polymerized by heating of orthophosphate at 900°C for 6 hr.
Concentration of solution: (○) 1, (×) 0.8, (△) 0.4 and (◎) 0.2 (g./100 ml.)

and the value of η_0 was determined on the basis of Eq. 3.

It was widely been known that the intrinsic viscosity of a solution is directly related to the average polymerization degree of the solute. In the case of solutions of sodium polyphosphate in the solvent 0.07 N sodium bromide, the relation between the intrinsic viscosity and the average molecular weight derived in the previous paper[7] can be rewritten as:

$$\bar{n}=877[\eta]-30.5 \qquad (4)$$

where $\bar{n}$ is the average polymerization degree.

The values of $[\eta_0]$ and $[\eta_\infty]$ were obtained on the basis of the values of η_0 and η_∞ respectively, measured at polymer concentrations of 0.1, 0.2, 0.4, 0.6, 0.8 and 1.0 g./100 ml. For the extrapolation to the infinite dilution, two equations,

$$\left.\begin{aligned}(\eta-1)/c&=[\eta]+k[\eta]^2c\\(\ln\eta)/c&=[\eta]-k'[\eta]^2c\end{aligned}\right\} \qquad (5)$$

together with the equation,

$$k+k'=0.5 \qquad (6)$$

were used to confirm the extrapolation[12,13].

As has already been stated in earlier in this paper, it has been concluded that the depolymerization is mainly due to the hydrolysis at the point of branching[5,6]. Therefore, $[\eta_0]$ should be related to the average polymerization degree of the whole molecule before the hydrolysis, that is, the branched molecule formed by the polymerization reaction. On the other hand, $[\eta_\infty]$ should be related to the average polymerization degree of hydrolyzed

10) A. C. Chatterji, *J. Polymer Sci.*, 35, 235 (1959).

11) The data shown in Fig. 1 were obtained by one of the authors (S. O.) at Kyushu University. The end group titration was made about 24h. after dissolution, and the P-O-H end group generated by the hydrolysis of a branching point was believed to be titrated as an end-group[6]. The values of $\bar{n}$ in Fig. 1, therefore, correspond to $\bar{n}_\infty$ of Figs. 3 and 4. The inexact agreement between the numerical values in these figures is probably due to the difference in the methods of $\bar{n}$ determination and also to a minor difference in the experimental techniques of the polymerization.

molecules, that is, the average length of each branch.

The Condensation Polymerization of Sodium Dihydrogen Orthophosphate.—Sodium dihydrogen orthophosphate anhydrate (NaH_2PO_4) was put in a platinum crucible and heated in an electric furnace. After the furnace reached the polymerization temperature, the heating was further continued for 1/2, 3 and 6 hr. at that temperature (700°C or 900°C). The intrinsic viscosities, $[\eta_0]$ and $[\eta_\infty]$, of the polymerization products were measured. The results are shown in Table I. The $[\eta_0]$ and $[\eta_\infty]$ values of the products polymerized at 900°C were greater than those polymerized at 700°C. The $[\eta_0]$ value for 900°C reaches a maximum value (0.298) at about 3 hr. and then decreases, but the $[\eta_\infty]$ value for 900°C and the $[\eta_0]$ and $[\eta_\infty]$ values for 700°C are the greater, the longer the polymerization time. The $[\eta_\infty]$ value approaches 0.198 for 900°C and 0.140 for 700°C.

The Ring-opening Polymerization of Sodium Trimetaphosphate. — Sodium trimetaphosphate kept in a platinum crucible at room temperature was put in an electric furnace. The furnace had been heated, in advance, to the polymerization temperature. When the heating of 5 min.~2 hr. for the polymerization was over, the product was taken out and the $[\eta_0]$ and $[\eta_\infty]$ values were measured. The results are shown in Table II. The relation between the intrinsic viscosities and the polymerization time is entirely different from the case of condensation polymerization. The maximum points of $[\eta_0]$ and $[\eta_\infty]$ are located at the reaction time shorter than 5 min. for 900°C and 11 min. for 700°C. Five or eleven minutes is required to melt the contents of the crucible. In the case of ring-opening polymerization, therefore, the polymerization is finished almost immediately after the material is melted. The

—	0	0.016*	0.016*

* Sodium trimetaphosphate itself

$[\eta_0]$ value is greater for 700°C than for 900°C, and decreases rapidly when the polymerization time becomes longer. The $[\eta_\infty]$ value decreases gradually and approaches 0.166 for 900°C and 0.145 for 700°C.

A Comparison of Condensation Polymerization and Ring-opening Polymerization.—The intrinsic viscosities, $[\eta_0]$ and $[\eta_\infty]$, were recalculated to the average degrees of polymerization, $\bar{n}_0$ and $\bar{n}_\infty$ respectively, according to Eq. 4, where $\bar{n}_0$ is the polymerization degree of the whole molecule[14] and $\bar{n}_\infty$ is the average polymerization degree of each branch in the molecule. Therefore, the apparent number of branches in one molecule, B, may be obtained by;

$$B=\bar{n}_0/\bar{n}_\infty \qquad (7)$$

The results of the calculation are shown in Figs. 3, 4 and 5.

On the basis of these results, the following points may be emphasized. In the case of the condensation polymerization, both $\bar{n}_0$ and $\bar{n}_\infty$ are the greater, the higher the temperature. This would mean that the polymerization due to the separation of water proceeds the further, the higher the temperature. When the reaction time is longer than 3 hr., the thermal separation of branches occurs simultaneously, so that B and $\bar{n}_0$ decrease to some extent, especially at a high temperature (900°C). The length of each branch, $\bar{n}_\infty$, however, shows no appreciable decrease. In the case of the ring-opening polymerization, on the contrary, the

14) In this case, the molecules are branched. The relation between $[\eta]$ and $\bar{n}$ for branched polymer should be different from that for unbranched polymer. The correction factor for the branching is not known in the case of a sodium polyphosphate solution, but it is not large in the case of an organic polymer. Therefore, Eq. 4 was used to obtain an apparent value of $\bar{n}$. The value thus obtained may be expected to be correct in its order of magnitude.

TABLE III. TEMPERATURE DEPENDENCE OF THE AVERAGE DEGREE OF POLYMERIZATION OF EACH BRANCH AT RELATIVELY LONG POLYMERIZATION TIME

Fig. 4	2	Trimeta	97	115	Viscometry

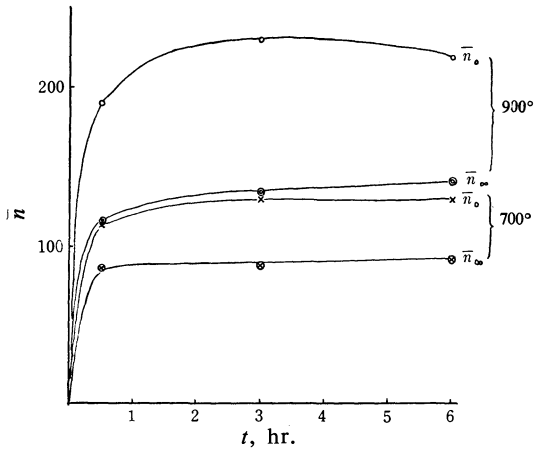

Fig. 3. Dependence of degree of polymerization on the time of polymerization of orthophosphate.

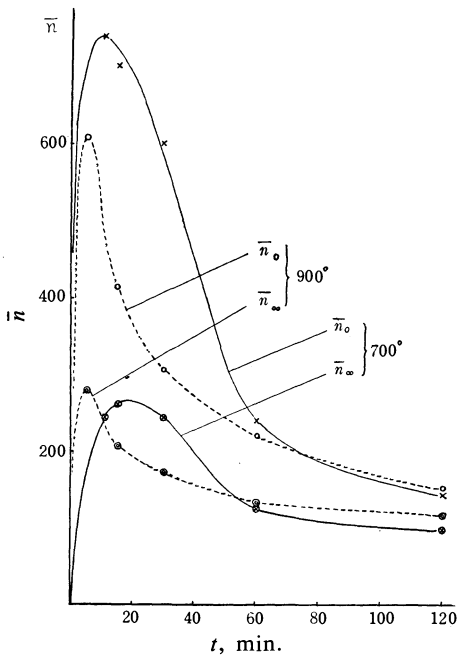

Fig. 4. Dependence of degree of polymerization on the time of polymerization of trimetaphosphate.

$\bar{n}_0$ and $\bar{n}_\infty$ values are the greater, the lower the temperature, if the reaction time is shorter than 1 hr., and they do not depend too much on the temperature if the reaction time is longer than 1 hr. This would mean that the polymerization is completed within 5~11 min., so that the thermal depolymerization is more important in this case. The higher the temperature, the more the separation of the branches proceeds and the more the degree of polymerization, $\bar{n}_0$, decreases. In this case, the thermal break-up of each polymer chain occurs within at least 1 hr., in addition to the separation of the branches at the branching points. After 2 hr., the $\bar{n}_\infty$ value becomes the larger, the higher the temperature. As is shown in Table III, these findings tend to accord with the results of Figs. 1 and 3, although the numerical values do not exactly coincide with each other, probably because of the differences in experimental methods, as has already pointed out[11].

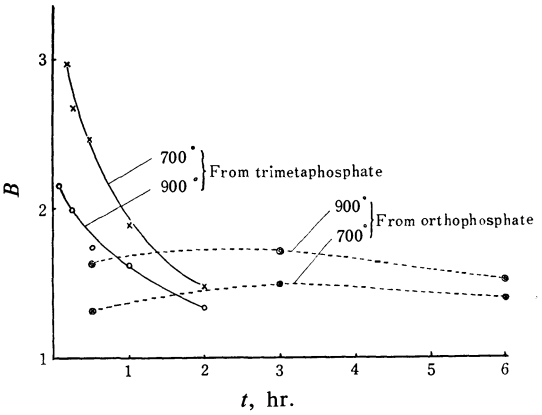

Fig. 5. Relation between the number of branching and the polymerization time.

Thus, the remarkable difference between the condensation polymerization and the ring-opening polymerization can be explained by considering that both the polymerization and depolymerization occur during the heating, and that the process of polymerization is more important in the case of the condensation polymerization because the removal of water needs much heating, while the process of depolymerization is more important in the case of the ring-opening polymerization because in

this case the polymerization is completed almost immediately after the material is melted.

Summary

Two kinds of polymerization reactions, the condensation polymerization of sodium dihydrogen orthophosphate anhydrate (NaH_2PO_4) and the ring-opening polymerization of sodium trimetaphosphate, have been compared by determining the average degree of polymerization of the whole molecule, $\bar{n}_0$, and of each branch, $\bar{n}_\infty$, and the average number of branches, B, per molecule.

As a result, it has been concluded that the remarkable difference between these two reactions can be explained by simultaneous polymerization and depolymerization during the heating. In the case of the condensation polymerization, the polymerization process is more important because the removal of water needs much heating, while, in the case of the ring-opening polymerization, the depolymerization process is more important because the polymerization is completed almost immediately after the material is melted.

Studies on Seven-membered Heterocyclic Compounds Containing Nitrogen. VII. Thiazolocyanine Dyes

By Akira Yokoo and Shiro Morosawa

(Received January 28, 1963)

No such thiazolocyanine dyes as condensed with the nitrogen-containing seven-membered ring have been synthesized. The present authors report here about the syntheses of these dyes.

Ethiodide (II) of 5-ethoxycarbonyl-2-methyl-5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazole (I)[1] was converted to 2-phenylaminoethenyl derivative (III). II and III reacted to yield 5, 5'-diethoxycarbonyl-1, 1-diethyl-(5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazolo)-carbocyanine iodide (IV), m. p. 193~195°C (decomp.). 2-Phenylaminoethenyl derivative (VII) was derived likewise from 2-methyl-5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazole (V)[1] via its methiodide (VI). VI and VII gave a dye assumed to be 1, 1', 5, 5'-tetramethyl-(5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]-thiazolo)carbocyanine iodide dimethiodide (VIII), m. p. 230~234°C (decomp.).

Another cyanine dye, 11-bromo-5, 5'-diethoxycarbonyl-1, 1'-diethyl-(5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazolo)-pentamethinecarbocyanine iodide (X) was also obtained from II and 2-bromo-3-anilino-2-propen-1-ylidenaniline (IX), m. p. 162~165°C (decomp.).

Experimental

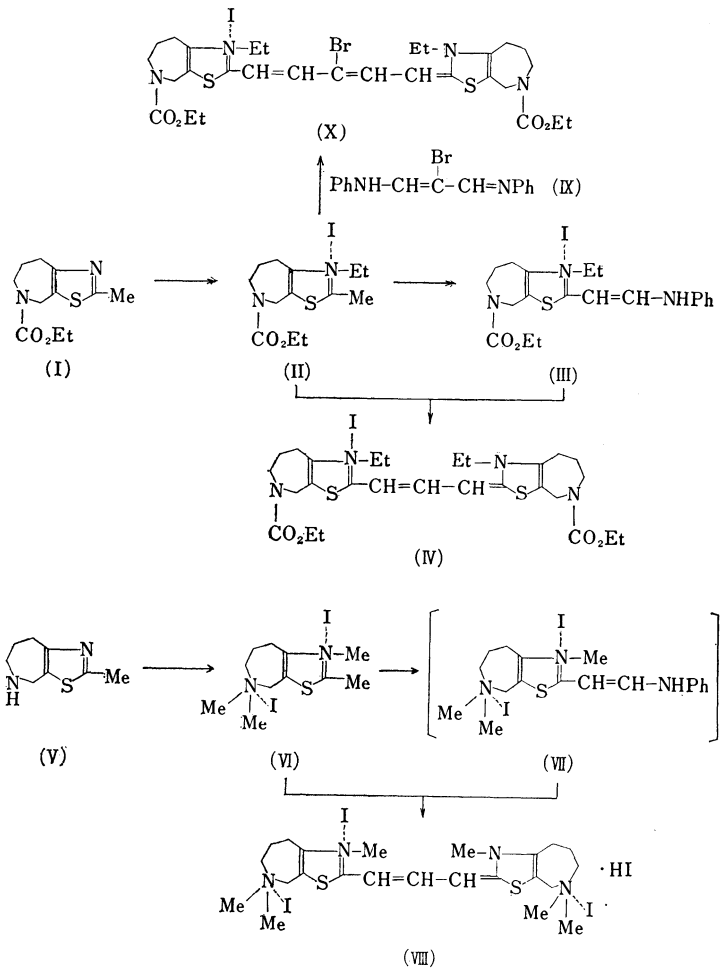
5-Ethoxycarbonyl-2-methyl-5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazole Ethiodide (II). — A mixture of 2 g. of I and 4 g. of ethyl iodide was heated under reflux for 4 hr. in a thick, round-bottomed flask. The flask was then stoppered tightly and heated for 5 hr. in a water bath. Precipitates, which formed on adding ether to the reaction mixture, were separated by decantation, and recrystallized from a small amount of ethanol to give 1.3 g. of light yellow crystals, m. p. 157~159°C.

Found: N, 6.94. Calcd. for $C_{13}H_{21}O_2N_2SI$: N, 7.07%.

2-Phenylaminoethenyl-5-ethoxycarbonyl-5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazole Ethiodide (III). — A mixture of 0.5 g. of II and 0.3 g. of diphenylformamidine was heated at 165°C for 20 min. The reaction mixture was dissolved in 2 cc. of absolute ethanol, and 2 cc. of ether was added. Crystals deposited were separated and recrystallized from ethanol to give 0.41 g. of orange crystals, m. p. 185~187°C.

Found: N, 8.15. Calcd. for $C_{20}H_{26}O_2N_3SI$: N, 8.42%.

5, 5'-Diethoxycarbonyl-1, 1'-diethyl-(5, 6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazolo)carbocyanine Iodide (IV). — A mixture of 180 mg. of II, 170 mg. of III, 250 mg. of anhydrous potassium acetate and 1.5 g. of acetic anhydride was heated at 63~65°C for 3 hr. The solid reaction mixture was washed with ether and then with water by decantation, and



dried in a vacuum desiccator. The solid was dissolved in 1 cc. of absolute ethanol and 1.5 cc. of ether was added to the solution. The solution was left to stand in a refrigerator to cause crystallization. The crystals were collected and dissolved in 0.5 cc. of methanol, followed by the addition of 1 cc. of ether. The resulted solution was filtered and left to stand in a refrigerator. The crystals thus obtained were again crystallized as above to give 18 mg. of dark purple crystals, m.p. 193~195°C (decomp.). UV λ_{max}^{MeOH} mμ(log ε) : 575 (4.99).

Found: C, 47.74; H, 5.81; N, 8.19. Calcd. for $C_{27}H_{39}O_4N_4S_2I$: C, 48.08; H, 5.84; N, 8.31%.

2, 5-Dimethyl-5, 6, 7, 8-tetrahydro-4(*H*)-azepino-[4, 3-d]thiazole Dimethiodide (VI).—To a solution of 2.1 g. of V in 5 cc. of methanol was added 9 g. of methyl iodide. After having been left to stand overnight, methanol was removed and the residue was heated with 5 g. of methyl iodide in a sealed tube for 3 hr. on a water bath. The excessive methyl iodide was removed and the remainder was recrystallized twice from methanol to yield 2.9 g. of light yellow crystals, m. p. 245~248°C (decomp.).

Found: C, 28.30; H, 4.19; N, 6.08. Calcd. for $C_{11}H_{20}N_2SI_2$: C, 28.32; H, 4.33; N, 6.01%.

2-Phenylaminoethenyl Derivative (VII) of V, and 1, 1', 5, 5'-Tetramethyl-(5, 6, 7, 8-tetrahydro4-(*H*)-azepino[4, 3-d]thiazolo)carbocyanine Iodide Dimethiodide (VIII).—A mixture of 300 mg. of VI and 300 mg. of diphenylformamidine was heated at 155°C for 10 min. The reaction mixture was dissolved in methanol and a large amount of ether was added. The resulting precipitates were collected, washed with ether and dried well in a vacuum desiccator to give 380 mg. of VII as an amorphous powder. A mixture of 300 mg. of VII, 230 mg. of VI, 230 mg. of anhydrous potassium acetate and 1.5 g. of acetic anhydride was heated at 70°C for 5 hr. The reaction mixture was washed three times with each 5 cc. portion of ether and dissolved in 1.3 cc. of water. To the solution were added 5 cc. of ethanol and 15 cc. of ether, and decanted after having been left to stand. The remaining crystals, after drying, were dissolved in 4 cc. of methanol and recrystallized by adding 6 cc. of benzene and leaving to stand in a refrigerator for 5 days. After collecting and washing with a mixture of methanol and benzene (1 : 1), the crystals were dissolved in 6 cc. of methanol and 6 cc. of benzene was added. The solution was left

to stand in a refrigerator for 2 days and the crystals formed were collected, dissolved in 3 cc. of methanol and filtered. The solution was left to stand as above and the resulted crystals were further recrystallized twice from methanol to give 18 mg. of dark purple crystals which turn light brown at about 220°C, m. p. 230~234°C (decomp.). UV λ_{max}^{MeOH} mμ (log ε): 575 (4.58).

Found: C, 29.53; H, 4.69; N, 6.02; S, 6.68; I, 52.38. Calcd. for $C_{23}H_{37}N_4S_2I_3 \cdot HI$: C, 29.30; H, 4.07; N, 5.95; S, 6.81; I, 53.85%

11-Bromo-5, 5'-diethoxycarbonyl-1, 1'-diethyl-(5,6, 7, 8-tetrahydro-4(*H*)-azepino[4, 3-d]thiazolo)pentamethinecarbocyanine Iodide (X). — A mixture of 200 mg. of II, 80 mg. of IX, 100 mg. of piperidine and 2.5 g. of pyridine was heated at 50°C for 2.5 hr. After cooling, a large amount of ether was added and decanted. This was repeated three times, followed by further washing with 2 cc. of water (twice) and with 1 cc. of hot water (twice). After drying in a vacuum desiccator, the crude product was dissolved in 1.5 cc. of methanol and the solution was left to stand in a refrigerator for 2 days. The crystals formed were collected and washed with methanol. Recrystallization (twice) as above gave 60 mg. of green crystals, m. p. 162~165°C (decomp.). UV λ_{max}^{MeOH} mμ (log ε): 635 (5.12).

Found: C, 44.05; H, 5.48; N, 7.13. Calcd. for $C_{29}H_{40}O_4N_4S_2BrI$: C, 44.64; H, 5.17; N, 7.18%.

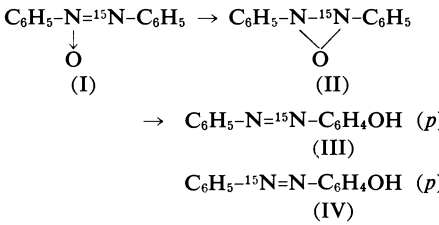
Mechanisms of the Wallach Rearrangement[1]

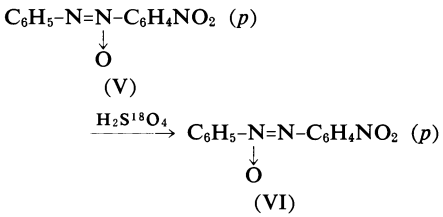
By Shigeru OAE*, Tsugio FUKUMOTO and Masayuki YAMAGAMI

(Received February 1, 1963)

Recently, Shemyakin, Maimind and Vaichunaite[2] have shown, using ^{15}N-labeled azoxybenzene (I) that the rearrangement of the azoxybenzene (I) gave 4-hydroxyazobenzenes (III) and IV under various condition[3,4], where the two benzene rings were attacked with equal ease. They also observed that azoxybenzene recovered from these reactions remained practically unchanged in isotope distribution, and suggested that the rearrangement proceeds through a symmetrical intermediate II.



The prior formation of the *N*, *N*-oxide intermediate, II, in the rearrangement was further emphasized by the Russian workers[5] from their observations that there was no incorporation of ^{18}O into *p*-nitroazoxybenzene from ^{18}O-labeled sulfuric acid in the isomerization of *β*-*p*-nitroazoxybenzene (V) to *α*-*p*-nitroazoxybenzene (VI).



Meanwhile, two mechanisms have been suggested[6]. The one is similar to that of the Bamberger reaction[7] and proceeds via monocation VII in which nucleophilic attack by either water or $-OSO_3H$ group is restricted to the far ring, while the other was suggested

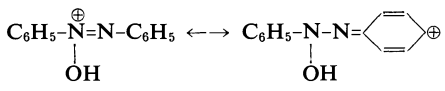
to involve the symmetrical dication VIII, which may be attacked at either ring.



(VII)

(VIII)

We have reported in the earlier communication[8] that no excess of ^{18}O was incorporated from the medium in *p*-hydroxyazobenzene obtained when the rearrangement of azoxybenzene was carried out with 83% sulfuric acid, labeled by 0.67 atom % of ^{18}O. However, we have found later that a part of our experiments were in error and hence presented a new interpretation with a new set of data[9]. Since then, we have learned that the Russian workers[10] have also worked out a similar problem and presented much the same interpretation from the Wallach rearrangement.

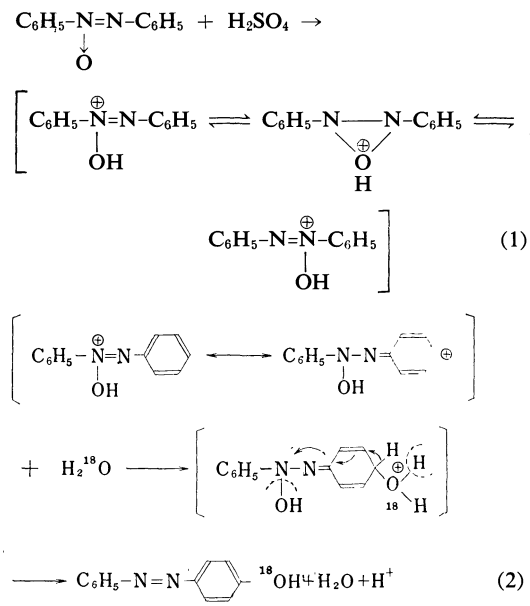
In this paper, we would like to correct a part of the published results and to summarize all the results of our studies hitherto being made on the Wallach rearrangement.

Azoxybenzene-^{18}O was prepared from ^{18}O-labeled nitrobenzene which was made by reacting benzene with the mixture of ^{18}O-labeled potassium nitrate and ^{18}O-labeled sulfuric acid. Then the rearrangement of this ^{18}O-labeled azoxybenzene was performed in 83% ordinary sulfuric acid. The resulting *p*-hydroxyazobenzene was found to have lost almost all the excess of ^{18}O, and only very small amount of excess of ^{18}O (about 10%) was found to be remaining. When an equivalent mixture of azoxybenzene-^{18}O and *o*-methylazoxybenzene was treated in the same medium, both *p*-hydroxyazobenzene and 4-hydroxy-2'-methylazobenzene obtained were also found to have lost most of the excess ^{18}O originally present in the starting azoxybenzene-^{18}O.

We also repeated the rearrangement of azoxybenzene in 83% sulfuric acid enriched with ^{18}O and found that the resulting *p*-hydroxyazobenzene was incorporated with ^{18}O from the medium, but the ^{18}O value was roughly 15~20% less than that of the medium used.

These observations suggest that the main portion of the Wallach rearrangement is an intermolecular process similar to Bamberger type where solvent water attack nucleophilically para position of benzene ring.

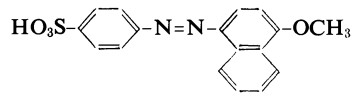
Combining with the observations of Russian workers on the prior isomerization, the overall mechanism of the main reaction may be depicted as follows;



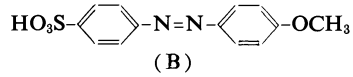
(1)

(2)

Recently, Bunnet, Buncel and Nahahedian[11] have shown that the phenolic products of hydrolysis of 4-(*p*-sulfophenylazo)-1-naphthyl methyl ether (A) and 4-(*p*-sulfophenylazo)-anisole (B) in oxygen-18 labeled water carry the oxygen-18 labeled in the phenolic hydroxy



(A)



(B)

group, and they suggested the following similar mechanism.

Okazaki and Okumura also have shown that the rearrangement of ^{18}O-labeled hydroxylamine in aqueous acid media gave *p*-aminophenol which have lost almost all the excess ^{18}O originally present in the starting material[12].

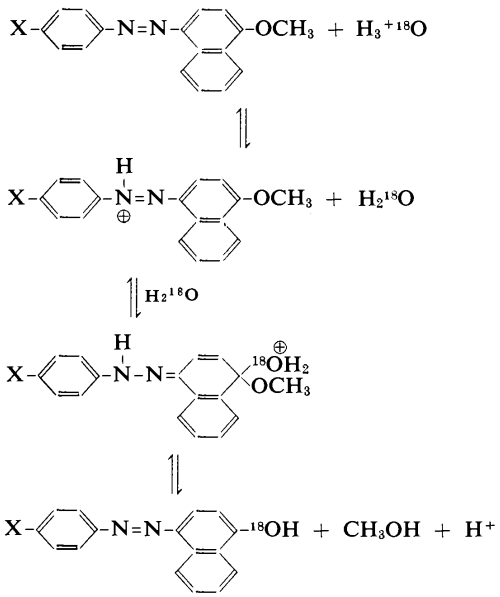
6	Azoxybenzene (1 g.)	UV light (40~45°C, 25 days)	*o*-Hydroxyazobenzene (0.92 g.)	0.38	0	0.35
7	α-4-Methylazoxybenzene (3 g.)	UV light (40~45°C, 7 days)	2-Hydroxy-4'-methylazobenzene (1.6 g.)	—	—	—
8	*p*-Hydroxyazobenzene (1 g.)	83% H_2SO_4 (90°C, 10 min.)	*p*-Hydroxyazobenzene (0.9 g.)	0	0.30	0

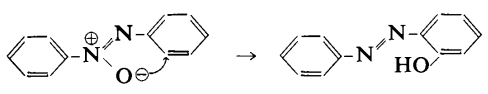


In both our experiments and the Russians, one finds that a small, but noticeable amount of oxygen appeared to be coming directly from the original azoxy-oxygen. Whether or not this is due to the direct oxidation we proposed earlier, one needs further experiments with a little higher concentration of ^{18}O before making any final comment.

Hahn and Jaffé[13] have recently shown that the rearrangement of 4-substituted azoxybenzene gives 2-hydroxy-4'-methylazobenzene as by-product of 4-hydroxy-4'-methylazobenzene. We have allowed 4-methylazoxybenzene to react in 83% sulfuric acid, labeled by 0.58 atom % of ^{18}O at 60~70°C for 10 min. and found that resulting 4-hydroxy-4'-methylazobenzene, the main product, incorporated ^{18}O in 80~90% from the medium, while 2-hydroxy-4'-methylazobenzene obtained as red crystals, m. p. 100~101°C, in a very small yield, incorporated very little excess ^{18}O from the medium.

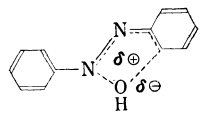
While the rearrangement to para position followed the Bamberger type intermolecular process, the rearrangement to ortho position apparently proceeded via intramolecular oxygen shift.

Since the oxygen migrated to the far ring in this case just as was shown by the Russian workers previously by the ^{15}N tracer studies[2], they adopted following Badger and Buttery's scheme[16] for the ortho rearrangement. Another alternative and probably more likely



13) Chi-Sun Hahn and H. H. Jaffé, *J. Am. Chem. Soc.*, **84**, 946 (1962).

path for the ortho rearrangement is via the following "intimate ion pair", similar to the one suggested for the formation of 4-tosyloxyisoquinoline by the reaction of isoquinoline *N*-oxide and *p*-toluenesulfonyl chloride[14].



A similar rearrangement of azoxybenzene to *o*-hydroxyazobenzene by ultraviolet light has been known[15,16]. The Russian workers[2] found that the original excess of ^{15}N was in the nitrogen group attached to the hydroxylated benzene when carried out the reaction in 85% ethanol for 65 hr. at 30~40°C. We have performed the reaction in 85% ethanol containing 15% $H_2{}^{18}O$ (enriched by 0.67 atom % of ^{18}O) and found that the resulting *o*-hydroxyazobenzene incorporated very little excess ^{18}O from the medium. We favor that the reaction proceed through an intramolecular oxygen radical shift from *N*-oxide. A similar free radical shift is known in the reaction of dimethylaniline-*N*-oxide with acetic anhydride[17a]. 2-Picoline *N*-oxide was also known to rearrange to 2-pyridinemethanol by ultraviolet irradiation[17b].

Experimental

Azoxybenzene was prepared by refluxing methanol solution containing both nitrobenzene and sodium hydroxide; m. p. 35~36°C.

^{18}O-Labeled Sulfuric Acid.—This preparation was described elsewhere[18].

^{18}O-Labeled Potassium Nitrate was prepared by Anbar's method[19].

^{18}O-Labeled Nitrobenzene was prepared by first dissolving ^{18}O-labeled potassium nitrate (5 g.) in $H_2S^{18}O_4$ (5 g., 0.75 atom % of ^{18}O) and then adding benzene (2 g.) dropwise in the mixture with vigorous stirring. Stirring was continued for 20 min. at 50~55°C after the benzene was added. The reaction mixture was then poured into water (20 ml.) and oily precipitate separated out was extracted with 30 ml. benzene. After drying and removing benzene, the remaining oil was distilled and the fraction of b. p. 93~95°C/17 mmHg was collected. The yield was 2.7 g. (83%).

^{18}O-Labeled Azoxybenzene was prepared by heating ^{18}O-labeled nitrobenzene (8 g., 0.84 atom % of ^{18}O) with sodium hydroxide (8 g.) in methanol (8 g.), m. p. 35~36°C, 0.69 atom % of ^{18}O.

Found: C, 72.60; H, 4.99. Calcd. for $C_{12}H_{10}N_2O$: C, 72.73; H, 5.05%.

2-Methylazoxybenzene was prepared by an improved method. Five grams of 2-methylazobenzene prepared by Parsons's method[20] was dissolved in 40 ml. of glacial acetic acid then, 15 ml. of 30% hydrogen peroxide was added and the mixture was heated for 1 hr. at 85~90°C. As the reaction progressed, the color of reaction mixture changed from brown to orange-yellow finally giving clear yellow solution. Then, the reaction mixture was poured into water. Oily layer separated was washed several times with water and was distilled and the fraction of b. p. 127~129°C/2 mmHg was collected. The yield was 5.2 g. (97%).

Found: C, 73.94; H, 5.77. Calcd. for $C_{13}H_{12}N_2O$: C, 73.58; H, 5.66%.

4-Methylazoxybenzene was prepared from 4-methylazobenzene by similar method as 2-methylazoxybenzene, m. p. 46~47°C.

Found: C, 73.80; H, 5.49. Calcd. for $C_{13}H_{12}N_2O$: C, 73.58; H, 5.66%.

Rearrangement Reaction of Azoxybenzene in ^{18}O-Labeled Sulfuric Acid.—A mixture of 1 g. of azoxybenzene and 4 g. of 83% sulfuric acid (0.50 atom % of ^{18}O) was heated for 10 min. at 90°C and then the reaction mixture was poured into ice water. A tarry product appeared was collected by filtration and this was refluxed for 10 min. with 50 ml. 3% potassium hydroxide solution. Insoluble material was removed by filtration and the black colored filtrate was refluxed with charcoal for 5 min. and filtered while hot. The filtrate was neutralized with 6 N hydrochloric acid solution. The precipitate appeared was collected by filtration and recrystallized from benzene. *p*-Hydroxyazobenzene was thus obtained, m. p. 151~152°C (lit.[21] 152°C), 0.45 atom % of ^{18}O. The yield was 0.5 g. (50%).

Found: C, 72.08; H, 4.96. Calcd. for $C_{12}H_{10}N_2O$: C, 72.73; H, 5.05%.

Rearrangement Reaction of ^{18}O-Labeled Azoxybenzene in Sulfuric Acid.—A mixture of 1 g. of ^{18}O-labeled azoxybenzene (0.69 atom % of ^{18}O) and 4 g. of 83% sulfuric acid was heated for 10 min. at 90°C and treated similarly as described above. *p*-Hydroxyazobenzene was obtained, m. p. 151~152°C, 0.26 atom % of ^{18}O. The yield was 0.5 g. (50%).

Reaction of a Mixture of ^{18}O-Labeled Azoxybenzene and 2-Methylazoxybenzene in Sulfuric Acid.—A mixture of 0.5 g. of ^{18}O-labeled azoxybenzene (0.69 atom % of ^{18}O) and 0.5 g. of 2-methylazoxybenzene was heated in 4 g. of 83% sulfuric acid for 10 min. at 90°C and treated similarly as described above. Crude product (0.5 g.) obtained was recrystallized from 2 ml. benzene. Crystalline powder appeared rapidly was collected by filtration and the filtrate was kept standing overnight. Rhombic crystals came out from the filtrate. The former crystals were recrystallized from benzene and the

latter were recrystallized from ligroin several times, respectively. The former, m. p. 150~151°C, 0.23 atom % of ^{18}O, 0.15 g. and the latter, m. p. 99~100°C, 0.24 atom % of ^{18}O, 0.15 g. were obtained. Both crystals did not depress the melting point of the two authentic samples, 4-hydroxyazobenzene and 4'-hydroxy-2-methylazobenzene[21] upon admixture.

Rearrangement Reaction of Azoxybenzene under Ultraviolet Irradiation.—In a sealed tube is placed a mixture of 1 g. of azoxybenzene and 20 ml. of 85% ethanol (consisted of 3 ml. of ^{18}O enriched water (0.67 atom % of ^{18}O) and 17 ml. absolute ethanol), and the mixture was irradiated for 65 hr. at 40~45°C under ultraviolet. After removing water and ethanol under reduced pressure, the remaining solid was added 50 ml. 3% potassium hydroxide aquous solution and was refluxed for 10 min. After cooling and removing unreacted azoxybenzene by filtration, the filtrate was neutralized with hydrchloric acid. Brown crystals appeared were recrystallized from ethanol and violet needles, m. p. 82.5°C, 0.21 atom % of ^{18}O, was obtained. The yield was 0.45 g. (45%). (*o*-Hydroxyazobenzene (lit.[22] m. p. 82.5°C)).

Rearrangement Reaction of ^{18}O-Labeled Azoxybenzene under Ultraviolet Irradiation.—In a sealed tube is placed a mixture of 1 g. of ^{18}O-labeled azoxybenzene (0.58 atom % of ^{18}O) and 20 ml. of absolute ethanol, and the mixture was irradiated for 25 days at 40~45°C and was treated similarly as described above. The product, m. p. 82.5°C, 0.55 atom % of ^{18}O, was obtained. The yield was 0.92 g. (92%).

Rearrangement Reaction of *α*-4-Methylazoxybenzene.—In a three-necked flask was placed a mixture of 20 g. of *α*-4-methylazoxybenzene and 80 g. of 83% ^{18}O-labeled sulfuric acid (0.58 atom % of ^{18}O) and the mixture was heated at 60~70°C for 10 min. and was treated similarly. The crude product, m. p. 147~150°C, 14 g. was obtained (70%). The separation of the *o*-isomer, 2-hydroxy-4'-methylazobenzene from the *p*-isomer was achieved by the following method. The product (14 g.) was dissolved in 20 ml. hot benzene and then allowed to stand for 5~6 hr. at room temperature. Yellow needles formed were separated and were recrystallized from benzene repeatedly. 4-Hydroxy-4'-methylazobenzene, m. p. 150~151°C, 0.54 atom % of ^{18}O, was thus obtained.

Found: C, 72.61; H, 5.78. Calcd. for $C_{13}H_{12}N_2O$: C, 73.58; H, 5.66%.

The filtrate was evaporated under reduced pressure, and the residue (ca. 5 g.) was distilled by steam distillation, then red crystals, m. p. 98~101°C, 80 mg. were obtained. The red crystals were converted to copper salt by precipitation with 50% alcoholic copper acetate solution. This copper salt contained 0.25 atom % of ^{18}O and was identified with authentic sample, which was prepared by ultraviolet irradiation of *α*-4-methylazoxybenzene, by infrared spectrophotometric method.

Found: C, 57.53; H, 3.99. Calcd. for $C_{13}H_{11}N_2 \cdot OCu$: C, 56.83; H, 4.01%.

2-Hydroxy-4'-methylazobenzene.—In a sealed tube is placed a mixture of 3 g. of *α*-4-methylazoxybenzene and 20 ml. of ethanol, and the mixture was irradiated under ultraviolet light for 7 days at 40~45°C. After removing ethanol, the solid was distilled by steam distillation and red crystals, m. p.; 100~101°C (1.6 g.) was obtained in 54% yield.

Found: C, 72.80; H, 5.11. Calcd. for $C_{12}H_{12}N_2O$: C, 73.58; H, 5.66%.

Determination of ^{18}O is described elsewhere[15].

The results of ^{18}O distribution of all the ^{18}O tracer experiments for this rearrangement are tabulated in Table. I.

Spectrophotometric Studies of the Nature of Several Iron-Pyridinecarboxylic Acid Complexes

By Ichirô MORIMOTO and Taijun SATÔ

(Received February 2, 1963)

Weidel[1] and Skraup[2] first studied the coloring reaction between iron and pyridinecarboxylic acids. The determination of iron based on this reaction has since been reported by several workers[3-7]. We ourselves have previously reported[5-7] on the 1 : 2 complex formed in the solution by the interaction of metal

ions with 2, 6-pyridinedicarboxylic acid or 2, 4, 6-pyridinetricarboxylic acid. Shinra et al.[3] and Rây and Banerjee[8] have suggested the formation of a 1 : 3 complex between the metal ions and 2-pyridinecarboxylic acid, while Majumder and Bag[4] have found a ratio of 1 : 2 for 2-pyridinecarboxylic acid or 2, 3-pyridinedicarboxylic acid. These are also some discrepancies among the conclusions reached by various workers on the composition of the complexes formed in solution by ferrous ions and pyridinecarboxylic acid. Also, the composition of the complexes formed by the iron with 2, 4-pyridinedicarboxylic acid or 2, 5-pyridinedicarboxylic acid is still obscure. For the present work, studies were made of the composition of the complexes formed in solution by the reaction between ferrous ions and several pyridine-2-carboxylic acids in the presence or absence of potassium cyanide and pyridine.

Experimental

Apparatus.—A Hirama photoelectric colorimeter was employed with 1 cm. cells for optical density measurement at room temperature. A Horiba-Hitachi model 3 pH meter was used for all pH determinations.

Iron Solution.—A standard solution was prepared by dissolving ferrous ammonium sulfate in twice-distilled water. Weaker solutions were prepared by diluting the standard solution.

Buffer Solution.—A Michaelis buffer solution and a 35% sodium acetate solution were used for the regulation of the pH value.

Hydroxylamine Hydrochloride Solution. — Ten grams of hydroxylamine hydrochloride were dissolved in 100 ml. of distilled water.

Reagent Solution. — 2-Pyridinecarboxylic acid, 2, 3-pyridinedicarboxylic acid, 2, 4-pyridinedicarboxylic acid, 2, 5-pyridinedicarboxylic acid, 2, 6-pyridinedicarboxylic acid, and 2, 4, 6-pyridinetricarboxylic acid were used. A 1/100 molar solution of each pyridinecarboxylic acid was used. 2, 5-Pyridinedicarboxylic acid was dissolved in 1 ml. of ammoniac water, and the solution was diluted with aliquots of water. Pyridine and a 0.1 N solution of potassium cyanide were used.

Procedure.—Aliquots of a standard ferrous solution were taken in 25 ml. flasks. To each flask, 1 ml. of the hydroxylamine hydrochloride solution, several milliliters of the reagent solution, a potassium cyanide solution or pyridine, a buffer solution, and water were added to make up the volume. The absorbance of the solution was measured at 420 and 460 mμ respectively.

Results and Discussion

Absorbance Curves. — The absorbance curves for the iron complexes in the ultraviolet range and in the visible range are shown in Figs. 1 and 2. In Fig. 1, curves 1, 2, 2', 3, 4 and 4' represent the absorbance of the colored complexes formed by 16 p. p. m. of iron in the absence of potassium cyanide; curve 5 represents the value with 8 p. p. m. of iron in the absence of potassium cyanide. Each of the solution of the complexes of pyridinecarboxylic acids has a maximum at 265~280 mμ. These maxima of absorption may be the absorption of pyridinecarboxylic acids. In Fig. 2, curves

8) P. Rây and B. Banerjee, *J. Indian Chem. Soc.*, **35**, 297, 493 (1958).

1, 2 and 3 represent the absorbance, in the absence of potassium cyanide, of the colored complexes formed by 16 p.p.m. of iron; curves 1', 3' and 5' represent the values obtained in the presence of potassium cyanide with 11 p.p.m. of iron. The complexes of pyridinecarboxylic acid have a maximum at 430~530 mμ. In the presence of potassium cyanide, these complexes have a maximum at 500~520 mμ.

Effect of Pyridine.—The authors frequently observed that the absorbance of the iron complexes was increased considerably by the addition of a small drop of pyridine[9]. The results are shown in Fig. 3. In Fig. 3, curves 1, 2, 3 and 4 show the values obtained at pH 5.9 in the presence of 2 ml. of pyridine and 11 p. p. m. of iron.

Nature of the Complexes in Solution. — The empirical formulas of the ferrous iron complexes were established by three independent methods: the continuous variation method of Job[10] modified by Vosburgh and Cooper[11], the mole ratio method of Yoe and Jones[12], and the slope ratio method of Harvey and Manning[13]. The results of these experiments are shown in Figs. 4—12. For Job's method, an equimolar solution (1/200 mol.) of iron and the reagent were taken in different quantities (total, 4 ml.) in 25 ml. flasks. The iron solution was mixed with 1 ml. of hydroxylamine hydrochloride, and the necessary amount of the reagent, 5 ml. of potassium cyanide, a buffer solution (pH 6.2~6.3), and water were added to make up the volume. Curves 1 and 1' in Figs. 4, 5 and 6 represent the results on the 2-pyridinecarboxylic acid and 2, 3-pyridinedicarboxylic acid, 2, 4-pyridinedicarboxylic acid, 2, 5-pyridinedicarboxylic acid, 2, 6-pyridinedicarboxylic acid and 2, 4, 6-pyridinetricarboxylic acid complexes systems respectively. Curves 3 and 3' represent the results on each pyridinecarboxylic acid complex system without potassium cyanide. Curves 2 and 2' represent those

of pyridinecarboxylic acid in the presence of pyridine (2 ml.). 2,4-Pyridinedicarboxylic acid is an exception. From the curves it can easily be inferred that, in the presence of potassium cyanide, the metal forms a 1 : 1 complex with these acids, whereas without cyanide and in the presence of pyridine, the ratio is always 1 : 2.

For the mole ratio method, the absorbance of the solution was obtained by adding various amounts of the organic acids and a fixed amount of potassium cyanide to a constant amount of iron ; the results are shown in Figs. 7 and 8. Curves 4 and 5 in Fig. 7 and curves 3 and 4 in Fig. 8 were obtained by adding different amounts of the reagent (5×10^{-3} mol.) to 2 ml. of an iron solution of the same molarity and by adjusting the pH to 6.2, without adding cyanide. Curves 1, 2 and 3 in Fig. 7, and 1 and 2 in Fig. 8 were obtained by adding different amounts of the reagent (5×10^{-3} mol.) to 2 ml. of an iron solution of the same molarity and to 5 ml. of potassium

cyanide and by adjusting the pH to 6.2~6.3. From these curves it can easily be inferred that, in the presence of potassium cyanide, the metal forms a 1 : 1 complex with 2-pyridinecarboxylic acid, 2, 3-pyridinedicarboxylic acid, 2, 5-pyridinedicarboxylic acid, and 2, 6-pyridinedicarboxylic acid, whereas without cyanide the ratio is always 1 : 2.

For the slope ratio method, two series of solution were used. In one series various amounts of a 5×10^{-4} mol. reagent solution were added to a constant amount of iron solution (2 ml. of 5×10^{-3} mol.), while in the other series, the amount of iron solution (5×10^{-4} mol.) was varied and that of the reagent solution was kept constant (5 ml. of 5×10^{-3} mol.). The results are shown in Figs. 9—12. The ratio of the slope of two straight lines supports the view that the complex formed without potassium cyanide contains the metal and the reagent in the ratio of 1 : 2. In the presence of potassium cyanide, the complex contained the metal and the reagent in the ratio of 1 : 1. In the case of 2, 4-pyridinedicarboxylic acid, the complex formed in the presence of potassium cyanide contains the metal and the reagent in the ratio of 1 : 2, while without potassium cyanide, it contains the metal and the reagent in the ratio of 1 : 3.

2, 4 Excess iron (2 ml. of 5×10^{-3} mol.)

With the exception of 2, 4-pyridinedicarboxylic acid, it was shown that, in the absence of potassium cyanide, iron in solution is associated with pyridine-2-carboxylic acids in a ratio of 1 : 2, while, in the presence of cyanide, the ratio is 1 : 1. The structure of the complexes, therefore, must be as shown in Fig. 13.

The degree of dissociation, α, and the stability constant, K, were calculated according to the equations of Harvey and Manning[12]. The degree of dissociation is given by $\alpha=(E_m-E_s)/E_m$, where E_m is the absorbance at

2,4-Pyridinedicarboxylic acid	5.0	4.9	4.5
2,5-Pyridinedicarboxylic acid	3.4	3.8	3.4
2,6-Pyridinedicarboxylic acid	3.3	3.6	3.0
2,4,6-Pyridinetricarboxylic acid	2.2	3.7	4.2

15±2°C, μ=0.1

460 mμ due to a given amount of metal ions being completely complexed with an excess of the reagent, and where E_s is the absorbance calculated for the same amount of the metal ions complexed with a stoichiometric amount of the reagent.

For 2-pyridinecarboxylic acid, the values for E_m and E_s are 0.377 and 0.276 for the complex with cyanide, and α is equal to 0.268 ; without cyanide, E_m and E_s are 0.197 and 0.055 respectively, and α is equal to 0.723.

The stability constant, K, of the complex is obtained by substituting the value of α in the equation $K=C(1-\alpha)/\alpha C(n\alpha C)^n$, where C is the concentration of the metal ions in moles per liter and n is the number of moles of the reagent required for complex formation with 1 mol. of the metal ions. Thus, for the complex with cyanide, $K=2.0\times10^3$, and for the complex without cyanide, $K=7.9\times10^3$. The results are given in Table I. From Table I, the value of log K for iron-pyridinecarboxylic acid complexes are concluded to be 3~5. When pyridinecarboxylic acids are used for the spectrophotometric determination of iron, it should be noted that the absorbance of the iron complexes is increased considerably by the presence of potassium cyanide.

The authors are greatly indebted to Professors Yoshimasa Hirata and Yoshito Kishi of Nagoya University and to Mr. Katushi Furuta of the Sanyo Denki Co., Ltd., for their measurement of the ultraviolet or visible range spectral absorbance of iron complexes. They also acknowledge the valuable advice of Dr. Keinosuke Suzuki of Nagoya University.

The Redetermination of the Crystal and Molecular Structure of Chloral Hydrate

By Kazuhide OGAWA*

(Received February 11, 1963)

From a chemical point of view, aldehyde hydrate in the form of the gem-dihydroxy compound is usually said to be unstable and seldom isolable. However, when the electon cloud of the carbon atom of a carbonyl group is attracted towards a strongly electron-attracting group by the inductive effect, giving rise to a positive charge on the carbon atom, the hydrate, with its two gem-C–OH bonds, often becomes stable. In this sense, the crystal of chloral hydrate may not contain the water of crystallization, as is shown by its name, but it may form a part of the molecule, as is evidenced upon its solution by its inability to react with Schiff's reagent.

As for the molecular structure of chloral hydrate, Davies[1] has shown from his infrared study of its carbon tetrachloride solution that there is considerable interaction between the

* Present address: Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka.

1) M. M. Davies, *Trans. Faraday Soc.*, **36**, 333, 1114 (1940).

OH groups and the adjacent CCl_3 radical, and that the OH groups are locked in the cis-position. Novak and Whalley[2] have obtained almost the same results from their infrared study of crystalline chloral hydrate and its solution. They inferred that in solutions of chloral hydrate one of the hydrogen bonds due to the two OH groups might be relatively weakly bonded to one, and the other relatively strongly bonded to the remaining one, of the two chlorine atoms in the same molecule.

According to the quadrupole spectra of chloral hydrate reported by Allen[3], there are three split lines, of which the two with a higher frequency make a pair, while the third is almost 1.25 Mc. lower. It was suggested that two of the three C–Cl bonds are nearly the same, while the third is somewhat different. Theoretical considerations indicated that the hydrogen-bonded chlorine should have a lower C–Cl frequency.

The crystal structure of this substance has been reported by Kondo and Nitta[4] using the X-ray method. However, it was later found by the present author that their results were in error. In view of these circumstances it was felt necessary to determine a new, correct structure for this substance.

Experimental

Chloral hydrate could be recrystallized from a chloroform solution by the evaporation method. At the first stage of crystallization, needle crystals are rapidly formed, but upon repeating recrystallization hexagonal tabular crystals come to grow slowly. The crystals grown along the monoclinic b axes and specimens cut out of hexagonal tabular crystals parallel to the a and c axes respectively were sealed in thin-walled glass capillary tubes to protect the specimens from sublimation by X-rays and from the humidity in the air.

Using Ni-filtered copper K_α radiation, oscillation and Weissenberg photographs were taken of the b and a axes. The photographs were indexed on the basis of a monoclinic unit cell of these dimensions:

$a=11.50\pm0.03$ $\quad b=6.04\pm0.02$

$c=9.60\pm0.03$ Å $\quad \beta=120\pm0.5°$

These dimensions agreed with values determined by Elliot[5] and by Kondo and Nitta within the range of experimental error. The well-developed face referred to by Groth as the c-face was taken here as (1 0 0), and the a, b and c axes designated by Groth agreed with the directions of the −c, b and [1 0 1] axes respectively in the present work. Reflections of the $0k0$ type with k odd and of the $h0l$ type with l odd were systematically absent from all single crystal photographs. The space group is therefore $P2_1/c$, which finding is different from that reported by previous workers[4,5]. The density of chloral hydrate is 1.91, so there are four molecules in the unit cell.

Intensity data were obtained from multiple film photographs using a Nonius-integrating Weissenberg goniometer for $(hk0)$, $(h0l)$, $(h1l)$, $(h2l)$, $(h3l)$ and $(h4l)$. MoK_α radiation was used for precession photographs of $(hk0)$ and $(0kl)$ around the b axis. Several precession photographs were taken under various exposures in order to correlate all reflections with a linear scale. Intensities were estimated visually by comparison with a calibrated scale of time exposures. The usual Lorentz and polarization corrections were applied. The linear absorption coefficients of this crystal are 15.0 and 132.6 for MoK_α and CuK_α respectively. Thin-walled glass capillary tubes prevented the precise determination of the crystal size, however, so that corrections for the absorption of CuK_α could be applied only roughly and those for MoK_α were not be applied.

Determination of Structure

Sharpened Patterson projections on $(0kl)$, $(hk0)$, and $(h0l)$ were computed. The predominant peaks were considered to be due to the intra- or inter-molecular Cl–Cl interactions. The intra-molecular Cl–Cl vectors were sought, at first, within a radius of 2.95 Å from the origin based on a model given by electron diffraction[6]. These vectors must be constructed from a projected figure of the planar regular hexagon with a side length of 2.95 Å. It was expected that the Patterson projection on $(h0l)$ along the short b axis would show a more or less satisfactory resolution of the Cl–Cl vectors. Thus, four possible orientations of the projected hexagon around the point of origin were found in the Patterson projection on $(h0l)$. With these orientations, the Patterson projection on $(hk0)$ was also allowed for. The Patterson projection on $(0kl)$ was not useful, because the number of predominant peaks which could be considered Cl–Cl vectors was so few. Each case of the eight possible molecular arrangements in the unit cell, consistent with the Patterson projections on $(h0l)$ and $(hk0)$, was tried on the basis of the orientations of the projected hexagons mentioned above. After several false starts, electron-density projections along [0 1 0] were computed which showed fairly good agreement with the assumed model. The several starting false models were the so-called false or pseudo structures, which show a convergence to some extent in the R factors. With the correct

structure mentioned above, the electron-density projection along the b axis was refined by the usual Fourier successive approximations. The final electron-density projection along [0 1 0] showed clearly the molecule of chloral hydrate as a whole (Fig. 1), but the electron-density peaks of the two carbon atoms did not show clear resolution owing to the overlapping with those of the oxygen or chlorine atoms. The Fourier projection along [0 0 1] was then computed on the basis both of approximate y parameters as determined from the molecules in the unit cell and of x parameters as known from the ($h0l$) projection. The Fourier projection along the c axis was also refined in the usual way. The final findings are shown in Fig. 2. The electron-density projection along the a axis was computed on the basis of y and z parameters determined from the Fourier projections along [0 1 0] and [1 0 0]. The results are shown in Fig. 3.

		C'(2)-O'(2)···Cl''(1)	156.8
		C(2)-O(1)···O'(2)	99.5
		C(2)-O(2)···O'(1)	94.0

The atomic parameters indicated by the final electron-density map projected along [0 1 0], [1 0 0] and [0 0 1] were further refined by the method of least squares. This least-squares refinement was calculated on the NEAC-2203 computer. In this case, off-diagonal terms were neglected except for those for x and z parameters and those for the scale and overall temperature factors. These results, with the values of the temperature factors for each atom, are listed in Table I. Bond lengths and bond angles calculated from the atomic parameters as determined by the least-squares

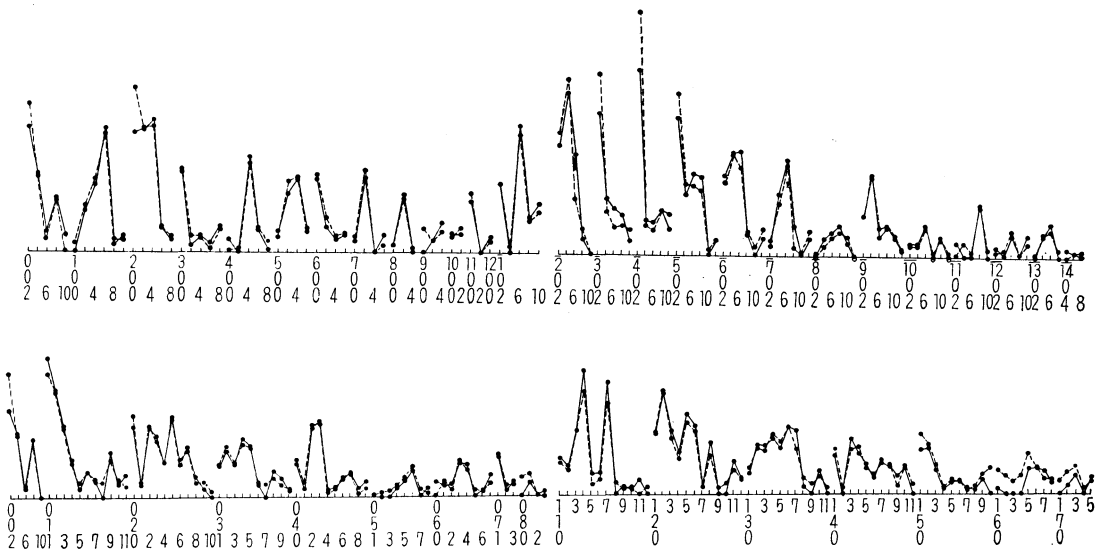

Fig. 4. Comparison between the observed F-values (solid lines) and calculated F-values (dotted lines).

method are listed in Table II. The observed and calculated values of the structure factors are shown in Fig. 4. Isotropic temperature corrections were included in the above calculated values. The R factors for the final coordinates are: $R(h0l)=18.3\%$, $R(0kl)=17.7\%$, $R(hk0)=25.5\%$. In this calculation, only observed structure factors were used.

Discussion and Description of the Structure

As shown in the electron-density maps of Figs. 1, 2 and 3, there is found no existence of the independent molecule of water, as in crystallization, but instead two OH groups attached to one of the two carbon atoms, as given by $CH(OH)_2CCl_3$. The conformation of these OH groups can be described as the staggered gauche referred to as the C–Cl_3 group. It is interesting to note that Davies[1] proposed a cis-conformation for this substance on the basis of his infrared study of its solution. Whether these different conclusion are due to the difference in states of aggregation will be an interesting point for further study.

The molecular arrangement in the crystal is shown in Fig. 5. For the sake of a description of the structure, let us first consider those layers of molecules in the structure parallel to the (0 1 0) plane. In each layer, a molecule is surrounded by six molecules. Such layers are juxtaposed in the direction of the b axis, the spacing of these layers being 6.04Å. The three chlorine atoms of a CCl_3 radical make a nearly regular triangle and face another triangle of chlorine atoms of the neighboring molecule related by a center of symmetry, but

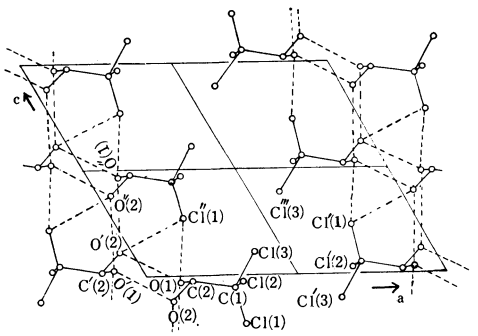

Fig. 5. Projection of the unit cell of chloral hydrate along the b-axis. Hydrogen bonds are shown by dotted lines.

the line joining the two centers of gravity of these triangles is not perpendicular to their triangular planes. The shorter Cl···Cl contracts between these triangles are of the lengths of 3.81, 4.08 and 4.92Å for Cl(1)···Cl′(3), Cl(2)···Cl′(3) and Cl(1)···Cl′(2) respectively, all of which values are greater than the sum of Pauling's van der Waals radius, 3.60Å. Around the Cl(1) atom the shortest approach to another Cl atom is 3.60Å, between Cl(1) and Cl(2) of the next layer above. Around the Cl(3) atom, the separation of 3.79Å is found between the Cl(3) and Cl‴(3) atoms of the molecule approaching diagonally in the same (0 1 0) layer. These circumstances, together with the hydrogen bond formation discussed below, explain the easy cleavage of the crystals parallel to (1 0 0).

In view of the difficulty, for several reasons, in obtaining sufficiently accurate intensity data, the atomic arrangement in the crystal, especially

that of carbon and oxygen, can not be discussed with sufficient precision. In addition to this, the position of the carbon atom bonded with the chlorine atom was still less accurately determined because of the overlapping in the three projected planes seen in Figs. 1, 2 and 3. The discrepancy between C–Cl values, therefore, may not be significant. The C–Cl, C–C and C–O bond lengths may roughly be supposed to be within the range of normal single bond distances.

Hydrogen bond formation is usually determined, in X-ray analysis, from the values of bond lengths and angles. In the crystal of chloral hydrate, the possible hydrogen bonds and angles are:

O(1)···O'(2)	2.8 Å	C(2)-O(1)-O'(2)	100°
O(2)···O'(1)	2.8	C(2)-O(2)-O'(1)	94
O(1)···Cl''(1)	3.1	C(2)-O(1)-Cl''(1)	115
O'(2)···Cl''(1)	3.1	C'(2)-O'(2)-Cl''(1)	157
O'(2)···O''(1)	2.9	C'(2)-O'(2)-O''(1)	143

There seem to be two kinds of bifurcated hydrogen bonds between O(1) and O'(2) or Cl''(1), and between O'(2) and O''(1) or Cl''(1). Such a bifurcated hydrogen bond of the O–H:$\begin{matrix}\cdot\cdot O\\ \cdot\cdot Cl\end{matrix}$ type has been found in the crystal of tetrachlorohydroquinone[7] and pentachlorophenol[8] by Sakurai. In the case of chloral hydrate crystal, the existence of one hydrogen-bonded chlorine atom is consistent with the results of the quadrupole study of Allen[3].

Some Further Structural Studies of Chloral Hydrate

Though the crystal structure of chloral hydrate at room temperature has been determined as stated above, it seemed necessary to examine further whether there is another phase in the crystal. A thermal differential analysis of this substance from room temperature to about 70°C was carried out*. The results thus obtained show that it is transformed into a high-temperature form at 52.6°C on heating and melts at 55.0~64.5°C. The staggered curve shown at a temperature above the melting point appears to suggest the complex nature of chloral hydrate in the molten state. It could be seen with chemical reagents that the decomposition into chloral and water partially took place.

The structure of a possible high-temperature phase could not be determined, but the Norelco

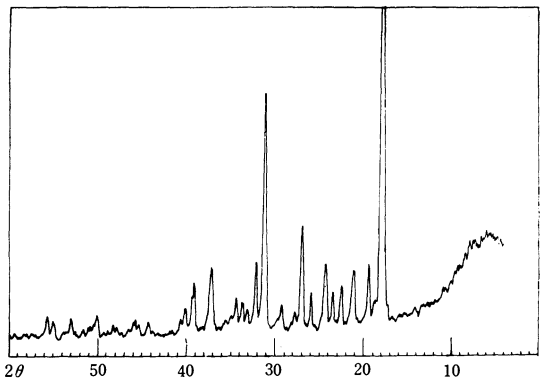

Fig. 6-a. Norelco diffraction powder pattern of chloral hydrate of room-temperature phase.

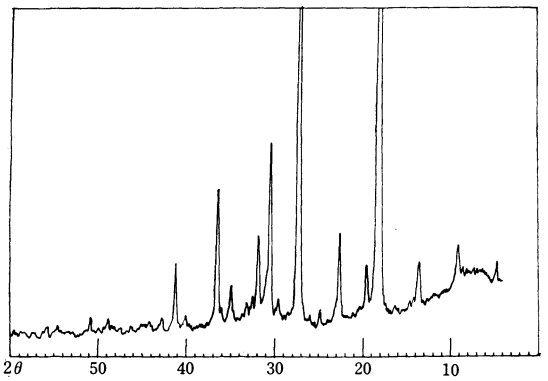

Fig. 6-b. Norelco diffraction powder pattern of chloral hydrate of high-temperature phase which may contain that of room-temperature phase.

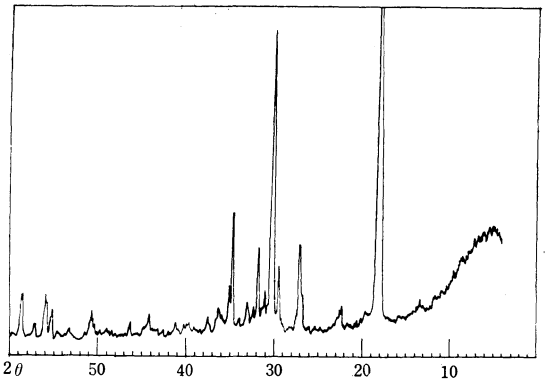

Fig. 6-c. Norelco diffraction powder pattern of chloral hydrate of high-temperature phase after 36 hr. passed from the experiment of Fig. 6-b.

diffraction powder patterns at different times after crystallization from the molten state appear to show that the high-temperature phase changes slowly and partially towards the room-temperature phase. (Fig. 6) The unit cell of the high-temperature phase seems to

7) T. Sakurai, *Acta Cryst.*, **15**, 443 (1962).
8) T. Sakurai, ibid., **15**, 1164 (1962).
* The author is indebted to Professor S. Seki and Dr. H. Suga for the measurements.

be large compared with that of the room-temperature phase, because the spacings of the former cell contain 19.19, 9.71 and 6.51 Å, which correspond to those of (0 0 1/2), (0 0 1) and (010) of the latter cell; these later values are absent because of the limitations of the space group and of the size of the latter cell.

To obtain further information on the molecular structure and on the nature of the intermolecular hydrogen bonds, the infrared spectra of chloral hydrate in a solid and in solutions of several kinds of solvents (benzene, chloroform, carbon tetrachloride and carbon disulfide) have been taken. The measurements were made with a Hitachi model EPI-2 spectrometer equipped with a NaCl or LiF prism. The chief absorption bands noticed are:

	O-H cm^{-1}	C=O cm^{-1}	H_2O cm^{-1}
Solid (KBr disk)	3360 (broad)	—	—
Benzene solution	3617, 3525	1770	1605

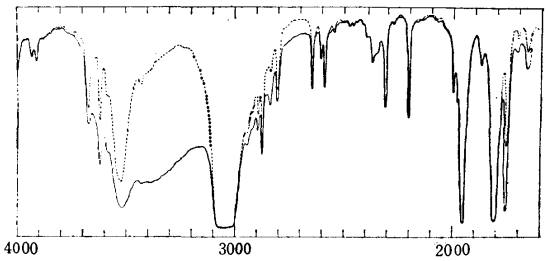

Fig. 7-a. Infrared spectra: (a) solid line, chloral hydrate in benzene solution; (b) dotted line, about one-third of concentration of a.

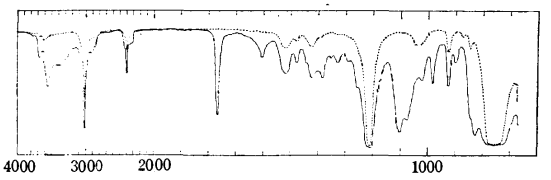

Fig. 7-b. Infrared spectra: (a) solid line, chloral hydrate in chloroform solution; (b) dotted line, pure chloroform.

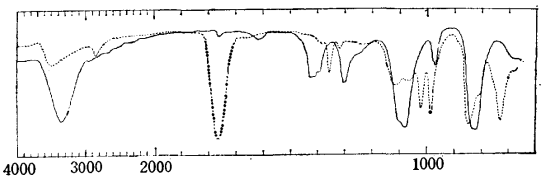

Fig. 7-c. Infrared spectra: (a) solid line, solid chloral hydrate as KBr disk; (b) dotted line, pure chloral.

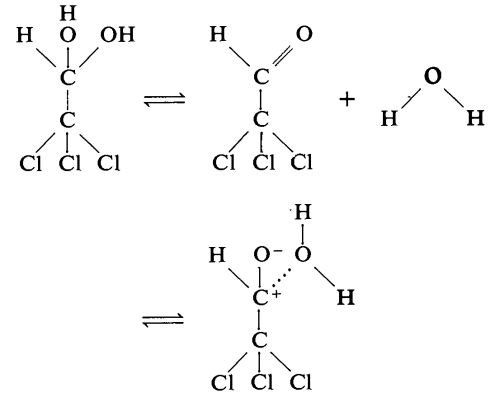
As has been indicated by previous workers[3,9,10], there are two sharp absorption bands due to two kinds of OH groups in solutions of chloral hydrate, of which the one with the higher frequency is due to the relatively weakly hydrogen-bonded groups and the other, to the relatively strongly hydrogen-bonded groups, whereas the crystalline chloral hydrate has a broad band which is of a lower frequency than the two bands in solutions and which is due to the intermolecular-bonded OH, as is shown in Fig. 7. The solution spectra of chloral hydrate show a strong absorption band at 1770 cm^{-1} and a weak broad band near 1605 cm^{-1}. The former band appears also in chloral, while the latter band often appears in substances containing water molecules, so that it can be considered that the former is due to carbonyl-stretching vibration and the latter, to the in-plane OH deformation vibration of a water molecule. Though the 1770 and 1605 cm^{-1} absorption bands appear very faintly in the solid state, they are caused by the dissociation of crystalline chloral hydrate into chloral and water, because a small part of the solid will dissolve either in moisture within a KBr disk or in Nujol.

On the one hand, chloral hydrate fails to show color with Schiff's reagent and reacts with Tollen's reagent or Fehling's solution, while these three reagents are said to be specific to aldehydes. On the other hand, it is to be noticed that aldose, in general, reduces Fehling's solution and Tollen's reagent, while it does not react with the Schiff reagent. It is said that this is due to the cyclic hemiacetal structure of aldose. From the characteristic chemical reactivity and the interpretation of the infrared absorption bands, it might be inferred that the following dissociation equilibrium would take place in a solution of chloral hydrate as seen in ordinary aliphatic aldehyde. Then, the water and chloral molecules produced by dissociation would re-combine without delay, as shown in the following equilibrium schemes:



9) D. M. W. Anderson, L. J. Bellamy and R. L. Williams, *Spectrochim. Acta*, 12, 233 (1958).
10) L. P. Kuhn, *J. Am. Chem. Soc.*, 74, 2492 (1952).

This water molecule would be combined with a chloral molecule by a weak bond, but it would be loosened upon being heated more or less, so that chloral hydrate might react differently with the Schiff reagent upon being heated according to the degree of dehydration in the solvents employed, and the color produced by the combination with the Schiff reagent would fade away sooner or later on cooling. At any rate, the molecular structure of chloral hydrate in a solution or liquid state seems to be different from that of a solid state and is so complex that other equilibrium schemes should be considered. Of these possible equilibria, the most predominant one would have the structure cited above.

Summary

The crystal structure of chloral hydrate has been redetermined by the two-dimensional Fourier method and the least-squares method on the NEAC-2203 computer. It is monoclinic and belongs to the $P2_1/c$ space group, with four molecules in a cell of the dimensions $a=11.50$, $b=6.04$, $c=9.60$ Å and $\beta=120.0°$. The molecular structure of chloral hydrate is of the gem-dihydroxy compound type with the two OH groups in the staggered gauche-position referred to the adjacent C–Cl_3 group. The molecules of chloral hydrate in the crystal are held together mainly by the van der Waals attraction of Cl···Cl and by the bifurcated hydrogen bonds of O–H:$\begin{matrix}\cdot\cdot\text{Cl}\\ \cdot\cdot\text{O}\end{matrix}$. As a result of differential thermal analysis, a high-temperature phase has been found between 53.6° and the melting point, which was ascertained by X-ray diffraction powder patterns. Some of the molecules of chloral hydrate appear to dissociate into water and chloral and attain equilibrium with them. This is inferred from infrared study and from the chemical reactivity with the Schiff reagent.

I wish to express my sincere thanks to Professors Isamu Nitta and Tokunosuké Watanabé for their continuous encouragement and helpful discussions in the course of this study. I am also indebted to Dr. Kenji Osaki for the use of his least-squares programs for the NEAC-2203 computer, to Mr. Hiroshi Okuto of Takeda Chemical Industry Co., to Mr. Kiyoaki Tatsuka of the Appraisal Division of the Osaka Custom House, and to Dr. Hiroyuki Tadokoro for providing infrared spectra and for their helpful discussions, and to Dr. Hiroshi Suga for providing differential thermal analysis data.

Recently, according to a private communication from Dr. George Marshall Brown of the Oak Ridge National Laboratory to Professor Isamu Nitta, he is now analyzing the structure of this crystal by the neutron diffraction method.

By Tadao SHINGAKI and Matsuji TAKEBAYASHI

(Received November 28, 1962)

It has been established that dichlorocarbene is formed by the reaction of haloform and bases, such as potassium *t*-butoxide[1], sodium hydroxide[2] and alkyl lithium[3], and the existence of carbene has been confirmed by Doering[1] with the formation of an adduct of carbene to cyclohexene. These facts might suggest that the so-called carbylamine reaction is a reaction involving dichlorocarbene as an intermediate, as has been suggested by Hine[4].

In order to confirm this speculation the present authors have studied the reaction using sodium *t*-butoxide in place of potassium or sodium hydroxide. To a hexane solution (or toluene-hexane solution) of an aromatic primary amine and sodium *t*-butoxide was added chloroform drop by drop at 0~5°C. The reaction took place immediately. After the addition of chloroform was over, the reaction mixture was left to stand at 0°C for thirty minutes, and then at 25°C for thirty minutes. The isocyanide was fractionated in the atmosphere of nitrogen or separated by the formation of silver complex compound[5].

$$ArNH_2 + CHCl_3 + 3(CH_3)_3CONa \longrightarrow ArNC + 3NaCl + 3(CH_3)_3COH$$

The results obtained are summarized in the following table.

As shown in the table, it is recognized that the reaction takes place also in the system of chloroform and *t*-butoxide, which has been recognized as a typical system to produce dichlorocarbene, and that the yield of isocyanides is increased according to increase of the concentration of chloroform (compare Expt. 3 with Expts. 4 and 5). Moreover, the yield of isocyanides in this case was much higher than that in the cases of sodium hydroxide.

TABLE I. YIELD OF ISOCYANIDES FROM PRIMARY AMINES

Primary amine, 0.2 mol. Chloroform, 0.2 mol. Sodium *t*-butoxide, 0.6 mol. Reaction time, 5 hr.

Expt. No.	Primary amine	Isocyanide (yield)
1	Aniline	Phenyl isocyanide (73%)
2	*o*-Toluidine	*o*-Tolyl isocyanide (71%)
3	*p*-Toluidine[a]	*p*-Tolyl isocyanide (72%)
4	*p*-Toluidine	*p*-Tolyl isocyanide (86%)
5	*p*-Toluidine[b]	*p*-Tolyl isocyanide (98%)
6	*o*-Chloraniline	*o*-Chlorophenyl isocyanide (93%)
7	*p*-Chloraniline	*p*-Chlorophenyl isocyanide (94%)

a) 0.1 mol. of chloroform was added.
b) 0.4 mol. of chloroform was added.

The results mentioned above indicate that the carbylamine reaction is a reaction involving dichlorocarbene as an intermediate.

We would like to suggest the following reaction mechanism for this reaction.

$$CHCl_3 + t\text{-}BuO^- \longrightarrow t\text{-}BuOH + Cl^- + :CCl_2 \quad (1)$$

$$Ar\text{-}\overset{\overset{H}{|}}{N}: + :CCl_2 \longrightarrow Ar\text{-}\overset{\overset{H}{|}}{N}\overset{(+)\ (-)}{-C-Cl} \quad (2)$$

$$Ar\text{-}\overset{\overset{H}{|}}{N}\overset{(+)\ (-)}{-C-Cl} \longrightarrow Ar\text{-}\overset{\overset{H}{|}}{N}\text{-}C\text{-}Cl \longrightarrow Ar\text{-}\overset{\overset{H}{|}}{\overset{+}{N}}{=}C + Cl^- \quad (3)$$

$$Ar\text{-}\overset{\overset{H}{|}}{\overset{+}{N}}{=}C + t\text{-}BuO^- \longrightarrow Ar\text{-}N{=}C + t\text{-}BuOH \quad (4)$$

$$Ar\text{-}N{=}\overset{\overset{H}{|}}{C} \longrightarrow Ar\text{-}\overset{+}{N}{\equiv}CH + Cl^- \quad (5)$$

$$Ar\text{-}\overset{+}{N}{\equiv}CH + t\text{-}BuO^- \longrightarrow Ar\text{-}\overset{(+)(-)}{N{\equiv}C} + t\text{-}BuOH \quad (6)$$

Abnormal Oxidation of 3-Nitro-2-thenyl Bromide by Cupric Nitrate

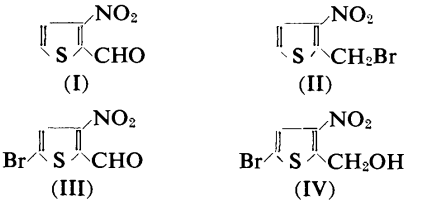
By Tyo SONE and Yasuo MATSUKI

(Received December 27, 1962)

The present authors have reported the synthesis of 3-nitro-2-thiophenealdehyde (I): Oxidation of 3-nitro-2-methylthiophene by chromic trioxide in acetic anhydride followed by hydrolysis gave I (m. p. 52~53°C), but the yield was poor[1].

It has been found that oxidation of some aralkyl halides of benzyl halide type substituted by an electronwithdrawing group on the aromatic ring by cupric or lead nitrate, affords corresponding aromatic aldehydes[2] and also that this method is applicable to the thiophene series[1,3]. Therefore, an attempt was made for the synthesis of I by this method starting from 3-nitro-2-thenyl bromide (II).

When II was heated in about 10% cupric nitrate solution (0.75 mol.) for 50 hr., two crystalline products melting at 78.5~79.5°C, and 81~82°C, respectively, were obtained. The low melting material (III) can be considered as an aldehyde from the method of separation of the products as described in the Experimental, but the infrared spectrum (Fig. 1) and the melting point of III are evidently different from those of I. The NMR spectrum of III (in acetone) shows a band of the aromatic hydrogen at 255.5 c. p. s., and a band due to the aldehyde hydrogen at 352.5 c. p. s., referred to cyclohexane. Gronowitz and Hoffman observed that the aldehyde hydrogen of thiophenealdehydes not substituted at the 5-position in the thiophene ring interacted with the hydrogen at the 5-position to split into two lines separated by about 1 c. p. s.[4], and this is also the case in some nitrothiophenealdehydes[1]. The splitting was not observed in the aldehyde hydrogen of III. In addition, III gave a positive test for the Beilstein test. These facts suggest that III is 5-bromo-3-nitro-2-thiophenealdehyde. Elemental analysis, in fact, gave corresponding values. III reacts with ordinary ketonic reagents, and with *p*-toluidine to yield the Schiff base.



The high melting material (IV) has infrared bands for OH group in the region of 3300~3100 cm^{-1} (Fig. 2). In the NMR spectrum of

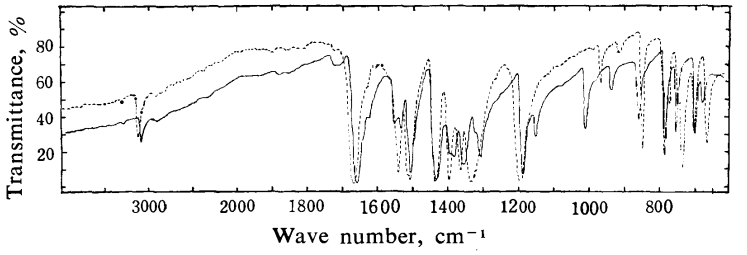


Fig. 1. Infrared spectra of I (----) and III (——) in KBr disk.

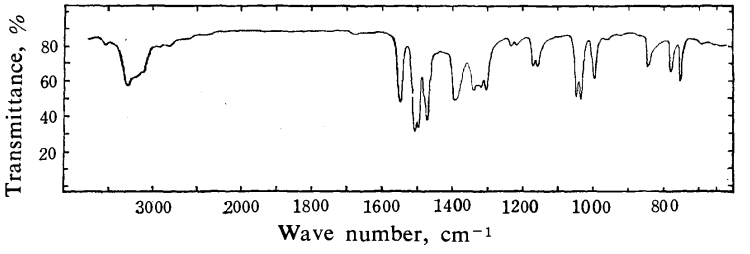

Fig. 2. Infrared spectrum of IV in KBr disk.

4) S. Gronowitz and R. A. Hoffman, *Acta Chem. Scand.*, 13, 1687 (1959).

IV (in carbon tetrachloride), the chemical shifts (69, 145 and 240 c. p. s.) and the relative peak areas (approximately 1 : 2 : 1) of the bands suggest that they are due to a hydroxyl group, a methylene group and a ring hydrogen of trisubstituted thiophene, respectively. IV gave also a positive test for halogen. From these facts, it may be presumed that IV is 5-bromo-3-nitro-2-thenyl alcohol. Elementary analysis and the formation of the benzoate support this assumption. An attempt to synthesize the alcohol by nitration of 5-bromo-2-thenyl acetate followed by hydrolysis was unsuccessful, because the nitration product could not be hydrolyzed by either acid or alkaline solution. Starting material, II, is entirely free from other substances such as 5-bromo-3-nitro-2-thenyl bromide, for the coupling constant (J=5.5 c. p. s.) in the NMR spectrum indicates that II is a 2, 3-disubstituted thiophene[5], and the reaction of II with potassium thiocyanate gave 3-nitro-2-thenyl thiocyanate in 70% yield.

Such an abnormal oxidation of aralkyl halides by a heavy metal nitrate, giving halogenated aldehyde and alcohol, has not been observed as far as the authors know. As it has been suggested that the normal oxidation involves the formation of a nitrate[6] as an intermediate and cupric halide[2] which can be used as a halogenating agent[7], the mechanism of the reaction presented here probably consists in the bromination of intermediate nitrate by cupric bromide to yield 5-bromo-3-nitro-2-thenyl nitrate, which subsequently gives III by elimination and IV by nucleophilic substitution.

Experimental

All melting points are uncorrected. The infrared spectra were measured with a Perkin-Elmer model 21 infrared spectrometer. The NMR spectra were obtained with a Varian Associates Model V-4300B spectrometer at 40 Mc. and cyclohexane was used as an internal reference.

3-Nitro-2-theyl Bromide (II).—Prepared according to the procedure described by Snyder et al.[8], m. p. 60~61°C (reported m. p. 60~62°C; Found: C, 27.04; H, 1.77; N, 6.18%). The chemical shifts are 141.5 (methylene protones), 231 (doublet) and 243.5 c. p. s. (doublet) (ring protons) and the coupling constant is J=5.5 c. p. s., characteristic of 2,3-disubstituted thiophenes (J_{23}=5.4±0.6[5a], 5.4 c. p. s.[5b]).

Reaction of II with Potassium Thiocyanate.—A mixture of II (0.22 g.) and potassium thiocyanate (0.15 g.) in ethanol was warmed at 60~65°C for 30 min. The resulting solution was poured into water and the precipitates were collected and recrystallized from ethanol to form 3-nitro-2-thenyl thiocyanate as pale yellow needles, m. p. 109~110°C. Yield 0.14 g.

Found: C, 36.20; H, 1.73; N, 13.79. Calcd. for $C_6H_4N_2O_2S_2$: C, 35.98; H, 2.01; N, 13.99%.

Oxidation of II by Cupric Nitrate.—A mixture of II (4.4 g.) and a cupric nitrate solution ($Cu(NO_3)_2 \cdot 3H_2O$, 3.6 g.; H_2O, 30 ml.) was gently refluxed for 50 hr. After cooling, the reaction products were extracted with ether and the ether extracts were washed with water and then shaken with excess of saturated sodium bisulfite solution to form the addition product; this was collected and dissolved in water, and the solution was acidified with hydrochloric acid and steam-distilled. The crystals precipitated in the distillate amounted to 1.23 g., m. p. 67~72°C, which, after recrystallization from petroleum ether, gave 5-bromo-3-nitro-2-thiophenealdehyde (III) as pale yellow needles, m. p. 78.5~79.5°C.

Found: C, 25.63; H, 0.89; N, 6.01; Br, 32.92. Calcd. for $C_5H_2BrNO_3S$: C, 25.44; H, 0.85; N, 5.93; Br, 33.85%.

The infrared spectrum showed absorption for the carbonyl group at 1658 cm^{-1}.

Semicarbazone.—Yellow crystals, m. p. 269°C (decomp.) (from dioxane).

Found: N, 18.98. Calcd. for $C_6H_5BrN_4O_3S$: N, 19.11%.

2, 4-Dinitrophenylhydrazone.—Orange needles, m. p. 252~253°C (from ethyl acetate).

Found: C, 31.59; H, 1.28; N, 16.46. Calcd. for $C_{11}H_6BrN_5O_6S$: C, 31.74; H, 1.45; N, 16.82%.

Reaction of III with p-Toluidine.—A mixture of III (0.1 g.) and *p*-toluidine (0.1 g.) in methanol (5 ml.) was left on standing at room temperature for two days. The yellow crystals precipitated were collected and recrystallized from ethanol to form the Schiff base as yellow needles, m. p. 129°C. Yield, 0.13 g.

Found: N, 8.44. Calcd. for $C_{12}H_9BrN_2O_2S$: N, 8.61%.

The ether solution, after separation of the addition product, was washed with water and dried. Evaporation of ether yielded 0.87 g. of crystals, m. p. 80.5~82°C, which were recrystallized from a mixture of ether and petroleum ether to give 5-brom-3-nitro-2-thenyl alcohol (IV) as colorless needles, m. p. 81~82°C.

Found: C, 25.25; H, 1.61; N, 6.01; Br, 33.73. Calcd. for $C_5H_4BrNO_3S$: C, 25.22; H, 1.69; N, 5.88; Br, 33.56%.

Benzoate.—Pale brown needles, m. p. 119~120°C (from ethanol).

Found: C, 42.18; H, 2.51; N, 4.01. Calcd. for $C_{12}H_8BrNO_4S$: C, 42.12; H, 2.35; N, 4.09%.

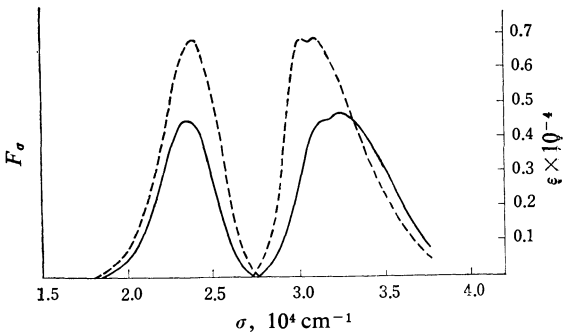

Fig. 1. Absorption and fluorescence spectra of DMNA (——) and NA (----) in acetonitrile. Concentrations of the solute: DMNA, 0.875×10^{-4} mol./l., NA, 0.8×10^{-4} mol./l.

The Electronic Structure of Excited N, N-Dimethyl-α-naphthylamine

By Noboru MATAGA

(Received January 10, 1963)

In the course of studying the effects of solvents on the electronic spectra of naphthalene derivatives, we have found that the solvent shifts of the first absorption band of *N, N*-dimethyl-α-naphthylamine (DMNA) are much smaller than those of α-naphthylamine (NA), whereas those of the fluorescence spectrum are quite large and are almost comparable to the shifts of NA.

On the other hand, Smith[1] has studied the dipole moments of various aromatic amines and their *N, N*-dimethyl derivatives. His results indicate that, in DMNA as compared with NA, the steric repression of the resonance effect of the substituent is very strong. This argument is in accordance with the fact that, as is shown in Table I, the wave numbers of the absorption band maximum (σ_a^m) of DMNA in several solvents are considerably larger than those of NA. The apparent first absorption bands of both NA and DMNA are composed of two electronic bands, ^1L_a and ^1L_b[2,3]. In Table I, the σ_a^m values given for NA are those of ^1L_a, while for DMNA the σ_a^m values of both ^1L_a and ^1L_b are given. In the case of NA, the fluorescent state seems to be ^1L_a[3], although the lowest absorbing singlet state is ^1L_b. It is quite probable that the lowest absorbing state of DMNA is ^1L_b. However, it is not quite clear whether the fluorenscent state of this molecule is ^1L_a or ^1L_b. Nevertheless, this circumstance will not affect the essential conclusion of the present study.

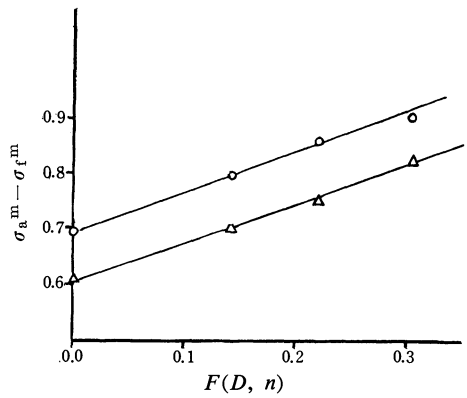

Fig. 2. $(\sigma_a^m - \sigma_f^m) \sim F(D, n)$ relations for DMNA.
○ $\sigma_a^m(^1L_a) - \sigma_f^m$ △ $\sigma_a^m(^1L_b) - \sigma_f^m$

As an example of the difference between the absorption and fluorescence spectra of DMNA and NA, the spectra in acetonitrile are indicated in Fig. 1. The smaller absorption intensity of DMNA compared with NA is also in accordance with the findings of Smith[1].

Thus, the resonance interaction between the substituent and the naphthalene ring in DMNA is rather small in the ground state and in the excited Franck-Condon state. Moreover, the interaction energy between DMNA and the surrounding solvent molecules is not very differemt in the ground state and in the Franck-Condon excited state respectively. However, the very large solvent shift of the fluorescence spectra indicate a rather large difference between the solute-solvents interaction energies in the Franck-Condon state and in the equilibrium excited state of DMNA, and, consequently, a large difference between the electronic structures of DMNA in the ground and in the fluorescent states respectively.

We can now roughly estimate the change of electronic structure in the fluorescent state, as

1) J. W. Smith, *J. Chem. Soc.*, **1961**, 81.
2) H. Baba and S. Suzuki, This Bulletin, **34**, 82 (1961).
3) N. Mataga, to be published.

TABLE I. WAVE NUMBERS OF BAND MAXIMA IN SEVERAL SOLVENTS
(in unit of $10^4\,cm^{-1}$)

Solvent	$F(D, n)$	DMNA			NA	
		$\sigma_a^m(^1L_a)$	$\sigma_a^m(^1L_b)$	σ_f^m	$\sigma_a^m(^1L_a)$	σ_f^m
n-Hexane	0	—	—	—	3.14	2.66
Cyclohexane	0	3.28	3.20	2.59	—	—
Monochlorobenzene	0.1429	3.27	3.17	2.47	3.10	2.51
Dichloroethane	0.2199	3.27	3.16	2.41	—	—
Acetonitrile	0.3054	3.25	3.17	2.35	3.07	2.38

compared with the ground state, by the following equation[4,5]:

$$hc(\sigma_a^m - \sigma_f^m) = \text{const} + 2\cdot F(D, n)\cdot\delta$$

$$F(D, n) = \left[\frac{D-1}{2D+1} - \frac{n^2-1}{2n^2+1}\right],\quad \delta = (\vec{\mu}_e - \vec{\mu}_g)^2/a^3$$

where D and n: the dielectric constant and the refractive index of the solvent, $\vec{\mu}_e$ and $\vec{\mu}_g$: the dipole moments of the solute molecule in the excited and ground states respectively, and a: the cavity radius in Onsager's theory of the reaction field.

The approximate linear relations between $(\sigma_a^m - \sigma_f^m)$ and $F(D, n)$ are satisfied for DMNA, as is shown in Fig. 2. From the linear relations, the δ value can be estimated to be $7500\,cm^{-1}$ for either value of $\sigma_a^m(\sigma_a^m(^1L_a)$ or $\sigma_a^m(^1L_b))$. This δ value is very close to and a little larger than the δ value of NA ($7300\,cm^{-1}$). Thus the change of the electronic structure of DMNA in the fluorescent state is quite large in spite of the steric repression of the resonance effect of the substituent in the ground state. The ionization potential of the nitrogen lone pair orbital of the dimethylamino group may be much smaller than that of the amino group. (The difference between the ionization potentials of methylamine and trimethylamine and the difference between those of ammonia and dimethylamine are both ca. 1 eV.[6]) Therefore, the energy of the CT (charge transfer) configuration, where one electron is transfered from the nitrogen lone pair orbital to a vacant orbital of naphthalene, is much smaller in DMNA than in NA. Accordingly, the interaction between the CT configurations and the locally excited states of naphthalene may be very strong if the core resonance integral between the nitrogen lone pair orbital and the carbon $2p\pi$AO's of naphthalene is not so small.

The large value of δ for DMNA observed in the present study indicates the structural change, i. e., the rotation of the dimethylamino group around the C–N bond during the life time of the excited state, leading to an increase in the overlap between the lone pair orbital and the π-orbital of naphthalene. This structural change is perhaps possible because the considerable increase of CT interaction in the excited state compensates for the increase in the steric repulsion.

SHORT COMMUNICATIONS

The Catalytic Polymerization of Vinyl Monomers by the Cobalt Cyanide Complex

By Mitsumi TAKAHASHI

(Received January 22, 1963)

In this study of the catalytic activity of the cobalt cyanide complex-hydrogen system, the author found that this complex has the ability to polymerize such vinyl monomers as methyl methacrylate, styrene, acrylonitrile and butadiene.

The polymerization was carried out as follows: 5 ml. of the monomer, 1 ml. of a potassium cyanide solution (3×10^{-1} mol./l.), 1 ml. of a 5% surfactant (non-ionic surfactant "Tween 80" aqueous solution and 2 ml. of water were placed in the main chamber of a Thunberg tube, and the air in the system was replaced with hydrogen. Then 1 ml. of the cobalt(II) chloride solution (5×10^{-2} mol./l.), which had been placed in the side chamber of the tube, was mixed with other components in the main chamber by tilting the side chamber, and the tube was shaken continuously at 25°C.

During the first stage of the reaction, small gel-like polymer particles separate out from the initial white emulsion. As the reaction proceeds, these particles coagulate to larger and harder particles or a mass.

The extent of polymerization on polymethyl methacrylate at various reaction times (in hours) is shown in Fig. 1.

As may be seen in the figure, an induction period was observed in the course of the polymerization of methyl methacrylate. While the surfactant was added to this system, the induction period was not observed (Curve A in the figure) and the reaction rate was accelerated remarkably. The highest yield in the polymerization reactions was 83% in the presence of the surfactant. It was noticed that, in the absence of the surfactant, the polymerization rate was slow (Curve B in the figure). It is recognized also that the intrinsic viscosity of the final product of polymethylmethacrylate was affected by the addition of the surfactant; when the surfactant was added to the polymerization system, the value of 2.75 was obtained for the intrinsic viscosity

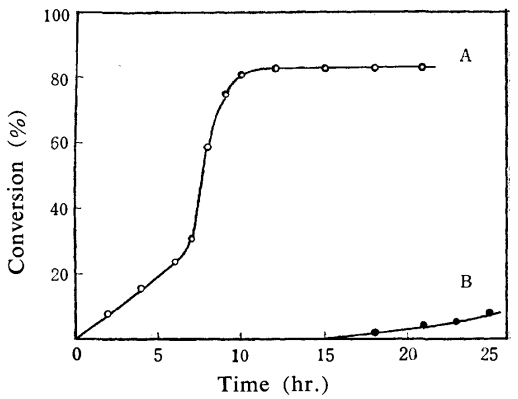

Fig. 1. Process of the polymerization of methyl methacrylate.

determined in benzene at 25°C, whereas it was 9.05 when the surfactant was not added.

Several results obtained for the other monomers are listed in Table I. Generally speaking, it appeared that the use of a surfactant yielded the higher conversion.

TABLE I. POLYMERIZATION* OF VINYL MONOMER BY COBALT CYANIDE COMPLEX POLYMERIZATION CONDITION

Vinyl monomers	Surfactant[a] wt. %	Time hr.	Conversion hr.	Intrinsic viscosity
Methyl methacrylate	1	10	83	2.75[b]
	0	24	12	7.05[b]
Styrene	1	30	90	1.75[b]
Acrylonitril	1	48	25	0.89[c]
Butadiene	1	48	13	—

a) Tween 80 was used as a surfactant.
b) Determined in benzene solution at 25°C.
c) Determined in dimethylformamide solution at 25°C.
* 5 ml. of monomer was polymerized with 5 ml. of cobalt cyanide complex solution (1×10^{-2} ml./l.) as a catalyst under 1 atm. pressure of hydrogen atmosphere at 25°C.

The polymerization rate and yield were depressed when nitrogen gas was used instead of hydrogen gas. When molecular oxygen was present in the reaction systems, the polymerization of these monomers did not occur at all.

From these results, it is deduced that the cobalt cyanide complex-hydrogen system posseses an activity as a polymerization catalyst.

Further details of such catalytic effects of the complex will be published elsewhere.

The author is especially indebted to Professor Masatami Takeda, Professor Masaakira Iguchi and Mr. Kazuyoshi Iimura for their kind and helpful suggestions in this work. Partial support by the Yawata Chemical Industry Co., Ltd., is also gratefully acknowledged.

The Absolute Configuration of Nupharamine

By Ichiro KAWASAKI, Shigeru MATSUTANI and Takeo KANEKO

(Received February 15, 1963)

The chlorination and subsequent dehydrochlorination of nupharamine (I)[1-3] gave olefins, which were separated into two isomers of anhydronupharamine, IIA and IIB, by alumina chromatography. IIA showed an infrared absorption at 880 cm^{-1} identified as an endomethylene group. The hydroboration-oxidation of IIA gave isonupharamine (III) (perchlorate m. p., 164~166°C ; Found: C, 51.35 ; H, 7.47 ; Cl, 10.07%). III was converted by chlorination and subsequent cyclization to quinolizidine derivatives, which were separated into two diastereoisomers, IVA and IVB, by alumina chromatography. The infrared spectrum of the isomer, IVA (eluted by 10% ether in petroleum ether, $[\alpha]_D$ −76.8°) was identical with that of natural l-deoxynupharidine[4], while the infrared spectrum of the other isomer, IVB (eluted by 15% ether in petroleum ether), was identical with that of rac-7-epi-deoxynupharidine[5]. Therefore, the absolute configuration of nupharamine should be represented by Formula I.

*The Activation Energy of Bromine Absorption by Carbonaceous Materials**

By Takashi MUKAIBO and Yoichi TAKAHASHI

(Received September 20, 1962)

The object of the present work, which forms a part of the investigation of the transfer of substances in and through carbonaceous materials, is to study the rate of absorption of bromine by carbonaceous materials, especially its temperature dependence.

It is well known that graphite absorbs several substances such as bromine or metal halides, forming so-called lamellar compounds[1]. The rate of the absorption is known to be rather rapid. It has been reported that, in the case of bromine absorption, equilibrium was established within several hours, even at room temperature[2]. As the absorption by carbonaceous materials contains a process by which the reactant molecules are taken up into the crystal structure of graphite, these experimental results suggest that the reactant molecules may diffuse or move rather easily through graphite layers in the lamellar compounds. Thus, a study of the rate of absorption (viz., the rate of the formation of lamellar compounds) will give useful information on the behavior of the reactant molecules in the lamellar compounds.

Preliminary experiments on this subject which have been reported on previously[3] show that the fractional absorption, plotted against the square root of time, gives a characteristic S-form, and that the rate and the saturation concentration of the absorbed bromine depend strongly upon the degree of graphitization of the materials. All the experiments were carried out at 0°C.

In the present paper, a study of the temperature dependence of the rate and the apparent energies of activation of the reactions at temperatures ranging from 0 to 50°C is described. The results and their relationship to the degree of graphitization of the carbonaceous materials are discussed.

Experimental

In the process of determining the apparent energy of the activation of the bromine absorption by carbonaceous materials, there are several problems to be considered.

The first of them is how to estimate the relative rate of the reaction from the absorption curve at different temperatures. As has been discussed previously[3], the bromine absorption is supposed to be the formation of a solid solution, and the saturation concentration of the absorbed bromine varies by changing such conditions as the temperature or the vapor pressure of bromine. In this case, the relative absorption rate could not be determined so simply. It was shown[3], however, that the bromine absorption curves of almost all samples, which were drawn by plotting the measured fractional absorption against the square root of the time, fell into a single curve by merely adjusting the time scale. The adjustment was done by multipling the time scale by a suitable factor.

The inverse of the multipling factor is considered to give the relative absorption rate. In practical estimations, any of the measured points of fractional absorption may be used for the adjustment of the time scale. For the present study, the fractional absorption of 0.3 was found to be most suitable for the estimation. The reason for this choice will be discussed later.

The second problem was the variation of the saturation concentration of bromine with the reaction conditions. It was desirable to carry out the absorption experiments while the saturation concentration of bromine in carbon samples were kept constant, even at different temperatures, because a difference in the saturation concentrations might affect the rate of absorption. It was expected from a previous work by Hennig[4] that this condition would be satisfied by keeping the vapor pressure of bromine saturated throughout the experiment.

In the course of experiments, however, the saturation concentration of absorbed bromine in carbonaceous materials was found to decrease with an increase in the temperature, even when the vapor pressure of bromine was kept saturated.

Thus, the Arrhenius plot might require some modification on this temperature dependence of the saturation concentration. In spite of this supposition, the Arrhenius plots obtained by the present experiments showed rather good linearities in all samples without any correction or modification of data. Therefore, the values of the apparent

energy of activation obtained below were estimated by the conventional method mentioned above.

Apparatus.—The apparatus is shown in Fig. 1. The rate of absorption of bromine was measured by means of a quartz spring balance. The reaction tube and the bromine container were kept at the same temperature, thus keeping the vapor pressure of bromine saturated at the reaction temperature. To avoid the condensation of bromine on the walls of the reaction tube or on the spring balance, the upper part of the reaction tube above the surface of the water bath was kept at the same temperature as the reaction part by circulating the water of the bath. The top of the tube was warmed by an infrared lamp for the same reason.

Nevertheless, a small quantity of bromine condensation on the specimen or on the spring balance was inevitable at the last period of a run lasting for a few hours. A little experimental error was supposed to be caused by the condensed bromine in the measurement of the last stage of absorption and of the saturation concentration of the bromine. This experimental error, however, was estimated to be negligible in calculating the activation energies, as will be described later.

Materials. — The samples of carbonaceous materials were supplied by the Nippon Carbon K. K. The carbon source, the temperature of heat treatment, the density, and the porosity of samples are listed in Table I.

The specimen for each run was cut into a plate, $30\times10\times1$ mm. in size, and weighed.

GR grade bromine was redistilled and passed over through concentrated sulfuric acid before use.

Procedure.—Redistilled bromine was introduced into the evacuated bromine container in a separate vacuum line. After closing the stop cock (shown in Fig. 1) to prevent contamination by the air, the container was removed from the vacuum line and was set to the reaction tube. After keeping both of them in a water bath for a while, a specimen was suspended by a quartz spring balance in the reaction tube. Then the tube was evacuated to 10^{-3} mmHg by a diffusion pump.

The reaction was started by opening the stop cock. The weight gain of the specimen by the absorption of bromine was measured with a running microscope, following the elongation of the spring balance. The sensitivity of the reading was about 0.5 mg. wt. change per division.

The temperature of the water bath was kept constant within ±0.1°C of the setting temperature.

Results

The Saturation Concentration of Absorbed Bromine.—It was found that the saturation concentration, C_s, of absorbed bromine by carbonaceous materials under the saturated vapor pressure of bromine had a tendency to decrease with an increase in the temperature. The findings are shown in Fig. 2, in which $C_s(T)$ values at different temperatures are presented as the ratio to $C_s(0)$ at 0°C. These results showed a definite tendency for C_s to decrease with an increase in the temperature, although there were a few deviations from a monotonic curve. These deviations might be caused by bromine condensation on the specimen or on the spring balance, or by some inconstancy of the reaction temperature. Even a small defference in temperature between the specimen and the bromine container was found to cause rather a large deviation.

The Rate of Bromine Absorption and its Temperature Dependence. — The absorption rate curves obtained by one of the samples are shown in Fig. 3, plotting the fractional absorption against the square root of the time. In order to determine the relative absorption rate, the fractional absorption of 0.3 was chosen as a standard in finding out the multipling factor for the adjustment of the time scale. The value of 0.3 was chosen because the experimental error caused by bromine condensation, mentioned earlier, was supposed to be relatively small at the beginning of the absorption, and because the time corresponding to the standard fractional absorption was supposed to be determined most accurately in this region according to the shape of the absorption curve.

Using the multipling factor for adjustment

thus obtained, the plots normalized to the curve obtained at 0°C are shown in Fig. 3, and in Fig. 4 for other samples. These plots fell into one line, as expected, indicating that the above-mentioned procedure was acceptable.

The relative rate of bromine absorption at different temperatures was the inverse of the multipling factor of each run. From the Arrhenius plotting in Fig. 5, the apparent energies of activation were calculated; they are shown in Table II.

Discussion

The Temperature Dependence of the Saturation Concentration of Absorbed Bromine in Carbonaceous Materials. — The fact that the C_s value of bromine in carbonaceous materials under the saturated vapor pressure of bromine decreases with an increase in the temperature has not yet hitherto been reported. Juza[5] predicted that this tendency to decrease might occur on the analogy of the decrease in the reactivity of chlorine gas to carbonaceous materials with an increase in the temperature. The saturation content of chlorine was found to decrease markedly at the temperature 100°C above the melting point of chlorine.

The present results show, however, that the decrease in the saturation concentration of bromine occurs gradually, even at temperatures as low as 30°C, which is only 37.3°C higher than the melting point of bromine.

At the present stage, the data are not numerous enough to enable us to discuss further the significance of the tendency to decrease. A more precise investigation of this problem is now being carried out, however, and will be reported on later.

The Activation Energies and their Relation to the Degree of Graphitization of Carbonaceous Materials.—The Arrhenius plots of the rate of bromine absorption gave good linearities for all samples, indicating that the rate of absorption was not very much affected by a small difference in the saturation concentration of bromine in the lamellar compounds. This fact may support the view that the bromine absorption is a kind of formation of a solid solution.

From the results presented in Table II, the apparent energies of activation are supposed to be dependent upon the degree of graphitization of the carbonaceous materials. To make this clear, the values of the true density of the samples were taken as the measure of the degree of graphitization. The results of X-ray diffraction measurement were not used for this purpose, because the samples were mixed with some binding materials in the course of production. The relation between the activation energies and the values of the true density of the samples is shown in Fig. 6. The plots show clearly that the apparent energies of activation decrease with an increase in the degree of graphitization.

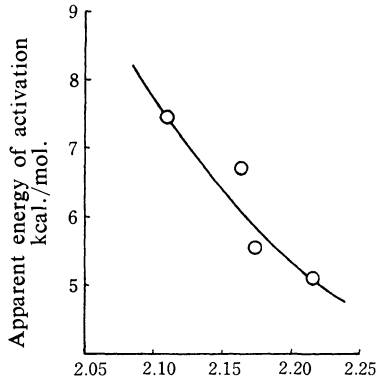

Fig. 6. Relation between the apparent energy of activation and the true density of carbonaceous materials.

The results indicate that the bromine absorption, followed by the diffusion or migration of absorbed bromine into the interior of graphite crystals, proceeds more easily with an increase in the degree of graphitization of the samples. This means that, with the growth of the net plane of graphite crystals, the movements of the molecules intercalated between the net planes of graphite crystals became easier.

Iwata et al.[6], in calculating the activation energy for the migration of Xe in the interlamellar positions of graphite crystal, have obtained the value of 0.69 kcal./mol. It should be noted that the self-energy of Xe interstitial atoms in graphite was also calculated to be 347 kcal./mol., in contrast to the small value of the migration energy. In the case of the bromine absorption, as bromine molecules have some interactions and are stabilized energetically in the lamellar compounds, the uptake of bromine molecules proceeds very easily. On the other hand, the activation energy for the migration of bromine molecules seems to be rather higher in comparison with that of inert Xe molecules. The present finding, the activation energy of 5～7 kcal./mol. for bromine absorption, revealed, however, that the migration of bromine molecules also proceeds very easily, even at room temperatures.

Summary

In the present paper, the temperature dependence of the rate of bromine absorption by the carbonaceous materials has been studied. The apparent energies of activation of the reaction have been found to be 5～7 kcal./mol. and had a dependence upon the degree of graphitization of carbonaceous materials. The value of the activation energy became smaller with an increase in the degree of graphitization. The results indicate that the mobilities of reactant molecules of the interlamellar compounds increase with the growth of the net plane of graphite crystals.

The saturation concentration of bromine in carbonaceous materials, under a saturated vapor pressure of bromine, was found to decrease with an increase in the temperature at temperatures above 30°C.

The authors wish to express their gratitude to Nippon Carbon K. K., which kindly provided them with the carbon samples. The authors are also indebted to Miss Chiyoko Tanabe for her assistance in the experiments.

*On the Permeation of Iodine through Graphite**

By Takashi MUKAIBO and Yoichi TAKAHASHI

(Received March 7, 1963)

Gas permeation through artificial graphite can occur, because of its porous nature, via three paths: through the pore volumes, along pore surfaces, and through the graphite structure. The relative importance of these paths depends on the pore structure of the graphite bodies and on the chemical nature of the diffusing substances.

We have previously reported on the permeation of inert gases through graphite[1] and also on the absorption of bromine to carbonaceous materials[2]; each report was concerned with a limiting case of the gas permeation processes through graphite.

In the present paper, the behavior of iodine permeating through graphite is discussed. It is known that iodine is non-reactive with graphite at any temperature and that it does not form a lamellar compound[3], in contrast to the well-known case of bromine.

Nevertheless, iodine possibly has some such weak interaction with graphite as chemisorption[4], and it is expected to show some interesting behavior upon its permeation through graphite because of its condensable character. Moreover, as one of the main fission products of uranium, the behavior of iodine in graphite neutron moderators has attracted recent attention[5,6].

The purpose of the present paper is to discuss the character of the iodine diffusion through graphite at temperatures ranging from 90 to 160°C on the basis of its dependence on temperature and pressure. The effect of the presence of inert gas on the rate of iodine permeation is also investigated.

Experimental

Preparation of the Graphite Specimens.—Samples of graphite were cut to disks, 3 mm. thick and 15 mm. in diameter, which had a ring-shaped depression on one side. As is shown in Fig. 1, glass tubes were cemented to the graphite specimens with silver chloride. The procedure of the cementing was as follows: The surface of the depression on the graphite specimens was electroplated with silver, using the electrolyte of a silver cyanide aqueous solution with which the depresssion was filled. After being washed and dried thoroughly, silver chloride powder was mounted on the electroplated silver and heated indirectly and slowly, until it melted. Then, a moderately preheated glass tube was immersed in the melt and cooled very slowly.

The glass-to-graphite seal was verified to be leak-proof by preliminary experiments, in which the values of the air permeability of the same graphite

specimen were compared between two cases with different seals, silver chloride and Araldite†. The results of the two cases agreed very well*.

Measurement of the Rate of Iodine Permeation.—About 1 g. of GR-grade iodine was sealed in a glass tube fitted to the graphite specimen. The capsule thus prepared (as shown in Fig. 2) was suspended by a quartz-spring balance in a reaction tube. The reaction tube was evacuated for about one hour, until the air in the capsule had also been evacuated through the graphite specimen.

The capsule was then heated in vacuo or in argon flow, and the rate of the weight loss of the capsule, which was caused by the iodine permeation through the graphite specimen, was measured at controlled temperatures. The whole apparatus is shown in Fig. 2.

The air permeability of each specimen was also measured by the method described in a previous report[2].

Samples.—Graphite samples were ordinary artificial graphite and high-density nuclear graphite,

produced by the Nippon Carbon K. K. and the Tokai Denkyoku Seizo K. K.*

The characteristics of the samples are listed in Table I.

Results and Discussion

Iodine Permeation into a Vacuum.—The rate of iodine permeation was determined from the gradient of a plot of the weight change of the sample capsule vs. time. The plots were found to be linear in a steady state for every run of the experiments.

The results are summarized in Fig. 3, which

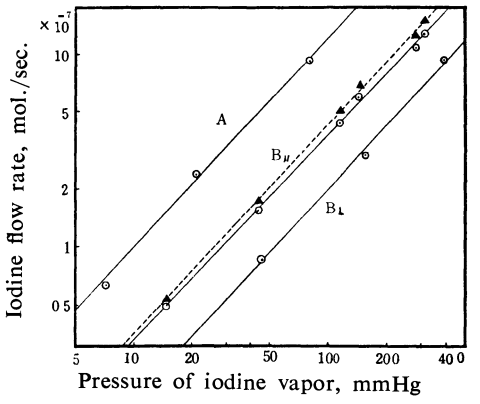

Fig. 3. Iodine flow rate as a function of the pressure of iodine vapor in log-log plot. The broken line is modified with respect to temperatures.
A, $B_{\parallel}$ and $B_{\perp}$ designate the graphite sample, characteristics of which are listed in Table I.

is a log-log plot of the rate of iodine permeation and the pressure of iodine vapor, which was equilibrated with solid or liquid iodine at each temperature of the experiments. The gradients of the plots in Fig. 3 have the same value, 1.06, for all samples. Accordingly, it was concluded that the rate of iodine permeation increased roughly proportionally to the pressure of iodine vapor at pressures lower than 400 mmHg.

It is natural to suppose, as a first appoximation, that the iodine permeation through graphite consists mainly of gas flow through the pore volumes of the media. When a single gas flows isothermally and in a steady state through the pore volumes of the media, the flow is usually considered to consist of two types, namely viscous and Knudsen flows; at any rate, it is known that it can be expressed by the following equation[1]:

$$q_m P_m = vRT = \frac{A}{L}(B_o P_m + K_o)\Delta P \qquad (1)$$

In Eq. 1, the viscous flow rate is expressed by the first term, characterized with the coefficient B_o, and the Knudsen flow by the second term, involving the coefficient K_o. q_m means the volume flow rate, cm³/sec., at a pressure of P_m, and v means the molar flow rate, mol./sec., A and L are the cross-section and the thickness of the specimen respectively.

For the present experiments, where the flowing gas consisted of the iodine gas only, P_m and ΔP in Eq. 1 were replaced by $P_{I_2}/2$ and P_{I_2} respectively. Thereby Eq. 1 becomes:

$$v = \frac{1}{RT} \cdot \frac{A}{L}\left(\frac{1}{2} B_o P_{I_2} + K_o\right) P_{I_2} \qquad (2)$$

Two limiting cases are derived from Eq. 2, pure viscous flow and pure Knudsen flow. In the case of the pure viscous flow, at a definite temperature, v increases with $(P_{I_2})^2$. On the contrary, v increases with P_{I_2} for the pure Knudsen flow.

The experimental resuls of Fig. 3, showing that v increased almost linearly with P_{I_2}, lead to the plausible conclusion that, for the iodine permeation through graphite, the Knudsen flow is predominant. This conclusion was further examined by considering the temperature dependence of the flow rate in Eq. 2. As the coefficient, K_o, for the Knudsen flow is also proportional to the spuare root of T, the values of v, which were measured at different temperatures, ought to be normalized as follows:

$$v_o = v\left(\frac{T}{T_o}\right)^{1/2} \qquad (3)$$

where v_o is the normalized molar flow rate at the temperature of T_o.

The re-plot of v_o normalized at $T_o = 300°K$ is presented in Fig. 3 as a broken line, which gives the gradient of 1.09. This result revealed that the conclusion mentioned above was appropriate.

The Knudsen model for iodine permeation was also supported by the comparison of the flow rates for air and iodine. The obtained values of the flow rates, which are normalized to the same condition of temperature and pressure for both air and iodine, are tabulated in Table I. It was also confirmed experimentally that the air flow at the normalized condition consisted mainly of the Knudsen flow.

Provided that the flows of both air and iodine are those of the Knudsen type, the ratio of the flow rates, (Q_{air}/Q_{I_2}), ought to be equal to the square root of (M_{I_2}/M_{air}), namely, 2.96 (where M means the molecular weight of the gases). The experimental values obtained were 2.68~2.85. The values of theory and experiments agree fairly well. The small discrepancies are possibly due to the small contributions of the viscous part to the total flow, since the mean free path of air is about 1.5 times longer than that of iodine at the same pressure and so the contribution of the viscous part of the air flow is probably smaller than that of the iodine flow.

Iodine Permeation in Argon Gas.—The rate of iodine permeation was measured also in an argon gas flow of controlled pressure in order to clarify the effects of inert gases on the behavior of gas permeation through porous media such as graphite. The apparatus used and the method of measurements were just the same as above, except that argon gas

streamed at the mean flow rate of 1 cm./sec. in the reaction tube shown in Fig. 2.

It was found that the rate of iodine permeation was depressed markedly in the stream of argon gas. As is clear from Fig. 4, in which a plot of $1/v$ vs. mean gas pressure ($P_{I_2}/2 + P_{Ar}$) is presented, even at the mean pressure of the Knudsen diffusion region (at pressure below 400 mmHg), the rate of iodine permeation decreased with an increase in argon gas pressure. This fact seems to be rather curious, because in the Knudsen region the flow rate of one species might not be affected by the presence of the other species.

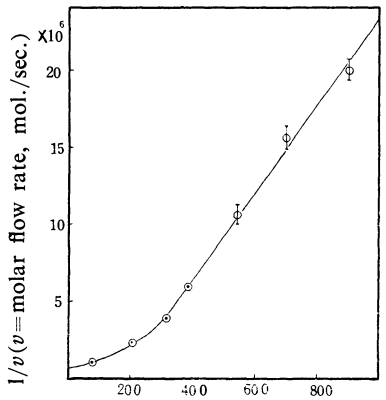

Fig. 4. The dependence of iodine flow rate on the pressure of argon gas.

It has been reported by Korsmeyer[7] and Evans et al.[8], however, that the same phenomena as have been described above were observed in the measurement of the counter-current mutual permeation of helium and argon through graphite septum. They pointed out that, for the gas flow through porous media such as graphite, even at the pressure of the Knudsen region, a pure Knudsen flow is not realized and that the mutual diffusion effect must be taken into account. The Knudsen coefficient, K_o, in Eqs. 1 and 2 is, therefore, replaced by a total diffusion coefficient, $(K_1)_{eff}$, and is represented by the Bosanquet type of an equation[9] as follows:

$$(K_1)_{eff}^{-1} = (D_{12})_{eff}^{-1} + K_o^{-1} \qquad (4)$$

where $(D_{12})_{eff}$ is the effective mutual diffusion coefficient proportional to D_{12}, the usual diffusion coefficient of the gases. The constant of proportionality is charcteristic of the internal geometry of the porous medium. Evans et al.[8] have theoretically derived just the same formula as Eq. 4, applying the "dusty gas model" for the diffusion of gases in porous media.

Since D_{12} in Eq. 4 is roughly inversely proportional to the mean pressure of gases, the relationship of $1/v$ vs. P_m obtained in the present study (as shown in Fig. 4), especially at the linear part of the figure, is explained reasonably by this model. The reason for the discrepancy in the lower pressure region is not clear, but it is likely that this is due to the character of the flow in this region, which is supposed to be intermediate between the capillary model and the "dusty gas model".

Summary

The rate of iodine permeation through graphite has been studied and the following results were obtained:

(1) The process of iodine permeation through graphite has been found to consist mainly of a simple gas flow through the pore volumes, just as in the case of inert gases. The chemical interaction between iodine and graphite has been observed to be negligibly small.

(2) At tempeatures ranging from 90 to 160°C, and under a corresponding pressure of iodine vapor below 400 mmHg the rate of iodine permeation has been observed to be almost linearly proportional to the pressure of iodine. It has been concluded that the Knudsen flow was the predominant element of the total flow.

(3) The ratio of the flow rates for air and iodine, which were interpolated to the value under the same conditions, has been calculated to be 2.68~2.85, close to the value 2.96, namely $(M_{I_2}/M_{air})^{1/2}$, as was expected from the Knudsen flow model.

(4) The rate of iodine permeation has been observed to decrease in the presence of argon gas, even in the region of Knudsen flow. It has been found that the rate is roughly inversely proportional to the pressure of argon gas. The "dusty gas model" discussed by Evans et al. has been adapted to give a reasonable explanation of this phenomena.

The authors are indebted to Mr. O. Lee for help in a part of the measurements.

The Synthesis of Azuleno[2, 1-b]pyridine Derivatives

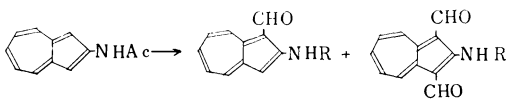
By Tetsuo NOZOE and Katsuo KIKUCHI*

(Received November 8, 1962)

Among the azulenes fused with heterocyclic rings, azuleno[6, 5-b]furans (furo[3, 2-f]azulenes)[1], azuleno[6, 5-b]pyrroles (pyrrolo[3, 2-f]-azulenes)[1], azuleno[2, 1-b]thiophenes (thieno-[3, 2-a]azulenes)[2] and azuleno[6, 5-c]pyrazoles (pyrazolo[4, 3-f]azulenes)[3] have already been synthesized. The present writers have synthesized azuleno[2, 1-b]pyridines (pyrido[3, 2-a]-azulenes) by the application of Friedeländer's method to 2-amino-1-formylazulene (I) and its acetate (II); their results have been described briefly elsewhere[4]. In the present paper we wish to report those results in some detail.

Treatment of 2-acetamidoazulene[5] in dimethylformamide with one equivalent of phosphorus oxychloride gave an immonium salt which, without purification, was then treated with aqueous sodium carbonate to afforded 2-acetamido-1-formylazulene (II) and a small amount of 2-acetamido-1, 3-diformylazulene (III). Hydrolysis of II with alcoholic sodium hydroxide afforded 2-amino-1-formylazulene (I). Similar treatment of III afforded 2-amino-1, 3-diformylazulene (IV).

The heating of compound I with acetylacetone in the presence of a small amount of piperidine gave dark greenish brown feathery crystals (V) in about a 50% yield. V easily afforded several kinds of complexes such as hydrochloride, trinitrobenzene complex and picrate, and it gave an oxime. V also showed positive iodoform reaction. The infrared spectrum of V in Nujol showed absorption at 1665 cm^{-1} (conjugated carbonyl). These facts reveal that compound V is 3-acetyl-2-methylazuleno-[2, 1-b]pyridine, as was expected.



I: R=H III: R=$COCH_3$
II: R=$COCH_3$ IV: R=H

A similar treatment of I with ethyl acetoacetate gave ethyl 2-methylazuleno[2, 1-b]pyridine-3-carboxylate (VI) and I with diethyl acetonedicarboxylate gave ethyl 3-ethoxycarbonylazuleno[2, 1-b]pyridine-2-acetate (VII). The compounds V, VI and VII have quite similar absorptions in the ultraviolet region (Fig. 1).

Prolonged heating of acetate II with diethyl malonate in the presence of piperidine at 50~60°C gave dark brown needles (VIII) in a 50% yield, instead of the expected 2-acetamido-1-(β, β-diethoxycarbonyl)azulene being isolated. The ultraviolet spectrum of VIII is shown in Fig. 2. Judging from the analysis of VIII and the following experimental facts, VIII is thought to be ethyl 1, 2-dihydro-2-oxoazuleno[2, 1-b]-pyridine-3-carboxylate. Compound VIII was not affected by aqueous sodium carbonate, but it gives a brown sodium salt with aqueous sodium hydroxide from which the original substance was regenerated with acetic acid. The prolonged heating of VIII with aqueous sodium hydroxide afforded the acid IX.

When heated with phosphorus oxychloride, VIII was converted to ethyl 2-chloroazuleno-[2, 1-b]pyridine-3-carboxylate (X). The heating of X with sodium methoxide or with sodium ethoxide afforded a 2-methoxy compound XI,

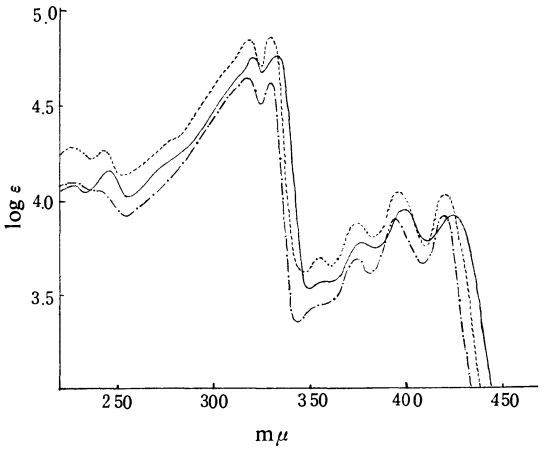


Fig. 1. The ultraviolet spectra of V (——), VI (----) and VII (—·—·) in methanol.

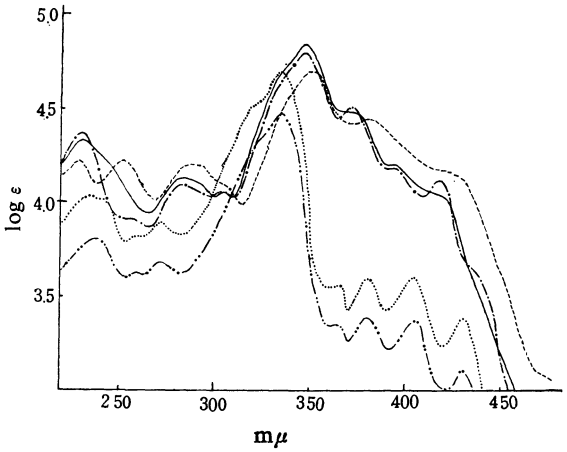

Fig. 2. The ultraviolet spectra of VIII (——), XV (----), XVI (—·—·), XI (·····, log ε−0.2) and XII (—··—, log ε−0.4) in methanol.

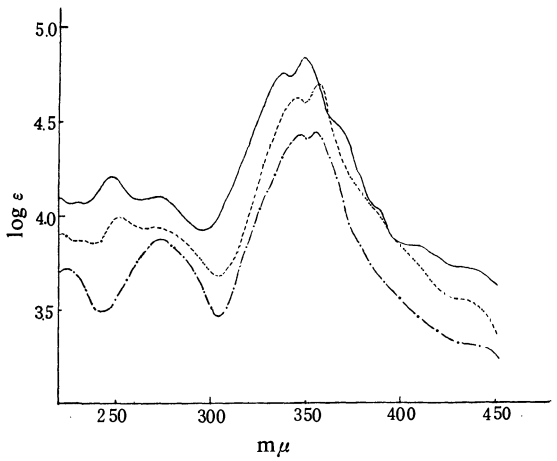

Fig. 3. The ultraviolet spectra of XVII (——), XIII (----, log ε−0.2) and XIV (—·—·, log ε−0.4) in methanol.

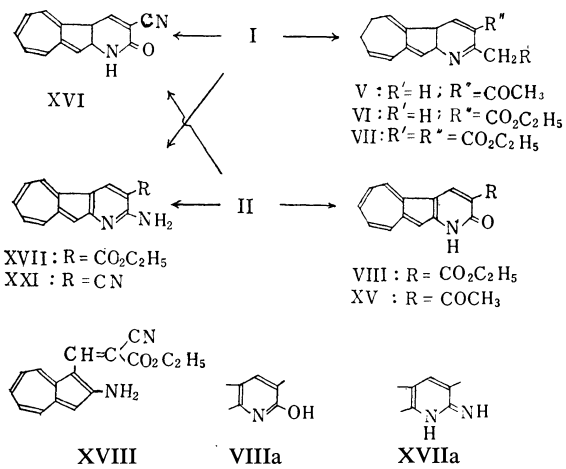
or a 2-ethoxy compound XII, respectively. The ultraviolet absorption curves of XI and XII (Fig. 2) are markedly different from that of VIII but rather similar to these of V, VI and VII. The infrared spectrum of VIII in Nujol exhibits a band at 1630 cm^{-1} (pyridone carbonyl) which is absent in those of compounds XI and XII. These fact indicate that compound VIII exists in the 2-pyridone form rather than in the tautomeric 2-hydroxypyridine form VIIIa.



Compound X also reacted with methylamine to give a 2-methylamino compound XIII, and with dimethylamine to give a 2-dimethylamino compound XIV, but the heating of X with alcoholic ammonia resulted in the recovery of the starting material. The ultraviolet spectra of XIII and XIV are shown in Fig. 3.

A similar reaction of compound II with ethyl acetoacetate gave brown crystals (XV) (m. p., 288°C) (decomp.), though in poor yield, compound VI not being isolated. From its analytical values and the resemblance of its ultraviolet absorption curve (Fig. 2) to that of compound VIII, XV is through to be 3-acetyl-1, 2-dihydro-2-oxoauzleno [2, 1-b] pyridine, formed by a mode of cyclization different from that of compound I and the same reagent.

X : R=$CO_2C_2H_5$ XI : R=$CO_2C_2H_5$; X=OCH_3
XIX : R=CN XII : R=$CO_2C_2H_5$; X=OC_2H_5
XIII : R=$CO_2C_2H_5$; X=$NHCH_3$
XIV : R=$CO_2C_2H_5$; X=$N(CH_3)_2$
XX : R=CN ; X=OCH_3

The reaction of I or II with ethyl cyanoacetate was next examined. When I has heated with this reagent reddish brown needles of $C_{14}H_8O_2N_2$ (XVI) (m. p., above 29°C) and a small amount of reddish brown needles (C_{16}·$H_{14}O_2N_2$) (XVIII) (m. p., 141°C) were also obtained. The ultraviolet spectrum of XVI (Fig. 2) resembles these of VIII and XV, and the infrared spectrum shows bands at 1655 cm^{-1} (pyridone carbonyl) and at 2210 cm^{-1} (cyano), indicating XVI to be 3-cyano-1, 2-dihydro-2-oxoazuleno [2, 1-b] pyridine. The infrared spectrum of XVII in Nujol shows bands at 3440, 3300 (amino) and 1680 cm^{-1} (ester carbonyl) thus XVII is thought to be ethyl 2-aminoazuleno-[2, 1-b] pyridine-3-carboxylate. XVIII, isomeric with XVII, shows a band at 2190 cm^{-1} (cyano) besides those at 3490, 3340, 3250 (amino) and 1670 cm^{-1} (ester carbonyl) in its infrared region and is thought to be 2-amino-1-(β-cyano-β-ethoxycarbonylvinyl)azulene. The reaction of II and ethyl cyanoacetate also gave XVI and XVII, with the latter predominating. The

ultraviolet spectrum of XVII (Fig. 3) resembles those of XIII and XIV, indicating that XVII has the 2-aminopyridine structure rather than the tautomeric 2-pyridone imine form XVIIa.

Reaction XVI with phosphorus oxychloride gave 2-chloro compound XIX which when treated with sodium methoxide, was converted to the 2-methoxy compound XX.

Malononitrile reacted with I or II smoothly to give 2-amino-3-cyanoazuleno [2, 1-b] pyridine (XXI).

Experimental

2-Acetamido-1-formylazulene (II) and 2-Acetamido-1, 3-diformylazulene (III). — To a solution of 800 mg. of 2-acetamidoazulene in 2.5 ml. of dimethylformamide was added a solution of 650 mg. of phosphorus oxychloride in 2.5 ml. of dimethylformamide with continuous ice cooling. After the reaction mixture had been left standing for 4 hr. at room temperature, the immonium salt that separated was collected by filtration. This salt was then dissolved in water and neutralized with dilute sodium carbonate solution, and II which crystallized out, was collected and washed with water. Yield; 595 mg; m. p., 148~150°C.

The original filtrate was diluted with water and neutralized with a dilute sodium carbonate solution to give 290 mg. of reddish brown crystals; m. p., 135~180°C. This solid was recrystallized from ethanol to give 70 mg. of III as brown crystals (m. p., 205~220°C) (decomp.) and 75 mg. of II as red crystals.

II was recrystallized from a mixture of benzene and cyclohexane to give red prisms, m. p. 150~115°C.

Found: C, 73.40; H, 5.10; N, 6.23. Calcd. for $C_{13}H_{11}O_2N$: C, 73.22; H, 5.20; N, 6.57%.

III was recrystallized from dimethylformamide to give brown feathery csystals; m. p. 225~235°C (decomp.).

Found: C, 69.76; H, 4.57; N, 5.67. Calcd. for $C_{14}H_{11}O_3N$: C, 69.70; H, 4.59; N, 5.80%.

2-Amino-1-formylazulene (I).—To a solution of 550 mg. of compound II in 20 ml. of ethanol was added 4.5 ml. of a 2 N sodium hydroxide solution and permitted to stand for 1 hr. The acidification of the reaction mixture with acetic acid and the evaporation of the ethanol under reduced pressure gave 420 mg. of a crystalline solid; m. p, 138~140°C. Recrystallization from a mixture of benzene and cyclohexane gave orange scales, m. p., 138~139°C.

Found: C, 77.46; H, 5.08; N, 7.93. Calcd. for $C_{11}H_9ON$: C, 77.17; H, 5.30; N, 8.18%.

Oxime.—Brown scale; m. p., 158~159°C.

Found: C, 70.91; H, 5.11; N, 15.05. Calcd. for $C_{11}H_{10}ON_2$: C, 70.95; H, 5.41; N, 15.05%.

Trinitrobenzene Complex.—Red scales; m.p, 146~147°C.

Found: C, 53.32; H, 2.95; N, 14.58. Calcd. for $C_{17}H_{12}O_7N_4$: C, 53.13; H, 3.15; N, 14.58%.

2-Amino-1, 3-diformylazulene (IV). — Treatment of 400 mg. of III similar to that given II gave 210 mg. of IV; m. p., 196~210°C. Recrystallization from dimethylformamide gave brownish orange needles; m. p., 213~215°C (decomp.).

Found: C, 72.52; H, 4.30; N, 6.89. Calcd. for $C_{12}H_9O_2N$: C, 72.35; H, 4.55; N, 7.03%.

3-Acetyl-2-methylazuleno[2, 1-b]pyridine (V). — A mixture of 150 mg. of I, 300 mg. of acetylacetone and a small amount of piperidine was heated on a water bath for 6 hr., and the crystals which separated out were collected by filtration. These crystals were dissolved in benzene and passed through an alumina column to give 7 mg. of V as greenish brown crystals; m. p., 143~145°C. The original filtrate was washed with petroleum ether and the insoluble portion was dissolved in benzene, and chromatographed on an alumina column giving 35 mg. of V, m. p., 141~143°C, and 35 mg. of I. Recrystallization from dilute ethanol gave dark greenish brown feathery crystals, m. p., 144~145°C.

Found: C, 81.50; H, 5.17; N, 5.88. Calcd. for $C_{16}H_{13}ON$: C, 81.68; H, 5.57; N, 5.95%.

A solution of 30 mg. of V in dioxane was treated with iodine in the usual manner to give approximately 5 mg. of iodoform.

Hydrochloride.—Deep brown crystals, m. p. over 280°C.

Found: C, 66.08; H, 5.24; N, 4.37. Calcd. for $C_{16}H_{14}ONCl \cdot H_2O$: C, 66.32; H, 5.57; N, 4.83%.

Trinitrobenzene Complex. — Dark violet needles, m. p. 119.5~121°C.

Found: N, 12.08. Calcd. for $C_{22}H_{16}O_7N_4$: N, 12.50%.

Picrate. — Yellowish brown microcrystals which showed no definite melting point (they gradually blackened around 190°C and completely carbonized 280°C).

Found: C, 57.48; H, 3.21; N, 12.04. Calcd. for $C_{22}H_{16}O_8N_4$: C, 56.90; H, 3.47; N, 12.07%.

Oxime. — Greenish brown microneedles, m. p. 250~260°C (carbonized).

Found: C, 76.52; H, 5.44; N, 10.83. Calcd. for $C_{16}H_{14}ON_2$: C, 76.77; H, 5.64; N, 11.19%.

Ethyl 2-methylazuleno[2, 1-b]pyridine-3-carboxylate (VI).—A mixture of 150 mg. of I, 170 mg. of ethyl acetoacetate and about 30 mg. of piperidine was heated on a water bath for 7 hr. The crystals which separated were collected by filtration, dissolved in benzene and passed through an alumina column in which manner 40 mg. of VI was thereby obtained as dark violet crystal; m. p., 137~138°C. The original filtrate was dissolved in a mixture of benzene and petroleum ether (1 : 1) and chromatographed on an alumina column giving an additional 40 mg. of VI; m. p., 137~138°C. Recrystallization from a mixture of benzene and petroleum ether gave dark greenish violet plates; m. p., 137~138°C.

Found: C, 77.04; H, 5.36. Calcd. for $C_{17}H_{15}O_2N$: C, 76.96; H, 5.70%.

Hydrochloride.—Dark brown microcrystals, m. p. 217°C (decomp.).

Found: C, 60.10; H, 5.73. Calcd. for $C_{17}H_{16}O_2NCl \cdot 2H_2O$: C, 60.44; H, 5.97%.

Picrate.—Greenish brown crystals, which gradually blackened at around 215°C but which showed no definite melting point.

Found: C, 56.64; H, 3.62; N, 10.98. Calcd.

for $C_{23}H_{18}O_9N_4$: C, 55.87; H, 3.67; N, 11.23%.

Ethyl 3-Ethoxycarbonylazuleno[2, 1-b]pyridine-2-acetate (VII).—A mixture of 150 mg. of I, 300 mg. of diethyl acetonedicarboxylate and a small amount of piperidine was treated as in the case of VI. Chromatographic separation on an alumina column giving an additional 40 mg. of VI; m. p., 137~138°C. Recrystallization from a mixture of benzene and petroleum ether gave dark greenish violet plates; m. p., 137~138°C.

Found: C, 77.04; H, 5.36. Calcd. for $C_{17}H_{15}O_2N$: C, 76.96; H, 5.70%.

Hydrochloride.—Dark brown microcrystals; m. p., 217°C (decomp.).

Found: C, 60.10; H, 5.73. Calcd. for $C_{17}H_{16}O_2NCl \cdot 2H_2O$: C, 60.44; H, 5.97%.

Picrate.—Greenish brown crystals, gradually blackened at around 215°C and showed no definite melting point.

Found: C, 56.64; H, 3.62; N, 10.98. Calcd. for $C_{23}H_{18}O_9N_4$: C, 55.87; H, 3.67; N, 11.23%.

Ethyl 3-Ethoxycarbonylazuleno[2,1-b]pyridine-2-acetate (VII).—A mixture of 150 mg. of I, 300 mg. of diethyl acetonedicarboxylate and a small amount of piperidine was treated as in the case of VI. Chromatographic separation on an alumina column gave 115 mg. of VII as deep violet crystals; m. p., 107~111°C. Recrystallization from ethanol gave dark violet needles; m. p., 116~117°C.

Found: C, 71.08; H, 5.64; N, 4.08. Calcd. for $C_{20}H_{19}O_4N$: C, 71.20; H, 5.68; N, 4.15%.

Hydrochloride.—Dark violet needles; m. p., 200°C (decomp., gradually blackened around 192°C).

Found: N, 3.26. Calcd. for $C_{20}H_{20}O_4NCl \cdot H_2O$: N, 3.57%.

Picrate.—Dark reddish violet crystals; m. p., 216°C (decomp., gradually blackened around 205°C).

Found: C, 54.97; H, 3.86; N, 9.62. Calcd. for $C_{26}H_{22}O_{11}N_4$: C, 55.12; H, 3.91; N, 9.89%.

Ethyl 1, 2-Dihydro-2-oxoazuleno[2, 1-b]pyridine-3-carboxylate (VIII).—To a solution of 300 mg. of II in 6 ml. of ethanol was added 400 mg. of diethyl malonate and 200 mg. of piperidine, and the whole was heated at 50~60°C for about 30 hr. in which manner 185 mg. of VIII was obtained as brown needles, m. p. 208~215°C (decomp.). Recrystallization from dioxane raised the melting point to 212~217°C (decomp.).

Found: C, 72.14; H, 4.77; N, 5.48. Calcd. for $C_{16}H_{13}O_3N$: C, 71.90; H, 4.90; N, 5.24%.

Picrate.—Orange microcrystals; m. p., 186~188°C (decomp.).

Found: C, 54.00; H, 3.25; N, 11.00. Calcd. for $C_{22}H_{16}O_{10}N_4$: C, 53.23; H, 3.25; N, 11.29%.

The addition of a dilute sodium hydroxide solution to a solution of VIII in dimethylformamide or the heating of VIII in a sodium hydroxide solution gave a brown sodium salt, which on acidification with acetic acid gave the original material.

1,2-Dihydro-2-oxoazuleno[2,1-b]pyridine-3-carboxylic Acid (IX).—The heating of 70 mg. of VIII, with the addition of 1 ml. of a 1 N sodium hydroxide solution on a water bath for 1.5 hr., gave a dark greenish-brown sodium salt. Acidification with acetic acid gave 55 mg. of acid as reddish brown crystals; m. p., above 280°C. Recrystallization from dimethylformamide gave reddish brown microneedles.

Found: C, 70.71; H, 3.47; N, 6.27. Calcd. for $C_{14}H_9O_3N$: C, 70.29; H, 3.79; N, 5.86%.

Ethyl 2-Chloroazuleno[2, 1-b]pyridine-3-carboxylate (X).—A mixture of 150 mg. of VIII and 0.8 ml. of phosphorus oxychloride in a sealed tube was heated on a water bath for 1.5 hr. The crystals which separated were collected, suspended in water, treated with aqueous sodium acetate, and extracted with chloroform. The chloroform solution was washed with water and passed through an alumina column. The solvent was evaporated from the effluent, and the crystalline residue was recrystallized from a mixture of benzene and petroleum ether to give 80 mg. of dark greenish violet needles, (m. p., 155~157°C). The original filtrate was poured onto ice to decompose any excess phosphorus oxychloride, treated with aqueous sodium acetate, and extracted with chloroform. The chloroform solution was passed through an alumina column to give 25 mg. of a second crop; m. p., 150~153°C. Recrystallization from a mixture of benzene and petroleum ether gave dark violet needles; m. p., 156~157°C.

Found: C, 67.30; H, 4.06; N, 4.62. Calcd. for $C_{16}H_{12}O_2NCl$: C, 67.25; H, 4.23; N, 4.90%.

Ethyl 2-Methoxyazuleno[2, 1-b]pyridine-3-carboxylate (XI).—To a solution of 40 mg. of sodium in 2 ml. of methanol was added 100 mg. of X; the mixture was then heated on a water bath for 10 min., cooled, diluted with water and extracted with chloroform, The chloroform solution was washed with water and passed through an alumina column. The crystalline residue which was obtained after the evaporation of the solvent from the elute was recrystallized from a mixture of benzene and petroleum ether to give 35 mg. of XI as dark violet crystals, m. p. 161~163°C. Further recrystallization from the same solvent gave dark violet needles; m. p., 162~163°C.

Found: C, 72.17; H, 4.78; N, 5.13.Cal cd. for $C_{17}H_{15}O_3N$: C, 72.58; H, 5.38; N, 4.98%.

Ethyl 2-Ethoxyazuleno[2, 1-b]pyridine-3-carboxylate (XII).—A similar treatment of 100 mg. of X with sodium ethoxide in ethanol gave 30 mg. of XII; m. p. 146~148°C. Recrystallization from ethanol gave dark greenish violet microneedles; m. p., 147.5~149°C.

Found: C, 73.37; H, 5.62; N, 4.59. Calcd. for $C_{18}H_{17}O_3N$: C, 73.20; H, 5.80; N, 4.74%.

Ethyl 2-Methylaminoazuleno[2, 1-b]pyridine-3-carboxylate (XIII).—A mixture of 50 mg. of X and 50 mg. of aqueous methylamine (40%) in 0.4 ml. of ethanol was heated on a water bath for 1 hr. in a sealed tube; it was then cooled, and the crystals which separated were collected to give 38 mg. of XIII (m. p., 146~147°C). Recrystallization from ethanol gave wine red needles.

Found: C, 72.97; H, 5.69; N, 9.61. Calcd. for $C_{17}H_{16}O_2N_2$: C, 72.83; H, 5.75; N, 9.99%.

Ethyl 2-Dimethylaminoazuleno[2, 1-b]pyridine-3-carboxylate (XIV).—The treatment of 50 mg. of X with aqueous dimethylamine (40%) in ethanol in a manner similar to that used in the case of XIII

gave 48 mg. of XIV; m. p., 133~135°C. Recrystallization from ethanol gave wine red plates; m. p., 134~135°C.

Found: C, 73.60; H, 5.85; N, 9.12. Calcd. for $C_{18}H_{18}O_2N_2$: C, 73.45; H, 6.16; N, 9.52%.

3-Acetyl-1, 2-dihydro-2-oxoazuleno[2, 1-b]pyridine (XV).—A solution of 200 mg. of II, 200 mg. of ethyl acetoacetate and 100 mg. of piperidine in 4 ml. of ethanol was heated on a water bath for 5 hr. The crystals which separated were collected and recrystallized from ethanol to give 50 mg. of crystals; m. p., 190~230°C. Repeated recrystallization from dimethylformamide gave brown microcrystals; m. p., 287~288°C (decomp.).

Found: C, 75.77; H, 4.49; N, 6.16. Calcd. for $C_{15}H_{11}O_2N$: N, 75.93; H, 4.67; N, 5.90%.

The Reaction of Compound I and Ethyl Cyanoacetate.—A solution of 400 mg. of I, 400 mg. of ethyl cyanoacetate and 50 mg. of piperidine in 1 ml. of ethanol was heated on a water bath for 2 hr. On cooling of the reaction mixture gave 95 mg. of 3-cyano-1,2-dihydro-2-oxoazuleno[2,1]pyridine (XVI) (m. p., above 290°C) as brown crystals. Evaporation of the solvent from the filtrate, followed by the addition of a small amount of benzene separated 25 mg. of ethyl 2-aminoazuleno[2,1-b]-pyridine-3-carboxylate (XVII) (m. p. 167~187°C). The filtrate was passed through an alumina column giving 35 mg. of 2-amino-1-(β-cyano-β-ethoxycarbonylvinyl)azulene (XVIII) as red crystals, (m. p., 135~139°C).

XVI was recrystallized from dimethylformamide to give reddish brown needles; m. p., above 290°C.

Found: C, 76.17; H, 3.74; N, 12.63. Calcd. for $C_{14}H_8ON_2$: C, 76.36; H, 3.66; N, 12.72%.

XVII was recrystallized from *n*-butanol to give reddish brown needles; m. p., 189~190°C.

Found: C, 72.52; H, 4.99; N, 10.46. Calcd. for $C_{16}H_{14}O_2N_2$: C, 72.16; H, 5.30; N, 10.52%.

XVIII was recrystallized from ethanol to give red prisms; m. p., 139.5~141°C.

Found: C, 71.96; H, 5.02; N, 10.58. Calcd. for $C_{15}H_{14}O_2N_2$: C, 72.16; H, 5.30; N, 10.52%.

The Reaction of Compound II and Ethyl Cyanoacetate.—A similar treatment of 300 mg. of II with ethyl cyanoacetate gave 305 mg. of brownish purple crystals (m. p., 190~230°C). The sparingly soluble portion of these crystals in chloroform afforded 75 mg. of XVI (m. p. over 290°C), while the easily soluble part gave 170 mg. of XVII (m. p., 188~189°C).

2-Chloro-3-cyanoazuleno[2, 1-b]pyridine (XIX).—A mixture of 90 mg. of XVI and 0.5 ml of phosphorus oxychloride in a sealed tube was heated on a water bath for 1.5 hr.; it was then cooled, and the crystals which separated were collected by filtration. Treatment of these crystals with a dilute sodium carbonate solution afforded 72 mg. of dark violet crystals (m. p., 256~261°C). Recrystallization from dimethylformamide gave dark greenish violet needles; m. p., 264~265°C.

Found: C, 70.24; H, 2.78; N, 11.60. Calcd. for $C_{14}H_7N_2Cl$: C, 70.45; H, 2.96; N, 11.74%.

3-Cyano-2-methoxyazuleno[2, 1-b]pyridine (XX).—To a solution of 20 mg. of sodium in 0.6 ml. of methanol was added 40 mg. of XIX; the solution was then heated on a water bath for 20 min. The crystals which were obtained were then dissolved in chloroform, passed through an alumina column, and the solvent was evaporated from the effluent. The residue was recrystallized from a mixture of ethanol and *n*-butanol to give 25 mg. of brownish violet needles; m. p., 229~230°C.

Found: C, 76.86; H, 4.17; N, 11.80. Calcd. for $C_{15}H_{10}ON_2$: C, 76.91; H, 4.30; N, 11.96%.

2-Amino-3-cyanoazuleno[2, 1-b]pyridine (XXI).—a) A solution of 70 mg. of I, 70 mg. of malononitrile and a small amount of piperidine in 0.3 ml. of ethanol was heated for 1 hr. on a water bath, and the resulting crystals (80 mg., m. p. 245~268°C) were recrystallized from dimethylformamide to give brownish violet needles (m. p., 266~268°C) (decomp.).

Found: C, 77.03; H, 3.92; N, 18.61. Calcd. for $C_{14}H_9N_3$: C, 76.69; H, 4.14; N, 19.17%.

Hydrochloride.—Reddish orange microneedles, m. p. over 280°C.

Found: C, 61.62; H, 4.09. Calcd. for $C_{14}H_{10}N_3Cl \cdot H_2O$: C, 61.43; H, 4.42%.

b) The treatment of a solution of 100 mg. of II, 50 mg. of malononitrile and 30 mg. of piperidine in 1 ml. of ethanol in a manner similar to that used in the case of a) afforded 75 mg. of XXI; m. p., 260~265°C. (decomp.). Recrystallization from dimethylformamide raised the melting point 266~268°C (decomp.); these crystals were shown to be identical with those obtained by a).

One of the authors, Katsuo Kikuchi, wishes to express his thanks to Japan Society for the Promotion of Science for the fellowship which has enabled him to carry out this work during his stay at Tohoku University as a visiting research associate.

Studies of the Electrolytic Conductance of a Dye Solution. I. Complex Formation in an Aqueous Solution of the Mixture of Chlorazol Sky Blue FF and Chrysophenine G

By Kinko SHINZAWA, Yoshié TANIZAKI and Noboru ANDO

(Received December 10, 1962)

As is commonly known, the McBain effect[1] caused by the aggregation of dye ions is observed in most direct dyes in an aqueous solution[2]. A typical McBain effect has been found in Methylene Blue[3], the basic dye, and later it was confirmed by a change in the absorption spectrum that this dye forms an aggregate with an increase of its own concentration[4].

Recently, studies have come to be made, by means of spectrophotometry, of the complex formation of unlike dye molecules in mixtures in an aqueous solution[5-7]. These studies have discovered the important fact that Chlorazol Sky Blue FF and Chrysophenine G form complexes in definite mole ratios[6,7]. In the case of Methylene Blue in water mentioned above, the evidence of its aggregation was found in the measurements of conductance[2] as well as in those of the absorpsion spectrum[8]. In the same way, it may be expected that a proof of complex formation between Chlorazol Sky Blue FF and Chrysophenine G will also be derived from the conductance measurement.

In the present paper, the authors will investigate the complex formation of a two-component dye mixture in an aqueous solution from the view point of electrolytic conductance. Unfortunately, however, in the field of conductance study, there is no rule such as Beer's law in the field of light absorption. Though a theoretical treatment of the conductance of a mixed electrolyte solution has been attempted by Onsager and his co-workers[9], no application of the theory to experimental results has yet been made. Considering that we can not yet analyze quantitatively the conductance of dyes, even in a single solution, much less can we expect to perform a satisfactory analysis of dye mixtures. Accordingly, as a first step towards a preliminary investigation, attention is directed to the examination of how the complex formation of Chlorazol Sky Blue FF and Chrysophenine G is reflected in the conductance of a mixed system. Also, we will examine how the complex formation is to be understood in relation both to the conductance characters of the mixture and to those of its components.

Experimental

The dye samples used were Chlorazol Sky Blue FF and Chrysophenine G, both of which had already been used in other reports by the present authors[7]. Potassium chloride (the extra pure grade of the Japan Pharmacopeia) was once recrystallized from distilled water. Sodium chloride (the extra pure grade of the Japan Pharmacopeia) was purified once by recrystallization from a water-alcohol solution. Conductance water was prepared from a specially-designed distilling apparatus; its specific conductance upon measurement was $(5\sim10)\times10^{-7}$ mho/cm. at 30°C.

Conductance measurement was carried out by means of the usual Wheatstone bridge. The frequency of the oscillator was 800 cycle/sec. A null point was determined with a cathode ray oscilloscope. Waves on the oscilloscope vanished in the cases of resistance under 10^5 ohm. In the other cases, however, the minimum point was regarded as a null point. The volumes of the four conductance cells employed were from 15 to 20 ml. The electrodes of two of the cells were square platinum plates $19\times13\times0.3$ mm^3, while those of the other two were $15\times13\times0.3$ mm^3; all of them had been platinized beforehand. The cell constants were determined by measuring the conductance of a 0.01 D aqueous potassium chloride solution[10] at 30°C. All the cell constants were redetermined every one or two months.

During the preparation and measurement of solutions, attention was paid to avoid the effect of the carbon dioxide in air. For this purpose,

desired volumes of distilled water or solutions were measured out in flasks through burettes under the carbon dioxide-free conditions by the use of a particular device; thus, the sample liquids were prepared without being exposed directly to the open air. The mother solution and distilled water were stored once in each stock bottle, and then sample solutions were prepared from them within 24 hr. All of the concentrations were determined by weight. Each series of solutions in concentrations was prepared by diluting a mother solution. All solution measurements prepared were carried out within two days. The three thermostated water bath were adjusted at 30, 40 and 60°C and were constant within ±0.02°C. The resistance of a cell containing a solution became constant over 10 min. after it had been soaked in a bath. In this report, the observed values are of 20 min. after. The resistance of water as a solvent approached a constant value in about 10 min., but it did not give a stationary value, showing an inclination to decrease slightly with the lapse of time. However, in this case the resistance after 20 min. was employed as an observed value of the water used.

Results and Discussion

Concerning the two series of binary mixtures at the respective constant ratios of Blue (Chlorazol Sky Blue FF) and Yellow (Chrysophenine G), the values of the observed specific conductance, κ_{obs}, divided by the total equivalent concentration of the dyes involved have been plotted against the square root of the total concentration. This provides the white and the half black circles in Fig. 1. A black circle in this figure represents the value, $\kappa_{sum}/(C_F+C_G)$, calculated by the following expressions, using the specific conductances of the components in a single solution:

$$\kappa_{sum}=k_F+\kappa_G=(C_F\Lambda_F+C_G\Lambda_G)\times 1/1000 \quad (1)$$

$$\kappa_{sum}/(C_F+C_G)=(f_F\Lambda_F+f_G\Lambda_G)\times 1/1000 \quad (2)$$

Here, C_F and C_G are the equivalent concentrations, Λ_F and Λ_G, the equivalent conductances, and $f_F=C_F/(C_F+C_G)$ and $f_G=C_G/(C_F+C_G)$, the equivalent fractions of Blue and Yellow respectively. The "sum" value defined here may give a standard for deciding whether or not the observed conductance is abnormally increased in a mixed system. This is because the value of κ_{sum} implies the conductance of mixture when no interaction is produced by mixing between ion species; therefore, κ_{sum} should be larger than κ_{obs}, according to the general tendency of electrolyte solutions for the mobility to decrease with an increase in the concentration. In the comparison of "sum" and "obs" conductances in the mixture, it may be convenient to express the conductance in the very form of κ divided by the total equivalent concentration at which κ was observed (Eq. 2). This form is considered to have the physical meaning that it is the mean conductance applied to a one-gram equivalent of the cations and anions in the solution.

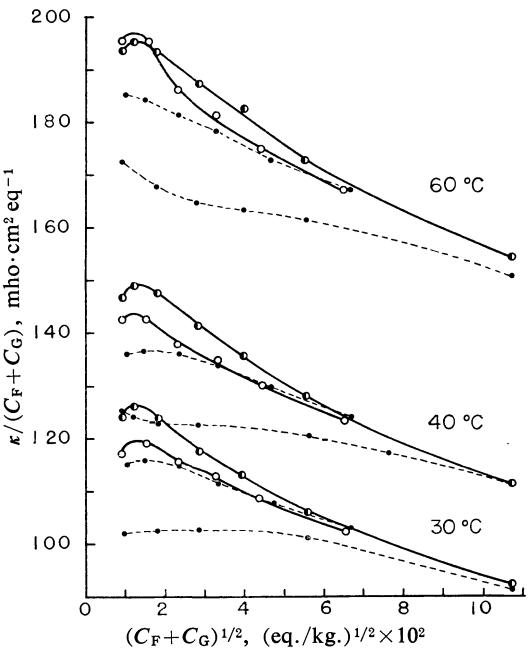

Fig. 1. Relation of conductance of the mixture of Blue and Yellow to square root of its total equivalent concentration.
In each series the concentration ratio of Blue and Yellow is constant.
○: $C_G/C_F=0.1034$ ◐: $C_G/C_F=1.1716$
●: sum

The conductance curves in Fig. 1 indicate the relation,

$$\kappa_{obs}/\sum C \geqq \kappa_{sum}/\sum C \quad (3)$$

in the greater part in the concentration region observed here. In Eq. 3, $\sum C$ means (C_F+C_G). This fact indicates that new ion species having a larger mobility per charge than any respective component are produced in this system. Considering the fact, already clarified by absorption spectra, that in such a system Blue (F) and Yellow (G) form the (FG and FG_2) complexes[6,7], the new ion species mentioned above may be regarded as such complexes.

In the two series of constant mixing ratios shown in Fig. 1, the differences between the corresponding conductances, $\kappa/\sum C$, of "obs" and "sum" are greater at the lower concentrations and decrease with an increase in the concentration. This tendency appears more remarkably in the case of $C_G/C_F=1.716$ than when the values is 0.1034. The correlations of "obs" and "sum" in the other series, which are not illustrated here, showed a similar tendency, but only in the case of the especially

large ratio of $C_G/C_F=4.811$ did the correlation at higher concentration go into the reverse tendency, i.e. $(\kappa_{obs}/\sum C)<(\kappa_{sum}/\sum C)$. In a series of constant ratios of mixing, the concentration ratio of the complexes formed to the respective residual components is considered to be nearly constant. Consequently, it may be said that the above fact indicates that the decreasing conductance rate of the complexes with its increasing concentration is greater than those of components. Moreover, this can easily be accepted because the ionic charges of complexs FG and FG_2 are 6 and 8 respectively.

Thus, in the series of constant mixing ratios, the correlation between $\kappa_{obs}/\sum C$ and $\kappa_{sum}/\sum C$ varied with the total concentration, even when the concentration ratio of the complex to the residual components is constant. However, the system in which the total equivalent concentration is kept constant will be give rise to the following advantage over the above system: the changes in the respective equivalent conductances of the complexes formed and in the residual dye components with the mixing ratio may be considered to be not very large*1. If the $\kappa_{obs}/\sum C$ curve agaist f reveals a marked bend point, with a system involving ion species of respective constant equivalent conductances, the fraction value for this point could be closely related to the composition of a complex formed (see Appendix). In the present case, it can be considered that each conductance value is constant in the neighborhood of the central part of f, so that a conclusion will be derived in the way just mentioned.

The $\kappa_{obs}/\sum C$ values for the total concentration of 2.25×10^{-4} eq./kg. in several mixture-compositions, obtained from Fig. 1 and from other, unshown ones, against the equivalent fraction of the component are expressed by white circles in Fig. 2. Here, black circles represent $\kappa_{sum}/\sum C$ values. The $\kappa_{obs}/\sum C$ and $\kappa_{sum}/\sum C$ values are connected by broad lines and broken ones respectively. This figure shows that $(\kappa_{obs}/\sum C)>(\kappa_{sum}/\sum C)$ in the whole region and that the differences between them are largest at about $f_G=0.5$. Inspecting in more detail, $\kappa_{obs}/\sum C$ at first increases rapidly, forms a shoulder, and then comes to a maximum value with an increase in f_G from 0.

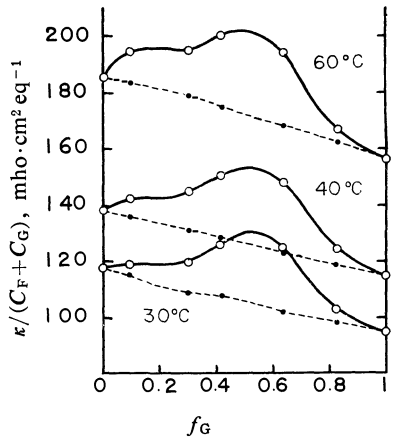

Fig. 2. Relation of conductance of the mixture of Blue and Yellow to equivalent fraction of its components.
The total equivalent concentration is kept at 2.25×10^{-4} eq./kg.
○: obs. ●: sum

This tendency appears more clearly at higher temperatures.

The same relation at six different concentrations of $(1\sim25)\times10^{-4}$ eq./kg. are shown in Fig. 3. Roughly speaking, the $\kappa_{obs}/\sum C$ curves at the several concentrations are similar

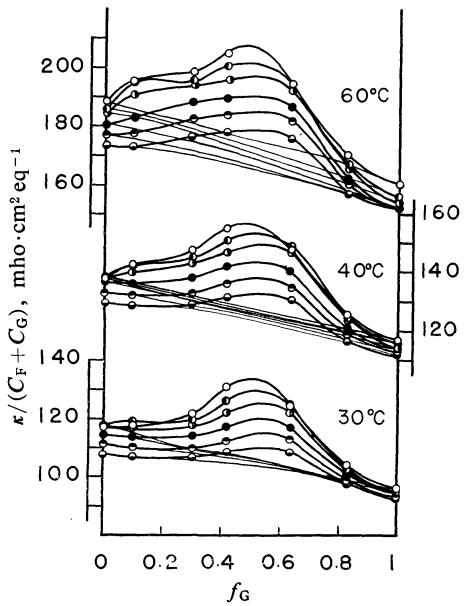

Fig. 3. Relation of conductance of the mixture of Blue and Yellow in six different total equivalent concentrations to equivalent fraction of its components.
The total equivalent concentrations are as follows; ($\times10^{-4}$ eq./kg.)
○: 1 ◐: 2.25 ◑: 4, ●: 9
◓: 16 ◒: 25 —: sum

*1 This concept is based on the fact that, in this series, the equivalent concentration of sodium ions and the sum of those of dye ions are constant. That the electrical effect on an ion due tothe other ions in a solution is constant, however, can be said of the systm in which the constant is not the total concentration but the ionic strength I', i.e., $\sum n_i z_i^2$ (n_i and z_i: the number and the charge of the i-th ion respectively). Since the value in this series changes because of the different charges of the two dye anions, the above assumption can not be exactly true. (See Ref. 9, p.117, Eq. 4-3-69).

to one another and show that $(\kappa_{obs}/\sum C) > (\kappa_{sum}/\sum C)$. However, the maximum points of the curves show a slight tendency to deviate from 0.5 to a large value in f_G with an increase in the total concentration. The shoulders of the curves observed at about $f_G=0.15$ in Fig. 2 disappear with an increase in the concentration.

On the other hand, as is well known, the aggregation of many dye anions is promoted by the presence of another electrolyte[8]. Thus, in this case each Blue or Yellow anion might be promoted in its aggregation by the effect of the partner dye. Consequently, the McBain effect caused by this effect must be taken into account. The promotion effect of the self-aggregation of the dye anion will be produced mainly by the co-existing electrolyte. Therefore, the magnitude of this effect is supposed to be estimated from that produced by the equivalent amount of sodium chloride. From this viewpoint, measurements of the binary system of Blue and sodium chloride were carried out in the first place. In Fig. 4 are shown the $\kappa/\sum C$ values, where $\sum C$ means (C_F+C_{NaCl}), versus the square roots of the total equivalent concentrations of two cases in these results. The solid and broken lines represent $\kappa_{obs}/\sum C$ and $\kappa_{sum}/\sum C$ respectively. This figure

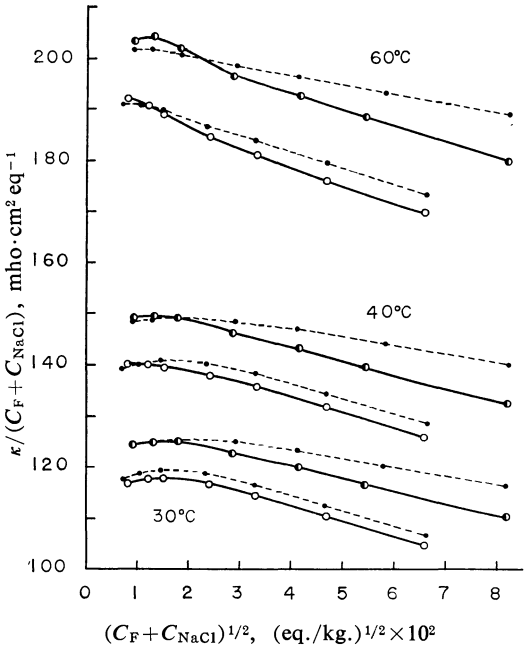

Fig. 4. Relation of conductance of the mixture of Blue and sodium chloride to square root of its total equivalent concentration.
In each series the concentration ratio of Blue and sodium chloride is constant.
◐: $C_{NaCl}/C_F=0.6970$
○: $C_{NaCl}/C_F=0.1015$ ●: sum

indicates that $(\kappa_{obs}/\sum C) < (\kappa_{sum}/\sum C)$ in the greater part, but that at a very low concentration a slight inverse relation appears. This would suggest that the aggregation of Blue anions is promoted more or less by the effect of sodium chloride. The $\kappa/\sum C$ values versus equivalent fractions for the binary mixture of Blue and sodium chloride, corresponding to the dye mixture in Fig. 3, are shown in Fig. 5. The

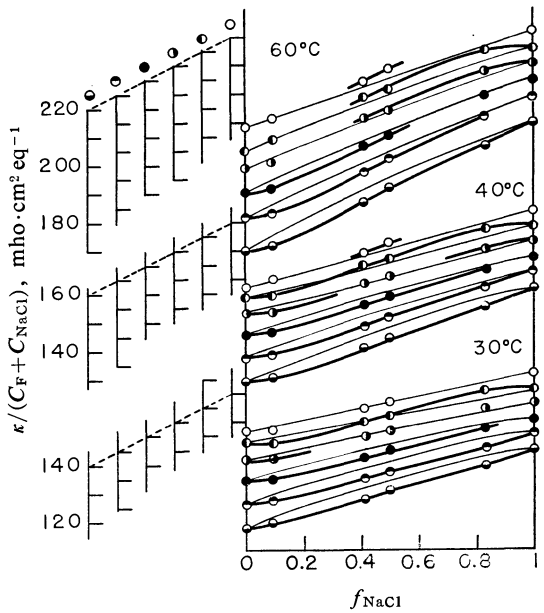

Fig. 5. Relation of conductance of the mixture of Blue and sodium chloride in six different equivalent concentrations to equivalent fraction of its components.
The total equivalent concentrations are as follows; ($\times10^{-4}$ eq./kg.)
○: 1 ◐: 2.25 ◑: 4 ●: 9
◓: 16 ◒: 25 —: sum

circles represent the observed values and are connected by broad lines. In order to avoid superposition of plots, the $\kappa/\sum C$ axes for respective concentrations are shifted from one another. This figure shows that the "obs" value is larger than the "sum" value when the total concentration is below 4×10^{-4} eq./kg. This tendency is clearer at a larger f_{NaCl} (or at a smaller f_F) value. On the other hand, when the total concentration is above 4×10^{-4} eq./kg., the "obs" value is smaller than the "sum" value over the whole region. A similar tendency appears for three different temperatures, though slightly clearer for higher temperatures. In short, the promotion of the self-aggregation of Blue anions in mixture with sodium chloride is certainly recognized by the increase of $\kappa_{obs}/\sum C$ in low concentrations, as has been shown above, but its increase is too

small to be compared with that in mixture with Yellow; further, the $\kappa_{obs}/\sum C$ curves in Fig. 5 do not show a tendency to have their maxima at $f=0.5$ as do these in Fig. 3.

Next, the results obtained in the same way with the binary mixture of sodium chloride and Yellow are shown in Fig. 6. From Fig. 6

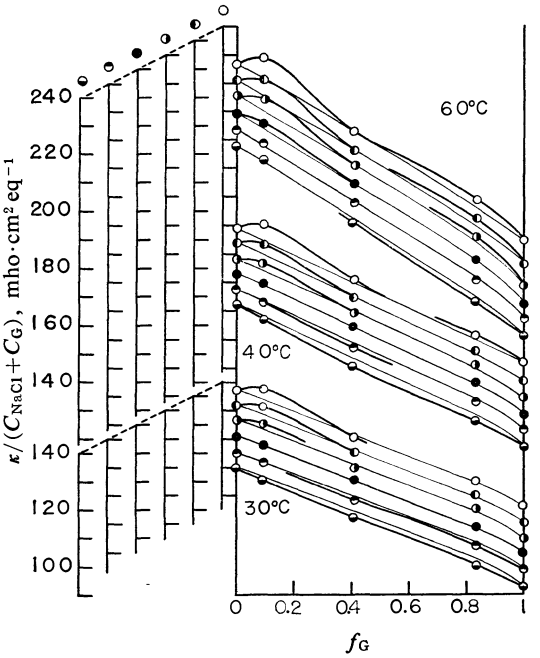

Fig. 6. Relation of conductance of the mixture of Yellow and sodium chloride in six different equivalent concentrations to equivalent fraction of its components.
The total equivalent concentrations are as follows; ($\times 10^{-4}$ eq./kg.)

○: 1 ◐: 2.25 ◑: 4 ●: 9
◓: 16 ◒: 25 —: sum

it is clear that, in the region where the total concentration is below 9×10^{-4} eq./kg., the relation $(\kappa_{obs}/\sum C)>(\kappa_{sum}/\sum C)$, where $\sum C$ indicates $(C_{NaCl}+C_G)$, appears for all equivalent fractions more clearly in the case of smaller f, and that in the region above this concentration the relation is reversed. As a whole, the results of this figure are similar to those of Blue and sodium chloride.

To sum up these results, we can certainly say that the conductance of Blue or Yellow is affected by sodium chloride, and also that the difference in "obs" and "sum" values in a mixture of the dye and sodium chloride is not so large as that in the combination of Blue and Yellow. Accordingly, it may probably be considered that the largest difference in "obs" and "sum" at about the same equivalent fraction of Blue and Yellow in Fig. 3 is due to the complex formation of FG_2. Thus, the formation of FG_2 is concluded from the above discussion, while the formation of another complex, namely FG, is found spectrophotometrically. According to the above argument, an abnormal feature responsible for FG is to appear at $f_G=1/3$, but Fig. 3 does not show any distinctive peak or shoulder at this part of the curve. Comparing the two parts into which a curve of Fig. 3 is divided at a maximum, the difference between $\kappa_{obs}/\sum C$ and $\kappa_{sum}/\sum C$ is greater in the region richer in F than in G. This seems to correspond to the formation of FG.

The shoulder of the $\kappa_{obs}/(C_F+C_G)$ curve at about $f_G=0.15$ in Fig. 3 may be explained by the fact that Yellow is accelerated in its aggregation by the presence of Blue, since the shoulder corresponds to the abnormal increase of $\kappa_{obs}/(C_{NaCl}+C_G)$ obtained with the same fraction of a mixture of sodium chloride and Yellow (Fig. 6).

In Figs. 2 and 3, it must be noticed that the relative increase in conductance due to the complex formation becomes larger with the temperature. If the complex formation is only considered in the system, this does not agree

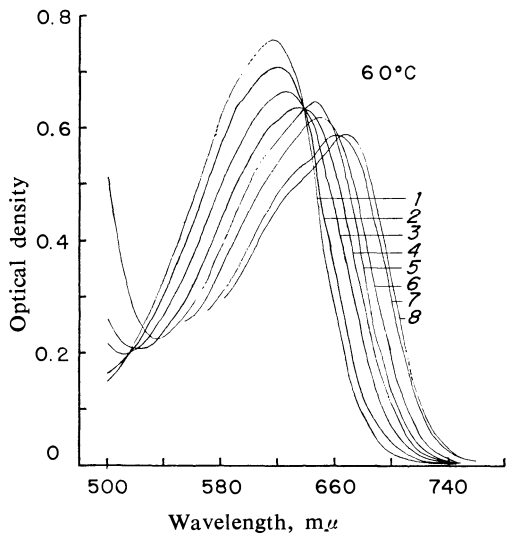

Fig. 7. The visible absorption spectra of Chrysophenine G-Sky Blue FF aqueous solution: temperature, 60°C; cell, 2 cm.

	Chrysophenine G mol./l.	Sky Blue FF mol./l.
1	0	4.000×10^{-6}
2	1.016×10^{-6}	4.000×10^{-6}
3	4.000×10^{-6}	4.000×10^{-6}
4	8.072×10^{-6}	4.000×10^{-6}
5	3.412×10^{-5}	4.000×10^{-6}
6	1.211×10^{-4}	4.000×10^{-6}
7	3.998×10^{-4}	4.000×10^{-6}
8	8.023×10^{-4}	4.000×10^{-6}

with the general rule that the amount of complex formed should decrease with the temperature. This will be understood by taking into account the self-aggregation which competes with the complex in decomposing by raising the temperature. In this case the self-aggregation should be considered to be more unstable than the complex. However, at the present stage, thermodynamic values of the self-aggregation which can be compared with those of the complex have not yet been obtained.

Some results, however, may support the above consideration. It has been reported that Blue and Yellow in an aqueous solution form a 1:1 and a 1:2 complex at room temperature[7]. According to further investigation[11], it may be concluded that even at 60°C the same complexes are formed, as is shown by the well-defined isosbestic points illustrated in Fig. 7. The estimated enthalpy changes show in this case -24 kcal./mol. for $F + G \rightarrow FG$ and -20 kcal./mol. for $FG + G \rightarrow FG_2$. These values are larger than the adsoption energies obtained for the respective components of the cellulose.

Next, the conductance curve of Blue in the single aqueous solution is shown in Fig. 8. It indicates that the McBain effect, which is due to the aggregation considered, comes to disappear with an increase in the temperature; the curve becomes nearly a straight line at 60°C, and then at 80°C it is bent conversely*2. In this case it must be said that at 80°C, the highest temperature observed, the dye anion is closest to the single and that at 30°C the aggregation number is largest.

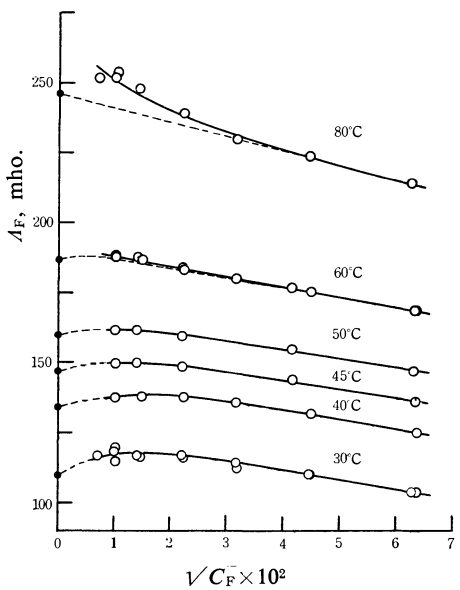

Fig. 8. Conductance of Chlorazol Sky Blue FF in aqueous solution. C_F stands for the equivalent concentration.

Assuming that the straight line of the higher concentration region at 80°C is due to the single dye ion species, the line is extraporated to obtain Λ_0. The Walden product, $\Lambda_0\eta_0$ (η_0: viscosity coefficient of water), is evaluated; then the correspoding Λ_0's at the respective temperatures are estimated by the Walden rule. The results are indicated in black circles in Fig. 8. When the black circles are connected with the corresponding observed curves, the broken lines shown in Fig. 8 are obtained. These curves evidently reveal the change in aggregation against the temperature. It may be supposed from the above discussion that Blue is nearly a single-dye ion species, though not quite a single one.

From the above interpretation, it is proper to consider that the compactness of the complexes in the system under consideration is stronger than that of the self-aggregates and that, for this reason, the higher the temperature, the larger the difference between the $\kappa_{obs}/(C_F+C_G)$ value and the corresponding $\kappa_{sum}/(C_F+C_G)$ value.

Summary

The conductances of aqueous solutions of Chlorazol Sky Blue FF (Blue), Chrysophenine G (Yellow), sodium chloride and their binary mixtures at various constant ratios have been measured. The conductance observed with a mixture of Blue and Yellow increased abnormally compared with that obtained by the sum of individual dye conductances; the difference between the observed and the sum values reached a maximum at about the same fraction of the equivalent concentration of component dyes. A similar relation of the conductance against the fraction of the equivalent concentration of components, obtained with mixtures in which component dye was substituted by sodium chloride, did not always show a coincidence between the observed value and the sum one. The difference, however, was much smaller than that obtained with dye mixtures. Thus, the abnormal increase described above may be attributed to the formation of complexes of Blue and Yellow;

11) T. Hoshi, Y. Tanizaki and N. Ando, to be published.

*2 The increase of conductance at the very low concentration is interpreted as due to the dissociation of the OH group. (cf. C. Robinson and H. E. Garrett, *Trans. Faraday Soc.*, **35**, 771 (1939).) Because, comparing the Walden products for the low concentration region at 80 and 60°C, that of the former is considerably larger than that of the latter, indicating the iecrease of charge per species.

a 1 : 1 complex and a 1 : 2 complex, consisting of Blue and Yellow already known, were sufficiently reflected in the conductance curve, especially in a 1 : 2 complex.

Appendix

A general theory of the relationship between the composition of the complex and that of the solution has been set forth by Eaton[12]. This theory will be applied to conductance as follows. Here we assume that the conductance of an electrolyte is linear to its concentration, C, with a gradient $\Lambda/1000$. For a binary mixture of A and B, whose total equivalent concentration is fixed, the Λ curve against the equivalent fraction f_A (or f_B) becomes a line connecting Λ_A and Λ_B, provided that no interaction exists between A and B, as follows:

$$\Lambda \equiv 1000\kappa_{sum}/(C_A+C_B) = \{f_A\Lambda_A + (1-f_A)\Lambda_B\}$$

When p mol. of A react with q mol. of B to form r mol. of complex AB: $pA+qB=rAB$, then

$$1000\kappa_{obs}/(C_A+C_B) = \{f_A\Lambda_A + (1-f_A)\Lambda_B\} + \{\Lambda_C - ap\Lambda_A/(ap+bq) - bq\Lambda_B/(ap+bq)\}f_C$$

where f_C is the equivalent fraction of the complex formed and a and b the charges of A and B respectively. Therefore, $\kappa_{obs}/(C_A+C_B)$ is linear to f_C. f_C reaches its maximum at $f_A=ap/(ap+pq)$ in the case of $a=b$. Accordingly, we can calculate p/q from the f_A value of $\kappa_{obs}/(C_A+C_B)$ at its maximum. However, when $a \neq b$, $f_{A(f_C=max)}$ is dependent on the equilibrium constant, K, and $f_{A(f_C=max)}=ap/(ap+bq)$ only when $K=\infty$. Though in the present case of the combination of Blue and Yellow, the charges are 4 and 2 respectively, namely $a \neq b$, it may safely be said that the above relation is applicable to this combination, as, for instance, the equilibrium constant of $F+2G=FG_2$ is 3×10^{10}.

The Photochemical Decomposition of α, α-Diphenyl-β-picrylhydrazyl (DPPH) in Solution. I. A Kinetic Study of the Reaction

By Atuo SUZUKI*, Makoto TAKAHASI and Kengo SHIOMI

(Received December 24, 1962)

α, α - Diphenyl - β - picrylhydrazyl (DPPH), which was first prepared by Goldschmidt and Renn[1], has been well known to be a stable radical both in the crystalline state and in solution, and it has been submitted to many studies of electron spin resonance. The chemical behavior of this compound, which was studied first by Goldschmidt and Renn, has recently been of interest because the compound serves as a scavenger of the reactive free radicals. Since there is a noticeable color change from violet to light yellow upon the reaction with other free radicals, the rate of the free radical formation can be followed colorimetrically. On the basis of this principle, Bawn and Mellish[2] measured the rate of the thermal decomposition of benzoyl peroxide and 2, 2-azobisisobutyronitrile in several solvents. In these measurements there was a tacit assumption that DPPH reacts quantitatively with a radical to produce stable products.

However, Hammond[3] and most recently Verdin[4] have observed that the reaction of DPPH with the radicals produced in the thermal decomposition of azobisisobutyronitrile is non-stoichiometric and is sensitive to oxygen.

Although as yet the stability of DPPH itself has scarcely come into quesion, some doubt about its stability has been aroused in the present authors, because they have observed that the solution of DPPH fades gradually on standing in diffused light at room temperature, indicating the photochemical decomposition of DPPH.

In order to investigate the mechanism of this phenomenon, an experiment has been undertaken by the present authors. The experiment is divided into two parts, the first being a kinetic investigation of the reaction, and the second consisting of the identification of the products, the determination of the ratio of the amount of the products, and the structure investigation of an unknown reaction product..

The first part of the experiment will be described in the present paper, while the second will be treated in a succeeding paper.

Results

Influence of the Wavelength of the Irradiating Light.—As is shown in Fig. 1, DPPH has two absorption maxima, at 520 and 330 mμ. The rates of reaction obtained with different filters are shown in Fig. 2.

Characteristic curves of transmission of the filters used are shown in Fig. 3. As the intensities of the light in the three runs with different filters are not the same, the absolute rates of decomposition cannot be compared with one another; however, since it is observed that the reaction proceeds fairly fast when a Corning (Cd)-filter, which completely cuts the light below 460 mμ, is used, it may be concluded that the decomposition of DPPH can proceed in the light at the first absorption band of DPPH ($\lambda_{max}=520$ mμ, $\varepsilon=1.23\times10^4$ $mol^{-1}cm^{-1}l.$). The rest of the kinetic experiments were carried out using a Corning (Cd)-filter.

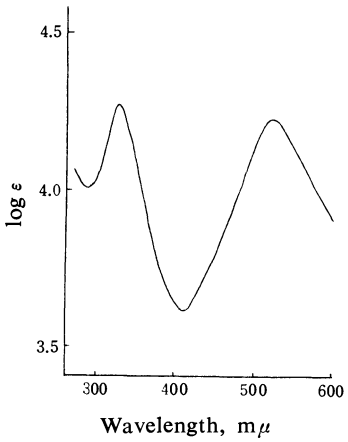

Fig. 1. Absorption spectra of DPPH in carbon tetrachloride.

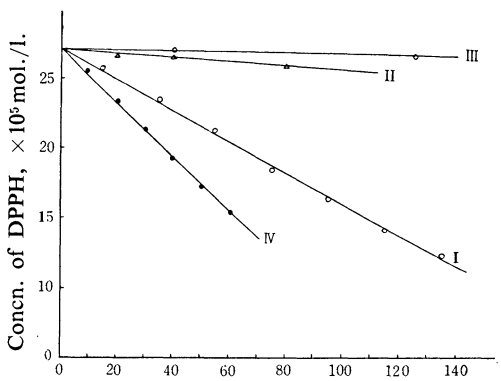

Fig. 2. Rate of decomposition of DPPH at 10°C in carbon tetrachloride with various kinds of filters.
I: Corning (Cd), II: Madzuda VB2, III: Madzuda VG1, IV: without filter. Concentration of DPPH was calculated from the optical density at 520 mμ using $\varepsilon=1.23\times10^4$ l./mol., and assuming $\varepsilon=0$ for the decomposition products.

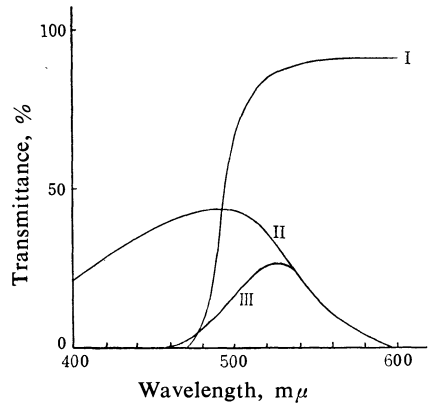

Fig. 3. Characteristic absorption curves of filters.
I: Corning (Cd), II: Madzuda VB2, III: Madzuda VG1.

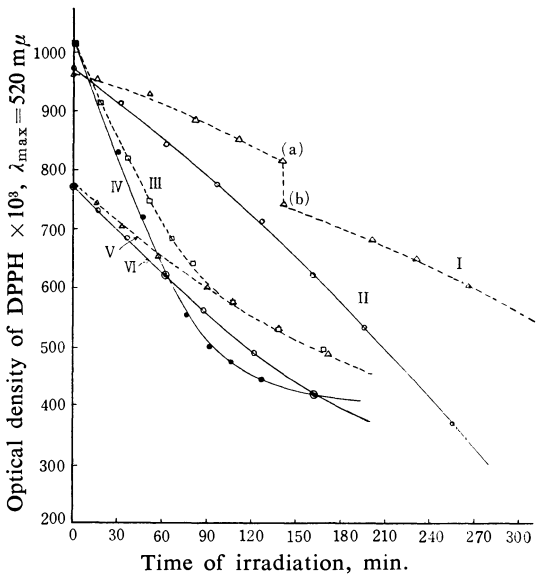

Fig. 4. Rate of decomposition of DPPH at 25°C in various solvents in the absence or in the presence of air.
I: in the absence of air in *n*-heptane, II: in the presence of air in *n*-heptane, (a)—(b) without irradiation for 12 hr. in the dark, showing after effect, III: in the absence of air in benzene, IV: in the presence of air in benzene, V: in the absence of air in carbon tetrachloride, VI: in the presence of air in carbon tetrachloride.

Influence of the Solvent and of Oxygen on the Reaction Rate. — The kinetic features of the decomposition in carbon tetrachloride and in benzene are almost identical, but in *n*-heptane it is different, as is shown in Fig. 4. A remarkable after-effect was observed in *n*-heptane, indicating the interaction of DPPH with the solvent. No further experiment in *n*-heptane was, however, undertaken in the present work. Oxygen slightly accelerates the decomposition, both in carbon tetrachloride and in benzene, but it does not seem to change the main features of the kinetics or of the reaction products, and the nature of its effect is not clear at present.

The Reaction Products. — The recation products were separated and identified by the paper chromatographic method. α, α-Diphenyl-β-picrylhydrazine, α-phenyl-α-(*p*-nitrophenyl)-β-picrylhydrazine and the third, unknown compound were separated on a paper chromatograph.

The details of the separation of these compounds, the determination of their molar ratio after different periods of reaction time, and the discussion of the structure of the third component will be given in the succeeding paper.

Influence of Light Intensity on the Decomposition Rate. — The experiment was carried out using the carbon tetrachloride solution of DPPH, changing the light intensity with copper nets. The plots of the optical densities of DPPH against the time of irradiation at various intensities of irradiating light are shown in Fig. 5.

The decompsition rate for each run was calculated from the slope of the initial part of the decomposition.

The experiments described here were carried out at a lower concentration (3.5×10^{-5} mol./l.) for convenience in determining the concentration of DPPH in the course of the reaction by photometry in vacuo without dilution*. In such a low concentration of DPPH, the amount of light absorbed could not be approximated as I_0, but it is expressed as $I_0(1-10^{-\varepsilon x l})$. However, since the initial concentrations of DPPH in these four runs are identical, the initial rate of the disappearance of DPPH is plotted against the relative intensities of the incident light instead of against the amount of light absorbed in Fig. 6, but this method is considered an approximation sufficient for obtaining a linear relationship between the rate and the amount of light.

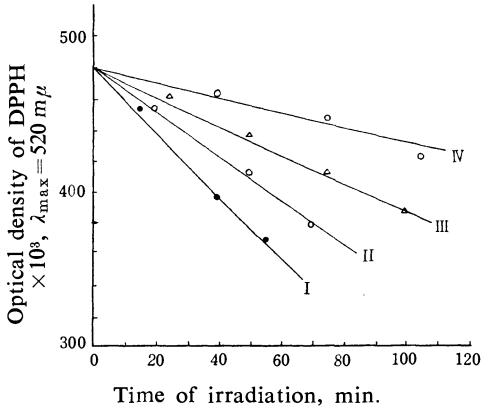

Fig. 5. Plot of the optical density of DPPH solution in carbon tetrachloride against time under the irradiations of various light intensities ranging 100 to 27% at 10°C.
I: 100%, II: 70%, III: 47%, IV: 27%. The initial concentration of DPPH is 3.10×10^{-5} mol./l.

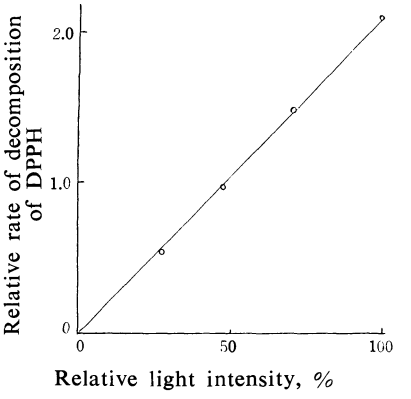

Fig. 6. Relationship between the relative intensity of the irradiating light and the relative rate of the decomposition of DPPH at 10°C.

The extrapolation of the correlation line passes through the origin; this is consistent with the fact that DPPH does not decompose in the dark.

Kinetic Expression of the Experimental Results.—As is shown in Fig. 7, a plot of the concentration against the time hardly shows any departure from linearity in the early stage of the reaction in any run of the experiments in a carbon tetrachloride solution, and the slope might be used as a measure of the observed zero-order rate constant.

This apparent zero-order rate constans was, however, found to be dependent upon the initial concentration of DPPH, and further

* The experiments of photolysis, except for the four runs shown in Fig. 5, were carried out at relatively high concentrations of DPPH (more than 10^{-4} mol./l. in order to keep the absorption of light close to one hundred per cent throughut course of the reaction except in the very late stage.

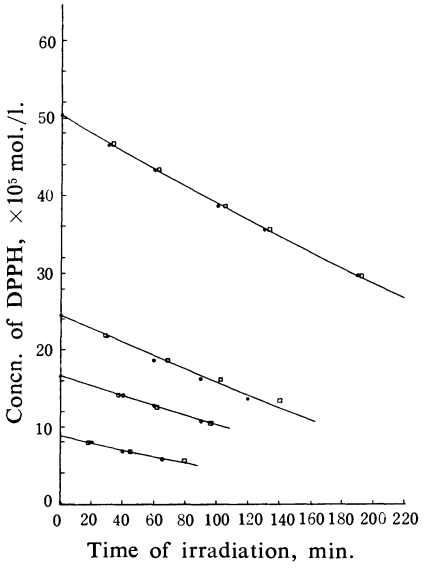

Fig. 7. Rate of decomposition of DPPH at various initial concentrations in carbon tetrachloride at 25°C. Marks of square □ show the calculated values from Eq. 3.

careful inspection of the plots of the concentration of DPPH against the time revealed their slight deviation from linearity, showing that more complicated processes are involved. The initial rate increases with the initial concentration of DPPH up to a limiting value at a higher concentration of 5.0×10^{-4} mol./l. of DPPH.

In order to obtain the appropriate kinetic expression for these experimental results, a plot of $1/(dx/dt)$ against $1/x$ is given in Fig. 8, which shows a fairly good linear relationship. Taking this result into consideration, the following empirical rate equation is introduced;

$$-dx/dt = KI_a x/(x+\alpha) \qquad (1)$$

or

$$-1/(dx/dt) = 1/KI_a + (\alpha/KI_a)/x \qquad (1')$$

where K and α are constants. I_a, the average rate of light absorption is kept constant through

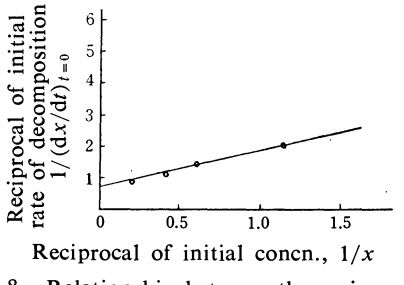

Fig. 8. Relationship between the reciprocal of initial concentration ($1/x$) and that of the initial rate of decomposition ($1/(dx/dt)_{t=0}$) obtained from Fig. 7.

the each series of experiments, though there is some variation between the different series of experiments. The determination of the amount of light absorbed has not been carried out, so that the quantum yield of this experiment is not known at present. As is shown in Fig. 7, the initial concentration of DPPH ranged from 10^{-4} to 5×10^{-4} mol./l., insuring a nearly complete absorption of light. In Table I, the values of α/KI_a and $1/KI_a$ as slope and as its intercept in the ordinate axis, calculated by the least square method from each run of I, II, III, IV in Fig. 7, are given. In addition the values of the slope and the intercept obtained by plotting $1/(dx/dt)_{t=0}$ against $1/x$ in the four runs in Fig. 7 are given in the last column.

TABLE I

	I	II	III	IV	
$\alpha/KI_a\times10^{-2}$	1.63	0.19	0.69	0.61	1.41
$1/KI_a\times10^{-5}$	4.88	10.21	10.10	14.05	5.65

The values of α and KI_a calculated from the figures in the last column are 1.8×10^{-4} mol./l. and 2.5×10^{-6} mol./l. min. respectively*.

As may be seen, the variations in the values of the slope and of the intercept in four runs seem to be fairly large, but the following procedure of the recalculation of x at the various intervals of the reaction time, using the values in the last column, shows that these values are actually within the range of experimental error.

Integrating Eq. 1, Eq. 2 is obtained,

$$(x_0-x)+2.303\ \alpha\log(x_0/x) = KI_a t \qquad (2)$$

where x_0 is the initial concentration of DPPH. Using $\alpha=1.8\times10^{-4}$ mol./l. and $KI_a=2.5\times10^{-6}$ mol./l. min., a relation between x and t was obtained. The calculated values of x from Eq. 2 at various time intervals are plotted in Fig. 7, with a square mark showing that the agreement between observed and calculated values is satisfactory.

The Influence of Temperature on the Decomposition Rate.—The rate of the decomposition of DPPH in carbon tetrachloride was measured at 10, 30 and 50°C. The results are shown in Fig. 9.

The increase in the reaction rate with the temperature indicates that some temperature-dependent processes are involved in the reaction. The plots of $1/(dx/dt)$ against $1/x$ for the curves in Fig. 9 are shown in Fig. 10; KI_a and α in Eq. 1′ at 10, 30 and 50°C were determined from each line. From the values of the

* The probable ranges of KI_a and α with 95% reliability are $3.7\times10^{-6}>KI_a>1.2\times10^{-6}$ and $6.8\times10^{-4}>\alpha>1.2\times10^{-4}$ respectively.

usual Arrhenius plot, the activation energy and frequency factor were evaluated. The results are listed in Table II.

TABLE II. KI_a AND α AT 10, 30 AND 50°C, AND THE CALCULATED ACTIVATION ENERGY (E) AND FREQUENCY FACTORS (A)

	10°C	30°C	50°C	ΔE	A
KI_a	1.27 $\times 10^{-6}$ a)	2.00 $\times 10^{-6}$	2.93 $\times 10^{-6}$	3.8 $\times 10^{3}$ c)	1.2 $\times 10^{-3}$
α	0.34 $\times 10^{-4}$ b)	0.58 $\times 10^{-4}$	0.84 $\times 10^{-4}$	4.1 $\times 10^{3}$	5.2 $\times 10^{-2}$

a) mol./l. min.
b) mol./l.
c) cal.

In addition to these experiments, the induction period and the after effect were investigated, but neither of them was noticeable in the carbon tetrachloride solution, as is shown in Fig. 9.

Discussion of the Reaction Mechanism

The kinetic data obtained above are not enough to establish a unique and overall reaction mechanism, but some possible mechanisms will be discussed. As in most photochemical reactions, the process of this reaction may consist of excitation, quenching (deactivation), and chemical reaction. No fluorescence of DPPH in solution is observed. The deactivation of excited DPPH may proceed by solvent or by another DPPH. As the primary process of chemical reaction, the three different mechanisms, (I) the spontaneous decomposition of excited DPPH, (II) the bimolecular decomposition of the excited DPPH with normal DPPH, and (II') the complex formation of excited DPPH with other molecules of DPPH and the successive decomposition of the complex, are considered, and the expression of the rate of disappearance of DPPH in terms of the concentration of DPPH is derived from each mechanism. The succeeding process of the reaction seems to be complicated, but it may be reasonably assumed that it does not modify the main character of the kinetic expression of the rate of disappearance of DPPH, because the relative ratio of the products is almost constant throughout the course of the reaction, as the succeeding paper will show.

Mechanism I

$$\begin{aligned} &D+h\nu &&\longrightarrow D^* && I_a \\ &D^*(+\text{Solvent}) &&\longrightarrow D && k_1 \text{ (I-1)} \\ &D^*+D &&\longrightarrow 2D && k_2 \text{ (I-2)} \\ &D^* &&\longrightarrow A+B && k_3 \text{ (I-3)} \end{aligned}$$

$$-dx/dt = I_a k_3/(k_1+k_3+xk_2) \qquad (3)$$

Mechanism II

$$\begin{aligned} &D+h\nu &&\longrightarrow D^* && I_a \\ &D^*(+\text{Solvent}) &&\longrightarrow D && k_1 \text{ (II-1)} \\ &D^*+D &&\longrightarrow 2D && k_3 \text{ (II-3)} \\ &D^*+D &&\longrightarrow A+B && k_4 \text{ (II-4)} \end{aligned}$$

$$-dx/dt = 2I_a k_4 x/\{k_1+(k_3+k_4)x\} \qquad (4)$$

Mechanism II'

$$\begin{aligned} &D+h\nu &&\longrightarrow D^* && I_a \\ &D^*(+\text{Solvent}) &&\longrightarrow D && k_{1'} \text{ (II'-1)} \\ &D^*+D &&\longrightarrow D^*D && k_{2'} \text{ (II'-2)} \\ &D^*D(+\text{Solvent}) &&\longrightarrow 2D && k_{3'} \text{ (II'-3)} \\ &D^*D &&\longrightarrow A+B && k_{4'} \text{ (II'-4)} \end{aligned}$$

$$-dx/dt = 2I_a\{xk_{2'}/(xk_{2'}+k_{1'})\}\{k_{4'}/(k_{3'}+k_{4'})\} \qquad (5)$$

where D is a molecule of DPPH, D* is an excited DPPH. The structures of A and B are not known, but it may be reasonably assumed that they are free radicals or reactive molecules, such as NO_2. Mechanism 1, which assumes the

spontaneous decomposition of excited DPPH, does not agree with the experimental results, because the rate expression derived from this mechanism requires a decrease in the rate with a decrease in the concentration of DPPH. The second and third mechanisms have similar kinetic characteristics of rate expression; that is, the rate increases with the concentration. Both satisfy the requirement of kinetic expression (1)*, making it impossible to choose a mechanism on the basis of the present experimental results only. These two mechanisms differ in the point that the complex has some definable lifetime in the latter. The authors are slightly in favor of the latter mechanism, considering similar experimental evidence. Förster and Kasper[5] presumed a complex formation of excited pyrene with normal pyrene from their observation of fluorescence. It is likely that excited DPPH forms a complex with normal DPPH, for many aromatic polynitro compounds tend to form a complex, even at the ground state. If the flash photolysis technique could be applied to the present case, it would be possible to determine whether or not a dimer complex of DPPH is present. According to the proposed reaction mechanisms II and II', the experimental constants, KI_a, in Eq. 1 are related to the rate constants of Eqs. 4 and 5.

According to mechanism II,

$$K=2k_4/(k_3+k_4)$$

and

$$\alpha=k_1/(k_3+k_4)$$

Considering the fact that K increases with the temperature, we might assume that $k_3 \gg k_4$, since otherwise K would actually be independent of the reaction temperature. Assuming $k_3 \gg k_4$, the relation

$$K \fallingdotseq 2k_4/k_3$$

would be derived; this also gives an interpretation of the experimental activation energy:

$$E_4-E_3 \fallingdotseq E_K=3.8 \text{ kcal./mol.}$$

and

$$2I_aA_4/A_3 \fallingdotseq A_{KI_a}=1.2\times10^{-3}$$

It is reasonable that reaction 4 has a larger activation energy than reaction II-3, because the latter is a simple deactivation process.

A similar treatment may be applied to the temperature dependence of α. Assuming $k_3 \gg k_4$, we might also derive the relation

$$\alpha \fallingdotseq k_1/k_3$$

$$E_1-E_3 \fallingdotseq E_\alpha=4.1 \text{ kcal./mol.}$$

and

$$A_1/A_3=A_\alpha=5.2\times10^{-2} \text{ l./mol.}*$$

The finding that reaction II-1 has an appreciable amount of activation energy is not well understood, since the reaction is a simple deactivation process of an excited DPPH with a solvent.

Since the value of I_a is not known, no further discussion of the frequency term will be attempted at this stage.

In mechanism II', a similar argument may be applied, giving the relations:

$$E_K=E_{4'}-E_{3'}, \quad A_{KI_a}=2I_aA_{4'}/A_{3'}$$

and

$$E_\alpha=E_{1'}-E_{2'}, \quad A_\alpha=A_{1'}/A_{2'}$$

Experimental

Material.—DPPH was prepared by the method of Porier[6], recrystallized from a chloroform-ether mixture (1 : 1 by volume), and dried in vacuo at 80°C for more than 10 hr.[7] The solvents used were purified by ordinary methods[8].

Procedure.—A solution of DPPH was irradiated in a thermostat with a light of a constant intensity, and after various periods of time the concentration of DPPH was determined with a spectrophotometer at its maximum absorption ($\lambda_{max}=520 \text{ m}\mu$). The light source was a tungsten lamp (100 V. 150 W), and variations of the source voltage were compensated for by a manual setting of a transformer. The range of wavelengths of the irradiating light was varied by choosing a proper filter.

The light intensity was varied with copper nets of several different meshes, blackened with ammonium sulfide.

In order to study the effect of oxygen on the photolysis of DPPH, the experiments were carried out both in the presence of air and in the absence of air. The solution in the latter experiment was prepared by the following procedure, using the apparatus shown in Fig. 11.

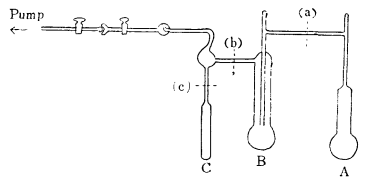

Fig. 11. Shematic diagram of the apparatus of preparing the sample in vacuo.
C: Reaction cell

* For convenince in comparing reaction mechanisms II and II', the rate constants are numbered k_1, k_3 and k_4 in the reaction II instead of k_1, k_2 and k_3. The following relation is easily derived by a comparison of the two mechanisms: $k_3=k_2'k_3'/(k_3'+k_4')$ and $k_4=k_2'k_4'/(k_3'+k_4')$.

5) T. Förster and K. Kasper, *Z. Elektrochem.*, **59**, 976 (1955).

* It is to be noted that k_1 is a pseudo-first-order rate constant and that the second-order rate constant, k_1*, is obtained by dividing k_1 by the number of moles of solvent (10.2 mol.) in one liter, giving the relation $A_\alpha/10.2=A_1*/A_3=5.1\times10^{-3}$.

6) R. H. Porier, E. J. Kahler and F. Benington, *J. Org. Chem.*, **17**, 1437 (1952).

7) J. A. Lyons and W. F. Watson, *J. Polymer Sci.*, **18**, 141 (1955).

8) A. Weisberger and E. S. Proskauer, "Technique of Organic Chemistry", Vol. VII, Interscience Publishers, Inc., New York (1955).

DPPH was placed in B, and a purified solvent was distilled into B from A after degassing. Then A was sealed at (a), a part of the solution in B was poured into C, and B was sealed at (b). The rest of the solution in B was used for the comparative experiments in the presence of air. The solution in C was degassed on a high vacuum line with several repetitions of freezing in liquid nitrogen (−196°C) and melting to remove the residual gas. A reaction cell C was then sealed at (c), and the concentration of the solution was determined photometrically, without contact of the solution with air.

Summary

Studies of the photochemical decomposition of DPPH in solution have been made by the kinetic method.

1) The decomposition proceeds by means of the light in the region of the first absorption band of DPPH ($\lambda_{max}=520\,m\mu$), and the decomposition rate has a linear dependence on the amount of light absorbed.

2) A rate expression fitting the kinetic experiment has been obtained, and this expression has been compared with the rate expession derived on the basis of the possible reaction mechanism, which includes the process of the reaction of an excited DPPH with another, normal DPPH.

3) An increase in the rate with the reaction temperature has been observed in the temperature range 10～50°C, and the two constants determined in the experiment have been related to the rate constants of the elementary processes in the proposed reaction mechanism.

The authors wish to express their thanks to Dr. Hiroshi Suzuki of The University of Tokyo for reading the manuscript and for his invaluable advice. Thanks are also due to Mrs. Robert Back of the National Research Council, Canada, for reading the manuscript.

*Syntheses and Structures of Acetylformoin and its Related Compounds. II. Neopentoylformoin**

By Yō MIYAGI and Ryozo GOTO

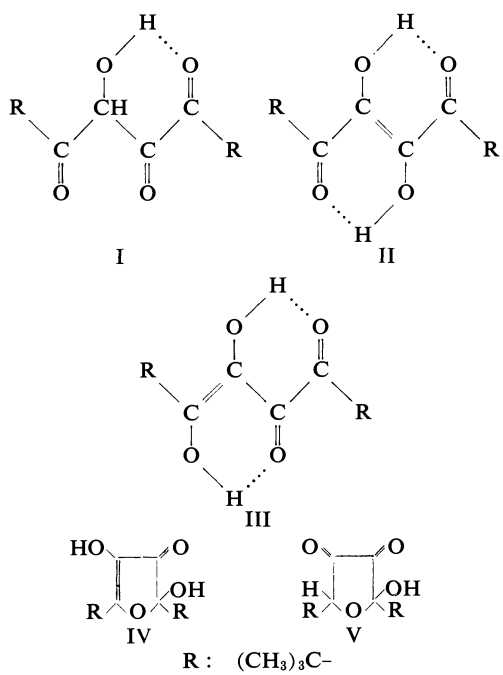
(Received December 27, 1962)

It is well known that the condensation of ketoaldehydes in the presence of alkali cyanide yields formoins:

$$2\ \mathrm{RCOCHO} \xrightarrow{CN^-} \mathrm{RCOCH(OH)COCOR}$$

Condensation products of phenyl-[1], *p*-methoxyphenyl-[2], *p*-chlorophenyl-[3], *p*-bromophenyl-[3], mesitoyl-[4] and methylglyoxal[5,6] have been reported. Benzoylformoin was synthesized by Abenius[7] in a totally different way.

For these formoins, the following five structures are possible. Structure IV was suggested for benzoylformoin on the basis of the fact



* Presented in part at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

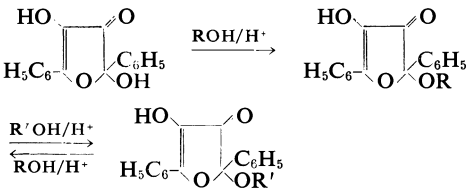
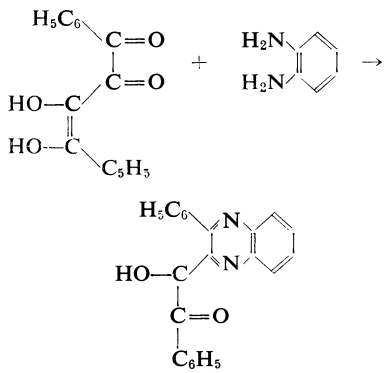
that it undergoes alcoholysis with an alcoholic solution of an acid to give an alkoxy compound[8]. This fact, however, can not afford a straight foreward deduction of structure IV

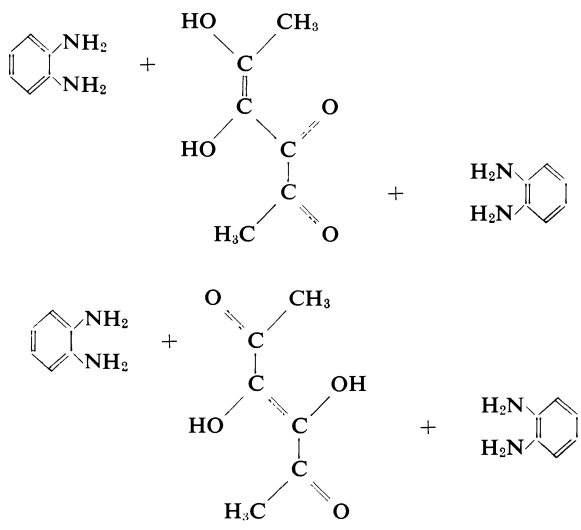


for benzoylformoin itself. The formation of a quinoxaline derivative suggested structure III.



On these bases, an equilibrium between III and IV in solution was proposed[8].

Steinbauer and Waldman[6] also studied the reaction of acetylformoin with *o*-phenyleneamine:



In a previous paper[1], the authors reported that the crystal of acetylformoin has the enediol structure II (R=CH_3) while that of benzoylformoin does the furanone structure IV (R=C_6H_5). In the present paper, the structure of neopentoylformoin and its properties are being reported.

Results and Discussion

Neopentoylformoin is prepared by the action of an alkali cyanide on an aqueous alcoholic solution of *t*-butylglyoxal. The chemical behaviors of neopentoylformoin are rather like those of benzoylformoin[8]. Neopentoylformoin suffers methanolysis with methanolic hydrogen chloride to give a mono-*O*-methyl derivative and ethanolysis with ethanolic hydrogen chloride to give a mono-*O*-ethyl derivative. Furthermore, the mono-*O*-methyl derivative is converted to the *O*-ethyl derivative and vice

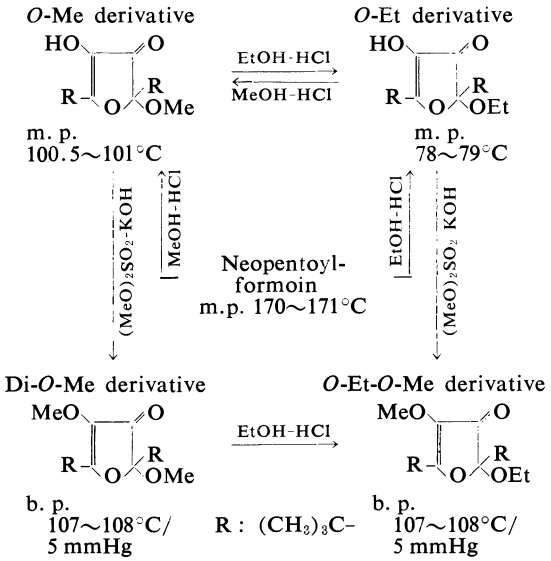


Fig. 1

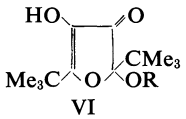
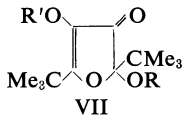
8) A. H. Blatt, *J. Am. Chem. Soc.*, **57**, 1103 (1935); **58**, 1894 (1936).

versa. Another methoxy group was introduced into the *O*-alkyl derivatives by the methylation with dimethyl sulfate or methyl iodide. It was also tried to convert the di-*O*-methyl derivative to an *O*-ethyl-*O*-methyl derivative, ethanolic hydrogen chloride being used as reagent. Though the boiling point of the product is the same as that of the starting di-*O*-methyl derivative, the completion of the conversion was proved by the fact that the alkoxyl group content and elementary analysis coincided quite well with the values calculated for the *O*-ethyl-*O*-methyl derivative.

This sequence of reactions may be illustrated as in Fig. 1, since the etherification with an alcoholic solution of an acid is characteristic of the glycosidic linkage. Therefore, the structure of the mono-*O*-alkyl derivatives and that of the di-*O*-alkyl derivatives are established as VI, 2, 5-di-*t*-butyl-2-alkoxy-4-oxy-furanone-3 and VII, 2, 5-di-*t*-butyl-2, 4-dialkoxy-furanone-3, respectively.



VI



VII

The above sequence of reactions, however, can not suggest structure IV for neopentoylformoin itself, because the equilibrium could be shifted to produce VI in the presence of acids:

$$\text{III} \rightleftharpoons \text{IV} \xrightarrow{H^+} \text{VI}$$

The structure of neopentoylformoin must be determined by another method.

The data of infrared spectra are listed in Table I.

Table I. Absorption bands of infrared spectra (cm^{-1})

Neopentoyl-formoin	Mono-*O*-Me deriv.		Di-*O*-Me deriv.	Benzoyl-formoin
Nujol	Nujol	CCl_4 soln.	CCl_4 soln.	Nujol
3330	3310	3290	—	3500
3180	—	—	—	3210
1690	1690	1693	1705	1688
1600	1600	1610	1615	1605
				1595

Neopentoylformoin and the mono-*O*-methyl derivative were examined as a solid state in Nujol*, then the latter and the di-*O*-methyl derivative as the solution in carbon tetrachloride.

In the regions of the C=O and C=C stretching absorption, there are found very little changes between the spectrum of neopentoylformoin and those of derivatives: neopentoylformoin and the mono-*O*-methyl derivative absorb at 1690 and 1600 cm^{-1}; the latter compound shows similar spectra both in Nujol and in solution; in the di-*O*-methyl derivative, the corresponding absorption bands arise at 1705 and 1615 cm^{-1}.

Since the spectrum of neopentoylformoin is very similar to those of its derivatives**, structure IV, 2, 5-di-*t*-butyl-2, 4-dioxy-furanone-3, may be assigned to neopentoylformoin. This assignment is further supported by the fact that the spectrum of neopentoylformoin is very similar to that of benzoylformoin, the structure of which was established as IV ($R=C_6H_5$)[1].

The absorption band at 1690 cm^{-1} and that at 1600 cm^{-1} may be assigned to the C=O and C=C stretching absorption, respectively. Other structures I, II, III and V seem to be unreasonable on the basis of similar reasons as seen in a previous paper[1].

In the region of the OH stretching absorption, neopentoylformoin shows two distinct bands at 3330 and 3180 cm^{-1} in Nujol. The mono-*O*-methyl derivative shows a distinct band at 3310 cm^{-1} in Nujol and broad one at 3290 cm^{-1} in solution. With *O*-alkylation there occurs a similar change of the spectra of neopentoylformoin and benzoylformoin in Nujol: both formoins show two OH stretching absorption bands while their mono-*O*-alkyl derivatives do only one of the OH stretching absorption. However, nothing conclusive can be deduced from these data of the OH stretching absorption bands, since the OH stretching absorption bands are easily shifted by the strength of hydrogen bondings.

On melting the color of neopentoylformoin turned to red. It is very interesting benzoylformoin changes its color from yellow to red on melting. Blatt considered, without striking evidence, that the reddish distillate of benzoylformoin was enediol II. The authors are also of opinion that the structure of melted neopentoylformoin is an enediol, II or III. However no evidece has been found.

Experimental

Synthesis of Neopentoylformoin.—In 100 ml. of 70% aqueous alcohol, *t*-butylglyoxal hydrate[9] (4 g.) was dissolved. The solution was cooled to 0°C. To this solution, a solution of 0.25 g. of sodium cyanide in 10 ml. of 50% aqueous alcohol was added with stirring. The solution immediately colored yellow. After stirring for 30 min.,

* Neopentoylformoin is insoluble in carbon tetrachloride or other desirable solvents for the spectrophotometric measurement.

** The structures of the derivatives are established as VI and VII, as mentioned above.

9) R. C. Fuson, H. Gray and J. J. Gouza, *J. Am. Chem. Soc.*, **61**, 1937 (1939).

alcohol was evaporated under reduced pressure. White crystals were collected by filtration and washed with water and dried in vacuo over phosphorus pentoxide. Yield, 2.3 g. (73%). Recrystallization was effected from isopropanol. Yield, 1 8 g. (56%). M. p. 170~171°C. Insoluble in ordinary organic solvent except alcohols.

Found: C, 63.04; H, 8.86; mol. wt. (Rast) 219. Calcd. for $C_{12}H_{10}O_4$: C, 63.16; H, 8.77%; mol. wt., 228.

When a crude glyoxal monomer[9] was used, the procedure was the same except for purification; crude formoin was dissolved in a minimum amount of alcohol and precipitated with addition of water.

Mono-*O*-methyl Derivative.—In about 10 ml. of 12% methanolic hydrogen chloride, 2 g. of neopentoylformoin was dissolved. After standing overnight at room temperature, alcohol and acid were evaporated under reduced pressure. The residue, dried in vacuo over potassium hydroxide, was washed quickly with cold water and dried in vacuo over phosphorus pentoxide. M. p. 100.5~101°C.

Found: C, 64.64; H, 9.25; MeO, 12.75. Calcd. for $C_{13}H_{22}O_4$: C, 64.64; H, 9.07; MeO, 12.81%.

Mono-*O*-ethyl Derivative.—The procedure was the same as in methanolysis. M. p. 77~78°C.

Found: C, 65.41; H, 9.43. Calcd. for $C_{14}H_{24}O_4$: C, 65.52; H, 9.38.

Di-*O*-methyl Derivative.—*Method A.*—In 20 ml. of water containing 1 g. of potassium hydroxide, mono-*O*-methyl derivative (4 g.) was dissolved. The solution was brilliant yellow. Into this solution, 2 g. of dimethyl sulfate was added during 30 min. with stirring, and stirring was continued for additional 30 min. After addition of 0.5 g. of potassium hydroxide, the dropping of 1 g. of dimethyl sulfate was continued during 30 min. and then the solution was stirred for additional 30 min. at 50°C. During the reaction, the yellow color of the solution was diminished and colorless oil separated. The whole solution was extracted with carbon tetrachloride. The extract was dried over anhydrous sodium sulfate. The solvent was evaporated and the residue of colorless liquid was distilled under reduced pressure. Fraction boiling at 107~108°C/5 mmHg was collected. Yield, 2.3 g. (53%).

Found: C, 65.51; H, 9.40; MeO, 24.12. Calcd. for $C_{14}H_{24}O_4$: C, 65.52; H, 9.38; MeO, 24.22%.

Method B.—In 30 ml. of absolute methanol containing 0.6 g. of sodium, mono-*O*-derivative (3.6 g.) was dissolved. The solution colored yellow. After addition of 20 g. of methyl iodide, the solution was refluxed for 4 hr. During this period, the color of solution was diminished as in method A. The solution was stood overnight at room temperature. After the addition of 10 ml. of water, methanol was evaporated under reduced pressure. The residue was extracted with ether. The extract was dried over anhydrous sodium sulfate. Ether was evaporated off. The residue of pale yellow liquid was distilled under reduced pressure. Fraction boiling at 107~108°C/5 mmHg was collected. Yield, 2.1 g. (58%).

Found: C, 65.51; H, 9.40%.

The infrared spectrum of the product in carbon tetrachloride solution was coincident with that of the product obtained in the method A even in details.

***O*-Ethyl-*O*-methyl Derivative.**—This compound was prepared as in the method A and boiling at 107~108°C/5 mmHg.

Found: C, 66.74; H, 9.41; RO, 27.94. Calcd. for $C_{15}H_{26}O_4$: C, 66.66; H, 9.63; RO, 28.14%.

The Conversion of the Mono-*O*-methyl Derivative to the Mono-*O*-ethyl Derivative and Vice Versa.—About 0.1 g. of mono-*O*-methyl derivative was dissolved in 1 ml. of 8% ethanolic hydrogen chloride and the procedure was the same as above. M. p. 78~79°C. Mixed melting point with the authentic *O*-ethyl derivative showed not any depression. The procedure was the same in the case of the conversion of the *O*-ethyl derivative to the *O*-methyl derivative. M. p. 100~101°C. Not any depression of the melting point was observed at a mixed melting point.

The Conversion of the Di-*O*-methyl Derivative to the *O*-Ethyl-*O*-methyl Derivative.—A solution of 3 g. of di-*O*-methyl derivative in 15 ml. of 12% ethanolic hydrogen chloride was stood overnight at room temperature. The solvent and the acid were evaporated under reduced pressure and evaporation was repeated with addition of absolute ethanol and the residue of liquid was dissolved in carbon tetrachloride. The solution was washed with cold water, then dried over anhydrous sodium sulfate. Removal of the solvent, followed by distillation, gave 2.2 g. of liquid; boiling at 105~109°C/5 mmHg.

Found: C, 66.65; H, 9.36; RO, 28.01%.

Spectra and Alkoxy Group.—The infrared spectra were recorded with a Koken model DS-301 spectrophotometer.

The alkoxy group content was determined by the method of Hoffman and Wolfrom[10].

Solvent Effects on the Absorption and Fluorescence Spectra of Naphthylamines and Isomeric Aminobenzoic Acids

By Noboru MATAGA

(Received January 10, 1963)

The solvent effects upon the absorption spectra and those upon the fluorescence spectra are different from each other.

From the study of this difference one may derive some information concerning the nature of the electronically-excited state in contrast to the ground state and also the nature of the interactions between solute and solvent molecules in the excited as well as the ground state.

On the other hand, the nature of the electronic states of such substituted aromatic hydrocarbons as hydroxy and amino derivatives seems to be not so well understood as that of the parent hydrocarbons[1-4] and their aza-derivatives[5-9].

Recently, a number of studies[10,11] have been carried out to elucidate the electronic structures and spectra of the former. Baba[10] has made comparative studies of the mono-substituted hydroxy and amino derivatives of benzene and naphthalene and has made the assignment of the electronic absorption bands of these molecules.

We present here a somewhat different approach to the electronic structures of naphthylamines. We are mainly interested in the electronically excited states and in the difference between the electronic structure in the excited state and that in the ground state. We shall demonstrate in the following the remarkable difference between the conjugation power of the hydroxy and that of the amino group by measuring the solvent effects on the electronic spectra.

Further, the results of similar measurements on isomeric aminobenzoic acids (ABA) will be described, with some discussion of the electronic structure of these molecules.

Experimental

Apparatus.—The absorption spectra were measured with a Beckman spectrophotometer model DU. Details of the fluorescence spectrophotometer have been described elsewhere[12]. The light source for *p*-ABA was a 300 W xenon discharge tube with a stabilizer. For other compounds used in the present study, a high-pressure mercury discharge tube was used as a light source.

The fluorescence of *p*-ABA was excited at 290 mμ, the monochromatic exciting light from the xenon discharge tube being taken out by a quartz prism monochromater. Doublet lines at 313 mμ, taken out from the high-pressure mercury discharge tube by the monochromator, were used for exciting the other compounds.

All measurements were carried out at room temperature ($\sim$20°C).

Materials. — The naphthylamines were recrystallized from ligroin and sublimated in a vacuum. The ABA's were purified by sublimation in a vacuum. Special grade benzene was dried over metallic sodium and distilled fractionally. Cyclohexane was dried over metallic sodium, distilled fractionally and the distillate was then passed through a column of activated silica gel for chromatographic use. *n*-Hexane was shaken with fuming sulfuric acid diluted with concentrated sulfuric acid, washed with water several times, dried over calcium chloride and distilled carefully. The acetic acid esters were dried over potassium carbonate and distilled fractionally. Acetonitrile was refluxed repeatedly over phosphorus pentoxide, distilled into potassium carbonate and fractionally distilled from it. Chloroform was shaken with concentrated sulfuric acid, washed with water, and after being dried over phosphorus pentoxide, distilled carefully. Methanol and ethanol were refluxed with silver nitrate, and after being refluxed with calcium-carbonate, fractionally distilled. Normal butanol was washed with dilute sulfuric acid and with a sodium bisulfate solution. The treated alcohol was then dried with potassium carbonate and fractionally distilled. Monochlorobenzene was dried with phosphorus pentoxide and fractionally distilled. Dioxane was refluxed with dilute hydrochloric acid, treated with potassium hydroxide, dried over metallic sodium and then fractionally distilled from it.

Experimental Results

Naphthylamines. — Some examples of the solvent shifts of the absorption and fluorescence spectra of naphthylamines are shown in Figs. 1 and 2. In these figures, the intensity of the maximum of each fluorescence band is brought to the same value as that of the corresponding absorption band.

One may observe from Figs. 1 and 2 that the red shift of the absorption and fluorescence spectra becomes larger, the greater the dielectric constant of the solvent, and that the shift of the fluorescence band is much larger than that of the absorption band. This anomalous Stokes red shift can be ascribed to the change in solute-solvent interaction during the lifetime of the excited solute molecule[14-15].

In other words, according to the Franck-Condon principle, the configuration of the solvent molecules surrounding the solute molecule does not change during the light absorption. The momentary excited state (Franck-Condon excited state) is, in general, not the most stable equilibrium state appropriate to the excited solute molecule. The equilibrium-excited state can be reached completely or partially by reorganization of the configurations of the surrounding molecules during the lifetimes of the excited solute molecule.

We can use this difference between the solvent shifts of absorption and fluorescence spectra in order to get experimental information on the electronic structure of the excited molecule[13-15].

In the present study, we have used the method (Eq. 1) proposed by Lippert[14] and by the present author[15], for the evaluation of $\vec{\Delta\mu}$, the difference between the excited state dipole moment, $\vec{\mu_e}$, and that in the ground state, $\vec{\mu_g}$, i.e., $\vec{\Delta\mu}=\vec{\mu_e}-\vec{\mu_g}$, where the excited state is the fluorescent state.

$$hc\Delta\sigma \simeq \text{Const.} + 2\cdot F(D,n)\cdot(\vec{\Delta\mu})^2/a^3$$

$$\Delta\sigma = \sigma_a{}^m - \sigma_f{}^m$$

$$F(D,n) = \left(\frac{D+1}{2D+1} + \frac{n^2+1}{2n^2+1}\right) \qquad (1)$$

In Eq. 1, $\sigma_a{}^m$ and $\sigma_f{}^m$: the wave number of a peak of the fluorescence band and that of the corresponding absorption band respectively; D and n: the dielectric constant and refractive index of the solvent and a: the cavity radius in Onsager's theory of the reaction field. The observed values of $\sigma_a{}^m$, $\sigma_f{}^m$ and $\Delta\sigma$ are given in Table I, together with the values of $F(D,n)$.

Thus, the observed values of $\Delta\sigma$ are plotted against the values of $F(D,n)$, in Fig. 3. As one can see from this figure, Eq. 1 is approximately satisfied, that is, an approximate linear

n-Hexane	0	3.14	2.66	0.48	2.96	2.66	0.30
Monochlorobenzene	0.143	3.10	2.51	0.59	2.93	2.58	0.35
n-Butyl acetate	0.171	3.07	2.46	0.61	2.90	2.51	0.39
Methyl acetate	0.220	3.06	2.43	0.63	2.92	2.51	0.41
n-Butanol	0.267	3.13	2.31	0.82	2.96	2.46	0.50
Ethanol	0.298	3.13	2.31	0.82	2.96	2.46	0.50
Acetonitrile	0.304	3.07	2.38	0.69	2.91	2.49	0.42

relation between $\Delta\sigma$ and $F(D, n)$ holds, although the $\Delta\sigma$ values of alcohol solutions deviate considerably from the linear relation.

Among the solvents used here, acetic acid esters and alcohols can form hydrogen bonds with naphthylamines of the types,

$$\mathrm{R{-}\underset{\underset{H}{|}}{N}{-}H\cdots O{=}C\langle^{R'}_{R''}},$$

and $\mathrm{R{-}\underset{\underset{H_2}{|}}{N}\cdots H{-}O{-}R'}$ or $\mathrm{R{-}\underset{\underset{H}{|}}{N}{-}H\cdots \underset{\underset{H}{|}}{O}{-}R'}$

or both, respectively. These hydrogen bonding interactions may somewhat complicate the interpretation of the observed results because only the long range dipolar interactions are taken into account in Eq. 1, and actually the values of alcohol solutions do not satisfy the linear relations. However, the hydrogen-bonding interactions with monochlorobenzene and acetonitrile are certainly very weak, and the $\Delta\sigma$ values for these solvents, together with that for *n*-hexane, well satisfy the approximate linear relation.

Equation 1 for naphthylamines can be written approximately as follows:

$$\beta\text{-}, \quad \Delta\sigma = 2900 + 4800\, F(D, n)$$
$$\alpha\text{-}, \quad \Delta\sigma = 4800 + 7300\, F(D, n)$$

From these equations, $\Delta\vec{\mu}$ values for naphthylamines can be evaluated as follows, assuming $a \sim 3$ Å: α-, 4.4 D, β-, 3.5 D. By the same method and with the same value of the cavity radius, the $\Delta\vec{\mu}$ values for naphthols were estimated to be 0.5D~1D[15]. In the latter case, the $\Delta\vec{\mu}$ value of the β-derivative was evidently greater than the $\Delta\vec{\mu}$ value of the α-derivative, in contrast with the former case.

At any rate, it is quite certain that the $\Delta\vec{\mu}$ values of naphthylamines are much larger than those of naphthols and that the relative order of magnitude of this value for α- and β-derivatives is reversed in naphthylamines when compared with naphthols.

ABA's. — The absorption and fluorescence spectra of *o*- and *m*-isomers in a benzene solution are shown in Fig. 4, while those of *p*-isomer in benzene and methyl acetate are given in Fig. 5.

The values of σ_a^m, σ_f^m, $\Delta\sigma$ and $F(D, n)$ for isomeric ABA's are collected in Table II. The relations between the $\Delta\sigma$ values and $F(D, n)$ are shown in Fig. 6.

It appeares, from Fig. 6, that Eq. 1 is not so well satisfied in these cases as in the case of naphthylamines. In particular, the deviations of the $\Delta\sigma$ values of alcohol solutions from the linear relation is quite remarkable.

We have not attempted to evaluate the $\Delta\vec{\mu}$

* σ's and $\Delta\sigma$'s are in unit of $10^4\,cm^{-1}$.

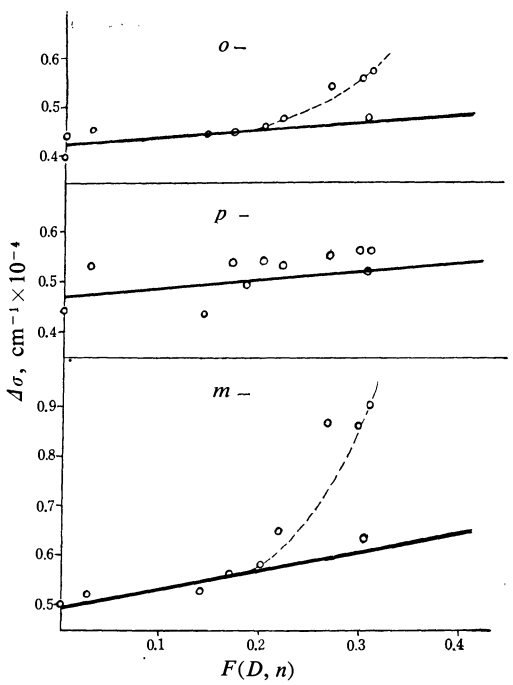

Fig. 6. $\Delta\sigma$ vs. $F(D, n)$ relation for aminobenzoic acids.

values of ABA's because the points are rather scattered and the more specific short-range interactions between solute and solvent molecules seem to be rather dominant. However, the inclinations of the full lines in Fig. 6 may give an approximate measure of th $\Delta\vec{\mu}$ values for these compounds, because the $\Delta\sigma$ values involved here mainly correspond to solvent molecules which make very weak hydrogen bond with solute molecules. The observed inclination is the largest for the *m*-isomer and the smallest for the *o*-isomer.

We can get only a rough estimate of the inclination for the *p*-isomer because the points in this case are scattered considerably. However, the inclination for the *p*-isomer is certainly rather close to that of the *o*-isomer.

Discussion

Deviations of $\Delta\sigma$ Values from the Linear Relation and Hydrogen Bonding Effects. — The lowest excited electronic state of naphthalene is ^1L_b, and the next one is ^1L_a[1-4]. Owing to the substitution by the hydroxy and amino groups, the electronic spectrum of naphthalene is modified considerably. Nevertheless, the lowest excited electronic states of naphthols and naphthylamines can be assigned to modified ^1L_b's and next ones to modified ^1L_a's[10].

It is well known that the electron migration or the charge transfer interaction between the substituent and the aromatic hydrocarbon is the most important factor which affects and determines the electronic spectra of aromatic derivatives[10,11,16-25].

In general, the extent of electron migration or the charge transfer interaction is greater in the excited electronic state than in the ground state. The observed $\Delta\vec{\mu}$ values presumably arise mainly from this difference.

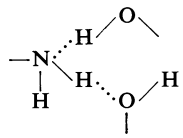
Baba[10] calculated the changes (decrease) in π-electron density on the substituent of naphthols and naphthylamines accompanying electronic transitions by a semiempirical ASMO CI method. The calculated results show that this decrease is much larger for naphthylamines than for naphthols, which is in accordance with the observed $\Delta\vec{\mu}$ values of these compounds, at least qualitatively.

This decrease of π-electron density on the substituent in the excited state is probably responsible also for the observed deviations of the $\Delta\sigma$ values of alcohol solutions in Fig. 3.

The hydrogen-bonding interaction in alcohol solutions probably involves both the types of hydrogen bonds indicated in Experimental Results, simultaneously, i. e., a bonding of the type:



The hydrogen bonding of the type, $H\rangle N\text{-}H\cdots O\langle$, causes a red shift of the absorption spectrum, whereas the other type of hydrogen-bonding interaction cause a blue shift of the absorption spectrum, because the former is favorable but the latter is unfavorable for the charge migration from the substituent to the aromatic ring.

As one can see from the tables, the $\sigma_a{}^m$ values of alcohol solutions are almost the same as or even larger than those in non-polar solvents.

This fact indicates that the effect of the latter type of hydrogen-bonding interaction on the spectral shift is rather important.

As is indicated in Fig. 7, the hydrogen-bonding interaction of the type, $-N\cdots H\text{-}O-$, is certainly very weak in the excited state of naphthylamines, and the other type of hydrogen-bonding interaction is a little stronger in the excited state than in the ground state.

The broken lines in Fig. 7 represent radiationless processes, which are reorganizations of hydrogen-bonding interactions. This sort of radiationless process may cause a large value of $\Delta\sigma$, leading to considerable deviations from the linear relation between $\Delta\sigma$ and $F(D, n)$.

The effect of hydrogen-bonding interaction of this type may be much stronger in the case of ABA's than in the case of naphthylamines because of the existence of the carboxyl group in the former. The near-ultraviolet absorption spectra of the ABA molecule have been interpreted as being due to the

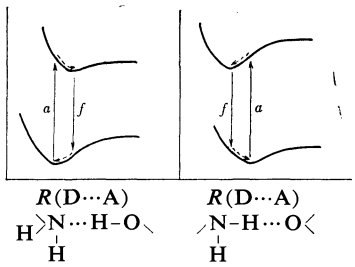


Fig. 7. Potential energy curves for the hydrogen bondings of the types: $-N\cdots H\text{-}O-$ and $-N\text{-}H\cdots O\langle$, respectively. $R(D\cdots A)$ is the distance between the proton donor and the acceptor. a and f indicate the light absorption and fluorescent transitions, respectively, and broken lines represent radiationless processes due to the reorganization of the hydrogen bond.

intramolecular charge-transfer transition from the aniline residue to the antibonding orbital of the carboxyl group[20]. Thus, the electron-accepting character of the carboxyl group results in a stronger decrease in the π-electron density on the amino group in the excited electronic state. This circumstance is probably responsible for the remarkable deviations in the $\Delta\sigma$ values of alcohol solutions in the case of *m*-ABA.

In the case of *o*-ABA, however, the circumstance may be somewhat different because of the existence of an intramolecular hydrogen bond between the amino group and the carbonyl group. Because electronic delocalization through the hydrogen bond is possible[26-29], the charge separation between the two substituents may be smaller in this molecule than in the other isomers. This delocalization is certainly stronger in the excited state than in the ground state because the electronic orbital is more extended, the ionization potential of the carbonyl becomes smaller, and the electron affinity of the amino group becomes larger in the excited electronic state than in the ground state.

In this way, the electronic delocalization through the intramolecular hydrogen bond may result in smaller deviations in the $\Delta\sigma$ values of *o*-ABA in alcohol solutions than is the case with *m*-isomer.

The same factor may be responsible also for

26) H. Tsubomura, This Bulletin, **27**, 445 (1954); *J. Chem. Phys.*, **23**, 2130 (1955); ibid., **24**, 927 (1956).

the small inclination of *o*-ABA in Fig. 6. However, the distance between the two substituents is the smallest for this isomer, and this may be the main cause for the small inclination. Because the distance between the two substituents is the largest for the *p*-isomer, one may expect the largest inclination for this compound. However, this expectation is not in agreement with the observed result.

As shown in Fig. 5, the absorption intensity of the *p*-isomer is much stronger than those of other isomers and naphthylamines. This very strong absorption intensity indicates a short life time of the fluorescent state, although the observed value of the life time is not available for this molecule. During the very short life time of the fluorescent state, the rearrangement of the solvent molecules surrounding the excited solute molecule may be reached only partially or it may be almost impossible. Such a circumstance has already been observed in the case of *p*-dimethylaminocinnamic-nitrile[30].

It is quite probable that the rearrangement of the solvent molecules during the life time of the excited state occurs only incompletely for *p*-ABA and that, accordingly, the observed inclination is so small as shown in Fig. 6.

Theoretical Calculation of the $\vec{\Delta\mu}$ Values of Naphthylamines and Naphthols. — As has been mentioned in Experimental Results, the observed $\vec{\Delta\mu}$ value for α-naphthylamine was larger than that for β-naphthylamine, contrary to the case of naphthols.

To interpret these facts, the observed results may be compared with the results of theoretical calculation as follows.

The Method of Calculation. — The semiempirical ASMO CI method[3] was used. In this treatment, an electronic state function, Ψ, for the π-electrons is approximated by a linear combination of the ground configuration function, χ_0, and singly excited configuration functions, χ_{ik}'s, where one electron is excited from an occupied MO ϕ_i to an unoccupied MO ϕ_k.

The orthonormal MO's are themselves linear combinations of 2pπAO's, ϕ_μ's:

$$\phi_i=\sum_\mu c_{i\mu}\phi_\mu \tag{2}$$

The theoretical expression for $\vec{\Delta\mu}$ in terms of the state function, Ψ, is given by:

$$\vec{\Delta\mu}=\langle\Psi_e|M|\Psi_e\rangle-\langle\Psi_g|M|\Psi_g\rangle \tag{3}$$

where

$$M=\sum_t e_t r_t \tag{4}$$

e_t and r_t are the charge and the position vector of t-th particle, respectively. In the π-electron approximation, M can be separated into two parts:

$$M=e\sum_\mu r_\mu+\sum_s e_s r_s \tag{5}$$

e is the electronic charge, the first summation being over the π-electrons and the second over the cores. The necessary formulas for the expansion of 3 in terms of integrals over MO's are given as follows:

$$\left.\begin{aligned}
&\langle\chi_0|M|\chi_0\rangle=2\sum_i^{\mathrm{occ}} M_{ii}+\sum_s e_s r_s\\
&\langle{}^1\chi_{ik}|M|{}^1\chi_{ik}\rangle=2\sum_i^{\mathrm{occ}} M_{ii}-M_{ii}\\
&\qquad\qquad +M_{kk}+\sum_s e_s r_s\\
&\langle\chi_0|M|{}^1\chi_{ik}\rangle=\sqrt{2}M_{ik}\\
&\langle{}^1\chi_{ik}|M|{}^1\chi_{jk}\rangle=-M_{ij}\\
&\langle{}^1\chi_{ik}|M|{}^1\chi_{il}\rangle=M_{kl}\\
&\langle{}^1\chi_{ik}|M|{}^1\chi_{jl}\rangle=0\\
&M_{ik}=\langle\psi_i|M|\psi_k\rangle
\end{aligned}\right\} \tag{6}$$

In Eq. 6, occ means the summation over the occupied MO's in χ_0.

In the present calculations, the wave functions calculated by Baba[31] were used. In his treatment, $\Psi_g\sim\chi_0$ and $\Psi_e\sim a^1\chi_{ik}+b^1\chi_{jl}$; therefore Eq. 3 reduces to the following:

$$\vec{\Delta\mu}=a^2(M_{kk}-M_{ii})+b^2(M_{ll}-M_{jj}) \tag{7}$$

In the expansion of M_{ii}'s in terms of integrals over AO's, the following approximation was used:

$$M_{ll}=\sum_{\mu,\nu} c_{i\mu}c_{i\nu}\langle\phi_\mu|M|\phi_\nu\rangle\simeq e[\textstyle\sum c^2_{i\mu}R_\mu] \tag{8}$$

where R_μ is the position vector of the μ-th atom.

All bond distances in naphthylamines and naphthols are assumed to be 1.39Å.

Calculated Results. — The $\vec{\Delta\mu}$ values for the ^1L_b state of naphthols were calculated as follows: α-, 1.63 D and β-, 2.75 D, which are much larger than the observed values.

The usual MO method seems to overestimate the values of dipole moments and also $\vec{\Delta\mu}$ values. Thus, the calculated $\vec{\Delta\mu}$ values for the ^1L_b state of naphthols were four times as large as the observed values.

Because we are concerned here with only the relative values of $\vec{\Delta\mu}$ for these molecules, the calculated values were divided by this factor. Then, one quarter of the $\vec{\Delta\mu}$ values for the ^1L_b state of naphthols was calculated

30) E. Lippert, *Angew. Chem.*, **73**, 695 (1961).

31) H. Baba, private communication; see also Ref. 10.

as: α-, 0.41 D and β-, 0.69 D. The same quantities (i. e., one quarter of the theoretical values) for the ^1L_b state of naphthylamines were: α-, 0.92 D and β-, 1.16 D. These values are considerably smaller than the observed values. However, a more serious disagreement with the experimental results is that the $\vec{\Delta\mu}$ value of the α-isomer is smaller than that of the β-isomer.

One-quarter of the theoretical value of $\vec{\Delta\mu}$ for the ^1L_a state of α-naphthylamine (abbreviated as $\vec{\Delta\mu}(^1L_a{}^{\alpha})$) was 1.35 D, which was larger than $\vec{\Delta\mu}(^1L_b{}^{\beta})$. Moreover, the ratio $\vec{\Delta\mu}(^1L_b{}^{\beta})/\vec{\Delta\mu}(^1L_a{}^{\alpha})$ is 0.86 for the calculated values, which is very close to the observed ratio, 0.80. These facts seems to indicate rather strongly that the fluorescent state of α-naphthylamine is not the ^1L_b but the ^1L_a state.

If all of the structures of the absorption band in *n*-hexane as shown in Fig. 1 belong to the same electronic band, the fluorescence band should have the corresponding structures and the absorption and fluorescence bands should present the "mirror image" appearance*. However, this seems not to be the case in the observed spectrum, because the shortest wavelength shoulder in the fluorescence band, which corresponds to the longest wavelength shoulder in the absorption band, seems to be missing. The latter shoulder was assigned[10] to ^1L_b, which seems to be quite reasonable. These facts also appear to support the above interpretation. Thus, the ^1L_a state of α-naphthylamine may probably become the lowest excited singlet state during the radiationless process from the Franck-Condon to the equilibrium excited state.

The Mechanism of the Level Reversal during the Life Time of the Excited State.—There is a noticeable difference between spectral changes caused by substitutions at the α- and β-positions of naphthalene. Several explanations have been already given for this interesting phenomenon[10,25,32,33].

The reversal of the ^1L_b and the ^1L_a states of α-naphthylamine during the life time of the excited state may be closely related to the factor which determine the spectral characteristics of the α- and β-isomers respectively.

The characteristic difference between the α- and β-isomers may be understood well if we write down the matrix elements of the interactions between the locally excited states of naphthalene and the charge transfer (CT) configurations which arise from the transfer of one electron from the occupied orbital of the substituent to the vacant orbitals of naphthalene.

Using the method developed by Longuet-Higgins and Murrell[22,34], the necessary matrix elements can easily be calculated as follows.

If the SCF MO's of naphthalene are written $\psi_1 \cdots \psi_n$ and those of the substitutent, $\theta_1 \cdots \theta_m$, then the energy of the CT configuration, $^1\chi_{sk}$, where one electron is transferred from an occupied orbital, θ_s, to a vacant MO, ψ_k, is given by:

$$\langle {}^1\chi_{sk} | \mathscr{H} | {}^1\chi_k \rangle = \varepsilon_k - \varepsilon_s - \langle \theta_s(1)\psi_k(2) | G_{12} | \theta_s(1)\psi_k(2) \rangle \quad (9)$$

where ε_k and ε_s are linear combinations of ψ_k and θ_s respectively, and ψ_k's are linear combinations of $2p\pi$AO's $\phi_1 \cdots \phi_n$,

$$\psi_k = \sum_{\mu} c_{k\mu}\phi_{\mu} \quad (10)$$

G_{12} is the two-electron operator, e^2/r_{12}, r_{12} being the inter-electronic distance.

For naphthylamines, ε_s will be given, to a good approximation, by the observed ionization potential of ammonia, i. e., $\varepsilon_s = -10.154$ eV.[35] The difference between the observed and calculated values of the electron affinity of benzene, $\Delta A = A_B{}^{obs} - A_B{}^{calc}$ [4], has been added to the calculated values of ε_k.

With neglect of differential overlap,

$$\langle \theta_s(1)\psi_k(2) | G_{12} | \theta_s(1)\psi_k(2) \rangle = \sum_{\mu} c^2{}_{k\mu}\gamma_{s\mu} \quad (11)$$

$$\gamma_{s\mu} = \langle \theta_s(1)\phi_{\mu}(2) | G_{12} | \theta_s(1)\phi_{\mu}(2) \rangle$$

For the evaluation of $\gamma_{s\mu}$, the equation[4,7,8], $\gamma_{s\mu} = e^2/(\rho + R_{s\mu})$, was used, where $\rho = 1.197$ Å. The value of ρ is the harmonic mean of the ρ for carbon[4,7,8] and that for nitrogen. The latter value was obtained from the one center value of γ for nitrogen calculated by Brown[36] using the VESCF method.

The matrix elements of the interactions between the CT configurations and various local configurations in naphthalene can be evaluated from the following formulas:

$$\langle {}^1\chi_{sk} | \mathscr{H} | {}^1\chi_{jl} \rangle = -\delta_{kl} \langle \theta_s(1) | H(1) | \psi_j(1) \rangle \quad (12)$$

where δ_{kl} is Kronecker's delta.

$$\langle {}^1\chi_{sk} | \mathscr{H} | \chi_0 \rangle = \sqrt{2} \langle \theta_s(1) | H(1) | \psi_k(1) \rangle \quad (13)$$

where χ_0 is the ground configuration.

* See, for example, Th. Förster, "Fluoreszenz organischer Verbindungen", Vandenhoeck and Ruprecht Göttingen (1951).

32) D. Peters, *J. Chem. Soc.*, **1957**, 646, 1993, 4182.

36) R. D. Brown and M. L. Heffernan, *Australian J. Chem.*, **12**, 319 (1959).

$$\langle {}^1\chi_{sk}|\mathscr{H}|{}^1\chi_{sl}\rangle = -\langle\theta_s(1)\phi_k(2)|G_{12}|\theta_s(1)\phi_l(2)\rangle = -\sum_{\mu} c_{k\mu}c_{l\mu}\langle\theta(1)\phi_\mu(2)|G_{12}|\theta_s(1)\phi_\mu(2)\rangle \quad (14)$$

The integral $\langle\theta_s(1)|H(1)|\phi_j(1)\rangle$ can be reduced to $c_{jr}\langle\theta_s(1)|H(1)|\phi_r(1)\rangle = c_{jr}\beta^c$, the substituent being attached to the carbon atom 'r'.

Now, by means of these formulas and the SCF MO's and state functions of naphthalene[4], the energy matrices for naphthylamines are calculated as follows (in units of eV.):

α-Naphthylamine

χ_0	${}^1B_{3u}^-$	${}^1B_{2u}^+$	${}^1B_{3u}^+$	${}^1B_{2u}^-$	${}^1\chi_{s6}$	${}^1\chi_{s7}$
0					$0.5995\beta^c$	$-0.3749\beta^c$
	3.99				$0.0023\beta^c$	$-0.2997\beta^c$
		4.51			$-0.4081\beta^c$	$-0.0009\beta^c$
			5.61		$-0.0023\beta^c$	$-0.2997\beta^c$
				7.30	$-0.1145\beta^c$	$0.0032\beta^c$
					6.1679	$-0.0734\beta^c$
						7.3736

β-Naphthylamine

χ_0	${}^1B_{3u}^-$	${}^1B_{2u}^+$	${}^1B_{3u}^+$	${}^1B_{2u}^-$	${}^1\chi_{s6}$	${}^1\chi_{s7}$
0					$-0.3749\beta^c$	$-0.5602\beta^c$
	3.99				$0.2801\beta^c$	$-0.1875\beta^c$
		4.51			$-0.2553\beta^c$	$-0.1069\beta^c$
			5.61		$-0.2801\beta^c$	$-0.1875\beta^c$
				7.30	$-0.0716\beta^c$	$0.3814\beta^c$
					6.5635	$-0.1573\beta^c$
						7.3829

In these matrices, observed values are used for the locally excited states of naphthalene.

The calculated matrix elements correspond quite well to the observed characteristics of the electronic spectra of α- and β-derivatives respectively. That is, there are weak interactions between the ${}^1B_{3u}^-$ and CT configurations and strong interactions between the ${}^1B_{2u}^+$ and CT configurations for the α-isomer, whereas either ${}^1B_{3u}^-$ or ${}^1B_{2u}^+$ interacts moderately with the CT configurations and the interactions of the ${}^1B_{3u}^-$ with CT configurations are a little stronger than those of ${}^1B_{2u}^+$, in the β-isomer. In the case of naphthylamines, the energies of CT configurations are considerably smaller than those of naphthols*. Moreover, the core resonance integral, β^c, for naphthylamines may be a little larger than that for naphthols**.

Therefore, only in the case of α-naphthylamine, the ${}^1L_a$ state will be very close to the ${}^1L_b$ state.

Now, in the excited state of naphthylamine, the more flattened structure of the amino group and the more stretched form of the N–H bond compared with those in the ground state may probably be favored because the gain of the CT interaction energy due to these changes in the structure of the amino group is much larger in the excited electronic state than in the ground state. In other words, these structural changes result in the lowering of the ionization potential of the lone-pair orbital of the amino group and the increase of β^c.

Thus, the excitation energies of the CT configurations becomes smaller and the CT interactions becomes stronger. Because the energy differences between the lower excited states of naphthalene and the CT configurations are much smaller than those between the ground configuration and CT configurations, the CT interactions are considerably larger in the excited electronic state.

Because of these circumstances, ${}^1B_{2u}^+$ mixed with ${}^1\chi_{s6}$ is lowered rather strongly, but the lowering of ${}^1B_{3u}^-$ may be small because of the very small interaction with ${}^1\chi_{s6}$ in the case of α-naphthylamine. Thus, the order of the ${}^1L_b$ and ${}^1L_a$ states may be reversed during the radiationless process in the excited state. This level reversal may be demonstrated by calculations using a simplified model, which are similar to those of an earlier treatment by Nagakura and Tanaka[21] but which take into account the inter-electronic interactions to some extent. In this treatment, we discuss the case of the structural change of the amino group from the pure sp^3 hydride to the pure sp_2 hydrid without a stretching of the N–H bond, and take into consideration only interactions among ${}^1B_{3u}^-$, ${}^1B_{2u}^+$ and ${}^1\chi_{s6}$.

We assume the proportionality of β^c to the corresponding overlap integral, S. Then we must evaluate the overlap integrals for the tetrahedral and trigonal hybrids respectively.

The lone-pair orbital used in this calculation for tetrahedral nitrogen is of the form:

$$\zeta = (1/2)s + (2/3)^{1/2}p_x - (1/12)^{1/2}p_z \quad (15)$$

where the x axis is taken perpendicular to the

* Calculations using similar approximations give for naphthols:

α-, $\langle {}^1\chi_{s6}|\mathscr{H}|{}^1\chi_{s6}\rangle = 8.3435$ eV.
$\langle {}^1\chi_{s7}|\mathscr{H}|{}^1\chi_{s7}\rangle = 9.6003$ eV.

β-, $\langle {}^1\chi_{s6}|\mathscr{H}|{}^1\chi_{s6}\rangle = 8.7971$ eV.
$\langle {}^1\chi_{s7}|\mathscr{H}|{}^1\chi_{s7}\rangle = 9.5860$ eV.

** If we assume the proportionality of the core resonance integral to the corresponding overlap integral, taking $\beta_c(-2.388$ eV.) and $S(0.25)$ between the nearest neighbor $2p\pi$AO's of benzene as a reference, then the β_c for naphthylamines is calculated to be -1.7 eV., whereas it is -1.4 eV. for naphthols. In this calculation, the AO's on the substituents are assumed to be pure $2p\pi$AO's perpendicular to the molecular plane, and the orbital exponent in the Slater AO of the heteroatom is the simple arithmetic mean of the values for the neutral atom and the singly ionized one respectively.

molecular plane. Taking the simple arithmetical mean of the values of neutral and singly ionized atoms for the orbital exponent in the Slater AO of nitrogen, the overlap integrals have been calculated, and from these the core reasonance integrals have been evaluated by the same procedure as described before**: β^c (tetrahedral)~ -1.43 eV., β^c (trigonal)~ -1.75 eV.

The change of the ionization potential of the lone pair orbital on nitrogen caused by this structural change was estimated by means of the following equation:

$$I(\mathrm{tr})/I(\mathrm{tet}) = I/I(\mathrm{NH_3})$$

where I(tr) and I(tet) are the ionization potentials of lone pair orbitals in the trigonal and tetrahedral valence states respectively. These values are evaluated from the valence state quantities given by Hinze and Jaffé[37]: $I(\mathrm{tr}) = 11.958$ eV., $I(\mathrm{tet}) = 14.157$ eV. $I(\mathrm{NH_3})$ is the observed ionization potential of ammonia. Thus, $I = 8.5768$ eV. Using these values of β^c's and I's, the relevant energy matrices can be written as follows:

(a) Tetrahedral $-NH_2$ (b) Trigonal $-NH_2$

$$\begin{array}{c} {}^1B_{3u}^- \quad {}^1B_{2u}^+ \quad {}^1\chi_{s6} \\ \begin{pmatrix} 3.99 & 0 & -0.0033 \\ & 4.51 & 0.5836 \\ & & 6.1679 \end{pmatrix} \end{array} \qquad \begin{array}{c} {}^1B_{3u}^- \quad {}^1B_{2u}^+ \quad {}^1\chi_{s6} \\ \begin{pmatrix} 3.99 & 0 & -0.0040 \\ & 4.51 & 0.7142 \\ & & 4.5909 \end{pmatrix} \end{array}$$

The interaction between ${}^1B_{3u}^-$ and ${}^1\chi_{s6}$ is very small and can be neglected practically. The lower energies and state functions for the interaction of ${}^1B_{2u}^+$ with ${}^1\chi_{s6}$ may then be given as follows:

(a) 4.325 eV. $\Psi = 0.953\,{}^1B_{2u}^+ - 0.302\,{}^1\chi_{s6}$

(b) 3.835 eV. $\Psi = 0.727\,{}^1B_{2u}^+ - 0.687\,{}^1\chi_{s6}$

Thus, the level is reversed and the ${}^1L_a$ state in the latter case contains a large amount of the CT configuration.

Of course, the above calculations are too simplified and the transformation from the tetrahedral to the trigonal structure may be realized only partially. However, the stretching of the N–H bond may also contribute to the level reversal, and the occurence of the latter seems to be plausible.

This change in the structure of the amino group, leading to the stronger CT interaction, may be responsible for the large difference between the theoretical $\vec{\Delta\mu}$ values (one-quarter of the calculated values) and the observed $\vec{\Delta\mu}$ values of the fluorescent state.

In the case of naphthols, such effects may not be important because the CT configurations are considerably higher and β^c is smaller than in naphthylamines.

Summary

The absorption and fluorescence spectra of naphthylamines and isomeric aminobenzoic acids in various solvents have been measured.

From the observed results, the difference in the dipole moments in the fluorescent and ground states respectively, i. e., $\vec{\Delta\mu} = \vec{\mu}_e - \vec{\mu}_g$, has been estimated for naphthylamines.

The effect of hydrogen bonding between solute and solvent molecules on the spectral shifts has been discussed. The hydrogen bonding between alcohol and amino nitrogen exerts a especially remarkable influence on the spectra, and the reorganization of this hydrogen bond during the life time of the excited solute molecule has been concluded from the observed results.

The intramolecular hydrogen bond of *o*-aminobenzoic acid considerably decreases the $\vec{\Delta\mu}$ value and the effect of the intermolecular hydrogen bonding on the spectra. This result has been explained as due to the charge transfer through the intramolecular hydrogen bond.

The $\vec{\Delta\mu}$ values for naphthylamines and naphthols have been calculated using the ASMO CI method and compared with the observed results.

This comparison, together with the theoretical interpretation of the characteristics in the spectra of α- and β-isomers, respectively, has indicated that the lowest excited singlet state in the light absorption is ${}^1L_b$, whereas the fluorescent state is ${}^1L_a$ in the case of α-naphthylamine and ${}^1L_b$ is the relevant excited state for both light absorption and fluorescence in the case of β-naphthylamine and naphthols.

The mechanism of this level reversal has been discussed as being due to the change in the structure of the amino group during the life time of the excited state.

The author wishes to express his deep gratitude to Professor Hiroaki Baba of Hokkaido University for sending us his unpublished results of ASMO CI calculations on naphthylamines and naphthols and for his fruitful discussions. The author also wishes to express his hearty thanks to Dr. Yozô Kaifu and Mr. Yoshikazu Torihashi for their help in the experimental measurements.

The Separation and Determination of Ruthenium in Fission Products by Liquid-Liquid Extraction with Pyridine

By Toshiyasu KIBA, Akiko MIURA and Yasuyuki SUGIOKA

(Received January 14, 1963)

When a fission product which contains ruthenium is dissolved in nitric acid, the element goes into the solution as the nitrosylruthenium radical (RuNO) III, complexed with nitrato, nitro, hydroxo and aquo ligands[1-3]. The element may have any oxidation number between 0 and +8, according to the composition and other conditions of the solution containing its compounds. The element may exist in various ion-species, polymers and compounds in intermediate states of oxidation[4], and it has been recognized that the separation of radioactive ruthenium from an aqueous solution containing other fission products requires the use of very difficult techniques.

Various methods have been proposed for this separation by many investigators; a summary of the methods intended for practical use has been given by Wyatt and Rickard[5]. According to their description, the isolation of radioactive ruthenium is generally accomplished by electrodeposition, ion exchange, distillation, liquid-liquid extraction or reduction by light metals. All isolation procedures naturally should consist of two steps: the first, to make the oxidation number of the element in all the compounds the same, preferably the lowest or the highest (that is, to convert the element to metallic ruthenium or the tetraoxide), and the second, to separate the compounds obtained by the first step. For separating the ruthenium tetraoxide, in which the element possesses its highest oxidation number, +8, distillation is usually adopted because of the volatility of the compound from an acidic solution containing a strong oxidizing agent, such as permanganate, silver peroxide, sodium bismuthate or periodic acid[6,7]. On the other hand, separation without distillation has been attempted by liquid-liquid extraction, in which ruthenium tetraoxide in an acidic solution is transferred into carbon tetrachloride by agitating the two phases in the presence of a strong oxidant in the aqueous phase. The tetraoxide transferred into the organic phase can be stripped again into another aqueous solution containing a reducing or chelating agent, and the colored, lower oxide is estimated colorimetrically. In both distillation and liquid-liquid extraction, however, some of the ruthenium tetraoxide is easily lost during the operations because of its volatility at moderately high temperatures. It has therefore been found desirable that the tetraoxide be treated in an alkaline rather than an acidic solution. It has already been known that all ruthenium oxide can be easily oxidized by sodium hypochlorite to perruthenate in an alkaline solution[8], and that the spectrophotometric measurement of the ruthenium content of the resulting solution can be made at 385 mμ[9]. This colored solution can also be obtained by passing the gaseous tetraoxide into a solution containing 6 N sodium hydroxide and 0.05 N sodium hypochlorite. Stoner[10] and Larson and Ross[11] employed this reaction for the photometric determination of ruthenium through distillation of the tetraoxide. Although as little as 200 μg. of the element can be determined by this method, however, it cannot be employed for the minute amounts of the element that are ordinarily met with in the radiochemical separation; moreover, accurate measurement of the radioactivity of the separated nuclide is impossible on account of the self-absorption of the radiation by the large amounts of alkaline salts present in the solution.

The present authors have found that the perruthenate ion formed in an alkaline solution, as described above, can be easily extracted by pyridine, just as the permanganate, perrhenate and pertechnetate ions can be[9,11]. The present paper describes a method for the rapid determination of radioactive ruthenium by liquid-liquid extraction.

Experimental

Radioactive Ruthenium.—Ruthenium-106 as nitrosylruthenium trinitrate in 8 M nitric acid was purchased from the Radiochemical Centre, Amersham, England, The original solution, containing 0.937 mc./ml. (assayed, 27th, Nov. 1957), was diluted with 3 M nitric acid to make its radioactivity about 1000 c. p. m. per 0.05 ml. The radiochemical purity of the ruthenium-106 was estimated to be above 99% and the radioactivity attributable to ruthenium-103, negligible.

Ruthenium Carrier.—Ruthenium red, that is, ruthenium oxychloride ammoniated $Ru_2(OH)_2Cl_4 \cdot 7NH_3 \cdot 3H_2O$, being regarded as a pure substance, was dissolved in water to prepare a solution containing a definite amount of ruthenium. On the other hand, 0.50084 g. of pure metallic ruthenium (Yokokawa Chem. Co., purity; over 99%) was dissolved in a small quantity of 10% "Antiformin" solution and kept for a time at 40°C. The solution was then filtered through a sintered glass G-4 into a 100 ml. measuring flask, after which the volume was adjusted to the mark with "Antiformin". This dark-brownish solution contains 5 mg. of ruthenium in one milliliter.

Chemical Reagents.—The reagents and solvents employed were all of the chemical pure grade. Among them, the solution of sodium hypochlorite was prepared from the commercial "Antiformin" with or without diluting the original solution. The "Antiformin" contains about 6 g. of active chlorine, 7.8 g. of sodium hydroxide and 32 g. of sodium carbonate per 100 ml.

Filter Paper for Chromatographic Use.—Toyo No. 53 paper (2 cm. by 40 cm.) was employed.

Spectrophotometer.—A Hitachi spectrophotometer, model EPU-2, was employed.

Measurement of Radioactivity.—A G-M counting set of the Kobe Kogyo Co., consisting of a No. 131 G-M tube (mica window; 2.8 mg./cm^2, counting efficiency for $^{90}Sr(^{90}Y)$: 11.7%) and a "100". scalor, was used for the β-counting, and a γ-ray spectrometer of the same company, Model-101 with a single-channel pulse height analyzer AN-105, was used for the γ-counting to identify the nuclide.

Separating Funnel.—A 30 ml. spindle-shaped separating funnel with a stout, short stem was used for the good separation of the two phases.

Shaking Machine.—The shaking of the separating funnel was effected by a vertical electric oscillator operating at 230 double strokes per minute.

The other utensils were of the ordinary laboratory type.

Experimental Results and Discussion

Paper Chromatographic Investigation.—One milliliter of a 3 N nitric acid solution of nitrosylruthenium (Ru-106) trinitrate was treated with 5 ml. of 6 M sodium hydroxide and a few drops of bromine water, and the test tube was held in a boiling water for a while till the brown color of the bromine vanished. The same quantity of the alkaline solution of radioactive ruthenium was prepared in another test tube, but instead of bromine water, 3 ml. of an "Antiformin" solution was added to it, and the mixture was left alone for a day. Paper chromatography was carried out on these two solutions and the original nitrosylruthenium (Ru-106) trinitrate solution as follows: one drop of the solution was placed on each of four strips of the chromatographic filter paper at a point 3 cm. from one end, allowed to dry in the air, and then developed chromatographically by the ascending method with four different solvents: ethanol-buthanol-NH_4CNS (50:50:50), glacial acetic acid-water (9:1), pyridine-water (3:2) and methylisopropyl ketone.

The solvent was allowed to rise about 20 cm. above the spot where the drop of the solution had been placed, and then the paper strip was dried and cut transversally into 1 cm. segments, in such a way that one of the segments included the location of the original drop. This segment was called No. 1, and the numbers from 2 to 20 were assigned to the 19 segments located higher up. Each segment was placed at the center of a counting sample pan, and its radioactivity was measured with an end-window counter. The results revealed that the pyridine-water mixture was the best for the purpose in view. Figure 1 gives the histograms obtained with this solvent.

From the figure it may be inferred that various ion species are present in the original

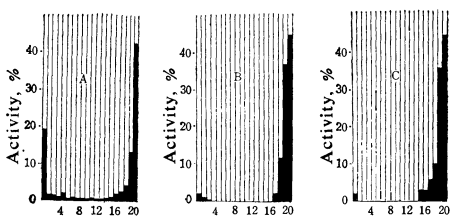

Fig. 1. Chromatograms of Ru-106 developed by pyridine-water (3:2).

B After oxidation with bromine in sodium hydroxide solution
C After oxidation with hypochlorite in alkaline solution

solution of ruthenium nitrosyltrinitrate, but when it has been made alkaline and oxidized by bromine or chlorine, almost all the ruthenium exists in a single ion species readily distributable in pyridine. Ruthenate ions, RuO_4^{2-}, are obtained by oxidation with bromine and perruthenate ions, RuO_4^-, with hypochlorite. However, the latter may be reduced to ruthenate ions by the cellulose during the chromatographic development. The experiments with the four solvents showed that a more complete separation was effected by pyridine than by any of the others, almost all that element being carried to the solvent front, as is shown in the figure. Therefore, pyridine was adopted as the most choice solvent in the liquid-liquid extraction.

Solvent Extraction Investigation.—To separate the perruthenate in the alkaline solution by liquid-liquid extraction, pyridine was first preferred for the above reason. In a separating funnel, 9 ml. of a sodium hydroxide solution and 1 ml. of a sodium hypochlorite solution were mixed well, and 1 ml. of a nitric acid solution of radioactive nitrosylruthenium trinitrate was added. The concentrations of sodium hydroxide and hypochlorite were so chosen as to make the final aqueous phase of predetermined concentrations. Milliliters of pyridine which had been pre-equilibrated with sodium hydroxide solutions of the corresponding working concentrations were poured into the funnel. The vessel was then tightly stoppered and shaken for five minutes with a shaking machine. After the phases had been disengaged, 1 ml. of the solution from each phase was pipetted out into a porcelain counting pan 1 inch in diameter and evaporated to dryness under an infrared lamp. The radioactivity of each sample was measured by an end-window G-M counter. The ratio of the counting rates of the two samples give the distribution coefficient of the extraction carried out under the given conditions. The dependence of the per cent extraction on the concentration of the reagents in the aqueous phase is summarily illustrated in Fig. 2. It is revealed that, at various concentrations of hypochlorite, the per cent extraction of perruthenate in pyridine is noticeably higher between three and four moles of sodium hydroxide in the aqueous phase. Next, the same experiments were carried out with varying concentrations of hypochlorite, while that of sodium hydroxide was kept constant at 4 M. The pyridine used in these experiments had been pre-equilibrated with 4 M sodium hydroxide. Figure 3 shows the increase in the per cent extraction with the increase in the concentration of hypochlorite, but even under the most favorable conditions,

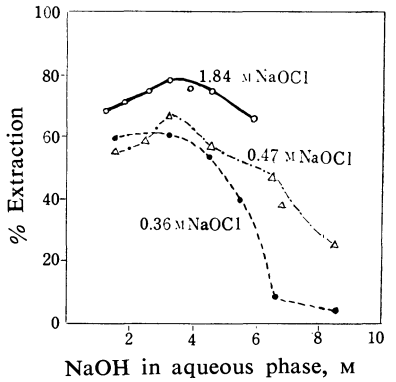

Fig. 2. Relation between % extraction of ruthenium and the concentration of sodium hydroxide and sodium hypochlorite.

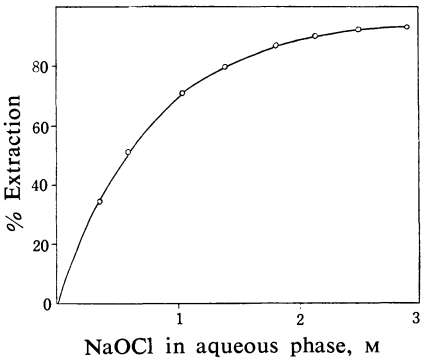

Fig. 3. Effect of concentration of sodium hypochlorite in 4 M sodium hydroxide aqueous solution.

in which the hypochlorite increases nearly to 3 M, the per cent extraction does not exceed 92%. This seems to be due to the incomplete oxidation of ruthenium(III) to perruthenate at room temperatures, so in the next experiment the aqueous phase was kept at 100°C for two hours before the extraction, but the recovery rose only to 95.1%. It was found that when the aqueous phase was left for 24 hr. at room temperature, the recovery percentage reached 100%. Therefore, the following procedure was finally adopted. One gram of sodium hydroxide was dissolved in 10 ml. of an "Antiformin" solution and then a small volume of nitrosylruthenium trinitrate solution was added to it, after which the whole mixture was allowed to stand for a day. Thereafter, extraction was carried out with 10 ml. of pyridine pre-equilibrated with a 4 M sodium hydroxide solution.

Another problem occurred in the estimation of the radioactivity of the separated radioruthenium in the pyridine and aqueous phases. In this case the pyridine contained a small amount of sodium hydroxide, which separated

TABLE I. AMOUNTS OF SODIUM HYDROXIDE WHICH CAN REMAIN IN THE ORGANIC PHASE AFTER EQUILIBRATION

Aqueous phase		Organic phase		Maximum amount of NaOH in the organic, phase, mg./ml.
2 N NaOH	10 ml.	Pyridine 10 ml.		2.3

out during the evaporation, mostly as sodium carbonate. The solidified salt affected the accuracy of the β-counting because of its self-absorption of the β-rays. However, it was proved that the effect was negligible if the sodium hydroxide in the sample pan did not exceed 0.2 mg./cm^2. Therefore, it was thought desirable to make the amount of sodium hydroxide in pyridine as small as possible. The amounts of sodium hydroxide present in pyridine after equilibration with aqueous solutions containing hydroxide and hypochlorite in various concentrations are shown in Table I. In order to minimize the amount of sodium hydroxide in the pyridine, it was attempted to put into it various diluents. Figure 4 shows the results obtained with *n*-butylacetate, toluene, benzene, xylene and *t*-amylalcohol as the diluent in the ratio by volume as indicated on the abscissa. The amount of ruthenium recovered was greatest when pyridine was used as the extracting solvent by itself, but a mixture of pyridine and *n*-butyl acetate was thought promising, even though only 93% of the ruthenium is recovered by it, because at a 1:1 volume composition it dissolved very little sodium hydroxide.

Spectrophotometric Investigation.—The absorption spectrum of the pyridine phase containing perruthenate was measured by a spectrophotometer. In this experiment a carrier ruthenium of 3.4×10^{-4} mol./l. was employed to develop the red-brownish color of the perruthenate. The wavelength-absorbancy curve of the pyridine solution, as well as the curve for pure pyridine, pre-equilibrated with 4 M

sodium hydroxide is shown in Fig. 5, which agrees well with that of perruthenate in an alkaline solution obtained by Stoner[10], by Larson and Ross[9] and by Koyama[12]. Therefore, it may be concluded that the perruthenate extracted into pyridine has the same constitution as that in the alkaline aqueous solution.

The Separation of Radioactive Ruthenium from Fission Products.—In this study of the fission products, those nuclides were considered which would account for more than one per cent of the total radioactivity after the products had been aged for one year. The nuclides which fall in this category are zirconium-niobium-95, cerium-praseodymium-144, promethium-147, strontium-yttrium-90, cesium-137-barium-137^{m}, strontium-89 and yttrium-91. Since the chemical behavior of strontium-89 and yttrium-91 are just the same as those of strontium-90 and yttrium-90 respectively, these were excluded from the scope of the present investigation. The short-lived daughters, praseodymium-144, rhodium-106 and barium-137^{m}, are not considered in this study either.

In a separating funnel 1 ml. of a nitric acid solution of the individual radioisotope, 3 ml. of a 10 M sodium hydroxide solution and 7 ml. of "Antiformin" were well mixed, kept on a water-bath at 80°C for three hours, and then kept standing for several hours. Next, 10 ml. of pyridine, which had been pre-equilibrated with 4 M sodium hydroxide, was added, and the vessel was shaken by an electric oscillator for five minutes. Then the aqueous phase was drained into another separating funnel. From the organic phase retained in the first funnel, 1 ml. of the solution was pipetted out and its radioactivity was measured. The residual organic phase was back-washed with a washing liquid consisting of 3 ml. of 10 M sodium hydroxide and 7 ml. of "Antiformin". The washing liquid was rejected, and the organic phase was pipetted out in order to measure the radioactivity. The results obtained for each nuclide are given in Table II, which shows that the radioactive ruthenium can be extracted satisfactorily into the pyridine phase. Only cesium has a tendency to migrate into the pyridine phase, since it behaves like the sodium contained as the sodium hydroxide in the pre-equilibrated pyridine. However, it can be removed from the pyridine phase by a

TABLE II. RECOVERY AND PARTITION COEFFICIENT OF INDIVIDUAL CARRIER-FREE NUCLIDE IN SOLVENT EXTRACTION WITH PYRIDINE

Nuclide	In the first org. phase %	In the first aq. phase %	Partition coefficient

single back-washing. The greater part of the last pyridine phase was evaporated under an infrared lamp, and its radioactivity was measured by a G-M counter. To make sure of the completion of the separation, γ-ray spectra were taken of the mixed fission products before the separation, of the residual aqueous phase, of the last organic phase after the extraction, and of the back-washing liquid, which might contain cesium-137 and cerium-144. These spectra are shown in Fig. 6. It is found that a satisfactory separation of ruthenium has been effected with little contamination by other fission products.

The Separation of Radioactive Ruthenium in the Presence of Ruthenium Carrier.—As has been described above, a perruthenate solution can also be prepared by dissolving metallic ruthenium in "Antiformin", and when this solution is treated with pyridine, the brownish-red color of the solution is completely transferred to the pyridine layer and the residual aqueous layer becomes colorless. The partition coefficient of ruthenium, by a preliminary experiment, was found to be 10^4 in the presence of 10 mg. of ruthenium between 10 ml. each of the organic and aqueous phases. Therefore, an experiment was carried out in a hope of getting a higher partition coefficient in the separation of radioactive ruthenium with a small amount of ruthenium carrier. In this experiment a definite amount of carrier ruthenium was added as perruthenate in "Antiformin" to the aqueous phase before the extraction. In the presence of 0.091 mg. to 2 mg. of ruthenium carrier per ml. of the aqueous phase, the results given in Table III were obtained; this table shows that the per cent extraction could be increased markedly by the presence of the carrier, but that the efficiency of the extraction is almost independent of the amounts of the carrier in this range. The per cent extraction was calculated as the ratio of the radioactivities of the two phases.

TABLE III. EXTRACTION OF RADIOACTIVE RUTHENIUM IN THE PRESENCE OF CARRIER

Ruthenium carrier taken in the initial aq. phase mg.	Ru-106 extracted in pyridine %	Ru-106 remaining in the aq. phase %	Partition coefficient
1.0	99.1	0.9	110
3.0	99.4	0.6	165
5.0	99.3	0.7	141
10.0	99.7	0.3	332

It was thought desirable to diminish the amount of pyridine employed so that less sodium hydroxide might accompany the dried ruthenium salt; some experiments were, therefore, carried out with smaller quantities of the solvent. The results are shown in Table IV, in which it can be seen that as much as 91.2% of the ruthenium present in 11 ml. of the aqueous phase could be extracted with as little as 2 ml. of pyridine, with the resulting presence of only 15 mg. of sodium hydroxide as an impurity.

TABLE IV. EXTRACTION OF RADIOACTIVE RUTHENIUM WITH SMALL VOLUME OF PYRIDINE IN THE PRESENCE OF 10 mg. RUTHENIUM CARRIER

Volume of pyridine used ml.	Volume of aq. phase ml.	Recovery of Ru-106 in pyridine %
11	11	99.7
6	11	96.6
4	11	95.5
3	11	91.1
2	11	91.2

The Separation of Technetium and Ruthenium by Pyridine Extraction.—Technetium can easily be extracted by pyridine[11] because it can exist in an alkaline solution as pertechnetate as its most stable form, but ruthenium can be extracted only when the perruthenate is in an alkaline solution with excess enough of a strong oxidizing agent; otherwise it is very unstable. This difference in chemical behavior between the elements was taken advantage of in effecting their separation.

Technetium-99 as potassium pertechnetate in a 0.1 M sodium hydroxide solution was taken by pipetting 0.5 ml. of the stock solution and mixing it well with 0.5 ml. of a solution of ruthenium-106 as nitrosylruthenium trinitrate in 3 M nitric acid in a separating funnel; then 4 ml. of 12 M sodium hydroxide was added, the total volume thus becoming 5 ml. To this solution was added 5 ml. of pyridine preequilibrated with 4 M sodium hydroxide. The funnel was shaken well for five minutes, and after the two layers had been disengaged, the lower aqueous layer was drained out through the stem into another funnel. One milliliter of the organic phase was pipetted into a counting pan and evaporated to dryness, and its radioactivity was measured by a G-M counter. Here the observed value was corrected for the self-absorption of the radioactivity by the sample. This count must be due to the technetium-99 separated by pyridine, for a Harley plot of the sample with a reference of calcium-45 agreed well with that of a pure technetium-99 within the range of permissible errors, showing its radiochemical purity to be above 99.5%. To the aqueous phase in the second separating funnel, 10 ml. of "Antiformin" and 5 ml. of pyridine were added, and

the funnel was shaken well for five minutes. In this case there was 15 ml. of the aqueous phase and only 5 ml. of the organic phase. After separating the two phases, 1 ml. of the organic layer was pipetted and its radioactivity was measured as above. This radioactivity is presumed to be due to ruthenium-106 separated into pyridine as perruthenate. As the per cent extraction of technetium in the first step could not reach 100%, but only about 94%, some residual technetium might be present in this sample. However, the energy of the β-ray of technetium-99 is so weak that it can be eliminated by an aluminum absorber of about 40 mg./cm^2, while the β-ray of ruthenium-106 has higher energy and is scarcely absorbed by the same absorber. Technetium and ruthenium can be almost completely separated by this procedure.

Summary

The present paper has described a method of separating, by liquid-liquid extraction with pyridine, radioactive ruthenium from fission products and technetium in an aqueous solution containing sodium hydroxide and hypochlorite. In the process, ruthenium in various ionic forms and various oxidation states is oxidized to perruthenate with the hypochlorite, and the perruthenate is transferred into pyridine from the aqueous solution. The partition coefficient of perruthenate was estimated for the carrier-free and the carrier-containing cases, as well as for the case where other fission products were present. Good separation of radioactive ruthenium from other fission products was achieved by this method, with a large decontamination factor. The results were examined by a γ-ray spectrum measured at each step of the extraction process.

The authors wish to express their thanks to Dr. Shigeru Ohashi and Dr. Kikuo Terada for their advice and criticism. A part of the expenses for this study was defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

*Stability Order in Metal Chelate Compounds. I. 4-Carboxy- and 4-Sulfocatechol Complexes**

By Yukito MURAKAMI, Katsuyuki NAKAMURA and Masasuke TOKUNAGA

(Received January 16, 1963)

Irving and Williams[1] collected and examined the stability data of complexes formed with bivalent metal ions of the first transition series and put forward the stability order, manganese < iron < cobalt < nickel < copper > zinc. This order has been shown to hold substantially for nitrogen-type, nitrogen-oxygen-type and oxygen-type ligands. On the other hand, it is of much interest to find a place for the bivalent zinc in the stability order ranging from bivalent manganese through bivalent copper, since the Irving-Williams order does not provide any knowledge about the stability of zinc complexes in comparison with the other transition metal complexes.

Meanwhile, Mellor and Maley demonstrated the stability order for bivalent metal chelates with salicylaldehyde[2] and ethylenediamine[3] and placed zinc between iron and cobalt in the first transition series, i. e., copper > nickel > cobalt > zinc > iron > manganese. However, the general applicability of the Mellor-Maley order has not yet been established, and the higher stability of bivalent zinc complexes than the corresponding bivalent cobalt complexes has been frequently observed. It seems, therefore, that the stability of a zinc complex is quite dependent on the ligand properties and the character of the resulting coordinate bonds. In this connection, the catechol derivatives were selected in this investigation as ligands for the first transition metals as well as for

alkaline earth metals, and the stability order was studied.

Experimental

Materials.—The bivalent metal nitrates, $Zn(NO_3)_2 \cdot 6H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Co(NO_3)_2 \cdot 6H_2O$, $Mg(NO_3)_2 \cdot 6H_2O$, $Ca(NO_3)_2 \cdot 4H_2O$ and $Sr(NO_3)_2$, and manganese sulfate, $MnSO_4 \cdot nH_2O$, are analytical reagents produced by the Wako Pure Chemical Industries, Ltd.

Reagent grade catechol of the Wako Pure Chemical Industries, Ltd. was purified by means of repeated recrystallization from benzene. Dotite Tiron (analytical grade) was used without further purification.

Preparation of Ligands.—*4-Carboxycatechol (Protocatechuic Acid).*—This catechol derivative was prepared from vaniline following the standard method reported by Pearl and Beyer[4] and was recrystallized from water. M. p. found, 203~204°C; reported, 199~200°C[4].

Found: C, 54.48; H, 4.00. Calcd. for $C_7H_6O_4$: C, 54.55; H, 3.92%.

Potassium Catechol-4-sulfonate.—This material was synthesized by the sulfonation of catechol[5] and was recrystallized from water as white platelets.

Found: C, 31.58; H, 2.39; K, 16.91. Calcd. for $C_6H_5O_5SK$: C, 31.57; H, 2.21; K, 17.13%.

Reagent Solutions.—Aqueous stock solutions of metal ions were standardized by the usual procedures of chelatometric titration[6]. Aqueous stock solutions of all the ligands were standardized by potentiometric titration with a standard base.

Potentiometric Measurements.—The apparatus and procedures for potentiometric titrations have been mentioned elsewhere[7].

Spectral Measurements.—The infrared spectra were measured by the KBr disk method with a Koken model DS-301 spectrophotometer equipped with sodium chloride optics.

Mathematical Treatment

Acid Dissociation Constants.—The equilibria and the dissociation constants involved in the dissociation process of catechol protons are:

$$H_2L \rightleftharpoons HL^- + H^+ \quad K_{H,L}=\frac{[HL^-]\,[H^+]}{[H_2L]} \tag{1}$$

$$HL^- \rightleftharpoons L^{2-} + H^+ \quad K_{HL}=\frac{[L^{2-}]\,[H^+]}{[HL^-]} \tag{2}$$

If T_L represents the total concentration of ligand species and T_{OH} represents the total concentration of base added to the system, the following stoichiometric relations may hold:

$$T_L=[H_2L]+[HL^-]+[L^{2-}] \tag{3}$$

$$T_{OH}+[H^+]-[OH^-]=[HL^-]+2[L^{2-}] \tag{4}$$

Combination of Eqs. 1 through 4 results in:

$$1/K_{H\,L}=A\,K_{HL}+B \tag{5}$$

where

$$A=\frac{\{2T_L-T_{OH}-[H^+]+[OH^-]\}}{\{T_{OH}+[H^+]-[OH^-]\}[H^+]^2}$$

$$B=\frac{\{T_L-T_{OH}-[H^+]+[OH^-]\}}{\{T_{OH}+[H^+]-[OH^-]\}[H^+]}$$

Thus, when $1/K_{H_2L}$ is plotted graphically as a function of K_{HL} with values of A and B corresponding to experimental values of T_L, T_{OH}, and $[H^+]$, straight lines obtained from a number of experimental points are found to intersect at one point, which represents the simultaneous solution of K_{H_2L} and K_{HL} for the dibasic acid.

Chelate Stability Constants.—If the pH value of the system is maintained in an appropriate range so that the metal chelates formed are the 1:1 (ligand to metal) and the 2:1 chelates in significant concentrations, the equilibria involved in metal chelate formation may be expressed as:

$$M^{2+}+L^{2-} \rightleftharpoons ML \quad K_1=\frac{[ML]}{[M^{2+}]\,[L^{2-}]} \tag{6}$$

$$ML+L^{2-} \rightleftharpoons ML_2^{2-} \quad K_2=\frac{[ML_2^{2-}]}{[ML]\,[L^{2-}]} \tag{7}$$

The stoichiometric relationships involved in this system are represented as:

$$T_M=[M^{2+}]+[ML]+[ML_2^{2-}] \tag{8}$$

$$T_L=[H_2L]+[HL^-]+[L^{2-}]+[ML]+2[ML_2^{2-}] \tag{9}$$

$$T_{OH}+[H^+]-[OH^-]=[HL]+2[L^{2-}]+2[ML]+4[ML_2^{2-}] \tag{10}$$

where T_M indicates the total concentration of all the metal species. Equations 6 through 10 may by combined to give an equation for the evaluation of K_1 and K_2:

$$(F-1)K_1[L^{2-}]+(2F-1)K_1K_2[L^{2-}]^2=1 \tag{11}$$

where

$$F=T_M/\{T_L-[H_2L]-[HL^-]-[L^{2-}]\}$$

and

$$[L^{2-}]=\frac{\{2T_L-T_{OH}-[H^+]+[OH^-]\}K_{H_2L}K_{HL}}{\{2[H^+]^2+[H^+]K_{H_2L}\}}$$

Therefore, K_1 may be plotted as a function of K_1K_2, and one straight line may be drawn for each experimental point on the titration curve; the lines thus obtained are to intersect at one point if the metal chelate formations expressed by Eqs. 6 and 7 predominantly hold in the system. This method of evaluation is quite

7) Y. Murakami, This Bulletin, **35**, 52 (1962).

similar to those mentioned for the determination of acid dissociation constants in the preceding section and for chelate stability constants elsewhere[7], and the intersect of the family of straight lines may provide the chelate stability constants, K_1 and K_2.

When more than three moles of ligand per gram-ion of metal are added to the titrating system and when an appropriate pH range is selected, the 3:1 (ligand to metal) chelate may be formed in a significant concentration, depending upon the coordination ability of the metal ion. Under such conditions, it was found in this investigation that reaction 6 was nearly completed and that reactions 7 and 12 are to be taken into consideration.

$$ML_2^{2-} + L^{2-} \rightleftarrows ML_3^{4-} \quad K_3 = \frac{[ML_3^{4-}]}{[ML_2^{2-}]\,[L^{2-}]} \qquad (12)$$

Then, an adequately modified form of Eq. 11 may be employed for the evaluation of the third stability constant, K_3.

Results and Discussion

Acid Dissociation Constants.—As the electron-withdrawing effect of a substituent group or groups in the catechol derivatives decreases in the order: Tiron, catechol-4-sulfonate, 4-carboxycatechol, catechol, an inflection region for the neutralization of the first catechol proton in their potentiometric titration curves becomes increasingly insignificant. Thus, the first and the second dissociation processes for Tiron do not overlap each other to any significant extent. On the other hand, those processes for catechol do overlap to a great extent, so the inflection region was not noticed.

A carboxy proton of 4-carboxycatechol is very acidic in comparison with other catechol protons, so the first dissociation process was separated clearly from the others in this case.

The acid dissociation constants of the catechol derivatives other than Tiron were calculated with the aid of Eq. 5 and are summarized in Table I.

Table I. Acid dissociation constants of the catechol derivatives

30±0.1°C, μ=0.10 M (KNO_3)

Ligand	pK_{H_3L}	pK_{H_2L}	pK_{HL}
Catechol		9.13	11.59
4-Carboxycatechol	4.38	8.67	11.94
Catechol-4-sulfonate		8.26	12.16
Tiron		7.54	12.26

It is of interest to consider the effect of electron-withdrawing substituents on the dissociation process of catechol protons among these four catechols. The two processes are

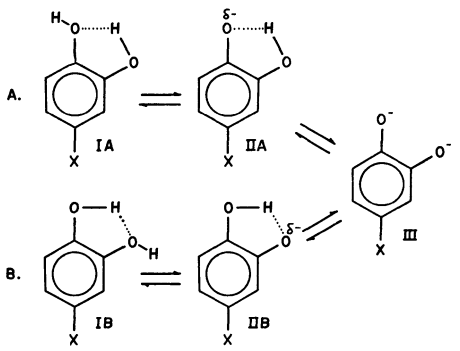

Chart 1. Dissociation processes of catechol-protons.

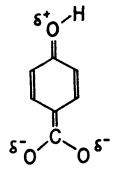
conceivable in this case, as is shown in Chart 1. A sulfonate and a carboxylate substituent in the benzene ring introduce a pronounced electron-withdrawing effect at their para position. For example, a dissociation constant of the phenol proton of hydroxybenzoic acid has a very close connection with the position of a carboxy group, as may be seen in Table II[8].

Table II. Acid dissociation constants of phenol derivatives[8]

20°C, μ=0.1 M

Acid	pK_{H_2A}	pK_{HA}
Phenol		9.80
m-Hydroxybenzoic acid	3.96	9.61
p-Hydroxybenzoic acid	4.36	8.985

The carboxylate group transmits its strong electronic effect to its para position in the benzene ring through such resonance interaction as is indicated by structure IV, while this



IV

group shows only a weak inductive effect at its meta position, as may be understood from the data in Table II.

As the pK_{HL} values in Table I indicate, the intramolecular hydrogen bond is strengthened as a ligand varies from catechol to Tiron in the order shown in the table. Because of the electrostatic nature of hydrogen bonding, the electrostatic potential ought to be increased in order to raise the strength of bonding. X being an electron-withdrawing group, an intramolecular hydrogen bond in IIA should be weakened

8) A. V. Willi and J. F. Stocker, *Helv. Chim. Acta*, **38**, 1279 (1955).

in comparison with catechol itself. This is, however, contrary to what is observed in this work. Therefore, IIB must be taken instead as a more favorable structure. As a result, process B in Chart 1 may be employed to elucidate the dissociation steps of the catechol protons. Meanwhile, the OH stretching vibrations involved in inter- and intramolecular hydrogen bonds were assigned, as Table III shows. The tendency of the OH frequency shift is in agreement with the change in pK_{HL} value except in the case of Tiron. The reason for the unexpected frequency shift in Tiron is not quite obvious at this moment.

Interaction of Metal Ions with 4-Carboxycatechol. — Titration curves are illustrated in Fig. 1 for the 4-carboxycatechol chelates of magnesium(II), manganese(II), cobalt(II), nickel(II), copper(II) and zinc(II) for a 2:1 ratio of ligand to metal ion. The titration curve for the calcium(II) chelate is not shown in the figure because higher concentrations of ligand and metal ion were employed. The drifting behavior of the pH value was noticed for the manganese(II) chelate system during the measurement in the region of $-\log[H^+]$ value ranging from 7.2 to 8.1. A similar phenomenon was observed for the manganese(II) kojate chelate system[7].

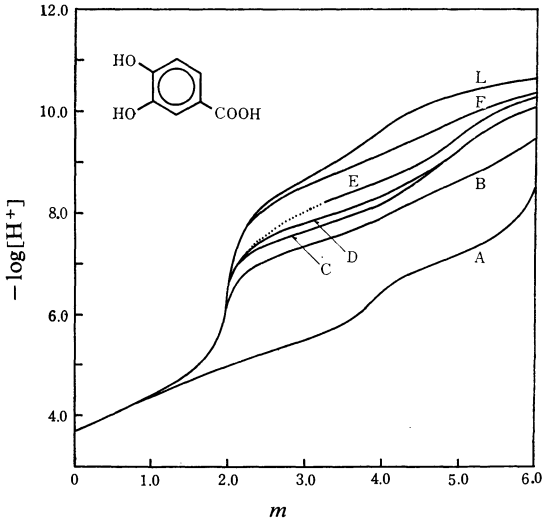

Fig. 1. Potentiometric titration of divalent metal chelates of 4-carboxycatechol in 0.10 M KNO_3 at 30°C, with 2:1 molar ratio of ligand to metal ion: A, Cu; B, Zn; C, Ni; D, Co; E, Mn; F, Mg; L, ligand alone; $T_M = 5.01 \times 10^{-4}$ M; m=moles of base added per gram-ion of metal. Dotted line indicates non-equilibrated region.

Potentiometric titrations for the 1:1 ratio of ligand to metal ion for calcium(II), magnesium(II), cobalt(II), nickel(II), copper(II), and zinc(II) were also performed at the same ligand concentration. Precipitations were found at the end of the titrations of the cobalt(II), nickel(II) and zinc(II) chelate systems where all the protons of the catechols were nearly neutralized. These precipitations were probably caused either by disproportionation to the corresponding 2:1 chelate and metal hydroxide or by further hydrolysis reactions of the 1:1 chelate. The addition of a base to the copper(II) chelate system resulted in neither drifting of the pH values nor precipitation in the range of m values of up to 3.1 ($-\log[H^+] \approx 7.5$). This phenomenon is ascribed to the profound stability of the copper(II) chelate; this chelate could not undergo disproportionation reaction with the ease of other metal chelates.

In the case where more than two moles of ligand were present per gram-ion of metal, no precipitation was observed over the whole pH range of the titration.

As may be seen in Fig. 1, no obvious depression of pH was observed in the lower buffer region (m=0~2.0), where the dissociation of a carboxy proton occurs predominantly, while only the titration curve of the copper(II) chelate system demonstrates such a depression to some extent in the last part of this region. On the basis of these experimental facts, no appreciable chelation was expected in such a pH region expect for the copper(II) chelate system, and the carboxy group was not involved in complex formation with metal ions. It is also obvious from Fig. 1 that stability with respect to the metal ions increases in the order: magnesium(II) < manganese(II) < cobalt(II) ~ nickel(II) < zinc(II) < copper(II). A small inflection at m=4 corresponding to the formation of the 1:1 chelate species and a rather steep inflection at m=6, which corresponds to the formation of the 2:1 chelate species, were observed only for the copper(II) system. The absence of such an inflection at m=4 suggests an appreciable overlapping of the two reactions producing the 1:1 and the 2:1 chelale species.

TABLE IV. STABILITY CONSTANTS OF THE METAL CHELATES OF CATECHOL DERIVATIVES

$30\pm0.1°C$, $\mu=0.10$ M (KNO_3)

Ligand	Catechol		4-Carboxycatechol			Catechol-4-sulfonate			Tiron	
	$\log K_1$	$\log K_2$	$\log K_1$	$\log K_2$	$\log K_3$	$\log K_1$	$\log K_2$	$\log K_3$	$\log K_1$	$\log K_2$
Zn(II)	8.46	6.78	8.91	6.71		9.40	7.20		10.19	8.33

Sr(II)						3.61	—			

Interaction of Metal Ions With Catechol-4-sulfonate.—In Fig. 2 are shown titration curves for solutions containing a 2:1 ratio of ligand to metal ion. The metal ions employed in these measurements were strontium(II), calcium(II), magnesium(II), manganese(II), cobalt(II), nickel(II), copper(II) and zinc(II). No precipitates were observed throughout those titrations where ligand concentration exceeded two moles per gram-ion of metal. A drifting of the pH reading was also realized in the titration of the manganese(II) chelate system in the lower pH region ($-\log[H^+]<8.2$). The stability order is obviously understood from these titration curves and arranged in the increasing order as: calcium(II) < magnesium(II) < cobalt(II) ~ nickel(II) < zinc(II) < copper(II). Again, a titration curve for the copper(II) system exhibits a significant inflection at $m=2$ and a steep one at $m=4$, corresponding to the formation of the 1:1 and 2:1 chelates respectively.

In titrations of solutions containing a 1:1 ratio of ligand to metal ion, pH drifting was observed to start for the transition metal chelate systems in the region where nearly all the catechol protons were neutralized ($m>1.8$ in most cases). This drifting may be ascribed either to disproportionation to the 2:1 chelate and metal hydroxide or to the hydrolysis reaction of the 1:1 chelate in the same manner as has been mentioned for the 4-carboxycatechol chelates.

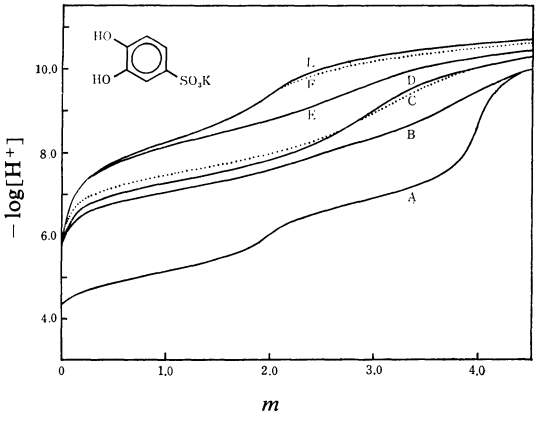

Fig. 2. Potentiometric titration of bivalent metal chelates of catechol-4-sulfonate in 0.10 M KNO_3 at 30°C, with 2:1 molar ratio of ligand to metal ion: A, Cu; B, Zn; C, Co; D, Ni; E, Mg; F, Ca; L, ligand alone; $T_M=5.00\times10^{-4}$ M; m=moles of base added per gram-ion of metal.

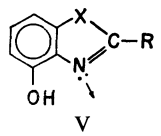
Stability Constants.—The stabilty constants for the metal chelate compounds with catechol and its derivatives as ligands have been calculated by the aid of Eq. 11 and its modified forms. The constants thus estimated are listed in Table IV.

For the bivalent transition metal series, the stability order for the metal chelates with 4-carboxycatechol and catechol-4-sulfonate follows the sequence: manganese < cobalt ~ nichel < zinc < copper. The stability order, nickel(II) < zinc(II), seems to be rather unusual. This order has, however, been found occasionally in the literature in the past and may be ascribed to the following two main effects involved in chelation:

Structural Effects.—In most instances where the stability of metal chelates follows the sequence, nickel(II) > zinc(II), a lone pair of valence electrons in a donor atom is directed toward the metal ion, with which coordination is performed, thus forming a stable coordinate bond. However, the perturbation effect may be introduced if such a lone pair is located in a direction unfavorable for a coordinate bond formation, in which case the above sequence is reversed (zinc(II) > nickel(II)). In such a case the ionic size of the metal ion seems to be another factor controlling the stability order. 4-Hydroxybenzimidazole and its analogous compounds (V)[9] may be taken as ligands to elucidate this effect.

9) T. J. Lane, C. S. C., A. Sam and A. J. Kandathil, *J. Am. Chem. Soc.*, **82**, 4462 (1960); T. J. Lane, C. S. C. and A. Sam, ibid., **83**, 2223 (1961).



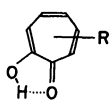
X=NH, O, S

V

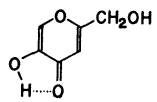
A lone pair of the donor nitrogen atoms in this case seems to have the greatest angular distribution toward external direction with respect to the coordinate bond. As a result this electron pair would have less overlapping with the bonding atomic orbital of a metal ion of smaller size.

Electronic Effects.—The stability of a metal chelate compound is certainly dependent on the electronic state of the donor atom. Thus, when a sulfur atom is involved in chelate ring formation as a donor atom, the stability is in favor of zinc chelates. For example, mercaptoacetic acid[10] and mercaptosuccinic acid[11] yielded the corresponding zinc chelates which were more stable than those of nickel.

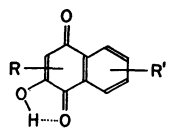
Even if the ligand species are limited to the nitrogen type, the oxygen type and the nitrogen-oxygen type, such a reversed order of stability for zinc and nickel chelates has been observed. However, such examples are found quite rarely to the best knowledge of the present authors. Tropolones (VI)[12] and kojic acid (VII)[13], as well as 2-hydroxynaphthoquinones (VIII)[13], were observed to form zinc



VI



VII



VIII

chelates with a favorable stability. It is of much interest to find that all these ligand species accommodate the same chelating site, as is shown by structure IX:

IX

The electronic configuration of whole ligand molecule and of the central ion, in addition to the electron delocalization effect through the coordinate bond formation, may come into play in these cases to control the stability of metal chelates thus produced.

13) H. Kido, W. C. Fernelius and C. G. Haas, Jr., *Anal. Chim. Acta*, **23**, 116 (1960).

The unusally high stability of zinc chelates in comparison with that of nickel chelates formed with 4-carboxy- and 4-sulfocatechol as well as with Tiron[12] must be associated to some extent with the electron delocalization through the interaction among zinc 3d orbitals, oxygen-orbitals not involved in σ-bonding, and π orbitals of the benzene ring. The configuration of these orbitals is depicted in Fig. 3.

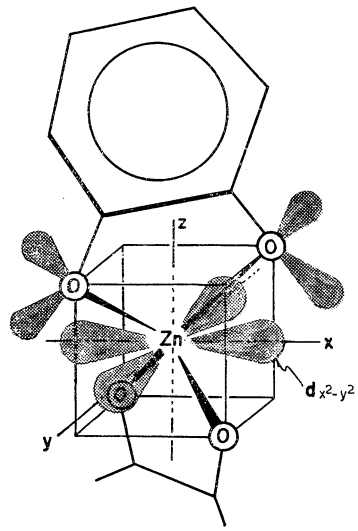

Fig. 3. Probable structure of the Zn(II)-catechol chelate with indication of metal d orbital and lone pair orbitals of oxygens.

The linear relationship between the basicity of the donor group (pK_{HL}) and the chelate stability (log K_n) has been found to hold in a large portion of the literature reported so far. Thus, the weaker the acidity of the donor group, the more stable the chelate compound would be. In this investigation the stability constants for copper(II) and zinc(II) chelates with the four catechols were obtained, as is shown in Table IV. These data obviously prove the parallel relationship between the ligand basicity and the stability constant in agreement with the past observation only if the second pK value (pK_{HL}) is taken. In the opinion of the present authors, the basicity of both hydroxy groups in the ligand molecule should be taken into consideration, since both groups are involved in chelate ring formation. The value of ($pK_{H_2L}+pK_{HL}$), as a measure of ligand basicity, decreases in the order:

Catechol > 4-carboxycatechol > catechol-4-sulfonate > Tiron.

The stability order, however, is antiparallel to this order and is found in the sequence:

Tiron > catechol-4-sulfonate > 4-carboxycatechol > catechol.

In spite of the fact that the second catechol proton is involved in the intramolecular hydrogen bonding, the catechol group (two phenolate groups) certainly lowers its electron density as the 4-substituent group demonstrates a greater electron-withdrawing effect, thus indicating less basicity. The relationship between ligand basicity and chelate stability found in this study is certainly due to ligand nature. It seems that these ligand molecules introduced a more covalent character to the coordinate bonds, and that the resonance contribution of the substituent group made electron delocalization through the coordinate bonds more effective.

For alkaline earth metal ions, no peculiar stability order was observed in this work, and these chelates demonstrate much less stability than the corresponding transition metal chelates, as is shown in Table IV. The stability order, magnesium(II) > calcium(II) > strontium(II), is parallel to the reciprocal of the ionic size of the metal ions.

Meanwhile, the formation of such a hydrogen complex as MHL was noticed in this investigation in the region of relatively low pH value, as has also been observed elsewhere for the Tiron chelates in an aqueous system[12]. A thorough investigation on this behavior has not yet been carried out. Investigations with other catechol derivatives, containing various 4-substituent groups, are under progress in these laboratories.

Summary

The stability constants of 4-carboxy- and 4-sulfocatechol chelates with bivalent transition metals and alkaline earth metals have been evaluated in aqueous media at 30.0±0.1°C and 0.10 M of ionic strength. The stability orders, manganese < cobalt ~ nickel < zinc < copper for transition metal chelates and strontium < calcium < magnesium for alkaline earth metal chelates, have been found to hold in these catechol chelate systems. A unique stability sequence, nickel < zinc, has been discussed in terms of the electron delocalization effect, in which metal d orbitals, lone pair orbitals of catechol oxygens and π orbitals of the benzene ring are involved. A reverse relationship for ligand basicity and chelate stability was observed for copper(II) and zinc(II) chelates, and the stability of metal chelates was found to increase in the sequence; catechol < 4-carboxycatechol < catechol-4-sulfonate < Tiron. Substituent groups were considered to play an important role in this case.

Studies of the Drawing of Polyamide Fibers. II. The Drawing of Heat-treated Nylon Monofilaments

By Hiroshi HATTORI and Yasuo TAKAGI

(Received January 22, 1963)

In a previous paper, the present authors reported that the tensile strength of nylon 6 filament showed a minimum value at a draw ratio near 2 and that, therefore, the structure seemed to become unstable at the intermediate stage of drawing[1]. For this paper, the authors have investigated the dependences on the draw ratio of some physical properties of nylon monofilaments drawn to various draw ratios after they had been heat-treated at various temperatures from 90 to 180°C; this has been undertaken in order to investigate how the change in the structure, especially the crystallinity, of an undrawn sample influences the behavior of the drawing. Althogh the effect of the heat-treating temperature of the undrawn nylon filament on the load-elongation curve has been studied by Yumoto[2], the change in the physical properties during the drawing of heat-treated samples has not yet been studied.

Experimental

Samples.—The undrawn nlyon monofilament (about 1300 denier), prepared under the same

1) H. Hattori, Y. Takagi and T. Kawaguchi, This Bulletin, **35**, 1163 (1962).

2) H. Yumoto, ibid., **29**, 353 (1956).

conditions as that in the previous paper[1], was heat-treated, more than a week after it had been meltspun, at the temperatures of 90, 110, 114, 150, 160, 170 and 180°C, in an air-bath for 30 sec. Each heat-treated undrawn sample was drawn in water of 90°C, at the feeding speed of 5 m./min.

Measurement. — Various physical properties (strength, shrinkage in boiling water, specific gravity and birefringence) of these variously-drawn samples were measured under the same conditions as those in the previous paper[1].

Results and Discussion

Tensile Strength.—If the decrease in strength observed near the draw ratio of 2 is caused by the flow phenomenon, which is called "super drawing", the decrease in strength will stop, because heat-treatment strengthens the interaction between the polymer molecules and, therefore, it becomes more difficult for the flow during drawing to occur. The experimental results, shown in Fig. 1, indicate that

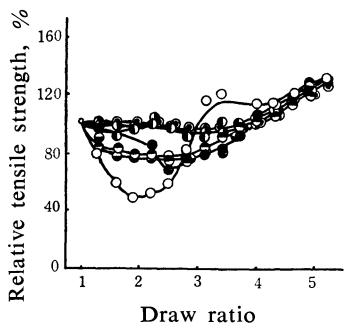

Fig. 1. Dependence of thensile strength on draw ratio.
○, Drawn immediately after spinning
●, Drawn many days after spinning
◓, Drawn after being heat-treated at 90°C
◒, Drawn after being heat-treated at 110°C
◐, Drawn after being heat-treated at 150°C
◑, Drawn after being heat-treated at 160°C
⊙, Drawn after being heat-treated at 170°C

the higher the heat-treating temperature, the less the decrease in strength at the minimum. Though a minimum point was observed near the draw ratio of 2 in the draw ratio-strength curve when the heat-treating temperature is below 110°C, no minimum point was observed when the heat-treating temperature was above 150°C. This fact suggests that the flow occurs during the drawing, and it can be one of the reasons for the minimum strength observed on the drawing of the less crystalline sample, but it seems unsatisfactory to explain this fact completely in terms of flow phenomenon, because even in case of samples which have no minimum in the draw ratio-strength curves, the strength does not increase but is kept nearly constant until it increases with the draw ratio from the ratio of 3~3.5.

Birefringence.—It is thought that the degree of molecular orientation due to the drawing will be lower when the flow occurs during the drawing than when it does not occur. Therefore, the degree of flow can be roughly estimated by comparing the draw ratio-birefringence curves. In the previous paper. the authors noticed the difference observed between the draw ratio-birefringence curve of samples drawn immediately after spinning (I) and that of samples drawn many days after spinning (II). For this paper, we have also compared the curves of samples drawn after the heat-treatment at various temperatures. The results are shown in Fig. 2. All curves,

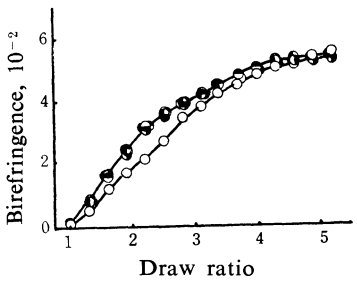

Fig. 2. Dependence of birefringence on draw ratio.

◑, Drawn after being heat-treated at 170°C

except the curve for the samples of group I quite overlap with each other, regardless of whether the minimum strength was observed or not. In consideration of the fact, it is obvious that the phenomenon of minimum strength observed in certain samples is due not only to the flow but also to some other reasons. It is thought that, even if the apparent degree of orientation is equal, the change in internal structure depends on the structure of the undrawn sample and that the difference in the change among heat-treated samples appears most remarkably at the draw ratio near 2, where the polymer structure becomes most unstable.

Shrinkage in Boiling Water.—In the previous part of this paper, the authors chiefly discussed the influence of the heat-treatment of an undrawn sample on the change of strength with the draw ratio, but it is thought that strength data are not precise or reliable

enough to be discussed in detail. From this point of view, the data of shrinkage in boiling water seem to be better as the basis for a discussion of the change of structure during drawing.

The shrinkage in boiling water of heat-treated samples, shown in Fig. 3, changed very peculiarly with the heat-treating temperature and draw ratio. In the case of samples drawn after heat-treatment, the degree of shrinkage rapidly increased in the initial stage of drawing, passed a maximum, and then decreased as the draw ratio increased. At the extreme draw ratio, the degree of shrinkage for all the

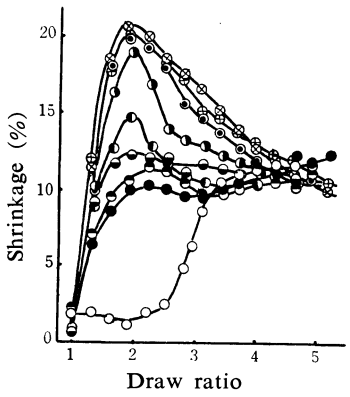

Fig 3. Dependence of shrinkage in boiling water on draw ratio.

●, Drawn many days after apinning
◓, Drawn after being heat-treated at 90°C
◒, Drawn after being heat-treated at 110°C
◐, Drawn after being heat-treated at 114°C
◑, Drawn after being heat-treated at 150°C
⊙, Drawn after being heat-treated at 160°C
⊗, Drawn after being heat-treated at 170°C
⊕, Drawn after being heat-treated at 180°C

samples seems to converge to the same value, regardless of the heat-treating condition. The maximum value always appeared near the draw ratio of 2 and increased as the heat-treating temperature of the undrawn sample was raised. It seems very important that the maximum point always appears at a draw ratio near 2. This implies that the internal structure of a nearly 100% drawn sample becomes most unstable and that some unknown change in the drawing mechanism occurs at a draw ratio near 2.

It is known that polyethylene terephthalate fiber also shows a maximum of heat-shrinkage near this draw ratio, but the mechanism seems quite different in polyethylene terephthalate and in nylon; in the former case[3], the undrawn polymer is almost perfectly amorphous and becomes partially crystalline when it is drawn, while in the latter case the higher the crystallinity of the undrawn polymer, the more remarkable the maximum of heat-shrinkage and the decrease of crystallinity due to drawing.

Though some possible reasons will be considered later in further detail, it is natural to think that the polymer structure becomes most unstable when the shrinkage is at its maximum.

Specific Gravity.—The change in specific gravity with the draw ratio is shown in Fig. 4. The specific gravity of a untreated sample or of a sample which had beed heat-treated at a lower temperature increased with the draw ratio, while that of a sample which had been heat-treated at a higher temperature decreased with the draw ratio. This fact indicates that when the crystallinity of an undrawn sample is low, it is increased by orientation, but when it is rather high, the orientation-induced crystallization is exceeded by the decrease of crystallinity due to the rupture of crystallites during drawing.

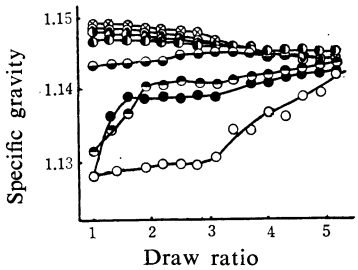

Fig. 4. Dependence of specific gravity on draw ratio.
○, Drawn immediately after spinnirg
●, Drawn many days after spinning
◓, Drawn after being heat-treated at 90°C
◒, Drawn after being heat-treated at 110°C
◐, Drawn after being heat-treated at 150°C
◑, Drawn after being heat-treated at 160°C
⊙, Drawn after being heat-treated at 170°C
⊗, Drawn after being heat-treated at 180°C

Similarly to such properties as strength and shrinkage in boiling water, specific gravity seems to converge to the same value at the extreme draw ratio, regardless of the kind of sample.

Therefore, we can deduce that the structure of highly-oriented nylon filaments is same, whether the crystallinity of an undrawn sample is low or high.

Further Discussion of the Change of Structure with the Drawing.—From the results mentioned above, especially of the shrinkage in boiling water, we believe that there is a certain difference between the mechanism of drawing

3) T. Kawaguchi, unpublished.

in the initial stage (of a lower draw ratio) and that in the later stage of drawing (of a higher draw ratio); in the former, the unstabilization of the polymer structure is predominant, while in the latter a stable structure of drawn polymer is constructed. In other words, a mechanism of drawing is proposed that consists of the unstabilization and stabilization of the polymer by orientation. The former is predominant in the initial stage of drawing, while the latter is predominant in the later stage of drawing.

Therefore, let us further discuss the results of shrinkage in boiling water, because the effect of heat-treatment is most pronounced in these results. It is considered that heat-shrinkage occurs because molecules become more labile upon a rise in the temperature and move in such a direction that the latent strain in the polymer is eliminated; the shrinkage is, then, a measure of the internal strain of polymer. Therefore, it is thought that the internal structure becomes most unstable when the heat-shrinkage becomes greatest.

In the case of ployethylene terephthalate fiber[3], the plot of heat-shrinkage against specific gravity falls on a single curve, in which the shrinkage decreases as the crystallinity increases, regardless of the condition of drawing. This fact implies that the orientation is fixed by the crystallization which occurred during the drawing. In case of nylon, however, this is not true, because the curve of shrinkage in boiling water against specific gravity, as shown in Fig. 5, depends on the heat-treating temperature of the undrawn sample. These facts indicate that, in addition to the degree of orientation and the crystallinity, some unknown factors contribute to the appearance of a maximum near the draw ratio of 2 in the draw ratio-shrinkage curve.

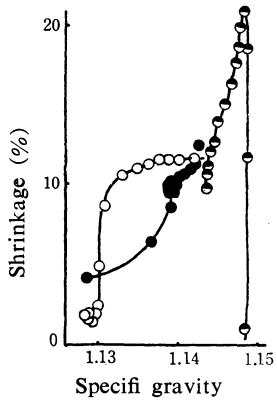

Fig. 5. Relation between specific gravity and shrinkage in boiling water.
○, Drawn immediately after spinning
●, Drawn many days after spinning
◓, Drawn after being heat-treated at 170°C

The curve of shrinkage against the heat-treating temperature of undrawm sample shown in Fig. 6 has an inflection near the temperature of 120°C. According to Yumoto[2], this temperature is a kind of transition, because inflection points are observed near this temperature in the curves of both specific gravity and yield load in the load-extension curve against the heat-treating temperature of undrawn nylon 6 filament. The heat-treating of undrawn nylon filament at a temperature above 120°C seems to tighten its structure much more than treating below this temperature. Therefore, the maximum value of shrinkage in boiling water is thought to be qualitatively proportional to the tightness of the structure of an undrawn filament.

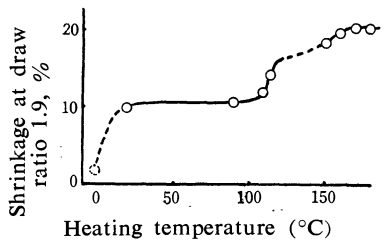

Fig. 6. Relation between heat-treating temperature and the shrinkage at the draw ratio of 1.9.

Now we will discuss the change in shrinkage in connection with that of specific gravity. When the crystallinity of an undrawn sample is low, its specific gravity increases with the draw ratio, but when the crystallinity of an undrawn sample is high, its specific gravity decreases as the draw ratio increases and a maximum of shrinkage is observed. Therefore, it is suggested that a transition from crystalline parts to amorphous parts occurs because of the destruction of crystallites during drawing as well as of a reverse transition owing to strain-induced crystallization, and that the higher the crystallinity of an undrawn sample, the more the destruction of crystallites and the acccumulation of internal strain, as a result of which the shrinkage in boiling water shows a maximum near the draw ratio of 2, where the structure becomes most unstable, though the authors cannot completely explain why it becomes most unstable.

In the case of isotactic polypropylene monofilaments which had been quenched and drawn to various draw ratios, a similar relationship to that of heat-treated and drawn nylon monofilament was also observed between the draw

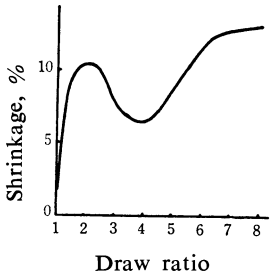

Fig. 7. Change of shrinkage in boiling water of polypropylene monofilament with draw ratio.

ratio and shrinkage in boiling water; that is, a maximum of shrinkage appeared at a draw ratio near 2 (Fig. 7). This phenomenon to seems to be due to the same reason as that for nylon 6, because the crystallinity of undrawn polypropyrene is thought to be rather high even when it is quenched.

Conclusion

Some physical properties have been measured on nylon monofilaments which had been drawn to various draw ratios after the heat-treatment of undrawn samples at various temperatures. The authors found that the shrinkage of a sample in boiling water changes very peculiarly with the draw ratio, showing a maximum, and suggested that the polymer structure becomes, unstable in the intermediate stage of drawing, though no satisfactory explanation of the unstabilization effect has been given. Further effort will be made to make sure of the "unstabilization" during drawing and to elucidate the mechanism of the drawing.

Summary

In order to investigate the influence of the structure of an undrawn sample on the change in physical properties upon drawing, undrawn nylon monofilaments were drawn to various draw ratios after having been heat-treated at several temperatures; some properties, such as tensile strength, shrinkage in boiling water and specific gravity, were then measured on these drawn samples. Although the minimum of tensile strength observed at the draw ratio near 2 had a tendency to disappear upon the heat-treatment of an undrawn sample, the strength did not increase in the range of a low draw ratio. When an undrawn sample was heat-treated above 150°C, a maximum appeared at a draw ratio near 2 in the plot of shrinkage in boiling water against the draw ratio. The higher the heat-treating temperature of an undrawn sample, the greater the maximum of shrinkage. The specific gravity decreased during drawing when the undrawn sample was of a rather high crystallinity, but it increased when the undrawn sample was of a low crystallinity. These results have been discussed, and it has been suggested that the polymer structure becomes most unstable at the intermediate stage of drawing.

The authors wish to express their gratitude to Dr. Haruo Kobayashi, the manager of the research department of Toyo Rayon Company, for permitting them to contribute this paper to this journal.

Spectrochemical Study of Microscopic Crystals. XXIII[1]. *The Structure and Light Absorption of Red Cupric Complexes with Succinimide*[2]

By Shoichiro YAMADA and Seiko MIKI

(Received February 1, 1963)

Succinimide readily loses a proton and is combined, in the anionic form, with various metal ions. There have been reported a number of cupric compounds with succinimidate anions, which are red or violet in the solid state and many of which change their color from red in the crystalline state to deep-blue in some solvents. On one hand, the formation of the red compounds of copper(II) is interesting, since it is well known that most quadri-co-ordinate cupric complexes are blue, green or violet; red cupric complexes, therefore, are

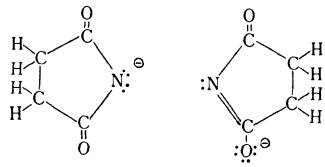

Fig. 1. Succinimidate ion.

rather unusual examples. On the other hand, the color change from the solid to the solution, as observed with these complexes, is so remarkable that the study of this phenomenon is thought to be interesting from the viewpoint of the co-ordination chemistry of cupric complexes. The present work was undertaken both in order to elucidate the structure of these and relevant compounds and in order to discuss the origin of the red color of the cupric compounds in terms of the stereochemistry and bonding involved.

Experimental

Materials.—Bis(succinimidato)diammine-copper-(II) was obtained as pink crystals from copper powder, succinimide and aqueous ammonia by the method of Tschugaeff[3], using ethanol as a solvent. The compound is insoluble in organic solvents.

Bis(succinimidato)bis(alkylamine)-copper(II) complexes with methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl and *n*-amyl amines, which had also been reported previously by Tschugaeff, were prepared as pink crystals according to the directions in the original report. Purification of the compounds was carried out by recrystallization from ethanol containing an excess amount of the free amines, as had also been reported in a previous paper[3].

All these compounds have the formula of Cu·(*sucim*)$_2$(amine)$_2$, except for the compound with ethyl amine, which contains two water molecules of crystallization[4]. The crystals are stable in the air at room temperature when completely free from the solvent. The crystals are not stable in water, methanol, ethanol, dioxan or pyridine. It has been found in the present work that the red crystals of the compounds are soluble and stable enough in non-co-ordinating solvents, such as chloroform, methylene chloride and benzene, to form a dark-blue solution; an exception is the compound with methyl amine, which is readily soluble in chloroform but sparingly soluble in methylene chloride and benzene. The stability of the red complexes seems to increase as the chain of the alkyl group becomes longer.

Potassium tetrakis(succinimidato)copper(II) hexahydrate was prepared as pink crystals according to the method of Tschugaeff[5].

The sample of bis(*N*,*N*-diethylethylenediamine)-copper(II) perchlorate, which is colored pink in the crystalline state and deep-blue in an aqueous solution, was kindly supplied by Dr. Hisao Ito of the medical department, to whom the present authors are grateful.

Measurements.—The dichroism in the visible and ultraviolet regions was determined by Tsuchida and Kobayashi's microscopic method[6] using polarized light on the well-developed faces, which are shown in the figures. The ultraviolet absorption spectra of the compounds in solution were determined with a Beckman DU spectrophotometer. The notations in the present paper are the same as those used in the former papers of this series.

Results and Discussion

The Absorption Spectrum of Potassium Tetrakis(succinimidato)cuprate(II) Hexahydrate.—It is possible that the succinimidate ion in $K_2Cu\cdot(sucim)_4\cdot 6H_2O$ is co-ordinated to the cupric ion through either the nitrogen or the oxygen

3) L. Tschugaeff, *Ber.*, **39**, 2897 (1905).
4) The notation, *sucim*, represents an anion which is derived when a succinimide molecule loses a proton.
5) L. Tschugaeff, *Ber.*, **40**, 1976 (1907).
6) R. Tsuchida and M. Kobayashi, This Bulletin, **13**, 619 (1938); "The Color and the Structure of Metallic Compounds" (Kinzokukagōbutsu no Iro to Kōzō), Zoshindo, Osaka (1944), p. 180.

atom (Fig. 1). The co-ordination of *sucim* with a copper(II) ion, however, is most probably, through the nitrogen atom, since the oxygen atom of the carbonyl group in the ion is capable of being linked only weakly with the cupric ion. The co-ordination of *sucim* as a chelated ligand using both the nitrogen and the oxygen atoms may not be impossible. In any case, the bonding is mainly through the nitrogen atom, judging from the steric condition and the weak bonding ability of the oxygen atom in the carbonyl group.

The polarized absorption spectra of $K_2Cu(sucim)_4 \cdot 6H_2O$ in the crystalline state are shown in Fig. 2, and the data are given in Table I. The free succinimide shows no absorption in the neighborhood of the ligand field bands of the cupric complexes[7]. Since the crystal structure analysis is not available, it is not possible to determine exactly the components of the absorption coefficient of the planar cupric complex. For the purposes of the present study, however, it is sufficient to find the qualitative characteristics of these absorption components. It is known empirically from dichroism measurements[8] that, for the ligand field absorption band of cupric complexes with the D_{4h} symmetry, the xy-absorption, the absorption with the electric vector along the $Cu(N)_4$-plane, has a much larger oscillator strength than the z-absorption, the absorption with the electric vector perpendicular to the complex-plane. On the basis of this empirical rule, it is found that the A-absorption in Fig. 2 is richer with the xy-absorption than with the z-absorption of the planar complex, and that the B-absorption is richer with the z-absorption. The difference between the A- and the B-absorption on this crystal-face is so remarkable, compared with the dichroism of other cupric complexes, that one may assume that the $Cu(N)_4$-planes are nearly parallel to each other and perpendicular to the B-direction of the crystal.

The compound shows its main ligand field band at about 61×10^{13} sec^{-1}, which corresponds to a much higher frequency than the values reported for an ordinary type of cupric complex with amines, such as ammonia and ethylenediamine. An inspection of data with nickel(II)-succinimidato complexes having the same configuration reveals[9] that the position of *sucim* in the spectrochemical series is as follows[10]: *en* > NH_3 > biguanide > *sucim* > OH_2. This order, in which *en* stands higher than *sucim*, is regarded as applicable to many metal ions, such as chromium(III), nickel(II), cobalt(II), cobalt(III), and copper(II), provided that the complexes have the same configuration. Hence, the fact that the tetrakis(succinimidato)-copper(II) ion shows its absorption band at such a high frequency is not understandable if $K_2Cu(sucim)_4 \cdot 6H_2O$ has a complex-ion with a configuration identical with that of the bis(ethylenediamine)copper(II) complexes. Bjerrum[11] et al. and Ito[12] concluded that the ligand field band of copper(II) suffered bathochromic shift as the cupric complex with a square-planar configuration took additional ligands to form a sexa-co-ordinate complex with a pseudo-octahedral configuration. Taking this and the spectrochemical series into consideration, a comparison of the maxima of the ligand field bands indicates that the co-ordination of the four nitrogen atoms around the cupric ion in $K_2Cu(sucim)_4 \cdot 6H_2O$ is square-planar, the fifth and sixth positions of the complex being unoccupied, whereas the ethylenediamine complex has a sexa-co-ordinate configuration, represented

by $[Cu\,en_2\,(OH_2)_2]^{2+}$. In other words, it is concluded that $K_2Cu(sucim)_4 \cdot 6H_2O$ contains a square-planar complex-ion, $[Cu(N)_4]^{2-}$, which leaves the fifth and sixth co-ordination sites empty, the water molecules in this compound being unbound with the cupric ion.

Some of the reasons why the complex-ion, $[Cu(sucim)_4]^{2-}$, leaves the fifth and sixth sites unoccupied seem to be (1) that the steric condition more or less, though not absolutely, prevents other ligands from coming close to the cupric ion and (2) that the oxygen atom in the carbonyl group has only a weak ability to be bound with the cupric ion. Another factor is the electronic state of the ligands, which will be discussed in the later part of this paper.

A similar discussion applies to the corresponding complex of biuret, which involves a chemical bond resembling the bond in the complex of succinimide. It seems to be significant that the position of the biuret ion in the spectrochemical series is close to that of *sucim*. The absorption maximum (505 mμ)[13] of the crystal of $K_2Cu(biuret)_4 \cdot 4H_2O$ also lies at a much higher frequency than that of the ethylenediamine-complex of copper(II). In the same way as in the case of $K_2Cu(sucim)_4 \cdot 6H_2O$, the inspection of the absorption maxima shows that the crystal consists of $[Cu(biuret)_2]^{2-}$ ions which have a square-planar co-ordination around the cupric ion, with the fifth and sixth co-ordination sites left empty, the water molecules being unbound with the cupric ion. This is in agreement with the crystal structure analysis[13] of the compound, which shows that the cupric ion is surrounded by four nitrogen atoms at a distance of about 1.93Å and by two nitrogen atoms of the neighboring complex at about 3.33Å.

It is theoretically predicted that the quadri-co-ordinate cupric complex of the D_{4h} field symmetry will display three ligand field bands, as shown in Fig. 3. There are two ways of assigning these vibronic transitions. According to one of them, the three transitions all fall in a rather narrow frequency range and the superposition of the three usually appears as apparently one absorption band in the visible or near-infrared region. According to the other way of assignment[14], the ν_3 band is assumed to lie at a much higher frequency than ν_1 and ν_2, and usually far from the visible region, covered by a much stronger absorption of a charge transfer type. The present authors regard the latter assignment as more likely on grounds, a detailed discussion of which will be reported shortly. The present dichroism measurements also seem to support this assignment.

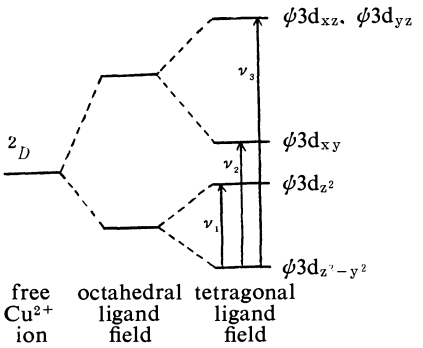

Fig. 3. Energy level scheme model for cupric complexes: (A) sexa-co-ordinate complexes with octahedral symmetry and (B) square-planar complexes of a [Cu A_4] type. In the figure, $\phi 3d_{z^2}$, for example, refers to the state, in which the d_{z^2} orbital is not completely filled.

As may be seen in Fig. 2, $K_2Cu(sucim)_4 \cdot 6H_2O$ shows two maxima, corresponding to the ligand field bands, at about 50 and 61×10^{13} sec^{-1}, for both of which the xy-absorption is more intense than z-absorption. An unambiguous assignment of the observed transitions seems to be difficult for the present, but a tentative assignment is given in Table I on the basis of the dichroism measurement and in terms of the second standpoint described above. Simple theoretical consideration, in terms of the ligand field theory, predicts that both the transitions, ν_1 and ν_2, will take place more readily along the xy-direction than along the z-direction, if it is assumed that the vibrations of the E_u symmetry are more effective in making allowed the originally forbidden electronic transitions than the other vibrations in the complex (Table II). The energy levels of the d_{z^2} and d_{xy} orbitals are usually close to each other, and the order of one with respect to the other

TABLE II. THE TRANSITIONS CORRESPONDING TO THE LIGAND FIELD BANDS OF SQUARE-PLANAR COMPLEXES OF [Cu A_4]-TYPE AND THE SYMMETRIES OF THE VIBRATIONS MAKING THE TRIPLET-TRIPLET TRANSITIONS ALLOWED

Transition	Polariz. of transition predicted from symmetry consideration
ν_1 $d_{z^2} \rightarrow d_{x^2-y^2}$	$x,y(E_u)$; $z(B_{2u})$
ν_2 $d_{xy} \rightarrow d_{x^2-y^2}$	$x,y(E_u)$; $z(B_{2u})$
ν_3 $\left.\begin{matrix} d_{xz} \\ d_{yz} \end{matrix}\right\} \rightarrow d_{x^2-y^2}$	$x,y(A_{2u}, B_{2u})$; $z(E_u)$

In the parentheses are shown the vibrations of the complex making the transition allowed.

possibly changes from one compound to another. The assignment, as given in the present work, is based upon the order of the d-orbitals assumed in Fig. 3. Irrespective of the order of the two levels, the polarization which has been determined in the present work is found to agree with the prediction from the theory, at least qualitatively.

The Absorption Spectrum of Bis(*N*, *N*-diethylethylenediamine)copper(II) Perchlorate. — The compound consists of complex-ions of a $[Cu(N)_4]$-type with a square-planar configuration. The two ethyl groups attached to a nitrogen atom prevent, to a greater or lesser extent, additional ligands from occupying the fifth and sixth co-ordination sites, although in an aqueous solution the complex takes up two molecules of water to form a sexa-co-ordinate complex. The polarized absorption spectra of the compound in the crystalline state are shown in Fig. 4. The crystal structure analysis

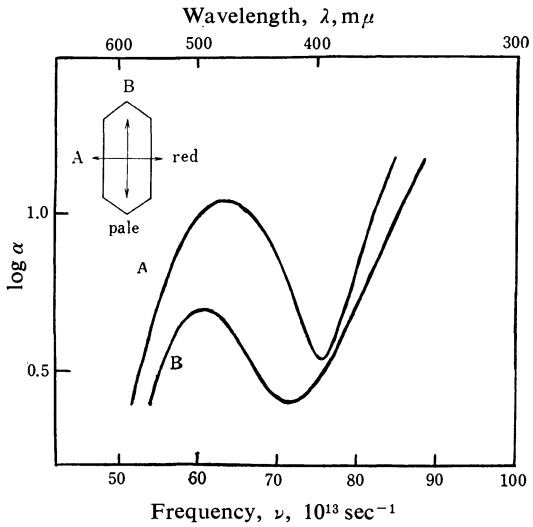

Fig. 4. Polarized absorption spectra of $[Cu(deen)_2](ClO_4)_2$ in the crystalline state.

of the complex salt is not available so far, and usually the planes of the complexes in the crystal are not exactly parallel to each other. However, it is readily found that the A- and B-absorptions in Fig. 4 represent the main features of the xy-absorption and the z-absorption respectively of the square-planar complex, since previous studies have shown that, for the ligand field absorption band, the xy-absorption has a larger oscillator strength than the z-absorption[8]. Strictly speaking, the symmetry of the complex deviates from D_{4h}, but the spectra may be discussed approximately in the scheme of the D_{4h} field symmetry. The absorption bands in the visible region in Fig. 4 probably represent a superposition of the

two kinds of electronic transitons, ν_1 and ν_2. A tentative assignment of the band which is shown in Table III is made in such a way that the assignment for the compound is consistent with the assignment for the $[Cu(sucim)_4]^{2-}$ ion and other square-planar cupric complexes.

An absorption band in the visible region in the A-absorption is assumed to consist of two electronic transitions, since the band is comparatively broad. The B-absorption shows only one ligand field band at about 61×10^{13} sec^{-1}, which probably arises from the electronic transition, ν_1. As is seen in Table III, the polarization observed for these transitions is found to agree with the prediction from the theory.

It is to be noted that the absorption maximum of the square planar ion of $[Cu(deen)_2]^{2+}$ lies at a much higher frequency than the maximum of $[Cu\,en_2(OH_2)_2](NO_3)_2$ in the crystalline state (57.2×10^{13} sec^{-1}) and that of $Cu\,en_2^{2+}$ (54.0×10^{13} sec^{-1}) and $Cu(NH_3)_4^{2+}$ (49.2×10^{13} sec^{-1}) ions in an aqueous solution. The difference in the maximum frequency between the crystalline $[Cu(deen)_2](ClO_4)_2$ and the latter type of complex is too large to be expected if the two contain complexes of a similar configuration, since the position of *deen* in the spectrochemical series is close to, and even lower than, en. This fact is understood if it is assumed (1) that the co-ordination of ligands at the fifth or the sixth site causes a bathochromic shift of the ligand field band, and (2) that bis(ethylenediamine)- or tetrammine-copper(II) ions in solution and in the crystalline state consist of complex-ions of copper(II), with the fifth and the sixth co-ordination sites occupied by some ligands.

The ligand field band of bis(*N*, *N*-diethylethylenediamine)-copper(II) perchlorate exhibits a great bathochromic shift on going from the square-planar complex, $[Cu(N)_4]^{2+}$, in the solid state to the trans-octahedral complex, $[Cu(N)_4(OH_2)_2]^{2+}$, in an aqueous solution. The following ratio obtains in this case:

$$\nu(\text{trans-octahedr.})/\nu(\text{square-plan.}) = 0.80$$

This value is nearly comparable with the values previously reportd for some cupric complexes[15]. In this connection, it is to be noted that bis(ethylenediamine)copper(II) perchlorate in the crystalline state shows a ligand field band at a comparatively long wavelength[16]. One may assume that the perchlorate ions come rather close to the copper(II) ion to form a sexa-co-ordinate complex, giving rise to the bathochromic shift of the band. The study of this is now in progress and will be reported elsewhere in more detail.

The Origins of the Red Color of Cupric Complexes.—There seem to be largely two kinds of origins of the red or orange color of some cupric compounds. On one hand, the red color results mainly from the charge transfer between the cupric ion and a ligand, and, on the other hand, it originates from the ligand field bands of the cupric ion. Red halide-complexes of copper(II) belong to the former group, owing their red color to a charge transfer between cupric and halide ions. The orange-color of Cs_2CuCl_4 and the red-color of $CsCuCl_3$, for example, are regarded as due to the charge transfer band in the visible region, which is much more intense than the ligand field band. In addition to the charge transfer band, the ligand field band due to the tetrahedral copper(II)-complex is expected to appear in the infrared region.

There are red cupric complexes of the other type, such as cupric complexes with succinimide, biuret, biguanide, phenylbiguanide, and *N*, *N*-diethylethylenediamine (Table IV). The quadri-co-ordinate, planar complex of copper(II) tends to take additional ligands, forming a sexa-co-ordinate complex with a pseudo-octahedral configuration and at the same time causing a bathochromic shift of the ligand field bands. Hence, if the sexa-co-ordination is not possible for one reason or another, the complex is expected to keep the quadri-co-ordinate, planar configuration, displaying the ligand field band in a frequency region much higher than when the sexa-co-ordination is allowed. An example is bis(*N*, *N*-diethylethylenediamine)copper(II) perchlorate in the crystalline state, which owes its red color to the steric condition of the ligands. In this case, the steric condition makes it more or less difficult for other ions or molecules to occupy the fifth and sixth positions of co-ordination around the cupric ion, although it does not completely exclude the sexa-co-ordination, so that the complex takes up two water molecules in an aqueous solution. This ligand has no nitrogen atom which is capable of participating in π-bonding with the cupric ion, excepting through hyperconjugation. The pink color of this compound, therefore, is due not to the π-bonding, but to the special steric condition of the ligand.

c) Quoted in Ref. 13 of the text.

On the contrary, the steric condition does not seem to be the main reason for the formation of the red cupric complexes of succinimide, biuret, biguanide and phenylbiguanide with a square-planar co-ordination. In these cases, there is little steric hindrance which might prevent other ligands from coming closer to the cupric ion in the direction perpendicular to the $Cu(N)_4$-plane. It is readily found that these ligands all involve a similar kind of linkage around the nitrogen atom, which is capable of entering into π-bonding with the cupric ion. It is likely that, in the cupric complexes of this sort, the π-bonding plays a part in leaving the fifth and sixth co-ordination sites unoccupied. It seems that π-bonding of this sort decreases the effective charge on the cupric ion, weakening the possible copper(II)-to-oxygen bond, which is probably strongly ionic.

The Crystal Absorption Spectra of Bis(succinimidato)bis(alkylamine) copper (II) Complexes.—The compounds with a composition of Cu·(*sucim*)$_2$(amine)$_2$, the amine being methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl or *n*-amyl amine as well as ammonia, are all red in the crystalline state. In order to examine the origin of the unusual color of these compounds, one of the compounds has been chosen. Thus, the dichroism of Cu(*sucim*)$_2$(isopropylamine)$_2$ has been determined by the microscopic method; the results of the measurements are shown in Fig. 5 and in Table V.

The succinimidate ion can be combined with the cupric ion through either the nitrogen or the oxygen atom. The co-ordination in this compound, however, is most probably through

TABLE V. ABSORPTION MAXIMA OF [Cu·(*sucim*)$_2$(*iso*-$C_3H_7NH_2$)$_2$] IN THE CRYSTALLINE STATE

	ν_{max}	log α	Half width	Assignment	K
A-abs.	62.6	1.38	12.0	ν_1, ν_2	54.5×10^3
B-abs.	59.1	0.99	11	ν_1	22.2×10^3

ν: 10^{13} sec^{-1}

In the calculation of K, the value of 1.38 was used for the density of the crystal, which was determined with a picnometer. $K=10\alpha M/\rho$ where M and ρ denote molecular weight and density, respectively.

the nitrogen atom, and not through the oxygen atom, as has been discussed in the earlier part of the present paper. There is very little doubt that the amine molecules, besides the unidentate succinimidate ions, are linked with the cupric ion.

The present measurement indicates that the red crystal of Cu(*sucim*)$_2$(*iso*-$C_3H_7NH_2$)$_2$ shows a ligand field absorption band, with its maximum at about 61×10^{13} sec^{-1}, in addition to a strong absorption in the far higher frequency. The absorption maximum of the ligand field band of this compound lies at a much higher frequency than that of most cupric complexes with nitrogen-co-ordinating ligands of an ordinary type, such as ammonia, ethylenediamine and related compounds. This fact shows that there is an essential difference in configuration between Cu(*sucim*)$_2$(*iso*-$C_3H_7NH_2$)$_2$ and [Cu en$_2$ $(OH_2)_2$] $(NO_3)_2$, since *sucim* stands much lower in the spectrochemical series than en, *deen* or ammonia. It was formerly assumed that an absorption maximum of the ligand field band is displaced bathochromically, when a square-planar complex of copper(II) takes up two more ligands to form a sexa-co-ordinate, pseudo-octahedral complex[11,12,15]. It is, therefore, concluded that Cu(*sucim*)$_2$(amine)$_2$ in the crystalline state consists of quadri-co-ordinate, planar cupric complexes, with the two co-ordination sites, perpendicular to the complex-plane, kept unoccupied. It has not been determined in the present study whether the complex belongs to a cis- or a trans-series.

Since the crystal structure analysis is not available and usually the complex-planes are not all parallel to each other, it is not possible to determine exactly the component absorption coefficients of the planar complex. From the empirical rules, however, one can readily find the main characteristics of the z- and xy-absorptions by using the polarization measurements, which are shown in Table V along with a tentative assignment of the absorption bands. It is found, from the intensity of the ligand field band, that the A- and B-absorptions represent the main features of the xy- and z-absorptions of the complex respectively. For Cu(*sucim*)$_2$(*iso*-$C_3H_7NH_2$)$_2$, the z-absorption shows one component band at about 59×10^{13} sec^{-1}, whereas the xy-absorption, having a much larger oscillator strength than the z-absorption, is assumed to represent the superposition of two component absorption bands, with the main maximum at about 62.7×10^{13} sec^{-1}. The observed polarization property of the absorption bands of this complex is quite similar to that of the other cupric complexes with a square-planar configuration, such as $[Cu(sucim)_4]^{2-}$ and $[Cu(deen)_2]^{2+}$, and agrees with the theoretical prediction. Strictly speaking, the symmetry of the complex, Cu·(*sucim*)$_2$(*iso*-$C_3H_7NH_2$)$_2$, deviates from D_{4h}, but it is assumed that the spectrum may be treated approximately in the scheme of D_{4h} field symmetry.

The corresponding compounds of the bis-(succinimidato)-copper(II) complexes with other amines are colored quite similarly to Cu(*sucim*)$_2$(*iso*-$C_3H_7NH_2$)$_2$. Although they are rather unstable in the atmosphere and undergo slow decomposition during the prolonged dichroism measurements, it was possible to determine, by quick measurements, the approximate band maxima of the compounds (about 60×10^{13} sec^{-1}); these lie in the neighborhood of the ligand field band of the corresponding compound with isopropyl amine, but they are at a much higher frequency than the maximum of [Cu en$_2$$(OH_2)_2$] $(NO_3)_2$. It is concluded that all these homologues consist of quadri-co-ordinate, square-planar complexes, with the fifth and sixth site kept empty. With ethyl amine, the compound has two water molecules

of crystallization, but these water molecules are presumed to have nothing to do with the linkage to the copper(II) ion.

There are violet complexes, in addition to the red ones, for ammonia and methyl amine. The examination of the violet form is now progress, and the results will be reported on elsewhere.

The Structure of Bis(succinimidato)bis(alkylamine)copper(II) in Solvents.—The red crystals of Cu(*sucim*)$_2$(amine)$_2$, in general, are unstable in water, ethanol and pyridine. In water, they apparently undergo decomposition and form a pale-blue precipitate upon standing in this solvent for a sufficiently long time. In ethanol and pyridine, the decomposition was not so fast as in water, but the replacement of one of the ligands by a molecule of the solvent seems to take place, along with the addition of the solvent molecules to the cupric complex. On the contrary, the red crystals of the compounds are dissolved in chloroform to form a stable solution with a dark-blue color, which is quite different from the color of the compound in the crystalline states.

The absorption spectra of these compounds in chloroform have been determined in the present work. As may be seen in Fig. 6 and Table VI, the compounds with a formula of Cu(*sucim*)$_2$(amine)$_2$ in chloroform exhibit, in the visible region, one ligand field band with a maximum at about 48 to 50×10^{13} sec^{-1} (625 to 600 mμ), which is far lower than the frequency of the absorption band of the same compounds in the crystalline state. The shift of the band on going from the crystal to the solution is found to be about 11×10^{13} sec^{-1} for the *n*-alkyl amines and about 13×10^{13} sec^{-1} for the isopropyl amine. The shift observed in the present study is much larger than would be expected for typical solvent effects upon the ligand field band with no change in the configuration of the complex. It seems to be evident that, when the crystals are brought into chloroform, some remarkable change in the configuration occurs to the complex-molecules existing in the crystals, in which the complex-molecules have a square-planar coordination of the four nitrogen atoms around the cupric ion.

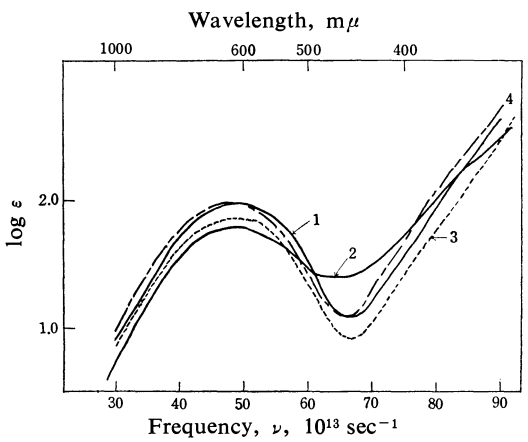

Fig. 6. UV-absorption spectra of [Cu(*sucim*)$_2$·(R·NH$_2$)$_2$] in chloroform 1, R=C_2H_5; 2, R=CH_3; 3, R=*n*-C_3H_7; 4, R=*iso*-C_3H_7

The dissociation of one of the four ligands is quite unlikely, since Beer's law is generally obeyed in the concentration range examined. The present study also reveals that no decomposition of the complexes takes place; at least none takes place at a concentration between 4×10^{-3} and 2×10^{-4} M. The replacement of one of the amine molecules seems to be improbable, since, though chloroform might be bound to a metallic ion, it could only be so very weakly, and since the linkage between the cupric ion and chloroform, if formed at all, would be far weaker than the linkage between the cupric ion and the amine or succinimidate.

It might also be assumed that the chloroform molecules would be co-ordinated, though very weakly, with the cupric ion slightly farther in the direction perpendicular to the complex-plane formed by the cupric ion and the four nitrogen atoms. Judging from the weak perturbing power of the chloroform molecule, this assumption does not seem to explain the enormously large shift of the band maximum on going from the crystal to the solution.

ν: 10^{13} sec^{-1} h. w.: half width in 10^{13} sec^{-1}

It is expected theoretically, and has been confirmed experimentally, that the ligand field band of a cupric complex suffers a more or less bathochromic shift when the square-planar complex takes up ligands to form an octahedral complex. However, the chloroform molecule usually has so slight an ability to be bound to the metallic ion that the band shift on going from the square-planar complex to the chloroform adduct with a pseudo-octahedral configuration would be much smaller than the corresponding effects of water as well as of ammonia molecules. On the contrary, the present measurements show that the difference in the band maximum between the crystal and the chloroform solution is usually great, the ratio of the maximum frequency of the crystal to that of the chloroform solution deviating remarkably from unity. The values ranging from 0.70 to 0.80 for the succinimidato-complex in chloroform are much smaller even than the values expected for the effects of ammonia molecules as the additional ligands as well as for those of water molecules. It is to be recalled that the corresponding ratio of the crystal to the aqueous solution is about 0.80 in the case of the bis(diethylethylenediamine) complex. The observed ratio for the chloroform solution seems to be too small for the octahedral model with the chloroform molecules in trans-positions.

It may be assumed that the ligand field around the cupric ion of the succinimidato complex is determined mainly by the four nitrogen atoms and is affected only very little by such other ligands, like chloroform molecules, as might occupy the remaining co-ordination sites in the compound. In the light of the discussion above, therefore, the enormous band shift on going from the crystal to the chloroform solution indicates that the co-ordination of the four nitrogen atoms around the cupric ion within the Cu(*sucim*)$_2$(amine)$_2$ complexes in chloroform deviates from a square-planar configuration. In this connection, it is to be noted that the ligand field bands of all these compounds in non-co-ordinating solvents have a much higher intensity and a larger half-width than most cupric complexes with a tetragonal field symmetry. This is in agreement with the theory which predicts that a complex of a transition element with no center of inversion will show a ligand field band of a higher intensity than a complex with a center of inversion. According to the crystal field theory, however, the regularly tetrahedral complex will show a ligand field band in a frequency region much lower than that observed in the present study, since the quadri-co-ordinate complex with a regularly tetrahedral configuration would have a ligand field-splitting parameter which is about 4/9 times that of the octahedral complex. The regular or near regular tetrahedral model seems to be less likely.

One may assume that the oxygen atoms of the carbonyl-groups will be bound to the cupric ion to form a pseudo-octahedral complex. This effect alone, however, is not regarded as strong enough to explain the observed remarkable difference in the absorption maximum between the crystal and the chloroform solution, since the oxygen atom of this type is known to be bound only very weakly to the metal ion. However, even so, this probably plays a part in causing the deviation from the square-plane of the co-ordination in such a way that this weak linkage may help and keep the configuration deviated from the square-plane.

The cupric complexes of the Cu(*sucim*)$_2$-(amine)$_2$ type are also soluble in methylene chloride and benzene to give a stable solution, which is colored dark-blue. As is shown in Fig. 7 and Table VI, the absorption spectra of the compounds in these solvents have main features which are similar to those of the compounds in chloroform. All the compounds show a similar spectrum in these solvents; therefore, the absorption spectra of only some of the compounds are shown in Fig. 7. It is found that bis-(succinimidato)bis(ethylamine)-copper(II) in benzene, for example, shows a ligand field band at a frequency nearly equal to that of the chloroform solution. As in the case of the chloroform solution, it is concluded that the co-ordination of the four nitrogen atoms around the cupric ion with the Cu-(*sucim*)$_2$(amine)$_2$ complex in these solvents

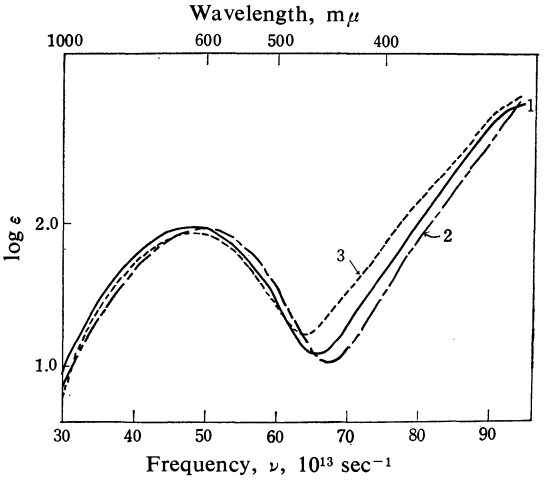

Fig. 7. UV-absorption spectra of [Cu(*sucim*)$_2$-(*iso*-$C_3H_7NH_2$)$_2$] in organic solvents. 1, Chloroform; 2, Methylene chloride; 3, Benzene

probably deviates from the square-planar configuration.

In these non-polar solvents, the oxygen atom of the succinimidate ion of the cupric complex may be subjected to repulsion by the molecules of the solvents, so that the rejected oxygen atom will point toward the cupric ion to form weak linkage with it. When alcohols or water are used as a solvent, however, the oxygen atom in the succinimidate ion is assumed to be associated with the solvent molecule, possibly through hydrogen bonding, since the affinity of this type of the oxygen atom to the cupric ion may be small. Moreover, the molecules of these polar solvents can be co-ordinated to the cupric ion, whereas the molecules of the non-polar solvents, in general, cannot. This probably explains the difference in the configuration of the succinimidato-complexes between the solutions in the polar and in the non-polar solvents. The minor difference in the frequency of the absorption maximum between the solutions in chloroform and the other non-polar solvents is to be ascribed not to the difference in the configuration of the complex in these solvents, but to an ordinary kind of perturbation on the complex by the solvents.

Summary

The dichroism in the visible and ultraviolet region has been determined by the microscopic method with single crystals of $K_2Cu(sucim)_4 \cdot 6H_2O$, $Cu(deen)_2(ClO_4)_2$ and $Cu(sucim)_2(iso\text{-}C_3H_7NH_2)_2$. From a comparison of these spectra with the spectra of most cupric complexes, it has been concluded that these compounds contain square-planar complexes of copper(II), with the fifth and sixth co-ordination sites left empty. It has been concluded, in a similar way, that the compounds with a formula of $Cu(sucim)_2(amine)_2$, the amine being methyl, ethyl, *n*-propyl, isopropyl, *n*-butyl and *n*-amyl amines as well as ammonia, consist of quadri-co-ordinate, square-planar complexes in the crystalline state.

The absorption spectra of bis(succinimidato)-bis(alkylamine)-copper(II) complexes in chloroform, benzene and methylene chloride, in which the compounds are colored dark-blue, have been determined. The enormously large band shift toward a lower frequency, on going from the crystal to the solution, seems to indicate that the configuration in these solvents is not the square-planar or trans-bis-(chloroform) configuration, but deviates from the square-plane.

The Photoisomerization of cis-Azobenzene in the Presence of Iodine

By Shigeru YAMASHITA, Desmond P. COSGRAVE, Hiroshi ONO and Osamu TOYAMA

(Received February 14, 1963)

We have recently studied the iodine-catalyzed thermal cis → trans isomerization of azobenzene in a *n*-hexane solution at room temperature[1]. The results obtained suggest that the isomerization takes place through an intermediate complex formed between *cis*-azobenzene and iodine. The existence of such a molecular complex in the solution has been shown spectroscopically, and the equilibrium constant and the heat of complex formation have been determined.

The purpose of the present work is to show that the iodine-complex of *cis*-azobenzene yields *trans*-azobenzene when excited by the absorption of light. The reaction can be distinguished from the direct photoisomerization of free *cis*-azobenzene in the solution, which has been studied previously[2]. For purposes of comparison, the isomerization has also been studied in the wavelength region where the only absorbing entity is free iodine in the solution.

2) S. Yamashita, H. Ono, and O. Toyama, ibid., **35**, 1849 (1962).

Experimental

Materials.—The preparation or purification of *cis*- and *trans*-azobenzene, iodine and *n*-hexane has already been described in previous papers[1,2].

Apparatus and Procedure.—The absorption bands of the iodine-complex of *cis*-azobenzene and its isomerization under irradiation of light were studied at −78°C, where the equilibrium constant for the complex, estimated from previous data[1] obtained at higher temperatures above 0°C, is as large as 6.62×10^4 l. mol^{-1}, compared to 1.92×10^2 l. mol^{-1} at 10°C. The metal Dewar vessel used for these measurements was similar in design to those described by Ham[3] and Potts[4]. It was set in a brass desiccator box equipped with quartz windows and containing silica gel to protect the cell windows from frosting.

Figure 1 shows the absorption curve for the *cis*-azobenzene-iodine complex thus determined at −78°C. The absorption maximum at 305 mμ has been assigned to a charge-transfer band characteristic of the complex, and the other one at 435 mμ, to a blue-shift of the iodine band due to the complex formation[1].

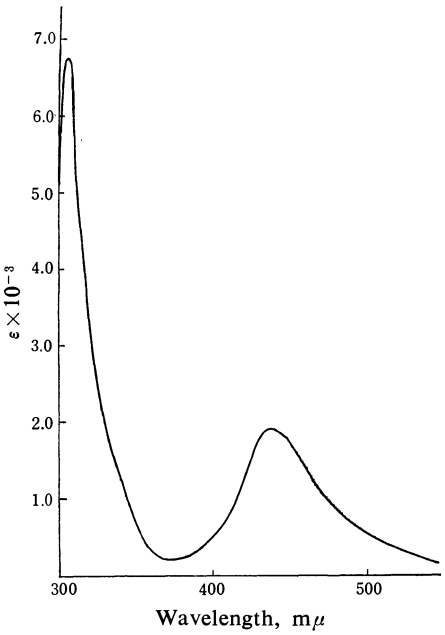

Fig. 1. Absorption curve of *cis*-azobenzene-iodine complex.

The isomerization reaction was studied by the use of the following three different kinds of irradiation: 313 mμ was used to investigate the effect of the charge-transfer absorption of the complex, 436 mμ, for that of the blue-shifted absorption of complexed iodine, and 546 and 577 mμ, for that of the absorption of free iodine in the solution. The filters used for these experiments are given in Table I.

Table I. Mercury lines and filters used for irradiation

Wavelength, mμ	Filter
313	Mazda UV-D2 and K_2CrO_4 aq.
436 (containing small amount of 405 mμ)	Mazda V-V1 and Walz UV
546~577	Walz R-1

Table I. The light source was a Mazda SHL-100 mercury lamp.

The progress of the isomerization reaction in each run was followed spectrophotometrically in a way similar to that described for stilbene in a previous paper[5]. Only the initial rates of conversion were determined in all the experiments; the dependence of the rate on the concentrations of the absorbing entity and other species was obtained from the initial rates determined under varied conditions.

Results and Discussion

Irradiation with Wavelengths of 313 and 436 (Containing a Slight Quantity of 405) mμ.—As may be seen in Fig. 1, 313 mμ approximately corresponds to the charge-transfer absorption maximum of the *cis*-azobenzene-iodine complex, and 436 (containing a small amount of 405) mμ, to the blue-shifted absoption maximum of the complexed iodine. The absorbance of free iodine in this wavelength region is negligible, so its contribution to the isomerization may be neglected. On the other hand, the absorbance of free *cis*-azobenzene in this wavelength range is considerable[1], and its contribution to the isomerization should be taken into account.

Tables II and III show the results obtained with 313 and 436 mμ at −78°C. The contribution of the isomerization of free *cis*-azobenzene was estimated from the extinction coefficients and the quantum yields for free *cis*-azobenzene, both determined previously[1,2], combined with the concentration of free *cis*-azobenzene calculated from the equilibrium constant for the complex at −78°C, 6.62×10^4 l. mol^{-1}.

Tables II and III thus indicate that the *cis*-azobenzene-iodine complex, when excited by 313 or 436 mμ, yields *trans*-azobenzene with a quantum yield which is approximately constant for varied concentrations of *cis*-azobenzene and iodine.

The isomerization caused by the excitation of the molecular complex might be supposed to result from an intermolecular energy transfer between the excited molecular complex and free *cis*-azobenzene. However, the quantum yields, independent of the concentration of

free *cis*-azobenzene, seem to exclude such an intermolecular-energy-transfer mechanism.

There have recently been discovered a number of complex molecules that exhibit intramolecular-energy-transfer processes on light absorption; the molecular complex of trinitrobenzene with anthracene, for instance, when excited by its charge-transfer absorption, dissociates and yields anthrancene in a triplet state which subsequently returns to its ground state by phosphorescence[6]. If a similar mechanism is operative in the present case, the isomerization may be explained by the following reaction scheme:

$$CI_2 + h\nu \rightarrow CI_2^*$$
$$CI_2^* \rightarrow C^* + I_2$$
$$C^* \rightarrow T$$

with appropriate deactivation processes for the excited CI_2^* and C*, where C and T represent *cis*- and *trans*-azobenzene respectively. Table IV shows that the relative magnitudes of the excitation energies and quantum yields for *cis*-azobenzene and its iodine-complex conform to such an interpretation[7].

In the case of the *cis*-stilbene-iodine complex, which has previously been studied[8], the blue-shifted visible absorption band of iodine has a maximum at 420 mμ in *n*-hexane. Although the excitation by this transition is effective for the isomerization, the kinetics is entirely different from that for *cis*-azobenzene reported here and is to be explained by the reactions:

$$CI_2 + h\nu \rightarrow CI_2^*$$
and
$$CI_2^* + C \rightarrow CI + CI$$

followed by the thermal isomerization of the CI complex. The inability of the CI_2^* excited complex to isomerize directly in this case may be explained from the energy relation as follows. Although *cis*-stilbene has π-π^* absorption in the wavelength region shorter

7) The intramolecular energy transfer to the donor component might be assumed to take place without dissociation of the complex if the excitation energies for *cis*-azobenzene were not appreciably changed by the complex formation. However, the complex apparently has no absorption to be assigned to the donor in the wavelength region 300 to 500 mμ, where free *cis*-azobenzene has absorption bands.
8) S. Yamashita, This Bulletin, **34**, 972 (1961).

than 350 mμ, it has no n-π^* absorption in the longer wavelength region; the excitation of the complex by the blue-shifted iodine absorption around 420 mμ cannot, therefore, yield the excited molecule of *cis*-stilbene that can isomerize to its trans-form.

Irradiation with 546 and 577 mμ.—These mercury lines are solely absorbed by free iodine in the solution; the absorbance of *cis*-azobenzene, as well as that of *cis*-azobenzene-iodine complex, is negligible in this wavelength range. Figures 2—4, which represent the experimental results obtained at 0°C, show, therefore, that the absorption of light by free iodine in the solution gives rise to the isomerization of *cis*-azobenzene, and that the kinetic data conform to the rate equation:

$$d(T)/dt = kI_0(C)(I_2)^{1/2} \qquad (1)$$

where I_0 is the incident light intensity[9].

Equation 1 is of the same form as the rate equation previously obtained for the iodine-photocatalyzed isomerization of *cis*-stilbene in the same wavelength region[8]. Hence, it may be explained in a similar way:

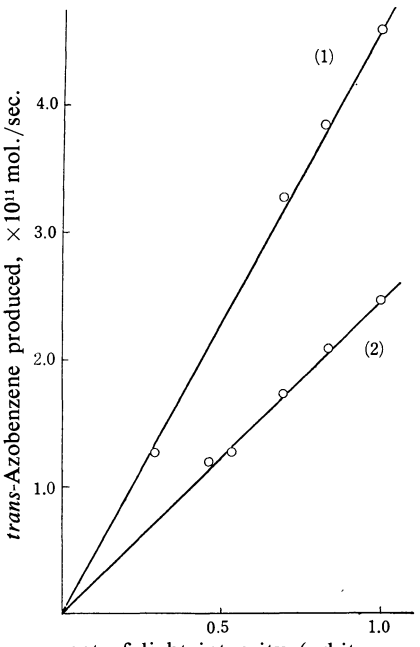

Fig. 2. Experiments with 546 and 577 mμ; dependence of the rate on light intensity. Concentration of iodine, 1.0×10^{-5} mol./l.; initial concentration of *cis*-azobenzene, 2.0×10^{-4} mol./l. for (1); 1.0×10^{-4} mol./l. for (2).

9) The equilibrium concentration of the *cis*-azobenzene-iodine complex at 0°C is so small that the concentrations of free species in the solution are practically equal to the respective initial concentrations.

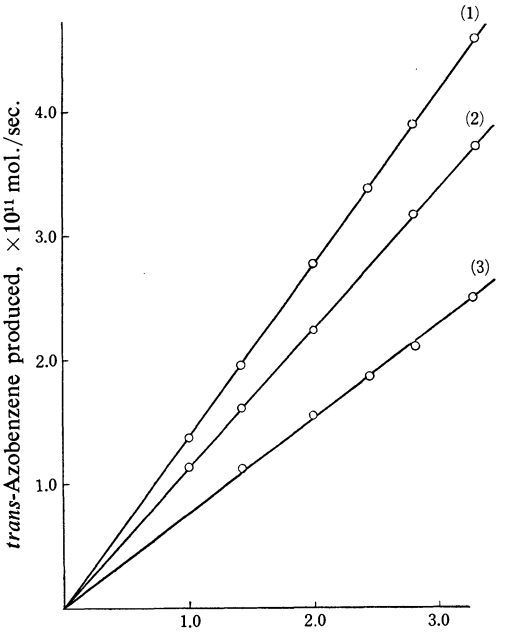

Fig. 3. Experiments with 546 and 577 mμ; dependence of the rate on iodine concentration.
Incident light quanta, 6.63×10^{-8} einstein/sec.; initial concentration of *cis*-azobenzene, 2.0×10^{-4} mol./l. for (1); 1.5×10^{-4} mol./l. for (2); 1.0×10^{-4} mol./l. for (3).

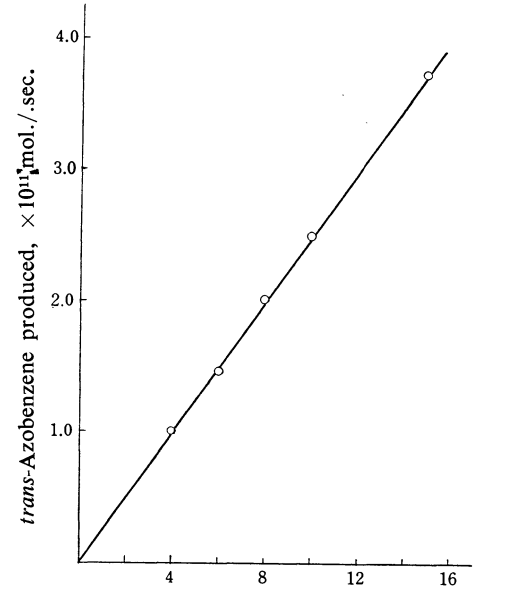

Fig. 4. Experiments with 546 and 577 mμ; dependence of the rate on *cis*-azobenzene concentration.
Incident light quanta, 6.63×10^{-8} einstein/sec.; concentration of iodine, 1.0×10^{-5} mol./l.

$$I_2 + h\nu \rightarrow I + I$$
$$C + I \rightarrow CI$$
$$CI \rightarrow C + I$$
$$CI \rightarrow TI$$
$$TI \rightarrow T + I$$
$$I + I \rightarrow I_2$$

By applying a steady-state treatment to this sequence of reactions, a rate equation that agrees with Eq. 1 is obtained, as has previously been shown for *cis*-stilbene.

For the present, we have no direct evidence for the intermediate complex, CI or TI. However, it is highly probable that atomic iodine forms such complexes, since it has an electron affinity of 3.2 eV.[10], greater than that of molecular iodine, 1.8 eV.[11] By means of a flash technique, Strong[12] and Porter[13] have shown spectroscopically the formation of a number of similar complexes of atomic iodine.

Summary

The conversion of *cis*-azobenzene in a *n*-hexane solution to its trans-isomer in the presence of iodine has been studied by light irradiation. The experiments with wavelengths of 313 and 436 mμ at −78°C have shown that the excitation of the molecular complex formed between *cis*-azobenzene and iodine, by its charge-transfer transition or by the blue-shifted absorption of complexed iodine, yields *trans*-azobenzene with a quantum yield independent of the composition of the solution. By comparing this finding with the results previously obtained for the cis-trans photoisomerization of free azobenzene in *n*-hexane, a probable mechanism has been presented: $CI_2 + h\nu \rightarrow CI_2^*$, $CI_2^* \rightarrow C^* + I_2$ and $C^* \rightarrow T$, where C and T denote *cis*- and *trans*-azobenzene respectively.

The results obtained at 0°C by irradiation at wavelengths of 546 and 577 mμ, which are solely absorbed by free iodine in the solution, are similar to those previously obtained for stilbene; they may, therefore, be explained in a similar way, i. e., by the photochemical dissociation of free iodine, followed by the iodine atom-catalyzed isomerization of *cis*-azobenzene.

The authors are grateful to Professor Teruo Hayakawa for his valuable discussions.

Preparation of Radioactive Antimony-120 of a High Specific Activity by the Irradiation of Tin with Protons

By Kazuo SAITO, Nobuo SUZUKI*, Kunio SETO** and Hidetsugu IKEGAMI

(Received February 15, 1963)

This paper describes the separation of pure radioactive antimony from a tin target irradiated by protons, and the preparation of a radioactivity source suitable for an accurate study of the decay scheme by the measurement of the angular correlation of its γ-rays and of the conversion electron spectrum. Separation of a trace of antimony from tin has been studied by several workers[1-4]. Since solvent extraction from a hydrochloric acid solution[5] and cation exchange in a weakly acid solution containing tartaric acid[2] appeared to be most

suitable for our present purpose, these two methods were examined, with commercially-available radioisotope ^{124}Sb[6]. It was found that both methods require significant modification in order to be applied to the irradiated target, because the amount of irradiated tin is very large.

A great deal of difficulty is involved in the preparation of an activity source which satisfies the following demand. The sample for the measurement of angular correlation of γ-rays must be a liquid less than 0.05 ml. in volume and more than 200 μc. in intensity. Nevertheless, the presence of carrier antimony is permissible. The source for the measurement of the internal conversion electron spectrum, on the other hand, must be practically carrier-free and placed on a thin finlm; the presence of any material brings about confusion in angular correlation. Evaporation of an ethereal or esterial solution of antimony pentachloride and electrolytic deposition provide a useful source for the angular correlation and the conversion electron spectrum measurement, respectively.

Experimental and Results

Materials.—Metallic tin of a high purity (containing less than 8×10^{-4}% Sb) was kindly supplied by Dr. K. Itsuki of Mitsubishi Metal and Mining Co. The organic solvents were purified by the usual method. The other chemicals are of extra pure grade.

Irradiation.—Metallic tin was fused, poured into four square holes in an aluminum slab, which was fixed onto a water-cooled target holder, covered with aluminum foil (20 μ thick), and inserted into the vacuum chamber of INSJ cyclotron (diameter of the magnet polepiece, 165 cm.; maximum proton energy, 15 MeV.; maximum proton current intensity, 1 mamp.). The target was irradiated with 11.5 and 14 MeV. protons with a mean current, 15 μamp. A greater current density caused metallic tin to melt in the shallow hole. With a total bombardment of 120 μamp. hr., about 10 mc. of radioactive substances was produced altogether, including ca. 1 mc. of ^{120}Sb.

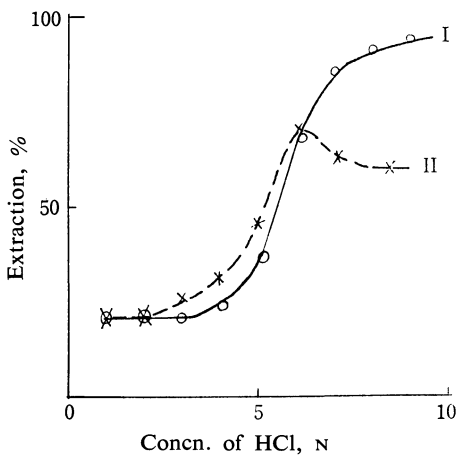

Fig. 1. Extraction of radioactive antimony-(V) from hydrochloric acid solution of irradiated tin.
vol. of the aq. phase, 100 ml.; vol. of org. phase, 30 ml.; I, amylacetate; II, ethylacetate.

The head of the target holder was taken off out of the chamber after a few hours' cooling and subjected to chemical separation.

Dissolution of the Target.—Tin was easily torn off from the aluminum plate, and each piece (2.5 g.) was either dissolved in 6 N hydrochloric acid (150 ml.) or in a mixture (100 ml.) of 6 N hydrochloric acid and concentrated nitric acid (3+1, v/v). In the former case, antimony remained in the tervalent state and was suitable for cation exchange separation from tin, but the time taken for dissolution was about 24 hr. In the latter case, dissolution was completed within 30 min.; the antimony was in the quinqui-valent state and extracted with organic solvent as shown below.

Solvent Extraction. — White et al. stated that the extraction of antimony with ethylacetate was best effected from 1 to 2 N hydrochloric acid solution in the presence of tartaric, acetic or oxalic acid. Our preliminary examination with ^{124}Sb disclosed that the extraction was facilitated by increased concentration of hydrochloric acid[6]. In a concentration greater than 6 N, however, the separation of the organic layer became incomplete, especially by the use of small quantity of the ester as compared with the volume of aqueous phase; hence, the extraction was less effective. By the use of amylacetate, such a defect was eliminated and the antimony, in both ter- and quinqui-valent state, was extracted almost quantitatively from more than 9 N hydrochloric acid. It appears as if the presence of organic acids little affects the extraction, when the antimony is in the quinqui-valent state. Nitric acid, used for the solution of the target, did not cause any interference. Tervalent antimony was extracted with less ease. A small amount of quadrivalent tin was extracted, because its concentration in the aqueous phase was great, but it was extracted back with 8 to 10 N hydrochloric acid. Only a negligible amount of antimony was transferred into the aqueous phase on the back extraction of tin. The amount of tin in the washed organic phase appears to be less than that of antimony coming from the impurity of the target metal. When antimony hydrolysed in too diluted an acid solution, solvent extraction was unsuccessful. Treatment with aqua regia, however, reverted the aged antimony to the ionic state

extractable with esters. The ester phase was evaporated and used for the γ-ray angular correlation measurement.

Ion Exchange. — Kimura et al. found that tervalent antimony in 0.4% tartaric acid of pH 1 passes through a column of cation exchange resin, bi-valent tin being quantitatively adsorbed on the resin[4]. Our re-examination made it clear that this method may satisfactorily be applied to the separation of radioactive antimony from a large amount of tin. However, it was also elucidated that the behavior of antimony was highly dependent on its state in the acid solution. So far as antimony(III) is not aged, the allowable pH range is rather

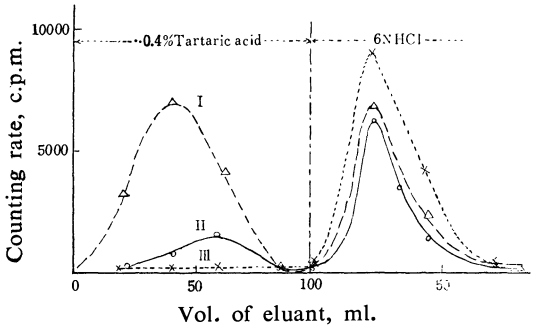

Fig. 3. Elution of radioactive antimony(III) after aging.

I Irradiated Sn (0.3 g.) was dissolved in 6 N HCl (30 ml.) mixed with tartaric acid (0.1 g.), evaporated to ca. 1 ml., set aside overnight and diluted to ca. 25 ml. (pH, 0.6).

II Prepared similarly to I; the tartric acid (1 g.) was added to the condensed soln., which was immediately diluted to ca. 25 ml. for ion exchange (pH, 0.6).

III Prepared similarly to I; the condensed soln. (1 ml.) was set aside overnight, mixed with tartaric acid (0.1 g.) and diluted.

wide, as is shown in Fig. 2. The tervalent antimony is apt to age in a dilute hydrochloric acid solution or in the presence of a less excess of hydrochloric acid. In the presence of tartaric acid, the aging was retarded in the cold, but not on boiling (see Fig. 3). When the antimony(III) was aged (perhaps by hydrolysis), its elution with a 0.4% tartaric acid solution of pH 1 was quite incomplete. It was partly eluted with 6 N hydrochloric acid, together with bivalent tin, but the remainder was eluted with great difficulty by the use of various agents including the following: 3 N hydrochloric acid containing 1% potassium chlorate, 3 N hydrochloric acid containing 5% (by volume) concentrated nitric acid, concentrated hydrochloric acid, 6 N hydrochloric acid containing various amounts of hydrogen iodide, and diluted hydrochloric acid containing various amounts of sodium bisulfite.

Electrolytic Deposition of Antimony.—Since the radioactive antimony consists of several kinds of nuclide, the scintillation spectrum is not resolving enough to enable an accurate study of the decay scheme. For the measurement of the internal conversion spectrum and the electron-gamma directional correlation, a source of a high specific activity is required. In order to minimize the scattering of electrons inside the source, the source thickness must be very small*. The lower the energy of electrons to be measured, the thinner the source should be. For the measurement in a rather high energy region, on the other hand, the influence of the scattering is less marked, and the conversion co-efficient is smaller. Hence, the demand for source thickness is less severe, but the intensity must be stronger.

The electrolysis of antimony is highly dependent on the state in the electrolytic solution. It is essential to avoid hydrolysis and to keep the antimony in an ionic state, either ter- or quinqui-valent. For this purpose, the radioactive antimony must be kept either in an organic solvent or in a hydrochloric acid solution more concentrated than 3 normal. When the organic solution is converted into an aqueous solution, care must be taken to maintain the acid concentration above this level. Aged antimony can be converted into an ionic state by boiling it with dilute aqua regia.

* In this measurement the source should be embedded in a metallic lattice. This condition is imperative in this case, where the nuclear transition occurs through an electron capture or internal conversion. The electronic shell will be excited by these processes, and the excited electronic shell will give a time-dependent perturbation. In a metallic surrounding, however, the recovery time is much shorter than the mean lifetime of the nuclear intermediate state and, consequently, there will be no attenuation.

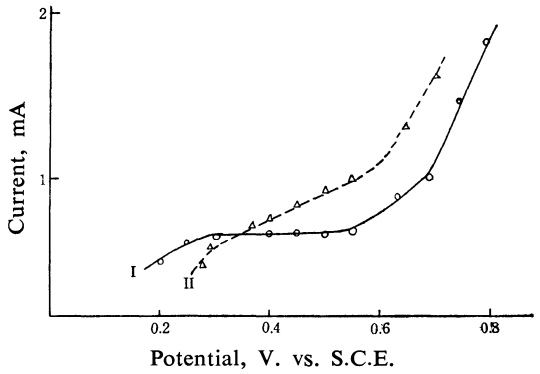

Fig. 4. Potential vs. current diagram for the electrolytic deposition of radioactive antimony in diluted hydrochloric acid.
I, in 1 N HCl; II, in 2.5 N HCl; 1% (w/v) hydroxylamine hydrochloride; 25°C; amount of Sb carrier < 2 μg.

Antimony was electrolytically deposited on a cathode (2×20 mm.) of silver or copper film (10 μg. per cm^2), which was evaporated in vacuo on a rubber hydrochloride film (0.25 mg. per cm^2), with platinum wire as anode. The potential-current diagram is shown in Fig. 4. About 70% of the radioactive antimony in ca. 1 N hydrochloric acid (ca. 10 ml.), containing 1% (w/v) hydroxylamine hydrochloride and less than 2 μg. of carrier antimony coming from the target, was deposited within 3 hr. with a terminal voltage 1.4 V. Under this condition the cathode potential vs. S.C.E. is −0.46 V. When the terminal voltage and the acid concentration were increased, the electrolysis was rather facilitated. However, an amorphous black substance appeared on the cathode surface, and the specific activity decreased. Such a black substance appeared even in the absence of antimony or by the use of pure carbon as anode. Spectrographic analysis indicated no other metal than the cathode metal. It appears as if the cathode is partly dissolved in the electrolytic solution owing to, e.g., local cell formation and then deposited again in the form of a very fine powder.

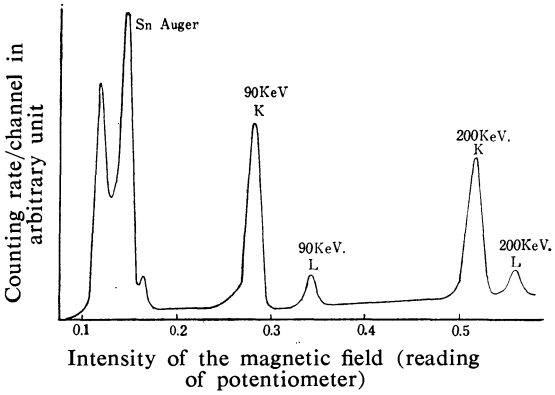

Fig. 5. Internal conversion electron spectrum of ^{120}Sb.

Measurement of the Internal Conversion Electron Spectrum. — Figure 5 illustrates the conversion electron spectrum in the lowest energy region; it clearly indicates that the source is so thin that the peaks corresponding to the Auger electron are distinctly separated. The form of the lines is symmetrical, indicating no source-scattering of low energy electrons.

Discussion

When tin with natural abundance ratio is irradiated with protons, radioactive antimony isotopes of mass numbers 115 to 124 are formed. Among these only Sb-119, 120 m and 124 survive after one day. The first gives only γ-rays of a low energy (23.8 keV.), and the last two are the main components of radioactive antimony. Although Sb-124 gives several γ-rays, they interfere neither with the accurate measurement of γ-ray energies by the conversion electron method nor with that of angular correlation of the γ-rays of Sb-120, because of the low abundance of ^{124}Sn.

Examination of solvent extraction, ion exchange and electrolysis of a micro amount of antimony disclosed that the procedures are satisfactorily effected so far as the antimony is not hydrolysed in the aqueous phase. Hence, care must be taken to avoid the hydrolysis especially in a rather low acid concentration. The recommended procedure is shown below.

The product is of so high a specific activity as to be more than 0.1 mc. per μg. of Sb. (The highest specific activity of Sb-124 produced in a reactor with a neutron flux of 10^{14} per cm^2 per sec. is ca. 0.01 μc. per μg. of Sb.) Figure 5 provides one of the rarest examples of low energy conversion electron spectra ever observed.

Recommended Procedure (*Separation by Solvent Extraction*).—Dissolve the target tin (4 g.) in a mixture (100 ml.) of 6 N hydrochloric and concentrated nitric acids (3+1 v/v), boil to decompose the nitric acid and treat it with concentrated hydrochloric acid to produce ca. 50 ml. of 8 N hydrochloric acid. Shake with amylacetate (25 ml.×2), and wash the ester layer with 8 N hydrochloric acid (20 ml.×2). Evaporate the organic phase almost to dryness with occasional addition of 8 N hydrochloric acid. Use the residual, rather viscous solution (ca. 0.1 ml. in volume) for γ-γ angular correlation study. Convert the residue into a 1 to 3 N hydrochloric acid solution (10 ml.) containing 1% (w/v) hydroxylamine hydrochloride and

electrolyse antimony, using the apparatus illustrated in Fig. 6 of Ref. 7, upon an evaporated film of silver (thickness: 10 μg. per cm^2) on rubber hydrochloride (0.25 mg. per cm^2) with a terminal voltage, 1.4 V.

Summary

1) By irradiation of a tin target (antimony content, less than 8×10^{-4}%) with 15 MeV. protons (120 μ amp. hr.), about 1 mc. of ^{120}Sb was produced, with a specific activity more than 30 μc. per μg. of antimony.

2) The radioactive antimony was either separated by extraction with amylacetate from more than 6 N hydrochloric acid containing tin(IV) or by cation exchange in a 0.4% tartaric acid solution of pH 0.6 to 1.6 containing tin(II).

3) ^{120}Sb is electrolytically deposited on an evaporated film of silver or copper from a 1 to 3 N hydrochloric acid solution containing 1% hydroxylamine hydrochloride with a yield of 70% within 3 hr.

4) Care should be taken to avoid hydrolytic aging of antimony in diluted hydrochloric acid, which vitiates the extraction, the ion exchange, and the electrolysis.

The authors wish to express their thanks to Drs. Mitsuo Sakai and Toshimitsu Yamazaki and the cyclotron crew of the Institute for their co-operation. They are also deeply indebted to Dr. Kamihiko Itsuki of Mitsubishi Metal and Mining Co. for kindly supplying them with very pure tin.

The Ultraviolet Spectra of Monohalo-, Mononitro- and Monoamino-p-terphenyls

By Kaoru IGUCHI, Tadashi NOZAKI, Akira IMAMURA and Setsuji TAKAHASHI

(Received February 16, 1963)

The molecule of *p*-terphenyl has a system of eighteen π-electrons and shows ultraviolet absorption with the peak at 276 mμ. When *p*-terphenyl is monosubstituted, the absorption peak shifts to red or blue and sometimes splits into two or three peaks according to the nature and the position of the substituent. These phenomena are due to the perturbation of the π-electronic system caused by the substitution. The perturbation consists principally of the following two factors: (1) interaction between the molecular orbital of *p*-terphenyl and the substituent orbital, and (2) the steric effect caused by the substituent. The ultraviolet absorption spectrum will give useful information concerning these factors.

The ultraviolet spectra of all isomers of monochloro-, monobromo-, monoiodo-, mononitro- and monoamino-*p*-terphenyl were measured, and the wavelength for maximum absorbance, the half-width of the absorption peak, the oscillator strength and the molar extinction coefficient were determined. For halo-*p*-terphenyls, the shift of the absorption peak was qualitatively treated theoretically by a molecular orbital method, which gave rather a good result considering its simplicity.

Experimental

The preparation of the compounds has been reported[1] previously, together with some of their properties. A weighed amount (ca. 1 mg.) of the sample was dissolved in purified *n*-heptane (10 ml.); then a definite volume (ca. 0.3 ml.) of the solution was withdrawn and added to the same solvent (10 ml.) in an absorption cell. The spectrum was measured at room temperature with a Shimadzu SV-50 A spectrophotometer in the range of 210~340 mμ. The oscillator strength (f) was determined by the use of Mulliken and Rieke's formula[2]:

$$f=\frac{mC^2}{\pi e^2 n}\int \gamma k_{\tilde{\nu}}\mathrm{d}\tilde{\nu}=\frac{4.318\times10^{-9}}{\text{mol. density}}\int D\mathrm{d}\tilde{\nu} \qquad (1)$$

2) R. S. Mulliken and C. A. Rieke, *Rep. Prog. Phys.*, 8, 231 (1941).

where n is the number of molecules in 1 ml. of solution; γ, the correction constant (here taken as unity); k_ν, the extinction coefficient, and D, the optical density ($\log_{10} I_0/I$). The integration was performed graphically by means of a planimeter.

Results and Discussion

The Absorption Peak and Oscillator Strength. —The measured spectra are shown in Figs. 1–5, while the numerical results are given in Tables I–V. The wavelength for the absorption peak depends strongly on the position of the substituent but only slightly on its nature. A similar tendency is also seen in the case of the melting point and the solubility[1], though the ultraviolet spectrum of the solution depends principally on the intramolecular state, while

the melting point and solubility should relate strongly to the intermolecular forces.

The ultraviolet spectra of the halo-*p*-terphenyls have the following characteristics; (1) The wavelenthgs of the absorption peaks are in the order 4-halo>3-halo>*p*-terphenyl; (2) Halogenation at 2- or 2'-position, on the other hand, shows a blue shift probably because of the steric effect; (3) The wavelength for the main absorption peak depends only slightly on the nature of the halogen atom; (4) The oscillator strength of a 4- or 3-halo-*p*-terphenyl is usually larger than that of the 2- or 2'-compound. Similar phenomena have also been observed with substituted biphenyl[3] and in more general cases[4]. The 238 mμ peaks of the iodo-*p*-terphenyls may be attributed to the absorption by the iodine atom itself[3].

LCAO MO Perturbation Treatment.—Many authors have tried to elucidate theoretically the effect of a substituent on the ultraviolet spectrum. Matsen[5] gave general formulas for the wavelength and oscillator strength of ultraviolet absorption using the perturbation theory and then applied them to benzene derivatives. Longuet-Higgins and Sowden[6] successfully explained the ultraviolet spectrum of methylated hydrocarbons. I'haya[7] also developed the perturbation theory and treated benzene derivatives.

We intend to explain our experimental results on the basis of a simple LCAO MO perturbation treatment. The substitution has an effect on both the electronic structure and the steric configuration of the *p*-terphenyl molecule. The substitution at the 3- or 4-position has influence only on the electronic structure, while that at the 2- or 2'-position has the further effect of twisting the molecule. The variation in electronic structure is due to the change in the degree of resonance and inductive effects. In the present paper, however, only the resonance effect is considered on the assumption that the difference in the inductive effect is small among the halo-*p*-terphenyls. The steric effect is taken up in the form of a variation in the resonance integral of the carbon-carbon bond between two benzene rings.

For the perturbed system, the energy, λ'_i, is given as follows, with the higher terms being neglected[8];

$$\lambda'_i=\lambda_i+2C^i_rC^i_s(\delta\beta)-\frac{(C^i_t)^2}{\alpha-\lambda_i}\gamma^2 \qquad (2)$$

where λ_i is the energy and C^i_r, the coefficient of the r-th atom in i-th non-perturbed MO; the subscripts r and s denote the atoms binding the two benzene rings being considered, and t is the position of the substituent. Here, α designates the energy of the highest occupied orbital of the substituent, while γ is the resonance integral of the bond between the substituent and *p*-terphenyl, $\delta\beta$ is the change in the resonance integral caused by the twist of *p*-terphenyl and is negative. All these quantities are expressed in units of $(-\beta)$, the resonance integral of the benzene carbon-carbon bond.

The lowest transition of *p*-terphenyl in the simple LCAO MO treatment can be regarded as $A_{1g}\rightarrow B_{3u}$ on the assumption that *p*-terphenyl has a plane structure. The energy differences between the lowest vacant and the highest occupied orbitals, ΔE, are calculated and listed in Table VI. Since the biphenyl molecule twists slightly, the *p*-terphenyl molecule should twist too. Using the above assumptions, however, we probably have not committed any serious errors in drawing our conclusions.

Since the value of any α in Table VI is larger than unity, all the second terms in the formulas are negative. Hence, for 4- and 3-halo-*p*-terphenyls, ΔE becomes smaller and a red shift occurs. Further, it is apparent that 4-substitution gives a larger red-shift than 3-substitution. These results agree well with the experimental data. Substitution at the 2- or 2'-position causes a remarkable blue shift owing to the third term, which is positive and has a larger absolute value than the second. Moreover, the blue shift is of nearly the same degree for 2 and 2' isomers, because the third terms are the same and the second terms differ only slightly between them. All these predictions are supported by the experimental data. The magnitude of the second term varies with the nature of the halogen. However, the change is too small to cause a shift of the peak, as may be seen in the experimental results. It is worth noticing that the all conclusions are derived independently of the values of the parameters in the formulas. In spite of the roughness in our treatment, the qualitative agreement with the experimental results is very good.

For the nitro- and amino-derivatives, however, the situation is too complicated to be treated by such a perturbation method; a more elaborate treatment is required.

*Anomalies in the Counting Rate of the Solid Thin Film of Tritiated Lauric Acid in Relation to its Film Structure**

By Kazuo TAJIMA, Tsunetaka SASAKI and Mitsuo MURAMATSU

(Received February 20, 1963)

Recently, increasing attension has been drawn to the special application of tritium as a radiotracer, because of the extremely soft nature of its β-radiation. Especially in the field of surface chemistry, tritium has proved to be very useful for studying the details of adsorption and related surface phenomena[1,2]. For this purpose, several tritiated compounds were prepared in our laboratory, and the condition of their solid counting was examined precisely[3] since the counting rate of tritium is highly dependent on the detailed geometry of each of the solid surface. In the course of this observation, we have found peculiar phenomena with a thin solid film of tritiated lauric acid.

A thin film of this substance deposited from benzene on a stainless steel dish and put in a 2π gas-flow counter gave a counting rate which decreased far more rapidly than was to be expected from the natural decay of tritium β-activity. Moreover, we could observe a distinct break point in the decay curve ten days after the deposition of the film, independent of the amount of sample taken, provided that the film was sufficiently thin. The present paper describes the details of these studies.

Experimental

The α,β-ditritiated lauric acid $CH_3(CH_2)_8(CHT)_2COOH$[4] was dissolved in benzene to give a 5.12×10^{-3} mol./l. solution, which was then spread on the stainless steel dish with a micro-pipette. The solid thin film of tritiated lauric acid left after the evaporation of the solvent was of a mean thickness of about 4~10 μg./cm^2. The β-counting rate of these films was then measured with a 2π gas-flow windowless counter ("Aloka DC-1001", a Nihon Musen Co. product), using propane[5] as a flow gas at the flow rate of 120 bubbles per minute. The results are shown in Fig. 1, where the counting rate is plotted against the time which elapsed after the formation of the thin film. We can notice in this figure that the radioactivity first decreases linearly with time, but its inclination is far steeper than is to be expected from the natural decay rate of tritium (half-life; 12.46 years), and that after ten days, a break point appears and another straight line of a smaller inclination follows. We can confirm that this behavior, especially the time of the appearance of the break point, is fairly reproducible, provided that the thickness of the sample film is sufficiently thin. At first, we presumed that this peculiarity comes from the extremely soft nature of the β-ray of tritium, but precise studies revealed that the phenomena are mainly due to the evaporation of the deposited film of an uneven structure. The following possibilities have been examined experimentally to arrive at the conclusion.

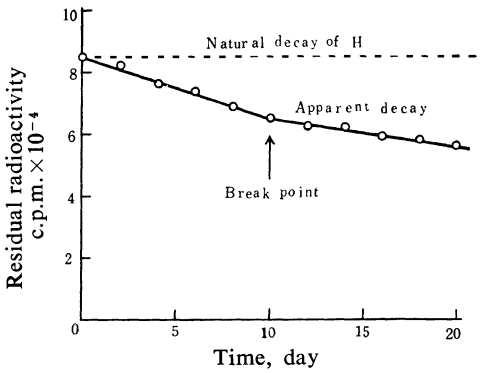

Fig. 1. The decrease in the radioactivity of the thin film of tritiated lauric acid with time.

Exchange with the Hydrogen from the Atmosphere Moisture and the Effect of Flow Gas.— First, as a possible cause of the anomalous rapid decay, we considered the labile position in the lauric acid molecule of the tritium atom, which can be removed by an exchange with a hydrogen atom of water vapor in the flow gas. To examine this possibility three similar tritium samples were prepared, two of which were allowed to come in contact with streams of dry and moist air respectively at the rate of 100 cc. per minute, while the remaining one was kept in a closed vessel without any air current. Changes in the counting rate with time were measured for these samples; the results are shown in Fig. 2. We can see in this figure that, as a whole, the curves are similar. This excludes the possibility that air flow and moisture can remove tritium. The possibility of flow gas itself producing the anomalous phenomena is also

excluded, since the tritiated stearic acid showed no such anomalies under similar conditions.

The Surface Migration of the Film Substance on the Dish. — If the film substance moves along the surface and clusters, it may decrease the surface area effective for counting. To examine this possibility, two tritium samples were prepared; in one of them tritiated lauric acid was spread in a uniform film, while in the other the substance was mounted as separate twenty-five small spots or clusters. The counting rate-agaist-time curves for these samples, as plotted in Fig. 3, failed to eliminate the anomalies, even for the spotted sample. This excludes the surface migration as an explanation.

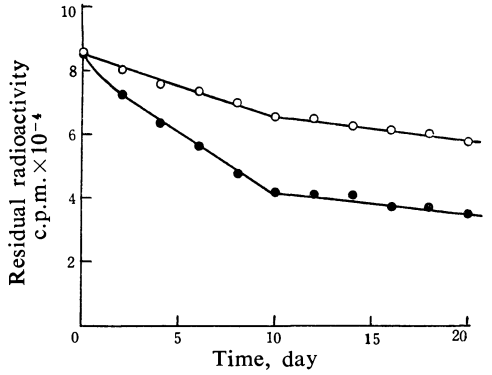

Fig. 3. The effect of the difference in mounting on the counting-rate-versus-time curve.
○ Uniform thin film
● Sample mounted in twenty-five spots

Chemical and Radiochemical Impurities. — Tritiated lauric acid may contain, for instance, other tritiated impurities which give rise to a rapid decrease in counting rate due to its evaporation. Such a possibility can, however, be excluded on the basis of the following experiments.

(1) We prepared at one time twenty samples of the film similar to that of Fig. 1, measured their weights, each on a different day, and constructed a diagram of weight loss due to evaporation versus

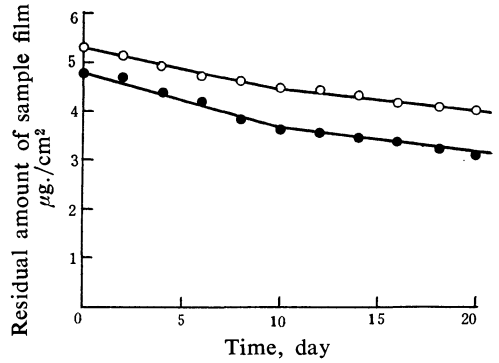

Fig. 4. The measurement of evaporation by radiotracer and surface trough experiment.
○ Surface trough measurement
● Radioactive measurement

time. Here the sample weight was determined by the monolayer method, that is, by dissolving the remaining sample film in 1 cc. of benzene, spreading the aliquot of the solution on a slightly acidified aqueous substrate, and determining, under a constant surface pressure, its limiting area, which is proportional to the amount of the remaining sample film. The results are shown in Fig. 4. We can see a break point on the 10th day similar to that found in Fig. 1. Thus we confirm that the evaporation is the main cause of these phenomena, as will be more precisely established later. Here the question arises as to whether this is exclusively due to the evaporation of the impurity. However, the weight loss during ten days is too large to explain the impurity, considering the m. p. of 43.5°C observed for the lauric acid and that of 75.5°C for the lauryl amide used. The presence of a volatile impurity has also been denied since in such a case we should have a simple horizontal straight line instead of the curve of Fig. 4, on account of the rapid evaporation of any such impurity from a spread monolayer for all samples.

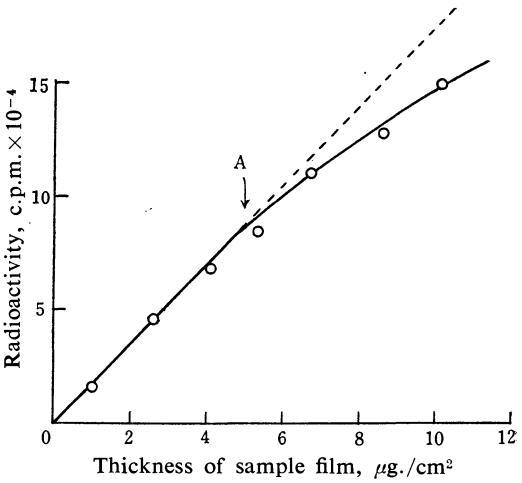

Fig. 5. The counting-rate-versus-sample-thickness curve.
A, Upper limit of linearity

However, the results did not agree with this expectation.

(2) If the phenomena are mainly due to the evaporation of volatile tritiated impurities, the slow decreasing curve attained after ten days, as shown in Fig. 1, is to be explained by the evaporation loss of impurities extending far deep from the solid surface contributing only a little to the actual loss in the β-counting rate. This critical depth roughly corresponds to point A of the counting rate curve shown in Fig. 5. This would indicate that the anomalies shown in Fig. 1 are largely independent of the film thickness, at least for a sufficiently thick film. However, the diagram for the extremely thick film of 530 μg./cm^2 proved to be practically a horizontal line, without a break, even after 10 days or more. These findings are contrary to the above expectation. The possibility of any other short-life radio-nuclide causing these phenomena can be excluded, since the radioactivity of the sample was completely absorbed with a sheet of thin polyethylene or paraffin paper about 3 mg./cm^2 thick.

The Evaporation of Lauric Acid and the Possible Explanation of the Phenomena. — According to the reasoning of the preceding section, the anomalies shown in Fig. 1 can reasonably be explained on the basis of the evaporation of the lauric acid film itself. This is further confirmed by comparing the β-counting rate of the samples of lauric acid films prepared from a benzene solution by evaporating it at 16.5 and 50°C. The marked evaporation at the higher temperature is evident, as may be seen in Fig. 6. As to the detailed explanation of the phenomena in terms of the evaporation of the lauric acid film, the heterogeneity of the deposited film should be pointed out, since a homogeous film and a uniform evaporation result, rather, in a simple straight line of a negative slope, without a break point. In fact, when a drop of lauric acid is put on the dish, most of it spreads as a thin film, while some portion remains as minute droplets. The solvent then evaporates, leaving lauric acid in a thin, uniform film with many clusters scattered upon it. Some of those can even be traced by the naked eyes. This behavior is quite similar to oleic acid on the water surface, which results in a monolayer and liquid droplets.

Therefore, a brief consideration indicates that the radioactive thin film of the thickness of a simple Gaussian-like distribution, as shown by A or B in Fig. 7(II), when exposed to the uniform evaporation, shows a decrease in radioactivity, as is illustrated by A or B in Fig. 7(I), according to whether the thickness is smaller or larger than the critical thickness of the self-absorption of tritium β-radiation, as is shown in Fig. 7(II). Neither of these curves can alone explain the observed curves of Fig. 1.

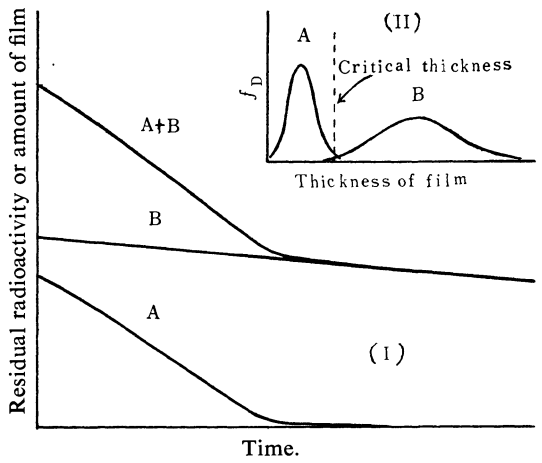

Fig. 7. A diagram showing the decrease in the counting rate depending on the thickness distribution of thin film. (I)A and (I)B indicate the c.p.m.-versus-time curves for the evaporation of films of the f_D thickness-distribution curve shown in (II)A (steep and narrow) and (II)B (flat and broad) respectively. (I)A+B represents c.p.m.-versus-time curve for the film composed of A and B. The dotted line represents the critical thickness for self-absorption.

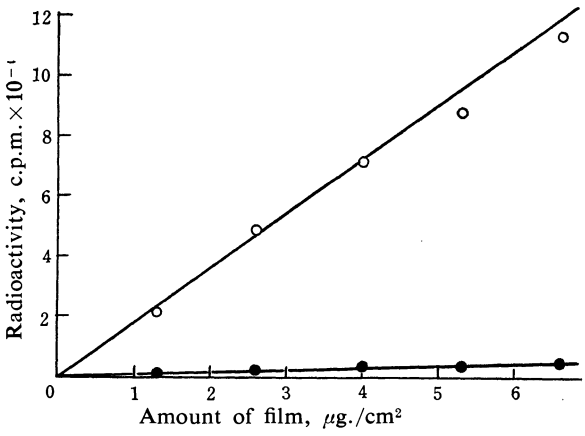

Fig. 6. The effect of the drying temperature on the counting rate of film.
○ Film prepared at 16.5°C
● Film prepared at 50°C

To explain the observed characteristics of the evaporation curve, a film having at least two peaks in the thickness-distribution curve, as in Fig. 7(II), should be taken into account. The composite evaporation curve of such a film is illustrated by curve A+B in Fig. 7(I), which closely resembles the actual evaporation curve. The abrupt decrease with time in surface area and, accordingly, in the slope of the counting-rate-versus-time curve is produced after the complete evaporation of the thinner film, A. The fact that the time of the appearance of the break point is largely independent of the amount of film taken is an indication of the relative constancy of the thickness distribution of the thinner film, which requires about ten days for complete evaporation.

The smaller inclination after the break point

corresponds to the rate of evaporation only from the thicker portion of film B. The disappearance of the break point for the film 530 μg./cm^2 thick may be explained as resulting from the initial deposit being sufficiently thick and consisting exclusively of film B. According to the results of our experiment, the thickness distribution of film A is considered to be constant, at least in the region of apparent thickness from 4 to 10 μg./cm^2. The thickness distribution presumably shifts towards a thinner region for a film of a much smaller apparent thickness, since the break point for the film of, say, 1 μg./cm^2 appeared five days earlier than the above film, as is shown in Fig. 8. It

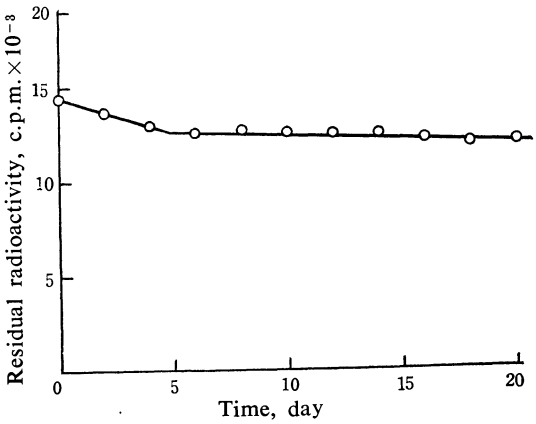

Fig. 8. The counting-rate-versus-time curve for the thinner film of 1 μg./cm^2.

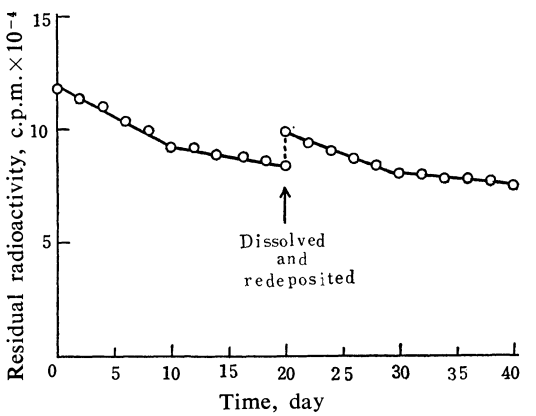

Fig. 9. The effect of the dissolution and redeposition of film on the counting-rate-versus-time curve.

should also be mentioned that the film already in the stage of a slow decrease in counting rate beyond the break point, when dissolved completely with benzene and redeposited by evaporation, again repeats all the changes of the curve of Fig. 1, as is shown in Fig. 9. This can be explained by the fact that the portion of film B still remaining thicker than the critical thickness at this stage and not contributing to the counting rate, when redeposited, produces a considerable amount of film A again, as is shown in Fig. 7(II). The slight increase in the counting rate (shown by the arrow in Fig. 9) when the film is redeposited can also be explained by the appearance of film A. It must be added that the experimental results showing the absence of the gas-flowing effect on the evaporation of the sample (cf. Fig. 2) seems, at first sight, to contradict our conclusion. However, it may be that the air current is insufficient to show the effect of evaporation in any perceptible amount in the case of such a small vapor pressure and rate of evaporation as those of lauric acid.

Summary

A thin film of α,β-ditritiated lauric acid $CH_3(CH_2)_8(CHT)_2COOH$ deposited from benzene on a stainless steel dish and put in a 2π gas-flow windowless counter gave a counting rate which decreased far more rapidly than was expected from the natural decay of the β-activity of tritium. We observed a distinct break point in the decay curve ten days after the deposition of the film, independent of the amount of sample taken, provided that the film was sufficiently thin.

Various factors, such as impurities, surface migration, exchange reaction and evaporation, were considered to explain the phenomena; among these the evaporation of the lauric acid from the deposited surface film of the composite structure was proved to be the main factor responsible for these phenomena.

In conclusion, the authors wish to express their thanks to the Ministry of Education for the Scientific Research Expenditure Grant given to Tsunetaka Sasaki.

The Crystal Structure of Ethylenediammonium Chloride

By Tamaichi ASHIDA and Sakutaro HIROKAWA

(Received February 25, 1963)

Ethylenediamine, as a ligand of the coordination compounds, has been studied by several authors[1-4]. In these crystals, ethylenediamine usually has a gauche-configuration. However, ethylenediamine in other types of compounds has not been sufficiently investigated. In the structure of ethylenediammonium sulfate[5], for instance, though it has not been fully studied, the ethylenediammonium ion has been reported to have a gauche-configuration. On the other hand, in ethylenediammonium adipate, of which only the crystallographic data have been reported[6], a planar and a trans-configuration can be expected on the basis of the data, because the ethylenediammonium ion seems to have a center of symmetry. Thus, the ethylenediammonium ion seems to have either a trans- or a gauche-configuration. Ethylenediammonium chloride was chosen to be investigated in order to add to the data on the trans- and gauche-stereoisomerism of the ethylenediammonium ion. The results of the investigation will be given here.

Recently, tetramethylenediammonium chloride has also been investigated by the present authors from a similar view-point. These results will be published later.

Experimental

The crystals of ethylenediammonium chloride, $H_3N(CH_2)_2NH_3Cl_2$, were grown from an ethylalcohol-water solution. Most of the crystals were obtained as needles elongated along the c axis, while others were obtained as plates, the main face of which was (0 0 1). This difference may be due to slight changes in the conditions of the recrystallizations. A marked cleavage was found perpendicularly to the c axis, as had been reported by Groth[7]. The crystals belong to the monoclinic system. The unit cell dimensions were obtained from the Weissenberg photographs of $(h\,0\,l)$ and $(h\,k\,0)$ by overlapping the powder patterns of aluminum as a standard on the same films; they are;

$$a=9.95\pm0.01 \qquad b=6.89\pm0.01$$
$$c=4.42\pm0.01\text{Å} \qquad \beta=90.7\pm0.3^\circ$$

and $$a:b:c=1.449:1:0.642$$

The axial ratios of the present investigation agree with the values given by Groth[7] to within the stated range of experimental error, though the β-angles differ a little from one other. The values given by Groth are:

$$a:b:c=1.4439:1:0.6439$$

and $$\beta=91^\circ35'$$

The space group of the crystal was found to be $P2_1/a$ from the systematic absences of the $(0\,k\,0)$ spectrum for $k=2n+1$ and the $(h\,0\,l)$ spectrum for $h=2n+1$. The density, 1.46 g. cm^{-3}, observed by the floatation method corresponds to two formula units in a unit cell; the calculated density is 1.46 g. cm^{-3}.

Weissenberg photographs were taken around the b and c axes, using Cu$K\alpha$ radiation. The multiple-film technique was used, and the intensities of the $(h\,0\,l)$, $(h\,k\,0)$ and a part of the $(h\,k\,1)$ reflections were estimated visually, comparing them with a standard scale made by the same crystal. The corrections for polarization and Lorentz factors were made. No absorption corrections were made because the shapes of the crystals used were irregular; they should have been made, however, because the linear absorption coefficient for Cu$K\alpha$ radiation is rather large ($\mu=85.0\,\text{cm}^{-1}$).

Structure Determination

Since the crystal belongs to the $P2_1/a$ space group and the number of formula units in a unit cell is two, the ethylenediammonium ion has to occupy a center of symmetry. The position of the chloride ion was determined from the projections of the Patterson function along the b and c axes. The projections of the electron-density functions along the two principal axes were synthesized using the structure factors whose phases were assigned by the coordinates of the chloride ion. The maps thus obtained showed the positions of the carbon and the nitrogen atoms. The coordinates of the atoms thus obtained were, then, refined by successive (F_o-F_c) syntheses. In these procedures, it was found that the

contributions of the hydrogen atoms to the structure factors were not negligible (the electrons which belong to the hydrogen atoms amount to 14% of the total number of electrons in the crystal). Therefore, the coordinates of all the hydrogen atoms were calculated geometrically, using the coordinates of the heavier atoms, and the presences of these hydrogen atoms were confirmed on the $(\rho_o-\rho_c)$ maps. They were included in the calculations of the structure factors, which were used in the further refinements of the structure, whereupon the R factors of two zones decreased by about 0.02. The final $(\rho_o-\rho_c)$ maps of $(h\,0\,l)$ are shown in Fig. 1, where significant changes due to the inclusion or exclusion of the hydrogen atoms are observed not only at the positions of the hydrogen atoms but also almost everywhere. The final atomic coordinates of the heavier atoms are listed in Table I. The isotropic temperature factors assigned for the atoms are: 2.66 for all the atoms for $F(h\,0\,l)$, and 1.40, 0.86, 0.91 and 1.00 for C, N, Cl^- and H's respectively for $F(h\,k\,0)$. Each absolute value of these temperature factors may not have significance, because no absorption corrections for the intensities were made. The observed and the calculated structure factors are compared in Table II. The final

R factors are 0.065 for all the observed reflections of $(h\,0\,l)$ and 0.081 for $(k\,k\,0)$, excluding four reflections which showed marked extinction effects (these are shown with asterisks in Table II).

Discussion

In Table III, some of the important interatomic distances and bond angles in this crystal are shown. Because the ethylenediammonium ion occupies a center of symmetry, the ion has a trans-configuration and the N-C-C-N chain of the ion is geometrically planar. The equation of the plane is:

$$0.895X-0.448Y-0.020Z=0$$

where $X=ax\sin\beta$, $Y=by$ and $Z=cz+ax\cos\beta$. Thus, in the crystals, the ethylenediammonium ion was found to have either a trans- or a gauche-configuration, depending on the structure of the crystals.

TABLE III. IMPORTANT INTERATOMIC DISTANCES (Å) AND ANGLES (deg.)

C-C	1.53	CCN	109.8
C-N	1.49		
		CNCl(1)	111.5
N-Cl(1)	3.20	CNCl(2)	103.8
N-Cl(2)	3.22	CNCl(3)	106.0
N-Cl(3)	3.14	Cl(1)NCl(2)	103.9
		Cl(1)NCl(3)	111.3
N-Cl(4)	3.48	Cl(2)NCl(3)	120.5
Cl(3)-Cl(4)	3.89		

The crystal structures projected on the (0 1 0) and the (0 0 1) planes are shown in Figs. 2 and 3. The nitrogen atom's three nearest neighbors are chloride ions (Cl(1), Cl(2) and Cl(3), cf. Figs. 2 and 3), the N-Cl distances being 3.20, 3.22 and 3.14 Å respectively. These N-Cl lengths may be compared

to the values 3.11 and 3.24Å found in hexamethylenediammonium chloride[8] and to many others[9]. Thus, these short contacts may be said to be hydrogen bonds, when we consider the $<$CNCl or $<$ClNCl angles shown in Table III and the positions of the hydrogen atoms shown in Fig. 1. One N–Cl contact 3.48Å in length may not have significance, judging from the argument given above, and such a length has also been reported in hexamethylenediammonium chloride[8] (3.37 and 3.58Å). The shortest Cl–Cl distance is 3.88Å, between those chloride ions which are related to each other by a twofold screw axis. Thus, in this crystal, the three N–H···Cl hydrogen bonds binds the organic ions and the chloride ions and make infinite two-dimensional networks perpendicular to the c axis. The forces which combine these layers along the c axis may be van der Waals forces, together with weak electrostatic forces, if any. These facts explain the perfect cleavage along the (0 0 1) plane.

9) G. C. Pimentel and A. L. McClellan, "The Hydrogen Bond", W. H. Freeman and Co., San Francisco (1960), p. 290.

Summary

The crystal structure of ethylenediammonium chloride has been determined. The crystal belongs to the monoclinic system with $a=9.95$, $b=6.89$, $c=4.42$Å and $\beta=90.7°$; the space group is $P2_1/a$. The unit cell contains two ethylenediammonium ions and four chloride ions. The ethylenediammonium ion occupies a center of symmetry and takes a transform; thus, the ethylenediammonium ion was found to be either a trans- or a gauche-form in the crystals, depending on the structures of the crystals. The bond distances and angles of the ethylenediammonium ion are: C–C 1.53, C–N 1.49Å and $<$CCN 109.8°. Three N–H···Cl hydrogen bonds (3.20, 3.22 and 3.14Å) make two-dimensional networks of the ions perpendicular to the c axis.

The Color Reactions of Lower Oxoacids[1] of Phosphorus with Molybdate and their Application to Colorimetric Determinations of $\overset{4}{P}-\overset{3}{P}-\overset{4}{P}-$ and $(-\overset{3}{P}-)_6$-Acid[2]

By Shigeru OHASHI and Norimasa YOZA

(Received February 28, 1963)

In the last ten years a number of salts of new, lower oxoacids of phosphorus have been reported[3]. Blaser and Worms[4,5] have synthesized a series of alkali salts of lower oxoacids by the oxidation of red phosphorus. Some of them, such as $\overset{4}{P}-\overset{3}{P}-\overset{4}{P}-$ and $(-\overset{3}{P}-)_6$-acid, are compounds in which more than two phosphorus atoms are bound directly. The former has a chain structure, while the latter has a ring structure. More recently two compounds, $\overset{4}{P}-\overset{4}{P}-O-\overset{4}{P}-\overset{4}{P}-$ and $(-\overset{4}{P}-\overset{4}{P}-O-)_2$-acid, which are obtained by the polymerization of $\overset{4}{P}-\overset{4}{P}$-acid have been reported[6].

It is well known that the $\overset{5}{P}$-acid reacts with molybdate in a mineral acid solution to produce molybdophosphate and that the resulting yellow salt produces a blue color in the presence of a reducing agent. In this paper the authors describe the color reactions of lower oxoacids of phosphorus with molybdate in

1) In this paper the authors use the term "lower oxoacids of phosphorus" for oxoacids of phosphorus with a lower oxidation number than 5.

2) These acids do not yet have chemical names. The authors use the notations proposed by Blaser and Worms for these two acids as well as for other oxoacids of phosphorus because of their simplicity. The Arabic numerals attached to the phosphorus atoms represent the oxidation numbers of the phosphorus atoms. See B. Blaser and K.-H. Worms, *Z. anorg. u. allgem. Chem.*, **300**, 225 (1959). The structural formulas of lower oxoacids of phosphorus represented by the notations are shown in Table I.

neutral or acid solutions. Samples include twelve lower oxoacids as well as $\overset{5}{P}$- and $\overset{5}{P}\text{-O-}\overset{4}{P}$-acid.

The authors found that three of the fourteen oxoacids, $\overset{2}{P}\text{-}\overset{4}{P}$-, $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$- and $(\text{-}\overset{3}{P}\text{-})_6$-acid, show characteristic color reactions with molybdate; i. e., the three oxoacids react with molybdate in acid solutions to produce a blue color without any reducing agent. These chemical properties give a means for the analysis of these compounds, especially for colorimetric determinations of $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$- and $(\text{-}\overset{3}{P}\text{-})_6$-acid.

Experimental

Materials and Equipment.—An aqueous solution of guaranteed reagent-grade ammonium molybdate tetrahydrate and an amidol (1-amino-2-naphthol-4-sulfonic acid) solution for a reducing agent were prepared by Nakamura's method[7].

Sample solutions of salts of fourteen oxoacids of phosphorus were prepared; $NaPH_2O_2 \cdot H_2O$ was used for $\overset{1}{P}$-acid, $Na_2PHO_3 \cdot 5H_2O$ for $\overset{3}{P}$-acid, $Na_2HPO_4 \cdot 12H_2O$ for $\overset{5}{P}$-acid, $Na_2P_2H_2O_5$ for $\overset{3}{P}\text{-O-}\overset{3}{P}$-acid, $Na_3P_2HO_6 \cdot 4H_2O$ for $\overset{3}{P}\text{-O-}\overset{5}{P}$-acid, $Na_4P_2O_7 \cdot 10H_2O$ for $\overset{5}{P}\text{-O-}\overset{5}{P}$-acid, $Na_3P_2HO_5 \cdot 12H_2O$ for $\overset{2}{P}\text{-}\overset{4}{P}$-acid, $Na_2H_2P_2O_6 \cdot 6H_2O$ for $\overset{4}{P}\text{-}\overset{4}{P}$-acid, $(CN_3H_6)_4P_3HO_8 \cdot$ aq. (guanidinium salt) for $\overset{3}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}$-acid, $(NH_4)_5P_3O_9 \cdot$aq. for $\overset{5}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}$-acid, $Na_6P_4O_{11} \cdot$aq. for $\overset{4}{P}\text{-}\overset{4}{P}\text{-O-}\overset{4}{P}\text{-}\overset{4}{P}$-acid, $Na_4P_4O_{10} \cdot 4H_2O$ for $(\text{-}\overset{4}{P}\text{-}\overset{4}{P}\text{-O-})_2$-acid, $Na_5P_3O_8 \cdot 14H_2O$ for $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$-acid, $(K(Na)PO_2)_6 \cdot$aq.[8] for $(\text{-}\overset{3}{P}\text{-})_6$-acid. The salts of $\overset{1}{P}$-, $\overset{3}{P}$-, $\overset{5}{P}$- and $\overset{5}{P}\text{-O-}\overset{5}{P}$-acid were commercial reagents, while the others were supplied by Blaser and Worms. It was confirmed by paper chromatography that all of these compounds were pure.

Measurements of absorbances were carried out with a Shimadzu spectrophotometer QB-50, with glass cells 1.00 cm. in width.

Paper Chromatography.—An ascending technique was employed. A basic solvent recommended by Thilo and Heinz[9] was made by mixing 150 ml. of 2-methyl-1-propanol, 190 ml. of ethanol, 225 ml. of water, and 3 ml. of concentrated aqueous ammonia. A spray reagent was made according to the method of Hanes and Isherwood[10] by mixing 5 ml. of 60% perchloric acid, 1 ml. of concentrated hydrochloric acid, and 1 g. of ammonium molybdate tetrahydrate, and diluting it to 100 ml. with distilled water. Rectangular battery jars and Toyo No. 51A filter papers were used.

Color Reactions and Measurement of Absorbances. — Three series of 10 ml. of 1% ammonium molybdate solutions were prepared. One of them was neutral (only dissolved in distilled water), and the others were 1 N acid solutions in relation to perchloric acid. One milliliter of the respective sample solutions (about 10^{-2} M) was added to each series of the molybdate solutions, and 1 ml. of an amidol solution was added to one of the series of acid solutions. They were shaken well, and the color reactions were observed for an hour at room temperature.

Five milliliters of the 10% ammonium molybdate solution and 10 ml. of a 5 N perchloric acid solution were added to a 50 ml. volumetric flask. It was diluted to 30 ml. with distilled water, and then each sample solution was added. The concentration of the sample, $\overset{4}{P}\text{-}\overset{3}{P}\text{-}\overset{4}{P}$- or $(\text{-}\overset{3}{P}\text{-})_6$-acid, was adjusted to $10^{-3} \sim 10^{-5}$ M. The volume was brought up to the 50 ml. mark with distilled water. The mixture was shaken well and, after 30 min., the absorbances were measured in the range of 400 to 800 mμ wavelength, using a reagent solution as a reference.

Determination of Total Phosphorus.—All the phosphorus in a sample was converted into $\overset{5}{P}$-acid and determined colorimetrically. Five milliliters of aqua regia were added to a 25 ml. flask containing

1 ml. of the sample solution. It was evaporated gently on the water bath so as to decompose and oxidize the lower oxoacid. The residue was dissolved and then diluted to 25 ml. with distilled water. An aliquot of the solution was transferred to a 25 ml. volumetric flask, and 10 ml. of the 5 N perchloric acid solution, 5 ml. of the 10% ammonium molybdate solution, 20 ml. of distilled water, and 5 ml. of the amidol solution were added. It was brought up to the mark with distilled water, shaken well and, after 30 min., the absorbance at 780 mμ, using a reagent solution as a reference.

Results and Discussion

The color reactions of fourteen oxoacids of phosphorus with ammonium molybdate were tested. The results are summarized in Table I, $\overset{1}{P}$–, $\overset{3}{P}$– and $\overset{3}{P}$–O–$\overset{3}{P}$–acid give no color reaction in either the neutral or the acid solutions, even in the presence of the reducing agent.

It is well-known that $\overset{5}{P}$–acid does not show any color change in a neutral solution but does give a yellow color in an acid solution, and that the yellow heteropoly acid changes into a blue compound in the presence of a reducing agent such as amidol. $\overset{3}{P}$–O–$\overset{5}{P}$– and $\overset{5}{P}$–O–$\overset{4}{P}$–$\overset{5}{P}$–acid show the same behavior as $\overset{5}{P}$–acid does, because they are readily hydrolyzed in the acid solution to produce $\overset{5}{P}$–acid. $\overset{5}{P}$–O–$\overset{5}{P}$–Acid gives no detectable yollow color in the acid solution because of the slower rate of hydrolysis of the $\overset{5}{P}$–O–$\overset{5}{P}$–acid in comparison with the other compounds containing a $\overset{5}{P}$–unit.

Four compounds which contain a $\overset{4}{P}$–$\overset{4}{P}$–unit and no $\overset{5}{P}$–unit show a blue color only in the presence of amidol. This may be because of the hydrolysis of $\overset{4}{P}$–$\overset{4}{P}$–acid into $\overset{3}{P}$– and $\overset{5}{P}$–acid in the acid solution[11].

$\overset{2}{P}$–$\overset{4}{P}$–Acid produces a faint bluish green color (absorbance, about 0.04) in the acid solution, when the concentration of the $\overset{2}{P}$–$\overset{4}{P}$–acid is 10^{-3} M. In the concentrations more than 10^{-3} M, it colors semiquantitatively, but the reproducibility is not good. It was shown by paper chromatography that a main product of the reaction is $\overset{3}{P}$–acid due to the hydrolytic decomposition of the $\overset{2}{P}$–$\overset{4}{P}$–acid. The bluish-green coloration may be due to the redox reaction between molybdenum(VI) and the $\overset{2}{P}$–$\overset{4}{P}$–acid, where a part of the $\overset{2}{P}$–$\overset{4}{P}$–acid is oxidized into $\overset{4}{P}$–$\overset{4}{P}$–acid and a part of the molybdenum(VI) is reduced to molybdenum(V).

$\overset{4}{P}$–$\overset{3}{P}$–$\overset{4}{P}$–Acid shows a bluish-green color reaction only in the acid solution. $(-\overset{3}{P}-)_6$–Acid produces bluish-green colors in both the neutral and the acid solution. However, the bluish-green color caused by the $(-\overset{3}{P}-)_6$–acid in the neutral solution is very unstable; its intensity diminishes rapidly with time.

By paper chromatography distinct spots of $\overset{3}{P}$– and $\overset{4}{P}$–$\overset{4}{P}$–acid and a faint spot of $\overset{5}{P}$–acid were detected in the reaction products of the $\overset{4}{P}$–$\overset{3}{P}$–$\overset{4}{P}$–acid and molybdate in the acid solution. It appears reasonable to consider the following scheme for this reaction:

$$\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}\text{–Acid} \begin{cases} \xrightarrow{A} \overset{3}{P}\text{–Acid} + \overset{4}{P}\text{–}\overset{4}{P}\text{–Acid} \\ \xrightarrow{B} \overset{5}{P}\text{–Acid} + \overset{4}{P}\text{–}\overset{4}{P}\text{–Acid} \end{cases}$$

Path A is the hydrolysis of the $\overset{4}{P}$–$\overset{3}{P}$–$\overset{4}{P}$–acid, and path B is the oxidation of the acid by molybdate. The larger part of the $\overset{4}{P}$–$\overset{3}{P}$–$\overset{4}{P}$–acid is decomposed by path A and the smaller part of the acid by path B.

The reaction between $(-\overset{3}{P}-)_6$–acid and molybdate in the acid solution seems to be more complicated. Unfortunately, paper chromatographic identification of the reaction products was not certain. On the paper chromatogram a spot of $\overset{3}{P}$–acid was observed, but spots of other species were spread near the initial point.

The authors found that the bluish-green color produced by the reaction of $\overset{4}{P}$–$\overset{6}{P}$–$\overset{4}{P}$– or $(-\overset{3}{P}-)_6$–acid with molybdate in the acid solution is quite stable, at least in the range of

10^{-5} M unit for $(-^{3}_{}P\text{-})_6$-acid (II)

30~100 min., as is shown in Fig. 1. The absorption curves of the bluish-green colors due to $^{2}_{}P\text{-}^{4}_{}P$-, $^{4}_{}P\text{-}^{3}_{}P\text{-}^{4}_{}P$- and $(-^{3}_{}P\text{-})_6$- acid are shown in Fig. 2. The curves are similar to one another, having their maxima at 780~785 mμ. An absorption curve of so-called heteropoly blue[12] produced by the reduction of molybdophosphate has a shape similar to the curves of Fig. 2, but it has its maximum at 830 mμ.

The molar extinction coefficients for $^{4}_{}P\text{-}^{3}_{}P\text{-}^{4}_{}P$- and $(-^{3}_{}P\text{-})_6$-acid at 780 mμ are 5.09×10^{2} and 5.30×10^{3} respectively. As is shown in Fig. 3, they comform well to Beer's law at 780 mμ.

Experimental results show that $^{1}_{}P$-, $^{3}_{}P$-, $^{5}_{}P$-, $^{4}_{}P\text{-}^{4}_{}P$- (10^{-2} M, respectively),-and $^{2}_{}P\text{-}^{4}_{}P$-acid (less than 5×10^{-4} M) do not inhibit the quantitative color development of $^{4}_{}P\text{-}^{3}_{}P\text{-}^{4}_{}P$- or $(-^{3}_{}P\text{-})_6$-acid in the acid solution. $^{2}_{}P\text{-}^{4}_{}P$-Acids more than 10^{-3} M increase distinctly the absorbance of the bluish-green color.

The methods described above are satisfactory when one component, either $^{4}_{}P\text{-}^{3}_{}P\text{-}^{4}_{}P$- or $(-^{3}_{}P\text{-})_6$-acid, is present, accompanying other oxoacids of phosphorus, in a given sample, but it is not applicable if the two components are both present. When both $^{4}_{}P\text{-}^{3}_{}P\text{-}^{4}_{}P$- and $(-^{3}_{}P\text{-})_6$-acid are present in a given sample, the problem is resolved by combining this method with another procedure in which lower oxoacids are converted into $^{5}_{}P$-acid and the total phosphorus is

12) D. F. Boltz, "Colorimetric Determination of Nonmetals", Interscience Publishers, Inc., New York (1958), p. 33.

determined by the usual heteropoly blue method. The concentrations of $\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}$– and $(\text{–}\overset{3}{P}\text{–})_6$–acid are obtained by calculating the absorbances measured by both methods. In this case it should be noted that three and six moles of $\overset{5}{P}$–acid are produced by the oxidation of one mole of $\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}$– and $(\text{–}\overset{3}{P}\text{–})_6$–acid respectively. The experimental results are shown in Table II. The errors for the components of the lower concentrations in Nos. 3 and 8 of Table II are so large that the application of apply this method most be avoided in cases where the differences between the concentrations of the two components are large.

Summary

The color reactions of twelve lower oxoacids of phosphorus, as well as of $\overset{5}{P}$– and $\overset{5}{P}\text{–O–}\overset{5}{P}$–acid with molybdate, have been described. Of these compounds, $\overset{2}{P}\text{–}\overset{4}{P}$–, $\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}$– and $(\text{–}\overset{3}{P}\text{–})_6$–acid react with molybdate in the acid solution to produce a bluish-green color without any reducing agent.

The bluish-green color caused by $\overset{2}{P}\text{–}\overset{4}{P}$–acid is not reproducible. Since the colors caused by $\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}$– and $(\text{–}\overset{3}{P}\text{–})_6$–acid are stable and since their intensities are proportional to their concentrations, one can detect and determine minute amounts of $\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}$– or $(\text{–}\overset{3}{P}\text{–})_6$–acid colorimetrically in the presence of the other oxoacids of phosphorus. When both $\overset{4}{P}\text{–}\overset{3}{P}\text{–}\overset{4}{P}$– and $(\text{–}\overset{3}{P}\text{–})_6$–acid are present in a given sample, one can determine each component by combining the method described above with the usual heteropoly blue method for the total phosphorus.

The authors wish to express their hearty thanks to Professor Jun Yoshimura for his kind suggestions made in the course of this work. The authors also wish to thank Dr. Bruno Blaser and Dr. Karl-Heinz Worms for supplying the samples used in this study.

The Preparation of Trimethylamine Oxide Complexes and Some Infrared Studies

By Sigeo KIDA

(Received March 4, 1963)

Metal complexes of pyridine *N*-oxide have been prepared, and their infrared studies have been recently reported[1-3]. In these investigations, it has been shown that pyridine *N*-oxide readily combines with various metal ions in organic solvents to form metal complexes, and that the infrared frequency of the N–O stretching vibration of pyridine *N*-oxide considerably shifts to lower frequencies upon coordination to metal ions (1265→1220∼1200 cm^{-1}). This shift has been attributed to a change in the contribution of the various resonance structures of pyridine *N*-oxide as a result of the coordination. In other words, the N–O stretching vibration shifts to a lower frequency, as the double bond character of the N–O bond decreases upon coordination A considerable difference in the behavior of the N–O stretching vibration would be expected in the case of trimethylamine oxide, since its N–O bond has no double-bond character. Infrared and Raman studies of trimethylamine oxide have been reported[4-8];

however, no investigation of its metal complexes has yet been reported*.

In the present investigation, it was attempted to prepare the metal complexes of trimethylamine oxide by the procedure used in the case of pyridine *N*-oxide, but it was found difficult, with the exception of the cobalt(II) complex, to obtain pure crystals of the products. The zinc(II) and cadmium(II) complexes were prepared as pure crystals by careful dehydration of the starting materials, but other metal ions, such as iron(II), nickel(II), copper(II), aluminum(III), chromium(III) and iron(III), failed to give pure products.

Matis-Noel et al.[7] measured the infrared spectra of trimethylamine oxide and its derivatives and assigned the strong band at 952 cm^{-1} to the N–O stretching vibration. This assignment was based only upon a comparison of the spectrum of trimethylamine oxide with those of its derivatives; it does not seem to be a definite assignment. In fact, in trimethylamine oxide the N–O stretching vibration may probably be coupled with the other mode of vibration. Hence, in the present investigation, the normal coordinate treatment has been carried out on trimethylamine oxide, and the discussion has been extended to the metal complexes.

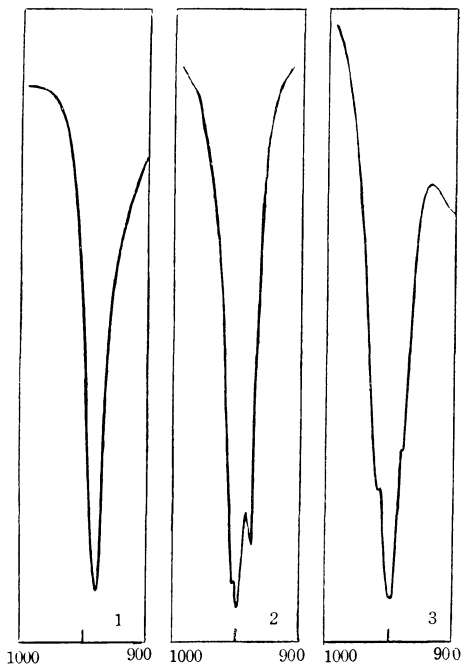

Fig. 1

1; Trimethylamine oxide in bromoform solution
2: Trimethylamine oxide hydrochloride in KBr disk
3: Trimethylamine oxide in KBr disk

While this work was in progress, Giguere and Chin[8] published a paper on the infrared spectra of trimethylamine oxide and its hydrochloride. They assigned the 937 cm^{-1} and 945 cm^{-1} bands to the N–O and the N–C stretching vibrations respectively. However, it appears to the present author that these two bands are due to a splitting of what should appear as a single band in a free molecule. One should be aware of the fact that a single band observed in solution or in a gaseous state may sometimes split into a couple of bands in the solid state. In fact, the frequencies of these two bands are close together, and the present experiment shows that, in a bromoform solution, only one band can be observed in this region; no splitting has ever been observed, as is shown in Fig. 1. Also, no such splitting was observed in the Raman investigation[4].

Experimental

Preparation of the Compounds.—*Trimethylamine Oxide.*—The hydrate, $(CH_3)_3NO \cdot 2H_2O$, was first distilled under reduced pressure, then resublimed twice in vacuo.

Tetrakis (Trimethylamine Oxide) Cobalt(II) Nitrate.—To a solution of 2.0 g. of trimethylamine oxide in 10 ml. of 95% ethanol was added 1.0 g. of cobalt(II) nitrate hexahydrate dissolved in 10 ml. of 95% ethanol. The resulting deep blue-violet solution was evaporated to half volume and cooled in a refrigerator. The blue-violet crystals which were formed were collected on a glass filter, washed with ethanol, and dried in vacuo over phosphoric anhydride.

Found: C, 25.56; H, 6.46; Co, 10.62. Calcd. for $[Co\{(CH_3)_3NO\}_4](NO_3)_2$: C, 25.81; H, 6.50; Co, 10.56%.

Tetrakis (Trimethylamine Oxide) Cobalt(II) Perchlorate.—The compound was prepared as described for the corresponding nitrate from cobalt(II) perchlorate hexahydrate and trimethylamine oxide in ethanol. Deep blue-violet crystals were obtained. The compound melts at 207°C and explodes at 213°C.

Found: C, 25.56; H, 6.46; N, 10.30; Co, 10.62. Calcd. for $[Co\{(CH_3)_3NO\}_4](ClO_4)_2$: C, 25.81; H, 6.50; N, 10.34; Co, 10.56%.

Tetrakis (Trimethylamine Oxide) Zinc(II) Perchlorate.—Eight-tenth grams of zinc(II) perchlorate, previously dried over phosphoric anhydride in vacuo, was dissolved in 15 ml. of absolute ethanol. This solution was added to 1.7 g. of trimethylamine oxide dissolved in 15 ml. of absolute ethanol. The mixture was kept in a refrigerator overnight. The white fine crystals which were

* Recently, the preparation of $CoBr_2L_2$ and $MnBr_2L_2$ (where L denotes trimethylamine oxide) has been reported: K. Isslied and A. Kreibich, *Z. anorg. u. allgem. Chem.*, 313, 338 (1961).

precipitated were separated, washed with absolute ethanol, and desiccated over phosphoric anhydride. All these procedures were carried out in a dry box. The compound decomposes in the presence of moist air or moist solvents and melts at 210~230°C with decomposition.

Found: C, 25.13; H, 6.62; Zn, 11.29; Calcd. for $[Zn\{(CH_3)_3NO\}_4](ClO_4)_2$: C, 25.52; H, 6.62; Zn, 11.58%.

Tetrakis (Trimethylamine Oxide) Zinc(II) Nitrate.—This compound was prepared by the method described above for the corresponding perchlorate, using zinc(II) nitrate instead of zinc(II) perchlorate. The white crystals have properties similar to those of the corresponding nitrate and melt at 169°C with decomposition.

Found: C, 29.43; H, 7.21; Zn, 13.36. Calcd. for $[Zn\{(CH_3)_3NO\}_4](NO_3)_2$: C, 29.42; H, 7.41; Zn, 13.35%.

Tetrakis (Trimethylamine Oxide) Cadmium(II) Nitrate.—One gram of trimethylamine oxide was dissolved in 5 ml. of absolute methanol, and to this solution was added 0.45 g. of cadmium(II) nitrate which had been dried over phosphoric anhydride in vacuo and dissolved in 10 ml. of absolute methanol. The solvent was evaporated in an evacuated desiccator at room temperature. The resulting fine white crystals were collected on a glass funnel, washed with absolute ethanol, and desiccated over phosphoric anhydride. All these procedures were carried out in a dry box. M. p., 172°C.

Found: C, 26.53; H, 6.94; Cd, 20.89. Calcd. for $[Cd\{(CH_3)_3NO\}_4](NO_3)_2$: C, 26.85; H, 6.76; Zn, 20.94%.

Absorption Measurements.—The infrared spectra were obtained using a Perkin-Elmer infrared spectrophotometer model 221 equipped with a grating (4000~1400 cm^{-1}), an NaCl prism (1400~650 cm^{-1}), and a CsBr prism (680~300 cm^{-1}). All the spectra were obtained in Nujol mulls. The spectra in KBr disks were also obtained in the NaCl region and were checked against those in Nujol.

Calculation of Normal Vibrations

Considering the methyl group to be a dynamic unit, the skeletal vibrations of trimethylamine oxide have been treated as those of a five-body model of the point group C_{3v}.

The secular equation was set up according to Wilson's[9] procedure, using a potential function of the Urey-Bradley type[10,11].

The symmetry coordinates for this calculation are the following:

$$S_1 = \Delta r_1$$

$$A_1 \quad S_2 = 1/\sqrt{3} \cdot \Delta(r_2 + r_3 + r_4)$$

$$S_3 = 1/\sqrt{6} \cdot \Delta(\alpha_{12} + \alpha_{13} + \alpha_{14} - \alpha_{34} - \alpha_{42} - \alpha_{23})$$

$$S_{4a} = 1/\sqrt{6} \cdot \Delta(2r_2 - r_3 - r_4)$$

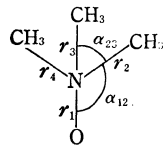
$$E \quad S_{5a} = 1/\sqrt{6} \cdot \Delta(2\alpha_{12} - \alpha_{13} - \alpha_{14})$$

$$S_{6a} = 1/\sqrt{6} \cdot \Delta(2\alpha_{34} - \alpha_{42} - \alpha_{23})$$

$$S_{4b} = 1/\sqrt{2} \cdot \Delta(r_3 - r_4)$$

$$E \quad S_{5b} = 1/\sqrt{2} \cdot \Delta(\alpha_{13} - \alpha_{14})$$

$$S_{6b} = 1/\sqrt{2} \cdot \Delta(\alpha_{42} - \alpha_{23})$$



The bond angles are regarded as tetrahedral, 109°28'. For the bond length, the values $r_{NO}=1.44$ and $r_{NC}=1.49$ Å, were used according to Rundle[12]. The force constants and intermolecular tension, κ, used in the calculation are shown in Table I. The values of F', the linear term of the interaction between non-bonded atoms, were determined using the relation, $F' = -1/10 \cdot F$[13].

TABLE I. FORCE CONSTANTS IN 10^5 dyn./cm. AND INTERMOLECULAR TENSION IN 10^{-11} dyn. cm. OF TRIMETHYLAMINE OXIDE

K		H		F		κ
N-O	2.30	O-N-CH_3	0.30	O···CH_3	0.80	0.05

Results and Discussion

The observed infrared frequencies are shown in Table II. They coincide with Giguere and Chins' values within the range of minimum experimental error. The assignment of the bands of the methyl group can be made as shown in the table according to the commonly accepted group frequencies of the methyl group[14]. Regarding the symmetry of the trimethylamine oxide molecule as a point group C_{3v}, there should be 3 non-degenerate vibrations in A_1 and 3 degenerate vibrations in E. Using the force constant values listed in Table I, we have obtained the results shown in Table III, in which each calculated frequency is related to the observed value. The values in Table I have been selected to produce the best agreement between the observed and calculated frequencies, but they also seem to be reasonable if compared with the values used in the calculation of trimethylamine[15] and tetramethylammonium ion[5] ($K=3.63$, $H=0.459$, $F=0.615$, for the former and $K=2.18$, $H=0.43$,

F=0.35, for the latter), considering that the nature of the C-N bond of trimethylamine oxide is intermediate between those of these compounds. Furthermore, no alternative assignments of the vibrations which have been tried so far have given reasonable results. Goubeau and Fromme[4] had calculated the frequencies of trimethylamine oxide using the central force field and had related each calculated frequency to the observed one, although the agreement between the calculated and the observed frequencies were poor compared with that of the present calculcula-tions. Though the present assignment was carried out independently from that of Goubeau and Fromme, the results do not conflict with their results. Thus, the author believes these assignments to be correct.

The assignments of the skeletal vibrations shown in Table III are based on the results of the calculation of the potential energy distributions shown in Table V. The assignment of the band around 950 cm^{-1} does not conflict with that of Matis-Noel et al.[7], in

which the N–O stretching vibration mainly contributes to this band. However, Table IV shows that the N–C stretching and the deformation vibrations also considerably contribute to it. It has also been found that the N–O and the N–C stretching vibrations almost equally contribute to the band at 755 cm^{-1}. In the band at 1125 cm^{-1} a coupling with the deformation vibrations of the methyl group is possible to some degree, although in the present calculation this effect was not taken into consideration.

As may be seen in Table II, the vibrations of trimethylamine oxide do not shift much in the sodium chloride region upon coordination to metal ions. It is notable that the band at ~950 cm^{-1}, which is mainly contributed by the N–O stretching vibration, shows very little shift to the low frequency region. This makes a remarkable contrast to the relatively large shift in the N–O stretching vibration of pyridine *N*-oxide.

The very small shift of the N–O stretching vibration on coordination may be explained as follows: 1) The coordination effect is small because of the weak covalent character of the O-metal bond; 2) unlike pyridine *N*-oxide, trimethylamine oxide can not form π-bonding, and 3) this vibration is affected not only by the force constant K_{NO}, but also by K_{NC}, H_{CNC} and H_{CNO}. Therefore, even if K_{NO} is changed on coordination, the frequency shift of this band could considerably be canceled by the simultaneous change of the other force constants (as is understandable by looking at the *J*-matrix in Table IV). It is not certain at the present stage which of these factors is mainly responsible for the observed spectral behavior.

The skeletal deformation vibrations appear in the cesium bromide region. As is shown in Table II, these bands undergo a large change upon coordination. This may be due to 1) a change in the character of the N–O bond due to the formation of the O-metal bond, or 2) a change in the steric arrangement of the surrounding groups. However, the latter reason seems more plausible to the author, since not only the frequencies but also the contour of the splitting changes upon coordination. However, further investigation is necessary to reach a definite conclusion on this point.

In the pyridine *N*-oxide complexes of cobalt(II) and zinc(II), the O-metal stretching vibration was observed in the 319~331 cm^{-1} region[3]. In the present investigation, however, no crresponding band was found. It is possible that the band appears in a lower frequency region, below 300 cm^{-1}. One may, therefore, assume that the metal-O bonding of trimethylamine oxide complexes has a less covalent character than that of pyridine *N*-oxide complexes.

In addition to the bands mentioned above, broad bands were observed at 892 and 865 cm^{-1}, while a rather intense broad absortion appeared at 623 cm^{-1}. No fundamental vibrations could be assigned to these bands. In the Raman spectrum[4] no corresponding Raman lines were observed; all normal vibrations belonging to A_1 and E are infrared and Raman active in C_{3v} symmetry. They appear to be absorptions specific of the solid state (probably containing water), but no final conclusion can be drawn at present.

Summary

Metal complexes of trimethylamine oxide with cobalt(II), zinc(II) and cadmium(II) have been prepared.

The infrared spectra of trimethylamine oxide and its complexes have been measured in the 1500 to 300 cm^{-1} range. Assignment of the observed bands has been made on the basis of the calculation of the normal vibrations of trimethylamine oxide.

The band at 950 cm^{-1} was found to be mainly contributed by the N–O stretching vibration, as was expected from the former investigations, but it was also considerably contributed to by the other mode of vibrations.

The metal-O stretching band was not found in the region of the present investigation; consequently, a rather weak bond was assumed to exist between trimethylamine oxide and metal ions.

The experiments of this investigation were carried out in the Department of Chemistry,

Florida State University. The author wishes to express sincere thanks to Professor J. V. Quagliano of the Florida State University for his kind help and valuable suggestions throughout this work. He also wishes to thank to Professor Yuzo Kakiuti of Rikkyo St. Paul's University for his helpful advice and discussion.

Thermal and Radiation Oxidations of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. I. The Thermal Behavior of Iron Sulfate and Chloride in Aqueous Solutions without Benzene

By Hiroshi HOTTA and Nobutake SUZUKI

(Received January 9, 1963)

Benzene can be oxidized to phenol in an aerated aqueous solution by cobalt-60 gamma rays at room temperature[1]. The yield is improved in the presence of iron and copper ions[2,3]. It has been reported that the yield also increases somewhat above 130°C, even in the absence of any metal ions[4,5].

This subject has been studied also in this Laboratory in co-operation with a group of researchers at Showa Denko Co., Tokyo. Especially, the effect of metal ions on the oxidation reactions has been studied at elevated temperatures. The experiments were rather troublesome due to the corrosion of the reactor and the precipitation of metal ions. In order to clarify such complicated phenomena, the first problem was to understand the thermal behavior of metal salt aqueous solutions, used for benzene oxidation, without benzene at elevated temperatures. Therefore, the experimental methods employed in benzene oxidation were also used for this purpose. The results for iron sulfate and chloride aqueous solutions will be given in the present paper.

Experimental

Solutions. — G. R. reagents without further purification were dissolved initially by 0.01 M-Fe[6] in 0, 0.01 and 0.1 N sulfuric acid for ferrous and ferric sulfates or in hydrochloric acid of these concentrations for these chlorides.

Apparatus and Procedure.—A hard-glass reaction tube with a stopper, having a small hole for gas, was set tightly in a 50 ml. stainless-steel reactor. Fifteen ml. of the solution was put in the glass tube under oxygen pressure of 30 atm. The temperature was varied in all cases by the same procedure, using an electric controlling-heater, that is, a) the reactor was heated up to the given temperature during 30 min. by the heater (first-stage), b) kept at that temperature within ±1°C for 30 min. (middle-stage), and c) cooled outside the heater by a fan (final-stage). For reference, the same experiments were carried out without the middle stage to find the contribution of reactions during the first and final stages[7]. The temperature was measured by thermocouple set in the wall of the reacter.

Analytical.—The solutions after reaction were analyzed by a spectrophotometer as follows: The concentration of total iron species dissolved was determined from the optical density of ferric-oxine complex in chloroform at 470 mμ at pH=3.5~4.5 (0.0105 for 1 μg. iron species)[8], and the concentration of ferrous species in it from that of ferrous-α,α'-dipyridyl complex in an aqueous solution at 522 mμ at pH 3~9 (ε=8520), adding some potassium fluoride if necessary. The amount of ferric species in the aqueous phase and the amount of precipitated iron species were evaluated from these observed values. The original impurities, ferrous species in ferric solutions and vice versa, were $2\sim4\times10^{-5}$ M respectively.

solutions dissolved by 0.01 M of ferric ion in 0, 0.01 and 0.1 N sulfuric acid respectively, are given by solid marks and solid lines in Fig. 1, with the results of the corresponding reference experiments given by open marks and dotted lines. The corresponding results for ferric chloride dissolved in hydrochloric acid are given in Fig. 2. The low values of the reference experiment at 75°C for the neutral ferric chloride solution was just equal to the value of the filtrate before experiment, namely, the saturated concentration at room temperature. All the ferrous concentrations after experiment for ferric salts were not so different from their initial concentration contained as impurities, namely, $(1\sim4)\times10^{-5}$ M.

The same results of ferric and ferrous concentrations as those in Fig. 1 were obtained within the range of experimental error between 130 and 200°C for the neutral ferric sulfate solution under the following conditions: a) with irradiation by cobalt-60 gamma rays for 25 min. at the middle-stage of the heating procedure (14000 r), and b) with and without the same irradiation under nitrogen pressure of 30 atm. Therefore, the precipitation

reaction is independent of oxygen and radiation. It is noted that the ferrous concentration dose not increase in all cases over that original impurities.

Ferrous Sulfate and Chloride.—The total iron and ferrous concentrations after experiment are shown in Figs. 3 and 4 for ferrous sulfate, and in Figs. 5 and 6 for ferrous chloride respectively.

Discussion

Oxidation of Ferrous Ions. — The oxidation of ferrous ions by oxygen in an aqueous solution is usualy assumed to be[9,10]

$$Fe^{2+} + O_2 + H^+ = Fe^{3+} + HO_2 \qquad (1)$$

The concentration of hydrogen ion for reaction 1 is supposed to be fairly higher at elevated temperatures than at room temperature due to the higher dissociation of iron salt and water[11].

Since the ferrous sulfate solution in 0.1 N sulfuric acid gave no precipitate at temperatures lower than 150°C (Fig. 3), the rate of ferrous oxidation, k_o, in such a non-precipitated system can be expressed as

$$\frac{dx}{dt} = k_o(a-x)$$

at a given oxygen pressure from reaction 1; that is,

$$k_o = \frac{1}{t} \ln \frac{a}{(a-x)} \qquad (i)$$

where a is the initial ferrous concentration, and x the amount which is oxidized in time t. On putting the observed value of the reference experiments to a and that of the actual experiments to $a-x$ in Eq. i, the oxidation rate, k_o, in 0.1 N sulfuric acid can be estimated as 1.24, 5.17 and 6.10×10^{-4} sec^{-1} at 100, 130 and 150°C respectively. Huffman and Davidson had estimated the rate to be 1.93×10^{-5} atm^{-1} sec^{-1} at 159°C, i. e., 6×10^{-4} sec^{-1} at 30 atm. of oxygen[12]. The activation energy, estimated from the present values is also nearly equal to their value, 13.4 kcal./mol.[12]

Similarly, the oxidation rates of ferrous chloride in 0.1 N hydrochloric acid are estimated as 0.83 and 2.78×10^{-4} sec^{-1} at 130 and 150°C respectively. These rates are slower than the above values of ferrous sulfate. The rate seems to increase as the complexing affinity of the anion for ferric ion increases[12,13]. However, the high oxidation rate in sulfuric acid may be partially due to decomposed products of sulfate ion, which is ignored in Eq. i.

Precipitation of Iron Species.—Milburn concluded, in his study of the hydrolysis of ferric ion at 25°C, that the dimerization of ferric monohydroxide is predominant in a solution more concentrated than 0.001 M[14]. In fact, more precipitate was found in the lower acidic solution. Therefore, it can be assumed that the precipitation reaction is through the dimerization of partially hydrolyzed ferric ions, for the equilibrium constant of ferric hydrolysis is much higher[15] and the stability of ferric hydroxide is lower[16] in comparison with ferrous species.

When the rate-determining step of the precipitation reaction is assumed from these facts to be bimolecular for the formal concentration of iron species in the solution, the precipitation rate, k_p, can be expressed as

$$\frac{dx}{dt} = k_p(a-x)^2$$

That is,

$$k_p = \frac{x}{ta(a-x)} \qquad (ii)$$

where a is the initial iron concentration in the solution, and x the amount of iron precipitate during time t.

The rates of the precipitation reaction, k_p, for ferric sulfate, estimated from Eq. ii like Eq. i, are plotted against the reciprocal of the absolute temperature in Fig. 7. This figure suggests that the ratio of the rates is 1.00 : 0.47 : 0.105 in 0, 0.01 and 0.1 N sulfuric

TABLE I. X-RAY ANALYSIS OF PRECIPITATE

Solute	Solvent	Precipitation temp., °C		
		100	130	200
$Fe_2(SO_4)_3$	Water	Completely amorphous	—	α-Fe_2O_3
	0.1 N H_2SO_4	—	—	α-Fe_2O_3
$FeSO_4$	Water	—	Amorphous α-Fe_2O_3	α-Fe_2O_3
	0.1 N H_2SO_4	—	—	α-Fe_2O_3

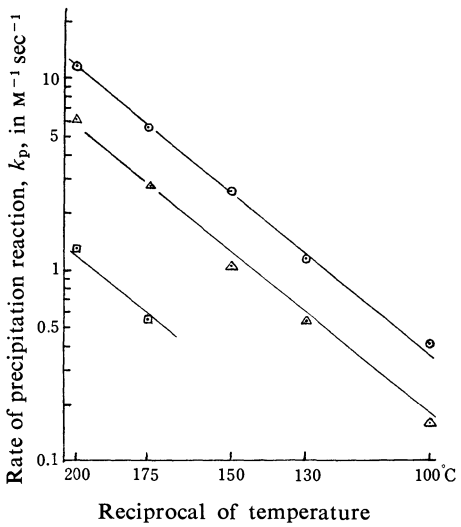

Fig. 7. Rate of precipitation reaction, k_p, from 0.01 M-Fe ferric sulfate aqueous solutions plotted against reciprocals of absolute temperature; (⊙) in neutral, (△) in 0.01 N sulfuric acid and (▣) in 0.1 N sulfuric acid.

acid over a wide range of temperature, and that the activation energy of this reaction is 12.5 kcal./mol. in this range of acid concentration. When the precipitation reaction is assumed as above, this ratio means the ratio of the proportions of hydrolyzed ions at the respective acidities, i. e., the ratio of the true reactants.

The precipitation in the ferrous solution should also be attributed to ferric hydroxide oxidized from ferrous species, for the precipitate is the same from the ferric solution as shown in Table I. (See the next section). When the results for the 0.1 N acid solutions shown in Figs. 1, 2, 3 and 5 are compared, it is noted that precipitation is independent of either sulfate or chloride species, but dependent on either ferric or ferrous species, and that the precipitation is retarded in the ferrous solution compared with the ferric, but there is no difference between ferric and ferrous species in the iron concentration after experimentation. On the other hand, when the ferric solution is heated with benzene, the precipitation is somewhat retarded upon the reduction of ferric ions, as will be shown in detail in the next paper. These facts also support the assumption about the precipitation as mentioned already.

Precipitates. — Since the precipitates, when dried in a vacuum, gave no pattern for X-ray analysis, they were dried for one day at 70°C. The results of their X-ray analysis are given in Table I; the precipitate at 100°C still did not give any pattern, but the one at 130°C gave a weak pattern of α-Fe_2O_3, and all the precipitates at 200°C gave a sharp pattern of α-Fe_2O_3 independent of ferrous and ferric sulfates. Therefore, it is concluded that the precipitate at the lower temperature is completely amorphous. The color varied from orange to brown with rise of the precipitation temperature.

According to Shipko and Douglas[17], the precipitate of ferrous hydroxide containing $Ni(OH)_2$ is decomposed spontaneously in this manner;

$$3Fe(OH)_2 = Fe_3O_4 + H_2 + 2H_2O \qquad (2)$$

with the activation energy of 10.2 kcal./mol. below 100°C, and the pure ferrous hydroxide is more stable, decomposing with the activation energy of 30 kcal./mol. at 150~200°C in the same manner. The former value for the amorphous precipitate is nearly equal to the activation energy from Fig. 7.

Summary

The rate of the ferrous oxidation at 150°C is 6.10×10^{-4} sec^{-1} for sulfate, and 2.78×10^{-4} sec^{-1} for chloride at the oxygen pressure of 30 atm. The precipitation reaction of iron species is through hydrolyzed ferric ions even in the ferrous solution. The rate of precipitation for ferric sulfate is given in Fig. 7, with the activation energy of 12.5 kcal./mol. The precipitate is amorphous at 100°C and completely α-Fe_2O_3 at 200°C.

The authors wish to express their appreciation to Mr. Akira Terakawa and Mr. Mitsuteru Nitto of the Showa Denko Co. for their kind

Thermal and Radiation Oxidations of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. II. The Effect of Iron Sulfate and Chloride on Phenol Yield

By Hiroshi HOTTA, Akira TERAKAWA[1], Kazuo SHIMADA and Nobutake SUZUKI

(Received January 9, 1963)

The yield of phenol in the thermal oxidation of gaseous benzene has been reported to be at its optimum at about 400°C in the presence of some organic promotors[2,3]. The thermal oxidation of benzene to phenol has usually been made at temperatures higher than 300°C, giving some amount of biphenyl as by-product.

As mentioned in the introduction to Part I of the present series[4], it is expected that benzene can be also oxidized to phenol with a good yield in the aqueous phase at lower temperatures by the use of cobalt-60 gamma rays. However, the irradiation method without metal salt also gives some amount of biphenyl[5]. On the other hand, it is well known that oxidation reaction is usually promoted in the presence of metal ions[6,7]. In fact, benzene is oxidized to phenol without biphenyl production in the presence of iron salts at temperatures lower than 200°C as is shown in the present paper.

Experimental

Apparatus and Procedure.—1 ml. of benzene, purified by the usual method, was put on 15 ml. of an aqueous solution of 0.01M iron ion, as has been mentioned in Part I[4], in a hard-glass tube in the reactor under the oxygen pressure of 30 atm. This system was heated by the controlled procedure mentioned in Part I. Although the reactor had no stirring device, the solution seemed to be agitated spontaneously at elevated temperatures, at least above 150°C. For the irradiation experiments, the solution was irradiated with cobalt-60 gamma rays for 25 min. (about 14000 r by the Fricke dosimeter) at the middle stage of the heating procedure, kept at a given temperature. (Cf. Part I). The reference experiment without the middle stage was also made as in Part I. The heating procedure is shown schematically Fig. 1.

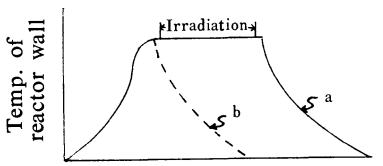

Fig. 1. Schematic heating procedure.
a) Actual experiment
b) Reference experiment

Analytical.—The produced phenol was first extracted from 1 ml. of the aqueous phase as an ether solution after the addition of 2 N hydrochloric acid. After the separation of acidic products from the ether solution by agitating with 5% sodium bicarbonate, phenol was again extracted in 1 N sodium hydroxide, and then, after being acidified by 2 N hydrochloric acid, extracted in ether. The phenol, in the benzene phase and mixed with iron precipites, was extracted together in 2 N sodium hydroxide, and then treated by the above procedure.

The amount of phenol in the above extract was determined from the optical density at 273.5 mμ ($\varepsilon=2167$), because Goodman and Steigman recommended the separation by ether[8]. The absorption curve of the extract was identical with that of pure phenol. In all cases, no biphenyl was found in the ether extract by gas-chromatography through a polyethylene-glycol column at 180°C.

The analytical methods for iron species were the same as in Part I.

Preliminary Experiment.—When the reactants were put directly in the reactor using no glass tube, reaction seemed to be promoted considerably above 150°C with corrosion of the stainless-steel wall. Next, the reaction was carried out in a Teflon tube set tightly in the reactor in order to prevent the corrosion effect. The yield of phenol was less in a Teflon tube than in a glass tube. The yield seemed to be the highest for 0.01M salt solutions. The present experimental conditions were decided on the basis of these results.

Results

Phenol Yield in Ferric Solutions.—The total yields of phenol produced in the ferric sulfate solution of 0, 0.01 and 0.1 N sulfuric acid (0.01M of ferric ion) are shown in mg. in Fig. 2 for the cases of irradiation (solid marks and solid lines) and non-irradiation (open marks and

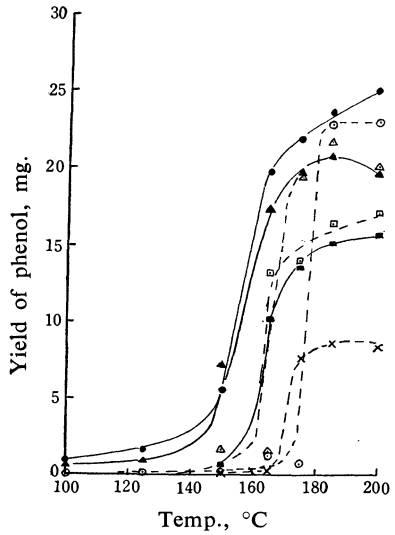

Fig. 2. Yield of phenol in 0.01M-Fe ferric sulfate solutions with radiation (solid marks) and without radiation (open marks) in neutral (● and ⊙), in 0.01N (▲ and △), in 0.1N sulfuric acid (■ and ▣), and in 1.0N sulfuric acid without radiation (×).

dotted lines), and, further, by crosses for the non-irradiated 1.0 N sulfuric acid solution. No phenol was found in any of the reference experiments. In general, as the acidity increases, the maximum yield at higher temperatures decreases, and the difference between the irradiated and non-irradiated systems disappears.

The results for 0.01M ferric chloride solutions in hydrochloric acid are shown in Fig. 3 in the same manner. The tendency of the yield is almost the same, but the yield is considerably suppressed by chloride ions.

The contribution of radiation is shown in

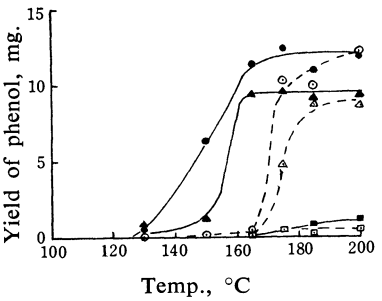

Fig. 3. Yield of phenol in 0.01M ferric chloride solutions with radiation (solid marks) and without radiation (open marks) in neutral (● and ⊙), in 0.01N (▲ and △) and 0.1N hydrochloric acid (■ and ▣).

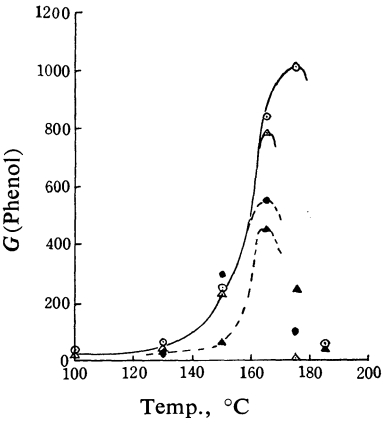

Fig. 4. G(Phenol) in ferric sulfate solutions (open marks) and in ferric chloride solutions (solid marks); in neutral (⊙ and ●) and in 0.01N acid (△ and ▲). G-values are evaluated as mentioned in text.

Fig. 4 by the G-value of phenol, estimated as the number of phenol molecules per 100 eV. of energy absorbed in 15 g. water, from the difference between the values of irradiated and non-irradiated systems plotted in Figs. 2 and 3.

Iron Concentration in Ferric Solutions after Reaction.—The total iron concentrations dissolved in the solutions of ferric sulfate and chloride after experiment, determined by the oxine method, are shown in Figs. 5 and 6 (the same marks as Figs. 2 and 3). The result for the ferric chloride solution in 0.01 N hydrochloric acid was almost the same as for that in the neutral solution. The precipitation reaction of iron salts seems to be somewhat retarded by phenol production as has been pointed out in Part I[4].

The ferrous content of these total iron species in the solutions, determined by the α, α'-dipyridyl method, is shown in Fig. 7 for the non-irradiated ferric sulfate solutions and

in Fig. 8 for the irradiated ones, using the same marks as in Fig. 2; and in Fig. 9 for the non-irradiated and irradiated ferric chloride solutions, using the same marks as in Fig. 3.

The ferrous concentration in these figures has a maximum, and increases with increase of

acidity. Moreover, the ferrous proportion of iron species increases as the reaction temperature rises. The iron species is mostly ferrous above 180°C. Such reduction in ferric ions is never found for ferric solutions without benzene, as has been mentioned in the ferric results of Part I[4]. When all the ferrous concentrations observed are plotted against the corresponding phenol yields as in Fig. 10, there is the interesting relationship. The decrease in the ferrous concentration at the high phenol yield is due to thermal precipitation at higher temperatures[4]. In fact, the hardly precipitated systems give the high ferrous yield instead of such a decrease.

Phenol Yield in Ferrous Solutions.—The yields of phenol in 0.01M ferrous sulfate solutions are shown in Fig. 11 using the same marks as in Fig. 2. Since the yield seems to increase with the lapse of time after the preparation of the solution, the values are rather scattered. However, it might be concluded that the yield is larger even without radiation than in the ferric sulfate solution with radiation in Fig. 2; and that the difference between with and without radiation is minor. Even after the deduction of the yield at the reference experiment from the value shown in Fig. 11, the yield is still higher below 175°C but lower above 175°C than the irradiated ferric sulfate solution. This means that the oxidation reaction is promoted by ferrous species and apparently retarded by phenol production as will be discussed later.

The results of the ferrous chloride solution, shown in Fig. 12, indicate more clearly that the yield for the ferrous solution is independent

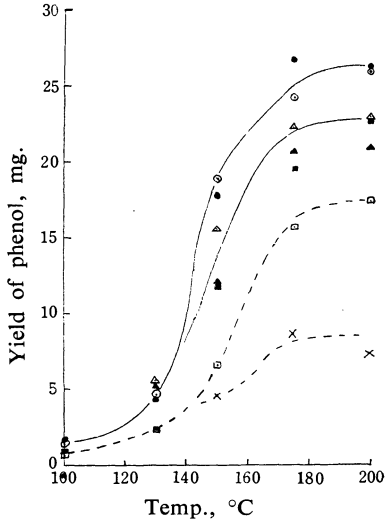

Fig. 11. Yield of phenol in 0.01M ferrous sulfate solutions; marks are the same with Fig. 2.

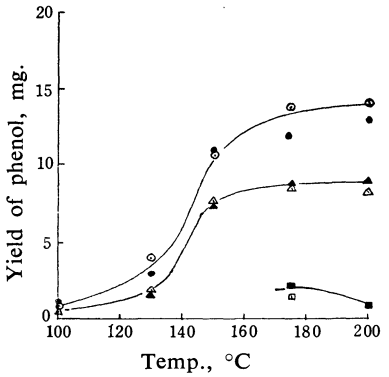

Fig. 12. Yield of phenol in 0.01 M ferrous chloride solutions; marks are the same with Fig. 3.

of radiation. This yield is also suppressed by chloride ions.

Iron Concentration in Ferrous Solutions after Reaction.—The concentrations of the total iron species and ferric species dissolved in the ferrous sulfate solutions after experiment are shown in Figs. 13 and 14 respectively, using

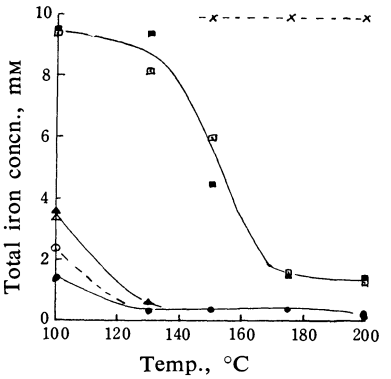

Fig. 13. Total iron concentration in ferrous sulfate solutions after experiment shown in Fig. 11; marks are the same with Fig. 2.

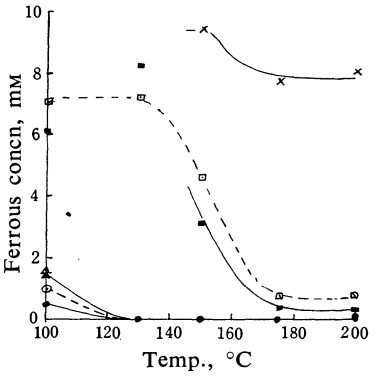

Fig. 14. Ferrous content in total iron concentrations shown in Fig. 13 for ferrous sulfate systems; marks are the same with Fig. 2.

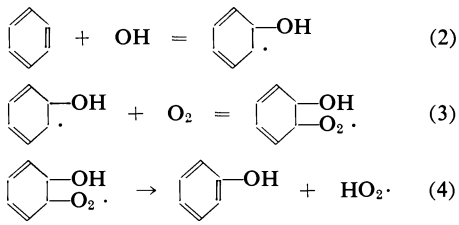
the same marks as in Fig. 2. The results are interesting in comparison with the corresponding ones without benzene in Part I[4]; there is no ferric ion above 130°C in 0 and 0.01 N sulfuric acid even though the present reactions were carried out under the high pressure of oxygen at elevated temperatures.

The results for the ferrous chloride solution were almost the same as those for the ferrous sulfate solution.

Discussion

The Effect of Radiation.—Dorfman et al. concluded, on the basis of electron-pulse radiolysis, that the radiation oxidation of benzene in an oxygenated aqueous solution at room temperature is through the following transient species[9];

$$H_2O \rightsquigarrow H,\ OH,\ H_2,\ H_2O_2 \qquad (1)$$



They estimated the rate of these reactions at 23°C to be $(4.3 \pm 0.9)\times10^9 M^{-1}sec^{-1}$ for reaction 2 and $(5.0 \pm 0.6)\times10^8 M^{-1}sec^{-1}$ for reaction 3. According to their observation, this hyroxycyclohexadienyl peroxy radical is fairly stable.

Hydrogen atom from reaction 1 combines with dissolved oxygen;

$$H + O_2 = HO_2 \qquad (5)$$

The rate of this reaction at 25°C is 1.1×10^9 $M^{-1}sec^{-1}$ in acid and $5.5\times10^9 M^{-1}sec^{-1}$ in a neutral solution[10]. The HO_2 radical and hydrogen peroxide is converted to OH radical as discussed in the next section. Ferric ions are not reduced by products of reaction 1 when oxygen exists[11,12]. In fact, the ferrous concentration in the ferric sulfate solution without benzene does not increase upon irradiation, as has been mentioned in the results section of Part I[4].

The suppression of phenol production in the chloride solutions is due to scavenging of the initiator of reaction 2;

$$Cl^- + OH + H^+ = Cl + H_2O \qquad (6)$$

The rate of this reaction at 25°C is supposed to be $1.8\times10^8 M^{-1}sec^{-1}$ at pH 2, and about ten times as fast as in 0.8 N sulfuric acid[13,14]. The effect of chloride ions, shown in Figs. 3 and 12, can be understood qualitatively by comparing these rates with the rates of reaction 2 and of reaction 11 to be discussed in the next section.

Initiation in Ferrous Solutions.—The results obtained by the same procedure in the aqueous phase containing no salt are given in Table I, in which the *G*-value in parentheses is reported by Proskurnin and Kolotyrkin[15]. Since a yield less than 0.04 mg. is unreliable, it can be said that no phenol is produced without any salt and radiation. Therefore, it is certain that the oxidation of benzene shown in Figs. 11 and 12 is neither initiated by the thermal cracking of benzene nor by the hydrogen abstraction of oxygen from benzene.

Table I. Phenol yield without iron salts

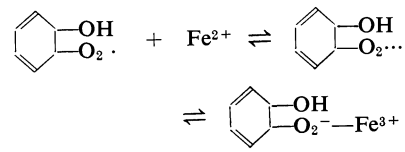
Medium	Radiation	Yield	
		mg.	*G*-Value
Water	Yes	0.33	16, (20)[15]
	No	0.02	—
0.1 N H_2SO_4	Yes	0.48	24
	No	0.04	—

As has been mentioned in Part I[4], the autooxidation of ferrous ions in an aqueous solution has usually been interpreted by the reaction

$$Fe^{2+} + O_2 + H^+ = Fe^{3+} + HO_2 \qquad (7)$$

Even if the HO_2 radical can not react directly with benzene, it can be converted to OH radical in the presence of ferrous ions. Therefore, it can be assumed that the oxidation of benzene in the ferrous solution is initiated by OH radical produced through reaction 7 and proceeds like reactions 2 and 3 even without reaction 1.

When the oxidation process is initiated through these reactions, hydroxycyclohexadienyl peroxy radical of reaction 3 is considered to be complexed in the ferrous solution in this manner;



as is usually assumed for the catalytic action

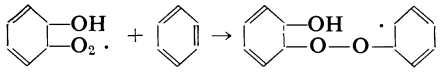
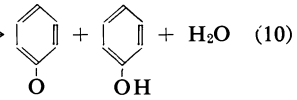
of redox ions[16]. Since such complexing stabilizes further the peroxy radical which has a fairly long life as has been pointed out already[9], the peroxy radical is allowed to react with benzene in this manner[17];



(9)



(10)

as well as via reaction 4. However, reaction 9 seems to have a threshold temperature.

The rate of reaction 7 at 150°C is 6×10^{-4} sec^{-1} in 0.1 N sulfuric acid under the present experimental conditions as was estimated in Part I[4]. Although OH radical is scavenged by ferrous ions thus;

$$Fe^{2+} + OH = Fe^{3+} + OH^- \qquad (11)$$

where the rate of this reaction is $2.6\times10^{8}M^{-1}$ sec^{-1} at pH 2 and 25°C[13], the rate of reaction 2 is very fast as has been mentioned already. According to the earlier results[14], the rate of reaction 2 at 25°C is 3.2 times as fast as that of reaction 11.

It may be open to doubt about the stability of the HO_2 radical and of hydrogen peroxide at elevated temperatures, especially in the presence of ferrous ions. The rate of the decomposition reaction

$$Fe^{2+} + H_2O_2 = Fe^{3+} + OH^- + OH \qquad (12)$$

is supposed to be $6.6\times10^{3}M^{-1}sec^{-1}$ at 150°C from extrapolation of the finding of Barb et al.[18], who extensively studied this subject in the room temperature range. The rate of reaction 2 is further faster than this rate. In any case, the present fact of phenol production is a good answer to the doubt.

When Figs. 2 and 11 are compared with Figs. 3 and 12, the yield of phenol in the non-irradiated ferrous solutions is almost the same as that in the irradiated ones, and it is larger than in the irradiated ferric solutions. Therefore, the overall yield of OH radicals by these thermal reactions seems to be considerably higher in spite of reacction 11, than by radiation-induced reaction 1 and reaction 5.

Initiation in Ferric Solutions.—Among the primary products of reaction 1, in the irradiated ferric solution, the OH radicals are not only scavenged like reaction 11, but they can also not be converted from the hydrogen atom and hydrogen peroxide, through reactions 5 and 12, to initiate the oxidation process. Therefore, the high yield of phenol is supposed also to be due to the complexing of the peroxide radical from reaction 3, with a trace amount of ferrous ions being present initially, as has been pointed out in Part I[4].

On the other hand, the oxidation process is also initiated without radiation in the ferric solution above 170°C, as is shown in Fig. 2. It can be understood similarly if ferrous ions are produced by any reaction in the ferric solution. Some reports seem to suggest such a possibility[19-21]. Recently the reaction

$$2Ce^{4+} + H_2O \rightarrow 2Ce^{3+} + \frac{1}{2}O_2 \qquad (13)$$

was assumed to account for the fact that cerric ions are reduced thermally in sulfuric acid at elevated temperatures[22]. Dobson and Hughes also discussed the possibility of ferric reduction in an irradiated ferric aqueous solution[12]. As if suggesting a process like reaction 13, the ferric solution gave an trace amount of ferrous species by about $2\times10^{-5}M$ as pointed out above.

Propagation Processes.—After reaction 10, the oxidation process of benzene is propagated through the following reactions [6,7,23]:

$$PhO + PhH = PhOH + Ph \qquad (14)$$

$$Ph + O_2 = PhO_2 \qquad (15)$$

$$PhO_2 + PhH = PhO_2H + Ph \qquad (16)$$

$$PhO_2H + Fe^{3+} = PhO_2 + H^+ + Fe^{2+} \qquad (17)$$

$$PhO_2H + Fe^{2+} = PhO + OH^- + Fe^{3+} \qquad (18)$$

(Ph: Phenyl radical)

in the iron solution, since ferrous and ferric ions are present together at once even if the reaction starts either with the pure ferrous or ferric solution.

Ferric ions are reduced considerably with phenol production as has been mentioned in the description of Fig. 10. This fact cannot be interpreted without the aid of reactions 10, 14 and 17. In the interpretation of Fig. 10, it should be noticed that some of the ferrous ions produced by reaction 17 are reoxidized by other reactions and precipitated, as has been mentioned already. Among the related reactions, the rate of the precipitation reaction in the neutral ferric sulfate solution is

$2.5 M^{-1}sec^{-1}$ at 150°C, as has been estimated in Part I[4]. The rate of the oxidation reaction 7 is slow as mentioned already. Although no report has been found on the decmposition of phenyl hydroperoxide, the rate of cumene hydroperoxide decomposition, as in reaction 17 in the presence of oxygen, is supposed to be $1.6\times10^{4} M^{-1}sec^{-1}$ at 150°C by extrapolation from the equation of Fordham and Williams[24]. Therefore, the rate of phenyl hydroperoxide decomposition is supposed to be the same order or faster than this rate, due to the high resonance energy of phenoxy radical[25,26]. At any rate, ferrous ions accumulate first with phenol production, as the reaction temperature rises, but the concentration decreases due to the precipitation at higher temperatures.

The mole ratio of the amount of ferrous ions to phenol is 0.46 ± 0.02, judging from the results at 175, 185 and 200°C in the non-irradiated 1.0 N sulfuric acid solution, which gave scarcely any precipitate. This ratio is represented by the dotted line in Fig. 10. Since ferrous ions for reaction 18 are produced only by reaction 17 in the ferric solution, this ratio means that the contribution of reaction 17 is greater than reaction 18, but not necessarily that the rate of the former is faster than that of the latter, when taking account of the difference between the initial concentrations of ferrous and ferric ions. In general, the dissociation energy of the O–O bond in hydroperoxide is smaller than the O–H bond. Especially, the decomposition

$$PhOOH = PhO + OH \qquad (19)$$

should be fast, even without redox ions, as has been discussed above[25].

Termination and Retardation Processes.—The yield of phenol hardly increases with rise of temperature at higher temperatures as at lower temperatures. Such saturation of the phenol yield is mainly attributed to the oxidation decomposition of phenol produced[27] rather than to the self-inhibition effect of phenols on oxidation reactions[28].

The other by-reactions between the reactants of the above reactions are also minor as the termination and retardation processes. For example, the present oxidation process is not terminated, as would usually be expected, by the reaction between phenyl peroxide;

$$2PhO_2 = PhO\text{–}OPh + O_2 \qquad (20)$$

as biphenoxy should be decomposed at least at elevated temperatures thus;

$$PhO\text{–}OPh = 2PhO \qquad (21)$$

due to the repulsion between the high dipoles[7]; that is, the overall reaction can be expressed as

$$2PhO_2 = 2PhO + O_2 \qquad (22)$$

Such a reaction is confirmed for cumene peroxide[6]. However, reaction 20 might play part in the retardation process at higher temperatures, at which phenyl peroxide is concentrated.

Effect of Acid Concentration.—As the acidity increases, the yield of phenol decreases due to the decrease of the concentration for the effective reactants of reactions 8 and 18. The reactivity of ions is very sensitive to the state in a solution, either free or complexed, dependent on the acidity[11].

The other effect of acids is as an anion, as in reaction 11. The decomposed products of sulfate ions might initiate the oxidation process of benzene in the concentrated acid solution.

Summary

In the ferric sulfate solution, benzene can be oxidized to phenol with a good yield above 170°C, when not irradiated, but at lower temperatures, when irradiated. In the ferrous sulfate solution, the yield of phenol is independent of irradiation, and somewhat larger than in the irradiated ferric sulfate solution. Such a high yield of phenol is due to the complexing of hydroxycyclohexadienyl peroxy radical, produced with OH radical and oxygen dissolved, with ferrous ions.

The authors wish to express their appreciation to Dr. Akibumi Danno of JAERI and Dr. Tōru Hirayama of Showa Denko Co. for their interest and kind encouragement, and also to Dr. Hiroshi Itatani of Osaka University and Dr. Akihisa Sakumoto of JAERI for their valuable advice on organic mechanisms.

The Mechanism of Azoxybenzene Formation[1]

By Shigeru OAE*, Tsugio FUKUMOTO and Masayuki YAMAGAMI

(Received February 1, 1963)

It has been well known for many years[2] that nitrobenzene is readily reduced to azoxybenzene by refluxing it with sodium alkoxide in alcohol, and the formation of azoxybenzene is generally believed to involve the condensation of phenylhydroxylamine and nitrosobenzene, both of which are produced in the reduction of nitrobenzene. Recently the condensation of phenylhydroxylamine and nitrobenzene has been studied and the formation of azoxy compounds discussed by Ogata, Tsuchida and Takagi[3]. More recently, Ogata and Mibae[4] have studied the kinetics and mechanism of azoxybenzene formation in the reduction of nitrobenzene by sodium methoxide and have suggested that the condensation of phenylhydroxylamine with nitrosobenzene to form azoxybenzene (4) is very fast compared with the reduction step of nitrobenzene with sodium methoxide and that the reduction step ((1) and (2)) is rate-determining. They have also indicated that nitrosobenzene and phenylhydroxylamine can be readily interconverted.

$$PhNO_2 + 2CH_3ONa \rightarrow PhNO + HCHO + NaOH + CH_3ONa \quad (1)$$

$$PhNO_2 + 2CH_3ONa \rightarrow PhNHOH + HCOONa + CH_3ONa \quad (2)$$

$$PhNHOH + PhNO_2 \rightarrow 2PhNO + H_2O \quad (3)$$

$$PhNHOH + PhNO \rightarrow PhN{=}NPh + H_2O \quad (4)$$
$$\downarrow$$
$$O$$

Shemyakin, Maimind and Vaichunaite[5] have studied the azoxy coupling reaction between phenylhydroxylamine and ^{15}N-labeled nitrosobenzene and have shown that the excess ^{15}N originally present in nitrosobenzene was distributed equally in both nitrogens of the azoxybenzene, suggesting the formation of an intermediate compound with an equivalent location of the N atom such as $(Ph\ ^{15}NOH)_2$.

During the course of our study of the Wallach rearrangement, we have also come to be interested in this azoxy-coupling reaction. Here again, our approach to this problem is through ^{18}O. When ^{18}O-labeled nitrobenzene was reacted with sodium methoxide in refluxing aqueous methanol, the resulting azoxybenzene was found to retain 0.69 atom % of ^{18}O; that is, about 22% of the excess ^{18}O was lost during the reaction, and the azoxybenzene retained 77% of the excess ^{18}O originally present in nitrobenzene. This means that a small portion of oxygen exchange is taking place at some stage, either at the reduction or at the azoxy coupling of the reaction.

We then examined the reaction of nitrosobenzene with ^{18}O-labeled phenylhydroxylamine in boiling ethanol containing potassium hydroxide and found that the amount of excess ^{18}O in the resulting azoxybenzene was almost exactly a half of that of the phenylhydroxylamine employed. This is excellent supporting evidence both for Ogata's idea that the azoxy-coupling reaction is a very fast step and for the Russians' mechanism of the prior formation of a symmetrical *N, N'*-diol intermediate in the coupling reaction. However, since we found that the reaction of phenylhydroxylamine alone with sodium methoxide gave azobenzene in a good yield and that of nitrosobenzene alone with sodium methoxide gave azoxybenzene in a superb yield, there remain the other possibility that nitrosobenzene was exchanging oxygen with ^{18}O-enriched water formed from the azoxy coupling of hydroxylamine before self-condensing to form azoxybenzene.

This, however, was not the case, because the reaction of nitrosobenzene alone with ^{18}O-labeled sodium methoxide was found to give azoxybenzene incorporated with no excess ^{18}O. The most likely path for the azoxy-coupling reaction appears to be via an intermediate, *N, N'*-diol before dehydration to give azoxybenzene in a rapid process, regardless of whether one uses both phenylhydroxylamine and nitrosobenzene or nitrosobenzene alone.

Since no oxygen exchange was observed in the azoxy-coupling stage, the loss of some of the excess ^{18}O found in the reduction of nitrobenzene to azoxybenzene must be taking place in the slow stage, where nitrobenzene is being reduced to nitrosobenzene. A similar loss of excess ^{18}O was observed in the reduction of ^{18}O-labeled nitrobenzene to phenylhydroxylamine with zinc and ammonium chloride. Here also about 22% of the excess ^{18}O was lost during the reduction. Probably, in both reductions, there is a common step where an incipient intermediate exchanges its oxygen with that of the solvent medium.

Experimental

^{18}O-Labeled Azoxybenzene was prepared by heating ^{18}O-labeled nitrobenzene[6] (8 g., 0.84 atom % of ^{18}O) with sodium hydroxide (8 g.) in methanol (8 g.); m. p., 35~36°C, 0.69 atom % of ^{18}O.

Found: C, 72.60; H, 4.99. Calcd. for $C_{12}H_{10}N_2O$: C, 72.73; H, 5.05%.

^{18}O-Labeled Phenylhydroxylamine.—In a 50 ml., three-necked flask fitted with a stirrer were placed 2.5 g. of ammonium chloride, 5 g. of nitrobenzene (0.66 atom % of ^{18}O) and 50 ml. of water; the mixture was then cooled to 5°C and 7 g. of zinc powder was stirred in over a period of 40 min., keeping the temperature between 5 and 10°C. Stirring was continued for 10 min. The zinc hydroxide formed was removed by filtration and washed with 40 ml. of hot water three times. The filtrate and washing were combined 25 g. of sodium chloride was added, and the mixture was allowed to stand overnight in a refrigerator. The precipitate formed was collected and recrystallized from a mixture of petroleum ether and benzene. Phenylhydroxylamine (m. p., 81°C) (lit.[7] 81°C), 0.56 atom % of ^{18}O) was thus obtained. The yield was 3 g. (70%).

The Condensation Reaction of ^{18}O-Labeled Phenylhydroxylamine and Nitrosobenzene Using Potassium Hydroxide.—In a three-necked flask was placed a mixture of 0.4 g. of ^{18}O-labeled phenylhydroxylamine (0.56 atom % of ^{18}O), 0.4 g. of nitrosobenzene and 10 ml. of ethanol; an ethanol solution which had been saturated with 0.45 g. of potassium hydroxide was stirred in and then allowed to react for 1 hr. at 75~80°C. After ethanol had been removed by evaporation under reduced pressure, the residue was poured into 100 ml. cold water. The yellow solid formed was collected and recrystallized from methanol. Azoxybenzene (m. p., 36°C, 0.38 atom % of ^{18}O) was thus obtained. The yield was 0.5 g. (80%).

The Condensation Reaction of Phenylhydroxylamine and Nitrosobenzene Using ^{18}O-Labeled Potassium Hydroxide.—^{18}O-Labeled potassium hydroxide was prepared by exchange reaction between potassium hydroxide and ^{18}O-enriched water. A mixture of 0.4 g. of phenylhydroxylamine, 0.4 g. of nitrosobenzene and ^{18}O-labeled potassium hydroxide (0.54 atom % of ^{18}O) was allowed to react similarly. The main product, azoxybenzene (m. p., 35°C) contained 0.22 atom % of ^{18}O. The yield was 0.5 g. (80%).

The Condensation Reaction of Phenylhydroxylamine alone with Potassium Hydroxide.—A mixture of 0.8 g. of phenylhydroxylamine and 0.45 g. of potassium hydroxide in 10 ml. of ethanol was allowed to react for 1 hr. at 75~80°C and was then treated similarly. The main product was red crystals (m. p., 66~67°C). The yield was 0.5 g. (75%). It did not depress the melting point of an authentic sample, azobenzene (m. p., 66~67.5°C) on admixture.

The Condensation Reaction of Nitrosobenzene alone with ^{18}O-Labeled Potassium Hydroxide.—A mixture of 0.8 g. of nitrosobenzene and 0.45 g. of ^{18}O-labeled potassium hydroxide (0.54 atom % of ^{18}O) in 10 ml. of ethanol was allowed to react for 1 hr. at 75~80°C and was then treated similarly. Azoxybenzene (m. p., 35~36°C) was the main product obtained, but unreacted nitrosobenzene was not recovered. This azoxybenzene contained 0.21 atom % of ^{18}O. The yield was 0.48 g. (66%).

The Determination of ^{18}O is described elsewhere[8].

The Formation of 1,6-Dithia-3a-azonia-2,3,4,5-tetrahydropentalene Salt

By Shuichi SETO and Yusaku IKEGAMI

(Received February 16, 1963)

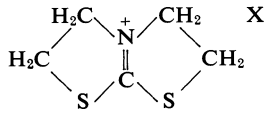
The reaction of bis(2-chloroethyl)amine hydrochloride with carbon disulfide in hydrous pyridine, under ice cooling, afforded colorless needles (I), (m. p., 95°C). The present paper deals with the structure of I and with some of its reactions.

The analytical values of I correspond to those of $C_5H_8NS_2Cl\cdot 2H_2O$, and the yield of its formation reaction is over 90%. I is quite easily soluble in water, but only sparingly soluble in organic solvents. The infrared spectrum of I indicated absorptions at 3405, 3340, 1643 and 1618 cm^{-1} due to the water of crystallization. When left in dry air or in a vacuum desiccator, I undergoes efflorescence with the loss of a part of the water of crystallization.

The addition of an excess of potassium bromide to the aqueous solution of I results in the precipitation of colorless crystals (II) (m. p., 95°C), $C_5H_8NS_2Br\cdot 2H_2O$, which are slightly more sparingly soluble in water than I. The addition of potassium iodide to the aqueous solution of I precipitates more sparingly soluble colorless cubic crystals (III) (m. p., 220°C) (decomp.), $C_5H_8NS_2I$. I forms a picrate (IV) of yellow needles, (m. p., 154°C), $C_5H_8NS_2\cdot C_6H_2O_7N_3$. It is certain from the foregoing reactions that the atom group, $C_5H_8NS_2$, in I to IV is present as a cation. From these facts and from considerations of NMR, infrared and Raman spectra to be discussed below, the structure of 1, 6-dithia-3a-azonia-2, 3, 4, 5-tetrahydropentalene can be given to this cation.

$$ClCH_2CH_2\diagdown\!\!\diagup NH\cdot HCl + CS_2 \rightarrow C_5H_8NS_2Cl\cdot 2H_2O$$
$$ClCH_2CH_2\diagup\!\!\diagdown$$

I



X

I ; X=$Cl^-\cdot 2H_2O$
II ; X=$Br^-\cdot 2H_2O$
III ; X=I^-
IV ; X=Picrate anion

The NMR spectrum of I in heavy water shows only one signal at 5.82τ, excluding that due to water, and only one signal at 5.70τ, in that of the iodide III. These facts indicate that the protons of the two methylene groups on either side of nitrogen atom are in an equivalent shielding state.

For this cation (A), a structure with all eight skeletal atoms in one plane, or a structure similar to it, is suggested. If all the skeletal atoms were included in one plane, this cation should have two symmetrical planes at right angles to each other. Consequently, its vibrational spectrum can be handled as the vibration of the C_{2v} symmetrical group, and the freedom of 42 vibrations can be classified into the following four species:

A_1	A_2	B_1	B_2	(Total)
13	8	12	9	42

Of these, the eight vibrations belonging to the A_2 species are infrared inactive, and the Raman lines due to the 13 vibrations belonging to A_1 species should show polarizability.

Under such assumptions, the infrared and Raman spectra of the chloride I were measured and their spectra were analyzed. The Raman spectrum was measured in an aqueous solution (ca. 32%), and the infrared spectrum, as a potassium bromide disk*1. The results of these measurements are shown in Table I, together with the infrared absorption frequencies of the bromide II and the iodide III.

The data in Table I show the following points:

a) The number of Raman lines of I was not as great as had been expected, but the majority of these Raman lines corresponded to the infrared absorption bands. The infrared spectra of the three compounds show that the absorptions due to the water of crystallization (3405~3220 and 1665~1618 cm^{-1}) are not present in the spectrum of III and that the majority of absorption bands, excluding specially weak ones, appear in all the three compounds, with only a slight difference in frequency and in a similar intensity. This will appear natural if it is assumed that the observed vibrations are virtually all due to the vibration of the cation (A).

b) The Raman line at 1566 cm^{-1}, assigned to the C=N stretching vibration shows an especially small depolarization factor (ρ); this fact, signifying that C=N stretching is a vibration belonging to the A_1 species which does not change the symmetry of a molecule,

*1 The same results were obtained by measurement in Nujol.

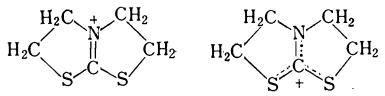
*1 Raman spectrum was measured as the aqueous solution; the relative intensities were given taking the peak intensity of the intense line at 2976 cm^{-1} as the standard.

ρ: Depolarization factor

*2 Infrared spectra were measured as the potassium bromide disk.
vs: very strong, s: strong, m: medium, w: weak, vw: very weak, sh: shoulder, b: broad

also indirectly endorses the correctness of the structure of I. Besides the above, the lines at 2976 and 2908 cm^{-1} (CH_2 stretching), 1310 and 1259 cm^{-1} (skeletal stretching or CH_2 wagging), and 674 and 599 cm^{-1} (skeletal stretching?) all have small depolarization factors; these can all be assigned to vibrations of the A_1 species.

c) The observed C=N stretching frequencies (1574~1566 cm^{-1}) are rather lower than those of 2-methylthiazolidine (1635 cm^{-1}; hydrochloride, 1630 cm^{-1})[1] and 2-phenylthiazolidine (1605 cm^{-1})[2]. This is thought to be due to the great contribution of the A′ structure, and it is also considered to be responsible for the appearance of eight signals as a singlet in the proton NMR spectrum of I.



A A′

d) The frequencies in the 1486~1439 cm^{-1} region are assigned to the scissor vibrations of CH_2 groups. The bands in the 1205~1170 and 1072~1048 cm^{-1} regions which are strong in the infrared spectra, may probably be assigned to the CH_2 twisting and skeletal stretching vibrations, respectively.

When the aqueous solution of I is allowed to stand for a long period of time, a liquid (V) sparingly soluble in water separates out. V shows infrared absorptions at 2550 and 1667 cm^{-1}, due to -SH and C=O respectively, and lacks the absorption at 1571 cm^{-1} seen in I. V forms a lead salt (VI) of yellow needles (m. p., 143°C), $(C_5H_8ONS_2)_2Pb$. This lead compound shows an absorption for carbonyl at 1661 cm^{-1}, but it does not show the infrared absorption characteristic of the SH group. From these facts, a structure of *N*-(2′-mercaptoethyl)-2-thiazolidinone can be given to V and its lead sulfide to VI. I changes into V even when its solution is heated on a water bath.

When the mercapto compound V is treated with hydrogen peroxide in ethanol, β-(2-thiazolidinon-3-yl)ethyl disulfide (VII) is obtained as colorless plates (m. p. 94°C). VII is also obtained on treating the picrate IV with dilute alkali. The oxidation of V to VII occurs easily, as is usually the case with mercapto compounds. Therefore, in the case of the preparation of V, the disulfide VII is obtained at times as the crystalline part insoluble in ether.

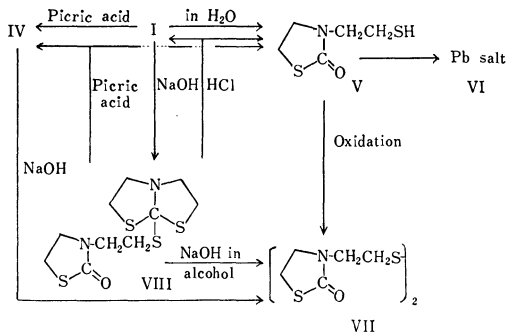
2) M. G. Ettlinger, ibid., **72**, 4699 (1950).

The drop-by-drop addition of a sodium hydroxide solution into the aqueous solution of I affords colorless crystals (VIII) of m. p., 114°C. The molecular weight of VIII is over 300; its infrared spectrum does not show absorptions characteristic of the C=N and SH groups, but it does show absorption bands in the finger-print region considered to be that due to the thiazolidinone group. The treatment of VIII with 2 N sodium hydroxide in ethanol gives the disulfide VII, and its passage through an alumina column gives a mixture of V and VII. The treatment of VIII with picric acid in ethanol results in the formation of approximately equivalent amounts of the picrate IV of the cation and the mercapto compound V. Similarly, the treatment of VIII with hydrochloric acid gives the chloride I and mercapto compound V. From the foregoing experimental results, the structure of 1a-[β-(2-thiazolidinon-3-yl)ethylthio]-1, 6-dithia-3a-aza-2, 3, 4, 5-tetrahydropentalene can be given to VIII.



Experimental*2

1,6-Dithia-3a-azonia-2, 3, 4, 5-tetrahydropentalene Chloride (I).—To a solution of 7.14 g. of bis(2-chloroethyl)amine hydrochloride dissolved in 4 ml. of water, with 10 ml. of pyridine added, 2.4 ml. of carbon disulfide was added drop by drop during about a 1 hr. period, during which time the solution was stirred while being cooled with ice. The white turbid solution so formed was stirred at room temperature for 45 min., warmed at 40°C for 20 min., and chilled in ice, after which process colorless crystals precipitated out. By filtration, 7.95 g. of crystals (yield, 91.4%) were obtained; these were then dissolved in a minimum amount of water and recrystallized by the addition of ethanol to colorless needles (I) (m. p., 95°C).

UV λ_{max}^{MeOH} 257 mμ (log ε 4.01).

Found: C, 27.54; H, 5.37; N, 6.30; S, 29.15;

*2 All melting points are uncorrected. Elemental analyses for carbon, hydrogen and nitrogen were carried out by Miss Yoko Endo and Miss Yukiko Endo of this Institute, while that for sulfur was carried out by the Takamine Research Laboratory, Sankyo Co., Ltd., to all of whom the authors thanks are due.

Cl, 16.34. Calcd. for $C_5H_8NS_2Cl \cdot 2H_2O$: C, 27.56; H, 5.56; N, 6.44; S, 29.46; Cl, 16.29%.

The drying of I over phosphorus pentoxide in a vacuum desiccator results in the loss of a part of the water of crystallization, and it effloresces to a white powder (m. p., 115~131°C).

Found: C, 30.28; H, 5.38; N, 7.43. Calcd. for $C_5H_8NS_2Cl \cdot H_2O$: C, 30.07; H, 5.05; N, 7.01%.

1,6-Dithia-3a-azonia-2, 3, 4, 5-tetrahydropentalene Bromide (II), Iodide (III) and Picrate (IV).—A solution of 2.5 g. of potassium bromide dissolved in 3 ml. of water was added to a solution of 1.6 g. of I dissolved in 3 ml. of water; the mixture was then allowed to stand under ice cooling, by which process 0.8 g. of the bromide (II) was obtained as colorless crystals (m. p. 95°C).

Found: C, 22.98; H, 4.99; N, 5.51. Calcd. for $C_5H_8NS_2Br \cdot 2H_2O$: C, 22.89; H, 4.62; N, 5.34%.

A solution of 3 g. of potassium iodide dissolved in 3 ml. of water was added to the solution of 1.6 g. of I dissolved in 3 ml. of water; the mixture was then allowed to stand. The crystals that separated out were collected by filtration (1.7 g. of colorless cubic crystals (III); m. p., 220°C (decomp.). Recrystallization from ethanol containing a small amount of water gave colorless rhombs of the same melting point.

UV λ_{max}^{MeOH} 258 mμ (log ε 4.03).

Found: C, 21.87; H, 2.73; N, 5.15; S, 21.90; I, 46.00. Calcd. for $C_5H_8NS_2I$: C, 21.97; H, 2.95; N, 5.13; S, 23.48; I, 46.47%.

To 114 mg. of I suspended in 3 ml. of ethanol, 2 ml. of a 6% ethanolic solution of picric acid was added; the mixture was then warmed on a water bath until the whole dissolved. When this solution was allowed to stand at room temperature, 194 mg. of yellow needles (IV) (m. p., 154°C) was obtained.

UV λ_{max}^{MeOH} mμ (log ε): 250 (4.29), 355 (4.21).

Found: C, 35.44; H, 2.67; N, 14.93. Calcd. for $C_{11}H_{10}O_7N_4S_2$: C, 35.29; H, 2.69; N, 14.97%.

The picrate IV was also obtained by the treatment of III with picric acid.

***N*-(2'-Mercaptoethyl)-2-thiazolidinone (V) and its Lead Salt (VI).**—A solution of 660 mg. of I dissolved in 3 ml. of water was heated in a sealed tube. After the solution had been heated for 3 hr., a liquid layer separated out; the tube was then heated for a further 15 hr. The separated aqueous layer was evaporated in vacuo to dryness at room temperature, and 5 ml. of benzene was added to its residue. From the insoluble crystals, 70 mg. of I were recovered, while from the benzene soluble part, 85 mg. of liquid mercapto compound V were obtained. The remaining liquid layer was washed with water and dried in a vacuum desiccator to 360 mg. of liquid V which is easily soluble in ether, benzene and alcohols and which vaporizes gradually at 120~140°C/0.1 mmHg.

This mercapto compound V was also obtained when an aqueous solution of I was allowed to stand in a sealed tube at room temperature for 4 months.

IR strong bands (liquid): 2925, 2865, 2550, 1667 (1690 in CCl_4), 1479, 1447, 1412, 1360, 1328, 1293, 1234, 1199, 1147, 935, 698 and 662 cm^{-1}.

The addition of a solution of 530 mg. of basic lead acetate dissolved in 5 ml. of water to a solution of 160 mg. of V dissolved in 5 ml. of ethanol resulted in the precipitation of yellow crystals. The crystals were collected by filtration and washed with water to 330 mg. of the lead salt (VI) as yellow needles (m. p., 143°C). VI is sparingly soluble in water and in organic solvents.

Found: C, 22.23; H, 3.08; N, 4.93; Pb, 39.27. Calcd. for $C_{10}H_{16}O_2N_2S_4Pb$: C, 22.59; H, 3.03; N, 5.27; Pb, 38.97%.

β-(2-Thiazolidinon-3-yl)ethyl Disulfide (VII).—a) A mixture of 100 mg. of V dissolved in 1.5 ml. of ethanol and 1.5 ml. of 10% hydrogen peroxide solution was allowed to stand overnight at room temperature. By the evaporation of the solvent, 90 mg. of crystals (m. p., 93.5~94°C) were obtained. Recrystallization from ethyl acetate gave colorless plates (VII) (m. p., 94°C).

IR strong bands (KBr disk): 1660, 1441, 1411, 1291, 1237, 1201, 923, 815 and 696 cm^{-1}.

Found: C, 37.31; H, 4.99; N, 8.72%; mol. wt. (Rast), 335. Calcd. for $C_{10}H_{16}O_2N_2S_4$: C, 37.01; H, 4.97; N, 8.63%; mol. wt., 324.5.

b) To a solution of 80 mg. of V in 2 ml. of ethanol, 3 drops of ammonia water were added; air was then blown on the mixture for 3 hr. With the evaporation of the solvents, 73 mg. of rhombic crystals (m. p. 91.5~93°C) were obtained. Those crystals showed no depression of the melting point on admixture with the VII obtained by afore-mentioned method a).

The Treatment of IV with Alkali.—To 40 mg. of the picrate IV suspended in 3 ml. of water, 2.2 ml. of 0.05 N sodium hydroxide were added; the mixture was then warmed on a water bath until in solution. This yellow solution was adjusted to pH 8 and allowed to stand; 15 mg. of VII were thereby obtained as colorless plates (m. p., 91~93°C).

1a-[β-(2'-Thiazolidinon-3'-yl)ethylthio]-1,6-dithia-3a-aza-2, 3, 4, 5-tetrahydropentalene (VIII).—Into a solution of 2.18 g. of I dissolved in 20 ml. of water, about 6 ml. of a 2 N sodium hydroxide solution were stirred drop by drop over a 1 hr. period; crystals were thereby precipitated out. The mixture was adjusted to pH 8.0, allowed to stand in an ice box overnight, and filtered to collect 1.40 g. of crystals (m. p., 108~110°C).

The filtrate with a pH value of 4.5 was adjusted to pH 8.0 by the addition of a 2 N sodium hydroxide solution and again allowed to stand in an ice box; 0.13 g. of crystals (m. p., 107~110°C) was thereby obtained.

The two crops of crystals were combined (quantitative yield) and recrystallized from benzene as rhombic crystals with an m. p. of 108.5°C. Further recrystallization from methanol gave colorless needles (VIII) (m. p., 114°C).

UV λ_{max}^{MeOH} 258 mμ (log ε 3.91).

IR strong bands (KBr disk): 1668, 1451, 1447, 1410, 1286, 1229, 1203, 1073, 930, 744, 735, 695 and 689 cm^{-1}.

Found: C, 39.26; H, 5.17; N, 9.15; S, 41.18%; mol. wt., 311. Calcd. for $C_{10}H_{16}ON_2S_4$: C, 38.93; H, 5.23; N, 9.08; S, 41.57%; mol. wt., 308.5.

The Treatment of VIII with Alkali in Ethanol.—A suspension of 50 mg. of VIII in 2.5 ml. of ethanol was stirred, and 0.5 ml. of 2 N sodium hydroxide solution was added. The mixture was stirred at room temperature for one hour until the whole dissolved and then allowed to stand overnight; the ethanol was then evaporated. The residue was acidified with hydrochloric acid and extracted with benzene. The extract was dried over anhydride. sodium sulfate, and the benzene was evaporated, leaving a liquid. A part of this liquid crystallized. A small amount of ether was added to this residue and filtered to collect 20 mg. of colorless crystals (m. p., 87~89°C), which showed the same infrared spectrum as that of VII.

The Reaction of VIII and Picric Acid.—A solution of 69 mg. of picric acid dissolved in 2 ml. of ethanol was added to a solution of 95 mg. of VIII dissolved in 6 ml. of ethanol while being warmed. The crystals that precipitated out were allowed to dissolve by warming, the solution was allowed to stand, and the crystals that precipitated out were collected by filtration (115 mg. of yellow needles; m. p., 154°C). This substance showed no depression of the melting point on admixture with the picrate IV obtained by the afore-mentioned method.

The filtrate was passed through an alumina column to remove the picric acid, and the ethanolic effluent was evaporated to remove the solvent, leaving 50 mg. of a colorless liquid. The infrared spectrum of this liquid agreed completely with that of the mercapto compound V.

The Reaction of VIII and Hydrochloric Acid.—Into a suspension of 120 mg. of VIII in 5 ml. of ethanol, 0.5 ml. of 2 N hydrochloric acid was added under stirring at room temperature, and the solution thus obtained was allowed to stand in an ice box overnight. After the evaporation of the solvent, a small amount of benzene was added to the residue, and it was filtered to collect 80 mg. of colorless crystals which were identified as cation chloride I. The solvent evaporated from the filtrate to 70 mg. of a liquid which showed the same infrared spectrum as the mercapto compound V.

Spectral Measurements.—The NMR spectra were measured in heavy water with a Varian V-4300 spectrometer (60 Mc.). The ultraviolet spectra were taken with a Hitachi model EPS-2 spectrophotometer, and the infrared spectra, with a Perkin-Elmer model 21 infrared spectrophotometer (sodium chloride and potassium bromide prisms) and a Hitachi model EPI-S2 infrared spectrophotometer (sodium chloride prism).

The Raman spectrum of I was measured with a Shimadzu automatic-grating Raman spectrometer, Type GRS-750, using the Hg-e line (4358 Å) from a Toronto-type mercury lamp as the exciting line.

The authors are indebted to Mr. Kensuke Takahashi for the measurement of the NMR spectra, to Mr. Tetsuo Hata for co-operation in the measurement of the Raman spectrum, and to Mr. Humio Sato for that of the ultraviolet spectra. The authors are also grateful to the Sankyo Co., Ltd., for its financial assistance in the present research.

Synthetic Resins Catalyzing the Racemization of Amino Acids. I. The Preparation of the Resins

By Koji Toi, Yoshiharu Izumi and Shiro Akabori

(Received February 16, 1963)

In general, optically-active free amino acids racemize only slowly even in a strongly alkaline or acidic solution at a boiling temperature. Heating the solution at a much higher temperature under high pressure accelerates the reaction, but this acceleration is accompanied by an appreciable decomposition of the amino acids. The racemization processes most commonly used involve heating suitable derivatives of optically-active amino acid with alkali or treating free amino acid with acetic anhydride or ketene in the presence of alkali and hydrolyzing the resulting acetyl-DL-amino acid. In the latter method, however, the recovery of the racemized amino acid has been achieved only with some difficult. Thus, it would be useful to prepare a catalyst which would accelerate the racemization of optically-active free amino acids under milder conditions.

In nature the so-called racemase catalyzes the racemization of amino acid under physiological conditions. These enzymes require pyridoxal phosphate as a coenzyme[1-5]. In

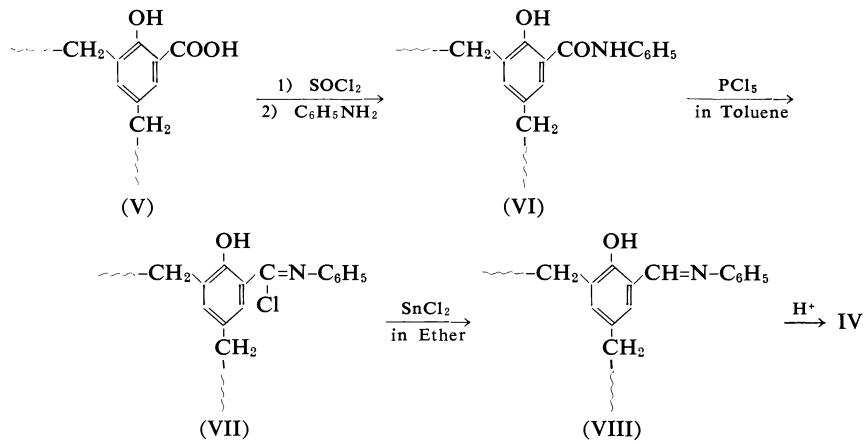
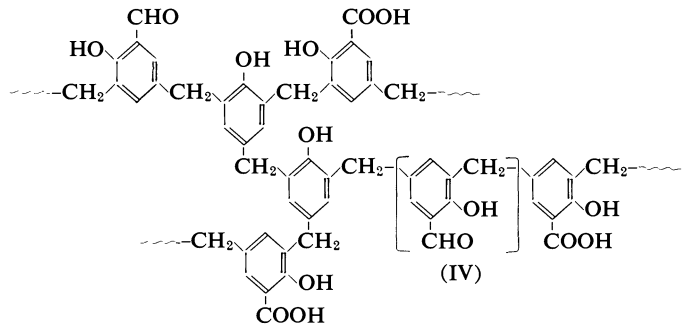
Structure of Resin A





Structure of Resin B

studies of the non-enzymatic reaction between pyridoxal and amino acids, Snell et al. found that pyridoxal itself catalyzes the racemization of amino acids in the presence of some metal ions[6] and proposed a general mechanism for pyridoxal-catalyzed reactions[7].

6) J. Olivard, D. E. Metzler and E. E. Snell, *J. Biol. Chem.*, **199**, 669 (1952).

Furthermore, it has been demonstrated that benzene analogues of pyridoxal, such as salicylaldehyde and its derivatives, namely 4- and 6-nitrosalicylaldehyde, also catalyze the racemization of amino acids in the presence of metal ions[8-10].

In a previous paper[11] it was reported that a resin, part of which was structurally similar to salicylaldehyde, namely, a benzene ring with formyl and hydroxy groups at positions ortho to each other (IV), accelerated the racemization of L-alanine, L-aspartic acid and L-glutamic acid in the presence of cupric ions.

In the present work, various methods of preparing such resin were investigated. Thus, four resins (Resins A—D) were prepared. All of them were found to be able to catalyze the racemization of amino acids in the presence of cupric ions.

Resin A, the activity of which has been reported in a previous paper[11], was prepared from *o*-cresol-phenol-formalin resin (I) by converting the methyl groups in the resin to formyl groups. The crushed resin was oxidized with chromium trioxide in a mixture of acetic acid and acetic anhydride, and then the acetal product III was hydrolyzed with 4 N hydrochloric acid to give IV.

Resin B was prepared from salicylic acid-phenol-formalin resin (V) by reducing the carboxy groups in the resin to formyl groups according to the Sonn-Müller method[12]. The crushed resin was treated with thionyl chloride and then with aniline to give the anilides VI in the resin. The anilides were converted to chloroimides VII by treatment with phosphorous pentachloride in toluene, and the chloroimides were then reduced to aldimines VIII with stannous chloride in ether saturated with hydrogen chloride. The aldimines were finally converted to aldehyde groups IV by hydrolysis with N hydrochloric acid.

Resins C and D were obtained from diazotized poly-*p*-amino styrene (XII) by coupling with pyridoxal and salicylaldehyde respectively. A cross-linked polystyrene resin (X) was nitrated with a mixture of nitric acid and sulfuric acid, and then the nitro groupings in the resin were reduced to amino groupings with stannous chloride in hydrochloric acid according to the procedure of D'Alelio[13]. The amino-resin (XI) was then treated with sodium nitrite in hydrochloric acid, and the XII produced was subjected to coupling with pyridoxal or salicylaldehyde. The coupling was carried out in a mixture of pyridine and water. The resins so obtained had the dark red color characteristic of the azo groupings.

The amount of formyl group in the resin was measured by Schultes' procedure[14]. A given amount of the resin was treated with aqueous hydroxylamine sulfuric acid, and the amount of sulfuric acid liberated was determined quantitatively by alkaline titration (Table I).

The racemization experiment was conducted

with L-alanine in the presence of cupric ions. The results are shown in Figs. 1 to 3. Racemization tests with Resin A for L-alanine, L-aspartic acid and L-glutamic acid have already been reported in a previous paper[11]. An aqueous L-alanine solution of pH 10 containing cupric ions and a borate buffer was heated with the resin at 100°C. Aliquots of the reaction mixture were removed at varying intervals and filtered. Each filtrate was diluted with an

equal volume of 12 N hydrochloric acid, and its optical rotation was measured. The amino acid contents of the reaction mixtures were checked in order to determine whether or not the simultaneous decomposition of amino acid had occurred. Appropriate aliquots of the acidic solutions, which had been prepared for rotation measurement, were evaporated to dryness. The residues were dissolved in water, and the solutions were made alkaline with sodium hydroxide. Each alkaline solution was evaporated to dryness. The residues was dissolved in water, and the amino acid content of each was determined by the ninhydrin colorimetric method[15]. The values of their optical densities are plotted in Figs. 1 to 3.

It is considered that the reaction conditions under which these catalysts will pass through their maximum activities depend on many factors, such as the pH value of the reaction mixture, the reaction temperature and the nature and concentration of metal ions used.

Experimental

Preparation of Resin A.—A mixture of 108 g. of *o*-cresol, 38 g. of phenol, 160 ml. of 37% formalin and 5 ml. of 50% aqueous sodium hydroxide was stirred at 80~90°C. When the mixture became viscous after 3 hr., stirring was stopped. This mixture was then heated at 100°C for 15 hr. The rigid mass which resulted was crushed to 50~200 mesh, thoroughly washed with water, and dried at 50°C under vacuum. Forty grams of this product were mixed with 240 ml. of acetic anhydride containing 5 ml. of concentrated sulfuric acid for 1 hr., and then 160 ml. of acetic acid were added. Into

15) E. W. Yemm and E. C. Cocking, *Analyst*, **80**, 209 (1955).

this mixture were slowly stirred 16 ml. of concentrated sulfuric acid while it was being externally cooled. When the temperature of the mixture decreased to 0°C, 20 g. of chromium trioxide were added in small portions at such a rate that the temperature did not rise above 5°C. Stirring at 4~5°C was continued for 3 hr. after the addition of the chromium trioxide. The reaction mixture was vigorously stirred into 1.5 l. of water. The product was separated by decantation and washed with water. This material was then hydrolyzed with 300 ml. of 4 N hydrochloric acid under reflux for 3 hr. The final product was filtered with suction, washed with aqueous 5% sodium bicarbonate and then thoroughly with water, and dried at 50°C under vacuum.

Preparation of Resin B.—A mixture of 13.8 g. of salicylic acid, 4.7 g. of phenol, 36 g. of 37% formalin, and 45g. of 20% aqueous sodium hydroxide was stirred at 100°C. When the mixture became viscous, stirring was stopped and the mixture was allowed to stand at 100°C for 12 hr. The resulting rigid mass was crushed to 100~200 mesh, washed thoroughly with dilute hydrochloric acid and then with water, and dried.

Ten grams of this product were swollen with *N*, *N*-dimethylformamide and stirred at 0°C in 65 ml. of thionyl chloride for 3 hr. The resulting resin was filtered, washed with chloroform, and stirred at 0°C for 5 hr. in a mixture of 60 ml. of chloroform, 20 ml. of aniline and 10 ml. of triethylamine. After the mixture had been allowed to stand overnight at room temperature, the product was filtered washed with chloroform and dried. The anilides produced were added to a solution obtained by dissolving 12 g. of phosphorous pentachloride in 100 ml. of toluene and stirred at 90°C for 6 hr. The resulting product, the chloroimides, was filtered, washed with toluene, and then subjected to reduction by stirring it with a solution which was prepared by dissolving 40 g. of stannous chloride dihydrate in 200 ml. of ether saturated with hydrogen chloride. The product obtained was filtered, washed with ether, and then stirred in 200 ml. of N hydrochloric acid at 60°C for 6 hr. The final product was filtered, thoroughly washed with water, and dried under vacuum. Yield, 12 g.

Preparation of Resin C.—A cross-linked polystyrene resin (8% of divinylbenzene, 100~200 mesh) was converted to a poly-*p*-aminostyrene following the procedure of D' Alelio[13]. The polystyrene resin was nitrated with nitric acid and sulfuric acid, and then the nitro groups were reduced to amino groups by stannous chloride in hydrochloric acid. The total capacity of its anion exchange was 1.02 meq. per g.

Ten grams of poly-*p*-aminostyrene resin were stirred in 50 ml. of N hydrochloric acid at 0°C with external cooling. To this suspension 5 ml. of 20% aqueous sodium nitrite were added drop by drop, and stirring was continued for 2 hr. at 0°C. The resulting resin was filtered and washed with cooled aqueous urea and then with cooled water. The diazotized resin was suspended in a solution which was cooled to 0°C and which was prepared by dissolving 3.0 g. of pyridoxal hydrochloride in a mixture of 20 ml. of pyridine and 20 ml. of water. The suspension was stirred at 0°C for 15 hr. The resulting resin was filtered, washed successively with dilute hydrochloric acid, dilute sodium acetate and water, and then dried under vacuum. Yield, 10.3 g.

Preparation of Resin D.—Ten grams of poly-*p*-aminostyrene were diazotized as has been described in the previous paragraph on Resin C. A solution was made of 3.7 g. of salicylaldehyde and 1 g. of sodium carbonate in a mixture of 30 ml. of N sodium hydroxide and 20 ml. of pyridine. This salicylaldehyde solution was cooled to 0°C, and the diazotized resin was added. This mixture was stirred at 0°C for 15 hr. The resulting resin was filtered and washed thoroughly with water. The washed resin was dried under vacuum. Yield, 10.5 g.

Measurement of the Aldehyde Contents of the Resins.—One gram of a resin was shaken for 3 hr. at 60°C with 5 ml. of N hydroxylamine sulfuric acid in a sealed test tube. The mixture was filtered, and an aliquot of the filtrate was titrated with 0.1 N sodium hydroxide, using bromphenol blue as an indicator.

Racemization Test. — An aqueous solution of L-alanine was prepared; it was adjusted to pH 10 with sodium hydroxide and was found to contain 17.8 g. of L-alanine and 0.45 g. of $CuCl_2 \cdot 2H_2O$ in a total volume of 100 ml. Fifteen milliliters of the above solution, 15 ml. of 0.2 M borate buffer of pH 10, and 5 g of the resin were stirred at 100°C.

Summary

1) Four resinous catalysts (Resins A—D) for the racemization of amino acids were prepared. They had structures partially similar to that of salicylaldehyde or pyridoxal. Resins A and B were prepared by the chemical modification of *o*-cresol-phenol-formalin resin and salicylic acid-phenol-formalin resin respectively. Resins C and D were obtained by attaching chemically pyridoxal and salicylaldehyde residues respectively to a styrene-divinylbenzene lattice.

2) These resins catalyzed the racemization of amino acids in the presence of cupric ions at 100°C.

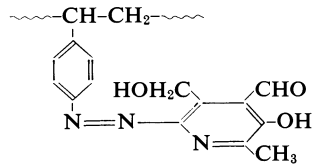
Synthetic Resins Catalyzing the Racemization of Amino Acids. II. The Activity of the Resins

By Koji Toi

(Received March 5, 1963)

In the previous paper it was reported that some synthetic resins, to which pyridoxal is partially attached or which have a structure partially similar to salicylaldehyde, catalyzed the racemization of amino acids in the presence of cupric ions[1,2]. It was suggested that the conditions under which these catalytic resins are maximally active probably depend on many factors, such as the pH of the reaction mixture, the reaction temperature, the concentration of substrate and the presence of metal ions. Thus, in the present work, a study will be made of the influence of these conditions on the resin-catalyzed racemization.

Studies were made using two typical resins in order to elucidate the general properties of the resins. One (Resin I) is a styrene-divinylbenzene resin, to part of which pyridoxal is attached through azo bondings.



Partial structure of Resin I

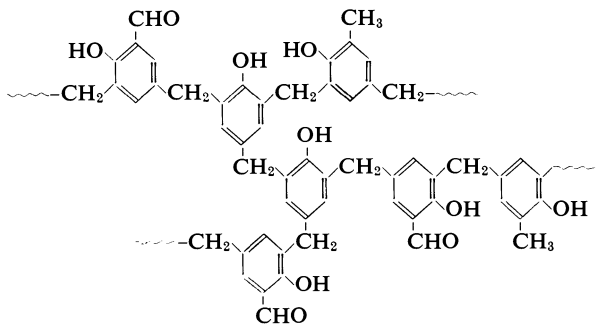
The other (Resin II) is chemically-modified *o*-cresol-phenol-formalin resin, part of which is structurally similar to salicylaldehyde, —a benzene ring with formyl and hydroxy groups ortho to each other—

Experimental

Amino Acid Solutions. — These solutions were prepared by dissolving 0.1 mol. of an amino acid and a given amount of a metal salt in a 0.1 M buffer solution and then adjusting it to the desired pH in a final volume of 100 ml. The buffers used were as follows: pH 4 to 5, acetate; pH 6 to 8, phosphate; pH 9 to 12, borate.

Catalytic Resins.—The preparation of Resins I and II was described in the previous paper[2]. Resin I was prepared from a styrene-divinylbenzene resin by nitration, reduction, diazotization, and subsequent coupling with pyridoxal in a mixture of water and pyridine. The formyl content was 0.10 mmol. per g. of dry resin. Resin II was prepared from *o*-cresol-formalin resin by converting the methyl groups in the resin to formyl groups. The crushed resin was oxidized with cromium trioxide in a mixture of acetic acid and acetic anhydride, and the acetal product was hydrolyzed with hydrochloric acid. The formyl content of Resin II was 0.24 mmol. per g. of dry resin.

Racemization Procedure.—A mixture of 5 ml. of an amino acid solution, prepared as described above, and 1 g. of Resin I or II was heated in a sealed test tube while being vigorous shaken in a water bath of the desired temperature. After the reaction, the catalyst was removed by filtration. The filtrate was diluted with a definite volume of 12 N hydrochloric acid, and its optical rotation was measured. For glutamic acid, the measurements were made after this acidic solution had been heated for 2 hr. at 100°C to reconvert the pyroglutamic acid formed during the racemization reaction to glutamic acid[3].



Partial structure of Resin II

Determination of the Amino Acid Content of the Reaction Mixture.—An aliquot of the solution used for optical rotation measurements was evaporated to dryness. The residue was dissolved in a small amount of water, and the solution was made alkaline. The alkaline solution was evaporated to dryness. The residue was dissolved in water, and the amino acid content of the solution was determined by the ninhydrin colorimetric method[4].

Results and Discussion

Effect of the pH Value of the Reaction Mixture.—The resin-catalyzed racemization of amino acids was tested as a function of pH in the presence of cupric ions. The test was conducted with L-alanine at 98°C. The results are shown in Figs. 1 and 2.

The reaction is influenced by the number of cupric ions, as is shown in Fig. 5. An increase in the concentration of cupric ions accelerates the reaction, but it also causes the racemization of amino acids in the absence of resin on heating in an alkaline medium, especially above pH 11. Therefore, it was undesirable to use much cupric salt in this test.

An aliquot of the L-alanine solution used for the test was simultaneously heated at the same temperature in the absence of resin, as a control for the resin-catalyzed racemization. The degree of racemization of the control was substracted from that of the sample heated with resin.

The results show that the catalysts have

optima at about pH 10.5. In their work on the pyridoxal-catalyzed racemization of L-alanine in a non-enzymatic system, Snell et al. found that the optimum pH of pyridoxal was between 9 and 10[5]. Thus the two results agree roughly with each other.

Effect of the Reaction Temperature. — The racemization of L-alanine with Resins I and II was carried out at 60, 80 and 97°C. The results are shown in Figs. 3 and 4.

The reaction mixture contained 1 g. of Resin I or II and 5 ml. of amino acid solution (pH 10) containing 1.0 M L-alanine, 0.06 M a metal salt, and 0.1 M borate buffer. The metal salts used were $Cu(CH_3COO)_2 \cdot H_2O$, $CoCl_2 \cdot 6H_2O$, $Ni(CH_3COO)_2 \cdot 4H_2O$, $MgSO_4 \cdot 7H_2O$ and $Zn(CH_3COO)_2 \cdot 2H_2O$. Reaction time, 1 hr. at 98°C. The optical rotation α_D was measured in acidic solution prepared by diluting the reaction mixture with two volumes of 6 N HCl.

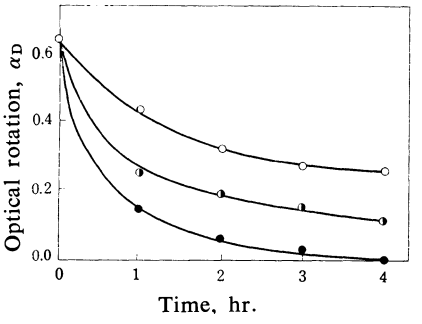

Fig. 4. Apparent racemization of L-alanine by Resin II at 60, 80 and 97°C (pH 10).

The reaction mixture contained 1 g. of Resin II and 5 ml. of amino acid solution containing 1 M L-alanine, 0.06 M $Cu(CH_3 \cdot COO)_2 \cdot H_2O$ and 0.1 M borate buffer.

○ Optical rotation in reaction at 60°C
◑ Optical rotation in reaction at 80°C
● Optical rotation in reaction at 97°C

In the presence of a given amount of cupric ion, the racemization reaction proceeded like an ordinary chemical reaction in that, as the temperature was increased, the rate of the reaction increased.

Effect of the Type of Metal Ion Present.—The racemization of amino acids catalyzed by the resin proceeds well in the presence, but not in the absence, of metal ions. A comparison was made of the effect of fixed concentrations of metal ions on the catalysis of the racemization by the resin. Table I shows the results of this test. Of the metal ions tested, cupric ions were the most effective, while cobaltous ions were quite active. Experiments with ferric and aluminum ions were impossible because these metals precipitated as hydroxides under the conditions used.

The concentration of metal ions in the reaction mixture has a considerable effect on the rate of racemization (Fig. 5). An increase in concentration of metal ions raises the rate of the reaction.

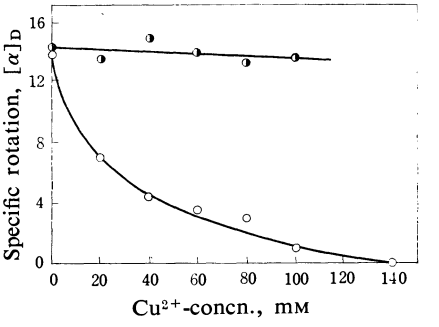

Fig. 5. Effect of the Cu^{2+}-concentration on racemization of L-alanine by Resin II.

The reaction mixture contained 1 g. of Resin II and 5 ml. of amino acid solution (pH 10) containing 1.0 M L-alanine and 0.1 M borate buffer. Reaction time, 1 hr. at 98°C.

○ $[\alpha]_D$ with Resin II
◑ $[\alpha]_D$ in absence of resin

Retention of Resin Activity.—It is desirable that the catalytic resin should retain its activity during the reaction and on repeated use. The activity of Resins I and II on repeated use was, therefore, tested; the results are given in Table II. L-Alanine was tested with the resin for 1 hr. at 98°C in the presence of cupric ions, and the resin was recovered by filtration. After recovery, the catalyst was washed with borate buffer and used for the next run. The activity of the resin was retained for at least seven runs.

The Racemization of Various Amino Acids.—A study was made of the extent of racemization of a series of amino acids. As may be

Table II. Retention of activity

	Apparent racemization, α_D	
	Resin I	Resin II
Before reaction	0.42	0.42
Original resin	0.17	0.08
After 1st recovery	0.16	0.10
After 2nd recovery	0.18	0.09
After 3rd recovery	0.19	0.08
After 4th recovery	0.18	0.12
After 5th recovery	0.11	0.08
After 6th recovery	0.16	0.11

The reaction mixture contained 1 g. of Resin I or II and 5 ml. of amino acid solution (pH 10) containing 1 M L-alanine, 0.06 M $Cu(CH_3COO)_2 \cdot H_2O$ and 0.1 M borate buffer. Reaction time, 1 hr. at 98°C.

seen in Table III, each of the amino acids tested underwent racemization to some extent. In the case of L-phenylalanine, L-tyrosine and L-methionine, cobaltous ions were chosen instead of cupric ions because of the insolubility of the copper complexes of these amino acids under the conditions used. L-Alanine racemized most rapidly, and L-aspartic acid, at quite a high rate. In the course of the reaction, amino acids underwent some spontaneous decomposition. The recovery of amino acid was estimated by the optical density of the ninhydrin colorimetric reaction of the amino acid after its isolation from the reaction mixture on a paper chromatogram.

A Comparison of the Activity of the Resin and of Pyridoxal.—In non-enzymatic systems, pyridoxal may be most effective as a catalyst for amino acid racemization. A comparison was made of the effects of the resin and of pyridoxal on the rate of racemization of L-alanine in the presence of cupric ions at 80 and 98°C, though pyridoxal was dissolved in the reaction systems. Conditions were used under which the catalytic resin passed through its maximum activity at a given temperature. The amount of each catalyst was adjusted to give equal contents of aldehyde.

The resin has no stereospecificity and can simultaneously catalyze the conversion of both the L- to the D-form and the D- to the L-form. Therefore, the racemization of amino acids is,

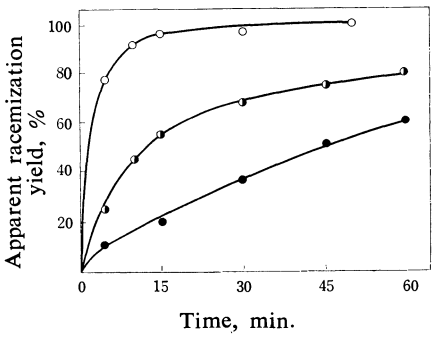

Fig. 6. Comparison of the activities of the resins and pyridoxal in catalysis of the racemization of L-alanine at 98°C.
The reaction system contained 1 g. of Resin I, 0.42 g. of Resin II, or 0.1 mmol. of pyridoxal hydrochloride and 6 ml. of L-alanine solution (pH 10.0) containing 0.83 M L-alanine, 0.083 M $Cu(CH_3COO)_2 \cdot H_2O$ and 0.1 M borate buffer. Reaction time, 1 hr. at 98°C.

The reaction mixture contained 1 g. of Resin I or II and 5 ml. of amino acid solution, containing 1 M amino acid, 0.06 M metal salt, and 0.1 M borate. Because of the insolubility of their metal complexes in the case of L-valine, L-tyrosine and L-methionine, the concentration was reduced to 0.5 M amino acid and 0.03 M metal salt.

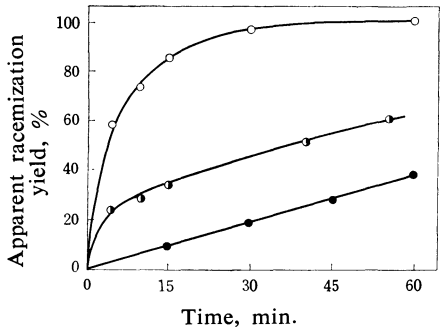

Fig. 7. Comparison of activities of the resins and pyridoxal in catalysis of racemization of L-alanine at 80°C.

The reaction system consisted of 1 g. of Resin I, 0.42 g. of Resin II, or 0.1 mmol. of pyridoxal hydrochloride and 6 ml. of L-alanine solution (pH 10.5) containing 0.83 M L-alanine, 0.033 M $Cu(CH_3COO)_2 \cdot H_2O$ and 0.1 M borate buffer. Reaction time, 1 hr. at 80°C.

○ Pyridoxal ◑ Resin II ● Resin I

in theory, a first-order reaction. The rate of the reaction should be proportional to the concentration of L-alanine at a fixed concentration of cupric ions.

The rate observed in the resin-catalyzed racemization of L-alanine described a curve like a first-order reaction, but it deviated from the theoretical course when the reaction period was long, as may be seen in Figs. 6 and 7. However, after a certain initial period, the rate may be approximately regarded as of the first order.

Thus, the rate constants, k, of the reaction with resin and pyridoxal were compared over the initial five-minute period. The values obtained are summarized in Table IV. At 98°C, the activities of Resins I and II were, respectively, about 8×10^{-2} and 2×10^{-1} of that of pyridoxal.

Table IV. Rate constant

Temp. °C	k, min^{-1}		
	Pyridoxal	Resin I	Resin II
98	3.0×10^{-1}	2.3×10^{-2}	6.4×10^{-2}
80	1.8×10^{-1}	9.2×10^{-3}	5.5×10^{-2}

The values of k were calculated with the formula,

$$k=\frac{2.3}{5}\log\frac{100}{100-x}$$

where x is the apparent racemization yield.

Summary

1) A study has been made of the factors influencing the racemization of amino acids by resinous catalysts with structures partially similar to those of pyridoxal and salicylaldehyde.

2) The optimum pH of the reaction was about 10.5.

3) A rise in temperature resulted in an increase in the rate of the reaction.

4) The racemization reactions catalyzed by the resins required the presence of metal ions, and cupric ions were found to be most effective.

5) Of the amino acids tested, L-alanine was racemized most rapidly.

6) The resinous catalysts retained activity after repeated usage.

7) The racemization-activity of the resins was compared with that of pyridoxal.

The author wishes to express his thanks to Professor Shiro Akabori and Dr. Yoshiharu Izumi for their valuable advice and encouragement throughout this work.

Spectrophotometric Study on the Interaction of Chromium(III) with Alizarinsulfonic Acid

By Wahid U. MALIK, Rizwanul HAQUE and Surendra PRATAP

(Received August 13, 1962)

The interaction of metal ions with alizarinsulfonic acid has been studied by a number of workers[1-6], but little seems to have been done as regards the chromium(III) complexes. Preliminary experiments show that chromic chloride does not react with alizarinsulfonic acid at room temperature. However, on heating the mixture at about 80°C for nearly half an hour a red color develops, indicating the probable existence of the complex. The work described here deals with the spectrophotometric studies on the composition of the red product obtained at 80°C.

Chromic chloride (A. R.) was dissolved in redistilled water and the concentration was determined by the usual methods. The solution of alizarinsulfonic acid (sodium salt) was prepared by dissolving a known amount in acetate buffer of pH 3.1. Absorption experiments were carried out with a Bausch and Lomb 'Spectronic 20'. Measurements of pH were made with a Beckman pH-meter model G.

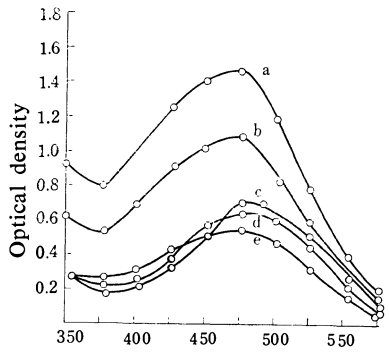

Fig. 1

d) 2 : 1 ratio of the reactants at pH 3.1
e) 3 : 1 ratio of the reactants at pH 3.1

Vosburgh and Cooper's[7] method was employed to determine the number of complexes formed. The reactants were mixed in different molar ratios (1 : 1, 1 : 2, 1 : 3, 2 : 1, 3 : 1), heated on a water bath for about half an hour, cooled to room temperature and their optical densities were measured. All the mixtures gave a maximum at 475 mμ (Fig. 1) showing thereby the formation of only one complex.

The Job's method of continuous variation[8] was followed for determining the composition of the complex. Solutions of chromic chloride and sodium alizarinsulfonic acid of two different concentrations, M/3000 and M/4000, were mixed according to the method of continuous variation and the optical densities measured at 475 mμ. In order to account for the absorption of alizarinsulfonic acid, the mixtures of water (in place of chromic chloride) and alizarinsulfonic acid were taken, heated on a water bath to 80°C, cooled and their optical densities were measured. The chromic chloride solutions prepared under exactly similar conditions showed almost negligible absorption at 475 mμ. A curve was plotted between the

difference in optical density of complex and alizarinsulfonic acid and the ratio $Cr^{3+}/(Cr^{3+}+$ alizarinsulfonic acid). The results are depicted in Fig. 2.

The results were also confirmed by the slope ratio[9] and the molar ratio methods[9]. Two sets of experiments were performed for the slope ratio method. In the first set the concentration of sulfonic acid (taken in excess) was kept constant while the concentration of chromic chloride was varied. In the other set the mixtures were prepared by mixing the reagents just in the reverse manner. The optical densities of the mixtures in the two sets were measured under exactly similar conditions as described above and curves drawn between the optical density of the solution and the volume of the reactant (Fig. 3) to be varied. case of molar ratio method the optical densities of the following two sets of mixtures were measured: (i) 5 cc., alizalinsulfonic acid of 0.5×10^{-3} M mixed with 0.5 cc., to 8.0 cc., chromium(III) chloride 0.5×10^{-3} M, total volume made upto 20 cc. by adding required amount of buffers; (ii) reagent mixed in just the reverse manner as given under (i). The results are shown in Fig. 4.

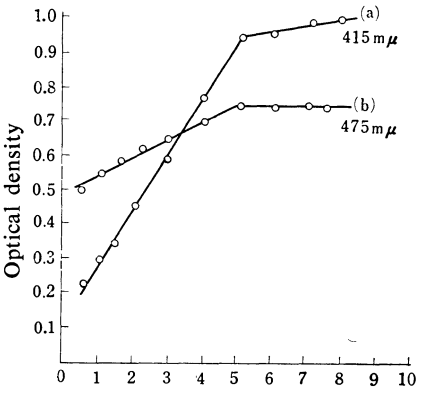

Fig. 4

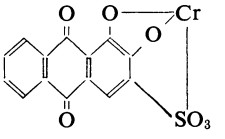
a) Alizarin variable
b) $CrCl_3$ variable

The Vosburgh and Cooper's method shows the existence of one complex with an absorption maximum at 475 mμ. By applying the Job's method at two different concentrations of the reactants, peaks are obtained corresponding to the molar ratio 1:1 (Fig. 2). The results obtained by the Job's method find support from the slope ratio and molar ratio methods. Hence the probable composition of the complex may be written as:



Dey and Mukherji[6] determined the stability constant and free energy of the red alizarinsurfonic acid complex by considering two concentrations of the reactants which gave the same optical density. No such attempt was made here in view of the inert nature of the chromium complex[10] and the slowness with which the reaction is expected to reach equilibrium. The composition put forward here, therefore, refers only to the product formed by the interaction of chromic chloride and alizarinsulfonic acid at 80°C.

Polarographic and Spectrophotometric Determination of Zinc in Zinc Stearate

By Wahid U. MALIK, Rizwanul HAQUE and Surendra Pal VERMA

(Received August 13, 1962)

The problem of the estimation of the metal content in heavy metal soaps has been a subject of detailed study in these laboratories for some time. Working with copper, nickel and cobalt soaps, it was found that their property of forming complexes with pyridine base[1] can be advantageously put to use for estimating the metal content by polarography[2] and spectrophotometry[3]. The present communication deals with the estimation of zinc in zinc stearate by the above two methods[2,3].

All the reagents used were either A. R. samples or purified products. Stearic acid (British Drug House) was crystallized with alcohol and finally fractionated under reduced pressure. A. R. pyridine and A. R. mercury (triple distilled) were used.

Zinc stearate was prepard by the precipitation method[4]. The solution was prepared in pyridine and metal content estimated gravimetrically.

Polarographic measurements were carried out with a Fisher Electropode in conjunction with a Multiflex galvanometer model MGF2. Experiments were performed in H-type cell[5] using dropping mercury cathode and a saturated calomel electrode. Lithium chloride and methyl hydrogen sulfate in 1 : 1 benzene-methanol mixture were used as supporting electrolytes[6]. The capillary constants, $m^{2/3}t^{1/6}$, for these supporting electrolytes (0.033 M) were 1.618 and 1.532 respectively in the open circuit. Two sets of experiments were performed: (1) fixed amount of soap (5 cc., approximately 1%) and varying amounts of supporting electrolyte (1.0, 2.0, 3.0, 5.0, 10.0 cc. of 0.165 M), making total volume 30 cc.; (2) fixed amount of supporting electrolyte (5.0 cc. of 0.165 M) and varying amounts of soap (3.0, 5.0, 8.0, 10.0, 12.0 cc. approximately 1%), making total volume 30 cc. Inert atmosphere was maintained in the cell by passing pure nitrogen and experiments were performed at 25±0.1°C in thermostatic water-bath (Townson and Mercer).

The typical polarograms of zinc stearate in lithium chloride and $MeHSO_4$ (concentration 0.005 M) are shown in Fig. 1, the values of

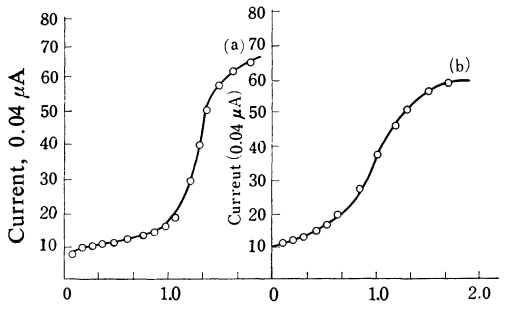

Fig. 1. Polarograms of zinc stearate pyridine complex.

a) 2.5 mM Zn^{2+} in Zn-stearate in 0.055 M LiCl

b) 2.5 mM Zn^{2+} in Zn-stearate in 0.055 M $MeHSO_4$

$E_{1/2}$ in the two supporting electrolytes being −1.4 and −0.9 V. respectively. The values of $E_{3/4}-E_{1/4}$, however, came out to be abnormally high indicating the irreversible nature of the wave. The limiting current was found to increase with increasing concentration of the soap. The values of the concentration of zinc in soap in millimoles per liter (C), the limiting current in microamperes (i_l) and i_l/C are summarized below.

Table I shows that the value of i_l/C remains fairly constant, showing thereby that the estimation of zinc can be made from these results.

TABLE I

C	0.033 M i_l	LiCl i_l/C	0.033 M i_l	$MeHSO_4$ i_l/C

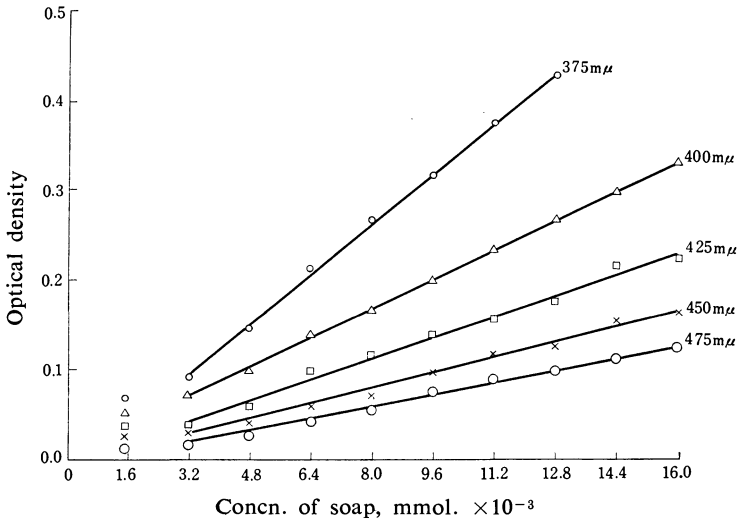

Fig. 2. Optical density as a function of concentration of soap.

Spectrophotometric measurements were carried out with a Bausch and Lomb 'Spectronic 20'. Solutions of zinc stearate of different dilutions were prepared by diluting the stock solution with pyridine. Measurements were carried out in the wavelength region 375 to 475 mμ.

The plot between the optical density and concentration of the metal in the soap gave straight lines upto a certain concentration of the soap solution (Fig. 2). Below this concentration the points did not lie on the straight line, showing thereby that the Beer's law is not obeyed for very dilute solutions and that the zinc ions can be estimated spectrophotometrically in the zinc stearate solution for concentrations higher than 3.2×10^{-3} mM.

*An Improved Synthesis of 1,3,5-Tri-t-butylbenzene**

By Setsuo WATARAI

(Received January 5, 1963)

Various methods of preparing tri-*t*-butylbenzene have been reported in the literature[1], but the first positive mention of 1,3,5-tri-*t*-butylbenzene (I) is to be found in a paper by McCaulay and Lien[2]; the material was obtained by the disproportionation of *t*-butylbenzene with hydrogen fluoride and boron trifluoride at 0°C. The same substance has also been obtained by the Friedel-Crafts alkylation of *p*-di-*t*-butylbenzene (II)[3,4] or by other reactions[3,5,6].

Undoubtedly the procedure of Barclay and Betts[4], who showed that I was obtained from the aluminum chloride-catalyzed alkylation of II with a large excess of *t*-butyl chloride in

** Theoretical yield; 42%

the cold, is very attractive when large quantities of this compound are to be prepared.

However, *p*-di-*t*-butylbenzene has some undesirable properties for this purpose in comparison with *m*-di-*t*-butylbenzene (III); a large excess of *t*-butyl chloride[4] or of other organic solvents[3], such as carbon disulfide or ethylene dichloride, should be used to dissolve *p*-di-*t*-butylbenzene, while III is misible in *t*-butyl chloride in all proportions. The m. p. (76~77°C) of II is close to that (73.5°C) of I; furthermore, a rearrangement other than alkylation should be involved in the reaction steps.

Some unusual cyclialkylation products, such as IV[7], V[8] and others[3], have been isolated from a complex mixture as by-products of the preparation of I by the aluminum chloride-catalyzed alkylation of II with a large excess of *t*-butyl chloride in the cold. The mechanism of the formation of these by-products has been discussed by several workers[7-10].

rather a little aluminum chloride, and the preparative condition for this hydrocarbon was proposed.

In the present paper, the *t*-butylations of *m*-di-*t*-butylbenzene and an improved method of preparing 1, 3, 5-tri-*t*-butylbenzene are reported.

The experiments shown in Tables I and II were carried out under several conditions, which involved different amounts of the alkylating reagent and the catalyst, reaction times, and temperatures. The reaction products were fractionated, and each fraction was identified by its physical properties by means of gaschromatographic (Fig. 1) and spectrometric analysis (Fig. 2).

In these alkylations with a slight excess or a small amount of *t*-butyl chloride, the remarkable side-reactions previously reported in the literatures could not be observed, even under the influence of a prolonged reaction time at or over room temperature, although few boiling fractions higher than I were isolated.

At −8°C, *m*-di-*t*-butylbenzene (III) treated with the equivalent alkylating reagent was almost entirely recovered; on the other hand, when III was treated with a large excess of *t*-butyl chloride, it was alkylated rapidly into I in the same yield as in the case of II. However, at or over room temperature, I was formed from III using a very small amount of catalyst (Exp. No. 7), and the quantity was increased with the reaction time (Exp. No. 4—6). Thus, 1, 3, 5-tri-*t*-butylbenzene (I) was obtained in a good yield from *m*-di-*t*-butylbenzene (III) without using large excess of an alkylating reagent and a catalyst, which are apt to cause side-reactions.

The disproportionation of III shown in Table II was also examined under the same conditions as in the case of alkylation. From these experiments of alkylation and disproportionation, it was found that alkylation proceeds before the isomerization of III and that too many reaction times should be avoided, even in the case of III in the preparation of I.

The melting point of the 1, 3, 5-tri-*t*-butylbenzene (I) obtained in this manner was identical with that of the hydrocarbon obtained by Barclay's method (Exp. No. 1), and the mixed melting point was not depressed. The infrared spectra of the two materials were also identical.

NOTES

Studies of the Recoil Tritium-labeling Reaction

By Teruhiko MESHI and Yoshishige SATO

(Received January 10, 1963)

In the reaction of the energetic tritium atom produced in the $Li^6(n, \alpha)T$ reaction with organic compounds, radiation-damage products with specific activities higher than the labeled parent molecule have been detected[1-3]. In order to investigate the specificity of the chemical reactions of recoil tritium, studies have been made of the reaction with crystalline glucose, lactose and α-hydroximinopropionic acid.

A finely powdered mixture of 20 g. of each sample and 2 g. of lithium carbonate was irradiated in the JRR-1 reactor for 21 hr. at a flux of $\sim 2.5 \times 10^{11}$ n/cm^2/sec. The irradiated materials were somewhat brownish as a result of radiation decomposition. Sugars were separated from lithium carbonate by hot water extraction and adsorption on Amberlite IR-120 resin. Since Rowland et al.[4] reported that macro amounts of organic acids were separated during the purification of the irradiated galactose, attempts were made to separate the neutral and acidic constituents by the use of ion-exchange resin.

The solution of sugars was passed through a column of Amberlite IR-45, which was washed with water to produce a neutral fraction. Acids were removed from the column with a 2 N ammonia solution, and free acids were liberated by passage of the solution through a column of Amberlite IR-120.

The constituents in both the neutral and the acidic fraction were separated chromatographically on Toyo paper No. 50. The acidic sugars

1) M. A. El-Sayed, P. J. Estrup and R. Wolfgang, *J. Phys. Chem.*, **62**, 1356 (1958).
2) R. M. White and F. S. Rowland, *J. Am. Chem. Soc.*, **82**, 5345 (1960).
3) J. K. Lee, B. Musgrave and F. S. Rowland, ibid., **82**, 3545 (1960).
4) F. S. Rowland, C. N. Turton and R. Wolfgang, ibid., **78**, 2354 (1956).

were developed with *n*-butanol-acetic acid-water (4 : 1 : 5) and detected with bromophenol blue or benzidine hydrochloride. The neutral sugars were irrigated with *n*-butanol-pyridine-water (6 : 4 : 3) and detected with benzidine hydrochloride or ammoniacal silver nitrate.

Paper chromatography of the neutral fraction of lactose showed five spots, but that of glucose showed only one spot. The R_f values of the three spots derived from lactose were identical with those of lactose (0.12), galactose (0.19) and glucose (0.23). The chromatogram of the acidic fraction of lactose revealed three spots which were identified as mucic acid (0.01), gluconic acid (0.12) and saccharic acid (0.20).

The irradiated oxime was extracted with ether, and the residue was chromatographed with *n*-butanol-acetic acid-water (4 : 1 : 1). The two spots produced by spraying ninhydrine corresponded to DL-alanine and glycine. The results obtained with the undegraded samples are summarized in Table I.

Table I. Incorporation of recoil tritium into organic compounds

Sample	Total tritium d.p.m./mg.	Nonlabile tritium incorporated d.p.m./mg.	Entry of tritium %	Recovery %
Glucose	2.2×10^5	5.3×10^4	24	89.0
Lactose	2.2×10^5	2.2×10^4	10	47.4
Oxime	2.2×10^5	2.0×10^4	9	55.0

The total tritium content, which was calculated from the bombardment condition, represents the number of tritons produced by the nuclear reaction. The low recovery of lactose as compared with that of glucose may be attributed to the fact that the glucoside linkage is ready to undergo radiolysis. The amount and the specific activity of the radioactive mucic acid produced by the irradiation of lactose was determined by the double dilution method. For a comparison of the specific activity, the isolated lactose was oxidized with nitric acid to mucic acid. As a result, the radiation-damage mucic acid had a specific activity about ten times higher than the chemically degraded mucic acid, as is shown in Table II.

Table II. Comparison of the specific activity of mucic acid produced by radiation damage and chemical degradation

Sample	Specific activity μc./mM	Yield %
Radiation-damage mucic acid	12.0	0.09
Chemically-degraded mucic acid	1.26	—
Lactose	3.4	—

Table III. The chemical state of tritium produced by the neutron irradiation of α-hydroximinopropionic acid

Sample	Specific activity μc./mM	Yield %
DL-Alanine	169.0	0.34
Glycine	75.0	0.17
Oxime	0.93	55.0

The production of mucic acid of high specific activity from lactose suggests that the initial substitution of T for H on the -CH- carbon leaves an excited molecule which eventually decomposes to the labeled mucic acid.

Table III shows the specific activities and the yields of tritium-labeled products formed by the reaction of recoil tritium with α-hydroximinopropionic acid.

The great difference in the specific activity between DL-alanine and oxime can be explained on the basis of the preferential utilization of the tritium atom for the addition of the double bond. White and Rowland[2] have demonstrated that the addition of recoil tritium to the double bond occurs in fumaric acid and maleic acid.

The radioactive glycine is presumably produced by the substitution of T for CH_3, Hoff and Rowland[5] have already shown the production of labeled acetaldehyde in the reaction of recoil tritium with acetone.

Detection of the Interaction between an Iron Surface and Organic Molecules by Means of Infrared Absorption

By Kaneko SAKURAI, Naoe HIRAI and Katsuya INOUYE

(Received February 22, 1963)

For the surface treatment of steel with organic substances or polymers to increase corrosion resistance and to improve appearance, the selection of materials with a strong enough interaction with the surface appears to be an increasingly significant problem.

The authors have tried to use an infrared absorption method to observe the anomaly in

the absorption bands which might be due to the interaction of the iron surface with some organic substance.

Examining the reflection of infrared light from organic films covering the surface of the metal plate, the intensity of the infrared light is not sufficient to serve for the present purpose. To increase the intensity, fine iron powders are mixed with organic substances.

The rouge (iron oxide) 0.2 to 0.5 μ in diameter was reduced to iron with pure hydrogen at 500°C for 4 hr., cooled in a flow of hydrogen, and replaced in pure ethyl alcohol. The gradual evaporation of alcohol at room temperature gave iron powders which are stable when exposed in air.

The absorption bands of mixtures of the powders and organic substances, described later, measured by means of an infrared spectrophotometer with an NaCl prism (e.g., Hitachi EPI-2) did not provide data enough on the presence of interaction.

A single-beam spectrophotometer with the grating system (Perkin-Elmer 112G) gave the following results.

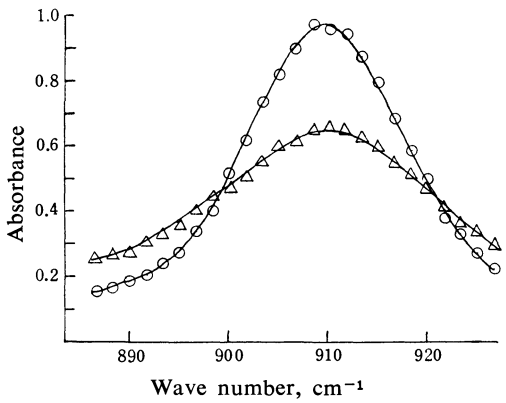

Fig. 1. Infrared absorption of styrene and styrene-iron mixture.

—○— Styrene —△— Styrene+Fe

Figure 1 shows the absorption bands of purified styrene and the reduced iron powders wetted completely with styrene. Table I gives the wave number, calculated from the micrometer readings (GD), of the main absorption bands and the discrepancy of wave number between styrene and the mixed system; no change in the absorption bands has been observed.

TABLE I. INFRARED ABSORPTION OF STYRENE AND STYRENE-IRON MIXTURE

	Wave number, ν (cm^{-1}) and intensity		
Styrene	1629.5(m)	1600.5(w)	908.2(s)
Styrene+Fe	1629.0	1600.2	908.4
$\Delta\nu$ (cm^{-1})	0.5	0.3	0.2

Figure 2 and Table II show similar results for vinylpyridine and the iron-vinylpyridine system. It is recognized that the strong absorption at 832 cm^{-1} for vinylpyridine splits into two bands at 830 and 837 cm^{-1}. The discrepancy of wave number between the mixed system and the vinylpyridine monomer is apparently over the expected experimental error, confirmed by a separate examination for vinylpyridine, of approximately 0.7 cm^{-1} in the region of 830~840 cm^{-1}.

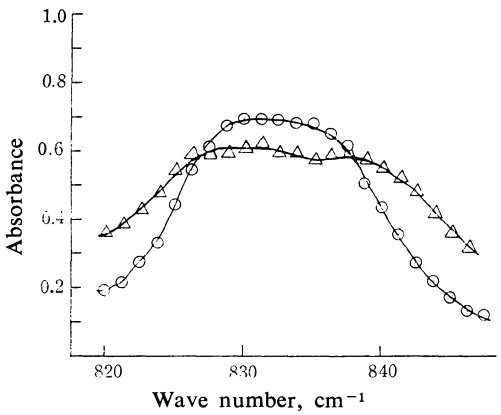

Fig. 2. Infrared absorption of vinylpyridine and vinylpyridine-iron mixture.

—○— Vinylpyridine
—△— Vinylpyridine+Fe

TABLE II. INFRARED ABSORPTION OF VINYLPYRIDINE AND VINYLPYRIDINE-IRON MIXTURE

	Wave number, ν (cm^{-1}) and intensity		
Vinylpyridine	1595.1(s)	1545.6(m)	832.4(s)
Vinylpyridine +Fe	1595.1	1546.2	837.2 830.4
$\Delta\nu$ (cm^{-1})	0	0.6	4.8 2.0

This may be attributed to the fact that the absorption in the region of 832 cm^{-1} corresponds to the out-of-plane bending vibration of the skeletal CH bonds. The splitting of the band might be due to an effect of the interaction between the iron surfaces and, possibly, the pyridine group. However, a doubt still remains because the intensity of the two split bands is almost identical, although it is presumed that only a fraction of the vinylpyridine monomer is affected by the iron surface.

It was purposely confirmed further that the coated film of polystyrene from the polymer solution on the steel plate adheres less than the similar film of the copolymer composed of

styrene and vinylpyridine, on which results a separate report will be published elsewhere.

*Terpenoids. V. A Note on the Diterpene Isolated from the Leaves of "Sugi" (Cryptomeria Japonica D. Don.)**

By Shizuo NAGAHAMA

(Received February 26, 1963)

A diterpene hydrocarbon named α-cryptomerene was first isolated by Uchida[1] from the steam-distillate of "Sugi" leaves. Another diterpene, α-podocarprene[2], has also been found to occur in the same oil[3]. Briggs and Cawley[4] have reported that α-podocarprene is identical with the kaurene** obtained from *Agathis australis*. Kaurene has been isomerized via its hydrochloride to isokaurene, and this isomer has recently been shown to be identical with Uchida's α-cryptomerene[5].

Upon careful re-examination of the "Sugi" diterpene fraction, the present author was able to obtain kaurene (or α-podocarprene) as the sole isolable product. The presence of isokaurene (or α-cryptomerene) could not be confirmed. This deviation from the observations of previous investigators should be ascribed to the changes in isolation procedures. In this investigation, the diterpene fraction was obtained by extracting "Sugi" leaves with acetone; the sesquiterpene alcohols were removed by distillation in vacuo, and the less volatile residue was subjected to chromatography on an alumina column to afford kaurene.

The heating of kaurene in the presence of abietic acid resulted in the formation of isokaurene, no isomerization being observed in the absence of the acid. These findings suggest that the previous isolation of isokaurene was presumably a consequence of the isomerization of kaurene during the isolation procedures.

Experimental

Isolation. — Foliage and terminal twigs of Sugi (6 kg.), collected on Mt. Seburi, near Fukuoka city, were chopped up and extracted twice with hot acetone for 20 hr. The precipitate was filtered off, and the acetone was evaporated. The residue was extracted with petroleum ether (b. p., 40~60°C), and the neutral fraction was steam-distilled. The steam volatile oil (15 g.) was dried over sodium sulfate and distilled under reduced pressure (5 mmHg) with a Claisen flask. When the bath temperature reached to 180°C and the sesquiterpene alcohol fraction had been removed, the heating bath was removed quickly and the distillation residue (about 3 g.) was chromatographed on an alumina column (20 g.). Petroleum ether eluted kaurene (1.5 g.); m. p., 49~50°C (lit.[4] m. p. 50°C) (recrystallized from ethanol), $[\alpha]_D$ −78° (*c* 2.09, chloroform) (lit.[4] $[\alpha]_D$ −75.2°). Mixed m. p. with authentic sample (m. p., 48~51.5°C), 48~51°C.

Isomerization.—A mixture of kaurene (200 mg.) and abietic acid (100 mg.) was heated at 200°C for 1 hr. Distillation under reduced pressure (10 mmHg, bath temp. 230~240°C) gave isokaurene, m. p. and mixed m. p., 62~64°C (lit.[4] m. p., 64°C) (recrystallized from ethanol) $[\alpha]_D$ −30° (*c* 1.27, chloroform) (lit.[4] $[\alpha]_D$ −27.4°C). The infrared spectrum was superimposable on that of an authentic sample. The distillation of kaurene under the same conditions without added abietic acid did not cause isomerization. Authentic isokaurene was obtained by heating kaurene with iodine[6].

The author wishes to express his thanks to Dr. Yoshiyuki Hirose, The University of Tokyo, for his gift of authentic kaurene and to Professor Tamio Kondo of this University for supplying him with abietic acid. He is also indebted to Professor Nobuo Izumiya for permitting him to make the rotation measurements, and to Dr. Tamaki Kubota for "Sugi" leaves.

SHORT COMMUNICATIONS

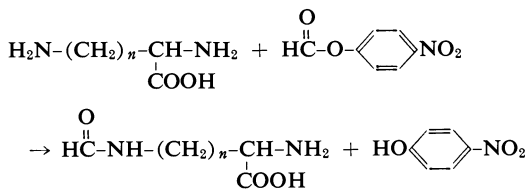
*The Synthesis of N_ω-Formyl Basic Amino Acid**

By Kenji OKAWA and Satoe HASE

(Received March 6, 1963)

It is a well-known fact that Sheehan's method[1], using formic acid and acetic anhydride, is the most convenient procedure for the formylation of α-amino acid because the reaction proceeds relatively well under mild conditions. This method can, however, be used for the *N*-formyl blocking of the α-amino acid; it can not be used for the selective formylation of one of two amino groups in such basic amino acids as ornithine or lysine.

The authors attempted to introduce a formyl group into the end amino group of ornithine or lysine selectively and found that the *p*-nitrophenyl formate was a useful reagent for this purpose, as is shown in the following scheme:



(n=3 or 4)

The formylation of arginine or histidine are now being investigated.

Experimental. — *p-Nitrophenyl Formate.* — A solution of 10.3 g. of *N, N'*-dicyclohexylcarbodiimide[2] in 30 ml. of tetrahydrofuran was added drop by drop into a stirred solution of 6.95 g. of *p*-nitrophenol and 2.76 g. of formic acid in 60 ml. of tetrahydrofuran in an ice bath. After the addition was over, the reaction mixture was allowed to stand for 1 hr. at room temperature. The urea produced was filtered off, and the filtrate was concentrated under reduced pressure until crystals appeared. From the mother solution, other crops of the crystals were obtained. The total yield was 5.3 g. (63.4%). Recrystallization from the mixed solution of tetrahydrofuran and ether gave 4.3 g. (51.4%) of fine crystals; m. p., 72~74°C.

Found: C, 50.48; H, 3.15; N, 8.26. Calcd. for $C_7H_5O_4N$: C, 50.30; H, 3.02; N, 8.38%.

N_δ-Formyl-L-ornithine.—An aqueous solution of 10.1 g. of L-ornithine mono-hydrochloride was neutralized with an equivalent amount of a 1 N aqueous sodium hydroxide solution. Into the above solution was added drop by drop 15.0 g. of *p*-nitrophenyl formate in tetrahydrofuran in an ice bath, while the solution was stirred. The stirring was continued for 6 hr. at room temperature; then the reaction mixture was extracted with ether to remove *p*-nitrophenol, and concentrated in vacuo, and the remaining solution was passed through a column of Amberlite IRC-50 to remove unreacted basic amino acid. The effluent was concentrated in vacuo, and methanol was added until the mixture became a little turbid. The mixture was then allowed to stand in a refrigerator. The crystals produced were filtered and dried. The yield was 5.0 g. (52%). Recrystallization from water methanol gave a pure compound; m. p. 217°C (decomp.); $[\alpha]_D^{15}$ +2.8° (3.97% in water); $[\alpha]_D^{15}$ +17.1° (2.17% in satd. sodium bicarbonate):

Found: C, 44.52; H, 7.64; N, 17.81. Calcd. for $C_6H_{12}O_3N_2$: C, 44.98; H, 7.55; N, 17.49%.

N_ε-Formyl-L-lysine[3].—L-Lysine monohydrochloride was treated with *p*-nitrophenyl formate as above; yield, 35%; m. p., 225~226°C (decomp.); $[\alpha]_D^{15}$ +3.0° (4.27% in water); $[\alpha]_D^{15}$, +17.7° (2.12% in satd. sodium bicarbonate):

Found: C, 48.74; H, 8.22; N, 16.22. Calcd. for $C_7H_{14}O_3N_2$: C, 48.27; H, 8.10; N, 16.08%.

Copper(II)-complexes of Schiff Bases Derived from Salicylaldehyde and Alkylamines

By Shoichiro YAMADA and Hiroaki NISHIKAWA

(Received March 8, 1963)

Four-co-ordinate copper(II) usually demands a planar configuration with comparatively strong ligands, and bis(*N*-*n*-alkyl-salicylideneiminato)copper(II)-complexes ($Cu(O\cdot C_6H_4\cdot CH:N\cdot R)_2$) are expected to have a four-co-ordinate, planar configuration. One can, however, expect cupric complexes of the Schiff bases which are distorted from the square-plane, when R denotes a group which causes steric hindrance to the planar co-ordination[1,2]. The present communication deals with the preparation of those anomalous cupric complexes with the Schiff bases which take a co-ordination distorted from the square-plane, it also discusses the stereochemistry of copper(II) in relation to that of cobalt(II) and nickel(II).

Bis(*N*-*n*-alkyl-salicylideneiminato)copper(II)-complexes, which are considered to have a planar configuration of $Cu(N)_2(O)_2$, on the basis of X-ray crystal structure analysis with the methyl-substituted complex[3,4], show almost identical ultraviolet absorption spectra in non-co-ordinating organic solvents and in the crystalline state, regardless of the number of the carbon atoms of the *n*-alkyl groups.

On the contrary, bis(*N*-*t*-butyl-salicylideneiminato)copper(II), which has newly been prepared as dark-red crystals by warming a solution of bis(salicylaldehyde)copper(II) and an excess of *t*-butylamine in ethanol, is expected to be tetrahedral, because of the steric condition imposed by the bulky *t*-butyl group[1,2]. Bis(*N*-*t*-butyl-salicylideneiminato)copper(II) in organic solvents (Fig. 1) displays a ligand field band at a much lower frequency (about $39.0\times10^{13}\,sec^{-1}$) than the *n*-alkyl-substituted complex (about $53\times10^{13}\,sec^{-1}$). This is in agreement with the presumption that the *N*-*t*-butyl-substituted complex has a tetrahedral configuration[5]. The ligands show nearly identical absorption curves, whether they contain for R a normal or a branched alkyl. The maxima in the crystal spectra nearly coincide with those in the solution spectra.

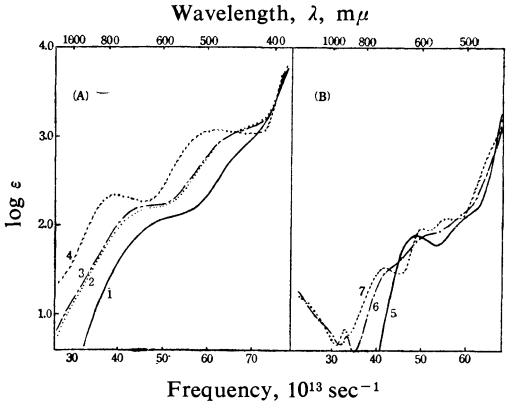

Fig. 1. Visible and near-infrared absorption spectra of (A) $Cu(O\cdot C_6H_4\cdot CH:NR)_2$ in chloroform: 1. R=methyl, 2. cyclohexyl, 3. isopropyl, and 4. *t*-butyl, and (B) $Ni(O\cdot C_6H_4\cdot CH:NR)_2$ in chloroform: 5. R=ethyl, 6. isopropyl and 7. *t*-butyl.

When R represents isopropyl, *sec*-butyl, 1-ethylpropyl or cyclohexyl, steric hindrance to the planar co-ordination may not be as serious as in the case of R=*t*-butyl, but nevertheless it seems significant[1,2]. The copper(II)-complexes with these substituents, which have been prepared in a way similar to that used for the *t*-butyl-substituted complex, show ligand field bands at a much lower frequency (about $47\times10^{13}\,sec^{-1}$) than when R=*n*-alkyl in non-co-ordinating organic solvents, indicating that the configuration of the cupric complexes with these substituents is not planar but tetrahedral. The absorption spectra of these four complexes are almost superposable with one another, so that the distortion from planarity is to a nearly equal degree in these complexes. The distortion is considered to be greater in the *t*-butyl-substituted complex, which shows a ligand field band at an appreciably lower frequency than when R is any of the other branched alkyls.

Quite a similar type of distortion is concluded for bis(salicylideneiminato)nickel(II) from an inspection of the ligand field bands[6]. The absorption spectra of the *N*-*t*-butyl, isopropyl and cyclohexyl-substituted complexes

4) L. Sacconi, M. Ciampolini, F. Maggio and F. P. Cavasino (*J. Inorg. Nucl. Chem.*, **19**, 73 (1961)) proposed a flattened pyramidal structure.

5) Bis(*N*-*t*-butyl-salicylideneiminato)cobalt(II) was also prepared and was established as having a tetrahedral configuration (H. Nishikawa and S. Yamada, to be submitted shortly).

6) A similar conclusion was reached recently from another kind of data by L. Sacconi, P. L. Orioli, P. Paoletti and M. Ciampolini (*Proc. Chem. Soc. (London)*, **1962**, 255).

in organic solvents (Fig. 1B) have the main features characteristic of tetrahedral nickel(II)-complexes and are quite different from the spectrum of bis(*N*-ethyl-salicylideneiminato)-nickel(II), which is known to be planar in chloroform. Similar by to the case of the cupric complexes, the slight difference in the spectrum between the branched alkyl-substituted complexes seems to be understood on the assumption that the extent of distortion from planarity becomes gradually smaller in the order: R=*t*-butyl, isopropyl, cyclohexyl. The hypothesis of the association of complexes in solution, which has currently been postulated, seems to be superfluous when R is one of the branched alkyls.

Since the bis(*N*-alkyl-salicylideneiminato)-cobalt(II)-complexes take a tetrahedral co-ordination around the cobalt(II) ion, whether the substituent is normal or branched alkyl[1,2,7], the present work indicates that copper(II) and nickel(II) are more inclined to take a planar co-ordination than cobalt(II), in agreement with the prediction from the simple crystal field theory.

The Polarography of o-Phenanthroline Cobalt(III) and Cobalt(II) Complexes

By Nobufumi MAKI, Taizo HIRANO and Soichiro MUSHA

(Received March 8, 1963)

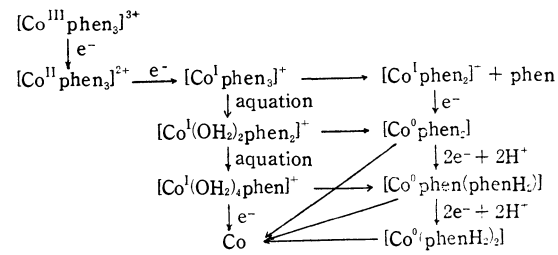
Vlček[1] and Waind et al.[2] found that the tris(dipyridyl) complex, $[Co^{III}\,dip_3](ClO_4)_3\cdot 3H_2O$, or $[Co^{II}\,dip_3](ClO_4)_2$*, is reversibly reduced to cobalt(I) ions, $[Co^{I}\,dip_3]^+$, at the dropping mercury electrode (DME). In the present communication, the tris(phenanthroline) cobalt(III) and cobalt(II) complexes, $[Co^{III}\,phen_3]Cl_3\cdot 7H_2O$ and $[Co^{II}\,phen_3]Cl_2\cdot 8H_2O$*, are found to be reduced irreversibly to the cobalt(0) state through cobalt(I) complexes in a 0.5 F sodium sulfate aqueous solution.

Figure 1 shows all the waves of the step-by-step reduction of the cobalt(III) complex. The cobalt(II) complex also gave the same waves after the second wave.

The first, the second and the third wave, each corresponding to an acceptance of one electron, represent the reduction of cobalt(III)→cobalt(II), of cobalt(II)→cobalt(I), and of cobalt(I)→cobalt(0) respectively. The limiting current of the waves, except that of the last one, is controlled only by diffusion. The diffusion current and the concentration of the complex are linearly related in the concentration range of $10^{-2}\sim10^{-4}$ F. The third wave disappears into the catalytic maximum one, decreasing the concentration of the complex.

In absolute alcohol, the cobalt(I) ion, $[Co^{I}\,phen_3]^+$, may dissociate into the $[Co^{I}\,phen_2]^+$ ion, and so on. Therefore, without excess ligands, the reduction to the cobalt(I) state is almost irreversible (Table I). In an aqueous solution, the shape of the wave for this system is quite different from that of the usual current-voltage curve of the S-type, and the current-rise at the half-wave potential is almost at right angles to the line of galva zero. This phenomenon is considered to be due to the hydrophobic effect of the phenanthroline ligands or to the adsorption of the complex at the surface of the DME.

The processes of the electrode reaction are as follows:



The tris(bathophenanthroline)cobalt(III) chloride**, $[Co^{III}\,bathophen_3]Cl_3$, gave similar polarographic waves.

As for the oscillopolarograms of the $dE/dt\sim E$ (potential) curves, the cut-ins in the cathodic branch are generally larger than those in the anodic branch. This means that the electrode process is irreversible, even in the

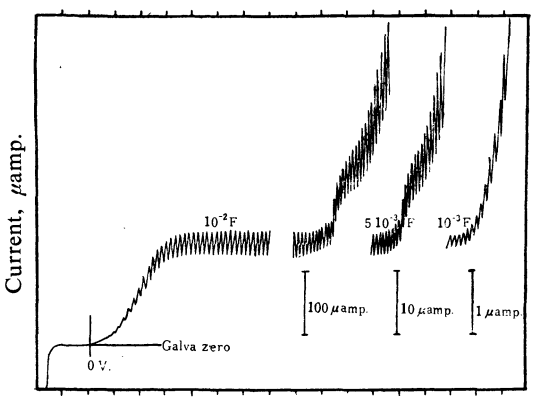
dropping mercury electrode (DME) in a 1 F lithium chloride ethanolic solution or in a 0.1 F potassium nitrate aqueous solution containing excess dipyridyl. In the present report, the mixed ligand complexes of the [$Co^{III}dip_2Y$] type are examined polarographically. It is found that unstable univalent cobalt complexes are formed during the course of reduction, where the bidentate ligand, Y, expresses the ion, $NH_2CH_2COO^-$ (glycinate), $NH_2CH(CH_3)COO^-$ (alaninate), $NH_2CH(COO^-)CH_2CH(CH_3)_2$ (leucinate), $HOC_6H_4C_2H_3(NH_2)COO^-$ (tyrosinate), or $CH_3C(NO)COO^-$ (α-keto-propionic acid oximate) respectively[3]. All the complexes treated here are new ones which were prepared from the praseo-salt, [Co Cl_2 dip_2]Cl, by the substitution reaction.



Applied potential, V. vs. S.C.E. 100mV./*absc.*

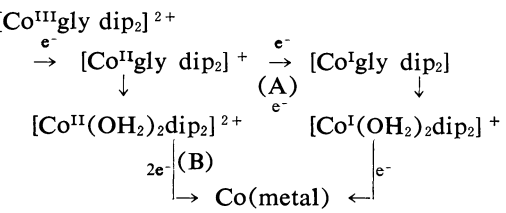
$E_{1/2}$ of 1st wave=−0.11 V. vs. S.C.E.
$E_{1/2}$ of 2nd wave=−1.31 V. vs. S.C.E.

These bis(dipyridyl)cobalt(III) complexes gave irreversible two-step waves at the DME in 1 F potassium chloride or in 0.5 F potassium sulfate supporting electrolyte. The first wave is well-defined, but the second one can be discerned only at a concentration of the complex higher than 10^{-2} F. The first and second waves, each corresponding to an acceptance of one electron, represent the reduction of cobalt(III) → cobalt(II) and of cobalt(II) → cobalt(I) respectively.

Figure 1 shows the polarograms of glycinato-bis(dipyridyl)cobalt(III) chloride at various concentrations. Upon a decrease in the concentration, the second wave disappears into the current-rise of the hydrogen wave because of the glycine partly liberated from the complex on the way of reduction.

The following processes of the electrode reaction are considered to be most plausible:



The more the concentration of the original complex increases, the more the electrode reaction proceeds along path A rather than along path B. Thus, such an unstable cobalt(I) complex as [Co^Igly dip_2] can be detected at a high concentration only by means of polarography.

Table I shows the half-wave potentials of the cobalt(III) complexes studied. As most of the second waves were fairly well covered by the hydrogen wave because of the amino acid liberated from the complex, the half-wave potentials could not necessarily be determined exactly. The oscillopolarograms of the $dE/dt \sim E$ (potential) curves also indicated that the

The Dual Effect of a Surface-active Substance on the Polarographic Electron-transfer Process

By Nobuyuki TANAKA, Yasuko KIKUCHI and Yuichi SATO

(Received March 27, 1963)

The deceleration and the acceleration of the polarographic electron-transfer process by the adsorption of a surface-active substance have been studied in connection with the heterogeneous reaction mechanisms at the electrode surface[1-3]. Frumkin and his co-workers reported the dual effect of a surface-active substance on the reduction of $PtCl_4^{2-}$ ions; the $(C_5H_{11})_4N^+$ ion accelerates the reduction at its lower concentration and decelerates at its higher concentration[4].

In the course of our study of the polarographic reduction of manganese(III) in an alkaline tartrate solution, we found a remarkable deceleration and acceleration of the electron-transfer process upon the addition of trimethyloctadecylammonium chloride, $(CH_3)_3(C_{18}H_{37})N^+Cl^-$, (TMOAC). An alkaline tartrate solution of manganese(III), which was obtained by air oxidation of that of manganese(II), gave the peculiar polarogram shown in Fig. 1 (curve 1)[5]. Current-potential curves obtained at various concentrations of TMOAC in alkaline tartrate solutions of pH 11.8 (Fig. 1) indicate that the addition of a small concentration of TMOAC depresses both the first round-shape and the second drawn-out wave, and that, at a higher concentration of TMOAC, the first wave was further depressed but the second, considerably improved. The dual (deceleration and acceleration) effect of a surface-active substance which is of a different type from that reported by Frumkin et al. is more clearly demonstrated by the current-time curves during the life of a mercury drop that were obtained at −0.82 V. vs. S. C. E. at varied concentrations of TMOAC (Fig. 2). In Fig. 2, curve 3 shows that the acceleration of the electron-transfer is controlled by the rate of adsorption of the surface-active cations.

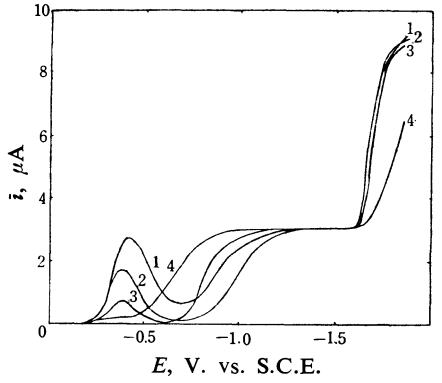

Fig. 1. Current-potential curves of Mn(III) in Britton-Robinson buffer of pH 11.8 containing 0.25 M sodium tartrate in the absence *(curve 1) and in the presence of 0.13 mM* (2), 0.25 mM (3), and 1.2 mM (4) trimethyloctadecylammonium chloride.

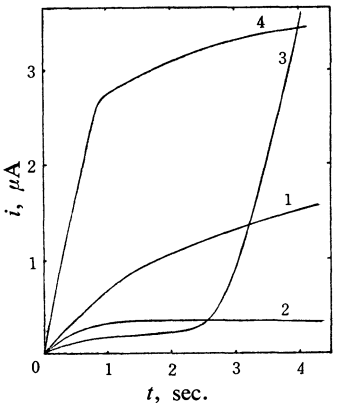

Fig. 2. Current-time curves at −0.82 V. vs. S.C.E. obtained with the same solutions as given in Fig. 1.

Manganese(III) is considered to form negatively-charged hydroxotartrato complexes in an alkaline tartrate solution. The adsorption of a sufficient amount of surface active cations, therefore, apparently lessens the repulsive interaction between the negatively-charged electrode and the electroactive anions, accelerating the electron transfer.

The Acyl Halide-initiated Polymerization of Styrene in Liquid Sulfur Dioxide

By Niichiro TOKURA, Tetsuyo KAWAHARA and Takeshi WATANABE

(Received April 5, 1963)

The polymerization of styrene in liquid sulfur dioxide initiated by various alkyl and aralkyl chlorides has recently been reported by two of the present authors[1]. We have now examined polymerization of styrene in liquid sulfur dioxide initiated by acyl halides and have found that various acyl halides, such as acetyl, chloroacetyl, propionyl, *n*-butyryl, isobutyryl and benzoyl chlorides, and acetyl and isobutyryl bromides are all effective initiators of the cationic polymerization of styrene in liquid sulfur dioxide. *p*-Toluenesulfonyl chloride is also an excellent initiator.

The polymerizations were performed at 25°C in liquid sulfur dioxide with 0.698 mol./l. of styrene and 0.004~0.34 mol./l. of an acyl halide in a total volume of 175 ml. The initial over-all rates of polymerization, the average degrees of polymerization of the polymer, and the conversion in 3 hr. are listed in Table I. The average molecular weight of the polymer was calculated from the intrinsic viscosity in benzene by Pepper's equation[2] to be:

$$[\eta] = 2.7 \times 10^{-4} M^{0.66}$$

The polymer produced by acyl halides was polystyrene, as was expected; it was identified by the infrared spectra. Sulfur analysis showed the product was not contaminated by polysulfone ruling out a radical nature of this polymerization process.

The results mentioned above and listed in Table I suggest that the polymerization is initiated by an acylium cation, $R\overset{+}{C}O$. which may be derived by the ionization of an acyl halide in liquid sulfur dioxide:

$$RCOCl \rightleftarrows RCO^+ + Cl^-$$

or by an associated ion, such as RCO^+Cl^--RCO^+, which may likely be present in a medium with a low dielectric constant[3]. The characteristic feature of this polymerization is that the over-all rate of polymerization seems to depend on the initiation, because the species of the initiator has a strong influence on the rate of the polymerization, while the counter anion (Cl^- or Br^-) is unchanged throughout the reaction and the nature of the propagation of the polymer chain remains the same.

The evidence for such an assertion is that: (a) Chloroacetyl chloride is a weaker initiator than acetyl chloride; (b) *p*-toluenesulfonyl chloride is an excellent initiator; (c) *p*-nitrobenzoyl chloride cannot initiate the polymerization, whereas benzoyl chloride can initiate the polymerization; (d) the acyl bromide is more reactive than the corresponding chloride; (e) the polymerizations are terminated by the addition of such substances as tetramethylammonium chloride or triphenylmethyl chloride, and (f) the time-conversion curve of the polymerization is flattened as time elapses, the polymerization being terminated at a lower conversion when an initiation is not so strong. These phenomena may partly be elucidated by the mass-law effect[4] on both the ionization of

the acyl halide and the growing ion pair in liquid sulfur dioxide. *p*-Toluenesulfonyl chloride is an excellent initiator in the sense that this halide initiates a polymerization which proceeds to over an 80% conversion within 2 hr.

We have not yet been able to identify the terminal acyl group or the carbonyl group in the polymer end; however, the inclusion of a sulfur atom in the polymer initiated by *p*-toluenesulfonyl chloride was verified by elementary analysis. No correlation has been found between the average degrees of polymerization and the initial rates of polymerization. The mechanism of the polymerization will be scrutinized again in a further study.

The Reaction of Olefines with Lead Tetracarboxylates

By Yasuhide YUKAWA and Mitsuru SAKAI

(Received April 18, 1963)

Recently decarboxylative syntheses using lead tetraacetate have been reported by Corey and Casanova[1]. We wish to report on the reaction of olefines with lead tetracarboxylates. Lead tetra-monocarboxylates (I), as well as lead di-dicarboxylates (II), can be prepared by warming the corresponding acid with lead tetraacetate (Table I). Bachman and Wittmann[2] reported recently a similar procedure for the synthesis of lead tetra-monocarboxylates.

$Pb(OCOR)_4$ (I) $Pb(OCORCOO)_2$ (IIa, $R=-(CH_2)_7-$; b, $R=-(CH_2)_8-$)

Lead diazelate (IIa) and lead disebacate (IIb) are colorless stable solids and have high melting points (m. p., 260°C and 233~236°C respectively).

It is well-known that the reaction of styrene with lead tetraacetate gives phenylacetaldehyde diacetate (a rearrangement product) (III) or 1-phenylpropanol acetate (an addition product of the methyl radical) (IV). The reaction of styrene with lead tetrapropionate gave 1-phenylbutanol propionate (an addition product of the ethyl radical) (V). On the other hand, styrene glycol dicarboxylates (VI) were obtained in the reactions with lead tetra-monocarboxylates prepared from higher carboxylic acids than propionic acid. In the case of lead di-dicarboxylates, the reaction proceeds slowly at 70°C in benzene and gives a macrocyclic compound (VII) in a 50% yield. Because the reaction of styrene is accompanied by some polymerization of styrene, the high yield of macrocyclic compound is striking in such a concentrated solution.

Table I. Lead tetra-monocarboxylates (I)

R-	M. p., °C
CH_3CH_2-	133.0~133.5
$CH_3(CH_2)_{10}-$	95~97
$CH_3(CH_2)_{12}-$	104~105
$CH_3(CH_2)_{14}-$	104
$CH_3(CH_2)_{16}-$	103~104
Ph-	180
$PhCH_2-$	170
Ph_2CH-	175~180
Ph_2CHCH_2-	109~113

$PhCH{=}CH_2 + Pb(OAc)_4 \rightarrow PhCH_2CH(OAc)_2$ (III) $+ PhCHCH_2CH_3$ (OAc) (IV)

$+ Pb(OCOCH_2CH_3)_4 \rightarrow PhCHCH_2CH_2CH_3$ ($OCOCH_2CH_3$) (V)

$+ Pb(OCOR)_4 \rightarrow PhCHCH_2OCOR$ ($OCOR$) (VIa, R=Ph; b, R=$PhCH_2$; c, R=Ph_2CH; d, R=Ph_2CHCH_2)

$+ Pb(OCORCOO)_2 \rightarrow$ PhCH——CH_2 ($OCORCOO$) (VIIa, $R=-(CH_2)_7-$; b, $R=-(CH_2)_8-$)

Ethyl vinyl ether, when reacted with lead tetra-monocarboxylate in benzene at room temperature, afforded 1-ethoxyethyleneglycol dicarboxylate (VIII) in a good yield. The hydrolysis of VIII gave glycolaldehyde (2, 4-dinitrophenylhydrazone; m. p., 159°C). No macrocyclic addition products were obtained in the reaction with lead di-dicarboxylate, in contrast to the case of styrene. The major product was IX namely, 1-ethoxyethyleneglycol dicaprylate, obtained from the reaction with lead diazelate. This means the occurrence of

1) E. J. Corey and J. Casanova, *J. Am. Chem. Soc.*, **85**, 165 (1963).
2) G. B. Bachman and J. W. Wittmann, *J. Org. Chem.*, **28**, 65 (1963).

the decarboxylation of a dicarboxylic residue to give a monocarboxylic residue.

$$EtOCH{=}CH_2 + Pb(OCOR)_4 \rightarrow EtOCH(OCOR)\text{-}CH_2OCOR \quad \text{VIII}$$

$$EtOCH{=}CH_2 + Pb(OCO(CH_2)_nCOO)_2 \rightarrow EtOCH(OCO(CH_2)_{n-1}CH_3)\text{-}CH_2OCO(CH_2)_{n-1}CH_3 \quad \text{IX}$$

When *t*-butylethylene was treated with two equivalents of lead di-sebacate in benzene at room temperature, a similar decarboxylated addition product, 3, 3-dimethylbutane-1, 2-diol dipelargonate (b. p., 100~103°C/0.9 mmHg, m. p. 6~8°C) was obtained in a 65% yield.

$$t\text{-}BuCH{=}CH_2 + Pb(OCO(CH_2)_8COO)_2 \rightarrow t\text{-}BuCH(OCO(CH_2)_7CH_3)\text{-}CH_2OCO(CH_2)_7CH_3$$

The infrared spectra of lead tetracarboxylates show that lead tetra-monocarboxylates (I) absorb at 1417 and 1510 cm^{-1}, indicating the presence of a carboxylate anion group, but lead di-dicarboxylates (II) absorb at 1405, 1505 and 1710 cm^{-1}, the last band being assignable to the carbonyl in the carboxyl group.

It is of interest that II has a band of the carbonyl group in addition to those due to the carboxylate anion group. This suggests that there are two types of bonds between the lead and carbonyl groups in II. The one has mainly an ionic character, while the other has mainly a covalent character X.

Homogeneous Hydrogenations of Organic Compounds with Cobalt Complex Ions[1]. *VII. Homogeneous Hydrogenations of Organic Compounds with a Cyano Cobalt Complex as a Catalyst*

By Masuo MURAKAMI and Jung-Wong KANG

(Received September 6, 1962)

Previous papers[2] from our laboratory have reported various successful reductions of unsaturated groups combined to with such divalent and trivalent cobalt complexes as bis-(pyruvic acid-oximato)-cobalt(II)[3] and phenylpyruvic acid-oximato-bis(propylenediamine)-cobalt(III) carbonate[4] by hydrogenations in an homogeneous solution. We have also reported[2] that the homogeneous hydrogenations were accomplished most effectively when 5~6 mol. of potassium cyanide were added as a co-catalyst to one mole of cobalt complex ions. In the meantime, Iguchi and his co-workers[5] have reported that, in the presence of sodium hydroxide and potassium chloride, unsaturated compounds (such as cinnamic acid, sorbic acid or nitrobenzene) are successfully reduced by homogeneous hydrogenation with a cyano cobalt(II) complex (pentacyanocobaltate(II)-ion) as a catalyst under atmospheric pressure and at room temperature.

It has been shown by Devries[6] that sorbic acid may be reduced, using pentacyanocobaltate-(II) ions selectively, to γ,δ-hexenoic acid. However, since these reactions were investigated in a small scale, neither the yield nor the separation of the reduction products were clearly shown; therefore, the mechanism of the homogeneous hydrogenations have not been touched upon. Kwiatek and his coworkers[7] reported recently that the homogeneous hydrogenations of unsaturated compounds had been successfully carried out by use of pentacyanocobaltate(II)-ions in an aqueous solution. In an earlier investigation[2], we ourselves reported that the hydrogenation of a cobalt chelate compound, in which the ligand containes unsaturated linkage, in the presence of potassium cyanide and the hydrogenation of an unsaturated compound with pentacyanocobaltate(II)-ions as a catalyst proceed through the entirely different intermediates.

The present paper describes in detail our study on the hydrogenation of an unsaturated compound with a cyano cobalt complex in comparison with other studies; it also presents a new method for the preparation of amino acid from α-keto acid[8].

Results and Discussion

The results of the hydrogenations with a cyano cobalt complex ($CoCl_2 6H_2O + 5KCN$) as a catalyst under the various conditions in an homogeneous medium are summarized in Table I.

The above findings on the hydrogenation of the oxime of phenylpyruvic acid with a cyano cobalt complex can be summarized as follows (runs 1—7).

(1) When the reaction was carried out under atmospheric pressure and at room temperature, phenylalanine could not be detected among the products, even by the paper chromatographic analysis.

(2) At a hydrogen pressure of 100 kg./cm^2 and at 100°C, phenylalanine was obtained in an about 30% yield, but it was found that the cobalt ions originally in the complex were quantitatively reduced to the metal. It has already been demonstrated that the oxime of phenylpyruvic acid was not reduced by the hydrogenation with a metallic cobalt[2] catalyst. We found that the oxime of phenylpyruvic acid was also reduced to phenylalanine in an about 30% yield by using a cyano cobalt complex which had been exposed to air for 72 hr.

(3) The homogeneous hydrogenation of the oxime of phenylpyruvic acid was carried out at 40~70°C under a hydrogen pressure of 100

b) The reaction was carried out under a hydrogen pressure of one atmosphere.
c) Potassium cyanide was not added to the reaction mixture.

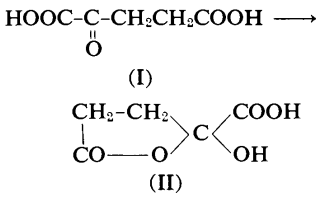
kg./cm² to give phenylalanine in 33~82% yield.

These results indicate that the appropriate hydrogen pressure and temperature are necessary in homogeneous hydrogenation with a cyano cobalt complex as a catalyst. The oximes of other α-keto acids were also reduced in a similar method; these results are shown in runs 8—10.

It has been known[9)] that reductive amination of an α-keto acid with aqueous ammonia can

9) F. Knoop and H. Oesterlin, *Z. Physio. Chem.*, **148**, 294 (1925); 170, 185 (1927).

be carried out with an active metal such as platinum, palladium or Raney nickel. In the present study, the reductive aminations of the various α-keto acids and their esters with 6% aqueous ammonia could be carried out with a cyano cobalt complex as a catalyst. These results are summarized in Table II. In runs 20 and 21, although esters of α-amino acids were not obtained, free amino acids were obtained in good yields. Perhaps when the ester of α-imino acid is coordinated with cobalt complex ions, the hydrolysis of the ester group takes place more easily than the hydrogenation of the α-imino group. In the reductive amination of α-keto-glutaric acid, a minimum amount of α-hydroxyglutaric acid was obtained as a by-product, together with glutamic acid. This result can be explained by saying that glutamic acid was obtained in a poor yield because α-keto glutaric acid formed the ring structure II in the process of the reductive amination.



(I)

(II)

In the reductive amination of the ester of a β-keto acid, neither the ester of the β-amino acid nor the β-amino acid was formed. The ester of β-keto acid may be more readily hydrolyzed by the action of the cyano cobalt complex ions to yield a stable, enolized compound before the formation of an imino compound. Consequently it can be concluded that the reductive amination of an α-keto acid is carried out smoothly when an α-imino acid is coordinated with cobalt complex ions.

When the reaction was carried out at room temperature under an atmospheric pressure, phenylalanine was not detected among the products, even by the paper chromatographic analysis of these products.

In the run 17, the reductive amination of phenylpyruvic acid was carried out with cobaltous chloride under similar conditions. A comparison of the runs 15 and 17 indicates that the yield of phenylalanine increases appreciably because of the action of potassium cyanide on the reaction mixtuure.

The above results indicate that a cyano cobalt complex serves as a new catalyst for the hydrogenation of an unsaturated compound and for the reductive amination of an α-keto acid with aqueous ammonia in the synthesis of an amino acid. The mechanism of these reactions seems to be as follows: The unstable intermediate, the α-imino acid or the α-isonitroso carboxylic acid, coordinates with cobalt complex ions, and then the complex is reduced. In the case of the ester of an α-keto

acid, the ester group of the α-imino acid is hydrolyzed and then the product is reduced through the intermediate IIIa (Eq. III).

When α-keto acids were treated with chloropentammine cobalt(III) chloride[10] alone or together with potassium cyanide at 70°C under a hydrogen pressure of 50 kg./cm² for five hours in an alkaline solution, α-amino acids were obtained. The results of the reductive aminations with $[Co(NH_3)_5Cl]Cl_2$ are summarized in Table III.

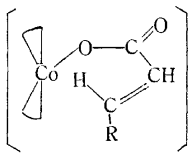
While the reductive amination[8] of phenylpyruvic acid with $[Co(NH_3)_5Cl]Cl_2$ gave phenylalanine in a 29.6% yield, phenylalanine was obtained in a good yield by the addition of five moles of potassium cyanide to the above reaction mixture. The yield of the amino acid decreased with the decrease in the molar ratio of $[Co(NH_3)_5Cl]Cl_2$ to the α-keto acid.

The mechanism of this reaction seems to be similar to that of the reductive amination of an α-keto acid with a cyano cobalt complex.

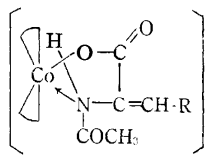
In the hydrogenations at 70°C under a hydrogen pressure of 50 kg./cm², cinnamic acid and sorbic acid gave dihydrocinnamic acid in a 70% yield and γ,δ-hexenoic acid in a 60% yield respectively. Runs 11 and 12 revealed that acetoxime and acetophenone oxime were hydrogenated under similar conditions. However, cyclohexene and styrene did not give any reduction product in a similar hydrogenation. This was confirmed by the gas chromatographic analysis (runs 25 and 26).

Table IV indicates that unsaturated hydrocarbons which can not coordinate with cobalt ions are not reduced, while the unsaturated compounds containing functional groups which can coordinate with cobalt ions are readily reduced. These results thus indicate that the homogeneous hydrogenation with a cyano cobalt complex proceeds along a different path from that of the heterogeneous hydrogenation with the metal catalyst. Probably, in the former, hydrogenations are taking place within the molecule of the cobalt complex.

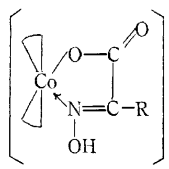
While the α-isonitroso carboxylic acids and the α,β-unsaturated acids were readily hydrogenated with a cyano cobalt complex (Table II, runs 23 and 24), the γ,δ-unsaturated acid was not (run 24). We found, in our previous work[2], that the homogeneous hydrogenations of $[Co\,pn_2\,OCOC(NHCOCH_3){=}CHC_6H_5]Cl_2$ and $[Co\,pn_2\text{-}OCOCH(NH_2){=}CHC_6H_5]Cl_2$ with six moles of potassium cyanide gave reduction products in a 45.5% and a 3.5% yield respectively. Thus, the hydrogenations of the unsaturated compounds in both cases seem to be carried out through the transition states in which the reducible double bond is fixed in the chelate ring with the cobalt atom (VI and VII) or can come in the same plane (V).



(V)



(VI)



(VII)

A question remains as to the nature of the intermediate in the hydrogenations of the unsaturated compounds with a cyano cobalt complex and in the hydrogenations of the mixed organo-cobalt complexes with potassium cyanide. When the hydrogenation of *N*-acetylaminocinnamic acid with a cyano cobalt complex was carried out at 100°C under a hydrogen pressure of 100 kg./cm², the yield of phenylalanine was small. Also, the metallic cobalt quantitatively separated. In the meantime, the mixture of $[Co\,pn_2\,OCOC(NHCOCH_3){=}CHC_6H_5]Cl_2$ and six moles of potassium cyanide gave phenylalanine in a 45.5% yield under the same conditions. Whereas phenylalanine was obtained in a 55% yield from the hydrogenation of $[Co\,pn_2\,OCOCCH_2C_6H_5(NO)](CO_3)_{1/2}$ with six moles

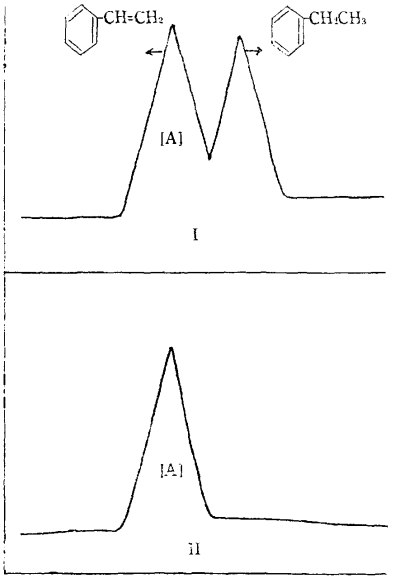

Fig. 2. Gas chromatographic analysis.

I: Standard sample (styrene+ethyl benzene), II: The reduction product of styrene. The employed resin is as follows; Silicon grease 30%, Celite 545, 80~100 mesh.

of potassium cyanide under a hydrogen pressure 100 kg./cm^2 and 100°C, it was also obtained in a 30% yield from the hydrogenation of the oxime of phenylpyruvic acid with a cyano cobalt complex under the same condition together with the metallic cobalt quantitatively deposited. A comparison of the two reaction enables us to conclude the following points: Whereas the yield of hydrogenation of an unsaturated compound with a cyano cobalt complex was high under mild conditions, the yield of the hydrogenation of the mixed organo-complex with potassium cyanide was low under the similar conditions. Under the drastic conditions, the results were contrary to those observed under the mild conditions.

Consequently, although the two hydrogenations do not seem to proceed through the same intermediate, the unsaturated compound and the cyano group should be combined in the same molecule of the cobalt complex. Accordingly, the homogeneous hydrogenations seems to occur very easily when cyanide and the unsaturated compound are combined with a cobalt ion simultaneously. However, at present we do not known the number of cyano groups which coordinate with a cobalt ion.

Experimental

Apparatus.—Hydrogenations were carried out in a stainless steel autoclave with a capacity of 100 ml.

Hydrogenation of the Oxime of Phenylpyruvic Acid.—To a solution of 0.37 g. (0.0021 mol.) of the oxime of phenylpyruvic acid and 0.082 g. (0.0025 mol.) of sodium hydroxide in 25 ml. of distilled water was added 0.685 g. (0.0105 mol.) of potassium cyanide. After the mixture had been poured into an autoclave, fine crystals of 0.5 g. (0.0021 mol.) of cobaltous chloride were added to the mixture and the autoclave was immediately sealed. The reaction completed at 70°C under a hydrogen pressure of 50 kg./cm^2 in eight hours. The reaction mixture was homogeneous. When 2 ml. of the reaction mixture was treated with the hydrochloric acid solution of 2,4-dinitrophenylhydrazine, only a trace of the hydrazone derivative was detected. The mixture was concentrated to dryness under reduced pressure. The residue was dissolved in the minimum amount of water and the solution was filtered. The filtrate was charged on a column of Ion-Exchange Amberite I. R. 120 (washed with 2 N ammonium hydroxide, water, 2 N hydrochloric acid and water) eluted with water until the elute was shown to be free of halide ions. The amino acid was then eluted with 2 N ammonium hydroxide, and the excess ammonia was evapolated to dryness under reduced pressure to give 0.28 g. (82.1%) of phenylalanine (m. p., 242~262°C decomp.). After the recrystallization from water-ethanol, it melted at 267~270°C with decomposition. The identity of the phenylalanine obtained was confirmed by the paper chromatographic analysis and by the mixed melting point determination.

The Reductive Amination of Phenylpyruvic Acid.—To a solution of 1.0 g. (0.0061 mol.) of phenylpyruvic acid in 25 ml. of 6% ammonium hydroxide was added 0.685 g. (0.0105 mol.) of potassium cyanide; the mixture was then poured into an autoclave. Fine crystals of 0.5 g. (0.0021 mol.) of cobaltous chloride were added to the mixture. The

reaction completed at 40°C under a hydrogen pressure of 50 kg./cm² in eight hours. The reaction mixture was homogeneous. When 2 ml. of the cooled reaction mixture was treated with a hydrochloric acid solution of 2,4-dinitrophenylhydrazine, only a trace of hydrazone derivative was detected. The residual solution was treated with hydrogen sulfide to remove the cobalt ion as its sulfide. The filtrate was concentrated to dryness under reduced pressure. After the residue was treated with a minimum amount of water, the mixture was filtered. The filtrate was then treated in a method similar to that of the previous experiment. The phenylalanine obtained was 0.856 g. (a 85.6% yield); m. p., 248~262°C (decomp.). The identity of the phenylalanine obtained was confirmed by the paper chromatographic analysis and by the mixted melting point determination.

The Reductive Amination of Ethyl Phenylpyruvate.—To a solution of 0.38 g. (0.0019 mol.) of ethyl phenylpyruvate in 25 ml. of 6% ammonium hydroxide was added 0.68 g. of potassium cyanide; the mixture was then poured into an autoclave. Fine crystals of 0.5 g. of cobaltous chloride were added to the mixture. The reaction completed at 40°C under a hydrogen pressure of 50 kg./cm² in eight hours. The cooled reaction mixture was repeatedly extracted with ether. When the ether layer was evaporated after dried over anhydrous magnesium sulfate, the ethyl ester of phenylalanine was not obtained. The aqueous layer was treated in a way similar to that above. The phenylalanine obtained was 0.24 g. (a 76.6% yield); m. p., 242~252°C (decomp.). The paper chromatographic analysis of the product proved its identity with the authentic phenylalanine.

The Hydrogenation of Acetoxime.—Into a solution of 1.0 g. (0.0141 mol.) of acetoxime and 0.6 g. (0.0150 mol.) of sodium hydroxide in 25 ml. of water was dissolved 0.685 g. of potassium cyanide. After the mixture had been poured into an autoclave, fine crystals of 0.5 g. of cobaltous chloride were added to the mixture. The reaction was completed under the condition similar to that used in the previous experiment. The cooled reaction mixture was extracted with the ethereal hydrochloric acid solution by means of extraction apparatus. The acidic ether extracts were concentrated to dryness under a reduced pressure, and the residue was dried over sulfuric acid in vacuo. The crude isopropylamine hydrochloride (0.34 g., 40%) melted at 121~138°C. After three additional recrystallizations from ethanol, it was identified with the authentic sample; m. p., 137~139°C.

Found: C, 37.08; H, 10.72; N, 14.05; Cl, 36.89. Calcd. for $C_3H_{10}NCl$: C, 37.48; H, 10.47; N, 14.55; Cl, 37.17%.

The Hydrogenation of Acetophenone Oxime.—A mixture of acetophenone oxime (1.0 g., 0.0074 mol.), sodium hydroxide (0.3 g., 0.0075 mol.), potassium cyanide (0.685 g.) and cobaltous chloride (0.5 g.) in 15 ml. of water was hydrogenated by the method similar to that of the above experiment. The homogeneous solution was repeatedly extracted with ether. After the ethereal extracts had been dried over anhydrous magnesium sulfate, the ether was removed and the product was collected at 81~82°C (16 mmHg). The yield of α-methylbenzylamine was 0.52 g. (57.8%).

Found: C, 79.36; H, 9.01; N, 12.00. Calcd. for $C_8H_{11}N$: C, 79.29; H, 9.15; N, 11.56%.

The Reductive Amination of Phenylpyruvic Acid.—To a solution of 1.0 g. (0.0061 mol.) of phenylpyruvic acid and 0.6 g. (0.015 mol.) of sodium hydroxide in 25 ml. of water was added 0.95 g. (0.0146 mol.) of potassium cyanide. After the mixture had been poured into an autoclave, fine powder of 0.75 g. (0.0030 mol.) of chloro pentammine cobalt(III) chloride was added to the mixture. The reaction completed at 70°C under a hydrogen pressure of 50 kg./cm² in five hours. The cooled reaction mixture was concentrated to dryness under a reduced pressure. To the residue was added the minimum amount of water and the mixture was filtered. The filtrate was charged on a column of Ion-Exchange Amberite I. R. 120 and eluted with water until the elute was shown to be free of halide ions. The amino acid was then eluted with 2 N ammonium hydroxide, and the excess ammonia was concentrated to dryness under a reduced pressure to give 0.94 g. (94%) of phenylalanine (m. p., 245~263°C (decomp.)). The identity of the phenylalanine obtained was confirmed by the paper chromatographic analysis.

The Hydrogenation of Cinnamic Acid.—To a solution of 1.0 g. (0.0067 mol.) of cinnamic acid, 0.3 g. (0.0076 mol.) of sodium hydroxide and 0.685 g. of potassium cyanide in 25 ml. of water, 0.5 g. of cobaltous chloride was added. The reaction completed at 70°C under a hydrogen pressure of 50 kg./cm² in eight hours. The cooled reaction mixture was acidified with 2 N hydrochloric acid and was repeatedly extracted with ether. After the mixture had been dried with anhydrous magnesium sulfate, the ether was removed to give 0.76 g. of the crystalline product (m. p. 43~65°C). The crude product was dissolved in 5 ml. of ethanol, and the insoluble material was filtered. After the ethanol had been removed, the residue was crystallized from 5 ml. of ligroin. The product weighed 0.7 g. (70%) and melted at 45~46°C. The product was identified with an authentic sample of hydrocinnamic acid.

The Hydrogenation of Sorbic Acid.—A mixture of sorbic acid (1.0 g., 0.0089 mol.), sodium hydroxide (0.36 g., 0.0090 mol.) potassium cyanide (0.685 g.) and cobaltous chloride (0.5 g.) in 25 ml. of water was hydrogenated and was treated in a way similar to that above. γ,δ-Hexenoic acid (0.61 g., 60%) was collected, its b. p. being 101~102°C (12 mmHg). The identify of γ,δ-hexenoic acid was confirmed by its infrared spectrum and by the titrimetric determination of the double bond of the product.

The Hydrogenation of Cyclohexene.—A mixture of cyclohexene (1.0 g., 0.0122 mol.), potassium cyanide (0.685 g.) and cobaltous chloride (0.5 g.) in 15 ml. of water was hydrogenated as above. The cooled reaction mixture was then acidified with 2 N hydrochloric acid and repeatedly extracted with ether. After the mixture had been dried with anhydrous magnesium sulfate, the ether layer was

removed and the residue (0.95 g.) was collected at a boiling point of 78~83°C. It was confirmed by the gas chromatographic analysis that cyclohexane was not present in the product obtained.

*The Spectrophotometric Determination of Uranium with Dibenzoylmethane**

By Yoshimi UMEZAKI

(Received October 17, 1962)

Recently, many organic reagents which are very sensitive to uranium, such as dibenzoylmethane[1], PAN[2] and arsenazo[3], have been used for the spectrophotometric determination of uranium. In general, however, these reagents are liable to be affected by diverse ions. Accordingly, it is preferable to separate uranium from diverse ions by extraction prior to its spectrophotometric determination.

Of these chromogenic reagents, dibenzoylmethane can be advantageously used for the direct color development in the organic phase; thus the time for the analysis may be shortened and, at the same time, the possible loss of uranium during stripping may be prevented. From this point of view, several kinds of extractant, such as tetrapropylammonium nitrate (in methyl isobutyl ketone)[4], tri-*n*-octylphosphine oxide (in cyclohexane)[5] and tributyl phosphate (in ethyl acetate[6], or in isooctane[7], or in no diluent[8]), in combination with the use of dibenzoylmethane, have been reported. Some of these, however, involve procedures too complicated for routine use, or are too greatly subject to interference from diverse ions.

This paper describes a simple direct spectrophotometric determination of uranium with dibenzoylmethane in combination with tributyl phosphate, which is selected as the extractant of uranium because of its popularity.

Experimental

Apparatus.—Absorbance measurements were made with a Beckman Model B spectrophotometer using 1-cm. glass cells.

Reagents.—*Standard Uranium Solution.*—A stock solution containing 100 μg. of uranium per ml. was prepared by dissolving uranyl nitrate in water. The standardization was made by titration with a standard potassium dichromate solution after the reduction of uranium with zinc amalgam. Dilutions of this solution were made as required.

Dibenzoylmethane Solution.—A 1% solution was prepared by dissolving 1 g. of dibenzoylmethane in 100 ml. of 95% ethyl alcohol.

Tributyl Phosphate Solution.—A 30% tributyl phosphate solution was prepared by mixing 300 ml. of tributyl phosphate with 700 ml. of benzene. This solution was washed first with a 5% sodium hydroxide solution and then with a 1 N nitric acid solution.

Aluminum Salting Agent.—An aluminum salting agent was prepared by dissolving 500 g. of aluminum nitrate nonahydrate and 70 ml. of concentrated nitric acid in enough water to make 1 l. of solution.

The other solvents and reagents were of an analytical reagent grade and were used without further purification.

Procedure.—*Extraction of Uranium.*—*a*) Samples which do not contain interfering ions.—Bring the nitric acid concentration of the sample solution to approximately 1N and then make it up to a definite volume with 1N nitric acid. Transfer 5 ml. of the sample solution to a 50-ml. separatory funnel. Add 5 ml. of a salting agent and 3 ml. of a tributyl phosphate solution. Shake vigorously for about 1 min. After it has settled, discard the aqueous layer and, if necessary, wash the organic layer with 2~3 ml. of a 10% sodium nitrate solution (1 N in acid) and discard the aqueous layer. Run the organic layer through a small plug of filter paper in the stem of the separatory funnel into a dried small vessel (e. g., a weighing bottle).

b) Samples containing chromium(VI) and cerium(IV).—Bring the nitric acid concentration of the sample solution to approximately 1 N in a definite volume. Transfer 5 ml. of the sample

solution to a small beaker. Add 1~2 ml. of a 10% sodium nitrite solution and warm this solution at 80~90°C until small bubbles of colored gas disappear. After cooling, transfer the solution into a 50-ml. separatory funnel and treat this solution as in a).

c) Samples containing thorium (IV) and zirconium (IV).—Bring the nitric acid concentration of the sample solution to approximately 1 N in a definite volume. Transfer 5 ml. of the sample solution to a 50-ml. separatory funnel. Add 3~5 ml. of a 1 M potassium fluoride solution. When 5 ml. of a potassium fluoride solution is used, the amount of salting agent should be doubled. In this case, solid aluminum nitrate nonahydrate is preferable. Treat this solution as in a).

Color Development.—Pipet 2 ml. of the extract into a 10-ml. volumetric flask. Add 1 ml. of a 1% dibenzoylmethane solution and 5 ml. of pyridine, and dilute with ethyl alcohol to the mark. Measure the absorbance at 410~425 mμ against a blank.

Results and Discussion

Effect of Salting Agent.—When uranium is extracted as the tributyl phosphate complex from a nitric acid solution, the optimum acidity is approximately 6 N[9]. However, if salting agents, e. g., sodium nitrate or aluminum nitrate, are used, uranium can be extracted quantitatively, even from a nitric acid solution of a lower acidity. In this case, the amount of pyridine used to neutralize the co-extracted acid may be reduced. The effect of the aluminum salting agent was examined while keeping other factors constant. As is shown in Fig. 1, 5 ml. of an aluminum salting agent is sufficient for the standard procedure.

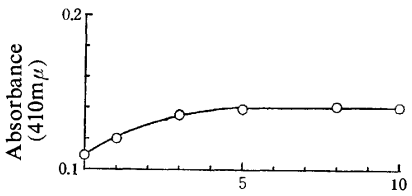

Fig. 1. Effect of salting agent.
2 p. p. m. U, extracted from 1 N nitric acid

Choice of Solvents.—An aliquot of the extract is mixed with dibenzoylmethane, a neutralizer and a diluent. The neutralizer is used to neutralize the acid extracted simultaneously in the organic phase in order to insure the full color development of the complex. Pyridine has been used almost exclusively by previous authors for this purpose.

Several kinds of solvents, such as kerosene, isooctane and ethyl acetate, have been used as a diluent for tributyl phosphate. In this method, benzene was chosen because of its high miscibility with pyridine.

Ethyl alcohol, used as the solvent for dibenzoylmethane, is useful at the same time to prevent the precipitation of a pyridinium compound, which is produced by the addition of pyridine to the extract. These solvents are miscible with each other and can be handled without special consideration because they are not extremely volatile at room temperature.

Pyridine Concentration.—Though it is known that the maximum color intensity is obtained in the "apparent" pH range of 6.5 to 8.5 in alcoholic aqueous media[1], these values can not be applied to the present organic solution because these pH values have no significance here. Therefore, the effect of the pyridine concentration on color development was studied in the extract which was obtained from a 1 N nitric acid solution with a salting agent, and in that obtained from a 6 N nitric acid solution without a salting agent. Other factors were kept constant.

As is shown in Fig. 2, with the former solution a 40~60% pyridine concentration is necessary to insure the full color development; a slight decrease in color intensity is observed with 80% pyridine. With the latter solution, a 60~80% concentration is necessary. The addition of 5 ml. of pyridine was therefore decided for the standard procedure.

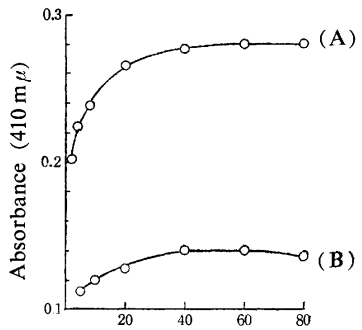

Fig. 2. Effect of pyridine concentration on absorbance.
(A) 4 p. p. m. U, extracted from 6 N nitric acid
(B) 2 p. p. m. U, extracted from 1 N nitric acid

The absorbance of the blank solution increases linearly with the increasing concentration of pyridine.

Dibenzoylmethane Concentration.—As is shown in Fig. 3, 1 ml. of a 1% dibenzoylmethane solution is necessary for full color development with 2 ml. of the 3 ml. extract. However, a

TABLE I. EFFECT OF DIBENZOYLMETHANE CONCENTRATION

U in aqueous solution μg.	Ext. used ml.	Dibenzoylmethane ml.	U found μg.
60	1	0.5	60.0
60	2	0.5	52.1
120	1	0.5	119
120	1	1.0	119
120	1+benzene 1 ml.	0.5	119
120	1+blank ext. 1 ml.	0.5	112

smaller portion of the extract may be used for samples of a higher uranium content. When 1 ml. of the 3 ml. extract is used for color development, which is frequently useful because the blank value is lowerd, 0.5 ml. of 1% dibenzoylmethane is sufficient. This value is independent of the uranium concentration in the sample solution. As summarized in Table I, this is because of the influence of excess tributyl phosphate in the organic phase. There is apparently some competition between tributyl phosphate and dibenzoylmethane in forming a complex with uranium.

Effect of the Acidity of the Sample Solution.—According to previous authors, strict control of the acidity of the aqueous solution is required in order to obtain reproducibility. In this method, where *in situ* color development is adopted, however, the change in acidity does not have any serious influence on the color intensity. This is as expected from Fig. 2. In fact, the change in the acidity of the sample solution within the range of 0.8 N and 2.0 N did not have any influence at all on the absorbance of the uranium complex in the standard procedure. This may be attributed to the fact that the amount of acid extracted simultaneously into the organic phase is not large compared with the pyridine used, while, at the same time, the excess of pyridine has little influence on the color intensity of the complex in the organic solution.

Effect of the Volume of Aqueous Solution.—In the standard procedure, the volume of aqueous solution is 10 ml., including the salting agent. In practice, however, a larger volume of aqueous solution is sometimes necessary, for instance, the complete dissolution of a precipitate. The influence of the volume of aqueous solution was studied while keeping the acidity and salting agent of the sample solution constant and using 3 ml. of tributyl phosphate.

The results reveal that when the volume of the aqueous solution is 20 ml. or 40 ml., the absorbance is 99% or 94% respectively of the absorbance from 10 ml. of the aqueous solution.

Wavelength.—The absorption spectra of the uranium complex, the thorium complex and dibenzoylmethane are shown in Fig. 4. Though

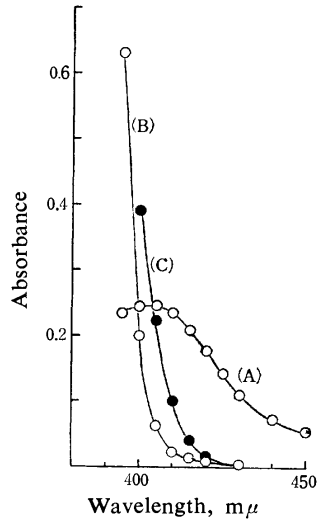

Fig. 4. Absorption spectra.
(A) 3.3 p. p. m. U
(B) Blank solution, 0.1% dibenzoylmethane
(C) 6.7 p. p. m. Th

the maximum absorption of uranium complex is observed at 400~405 mμ, the absorbance of the blank solution is fairly large at this wavelength. Moreover, as the slope of this curve is very sharp in this region, the results are liable to fluctuate when some of the factors are slightly varied. From this point of view, it is preferable to use a wavelength 410 mμ long or longer, even though the absorbance of the uranium complex decreases.

Stability.—The yellow color develops instantaneously on the addition of the reagent and

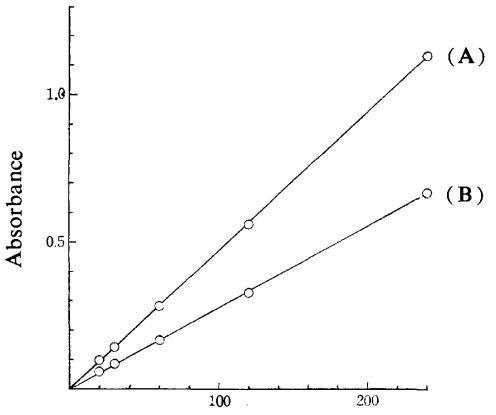

Fig. 5. Calibration curves.
(A) 410 mμ (B) 425 mμ

pyridine and is stable for at least 20 hr. at room temperature, provided the container is sealed.

Beer's Law.—Beer's law is obeyed up to 240 μg. of uranium in the aqueous solution, as Fig. 5 shows.

Diverse Ions.—In order to simplify the method, it is desirable to use the extract directly for color development without any washing procedure. The results obtained by this procedure are shown in Table II. When large amounts of a foreign ion, e.g., iron, are present in the sample solution, it is better to wash the extract with 2~3 ml. of a 10% sodium nitrate solution (1 N nitric acid) in order to reduce the interference, which may be attributed, in part, to the contamination of the extract with the aqueous suspension in the organic phase. The presence of chloride and iron ions in the same solution should be avoided. Bismuth may be present up to 3 mg. when measuring the absorbance at 425 mμ.

The interference of chromium(VI) and cerium(IV) can be minimized or eliminated by reduction with a proper reductant. For this purpose, sodium nitrite and sodium sulfite were each tried. At a low cerium(IV) concentration, sodium sulfite can be used without any difficulty. At a high concentration (e.g., 50 mg. Ce), however, a precipitate, presumably cerium(III) sulfate, is sometimes produced. When sodium nitrite is used as a reductant, caution should be taken to expel the colored gas which is liberated by the addition of nitrite; otherwise it is extracted into the organic phase and produces a positive error. In order to expel this gas completely, the solution is warmed at 80~90°C for several minutes until the fine bubbles disappear.

Thorium and zirconium interfere seriously because they are extracted into the organic phase and react with dibenzoylmethane. The absorption of these complexes decreases rapidly at longer wavelengths (shown in Fig. 4 for thorium). Masking these ions with fluoride is effective to some extent, even in the presence of a large number of aluminum ions, which form a stable complex with fluoride ions. Thus, the interference up to 2 mg. of each of these ions can be minimized. The results of the reduction and the masking experiments are shown in Table III.

* Precipitate is produced in aqueous solution upon standing.

The Determination of Uranium in Ores.—The above-mentioned procedure was applied to the determination of uranium in uranium ores and in monazite.

For uanium ore, 1 g. of sample was decomposed with aqua regia. After filtration, uranium was precipitated with ammonium hydroxide. The precipitate was dissolved in enough nitric acid to make exactly 50 ml. or 250 ml. of a 1~1.5 N nitric acid solution.

For monazite, 1 g. of sample was decomposed with 10 ml. of fuming sulfuric acid. After cooling, the solution was poured into cold water. After filtration, the filtrate was transferred to a 250-ml. volumetric flask and made up to volume with water.

Using an aliquot of these stock solutions, uranium was determined according to the above-mentioned procedure. In the case of monazite, 1 ml. of nitric acid (1 : 1), 1 ml. of a 10% sodium nitrite solution*, and 5 ml. of a 1 M potassium fluoride solution for 5 ml. of sample solution were used.

The absorbance measurements were made at 410 mμ and 425 mμ respectively. The results shown in Table IV show good agreement with the values obtained by the authorized method.

* When sodium sulfite was used a white precipitate was produced in the organic phase after neutralizing the extracts with pyridine. This could be prevented by expelling the excess of sulfur dioxide before extraction.

*The Volatilization of Chlorine and Fluorine Compounds from Igneous Rocks on Heating**

By Minoru YOSHIDA

(Received November 30, 1962)

It is important for the study of volcanic phenomena to make clear the nature of the volcanic emanation. There are many ways of investigation. Some of the most important information on the problem are provided by analyses of volcanic gases, volcanic sublimates and other products of volcanic activity. An investigation of the chemical composition of volcanic gases from more than 600 fumaroles and hot springs in Japan has, accordingly, been carried out by Iwasaki et al.[1] However, the environmental conditions which affect the chemical composition of volcanic gases are so

* Read at the Symposium on Geochemistry of the Chemical Society of Japan, October, 1961.

1) I. Iwasaki, T. Ozawa, M. Yoshida, T. Katsura, B. Iwasaki, M. Kamada and M. Hirayama, *Bull. Tokyo Inst. Tech.*, No. 47, 1 (1962).

complicated that it is difficult to understand the nature of volcanic emanations satisfactorily on the basis of this information alone.

The second way to investigate the nature of volcanic emanation is to study the equilibrium between the gas phase and the condensed phase represented by the igneous rocks with which the gas phase is thought to be in contact. Some calculations of these gas-solid equilibria have been made by Ellis[2], Krauskopf[3], Matsuo[4], and others. In some cases, a close approach has been made to the chemical composition of natural volcanic gases by theoretical calculations. There remain, however, many difficult problems concerning the maintenance of equilibrium and the insufficiency of thermochemical data on rock-forming minerals.

The third way is to study the nature of the gases obtained by heating igneous rocks. The components of those gases obtained by heating samples of igneous rocks have been studied by many investigators[5-13]. Little work has, however, been done on the halogen compounds evolved from igneous rocks on heating. Shepherd[9-11] studied the amount of chlorine and fluorine compounds evolved at 1200°C. Brun[8] reported that chlorine compounds were evolved from igneous rocks at temperatures higher than "the explosion temperature". Iwasaki et al.[13] reported that the evolution of hydrogen chloride occured when rocks were heated at temperatures above 800°C. However, the exact relationships between the temperature and the amount of evolved halogen compounds, especially that of fluorine, have not yet been established. The objectives of the present paper are to make clear the volatilization of chlorine and fluorine compounds from igneous rocks at various temperatures ranging from 400 to 1200°C.

Experimental

Materials.—The rock samples used in this study are listed in Table I, together with their chlorine and fluorine contents. The chlorine in the rocks was determined by the method of Iwasaki et al.[13] with some improvements, while the fluorine in the rocks was determined by the method of Kamada et al.[14] The main chemical composition of these rocks is also known.

Reagent grade chemicals and redistilled water were used in the preparation of all reagents and in the procedures.

Methods of Collecting Halogens Evolved from Rock Samples.—The apparatus used in this study is shown in Fig. 1. The maximum temperature attained by electric furnace A is about 1300°C, and the temperature can be controlled with an accuracy of ±20°C. A pyrometer with a platinum-platinum, 10% rhodium thermocouple D was used to measure the temperature of the furnace. A silica-glass tube B (1 m. in length, 25 mm. in inside diameter) was connected to the commercial nitrogen gas cylinder and absorption vessels E by taper joints. Two absorption vessels were connected in a series, each of them containing about 75 ml. of a 0.05 N sodium hydroxide solution.

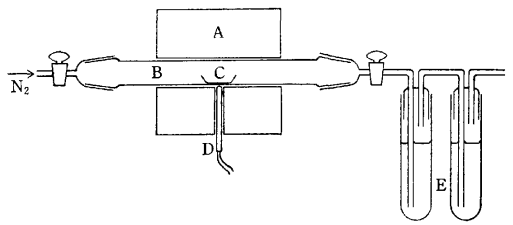

Fig. 1. Apparatus.
A Electric furnace
B Silica-glass tube
C Platinum boat
D Thermocouple
E Absorption vessels

One gram of a finely powdered sample was placed in a platinum boat, which was then inserted in silica-glass tube B and placed in the center of the furnace. The flow of nitrogen gas was then started at the rate of 20~30 l./hr. After the air in the apparatus had been replaced by nitrogen, the sample was heated to a programmed temperature and was maintained at that temperature for one hour. Experiments were carried out at 400, 600, 800, 1000 and 1200°C (in one case, also at 200°C). The acid gas species evolved from the sample in the nitrogen gas were absorbed by the solution in absorption vessels. After the furnace had been cooled, the solutions in each absorption vessel were diluted to 100 ml. in a volumetric flask. An aliquot of the solution was used for the determination of fluoride. Another portion was used for the determination of chloride after oxidizing the sulfide ion by heating the solution with a small amount of sodium peroxide. Sublimates were deposited on the inside surface of the silica-glass tube on outgassing the rocks. These sublimates were dissolved in water by washing the inside of the silica-glass tube three times. All the washings were transferred

10	Granite (Kiuragi, Saga Pref.)	0.028	0.005	10

into a 100 ml.-volumetric flask and diluted to the mark to determine the chlorine and fluorine contents. To minimize the contamination during the procedure, the silica-glass tube and platinum boat were heated and washed in duplicate before being used.

Methods of Determining the Chloride and Fluoride in the Solution.—The chloride was determined by the mercuric thiocyanate method[15] with some improvements. By using this method a difference of 5 μg. of chloride per 100 ml. can be distinguished in the range of 5~200 μg. per 100 ml.

The fluoride was determined by the *p*-dimethylaminoazophenylarsonic acid-zirconium method[16]. A difference of 1 μg. fluoride per 100 ml. can be distinguished in the range of 2~100 μg. per 100 ml. by procedure **A**, while a difference of 10 μg. of fluoride per 100 ml. can be distinguished in the range of 20~1000 μg. per 100 ml. by procedure **B**. The accuracy and precision of the methods are enough for the present purposes.

Results and Discussion

Amount of Chlorine and Fluorine Evolved from Igneous Rocks.—To determine the amounts of chloride and fluoride contaminated from reagents, nitrogen gas, or experimental procedures, blank tests were carried out at 1200°C. 10 μg. of chlorine was found from the solutions in each absorption vessel, and 6 μg. of chlorine was found from the solution washed inside the silica-glass tube. However, fluorine was found in neither of them. The data of chloride were corrected for these blank values.

Two absorption vessels connected in a series were used for absorbing the acid gases, but usually both chlorine and fluorine were absorbed almost completely by the solution in the first vessel.

Very small amounts of chlorine and fluorine were evolved from the sample which had once been heated at 1200°C for one hour on reheating at the same temperature for two hours.

The data obtained are shown in Table II. In this table, "Abs." means the amount of chlorine or fluorine determined from the solution in absorption vessels, "Sub." means the amount of chlorine or fluorine determined from the solution washed inside the silica-glass tube, and "Total" is equal to "Abs." plus "Sub.". In the last two columns of the same table, the atomic ratios F/Cl and $(F/Cl)/(F/Cl)_{original\ rock}$ are given. In these two columns, ( ) means that the amounts of evolved chlorine and fluorine are fairly small and that the F/Cl ratio might, therefore, contain comparatively a larger error, while > means that the exact value of F/Cl can not be calculated, but only a lower limit of the value given, because the amount of evolved chlorine is smaller than the limit of exact determination.

To examine the reproducibility of the processes, the experiments were duplicated by using basalt from Ō-sima. The results are to be seen in Table II-1. The reproducibility is enough to illustrate the releasing tendency of halogen in rocks at different temperatures.

The percentage of X_{max} to the amount of halogen originally contained in 1 g. of rock sample is shown in Table III. X_{max} means the amount of halogen evolved from 1 g. of a certain rock sample at a temperature where the amount reaches its maximum value in each series of experiments. In most cases the temperature was 1200°C. This table shows that, in general, chlorine and fluorine in a rock can not be completely evolved at temperatures at or below 1200°C, as was reported in previous papers[11,13]. As may be seen in Tables II and III, chlorine is generally easier to release by heating than fluorine, so the

$(F/Cl)_{evolved,\ total}$ ratio is smaller than the $(F/Cl)_{original\ rock}$ ratio. The $(F/Cl)_{sub}$ ratio is always larger than the corresponding $(F/Cl)_{abs}$ ratio. The results indicate that fluorine is more easily deposited on the surface of the silica-glass tube than chlorine.

$(F/Cl)_{total}$ at 1200°C is plotted against $(F/Cl)_{rock}$ (Fig. 2), and $(F/Cl)_{abs}$ is plotted against $(F/Cl)_{sub}$ (Fig. 3). In these figures, F/Cl values with ( ) or > in Table II are omitted. The almost linear relations, how the F/Cl value of the gas increases as the F/Cl value of the original rock increases, and how the F/Cl value of the sublimate increases as the F/Cl value of the gas from which the sublimate is deposited increases, will be readily seen in these figures.

It has been already stated that 30% or more of the fluorine in the rock is not given off at temperatures at or below 1200°C. However, it can not be decided from the data given in

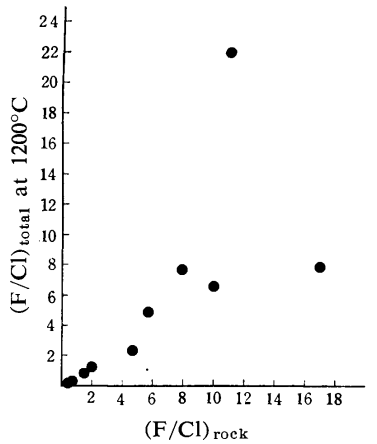

Fig. 2. Relation between $(F/Cl)_{rock}$ and $(F/Cl)_{total}$.

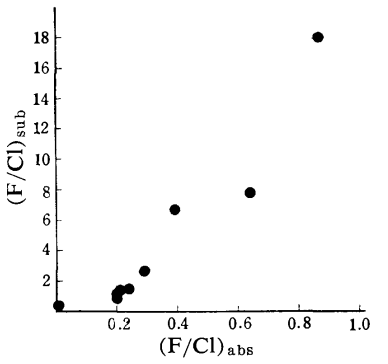

Fig. 3. Relation between $(F/Cl)_{abs}$ and $(F/Cl)_{sub}$.

Table II whether this 30% of the fluorine still remains in the rock or is deposited on the silica-glass tube in a water-insoluble form. In order to make clear the balance of fluorine, rock samples (basalt from Ō-sima and andesite from Tamagawa) which had been heated at 1000°C were analyzed for fluorine and were compared with F_{abs}, F_{sub}, and $F_{original\ rock}$ (Table IV). It may be safely said that the amount of fluorine which deposits on the surface of the silica tube in a water-insoluble form is fairly small compared with that in other forms.

TABLE IV

	F corresponding to 1 g. of original rock (μg.)	
	Basalt Ō-sima	Andesite Tamagawa
Abs.	26± 1	220±10
Sub.	18± 1	55± 1
Residual in the rock	60±20	100±20
Sum	104	375
Original rock	110±20	420±20

The percentage of F_{max} to the amount of fluorine originally contained in the rock sample has a correlation with the fluorine contents of the rock sample, as may be seen in Fig. 4.

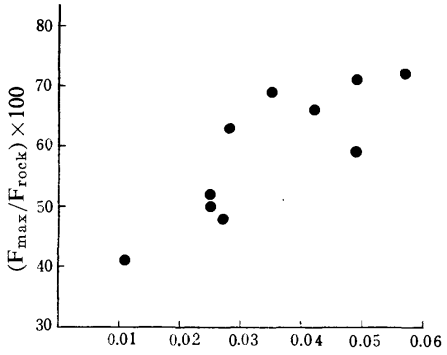

Fig. 4. Relation between F content of original rock and $(F_{max}/F_{rock})\times100$.

To see the change in the amounts of evolved fluorine and chlorine at different temperatures, the value [(the amount of chlorine or fluorine evolved from a certain rock sample at a certain temperature)/X_{max}] $\times$ 100 is plotted against the temperature (Figs. 5 and 6). Using this value, the results of experiments with various rock samples can be compared with each other in the same diagram. Chlorine compounds are evolved at 600°C (in the experiment with liparite from Kōzu-sima at 400°C), and the amount of evolved chlorine compounds increases gradually with the elevating temperature. On the other hand, although fluorine compounds are evolved scarcely at all at temperatures below 800°C, the amount of evolved fluorine increases suddenly at a certain temperature above 800°C. The temperature above which fluorine compounds are evolved varies from 800 to 1200°C with the kind of rocks.

From these results, it is obvious that the behavior of fluorine and chlorine in the igneous rocks differs markedly when they are heated at high temperatures.

The temperature above which fluorine compounds are evolved must be related to the state of fluorine in rocks. It is interesting to compare this temperature with the various natures of igneous rocks. For this purpose, it is best to determine this temperature by continuous measurement of the amount of evolved fluorine. It is, however, hard to make such experiments, with various kinds of rocks. In this paper, only the values measured at intervals of 200°C are available. The $1/2\cdot[\{(\text{Amount of F evolved at } 800°C)/F_{max}\}\times 100 + \{(\text{Amount of F evolved at } 1000°C)/F_{max}\}\times 100]$ value is used in place of the temperature above which fluorine compounds are evolved. As will be readily understood from the formula mentioned above, the larger the value the lower the temperature above which fluorine compounds are evolved. Comparing this value with the chemical composition of the rocks, it is found that the value has a relation with the fluorine and chlorine contents of the rock. The values mentioned above are plotted against the F/Cl and 1/Cl of the rocks (Figs. 7 and 8). Very good correlations are seen in these figures. The phenomena observed in Figs. 4, 7 and 8 may give interesting suggestions on the distribution of fluorine and chlorine in the igneous rocks.

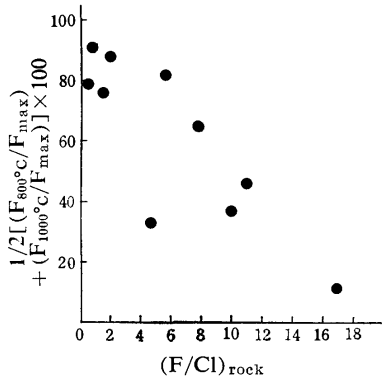

Fig. 7. Relation between $(F/Cl)_{rock}$ and $1/2[(\text{Amount of F evolved at } 800°C/F_{max})\times 100+(\text{Amount of F evolved at } 1000°C/F_{max})\times 100]$.

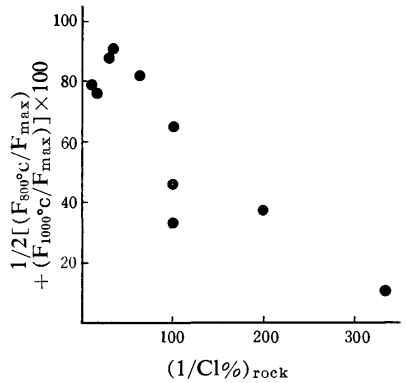

Fig. 8. Relation between $(1/Cl)_{rock}$ and $1/2[(\text{Amount of F evolved at } 800°C/F_{max})\times 100+(\text{Amount of F evolved at } 1000°C/F_{max})\times 100]$.

A Comparison with Natural Volcanic Emanation.—Data on the chlorine and fluorine contents of volcanic gases are rather scarce. Day and Shepherd[17] determined the chlorine and fluorine contents of condensed water from magmatic gases which were exhaled directly from a lava lake of Kilauea volcano, Hawaii, thus obtaining 4 g.Cl/l. and 10 g.F/l. data. Iwasaki et al.[18] obtained condensed water from magmatic gas exhaled from a lava lake of Mt. Mihara, Ō-sima volcano; its chlorine content was 67.7 g./l. The present author has determined the chlorine and fluorine contents of many samples of condensed water from active fumarolic gases in Japan*; their maximum values are 42 g.Cl/l. and 3 g.F/l. (Kamanokuti fumarole, Iwo-zima volcano).

The H_2O (+) content of the basalt from Ō-sima volcano used in the laboratory experiments is 0.3% (analyst: B. Iwasaki). Therefore, 3 mg. (3 μl. as liquid water) of water will be obtained from 1 g. of rock sample on heating. The laboratory experiments in this paper show that 240 μg. of Cl and 45 μg. of F are evolved from 1 g. of basalt from Ō-sima volcano at 1200°C. If we made condensed water from the gas evolved from this rock sample, the concentration of halogen in the water would be 80 g.Cl/l. and 15 g.F/l. respectively. It is interesting that these values agree well with the maximum halogen concentrations in water condensed from natural volcanic gases.

The "$F/Cl_{rock} > F/Cl_{gas}$" and "$F/Cl_{sublimate} > F/Cl_{gas}$" relations were obtained in laboratory experiments. To ascertain whether or not these relations are also true in natural volcanic phenomena, comparisons among the data on natural volcanic products were made. Many data on the fluorine and chlorine contents in igneous rocks are reviewed by Correns[19]. The mean value of the F/Cl (atomic ratio) calculated from those data and from data on

* Partly reported in Ref. 1. The details of the study will be reported on in another paper.

19) C. W. Correns, *Neues Jb. Mineral. Abh.*, 91, 239 (1957).

Japanese volcanic rocks[20] is 5.3 for igneous rocks. The mean value of F/Cl (atomic ratio) for the volcanic gases in Japan* is about 0.1, and a comparison between the mean values gives the "$F/Cl_{rock} > F/Cl_{gas}$" relation again. It is difficult to find representative data on the F/Cl value of natural volcanic sublimate to be compared with sublimate in laboratory experiments. There are indeed some data on the fluorine and chlorine content of volcanic sublimate. However, in natural conditions, several halogen-bearing minerals are formed by the fractional sublimation from a certain volcanic gas, and the distribution of halogen in these minerals is not uniform. Investigators of the volcanic sublimate usually endeavor to obtain mineral samples of a high purity, but these individual samples represent only a part of the whole sublimate which corresponds to the sublimate in the laboratory experiments. In this paper, the author used the data on the water-soluble component of volcanic ash as a representative of the natural volcanic sublimate, because the volcanic ash is discharged from a volcanic vent with large amounts of volcanic gas and is cooled rather quickly; it is hard, therefore, for fractional separation to occur. The fluorine and chlorine contents of volcanic ash have been studied by Kamada et al.[21] Their study shows that the F/Cl of the water-soluble component of volcanic ash was 0.1~7 (mean value 0.8). The "$F/Cl_{sublimate} > F/Cl_{gas}$" relation is obtained by comparing mean values.

The comparisons of mean values are somewhat ambiguous and may sometimes lead to a wrong conclusion. Therefore, the F/Cl value of the volcanic gas, volcanic rock and water-soluble parts of volcanic ash from the same volcano should be compared with each other. Such data are rather scarce, however; only two sets of data are available, one of Naka-dake Aso volcano[22], and another of Mt. Mihara, Ō-sima volcano. They are shown in Tables V and VI respectively. It may be readily seen in the tables that F/Cl_{rock} is larger than F/Cl_{gas} and that $F/Cl_{sublimate}$ is larger than F/Cl_{gas}.

TABLE V. F/Cl (ATOMIC RATIO) OF VOLCANIC PRODUCTS OF 1958 ACTIVITY OF NAKA-DAKE ASO VOLCANO (BY H. MATSUMOTO and S. TANAKA)[22]

Fumarolic gas	June (231°C)	0.077
Fumarolic gas	July (139°C)	0.0080*

	Aug. 1958	1.35
Lava of 1950		0.66*

* Determined by the present author

Conclusion

From the foregoing results, it may be concluded that chlorine and fluorine behave in different ways in the process of the separation of the gas phase from the solid phase. Fluorine compounds are less volatile than that of chlorine and are more liable to be fixed in solid phases as a sublimate.

A comparison between the results of the laboratory experiments and the data on natural volcanic products suggests that the study of the behavior of halogen compounds during heat treatment would be useful in understanding volcanic phenomena.

The author wishes to express his deep thanks to Professor Iwaji Iwasaki, Tokyo Institute of Technology, for his constant guidance throughout this study. He is also much obliged to the members of Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, for their fruitful discussions. In addition, he wishes to express his hearty thanks to Dr. Takashi Katsura, Tokyo Institute of Technology, Dr. Masaakira Kamada, the Laboratory of Analytical Chemistry, Faculty of Liberal Arts, Kagoshima University, and Dr. Hatao Matsumoto, the Institute of Geology, Kumamoto University, for their valuable advice and criticism.

The Urey-Bradley Force Constants of Boron Halides and their Transferability

By Hiroshi TOYUKI, Kazuhiro SHIMIZU and Hachiro HIYAMA

(Received January 21, 1963)

The infrared and Raman spectra of several boron trihalides have been recorded[1-9] and their Urey-Bradley force constants[10], except for those of boron triiodide, have already been calculated.

We have now recalculated the force constants of the boron trihalides BX_3 (X: F, Cl, Br and I) by using the most probable observed values of the fundamental frequencies of ^{10}B and ^{11}B compounds as a means of studying the transferability of force constants from boron trihalides to boron mixed halides.

The force constants for boron mixed halides were estimated by applying the usual additive property[11] to the recalculated values for boron trihalides.

The calculated values of the normal vibrational frequencies of boron mixed halides were obtained by using these constants and were compared with the observed values[7].

Calculations

The boron trihalides have a planar configuration and belong to the point group D_{3h}[12]. These tetraatomic molecules have six normal modes of vibration, of which two are degenerate; $\nu_1(A_1')$, $\nu_2(A_2'')$, $\nu_3(E')$ and $\nu_4(E')$. The A_1' mode is active only in the Raman and the A_2'' only in infrared spectra, while the doubly degenerate E' vibrations are both infrared and Raman active.

Unfortunately we have no configuration data for boron mixed halides. If the boron mixed halides of the BX_2Y type are assumed to have a planar configuration, they belong to the point group C_{2v}. All six normal modes, thus, are nondegenerate; $\nu_1(A_1)$, $\nu_2(A_1)$, $\nu_3(A_1)$, $\nu_4(B_2)$, $\nu_5(B_1)$ and $\nu_6(B_1)$. All the vibrations are both infrared and Raman active.

In this paper, only the in-plane vibrations (BX_3; A_1' and E', BX_2Y; A_1 and B_1) are described.

The following symmetry coordinates are used for the transformation into the factored $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices defined by Wilson[13]:

For BX_3 molecules;

A_1'; $S_1=(\Delta r_1+\Delta r_2+\Delta r_3)/\sqrt{3}$

E'; $S_3=(2\Delta r_1-\Delta r_2-\Delta r_3)/\sqrt{6}$

$S_4=(2\Delta\alpha_{23}-\Delta\alpha_{12}-\Delta\alpha_{13})/\sqrt{6}$

For BX_2Y molecules;

A_1; $S_1=(\Delta R_1+\Delta r_2+\Delta r_3)/\sqrt{3}$

$S_2=(2\Delta R_1-\Delta r_2-\Delta r_3)/\sqrt{6}$

$S_3=(2\Delta\beta_{23}-\Delta\alpha_{12}-\Delta\alpha_{13})/\sqrt{6}$

B_1; $S_5=(\Delta r_2-\Delta r_3)/\sqrt{2}$

$S_6=(\Delta\alpha_{12}-\Delta\alpha_{13})/\sqrt{2}$

The internal coordinates used in boron trihalides and boron mixed halides are shown in Fig. 1.

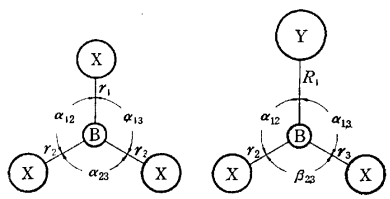

Fig. 1. Definition of internal coordinates for BX_3 and BX_2Y molecules.

The Urey-Bradley force constants of boron trihalides can be calculated uniquely by using the three observed values of fundamental frequencies (ν_1, ν_3 and ν_4) which are listed in Table I.

In the calculation, the force constant F' is

b) From Ref. 9

assumed to be equal to $-0.1F$, as usual[11], and the following molecular constants which have been previously reported are used; r(B–F) = 1.295 Å[14], r(B–Cl) = 1.73 Å[12], r(B–Br) = 1.87 Å[15] and r(B–I) = 2.10 Å[9], while all bond angles = 120°[12,14,15].

For boron triiodide, the tentative values which had been proposed by Wentink and Tiensuu[9] were used because there are no experimental values.

The force constants calculated for each boron trihalide to fit the most probable fundamental frequencies are shown in Table II.

In Table II, the force constants for the ^{10}B compound of boron trichloride are not given because the frequency ν_4 for this molecule has not been observed, as is shown in Table I.

The observed values are cited from the Ref. 7.

the usual additive property to the constants for ^{11}B compounds of boron trihalides.

The bending force constant, H, and the repulsive force constant, F, are evaluated from the following equation;

$$H(X\text{-}B\text{-}Y) = [H(X\text{-}B\text{-}X) + H(Y\text{-}B\text{-}Y)]/2$$

$$F(X\cdots Y) = [F(X\cdots X) + F(Y\cdots Y)]/2$$

The stretching force constant, K, is assumed to be equal to one in boron trihalides.

The values estimated for boron mixed halides are shown in Table III.

The normal vibrational frequencies of boron mixed halides are calculated by using these constants.

The molecular constants for these compounds have not been given. Since it may be assumed that the nature of bonds of these molecules does not differ greatly from that of boron trihalides, their values are taken from those of the boron trihalides.

Results

It has been described how Urey-Bradley potential function is quite suitable for calculating the normal vibrational frequencies of saturated hydrocarbons and their halogen compounds[11].

Making use of this function with reference to boron halides, we have obtained a good agreement between the observed and the calculated values of vibrational frequencies for boron mixed halides, as Table IV shows.

The frequencies for ν_4 corresponding to the out-of-plane bending vibration are omitted in Table IV.

The greatest difference between the observed and the calculated values was about $\pm 2\%$, while the average deviation was about $\pm 1\%$.

It has thus been found that the transferability of Urey-Bradley force constants from boron trihalides to boron mixed halides was reasonable and that the error due to the assumed planar configuration and molecular constants of boron mixed halides had no great effect to the transferability of the force constants.

The authors wish to thank Professor Haruo Shingu of Kyoto University, Professor H. Murata of Hiroshima University, and Dr. K. Kawai of the author's institute for their helpful advice.

Formaldehyde Resins. LXXVII. The Synthesis of Some Anthracene Derivatives as a Wavelength Shifter of a Plastic Scintillator*

By Minoru IMOTO and Tadao NAKAYA

(Received February 15, 1963)

A liquid or plastic scintillator generally contains two kinds of organic compounds. One is called the primary solute, and the other, the secondary solute. They disperse themselves in the solute or the plastic to set one of their fluorescent wavelengths by the most sensitive wavelength of a photoelectron amplifier. As the primary solute, terphenyl, tetraphenylbutadiene or quaterphenyl are widely used, while for the second solute, many kinds of aromatic compound are used. POPOP (*p*-di-(5-phenyl-2-oxazol)benzene)[1] is said to be the best second solute.

Recently, one of the present authors synthesized 9, 10-bis(2, 4-dimethylbenzyl)anthracene (I)[2], which was proved to behave excellently as a second solute[3].

The present paper concerns the syntheses of three compounds similar to I and a study of their ultraviolet and fluorescent spectra. The first compound synthesized was 9, 10-di-*m*-xylylanthracene (II), in which the nucleus of benzene is attached directly to the nucleus of anthracene. The two other compounds are derivatives of I with methyl groups in different positions, 9, 10-bis(4-methylbenzyl)anthracene (III) and 9, 10-bis(2, 3, 5, 6-tetramethylbenzyl)anthracene (IV).

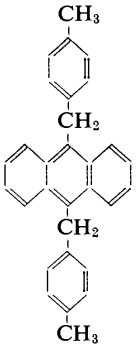
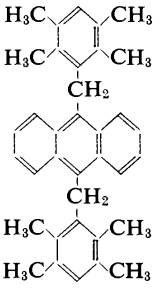
(I)

(II)



(III)



(IV)

These compounds have been little described in literature but have been proved by Osio et al.[3] to be more usable as second solutes than POPOP.

Experimental

9, 10-Bis(2', 4'-dimethylphenyl)anthracene (II).— 4-Iodo-*m*-xylene was obtained by the method described in the literature[4]; b. p., 105°C/12 mmHg; yield, 44%. A mixture of anthraquinone (27 g.) and 200 ml. of tetrahydrofuran was gradually added to a Grignard solution prepared from the mixture of 102 g. of 4-iodo-*m*-xylene, 9.7 g. of magnesium, 200 ml. of tetrahydrofuran and a trace of iodine. After the mixture had been heated under reflux for 4 hr., a saturated solution of ammonium chloride was added to decompose the excess reagent. The solid product, 9,10-dihydroxy-9,10-(2',4'-dimethylphenyl)anthracene, was twice extracted with ethyl acetate. The extract was then concentrated to give crystals. After recrystallization from a mixture of benzene and ethanol (1 : 1 in vol.), white needle crystals melting at 277~288°C were obtained in a 76% yield.

Found: C, 85.22; H, 6.74. Calcd. for $C_{30}H_{28}O_2$: C, 85.72; H, 6.67%. IR: ν-OH 3620 cm^{-1} in Nujol mull.

9,10-Dihydroxy-9,10-(2',4'-dimethylphenyl)anthracene was heated under reflux with 1 g. of zinc dust in 30 ml. of acetic acid for 1 hr. The mixture was then concentrated and cooled, and the crystals separated were extracted with toluene. Recrystallization was performed from a mixture of ethanol and benzene (2 : 1 in vol.). 9,10-Bis(2',4'-dimethylphenyl)anthracene was obtained as pale yellow crystals melting at 289~291°C. In the infrared spectrum, ν-OH was not observed in Nujol mull.

Found: C, 93.01; H, 6.89. Calcd. for $C_{30}H_{26}$: C, 93.21; H, 6.79%. UV absorptions: λ_{max}(mμ): 260, 356, 376, 397 in dioxane, as shown in Fig. 1.

9, 10-Bis(4-methylbenzyl)anthracene (III).— Twenty eight grams of *p*-xylylene chloride was added to 400 ml. of carbon disulfide already containing 17 g. of anthracene and 5 g. of zinc dust. The mixture was heated under reflux for 30 hr. while being stirred and then cooled. The precipitate was collected and recrystallized from benzene. Colorless crystals melting at 288~289°C were obtained in a 22% yield.

Found: C, 93.02; H, 6.98. Calcd. for $C_{30}H_{26}$: C, 93.26; H, 6.74%. λ_{max} (mμ): 260, 357, 378, 400 in dioxane.

9, 10-Bis(2, 3, 5, 6-tetramethylbenzyl)anthracene (IV).— By a method similar to that which gave 9,10-bis(4-methylbenzyl)anthracene, the reaction of 16.9 g. of anthracene with 36.5 g. of tetramethylbenzyl chloride was carried out in 350 ml. of carbon disulfide under refluxing for 30 hr. Colorless powder with a m. p. of 369~370°C was obtained from benzene in a 18% yield.

Found: C, 91.96; H, 7.94. Calcd. for $C_{30}H_{38}$: C, 91.92; H, 8.08%. λ_{max} (mμ): 260, 356, 376, 397 in dioxane.

Discussion

Ultraviolet Absorption Spectra. — The ultraviolet absorption spectra of compounds I, II, III and IV are shown in Figs. 1 and 2. The O–O bands of the absorption spectra are tabulated in Table I. The O–O bands may be compared with the B-bands of the phenyl type and with benzyl-type derivatives of anthracene.

TABLE I. THE WAVELENGTHS OF THE O–O BANDS OF ULTRAVIOLET ABSORPTION SPECTRA

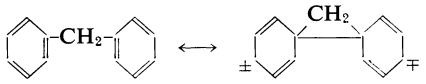
Compound	O–O, mμ	Log ε	Solvent
I	403	3.75	Dioxane
II	397	3.73	Dioxane
III	400	3.74	Dioxane
IV	397	3.73	Dioxane
Anthracene[5]	380	3.90	Ethanol

Comparing the absorption wavelengths of compound II with those of compounds I and III, it is clear that the CH_2 group between the anthracene and benzene rings shifts the absorption band toward longer wavelengths. In order to explain the fact that the extent of conjugation is greater when the CH_2-group was present between the nuclei, two interpretations may be possible. One of them is the concept of hyperconjugation by the CH_2-group; the other is the direct conjugation of the rings of anthracene and benzene.

From the identical values of the λ_{max} in compounds II and IV, it can not be possible that the hyperconjugation effect of the CH_2-group plays an important role.

Actually, when the model of 9,10-bis(2',4'-dimethylphenyl)anthracene (II) was constructed by use of Stuart model, it was observed that the benzene and anthracene rings twist by an angle of about 60° to each other; it was therefore considered that the direct conjugation of the two rings may be very small. However, in the case of 9,10-bis(2',4'-dimethylbenzyl)anthracene (I), the rings of anthracene and benzene are situated opposite one another at an angle of about 110°. Accordingly, the molecular orbitals of the anthracene ring and the benzene rings may directly interact; thus, the absorption bands may shift to longer wavelengths.

In 1950, Bartlett[6] considered a direct conjugation in the mode of the following formula:



Also, McClure and Coffman[7] and Stewart[8] observed the same phenomenon in polyphenylalkanes and agreed with the idea of direct conjugation.

As for the identical absorption maxima of compounds II and IV, it may be considarable that the 2',6'-dimethyl groups of the durene nucleus prevent the conjugation.

Fluorescence Spectra.—The fluorescence spectra measured are shown in Figs. 3 and 4. The O–O and O–1 bands are tablated in Table II, along with the differences in the wavelengths between the O–O bands of the fluorescence spectra and the O–O bands of the ultraviolet absorption spectra.

The fluorescence O–O bands shifted toward wavelengths longer by 5~7 mμ than those of the ultraviolet absorption spectra. This may be ascribed to the fact that the conjugation between the anthracene and two benzene rings

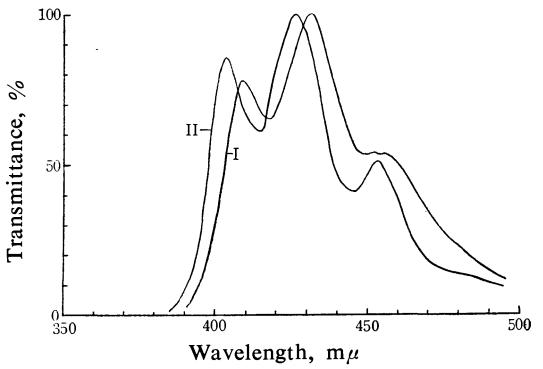


Fig. 3. Fluorescence spectra I and II in dioxane (concn. 2×10^{-4} mol./l.).

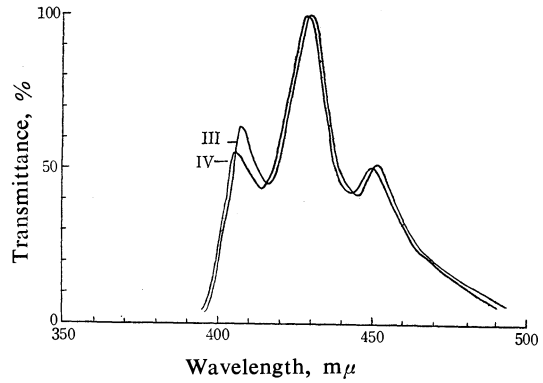

Fig. 4. Fluorescence spectra III and IV in dioxane (concn. 2×10^{-4} mol./l.).

Table II. The wavelengths of the O-O and O-1 bands of the fluorescence spectra

Compound	O-O mμ	O-1 mμ	Differences in O-O bands between fluores. and UV absorption, mμ
I	408	432	5
II	403	427	6
III	407	430	7
IV	404	428	7

occur more easily in the excited state than in the ground state, because the molecule is somewhat less strained in the excited state.

Since the best sensitivity of the photoelectron amplifier exists at the wavelength of about 450 mμ, it is desirable to have the fluorescence also in this region. While the strongest band of the POPOP is 417 mμ, those of compounds II and III are 429 and 430 mμ respectively. The compounds described in the present paper are, therefore, considered to be better second solutes of the plastic scintillator than POPOP[2].

Summary

Three anthracene derivatives, 9, 10-di-*m*-xylyl-anthracene (II), 9, 10-bis(4-methylbenzyl)-anthracene (III), and 9, 10-bis(2, 3. 5, 6-tetramethylbenzyl)anthracene (IV), have been synthesized and their ultraviolet and fluorescence spectra measured. The shift of the spectrum to the longer wavelength by the presence of methylene groups between anthracene and benzene rings may be explained in terms of direct conjugation between three rings.

According to the spectra, these compounds are believed to be better second solutes of the plastic scintillator.

The authors are indebted to Professor K. Osio and his coworkers for measuring the ultraviolet and fluorescence spectra and for their helpful discussions.

Crystal Structure of m-Methylbenzamide

By Seiki ORII[*1], Toshio NAKAMURA[*2], Yoshito TAKAKI[*3], Yoshio SASADA and Masao KAKUDO

(Received February 18, 1963)

The crystal structure of *m*-methylbenzamide, C_8H_9NO, has been investigated as a part of a study of the crystal structure of carboxyamide. The main interests of this study have been to determine the molecular configuration and to learn the features of the hydrogen bonding in the crystal.

In recent studies, the molecular configurations of salicylic acid[1], benzoic acid[2], nicotinic acid[3] and α-pyrazinamide[4] have been shown to be approximately planar, while nicotinamide[5] and benzamide[6] are non-planar, with an angle of 25~26° between the amide group and the six-membered ring plane.

It is interesting to compare the crystal structure of *m*-methylbenzamide with the above-mentioned crystal structures.

Experimental

m-Methylbenzamide crystals were obtained from an alcohol-water solution[*4]. They are colorless plates, with the a axis normal to the plates, and have a cleavage plane parallel to (1 0 0).

The crystallographic data obtained were as follows:

$a=8.93\pm0.03$ Å $b=16.02\pm0.03$ Å

$c=5.12\pm0.02$ Å $\beta=95.0\pm0.6°$

Absent spectra: $(h\,0\,l)$ when h is odd
$(0\,k\,0)$ when k is odd

Space group: $P2_1/a$

Four molecules per unit cell

Volume of the unit cell: 729.6 Å^3

Density (flotation): 1.22_5 g. cm^{-3}
(calculation): 1.23_0 g. cm^{-3}

The unit cell dimensions were determined from oscillation and Weissenberg photographs. The sets of intensities for $(h\,k\,0)$, $(0\,k\,l)$ and $(h\,0\,l)$ were obtained by the multiple-film Weissenberg technique, with CuK_α radiation and using a Ni filter. Intensities were estimated by visual comparison with a calibrated intensity scale.

Corrections for Lorentz and polarization factors were applied in the usual way, while that for absorption was disregarded. Preliminary scaling and temperature factors were determined by Wilson's method[7] and were further improved during the later stages of the refinement.

Structure Determination

Approximate Structure on the (0 0 1) Projection.—It is to be expected from the axial length that an approximate crystal structure should be obtained without serious overlapping of the molecule from the electron-density projection on (0 0 1). A trial molecular model was set up as planar, with conventional bond lengths and angles. The approximate structure on the (0 0 1) projection was obtained by the trial and error method, using the structure factor maps successively. The ordinary Fourier syntheses were followed. In the calculation of structure factors, an isotropic temperature factor $\exp\{-3.0(\sin\theta/\lambda)^2\}$ was applied. After several successive Fourier refinements, the R-value ($R=\sum\{|F_o|-|F_c|\}/\sum|F_o|$) became 0.25.

Approximate Structures on the (1 0 0) and (0 1 0) Projections. — The approximate structures on the (1 0 0) and (0 1 0) projections

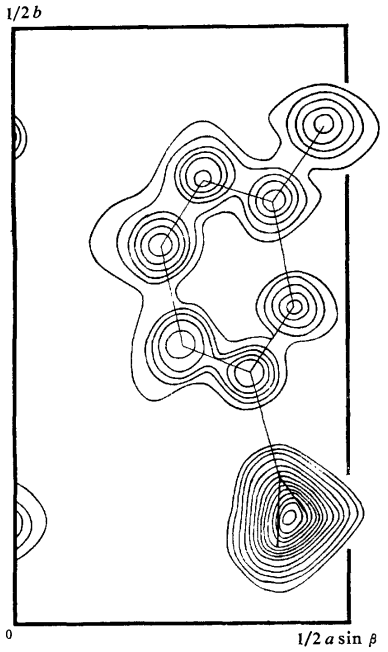

Fig. 1 (a)

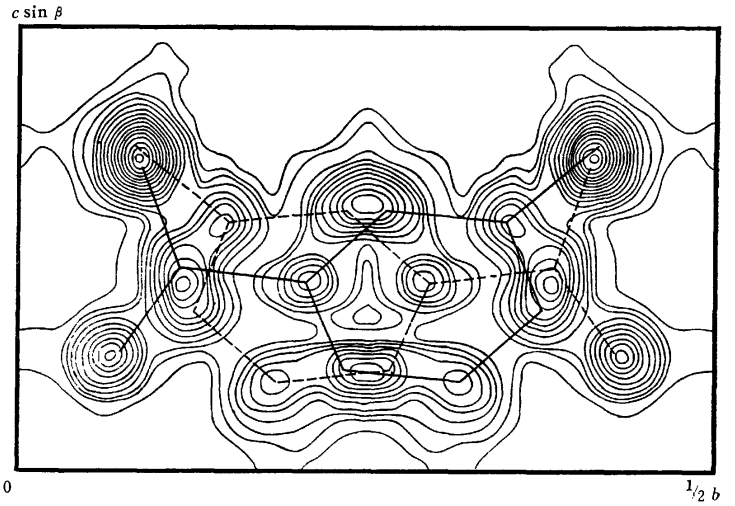

Fig. 1 (b)

Fig. 1. The final electron-density projections (a) along the c axis, (b) along the a axis. Contours are at an interval of 1 e. Å^{-2}, the lowest being at 2.0 e. Å^{-2}.

were given by assuming the planarity of the molecule with x and y coordinates obtained from the (0 0 1) projection. After several successive Fourier syntheses for the (1 0 0) and (0 1 0) projections, the R-values became 0.31 for ($0\,k\,l$) and 0.44 for ($h\,0\,l$). In the calculation of the structure factors, the isotropic temperature factor $\exp\{-3.0(\sin\theta/\lambda)^2\}$ was applied.

Refinement of Structure

Refinements of the structure were made by the method of modified (F_o-F_c) syntheses[8]. Preliminary hydrogen atoms were placed at the distance of 1.0Å from each of the C_2, C_4, C_5 and C_6 atoms, and two hydrogen atoms in the amino group were placed at the distance of 1.0Å from the nitrogen atom of the amino group on the N-O′ and N-O″ lines.

The locations of hydrogen atoms in the methyl group were obtained at the later stage of refinements. The isotropic temperature factor of each atom was corrected in each stage of the refinement. After ten successive (F_o-F_c) syntheses, the R-values reduced down to 0.11, 0.11 and 0.20 for ($h\,k\,0$), ($0\,k\,l$) and ($h\,0\,l$) respectively. The observed and calculated structure factors are listed in Table I. The final atomic parameters are given in Table II, while the final Fourier maps are shown in Fig. 1.

Throughout this study, the calculations of the structure factors were carried out on an NEAC 2101 electronic computer.

Description of the Structure and Discussion

Molecular Structure.—The bond lengths and angles found in *m*-methylbenzamide are shown in Fig. 2. None of the bond lengths observed in the benzene ring differ significantly from

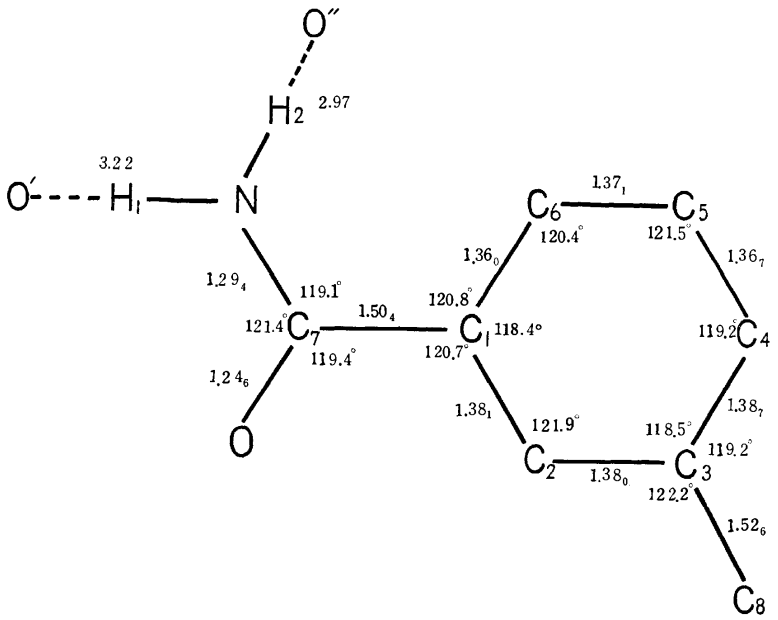

Fig. 2. Bond lengths (Å) and bond angles in *m*-methylbenzamide.

each other or from the mean observed value of 1.37$_5$Å which is in good agreement with the mean C–C bond length, 1.38Å, in the benzamide[6].

The C_1–C_7 bond length (1.50Å) leading to the amide group is somewhat less than 1.54Å, the standard length for a single bond. This value is, however, in good agreement with the 1.50, 1.52, 1.48, 1.48 and 1.48Å observed in α-pyrazinamide[4], nicotinamide[5], benzamide[6], benzoic acid[2] and nicotinic acid[3] respectively, though it is somewhat less than that observed in oxalic acid dihydrate[9] (1.53Å and α-oxalic acid[10] (1.56Å).

The shortening of this C_1–C_7 bond may indicate that there is some double bond character caused by the resonance effect between the amide or acid group and the six-membered ring.

The bond length C_3–C_8 (1.52$_6$Å) is in fairly good agreement with the standard single bond length.

TABLE III. DIMENSIONS OF THE AMIDE GROUP IN THE ANALOGOUS COMPOUNDS

	m-Methylbenzamide	Benzamide[6]	Nicotinamide[5]	α-Pyrazinamide[4]
	Å	Å	Å	Å
C-N	1.29	1.31	1.34	1.31
C-O	1.25	1.24	1.22	1.24

9) F. R. Ahmed and D. W. J. Cruickshank, *Acta Cryst.*, **6**, 385 (1953).
10) E. G. Cox, M. W. Dougill and G. A. Jeffrey, *J. Chem. Soc.*, **1952**, 4854.

The dimensions of the amide group agree closely with those observed in the analogous compounds. Some examples are shown in Table III.

The plane of the benzene ring can be represented by the equation:

$$0.550X' + 0.072Y - 0.403Z' - 1 = 0$$

where X', Y and Z' refer to the orthogonal axes a, b and c*, and the values of the coefficients are determined by means of the least squares. The perpendicular displacements of atoms from the mean plane are shown in Table IV.

TABLE IV. DISPLACEMENT OF EACH ATOM FROM THE MEAN PLANE OF THE BENZENE RING

	Å		Å
C_1	+0.006	C_6	+0.001
C_2	−0.013	C_7	+0.008
C_3	+0.007	C_8	+0.062
C_4	+0.006	N	+0.570
C_5	−0.012	O	−0.487

The mean value of the displacements for atoms in the benzene ring is 0.007$_5$Å, that is, the benzene ring is concluded to be planar. On the other hand, the nitrogen atom and oxygen atom deviate significantly from the mean plane of the benzene ring, and the angle between the ring plane and the amide plane is 28.7°.

It has been shown that the amide planes in nicotinamide[5] and benzamide[6] make an angle

about 25~26° to their ring planes, while in salicylic acid[1], benzoic acid[2], nicotinic acid[3] and α-pyrazinamide[4] the molecules are approximately planar.

The twists of the amide group around the C_1-C_7 axis in *m*-methylbenzamide can be explained by the steric hindrance on the contact of H_6 in the benzene ring and H_{N2} in the amino group, as has been suggested by Penfold and White[6].

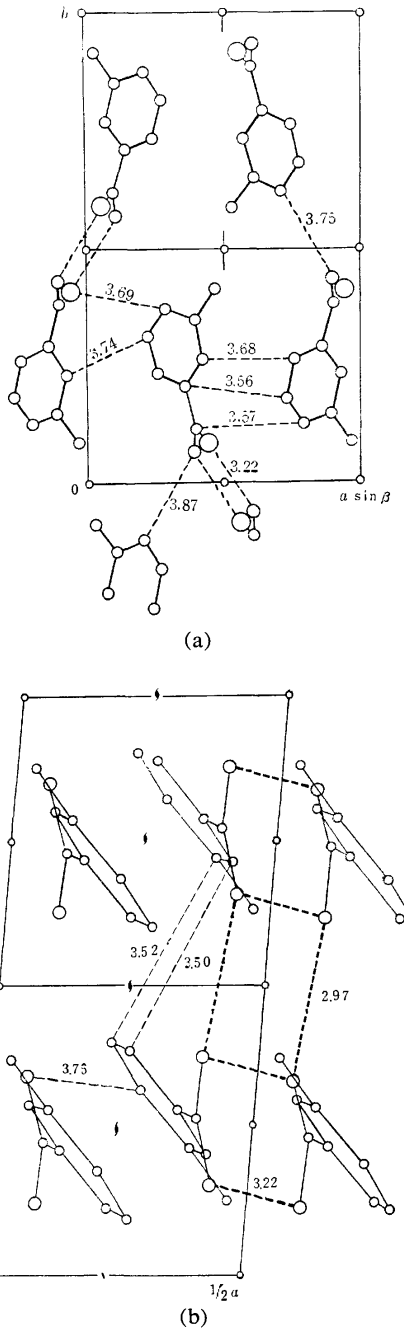

Fig. 3. Views of the arrangement of molecules (a) along the c axis, (b) along the b axis showing hydrogen bond as broken lines.

Crystal Structure. — The projection of the crystal structure along the c and b axes is shown in Fig. 3. The molecules are connected by the two NH-O hydrogen bonds, the first set 3.22Å in length forming a dimer across the center of symmetry, and the second set 2.97Å in length joining such dimers into endless chains extended along the c axis. The linkage of molecules by hydrogen bonding is of a type very similar to that found in the crystals of benzamide[6] and δ-pyrazinamide[12]. The hydrogen bond lengths in *m*-methylbenzamide are in agreement with those found for the NH-O type hydrogen bond, which have values ranging from 2.67 to 3.17 Å[11]. This crystal consists of endless chains linked by the NH-O hydrogen bonds, and the intermolecules between these chains are held in contact by the van der Waals force; such molecular arrangements as shown in Fig. 3 can reasonably explain the existence of the cleavage parallel to the (1 0 0) plane.

Summary

The crystal structure of *m*-methylbenzamide has been determined by two-dimensional X-ray methods. The atomic positions obtained from the trial and error method are refined by the modified $(F_o - F_c)$ synthesis[8].

1. The mean C-C distance in the benzene ring is 1.37_5Å, while C_3-$C_8 = 1.52_6$, C_1-$C_7 = 1.50_4$, C_7-$N = 1.29_4$ and C_7-$O = 1.24_6$Å.
2. The amide group twists around the C_1-C_7 axis with an angle of 28.7° because of the steric hindrance on the contact of H_6 and H_{N2}.
3. The molecules are connected by NH-O hydrogen bonds, 3.22Å, forming dimers which are linked with each other by other NH-O hydrogen bonds, 2.97Å, into endless chains.

The crystal structure is of a type analogous to benzamide[6] and δ-pyrazinamide[12].

Polarographic Determination of the Formation Constants of Sulfato, Acetato and Sulfatoacetato Complexes of Nickel(II) at Ionic Strength 1.0

By Nobuyuki TANAKA, Yu SAITO and Hiroshi OGINO

(Received February 27, 1963)

In the previous study[1], a method for the polarographic determination of the formation constants of weak complexes, $Ni(OAc)_i \cdot (Z)_j^{(2-i-zj)+}$ $(0 \leq i \leq n,\ 0 \leq j \leq p)$, was developed and applied to the nickel(II) complexes in sulfate-acetate media. The results indicated that mixed ligand complexes were not present in appreciable concentrations at ionic strength 0.2.

Because of the increasing interest in the determination of the formation constants of weak complexes with two or more different ligands, it seems worthwhile to apply the method under the conditions favorable for the formation of mixed ligand complexes. In the present paper, the formation of complexes of nickel(II) with sulfate and/or acetate is demonstrated in a solution containing higher concentrations of these anions, and the formation constants of these complexes determined at 25°C and ionic strength 1.0 are presented.

Experimental

The method employed in this study was in principle the same as in the previous paper[1]. However, the ionic strength of the solution was adjusted to 1.0 with sodium perchlorate, and sodium sulfate was used instead of potassium sulfate.

Results and Discussion

The polarograms were recorded with the acetate buffer solutions of pH 3.72 containing 9.90×10^{-4} M nickel nitrate, 1.06×10^{-3} M NTA, and various concentrations of sulfate and acetate. The limiting current of nickel(II) was found to be diffusion-controlled.

The values of $[Ni^{2+}]_{app}$, which is the sum of the concentrations of hydrated nickel ions and nickel(II) complexes with sulfate and/or acetate, were obtained at various concentrations of acetate and the given concentration of sulfate. The F_0 values were calculated according to the left-hand side of Eq. 13 of the previous paper[1] and were plotted against the acetate concentration (Fig. 1). The straight plots

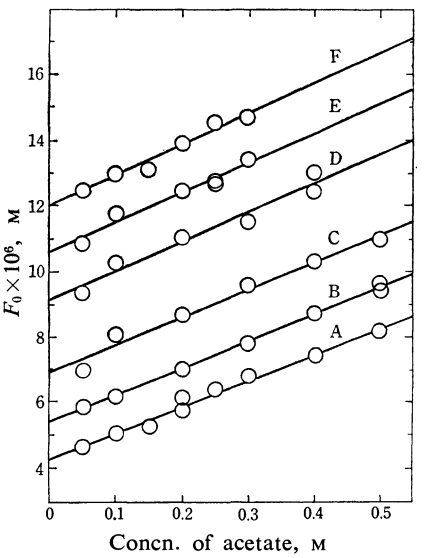

Fig. 1. F_0 as a function of acetate concentration at 25°C. Concentrations of sulfate are: 0 (A), 0.05 M (B), 0.10 M (C), 0.15 M (D), 0.175 M (E) and 0.20 M (F).

clearly indicate that n is equal to 1 and that no appreciable amount of complexes with two acetates or more coordinated is present in the solution investigated. Consequently, the F_0 function is written as follows:

$$F_0 = \frac{\alpha}{\beta K_{NiX}} \times \sum_{i=0}^{1} \sum_{j=0}^{p} K_{Ni(OAc)_i(SO_4)_j} [OAc^-]^i [SO_4^{2-}]^j \quad (1)$$

Next, F_0 was calculated with $[Ni^{2+}]_{app}$ obtained at various concentrations of sulfate and the given concentration of acetate and plotted against the sulfate concentration. A typical example of these F_0 plots is shown in Fig. 2. By extrapolating the F_0 plot as given in Fig. 2 to the zero sulfate concentration, the value of

$$\frac{\alpha}{\beta K_{NiX}} \quad (1 + K_{NiOAc}[OAc^{-1}])$$

was obtained. The F_1 function

1) N. Tanaka and H. Ogino, This Bulletin, 34, 1040 (1961).

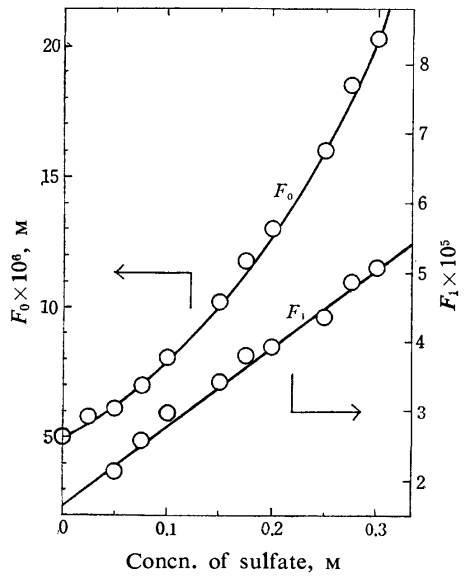

Fig. 2. F_0 (Eq. 1) and F_1 (Eq. 2) as a function of sulfate concentration at 25°C. Acetate concentration is 0.1 M.

$$F_1 \equiv \frac{F_0 - \frac{\alpha}{\beta K_{\mathrm{NiX}}}(1+K_{\mathrm{NiOAc}}[\mathrm{OAc}^-])}{[\mathrm{SO_4}^{2-}]} = \frac{\alpha}{\beta K_{\mathrm{NiX}}} \times \sum_{i=0}^{1}\sum_{j=1}^{p} K_{\mathrm{Ni(OAc)}_i(\mathrm{SO_4})_j}[\mathrm{OAc}^-]^i[\mathrm{SO_4}^{2-}]^{j-1} \quad (2)$$

was calculated from the F_0 plot and plotted against the sulfate concentration, as seen in Fig. 2, where the F_1 plot shows as a straight line. This indicates that p is equal to 2 and that no appreciable amount of complexes with three sulfates or more coordinated is present in the solution investigated. The same result was also obtained with other concentrations of acetate.

The fact that n and p are equal to 1 and 2 respectively suggests that complex species of $NiOAc^+$, $Ni(SO_4)$, $Ni(OAc)(SO_4)^-$, $Ni(SO_4)_2^{2-}$, and $Ni(OAc)(SO_4)_2^{3-}$ may exist in the solution. Therefore, Eq. 1 is written as

$$F_0 = \frac{\alpha}{\beta K_{\mathrm{NiX}}}\{1+K_{\mathrm{NiOAc}}[\mathrm{OAc}^-]+K_{\mathrm{NiSO_4}}[\mathrm{SO_4}^{2-}] + K_{\mathrm{Ni(OAc)(SO_4)}}[\mathrm{OAc}^-][\mathrm{SO_4}^{2-}]+K_{\mathrm{Ni(SO_4)_2}}[\mathrm{SO_4}^{2-}]^2 + K_{\mathrm{Ni(OAc)(SO_4)_2}}[\mathrm{OAc}^-][\mathrm{SO_4}^{2-}]^2\} \quad (3)$$

The formation constants and the value of $\alpha/(\beta K_{\mathrm{NiX}})$ were determined from the plots in Fig. 1 by a graphical treatment similar to that reported previously[1]. The value for $\alpha/(\beta K_{\mathrm{NiX}})$ was obtained to be $4.2_8\times10^{-6}$ mol. l.$^{-1}$ at pH 3.72, and the formation constants obtained are given in Table I. The uncertainties of the

Table I. Formation constants of nickel(II) complexes at 25°C and ionic strength 1.0

K_{NiOAc}	1.9	l. mol^{-1}
$K_{\mathrm{NiSO_4}}$	3.7	l. mol^{-1}
$K_{\mathrm{Ni(SO_4)_2}}$	2.6×10	l.^{2} mol^{-2}
$K_{\mathrm{Ni(OAc)(SO_4)}}$	1	l.^{2} mol^{-2}
$K_{\mathrm{Ni(OAc)(SO_4)_2}}$	~3	l.^{3} mol^{-3}

determined values were examined by a graphical method[2,3].

Using the $\alpha/(\beta K_{\mathrm{NiX}})$ thus obtained and the formation constants given in Table I, the values of F_0 can be calculated at various concentrations of sulfate and acetate. Two sets of F_0 values were calculated as a function of sulfate concentration at two different concentrations of acetate. The solid curves in Fig. 3 indicate

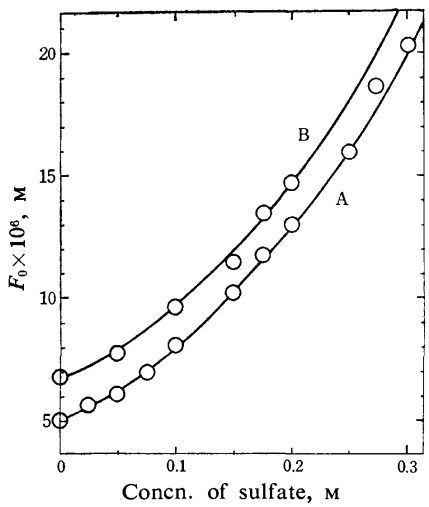

Fig. 3. Calculated and experimental values of F_0 at various concentrations of sulfate in the presence of 0.1 M (A) and 0.3 M (B) of acetate at 25°C: — indicates the calculated, and ○ the experimental value.

these calculated values, which are in satisfactory agreement with the F_0 values obtained experimentally at various sulfate concentrations.

The formation constants of K_{NiOAc} and $K_{\mathrm{NiSO_4}}$ at 25°C and ionic strength 0.2 have been given as 2.5 and 11.6 respectively[1]. The formation constants given in Table I are apparently smaller than these values; especially, $K_{\mathrm{NiSO_4}}$ at ionic strength 1.0 is considerably smaller than that at ionic strength 0.2.

In the previous study, at ionic strength 0.2, complex species, $Ni(SO_4)_2^{2-}$, $Ni(OAc)(SO_4)^-$ and $Ni(OAc)(SO_4)_2^{3-}$, were not found to exist

2) A. E. Martell and M. Calvin, "Chemistry of the Metal Chelate Compounds", Prentice-Hall, Inc., N. J. (1959), p. 91.

3) G. Schwarzenbach, A. Willi and R. O. Bach, *Helv. Chim. Acta*, **30**, 1303 (1947).

in appreciable concentrations, whereas in the present study, at ionic strength 1.0, the existence of these complexes is confirmed. It should be noted that the existence of these complex species was confirmed not because of the increase in ionic strength but because of the increase in the concentrations of sulfate and acetate ions. This obviously suggests that the increase in ligand concentration is one of the most important conditions in the study of weak complexes with two or more different ligands.

Summary

The formation of nickel(II) complexes with sulfate and/or acetate has been studied at 25°C and ionic strength 1.0 by the polarographic method reported previously[1]. The results obtained reveal that complex species, $NiOAc^+$, $NiSO_4$, $Ni(SO_4)_2^{2-}$, $Ni(OAc)(SO_4)^-$ and $Ni(OAc)(SO_4)_2^{3-}$, are present in the solution. The formation constants determined are: $K_{NiOAc}=1.9$, $K_{NiSO_4}=3.7$, $K_{Ni(SO_4)_2}=2.6\times10$, $K_{Ni(OAc)(SO_4)}=1$ and $K_{Ni(OAc)(SO_4)_2}=\sim3$ at 25°C and ionic strength 1.0.

*Brown Nitrosylpentamminechromium(III) Salts and Green Nitrosylpentamminechromium(III) Perchlorate**

By Masayasu MORI, Shigeru UESHIBA and Shinichi KAWAGUCHI

(Received March 5, 1963)

An ammoniacal solution of chromium(II) salt is readily oxidized; the oxidation products vary widely, depending upon the kind of oxidizing agent employed. Thus, when it is allowed to evolve hydrogen at a temperature near 0°C, especially in the presence of iron(II) salt as a catalyst, the main product is hexamminechromium(III) salt[1,2], while a rapid stream of oxygen produces μ-hydroxobis{pentamminechromium(III)} salt as an oxidation product[3]. The present authors have found that the same binuclear complex is also formed by oxidation with ammonium nitrate and that, in this case, brown crystals, however small in quantity, are often found admixed in the red μ-hydroxo salt. Further research has shown that the brown crystals are nitrosylpentamminechromium(III) dichloride, a new type of acidopentamminechromium salt, and that the perchlorate prepared by metathesis is green in contrast to chloride, bromide and nitrate, all of which have been found to be brown; that is to say, the color of crystals is completely changed by a mere substitution of an anion which is not coordinated in the ordinary sense. Such an example seems to be quite rare, though analogous cobalt compounds might be regarded as another example. There are, however, points of considerable difference between these two cases, as will be discussed below. In this paper the method of preparation of and an investigation of infrared absorption spectra pertaining to the new chromium ammines will be described.

Experimental

Preparation.—Although nitrosylpentamminechromium(III) salts were first obtained as described above, the best way of preparing them is by oxidizing an ammoniacal chromium(II) solution with sodium nitrite. The reaction may be represented by the equation:

$$2[Cr(NH_3)_6]Cl_2+NaNO_2+NH_4Cl \rightarrow [CrNO(NH_3)_5]Cl_2+[CrOH(NH_3)_5]Cl_2+NaCl+3NH_3$$

Nitrosylpentamminechromium(III) Chloride. — Fifteen grams of potassium dichromate are mixed in a 1 l. beaker with 20 ml. of ethanol and 40 ml. of 12 N hydrochloric acid. When the violent reaction has ceased somewhat, the mixture is heated on a hot plate until no orange crystals of potassium dichromate are left at the bottom of the beaker.

Abbreviations: v, very; s, strong; w, weak; stretch., stretching; deg., degenerate; def, deformation; sym., symmetric; rock., rocking.

The green solution is then transferred into a smaller beaker and covered with a 3 cm. layer of ligroin or liquid paraffine. It is then kept at 80~90°C, together with 30 g. of pure zinc grains, until the green chromium(III) solution has been completely reduced to the bivalent state with a pure blue color. If the solution has become turbid before the complete reduction, 1~2 ml. of hydrochloric acid may be added and heating continued.

The pure azure-colored solution is cooled in running water to room temperature and quickly poured, together with the mineral oil, into an Erlenmeyer flask containing a mixture of 40 g. of ammonium chloride and 100 ml. of 15 M aqueous ammonia; the whole mixture is then carefully stirred and cooled in an ice bath. To this is then added 15 g. of sodium nitrite dissolved in 25 ml. of 15 M aqueous ammonia; the mixture is stirred vigorously and allowed to stand for several minutes, and the precipitate of crude chloride is separated by filtration. Not only the chloride, but also various other salts may be prepared from this crude product.

In order to prepare pure chloride, the crude product is dissolved in the smallest possible quantity (ca. 1000 ml.) of cold water, and after filtration pure nitrosylpentamminechromium(III) chloride is recrystallized by the slow addition of 200 g. of ammonium chloride and 10 ml. of 12 N hydrochloric acid. The brown crystals are washed with ethanol, air-dried, and kept in a desiccator protected from light. Yield, 9 g.

Found: Cr, 22.69; N (total), 34.85; NH_3, 35.70; Cl, 30.02. Calcd. for $[CrNO(NH_3)_5]Cl_2$: Cr, 22.32; N (total), 36.06; NH_3, 36.53; Cl, 30.42%.

Nitrosylpentamminechromium(III) Nitrate. — The crude precipitate of nitrosylpentamminechromium-(III) chloride is dissolved in ca. 1000 ml. of cold water, and the solution is filtered. The nitrate may be crystallized by slowly adding 300 g. of ammonium nitrate and 10 ml. of 14 N nitric acid. Yield, 3.6 g. The precipitate may be further purified by dissolution in water and recrystallization with ammonium nitrate.

Found: Cr, 18.12; NH_3, 28.76. Calcd. for $[CrNO(NH_3)_5](NO_3)_2$: Cr, 17.86; NH_3, 29.25%.

Nitrosylpentamminechromium(III) Bromide. — The bromide can be obtained by a procedure analogous to that used for preparing the nitrate. The bromide is much less soluble and a better yield is obtained by the use of a somewhat smaller quantity of ammonium bromide. However, special care should be taken to prevent the precipitate from becoming too fine. Thus, ammonium bromide is added little by little while the solution is continuously agitated.

Found: Cr, 15.91; NH_3, 25.62; Br, 49.72. Calcd. for $[CrNO(NH_3)_5]Br_2$: Cr, 15.91; NH_3, 26.04; Br, 48.86%.

Nitrosylpentamminechromium(III) Perchlorate.—The precipitate of crude chloride is dissolved in a mixture of 180 ml. of 6 N sulfuric acid and 220 ml. of water, and the solution is filtered. To the filtrate is added 200 ml. of 60% perchloric acid. The mixture is cooled in an ice bath, and the green precipitate of the perchlorate is collected on a glass filter under suction and washed with ethanol. Yield, 6 g. It may be purified by dissolution in the smallest possible quantity of water and by recrystallization with perchloric acid in an ice bath.

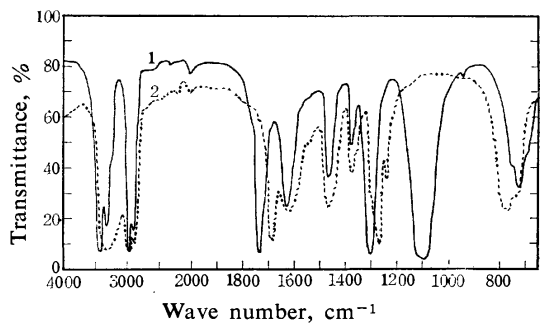

Fig. 1. Infrared absorption spectra of nitrosylpentamminechromium(III) salts.
1: Perchlorate 2: Chloride

Found: Cr, 14.58; NH_3, 22.73; Cl, 19.79. Calcd. for $[CrNO(NH_3)_5](ClO_4)_2$: Cr, 14.21; NH_3, 23.26; Cl, 19.37.

Infrared Absorption Spectra. — The infrared absorption spectra of powder samples of the chloride and the perchlorate were obtained by the Nujol mull technique in the rock salt region with a Hitachi EPI-2 spectrometer. The spectra are given in Fig. 1.

Results and Discussion

The wave numbers of the main infrared absorption peaks and their possible assignments are given in Table I. The assignments were made on analogy with the nitrosylpentamminecobalt(III) salts studied by Bertin, Mizushima, Lane and Quagliano[4]. All the features of the spectra are analogous to those of cobalt compounds, but the rocking frequency of the ligating NH_3 is somewhat lower in chromium ammines and especially so in green perchlorate (chloride: 770; perchlorate: 730; cobaltammines: 800 cm^{-1}). This seems to show indirectly that the coordinate linkage is weaker[5], especially in green nitrosylpentamminechromium(III) perchlorate. The spectra also show that the vibrational frequency of NO is higher in the green perchlorate (1730) than in the brown chloride (1690)*. This would seem to be evidence that in the green form the ligating NO is influenced less by the central ion than in the brown chloride. (Gaseous NO: 1876 cm^{-1})

There is evidence to show that nitrosylpentamminechromium(III) compounds are not simple analogues of similar cobalt compounds[6]. For example, the black series of nitrosylpentamminecobalt(III) salts can be prepared only in the absence of air, the pink series, in the presence of air[7], and the two series are not interchangeable[8]. Moreover, they are reported to behave differently toward acids: the salts of the black series are readily decomposed to give cobalt(II) salts, whereas those of the pink series form acidopentamminecobalt(III) salts[8]. Thus, in cobalt compounds the difference in anions is probably not the only factor causing color change.

On the other hand, both green nitrosylpentamminechromium(III) perchlorate and brown nitrosylpentamminechromium(III) chloride are stable when dissolved in cold water, both solutions presenting exactly the same absorption spectra; from any such solutions, either the perchlorate or the chloride may be crystallized by a mere choice of the precipitant (i.e., perchloric acid or hydrochloric acid). Thus, the environment in the ionic lattices seems to have an effect sufficient to cause a difference in the state of the complex cation, as is evidenced by the difference in color and vibrational frequencies.

A spectroscopic investigation of these chromium compounds is now under way and will shortly be reported. Let us say here, however, that the color of the chloride changes to orange when cooled to the temperature of liquid nitrogen, but that the color of the green perchlorate does not change appreciably down to this temperature.

Summary

A new series of chromium ammines, i.e., nitrosylpentamminechromium(III) salts, were obtained by the reaction of an ammoniacal chromium(II) solution with sodium nitrite. The derivatives are usually reddish brown, but only the perchlorate is bright green. The infrared absorption spectra indicate that in the green perchlorate the rocking frequency of ligating ammonia is lower, while the stretching frequency of the nitrosyl group is higher than in the brown chloride. These results seem to show indirectly that the coordinate linkage is weaker in the green perchlorate.

It is the authors' pleasure to express their gratitude to Professor Tatsuo Miyasawa of Osaka University for his valuable suggestions.

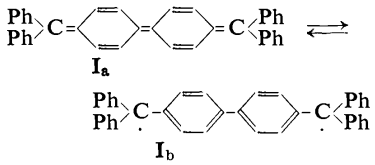
Acetylenic Analogues of Chichibabin Hydrocarbon

By Hirohisa KATAOKA and Masazumi NAKAGAWA

(Received March 14, 1963)

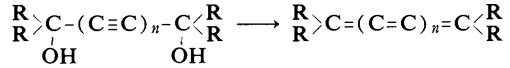
There have been many discussions of the unstable nature of Chichibabin hydrocarbon (I), which was prepared by Chichibabin as early as 1907[1]. Schwab and Agliardi have observed that hydrocarbon I catalyzed the interconversion of ortho- and para-hydrogen; they have attributed this catalytic activity to the presence of the biradical structure (I_b) in the hydrocarbon[2]. On the other hand, Müller and Müller-Rodloff have assigned the quinomethane structure (I_a) on the basis of the diamagnetic behavior of this hydrocarbon[3]. More recently, Huchison has measured the ESR spectrum of a solution of I and concluded that I in the solution contained 4~5% of the biradical (I_b)[4]. However, in a private communication to Ingram, he has pointed out that



I_a

I_b

there is a distinct possibility of the presence of an impurity to which the observed signal may be attributable*. Also, there have been fairly many investigations concerning the quinomethane or biradical structure of Chichibabin type hydrocarbons[5]. If there exists an equilibrium between the quinomethane and biradical structures, it would be reasonable to conclude that the energy levels corresponding to these two possible structures do not differ appreciably. If Chichibabin hydrocarbon (I) exists mainly in the form of the quinomethane (I_a), the loss of the resonance energy of the central benzene rings should be covered by an increase in the resonance energy of the newly-formed, more extended conjugate system.



II III

On the other hand, the formation of cumulene (III) from the acetylenic glycol of type II is well-known[6]. Also, the rearrangement of the acetylenic linkage to an allenic system under rather mild conditions has been shown in several instances[7]. Therefore, the insertion of a triple bond to I or a substitution for the central benzene ring in I of a triple bond seems to cause a change in the valence tautomeric equilibria between the quinoid and the biradical structures of these acetylenic analogues of Chichibabin hydrocarbon.

The present paper deals with the synthesis and the properties of the following acetylenic analogues of I:

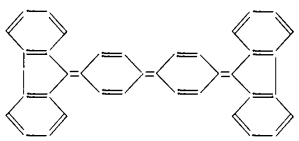
VIII VII

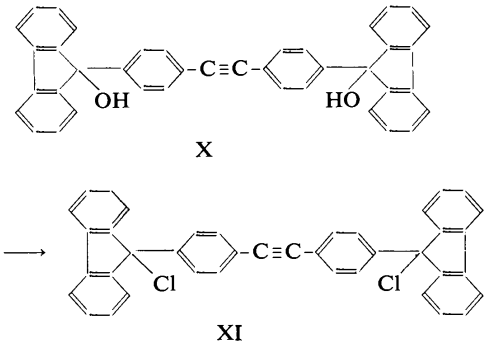
The successive treatment of the tolan with *n*-butyllithium and then with benzophenone yielded 4,4'-bis(diphenylhydroxymethyl)-tolan (VII) in an almost quantitative yield. The reaction of thionyl chloride with the glycol VII resulted in the formation of 4,4'-bis-(diphenylchloromethyl)-tolan (VIII) in a good yield. The dichloride VIII was found to be a fairly unstable compound which decomposed easily upon the heating of the solution or of the crystals. The development of a blue band was obseved when a solution of VIII was passed through a column of activated alumina. The blue-colored material could not be eluted with various kinds of polar solvents, and the blue color disappeared gradually without the movement of the band. From the eluate with ethyl acetate, the glycol VII was obtained as the sole decomposition product.

4,4'-Bis(9''-chloro-9''-fluorenyl)-tolan (XI).—The synthesis and interesting properties of the biphenylene analogue of Chichibabin hydrocarbon (IX) have been reported by Theilacker[5e].



IX

In order to prepare the acetylenic analogue of IX, the corresponding dichloride (XI) was synthesized according to the following scheme. The metalation of 4,4'-dibromotolan by means of *n*-butyllithium, followed by the reaction with fluorenone, afforded the glycol X in a good yield. It was found that the displacement of the hydroxyl groups by chlorine proceeds



X XI

sluggishly compared with the case of VII. The dichloride XI was obtained in a reasonable yield after refluxing the mixture of X with a large excess of thionyl chloride for over 6 hr.

1-Diphenylchloromethyl-4-(3'-chloro-3',3'-diphenyl-1'-propynyl)-benzene (XVII).—The successive treatment of *p*-bromophenylacetylene with *n*-butyllithium and benzophenone gave the glycol XVI in a poor yield, together with an appreciable amount of 1,1-diphenyl-3-(4'-bromophenyl)-propyn-1-ol (XVIII). It was found that this reaction was scarcely feasible, however, because of the poor yield and the poor reproducibility. *p*-Bromoacetophenone was converted to *p*-acetylbenzonitrile (XIII)[9]. This was hydrolyzed to give the corresponding benzoic acid XIII. Methyl *p*-ethynylbenzoate (XV) derived from XIII via two steps was treated with phenyllithium and benzophenone successively, affording the glycol XVI in a reasonable yield. The glycol XVI thus obtained was heated with a large excess of thionyl chloride in benzene or acetyl chloride in hydrochloric acid[5b], yielding the unstable dichloride XVII.

1, 4-Bis-(3'-chloro-3, 3'-diphenyl-1'-propynyl)-benzene (XX). — 1, 4-Bis(3'-hydroxy-3', 3'-diphenyl-1'-propynyl)-benzene (XIX) was prepared according to the method of Ried[10] by the reaction of the lithium derivative of *p*-diethynylbenzene with benzophenone. The dichloride XX was obtained by treating the glycol XIX with thionyl chloride in benzene or acetyl chloride in hydrochloric acid at a low temperature. XX was found to be extremely unstable in the presence of heat.

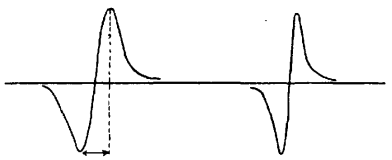
XX

Results

On 4, 4'-Bis-diphenylmethylyl-tolan (IV).— The rapid development of an intense blue-violet color was observed when a solution of the dichloride VIII in benzene or tetrahydrofuran was shaken with mercury or zinc dust at room temperature in an atmosphere of pure nitrogen. The solution could be kept without change of its color for several hours at the temperature of −70°C. A rapid change of the color to orange was observed when the solution was warmed to room temperature. Also, the exposure to air of the blue-violet solution caused an instant decolorization of the solution. The ultraviolet absorption spectrum of the orange solution exhibits a distinct peak at 465 mμ and the broad absorption, at a shoter wavelength. The ESR spectra were measured to determine the presence of the biradical structure IV_b employing tetrahydrofuran solutions (5.1×10^{-3} mol./l. and 2.0×10^{-2} mol./l. based on the dichloride, VIII) at 21°C. The spectrum is illustrated in Fig. 1, together with that of diphenylpicrylhydrazyl (solid) for purposes of comparison. The shape of the differential absorption curve was found to be a typical one for a carbon radical. Calculation of the concentration of the biradical IV_b, which was carried out by a comparing the integrated differential absorption curve of IV_b with that of diphenylpicrylhydrazyl, showed that 5% and 7% of IV_b should be present in the above-mentioned solution, assuming that the dechlorination of the dichloride VIII by zinc dust proceeds to 100% conversion.



(a) (b)

Fig. 1. The ESR spectra of IV_b (a) and diphenylpicrylhydrazyl (b).

The attempts to isolate the unstable IV in a solid state failed. The concentration of the blue-violet solution in vacuo at a low temperature resulted in the formation of an orange-yellow polymeric substance.

As the structure of a cyclic dimer has been assigned to the peroxide of Chichibabin hydrocarbon by Müller[11], the formation of the same type of cyclic peroxide as XXI was expected in the case of IV_b. An intense blue-violet solution of IV in tetrahydrofuran was exposed to air, resulting in the formation of a light brown solution. The attempts to isolate XXI in a pure state gave unsatisfactory results. The absorption of oxygen by IV was measured using a Warburg manometer. A rapid uptake of oxygen was observed when the dichloride VIII in tetrahydrofuran was shaken with an excess of zinc dust in an atmosphere of pure oxygen. A representative absorption

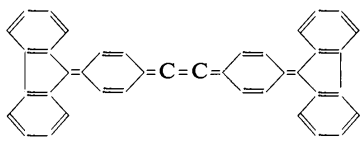
11) E. Müller and E. Tietz, *Ber.*, **74**, 807 (1941).

curve is presented in Fig. 2. The ultraviolet spectrum of the peroxide was found to be closely related with that of the glycol VIII illustrated in Fig. 3. The peroxide solution was chromatographed on alumina, and colorless needles (m. p., 175~177°C) were isolated; these were proved to be identical with the glycol (VIII; m. p., 179~179.5°C) by a mixed melting point determination (mixed m. p., 173~178°C). The mode of the formation of the glycol VII is not clear, but it seems to arise from the peroxide XXI by a decomposition on the surface of alumina.

The ultravoilet spectrum of IV could not be measured accurately because of the unstable nature of IV. A fairly rapid change in absorption intensity was observed during the course of the measurement. Approximate absorption maxima were found at the wavelengths of 750, 678, 590 (strongest) and 439 mμ.

The Attempted Formation of 4, 4-Bis-(9''-fluorenylyl)-tolan (XXII).—The replacement of the diphenylmethylyl group in IV by a 9-fluorenyl group constitutes an interesting system XXII, which can be regarded as an acetylenic analogue of Theilacker's hydrocarbon IX[5e]. It was hoped that the terminal fluorenyl groups might stabilize the quinomethane structure, but all attempts to remove the chlorine atoms from the dichloride XI or to subtract the hydroxyl groups from the glycol X failed. No developement of an intense color was observed under various reaction conditons.



XXII

The Formation of 1-Benzhydryliden-4-(3', 3'-diphenylpropadienyliden)-1, 4-dihydrobenzene (V_a).—Powdered anhydrous stannous chloride was added to a dilute solution of the dichloride XVIII in benzene, and the mixture was shaken for several hours. A small quantity of black-violet needles with a greenish surface luster was isolated from the reaction mixture. It was found that this substance was contaminated with a small amount of chlorine compound, but the impurity could not be removed by chromatography on alumina or by treatment with molecular silver. The ultraviolet spectrum of this substance is illustrated in Fig. 4, together with those of the related compounds. The stability of this substance in the solid state or in a benzene solution suggests the quinomethane structure of the substance V_a. However, it was observed that the reddish-violet color of a benzene solution of V_a rapidly

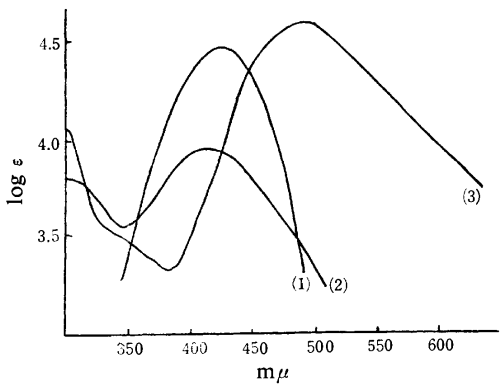


Fig. 4. The ultraviolet spectra of (1) Thiele's hydrocarbon (XXIII), (2) the mono-radical (XXV) and (3) the quino-cumulene (V_a).

changed to light brown on exposure to light. The measurement of the ESR spectrum showed no signal, indicating the absence of the biradical structure V_b.

The characteristic features of the infrared spectrum of V_a are the absence of cumulenic absorption (1900~2050 cm^{-1})[12] and the presence of strong absorptions at 822 and 1365 cm^{-1}. The absorption at about 800 cm^{-1} is usually attributed to the out-of-plane deformations of the two adjacent hydrogen atom in a para-disubstituted benzene derivative. This argument, however, is not consistent with the structure of V_a, in which the disubstituted six-membered ring has a cyclohexadiene structure. The infrared spectrum of Thiel's hydrocarbon[13], which has been regarded as having a quinomethane structure XXIII, also exhibits absorption at 831 cm^{-1}. Quite recently, it was

XXIII

found that *cis*-1, 3, 5-hexatriene showed a strong absorption in this region (818 cm^{-1}) which was lacking in the spectrum of the trans-isomer[14]. Therefore, the strong absorption at 822 cm^{-1} in V_a may reasonably be attributed to the out-of-plane deformation of the hydrogen atoms of the conjugated cis-double bonds in the cyclohexadiene structure.

A solution of the dichloride XVII in benzene was treated with molecular silver at 60°C, resulting in a deep brown solution. The solution was passed through a column of alumina, and the filtrate was evaporated, affording a red-brown solid. The free radical nature of

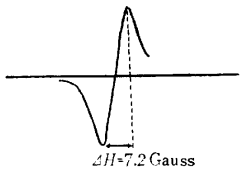

Fig. 5. The ESR spectrum of the mono-radical (XXV).

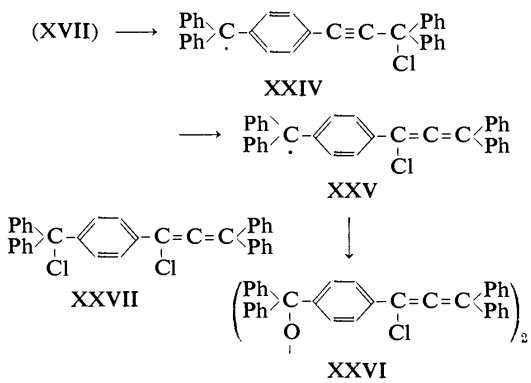
this substance was revealed by an ESR measurement employing a specimen which had been kept in an evacuated desiccator for two days (Fig. 5). The sharp and highly symmetrical absorption curve suggests that the radical center should not be an oxygen atom, but it concerns a carbon radical. The analytical data ($C_{34}H_{24}OCl$) indicates the presence of chlorine and oxygen in the molecule. From these observations, it seems highly probable that the red-brown solid consists mainly of the peroxide XXVI, containing a small amount of the mono-radical XXV. The remaining chlorine atom seems, in view of its inertness to molecular silver, to attach to an unsaturated carbon atom. There are two possibilities of the formation of such a rearranged product. One of



them is that the starting dichloride was already a mixture of XVII and the rearranged dichloride XXVII which had been formed during the course of the displacement of the hydroxyl groups by chlorine atoms. Another is the rearrangement of XXIV to the isomeric radical XXV by the catalytic action of molecular silver.

Attempts to form 1, 4-Bis(3', 3'-diphenyl-1'-propadienyliden)-1, 4-dihydrobenzene (VI_a) or 1, 4-bis(3', 3'-diphenyl-1'-propynylyl)-benzene (VI_b).—Recently, Ried has reported that the treatment of 1, 4-bis(3'-hydroxy-3', 3'-diphenyl-propynyl)-benzene (XIX) with Stephen's reagent resulted in the formation of a dark red solution. He has assigned the biscumulene structure VI_a to the reaction product on the basis of the stable color of the solution[10]. The initially-developed blue color of the reaction mixture rapidly changed to red-violet, then to reddish-brown, and finally to brown. When the glycol XIX in tetrahydrofuran was mixed with Stephen's reagent in the same solvent at −70°C, the immediate development of a transient, deep violet-blue color was observed; this color rapidly changed to red-violet, then to orange-red. The orange-red color of the solution changed to blood-red gradually at −70°C or rapidly at room temperature. The blood-red solution was found to be fairly stable, but it gradually changed to a yellow-brown solution on exposure to air at room temperature. The electronic spectra of the deep violet-blue and the red-violet solutions could not be determined because of their instability. The blood-red and the yellow-brown solutions exhibited the absorption maxima at 284, 482 mμ and 328, 540 mμ respectively. The absorption of the yellow-brown solution coincides with the reported values (333.0 and 539.5 mμ)[10]. Ried has assigned the structure of VI_a to this substance, but, as has been mentioned above, the yellow-brown solution is the ultimate stage of the complex color change in the transformation of the glycol XIX. Therefore, it seems highly probable that the yellow-brown solution consists mainly of a decomposition or a polymerization product. The absorption maximum of the bloodred solution (482 mμ) shifted to a shorter wavelength than that of V_a (492 mμ). In view of the presence of the more extended conjugate system in VI_a, this fact seems to exclude the possibility of the existence of the quinocumulene (VI_a) in the blood-red solution.

The treatment of the dichloride XX with various kinds of dehalogenation reagents, such as zinc dust, mercury, molecular silver, or anhydrous stannous chloride in benzene, tetrahydrofuran or dioxane, gave unsatisfactory results.

It was found from the above-mentioned experiments that the isolation of the reaction product in substantia was difficult, but the extremely unstable nature of the reaction product of the glycol XIX seems to suggest the transient formation of the biradical VI_a.

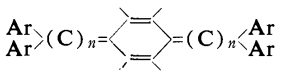
Discussion

As has already been mentioned, the ESR spectrum of IV showed a strong signal, indicating the presence of the double doublet IV_a[5b], which may be in an equilibrium with the quinocumulene structure IV_a. This finding indicates that the resonance energy of the central benzene nuclei in IV is large enough to prevent the complete interaction of the two unpaired electrons through the conjugate π-electron system which necessarily accompanies

the transformation of benzenoid to the *p*-quinoid structure of the central nuclei. The stable triphenylmethyl structure of the radical center in IV_b may also contribute to the stabilization of IV_b.

In the case of the dechlorination of XVII, the product could be isolated in substantia and the structure of V_a assigned on the basis of analytical and ESR evidence. Although the possibility that this substance exists in a triplet state can not be excluded, the high stability of V to air in a pure state seemed to reflect the singlet state, at least at room temperature.

Recently, various kinds of stable quinocumulenes of type XXVIII bearing anthracene or pentacene nucleus in the center of the molecule have been synthesized[10,15]. VI can be regarded as a parent compound of these quinocumulenes. Therefore, it was expected that VI might



XXVIII

form a more stable quinocumulene (VI_a) than V or IV. In fact, however, the dehydroxylation of the glycol XIX gave an extremely unstable product. Because it has been well recognized that the tendency of polyacene to form a quinoid structure is more pronounced than that of benzene or naphthalene, the marked difference between XXVIII and VI seems to be attributable to the difference in the delocalization energy which accompanies the trasformation of the central aromatic system to the quinoid structure. Also, the instability of the radical seems to be related to the lack of a triphenylmethyl structure in the radical center of VI_b.

Experimental*

4, 4'-Bis(diphenylhydroxymethyl)-tolan (VII).—4, 4'-Dibromotolan was prepared according to the method of Barber[9]. The tolan (5.0 g., 0.015 mol.) in anhydrous ether (50 ml.) was mixed with *n*-butyllithium (0.04 mol.) in the same solvent (35 ml.) in an atmosphere of nitrogen. After the solution had been stirred for 15 min. at room temperature, a solution of benzophenone (6.0 g., 0.033 mol.) in anhydrous ether (50 ml.) was added drop by drop over a one-hour period, resulting in a light yellow solution. The reaction mixture was then refluxed for an hour. After standing overnight, the mixture was stirred a further 2 hr. at room temperature and 1.5 hr. under reflux. A saturated solution of ammonium chloride was added to the reaction mixture, and the organic layer was worked up according to the usual manner, affording a light yellow solid (10.0 g.). The solid was crystallized from benzene-petroleum benzine (1 : 1), yielding colorless grains; m. p., 177~179°C (8.1 g., quantitative). Further recrystallization from the same solvent gave an analytical specimen; m. p., 179~179.5°C.

Found: C, 88.57; H, 5.39. Calcd. for $C_{40}H_{30}O_2$: C, 88.53; H, 5.57%.

4, 4'-Bis(diphenylchloromethyl)-tolan (VIII).—Thionyl chloride (20 ml., 32.8 g.) was added to the suspension of the above-mentioned glycol (VII), (1.6 g., 0.003 mol.) in benzene (40 ml.). The mixture was refluxed for 2 hr., resulting in a brownish pink solution. The volatile material was removed under reduced pressure. The residue was dried over potassium hydroxide in an evacuated desiccator and then dissolved in benzene-petroleum benzine without heating. The solvent was partly removed under reduced pressure at room temperature, yielding crystals. The crystals were treated in the same way, affording pure VIII as light brown cubes; m. p., 198~203°C (1.2 g., 70%).

Found: C, 82.71; H, 4.84; Cl, 12.01. Calcd. for $C_{40}H_{28}Cl_2$: C, 82.89; H, 4.87; Cl, 12.24%.

4, 4'-Bis(9''-hydroxy-9''-fluorenyl)-tolan (X).—In an atmosphere of nitrogen, a solution of *n*-butyllithium in ether (36 ml., 0.042 mol.) was added over a 10-min. period to a solution of 4, 4'-dibromotolan (6.7 g., 0.02 mol.) in ether (60 ml.) and tetrahydrofuran (10 ml.). The blue-white suspension formed was stirred for 15 min., and then fluorenone (7.2 g., 0.04 mol.) in ether (60 ml.) was added drop by drop over a 15-minute period. After being stirred for 1.5 hr. at room temperature, the mixture was left to stand overnight, yielding a yellow brown suspension. The suspension was stirred another hour and then heated under reflux for 1.5 hr. The reaction mixture was decomposed by the addition of a saturated aqueous ammonium chloride. The organic layer was separated, and the aqueous layer was extracted with benzene (300 ml.). The insoluble material was filtered and washed with a small amount of benzene. The solid (8.0 g., m. p., 277~280°C) was recrystallized from aqueous acetone to yield X as colorless needles; m. p., 307~312°C (7.0 g., 64.7%).

Found: C, 89.04; H, 4.61. Calcd. for $C_{40}H_{26}O_2$: C, 89.19; H, 4.87%.

A chromatographic purification of the residue which had been obtained from the combined organic layer afforded a small amount of X.

4, 4'-Bis(9''-chloro-9''-fluorenyl)-tolan (XI).—The glycol (X, 0.5 g.) was added to a mixture of benzene (7 ml.) and thionyl chloride (8 ml.), and the mixture was refluxed for 6.5 hr., resulting in a brown solution. The red brown residue obtained by the evaporation of the volatile material was dried over sodium hydroxide. Recrystallization of the dried material from carbon tetrachloride-petroleum benzine yielded crude XI as brown needles; m. p., 200~226°C (0.3 g.). Further recrystallization from benzene afforded pure XI as brown plates; m. p., 224~226°C (0.2 g., 40%).

* All melting points are uncorrected. The nitrogen used was purified by passing the gas from a commercial steel cylinder through a Fieser solution. The ESR spectra were measured by Dr. S. Onishi in the Osaka Laboratories of the Japanese Association for Radiation Research on Polymers.

Found: C, 83.36; H, 4.15; Cl, 12.48. Calcd. for $C_{40}H_{24}Cl_2$: C, 83.46; H, 4.20; Cl, 12.32%.

***p*-Bromophenylacetylene.**—The acetylene was prepared from *p*-bromoacetophenone according to the well-known method[16].

***p*-Acetylbenzoic Acid (XIII).**—*p*-Cyanoacetophenone (XII, 4.9 g., 0.034 mol.) which was prepared from *p*-bromoacetophenone[9] was heated with 58% sulfuric acid (7.8 g.) at 150°C for an hour. The yellow crystals deposited were recrystallized from boiling water, yielding XIII as yellow long needles; m. p., 207~209°C (3.8 g., 69%); lit. value[17], m. p., 205°C.

***p*-Ethynylbenzamide (XIV).**—A mixture of the acetylbenzoic acid (XIII, 6.6 g., 0.04 mol.), phosphorus pentachloride (19.0 g., 0.09 mol.) and phosphorus oxychloride (8.0 ml.) was refluxed for 2 hr., and the oxychloride was removed under reduced pressure. The residual viscous brown oil was dissolved in ether (100 ml.) and added drop by drop into a solution of sodium amide (prepared from sodium, 6.6 g., 0.29 g. atom) in liquid ammonia (250 ml.) over a 15-min. period. The mixture was kept overnight at −70°C and was then stirred for 8.5 hr. at −33~−40°C. After evaporation of the ammonia, the reaction mixture was decomposed with a saturated aqueous ammonium chloride. The ethereal layer was separated, and the aqueous layer was extracted with ether (200 ml.×5). The combined ether solution was washed with a saturated solution of sodium chloride and dried (Na_2SO_4). Evaporation of the solvent yielded crude XIV as light yellow powder; m. p., 172~173°C (2.7 g., 46.5%). IR ν_{max}, 3440 (NH); 1662, 1630 (-$CONH_2$); 3235 (≡CH); 2250 cm^{-1} (-C≡C).

This was used without further purification for the following reaction.

Methyl *p*-Ethynylbenzoate (XV).—A mixture of the benzamide (XIV, 2.7 g., 0.017 mol.), methanol (40 ml.) and concentrated sulfuric acid (3 ml.) was refluxed for 5 hr. on an oil-bath (110°C). The reaction mixture was poured into water (100 ml.) and extracted with ether (100 ml.×3). The ethereal extracts were successively washed with saturated aqueous solutions of sodium chloride, sodium hydrogen carbonate and sodium chloride and dried (Na_2SO_4). Evaporation of the solvent yielded brown needles; m. p., 88~94°C (2.9 g., 96.6%). The crude crystals were recrystallized from methanol to give pure XVII; m. p., 93~95°C.

Found: C, 74.92; H, 5.02. Calcd. for $C_{10}H_8O_2$: C, 74.99; H, 5.03%.

1-Diphenylhydroxymethyl-4-(3',3'-diphenylhydroxy-1'-propynyl)-benzene (XVI).—*a) From p-Bromophenylacetylene.*—Into a solution of *p*-bromophenylacetylene (6.0 g., 0.03 mol.) in ether (100 ml.) in an atmosphere of nitrogen was added an ethereal solution of *n*-butyllithium (45 ml., 0.07 mol.) over a 30-min. period. The mixture was stirred another hour at room temperature and then refluxed for an hour. Benzophenone (12.0 g., 0.067 mol.) in ether (100 ml.) was added to the mixture over a 40-min. period. The reaction mixture was kept for 2 days at room temperature and then stirred for 1.5 hr. under reflux, resulting in a pale yellow solution with a white precipitate. After decomposition with aqueous ammonium chloride, the ethereal layer was separated, washed with saturated sodium chloride solution, and dried ($MgSO_4$). Evaporation of the solvent resulted in a brown oily material (17.2 g.). A benzene solution of this substance was passed through a column of alumina and eluted with ether containing 1% of methanol. The eluate was evaporated to give a light yellow liquid. The liquid was treated with benzene-petroleum benzine (1 : 1), yielding colorless needles; m. p., 80~86°C (containing benzene of crystallization), 2.8 g. The crystals were heated at 80°C for 5 hr. in vacuo, affording XVI; m. p., 131~132°C. IR ν_{max}, 3400 cm^{-1} (OH).

Found: C, 87.21; H, 5.72. Calcd. for $C_{34}H_{26}O_2$: C, 87.52; H, 5.62%.

The mother liquor obtained by filtrating XVI was distilled, yielding viscous oil; b. p., 193°C/0.008 mmHg, (6.0 g.). Treatment of this substance with *n*-butyllithium, followed by hydrolysis, afforded a viscous oil. The oil could be crystallized by the addition of a small amount of benzene-petroleum benzine. Recrystallization from the same solvent yielded 1, 1, 3-triphenylpropyn-1-ol. It showed no depression of the melting point on admixture with an authentic specimen*. Also, the infrared spectrum was found to be identical with that of the specimen. On the basis of this evidence, the structure of XVIII was assigned to the viscous oil obtained from the mother liquor.

b) From Methyl p-Ethynylbenzoate (XV).—Methyl *p*-ethynylbenzoate (XV, 1.6 g., 0.01 mol.) in ether (30 ml.) was stirred drop by drop into a solution of phenyllithium (0.033 mol. in 35 ml. of ether) under an atmosphere of nitrogen. The mixture was added for 1.5 hr. at room temperature and then refluxed for another hour. To the cooled mixture, benzophenone (1.8 g., 0.01 mol.) in ether (30 ml.) was added. After being left standing overnight, the mixture was stirred for 2 hr. and mixed with a saturated aqueous ammonium chloride. The aqueous layer was extracted with ether (80 ml.× 3) and combined with the ethereal layer. The combined ethereal solution was washed with a saturated sodium chloride solution and dried (Na_2SO_4). Evaporation of the solvent gave a brown viscous oil. This was dissolved in benzene and chromatographed on alumina. Elution with ether containing 1% of methanol, followed by recrystallization from benzene-petroleum benzine, afforded XVI (2.8 g., 61.4%), which was proved to be identical with the specimen obtained by method a) by mixed melting point determination and infrared spectroscopy.

1-Diphenylchloromethyl-4-(3'-chloro-3', 3'-diphenyl-1'-propynyl)-benzene (XVII).—A mixture of XVI (1.5 g., 0.003 mol.), benzene (15 ml.), and thionyl chloride (15 ml.) was refluxed for 2 hr., and the volatile material was removed under reduced pressure. The residue was dried over sodium hydroxide in vacuo, yielding a yellowish brown solid (XVII, 1.5 g.). XVII was also obtained by treating

16) T. L. Jacobs, "Organic Reactions", Vol. 5, 50 (1949).
17) H. Ingle, *Ber.*, 27, 2527 (1894).

* The authentic specimen was kindly supplied by Dr. G. Nakaminami of this Laboratory.

XVI with a mixture of acetyl chloride and hydrochloric acid[5b]. Further purification of XVII by recrystallization was proved to be difficult owing to its unstable nature in the presence of heat and light. The infrared spectrum of the crude XVII lacks the absorption of the hydroxyl group.

1-Benzhydryliden-4-(3', 3'-diphenylpropadienyliden)-1, 4-dihydrobenzene (V_a).—A mixture of finely powdered anhydrous stannous chloride (2.0 g.), XVII (0.4 g.), and benzene (1500 ml.) was shaken for 2 hr.; then fresh anhydrous stannous chloride (2.0 g.) was added, and the shaking was continued for a further 5 hr. The reaction mixture was filtered, and the filtrate was washed with water and then dried over anhydrous sodium sulfate for 30 min. The dried solution was passed through a column (20 cm.) of alumina (25 g.). The filtrate was concentrated under reduced pressure below 40°C, yielding a partly crystallized solid. Treatment of the solid gave a small amount of deep purple needles with a green metallic surface luster. The melting point (ca. 170°C (decomp.)) could not be determined accurately because of its deep color. A qualitative analysis of this substance revealed the contamination of a chlorine compound.

Found: C, 92.96; H, 5.71; Calcd. for $C_{34}H_{24}$: C, 94.41; H, 5.59%.

Formation of 4-(3', 3'-Diphenyl-1'-chloro-propadienyl)-phenyl-diphenylmethyl (XXV) and its Peroxide (XXVI).—A mixture of molecular silver (4.0 g.) and XVII (1.0 g.) in benzene was stirred at 60°C for 2 hr. in an atmosphere of nitrogen in a dark place, forming a dark brown solution. The molecular silver was removed by filtration, and the filtrate was passed through a column (20 cm.) of alumina (25 g.). The red-violet filtrate thus obtained was concentrated under reduced pressure in a nitrogen atmosphere, yielding a dark brown solid (0.1 g.). The solid gradually changed to a red-brown solid on being kept in an evacuated desiccator.

Found: C, 84.11; H, 4.74; Cl, 7.49. Calcd. for $C_{34}H_{24}ClO$: C, 84.36; H, 4.99; Cl, 7.33%.

After 2 days, the substance was subjected to ESR measurement without further purification.

1, 4-Bis-(3'-hydroxy-3', 3'-diphenyl-1'-propynyl)-benzene (XIX).—This substance was prepared according to the method of Ried[10] by the action of benzophenone (14.5 g.) on the dilithium derivative of *p*-diethynylbenzene (5.0 g.)[18]. Pale yellow plates; m. p., 222~226°C (11 g., 56%) (lit. values, m. p., 226°C, 56%)[10].

1, 4-Bis(3'-chloro-3', 3'-diphenyl-1'-propynyl)-benzene (XX).—Hydrogen chloride was introduced for 30 min. into a mixture of XIX (1.0 g.), ether (80 ml.), tetrahydrofuran (20 ml.) and acetyl chloride (0.5 ml.). The mixture was allowed to stand overnight in an ice-bath. The precipitate formed was filtered and washed repeatedly with cold ether, yielding XX as colorless needles (1.0 g., 91%). This substance decomposed at 130°C, forming a red solid which did not fuse at temperatures over 300°C. Also, the action of thionyl chloride (15 ml.) with a suspension of XIX (0.5 g.) in benzene (15 ml.) at 0.5°C resulted in the formation of XX in a low yield (0.1 g., 18%). Several attempts to purify XX failed, but the absence of a hydroxyl group was proved by infrared spectroscopy.

The authors wish to express their hearty thanks to Dr. Shun'ichi Onishi of the Osaka Laboratories of the Japanese Association for Radiation Research on Polymers for his measurements of the ESR spectra and for his valuable discussions. We are also grateful to Mr. Masakazu Okumiya for his microanalyses.

Synthetic Studies of the Flavone Derivatives. II[1]. *The Synthesis of Meliternatin and Some 3,5-Dimethoxy-6,7-methylenedioxyflavones*[*1]

By Kenji FUKUI and Takashi MATSUMOTO

(Received March 15, 1963)

Meliternatin was first isolated from the bark of *Melicope ternata* by Briggs and Locker[2], together with wharangin, meliternin and ternatin, in 1949; it has also been recently isolated from the bark of *M. mantelli* by Cambie[3]. It has been shown to contain two methoxy groups and two methylenedioxy groups; up to now it has been only known naturally-occurring 3-methoxyflavone containing two methylenedioxy groups. From degradative experiments, Briggs and Locker first identified

it as 3, 5-dimethoxy-7, 8 ; 3', 4'-bismethylenedioxyflavone (I)[2]. On the basis of further experiments[4], however, they proposed the revised formula of 3, 5-dimethoxy-6, 7 ; 3', 4'-bismethylenedioxyflavone (II). It would be interesting to confirm the structure of meliternatin by synthesis.

(IX) R=$COCH_3$

The present report describes the synthesis of meliternatin and some related compounds. The Hoesch condensation of 3-methoxy-4, 5-methylenedioxyphenol (III)[5] and methoxyacetonitrile yielded a ketone, $C_{11}H_{12}O_6$. Two structures (IV and V) were expected for this ketone. Since Folkers et al.[6] have demonstrated that III is condensed with *o*-acetoxybenzylcyanide to given 2'-(6-hydroxy-2-methoxy-3, 4-methylenedioxyphenyl)-benzofuran (VI), it seems probable that III is substituted not at the 6-position but at the 2-position in the Hoesch condensation. Therefore, IV was formed from the reaction with methoxyacetonitrile. In order to elucidate the structure of the ketone, a flavone was prepared with piperonylic anhydride from the ketone. This product did not agree in its properties with 3, 7-dimethoxy-5, 6 ; 3', 4'-bismethylenedioxyflavone (VII) (cf. our succeeding paper). On the basis of this evidence, IV, 6-hydroxy-2, ω-dimethoxy-3, 4-methylenedioxyacetophenone is postulated as the structure for the ketone. Judging from its physical and chemical properties, IV was identical with the ketone which was obtained as the main phenolic product[2] of the action of alcoholic potassium hydroxide on meliternatin. According to Allan and Robinson's flavone synthesis[7], the condensation of IV with piperonylic anhydride in the presence of potassium piperonylate, followed by treatment with alcoholic potassium hydroxide, afforded the desired flavone II, whose identity with natural meliternatin was confirmed by mixed melting point, infrared and ultraviolet spectral comparison (Table I, Fig. 1 and Fig. 2). Synthetic meliternatin was also characterized as 5-demethyl compound VIII and its acetate IX (Table I).

By a similar method, the condensation of the ketone IV with acid anhydrides (benzoic anhydride, anisic anhydride, veratric anhydride and trimethylgallic anhydride) in the presence of the potassium salt of the corresponding acids gave 3, 5-dimethoxy-6, 7-methylenedioxyflavone (X), 3, 5, 4'-trimethoxy-6, 7-methylenedioxyflavone (XI), 3, 5, 3', 4'-tetramethoxy-6, 7-methylenedioxyflavone (XII) and 3, 5, 3', 4', 5'-pentamethoxy-6, 7-methylenedioxyflavone(XIII) respectively. These flavones gave a negative ferric chloride reaction and were soluble in concentrated sulfuric acid to a yellow solution.

Experimental[*2]

6-Hydroxy-2, ω-dimethoxy-3, 4-methylenedioxyacetophenone (IV).—A mixture of 3-methoxy-4, 5-methylenedioxyphenol (III) (790 mg.)[5], methoxyacetonitrile (0.4 g.) and anhydrous zinc chloride (0.7 g.) in anhydrous ether (40 ml.) was saturated with dried hydrogen chloride at 0°C and allowed to stand overnight. The ethereal solution was decanted from the oily layer of ketimine hydrochloride, which had separated. The oily layer was washed twice with dry ether and heated on a steam bath with water (40 ml.) for 30 min. After cooling and standing, the product was collected and recrystallized from ethanol giving IV (m. p., 140～142°C) (reported m. p., 142～144°C[2]) (golden yellow prisms), which showed a dark green ferric chloride reaction in ethanol; yield, 460 mg.

IR 1640～1606 (broad) (C=O), 1046 (=C-O-C), 930 (O-CH_2-O) cm^{-1}.

Found: C, 55.15; H, 5.13. Calcd. for $C_{11}H_{12}O_6$: C, 55.00; H, 5.04%.

Meliternatin (3,5-Dimethoxy-6,7;3',4'-bismethylenedioxyflavone) (II).—Ketone IV (240 mg.), piperonylic anhydride (780 mg.) and potassium piperonylate (300 mg.) were ground together and heated at 170～180°C under reduced pressure for 3.5 hr. The reaction mixture was then ground and boiled with 10% aqueous alcoholic (1 : 9) potassium hydroxide (20 ml.) for 7 min. After the removal of the solvent in vacuo, water (10 ml.) was added to the pasty mass. The precipitated solid was collected, washed with water, and recrystallized from ethanol, giving II (m. p., 196～197°C) (colorless needles), which gave a negative ferric chloride reaction in ethanol; yield, 120 mg. The melting point was undepressed on admixture with natural meliternatin kindly supplied by Dr. Cebalo.

IR 1640 (C=O), 1033 (=C-O-C), 921 (O-CH_2-O) cm^{-1}. UV λ_{max}^{EtOH} mμ (ε×10^{-4}); 248 (1.86), 270[*3] (1.31), 337 (2.73).

Found: C, 61.98; H, 3.90. Calcd. for $C_{19}H_{14}O_8$: C, 61.62; H, 3.81%.

According to the method of Briggs and Locker[4], II was demethylated with aluminum chloride to the 5-demethyl derivative VIII (m. p., 256～257°C) (reported m. p., 258～258.5°C[3]) (slender yellow needles). IR 1678 (C=O), 1026 (=C-O-C), 929 919 (O-CH_2-O) cm^{-1}.

Found: C, 60.42; H, 3.50. Calcd. for $C_{18}H_{12}O_8$: C, 60.68; H, 3.40%.

With acetic anhydride and pyridine, VIII gave the acetate IX (m. p., 205～206°C) (reported m. p., 208.5～210°C[4]) (pale yellow needles).

Found: C, 60.33; H, 3.76. Calcd. for $C_{20}H_{14}O_9$: C, 60.30; H, 3.56%.

3, 5-Dimethoxy-6, 7-methylenedioxyflavone (X).—From ketone IV (360 mg.), benzoic anhydride (700 mg.) and potassium benzoate (400 mg.), synthesis was carried out by a method similar to that used for II. Recrystallization from ethanol gave X (m. p. 192.5～193.5°C) (colorless needles); yield, 180 mg. IR 1624 (C=O), 1013 (=C-O-C), 920 (O-CH_2O) cm^{-1}. UV λ_{max}^{EtOH} mμ (ε×10^{-4}); 251[*3] (1.63), 268.5 (1.99), 314 (1.98).

Found: C, 66.06; H, 4.36. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

3, 5, 4' - Trimethoxy - 6, 7 - methylenedioxyflavone (XI).—Ketone IV (360 mg.), anisic anhydride (860 mg.) and potassium anisate (430 mg.) were treated with the same procedure as has been described for II. Recrystallization from ethanol gave XI (m. p., 184～185°C) (colorless needles); yield, 150 mg. IR 1638 (C=O), 1034 (=C-O-C), 925 (O-CH_2-O) cm^{-1}. UV λ_{max}^{EtOH} mμ (ε×10^{-4}); 272 (1.70), 328 (2.85).

Found: C, 64.04; H, 4.57. Calcd. for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%.

[*2] All melting points are uncocrrected; the infrared spectra were measured in Nujol.

[*3] Inflection point.

3, 5, 3′, 4′ - Tetramethoxy - 6, 7 - methylenedioxyflavone (XII). — Ketone IV (360 mg.), veratric anhydride (1.00 g.) and potassium veratrate (500 mg.) were treated with the above method. Recrystallization from ethanol gave XII (m. p.. 172~173°C (dried at 100°C)) (pale yellow needles); yield, 110 mg. IR 1621 (C=O), 1016 (=C-O-C), 930 cm^{-1} ($O-CH_2-O$). UV λ_{max}^{EtOH} $m\mu$ ($\varepsilon \times 10^{-4}$); 247 (1.87), 269*[3] (1.48), 335 (2.69).

Found: C, 62.03; H, 4.69. Calcd. for $C_{20}H_{18}O_8$: C, 62.17; H, 4.70%.

3, 5, 3′, 4′, 5′-Pentamethoxy - 6, 7-methylenedioxyflavone (XIII).—Ketone IV (360 mg.) trimethylgallic anhydride (1.20 g.) and potassium trimethylgallate (600 mg.) were treated with the above method. Recrystallization from acetone gave XIII (m. p., 226~227°C) (colorless needles); yield, 150 mg. IR 1635 (C=O), 1018 (=C-O-C), 925 ($O-CH_2-O$) cm^{-1}. UV λ_{max}^{EtOH} $m\mu$ ($\varepsilon \times 10^{-4}$); 244 (1.57), 275 (1.37).

Found: C, 60.42; H, 4.95. Calcd. for $C_{21}H_{20}O_9$: C, 60.57; H, 4.84%.

The authors are grateful to Dr. T. P. Cebalo, the University of Auckland, for his gift of a specimen of natural meliternatin. Grateful acknowledgement is also made to the members of the Microanalytical Center of Kyoto University, and to Mr. Ichiro Nitta for his technical cooperation. The cost of this research was partly defrayed by the Scientific Research Expenditure Found of the Ministry of Education, to which the author's thanks are due.

The Spectrophotometric Determination of Aluminum with Xylenol Orange[1]

By Makoto Otomo

(Received November 5, 1962)

Various workers have proposed a variety of reagents for aluminum determination, including aluminon[2], hematoxylin[3], pontachrome blue black R[4], oxine[5], eriochrome cyanine R[6,7], quinalizarin[8], alizarin S[9], arsenoazo[10], cupferron[11], stilbazo[12], quercetin[13] and morin[14]. Of these reagents, the most promising one appears to be eriochrome cyanine R[15], which is sensitive for 0.004 μg. of aluminum per cm^2 for log $I_0/I=0.001$.

The present paper describes a new spectrophotometric method for the determination of aluminum, based on the highly sensitive color reaction of xylenol orange with aluminum in an acetate buffer solution. The development of the method includes a study of the effects of pH value, reagent concentration and foreign ions. The composition of the complex is also discussed.

It is found that, for aluminum, xylenol orange is a more sensible reagent than eriochrome cyanine R.

Experimental

Reagents. — An aluminum stock solution was prepared by dissolving aluminum nitrate crystals of analytical grade in dilute nitric acid; it was then standardized against a standard EDTA solution[16]. It was diluted with water to desired concentrations.

Acetic acid and sodium acetate solutions were used for all pH adjustments.

Apparatus. — Spectrophotometric measurements

were made with a Hitachi Model EPV-2 spectrophotometer, using 1 cm. glass transmission cells.

All experiments were carried out at 25±0.5°C.

Procedure. — To an aliquot portion of the aluminum nitrate solution in a 50 ml. Erlenmeyer flask, 10 ml. of a pH 3.4 buffer solution and 2 ml. of a 1×10^{-3} M xylenol orange solution were added. The solution was heated on a boiling water bath for a few minutes, cooled with water to room temperature, and transferred to a 25 ml. volumetric flask. The volume of the content was then made up to the mark with water. After the solution had been kept for about 15 min. in a 25°C thermostat, the absorbance of the solution was measured at 536 mμ using a reagent blank.

Results and Discussion

Absorption Spectra. — Figure 1 shows the absorption spectra of solutions containing 6.2 μg. of aluminum with xylenol orange added in various amounts up to 6×10^{-5} M. These spectra show an isosbestic point at 536 mμ. The absorption maximum at about 555 mμ shifted slightly towards a shorter wavelength,

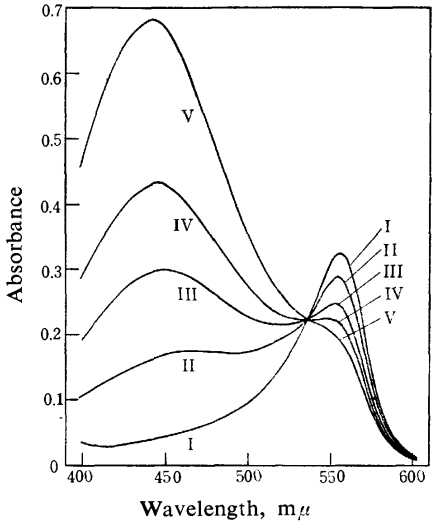

Fig. 1. Absorption spectra of aluminum-xylenol orange at pH 3.4.
Al: 6.2 μg.
XO concn.: I, 1×10^{-5} M; II, 2×10^{-5} M; III, 3×10^{-5} M; IV, 4×10^{-5} M; V, 6×10^{-5} M

and the extinction coefficient at this wavelength decreased, with increasing amounts of xylenol orange. From these observations it is expected that, by adding an xylenol orange solution in excess, a new complex other than one with an absorption maximum at about 555 mμ may be formed. The optimum pH range for the color development was found to be 3.4±0.1.

Effect of Heating. — As in the case of the titration of aluminum with EDTA[17], the color reaction of xylenol orange with aluminum was very slow at room temperature. About 4 hr. were required for complete color development. When a solution containing xylenol orange and aluminum was heated on a boiling water bath, however, the reaction was greatly accelerated, and the maximum color development was obtained within only a few minutes.

Stability of Color.—The absorbance of the solution of the aluminum-xylenol orange complex at 555 mμ decreased gradually with the time of standing. About 10% of its intensity was diminished within the first 2 hr., and about 2% within an additional 2 hr. However, the absorbance at the isosbestic point of 536 mμ remained constant for several hr.

The Effect of Reagent Concentration. — In order to study the effect of the concentration of xylenol orange, a series of absorbances was measured under various concentrations of xylenol orange, using water and reagent blanks of the same concentration as points of reference. At 555 mμ, as is shown in Fig. 2, the maximum absorbance is obtained with a molar ratio of the reagent to aluminum of 1 : 1. Above this ratio, the additional reagent decreases the absorbance greatly, showing that a complex other than a 1 : 1 complex may be formed in this region. However, the absorbance at the isosbestic point of 536 mμ is not affected by the amounts of xylenol orange. In the actual aluminum determination, therefore, 2 ml. of a 1×10^{-3} M reagent solution were used, and the absorbance measurements were made at 536 mμ.

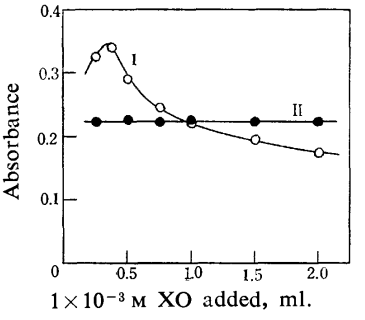

Fig. 2. Effect of reagent concentration.
Al: 6.2 μg. I: 555 mμ II: 536 mμ

Calibration.—Measurements of the absorbance were made with a number of colored solutions containing varying amounts of aluminum. Figure 3 shows that Beer's law is obeyed over the range 5 to 25 μg. of aluminum. The sensitivity is 0.001 μg. of aluminum per cm² for $\log I_0/I=0.001$. The molar extinction

17) K. Ueno, ibid., p. 205.

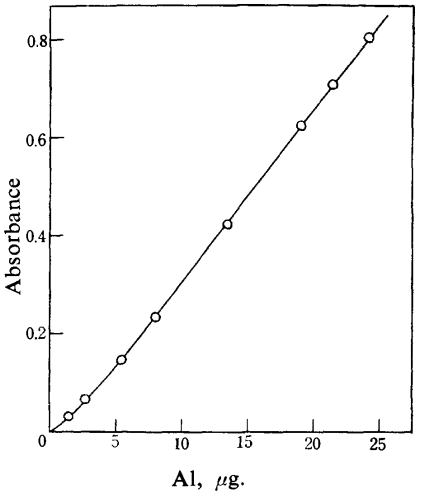

Fig. 3. Calibration curve at 536 mμ.

coefficient is 21100. Of the reagents proposed for aluminum determination, xylenol orange seems to be the most sentitve.

The Effect of Anions.—The effect of 15 cations was studied, along with that of the corresponding sodium salts. Chloride and nitrate ions did not interfere. Large amounts of sulfate, phosphate, tartrate and citrate reduced the absorbance considerably. Such anions as fluoride, nitrilotriacetic acid (NTA) and EDTA could form more stable complexes with aluminum than xylenol orange, giving very low results.

The Effect of Cations.—In order to test the effect of diverse cations upon the aluminum determination, absorbance measurements were made for the solutions containing 13.0 μg. of aluminum and 0.5 μmol. of several cations. The results are presented in Table I. Some of cations tested produce a red color, giving too high results. This is the only weak point in applying the present method to aluminum determination. However, the interferences from some cations such as chromium and nickel can be tolerably eliminated by shortenning the time of heating for color development and prolonging the time of standing.

The Composition of the Complex.—As has been suggested above, two complexes which differ in composition are probably in equilibrium with each other. From Fig. 2, one of them seems to be a 1 : 1 complex.

In order to observe the spectral changes on varying pH values, absorption curves for the aluminum complex were prepared at various pH values, using the reagent blanks of the same concentration and pH value. The results are shown in Fig. 4. The absorption maximum at 555 mμ arising at pH 2 to 2.5 is shifted towards a shorter wavelength with an increase

in the pH value; at pHs 3.0, 4.0 and 4.5 to 5.5, the maxima are found at about 520, 510 and 505 mμ respectively. These shifts in absorption maximum mean that probably two species of absorbing entity are involved; the one is a complex having an absorption maximum at about 555 mμ, which is formed at pH

below 3, while the other is one having a maximum at about 505 mμ, which is formed at pH above 4.5.

Figures 5 and 6 indicate the absorption spectra at pHs 2.0 and 5.0 respectively. In both cases, the spectra were prepared with solutions containing 0.5, 1 and 2 parts of xylenol orange to one part of aluminum, using

water as a reference. No change in the position of the absorption maximum is observed, when 1 : 2 and 1 : 1 are the molar ratios of xylenol orange to aluminum. Almost the same position of the absorption maximum is obtained at pH 2.0, even if the ratio is changed to 2 : 1. At pH 5.0, however, as is shown in Fig. 6, the absorption maximum at 555 mμ fades away to give a new maximum at a shorter wavelength when the ratio is changed to 2 : 1. The appearance of this new band means that, in a higher pH region, a new complex is also formed by adding xylenol orange in a slight excess.

Figures 7 and 8 show plots of the results obtained by applying the method of continuous variations. These results indicate that only a 1 : 1 complex is formed at pH 2.0 and a 1 : 2 complex at pH 5.0. Although the data are not, because of the large corrections for the absorption of xylenol orange, precise enough to permit a further interpretation of the plots in Fig. 8, it is possible to consider that a small amount of 1 : 1 complex is also formed, even at pH 5.0.

From Figs. 5 to 8, it may be concluded that the complex formed at pH less than 3 has a different composition from one formed in a higher pH region. Namely, one of them has 1 : 1 as the ratio of the reagent to aluminum, and the other is a mixture of 1 : 1 and 1 : 2 complexes. It seems that formation of the 1 : 1 complex gradually diminishes with increasing pH value, whereas the 2 : 1 complex increases with pH. Similar relations were also observed for gallium- and thallium-xylenol orange complexes[18].

Summary

Aluminum reacts with xylenol orange in a slightly acidic solution to form two red complexes which are in equilibrium with each other. At pH 3.4±0.1, Beer's law is obeyed up to an aluminum concentration of 1.0 p.p.m. in 1 cm. absorption cells. The absorbance was measured at the isosbestic point of 536 mμ. The molar extinction coefficient was found to be 21100. This method seems to be the most favorable one for aluminum determination if the aluminum is first separated from any interfering ions. The composition of the complexes has also been discussed.

The author wishes to express his hearty thanks to Professor Kôichi Tonosaki for his kind guidance, to Mr. Yasuo Watanabe for his assistance, and to Dr. Kengo Uchida of the Faculty of Science, Tohoku University, for his helpful discussion.

The Surface Activities of Bivalent Metal Alkyl Sulfates. II. The Solubilization of Some Hydrocarbons in Aqueous Solutions of Bivalent Metal Alkyl Sulfates

By Iwao SATAKE and Ryohei MATUURA

(Received February 25, 1963)

In a previous paper[1], we studied some basic surface chemical properties of bivalent metal alkyl sulfate detergents in aqueous solutions. It was found that the critical micelle concentrations (CMC) of bivalent metal alkyl sulfates are nearly independent of the kind of bivalent metals and considerably smaller than that of corresponding monovalent metal alkyl sulfates; light-scattering experiments indicated that the micellar aggregation number of various bivalent metal dodecyl sulfates lies in the comparatively narrow range from 100 to 120, about 2 to 3 times higher than that of sodium dodecyl sulfate (SDS) reported by some authors[2-4]. In this connection it seemed interesting to study the solubilizing power of the bivalent metal alkyl sulfates, since the phenomenon of solubilization is generally considered to have much to do with the micelle formation in the detergent solution. The solubilization of substances by various detergents has widely been studied by a number of authors, and the general features of the phenomena have been summarized, for example, in the critical reviews of Klevens[5] and Hutchinson[6]. However, no data have been published on the solubilization by the solutions of ionic detergents containing bivalent metals. The purpose of the present paper is to determine the solubilizing powers of some bivalent metal alkyl sulfates towards some typical hydrocarbons, and to discuss the differences, if any, among them.

Experimental

Materials.—The detergents used in the present experiment are copper(II), cobalt(II), magnesium-(II) and nickel(II) dodecyl sulfates, and copper(II) tetradecyl sulfate. The preparation and the results of elementary analysis have previously been reported[1]. The values of CMC are 1.2×10^{-3} mol./l. at 30°C for all the bivalent metal dodecyl sulfates used and 2.5×10^{-4} mol./l. at 47°C for copper tetradecyl sulfate. For the sake of comparison, the solubilizing power of sodium dodecyl sulfate (CMC, 7.2×10^{-3} mol./l.) was also measured. Benzene, toluene, *m*-xylene and *n*-hexane were used as solubilizates. They were purified by distillation.

Method.—The maximum amounts of hydrocarbons solubilized at any given temperature and the detergent concentration were determined optically as follows: a series of vessels, each containing

10 ml. of a detergent solution of a fixed concentration with an increasing amount of the hydrocarbon added, is shaken at a constant temperature for several hours. It took about six hours for the solubilization to reach an equilibrium. Then the turbidities of the solutions were measured using a Hitachi Photoelectric Photometer EPO-B at 430 mμ for copper and magnesium salts, at 610 mμ for cobalt salt, and at 500 mμ for nickel salt. The turbidity of the solution rose sharply when a definite amount of the hydrocarbon was added. Figure 1 shows the typical turbidity curve of

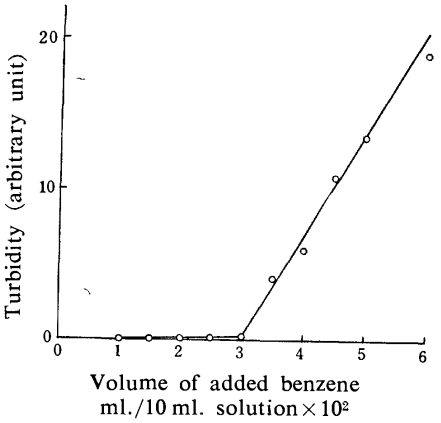

Fig. 1. Typical turbidity curve for benzene in 3×10^{-3} mol./l. copper dodecyl sulfate solution at 30°C.

benzene in 3×10^{-3} ml./l. copper dodecyl sulfate at 30°C. The apparent amount of hydrocarbon solubilized can be determined by the interpolation of the two linear portions of the turbidity curve. Then the net amount of hydrocarbon solubilized is obtained by subtracting the solubility of hydrocarbon in pure water from the apparent amount of solubilization.

The measurements were conducted at 30°C or above for bivalent metal dodecyl sulfates and at 40°C for copper tetradecyl sulfate in order to make experiments above the Krafft point of each detergent[1,7].

Results and Discussion

In Figs. 2 and 3, the amount of benzene solubilized in grams per liter of solution is plotted against the detergent concentration at 30 and 40°C respectively. For the sake of comparison, the amount of benzene solubilized by the SDS solution is also shown. The amount of benzene solubilized by bivalent metal dodecyl sulfates is found to be much larger than that by SDS, and only small differences in solubilizing power can be observed among the different bivalent salts. As has previously been reported[1], the nature of bivalent metal

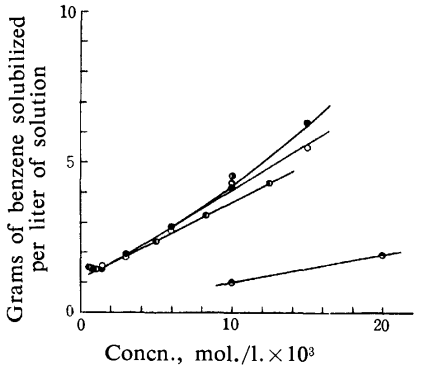

Fig. 2. Solubilization of benzene in aqueous solutions of bivalent metal dodecyl sulfates at 30°C.
○ ; Copper ● ; Cobalt ◐ ; Magnesium

○ ; Copper ● ; Cobalt ◐ ; Magnesium
◓ ; Sodium

has no detectable effect on CMC. Thus, all the bivalent salts used had the identical CMC value of 1.2×10^{-3} mol./l., which is quite small compared with the value of 8×10^{-3} mol./l. for SDS. In addition, the micellar aggregation numbers of bivalent salts determined by a light-scattering experiment[1] are 97 for copper, 114 for cobalt, 118 for magnesium and 106 for nickel, aggregation numbers which are 2 to 3 times those for SDS[2-4]. The marked increase in the solubilizing power of bivalent metal dodecyl sulfates may reasonably be explained in terms of the increased micellar aggregation numbers.

A nearly linear relation is observed between the amount of benzene solubilized and the detergent concentration. Mankowich[8] has pointed out that there are linear relations between log of solubilized amount and log of concentration for dye solubilization by various detergents,

7) S. Miyamoto, This Bulletin, 33, 371 (1960).

8) A. M. Mankowich, *J. Colloid Sci.*, 14, 131 (1959).

but he has given no theoretical considerations. In a narrow concentration range as in the present experiment, the micellar aggregation number and the micellar size may be assumed to be independent of the detergent concentration, as is shown by the light-scattering experiment[1]. If this is true, a linear relation between the amount of benzene solubilized and the detergent concentration is most probable. The slope of these lines indicates the amount of benzene solubilized per mole of micelle-forming detergent molecules. The available volume, v, for the solubilization in a micelle of a solubilized state can be evaluated from the micellar aggregation number, n, and the slope of these lines, provided that the partial molar volume of the solubilizate is assumed to be nearly identical with the molar volume of its pure state. The value of v is given by nmV/ZN, in which V is the molar volume of benzene; m, the number of moles of benzene solubilized per mole of micelle-forming detergent molecules; Z, the valency of gegen ions, and N, the Avogadro number. The values of v thus calculated are about $(3\sim4)\times10^4$ Å^3 for bivalent metal dodecyl sulfates and about $(7\sim9)\times10^3$ Å^3 for SDS, when we use the values of m taken from Figs. 2 and 3. In the calculation of the v for the SDS micelle, we take the micellar aggregation number of 40. Then the available volume for solubilization in a micelle of bivalent metal dodecyl sulfates is about four times that of the SDS micelle.

Now, we assume the spherical micellar models for both SDS and bivalent metal dodecyl sulfates; further, the area, s, which is occupied at the micellar surface by a polar head of a micelle-forming detergent molecule is assmed to be nearly independent of the micellar aggregation number and the nature of gegen ion. Therefore, the geometrical volume of a spherical micelle is given by $(ns)^{3/2}/6\pi^{1/2}$. If, therefore, the micellar aggregation number, n, is increased, the volume of the spherical micelle will be increased being proportional to $n^{3/2}$. Thus, the ratio of the available volume for solubilization in a micelle may be expected to be proportional to $(n_1/n_2)^{3/2}$, because the available volume for solubilization would be proportional to the total micellar volume. Here n_1 and n_2 are the micellar aggregation numbers of SDS and of bivalent salt respectively. In the present case, the ratio of the micellar aggregation number is taken to be about 2.5 to 3.0, from which the ratio of the micellar volume may be estimated to be 4 to 5. Thus, the experimental results obtained above may approximately be explained by the simple spherical micellar model of the detergent.

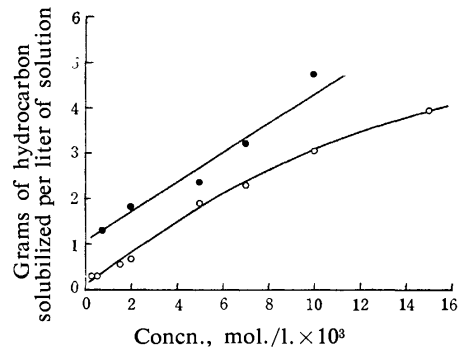

Fig. 4. Solubilization of toluene and n-hexane in aqueous solution of coopper dodecyl sulfate at 40°C.
○; Toluene ●; n-Hexane

The increase in the molar volume of the solubilizate has the normal effect of decreasing the solubilization. Figure 4 shows the amounts of toluene and n-hexane solubilized by copper dodecyl sulfate at 40°C. Table I gives the effect of the size of the solubilizate on the solubilization by metal dodecyl sulfates at 30°C. The effect of the molar volume of the solubilizates on the extent of solubilization has been investigated by several authors[5,9,10]. Especially, Harkins et al.[9] pointed out, on the basis of their solubilization experiments on a number of hydrocarbons using potassium laurate and myristate, that the amount of hydrocabon solubilized is inversely proportional to the molar volume of the solubilizate so far as the same homologous series is concerned. In the present experiment, however, one can find no such simple relationships between the molar volume and the amount of hydrocarbon

solubilized, as is shown in Fig. 5. It can only be said that the extent of solubilization decreases as the molar volume of the solubilizate increases; no unique and quantitative relation has been found between them.

Table II shows the effect of temperature on the solubilization of benzene and toluene by bivalent metal dodecyl sulfates. The temperature change has no appreciable effect on the extent of the solubilization of benzene or toluene, as may be seen from Table II, suggesting that the heat of the solubilization of benzene or toluene in these detergent micelles is negligibly small. This is not unreasonable if the micellar interior is assumed to be of a liquid hydrocarbon-like structure.

In Fig. 6 the solubilization of benzene, toluene and *n*-hexane by copper tetradecyl sulfate is plotted against the concentration at 40°C. The considerable increase in the solubilizing power of copper teradecyl sulfate is to be noted. At the same detergent concentration, say at 10^{-2} mol./l., the ratio of the amount of hydrocarbons solubilized by copper tetradecyl sulfate to that by copper dodecyl sulfate is found to be 1.5 for benzene, 1.6 for toluene and 1.4 for *n*-hexane. The effect of chain length on the solubilizing power of the detergent has already been studiend by several authors. Harkins et al[9], for example, have shown in their study of the solubilization of benzene and *n*-hexane that the solubilizing power of potassium myristate is about twice that of potassium laurate. The same order of increase in solubilizing power was reported by Klevens[5] for the solubilization of ethylbenzene by the same detergents as above. If the above-mentioned spherical micellar model can also be applied to the copper tetradecyl sulfate micelle, meaning that the increase in the solubilizing power of copper tetradecyl sulfate may be ascribed to the increase in micellar volume caused by the change in micellar aggregation number, we can estimate the micellar aggregation number of this detergent to be 127.

It is to be noted that a small number of hydrocarbons can be solubilized at quite low concentrations of the detergents, as may be seen in Figs. 2, 3, 4 and 6. It is really a well-known fact that the CMC value of the detergent solution decreases with the solubilization of hydrocarbons[11,12], but, for example, the depression of the CMC value caused by the addition of hydrocarbons has been found to lie only within the range of 10 to 30 per cent for sodium alkyl sulfonate[11]. If this is the case with the metal dodecyl sulfates, the

11) H. B. Klevens, *J. Phys. & Colloid Chem.*, 54, 1012 (1950).
12) W. C. Lin, This Bulletin, 28, 227 (1955).

solubilization of hydrocarbons at very low concentrations of these detergents could not be due to their micelles. It seems that a small amount of some hydrocarbons is bound with singly-dispersed detergent molecules or ions in order to be soluble in the solution. The scheme of this binding is a problem to be examined in the future.

Summary

The solubilizing power of the bivalent copper, cobalt, nickel and magnesium dodecyl sulfates, and of copper tetradecyl sulfate towards benzene, toluene, *m*-xylene and *n*-hexane has been determined over the concentration range from 10^{-3} to 1.5×10^{-2} mol./l. at various temperatures. There were approximately linear relationships between the amounts of hydrocarbons solubilized and the detergent concentration. No fundamental difference could be observed among the solubilizing powers of the various bivalent salts studied, in accordance with such other micellar properties as CMC or micellar aggregation number. The solubilizing power, in moles of hydrocarbon solubilized per equivalent detergent, was found to be about 2.0 for the solubilization of benzene by bivalent metal dodecyl sulfates, which is about 1.5 times that by sodium dodecyl sulfate. This increased solubilizing power of bivalent salts was ascribed to the increased micellar volume and to the increased micellar aggregation number compared with that of sodium dodecyl sulfate. The increasing chain length causes a normal increase in solubilizing power. The ratio of the amount of hydrocabons solubilized by copper tetradecyl sulfate to that solubilized by copper dodecyl sulfate was about 1.5.

*The Radiation-Induced Addition of Acetaldehyde to Isobutylene**

By Shinji IIZUKA, Motoyoshi HATADA and Kozo HIROTA

(Received March 2, 1963)

It has been found by the present authors that several ketones of the $CH_3CO(CH_2)_nH$ ($n=1, 2, 3, \cdots$) type can be synthetized by the radiation-induced telomerization of acetaldehyde to olefins, propylene[1] and ethylene[2] at room temperature with high G values. The mechanism can be ascribed to a chain telomerization reaction as follows,

$$CH_3CHO \rightsquigarrow CH_3\dot{C}O + H\cdot \quad (1)$$

$$CH_3\dot{C}O + RCHCH_2 \longrightarrow CH_3COCH_2\dot{R}CH \quad (2)$$

$$CH_3COCH_2\dot{R}CH + CH_3CHO \xrightarrow{k_d} CH_3COCH_2RCH_2 + CH_3\dot{C}O \quad (3)$$

$$\text{or } CH_3COCH\dot{R}CH + RCHCH_2 \xrightarrow{k_p} CH_3COCH_2RCHCH_2\dot{R}CH \quad (4)$$

and so on.

The first purpose of the present paper is to investigate the effect of the structure of taxogens on such a telomerization reaction, making isobutylene a taxogen of branched olefins. The second purpose is to analyze the products in detail so as to investigate the radical mechanism described above, because this monomer is easily polymerizable by a cationic mechanism.

Experimental

Materials.—Acetaldehyde was prepared by heating commercial paraldehyde, which had been purified by distillation at 70°C, with a small amount of concentrated sulfuric acid. The final product was again distilled in vacuo. Isobutylene was prepared by dehydrating commercial *t*-butyl alcohol with concentrated sulfuric acid at 70°C. Impurities were found to be less than 0.5% by the gas chromatographic method.

Procedure.—The sample was carefully deaerated by evacuation; then, while being kept at −80°C, it was enclosed and irradiated in a glass ampoule. Irradiation was carried out in the ampoule with a gamma-ray source (ca. 1000 curie Co-60) installed in the present laboratory. The dose rate was determined with a Fricke dosimeter.

* Chain Telomerization Induced by Radiation. IV.

1) K. Hirota and M. Hatada, This Bulletin, **33**, 1682 (1960).

2) K. Hirota, S. Iizuka, H. Ochi and M. Hatada, ibid., **36**, 115 (1963).

For the detailed analysis of the irradiation products, a large amount of the sample (acetaldehyde/isobutylene=1.6; 200 g.) was irradiated at the dose rate of 4×10^4 r/hr. and the total dose of 5×10^7 r. After the irradiation, unreacted acetaldehyde and isobutylene were separated by distillation, and the residue obtained was fractionally distilled. Each fraction was analyzed by the use of a gas chromatograph (apparatus: Shimadzu GC-1A), an infrared spectrometer (Shimadzu AR-275), and a nuclear magnetic resonance spectrometer (Varian V-4300 B; field modulation, 40 Mc./sec.). In some cases they were derived to 2, 4-dinitrophenylhydrazone, whose melting point was determined. However, in most cases, 10 g. of the sample was irradiated in an ampoule (1.2 cm. in diameter; 15 cm. in length), and the products were analyzed. In the case of irradiation at a higher temperature, 5 g. of the sample was used in an ampoule (1.2 cm. in diameter; 5 cm. in length), the ampoule being get up in a small autoclave. After irradiation, each ampoule was opened, and unreacted acetaldehyde and isobutylene were carefully distilled out. The residue obtained was quantitatively analyzed by gas chromatography.

The effects of catalysts on the reaction were investigated, enclosing the catalysts prepared as follows; a) Nickel: nickel, prepared by decomposing commercial nickel formate (12 g.) for 2 hr. at 380°C, was evacuated for 2 hr. at the same temperature. b) Zinc oxide: commercial zinc oxide (5 g.) was evacuated for 2 hr. at 250~300°C. c) Alumina for chromatography (8 g.) was evacuated for 2 hr. at 350~400°C. d) Silica gel: silica gel for chromatography (8 g.) was evacuated for 2 hr. at 350~400°C. After irradiation, the ampoule was opened, and the catalyst was filtered off by a glass filter (G-4). The filtrate was analyzed by the method described above.

Results and Discussion

Identification of the Irradiation Products.— Figure 1 shows the gas chromatograms of the irradiation products. The large peak, P_1, was easily assigned to acetaldehyde. The P_2 peak was separated into two peaks, P_{2-1} and P_{2-2}, by the use of a 3.0-m. column of dioctylphthalate at 120°C instead of a 5.3 m. column of high vacuum oil. The retention times of P_{2-1} and P_{2-2} agreed with those of methyl *t*-butyl ketone and methyl isobutyl ketone, which in turn correspond to two isomeric 1:1 telomers. The formation of two types of telomers had been found previously in the acetaldehyde and propylene system[1].

From a large irradiated sample, two fractions were obtained by distillation. The first fraction (b. p., 114~117°C at 760 mmHg) corresponds to P_{2-2} and was identified as methyl isobutyl ketone, 1:1 telomer, by the retention time of the gas chromatogram, the boiling point and the melting point of its 2, 4-dinitrophenylhydrazone. The second fraction (96~101°C at 37~38 mmHg) corresponds to the P_4 peak. The reaction of this fraction with 2, 4-dinitrophenylhydrazine gave a red brown oily substance. The infrared spectrum of the second fraction showed a carbonyl band at 1720 cm^{-1} and isopropyl bands at 1150 and 1170 cm^{-1}.

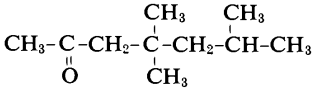
* One third of the area of the CH_3CO signal was taken as the unit of relative areas.

The NMR spectra (D, A, B and C) in Fig. 2 are that of this fraction and those of its related compounds, i. e., methyl *n*-propyl ketone, methyl isobutyl ketone and methyl *t*-butyl ketone. When one compares the D spectrum with the A, B and C spectra, it is apparent that each signal from S_1 to S_6 in D relates to the proton of the following groups; S_1 to $-CH_2-CO-$ (α-position), S_2 to CH_3-CO, S_3 and S_4 to $-CH_2-$ (β- and more portions) and/or $-CH-$, S_5 and S_6 to CH_3-C. Table I shows the chemical shift δ, taking water as the reference and with the relative areas of the signals making one-third of the area of the CH_3-CO signal as a unit. It can be estimated, therefore, that the second fraction contains substances of one CH_3CO-, one $-CH_2C$ (α) and four CH_3-C groups as well as a few $-CH_2-$ (β- and more positions) and/or $-\underset{|}{C}H-$groups. The mean molecular weight of these substances was determined to be 155 from the freezing point depression of benzene. On the basis of the results described above, the structure of the main substance in the fraction was reasonably estimated to be the 1 : 2 telomer; i. e.,



(molecular weight : 156)

Although the minor products corresponding to the other peaks of the gas chromatogram were not isolated, it may be estimated that two peaks, P_3 and P_5, are due to the isomeric 1 : 2 telomer and 1 : 3 telomer respectively. It is possible, however, that the amount of isomeric 1 : 4 telomer was too small to be detected because of steric hindrance.

The Effect of the Dose on Yields.—The effect of the total dose on the yields of each telomer is shown in Fig. 3 where the dose rate was kept constant at 4.0×10^4 r/hr., while the molar ratio in the feed R, as defined by acetaldehyde/isobutylene, was kept constant at 1.5. After an induction period observed in the initial part of the curves, the amount of each telomer increased linearly. It is interesting to note that similar induction periods had been also observed in the gamma-ray-induced addition of acetaldehyde to ethylene[2] and of propanol-2 to ethylene[3]. It is not certain whether

3) K. Hirota and M. Hatada, ibid., 34, 1644 (1961).

or not this tendency is due to the presence of some undetectable impurities, e. g., oxygen or other radical-scavengers.

Generally speaking, the yields decreased by one or two orders of magnitude upon the substitution of isobutylene for propylene or ethylene as the taxogen. The reason for such a smaller reactivity of isobutylene will be discussed later.

The Effect of the Dose Rate on *G* Values.—In Fig. 4, the logarithms of the *G* values of the telomers, $G(1:n)$, are plotted against the logarithm of the dose rate. It is shown that in the cases of $G(1:1)$, $G(1:2)$ and $G(1:3)$, linear relations were otained, their inclination being nearly equal to −0.50, i. e., −0.47, −0.47 and −0.52 respectively. Since −0.50 is expected to occur in the case of the bimolecular termination of radicals, this finding seems to indicate a radical chain mechanism. However, $G(1:1_{iso})$ and $G(1:2_{iso})$ were not affected by the dose rate; thus suggesting a contrary thesis that these telomers were produced according to a mechanism different from that of the major telomers.

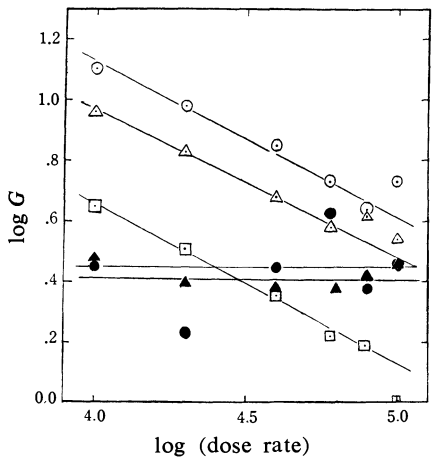

Fig. 4. log *G* vs. log (dose rate).

⊙, 1 : 1; ●, 1 : 1_{iso}; △, 1 : 2;
▲, 1 : 2_{iso}; ◙, 1 : 3 telomer

The Effect of the Molar Ratio in the Feed on *G* Values.—In Fig. 5, the *G* values of the telomers produced at 15°C are plotted against the molar ratio in the feed, taking both total dose and dose rate at constant values, i. e., at 2.2×10^7 r and 4.0×10^4 r/hr. respectively. It is shown that $G(1:1)$ was larger than the other *G*'s and that it increases markedly with the molar per cent of acetaldehyde, but that even its maximum value was smaller by one or two factors than the corresponding one when ethylene or propylene was adopted as the taxogen.

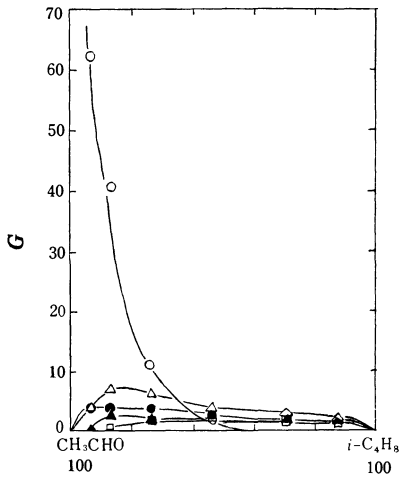

Fig. 5. *G* vs. molar percent.
Dose rate 4.0×10^4 r/hr.
Total dose 2.1×10^7 r
Irradiation temp., 15°C
⊙, 1 : 1; ●, 1 : 1_{iso}; △, 1 : 2;
▲, 1 : 2_{iso}; ◙, 1 : 3 telomer

Another point to be mentioned is the finding that $G(1:1_{iso})$ and $G(1:2_{iso})$ did not depend on the molar ratio so markedly; this is the second fact which seems to be related to the mechanism of these products.

The Effect of the Irradiation Temperature on *G* Values.—The *G* values of telomers are plotted against the irradiation temperature in Figs. 6 and 7, where the R's are very different (1.5 and 15 respectively). The *G* values of the 1 : 1, 1 : 2 and 1 : 3 telomers markedly increased with the temperature below 100°C and show a maximum at a temperature between 110 and 150°C. The decrease in the *G* values of these products at higher temperatures may result from the decomposition of the acetaldehyde molecule, the acetyl radical and/or other intermediate radicals.

By plotting the logarithm of these values at a low temperature against $1/T$, relatively good straight lines were obtained. The apparent activation energies of formation were thus determined to be 6.5, 5.8 and 7.0 kcal./mol. for 1 : 1, 1 : 2 and 1 : 3 telomer respectively. These values are slightly larger than those observed in the case of acetaldehyde and ethylene[2], i. e., 5.0 kcal. for the 1 : 1 telomer. However, it seems that $G(1:1_{iso})$ and $G(1:2_{iso})$ remained constant in relation to the temperature, suggesting a low activation energy. This point will be taken up again below.

Reaction Mechanism.—Considering the effects on the G(telomers) described above, it may be said that the major parts of the telomers are produced by the following chain schemes, which have been proposed by the present authors[1,2] or by others[4].

$$CH_3CHO \rightsquigarrow CH_3\dot{C}O + H$$

$$CH_3\dot{C}O + CH_2{=}C(CH_3)_2 \xrightarrow{k_{po}} CH_3COCH_2\dot{C}(CH_3)_2$$

$$CH_3COCH_2\dot{C}(CH_3)_2 + CH_3CHO \xrightarrow{k_{dl}} CH_3COCH_2CH(CH_3)_2 + CH_3\dot{C}O$$

or

$$CH_3COCH_2\dot{C}(CH_3)_2 + CH_2{=}C(CH_3)_2 \xrightarrow{k_{pl}} CH_3COCH_2C(CH_3)_2CH_2\dot{C}(CH_3)_2$$

and so on.

On the basis of the data in Fig. 5, the molar fractions F_n's, of the 1 : n telomers to the total telomers were calculated; they are plotted against R in Fig. 6. The lines in the figure indicate the theoretical curves based on the following equation;

$$F_n = \frac{C_n R}{\prod_{i=1}^{n}(C_i R + 1)} \qquad (C = k_{dn}/k_{pn})$$

which was derived by assuming the above scheme[5]. The chain transfer constants, C_n's, 0.6_0, 1.2_7 and 2.0 were selected as the most

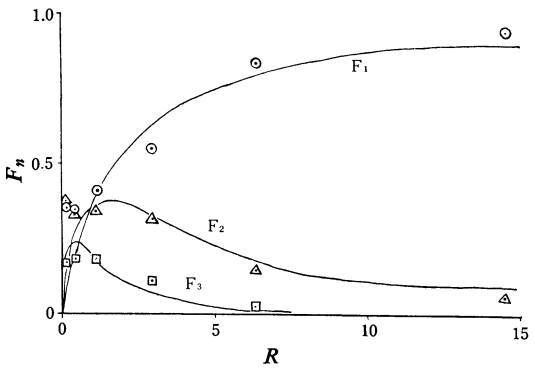

Fig. 8. Molar fractions of 1 : n telomers vs. molar ratio of acetaldehyde/isobutylene in the feed.

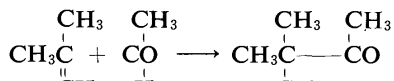
TABLE III. THE EFFECT OF THE PRESENCE OF CATALYSTS ON THE G VALUES OF TELOMERS

Dose rate: 4×10^4 r/hr.; total dose: 1.5×10^7 r

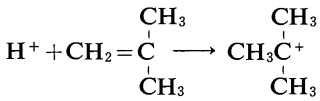
	Absence	Nickel	Zinc oxide	Alumina	Silica gel
1 : 1	17	7.4	2.5	3.1	5.7
1 : $1_{iso.}$	3	—	—	—	—
1 : 2	13	1.9	0.9	7.0	3.4
1 : $2_{iso.}$	3	0.2	0.1	1.3	0.6
1 : 3	7.5	0	1.0	5.7	2.1

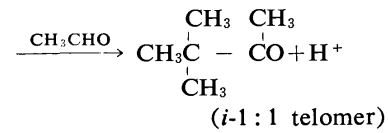
probable values. However, the observed values at a smaller R value do not lie on the calculated curves. This may be due to the errors caused by the use of $G(1:1)+G(1:1_{iso})$ instead of $G(1:1)$ in this region*, and also to the approximation where the amounts of higher telomers ($n\geq4$) were assumed. For the sake of comparison, chain transfer constants of similar reactions are shown in Table II. As ought to be expected, they are much larger than those in the case of polymerization and take values of an order of magnitude similar to those of peroxide initiation.

However, to summarize the effects of the dose rate, the molar ratio and the irradiation temperature on G values, the mechanism of producing the isomeric 1 : 1 and isomeric 1 : 2 telomers will be different from the above scheme, as has already been suggested. It is natural for the reaction to assume another mechanism; e. g., isomeric 1 : 1 telomer will be produced in accordance with the Markownikoff rule on the addition to a double bond as follows:



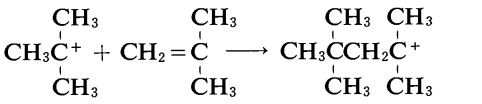
However, the production of the isomeric 1 : 2 telomer is difficult to explain by this mechanism. Therefore, the following ionic mechanism is more reasonable:

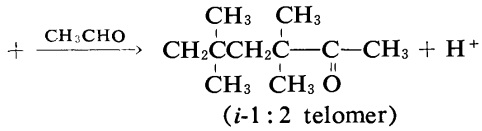




(*i*-1 : 1 telomer)

or





(*i*-1 : 2 telomer)

Such an ionic mechanism may be allowed, because isobutylene can be cationically polymerized by gamma-rays, according to Dainton et al.[8] Moreover, it may be explained on the basis of this ionic nature of isobutylene and on the basis of steric hindrance why the G values of this system are much lower than those when ethylene or propylene was used as the taxogen.

The Effect of the Presence of Catalysts on G Values.—Table III shows the effects of the presence of catalysts, i. e., nickel, zinc oxide, alumina and silica gel, on the G values of telomers to be produced at room temperature. The G values of all the telomers decreased whenever the catalysts were present. This finding suggests the possibility of the catalytic decomposition of acetyl and other intermediate radicals, but since several by-products were detected in the gas chromatogram, it can be concluded that aldehyde was also decomposed by the contact with these catalysts and was turned into the by-products.

* Due to experimental reasons, these $G(1:1_{iso.})$ and $G(1:1_{iso.})$ values could not be determined separately.

Summary

The radiation-induced addition of acetaldehyde to isobutylene has been found to proceed at room temperature; the G(telomer)'s are smaller by one or two orders of magnitude than those when ethylene or propylene is adopted as the taxogen, and they increase markedly with the temperature, reaching a maximum at 110~150°C.

It has been shown from the gas chromatographic and NMR analyses of the telomer produced that the radical chain mechanism proposed in former papers by the present authors is reasonable, although minor products seem to be formed in accordance to an ionic mechanism.

It has been found that the G values of all the telomers decrease in the presence of several solid materials, suggesting the catalytic decomposition of acetyl and other intermediate radicals.

The authors wish to express their sincere thanks to Dr. Hazime Kusumoto of the Research Institute of Industry and Science, Osaka University, for his measurement of NMR spectra.

A part of the expense has been defrayed by a grant given by the Ministry of Science and Technology, to which the authors' thanks are due.

Terpenoids. VI. The Structure of Thunbergene[*,1]

By Hiroshi KOBAYASHI and Saburo AKIYOSHI[**]

(Received March 4, 1963)

Thunbergene (I) $C_{20}H_{32}$; m. p., 60°C, $[\alpha]_D$ +233°, is a monocyclic diterpene hydrocarbon which was first isolated from the wood turpentine oil of *Pinus thunbergii, Parl.* by one (S. A.) of the present authors[2]. The compounds which are identical with thunbergene or which are considered to be so have been found to occur in the exudates of many other *Pinus* species[3].

In their studies of the structure of this compound, the authors have arrived at the conclusion that thunbergene has the structure shown in Fig. 1. At almost the same time

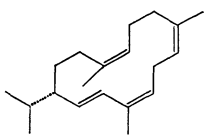

Fig. 1. Thunbergene (I)

Professor Dauben proposed that the structure of cembrene is 1-isopropyl-4, 8, 12-trimethylcyclotetradeca-2, 4, 7, 11-tetraene[4]; direct comparison of cembrene with thunbergene proved them to be the same[5].

The present paper describes the author's own work on this compound. A preliminary communication proposing the structure I (Fig. 1) has already appeared[6]. This structure was assigned to thunbergene (I) on the basis of the following evidence.

5) The authors are indebted to Professor William G. Dauben of the Department of Chemistry, University of California, Berkeley, for identifying thunbergene with cembrene. For the systematic index of this compound, the authors suggest employing the single name, thnnbergene, which was given to the compound by its first reporter.

6) H. Kobayashi and S. Akiyoshi, This Bulletin, **35**, 1044 (1962).

The hydrogenation of I gives an octahydro-derivative (II), $C_{20}H_{40}$, $[\alpha]_D \pm 0°$; thus I contains four double bonds and one ring. The infrared spectrum of I shows the strong band at 963 cm^{-1} characteristic of a trans-disubstituted double bond. Its ultraviolet absorption spectrum shows a band at 246 mμ (ε, 17100) indicative of a conjugated diene. The partial hydrogenation of I gives a dihydro-derivative (III) which shows no infrared band near 963 cm^{-1} and a weakened ultraviolet band at 246 mμ (ε, 355). The trans-disubstituted double bond is, therefore, a part of the conjugated diene system.

The ozonolysis of I gives levulinic acid (IV) and 2-isopropyl-5-oxohexanoic acid (V). The latter V, $[\alpha]_D -30°$, is the only optically active product of the ozonolysis and affords a semicarbazone melting at 140°C[7]. The hypobromite oxidation of V furnishes an optically active 2-isopropylglutaric acid (VI), $[\alpha]_D -20°$. Formaldehyde, acetaldehyde and acetone are not found to occur among the ozonolysis products, in contrast to the findings of previous reports[3a,b].

The presence of an isopropyl group is suggested by the infrared doublet band at 1368 and 1387 cm^{-1} of I; it is confirmed by the NMR study (two doublets centered at 9.20 and 9.10 p.p.m.[8], both J, 2.3 c.p.s.) and by the occurrence of V upon the ozonolysis of I. In connection with the conformation of I, it is noted that the NMR bands associated to the methyl of the isopropyl group split to two doublets indicative of the hindered rotation of the isopropyl group.

The lack of infrared bands characteristic of terminal methylene and of vinyl group is consistent with the absence of formaldehyde among the ozonolysis products. The NMR spectrum indicates the presence of two methyl groups attached to ethylenic carbons (8.52 and 8.42 p.p.m.) and of one methyl group on a conjugated diene (8.22 p.p.m); these are concidered to be on double bonds which are in the midst of carbon chains. If this were not the case, I would give acetaldehyde upon ozonolysis.

The groupings of seventeen carbon atoms are now clarified, namely, those corresponding to two ozonolysis products, IV and V, and the conjugated diene bearing a methyl group. The three remaining carbon atoms must belong together to a single group, which cannot be trifunctional or vicinal bifunctional; therefore, the C_3-group must be a propanediylidene-type one. Thus, the groupings of all the carbon atoms are known to be bifunctional, and consequently, the ring structure of I must consist of fourteen carbon atoms and four double bonds.

Consistent with the fourteen-membered ring structure of I is its dehydrogenation with selenium to give an aromatic hydrocarbon (VII) ($C_{19}H_{20}$; m. p., 78°C[9]) which has an ultraviolet spectrum indicative of alkylphenanthrene. Its NMR spectrum can be explained by formula VII (Fig. 2); it reveals the presence of two methyls of an isopropyl group

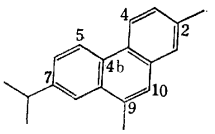

Fig. 2. (VII)

(9.0 p.p.m.), two methyl groups attached to a phenanthrene nucleus (8.0 p.p.m.) and seven hydrogens on a phenanthrene nucleus (2.5 and 1.5 p.p.m), two of them at a lower field position being at the 4- and 5-positions of the nucleus[10].

As known already, phenanthrene, if its 9- and 10- positions are both unsubstituted, is readily oxidized, giving an *o*-quinone which shows a characteristic visible absorption above 400 mμ[11]. The oxidation of VII brings about no change in the visible absorption of this region, indicating that VII resists the oxidation and that, consequently, either the 9- or 10-position should be substituted.

For the first maximum of the *p*-group[12] of the ultraviolet spectrum of VII occurring at 299 mμ, assignment of the three substituted positions can be made on the basis of the known relationship[13]. Provided that the parent cyclic system is fourteen-membered, an application of the isoprene rule indicates the unique structure of VII as 7-isopropyl-2, 9-dimethylphenanthrene (Fig. 2); this presumption has been confirmed synthetically[14]. A methyl group lost upon the dehydrogenation would have attached to the 4b-position, and the structure II is given to the octahydro-derivative (II) (Fig. 3).

Together with the preceding structural data regarding to the groupings of the carbon atoms,

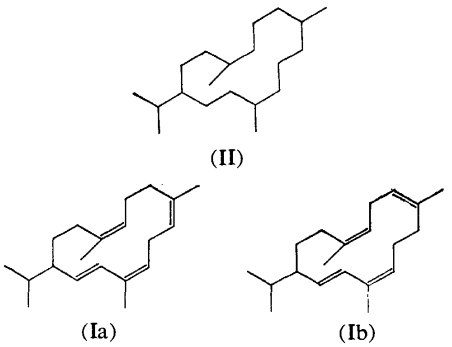

Fig. 3.

structure II gives two equally probable structures, Ia and Ib, for I (Fig. 3). From the biogenetic point of view, structure Ia is rather preferable since this diterpene hydrocarbon I is considered to be derived from geranylgeraniol in a manner analogous to the formation of the ten-membered monocyclic sesquiterpenoids from farnesol[15] (Fig. 4).

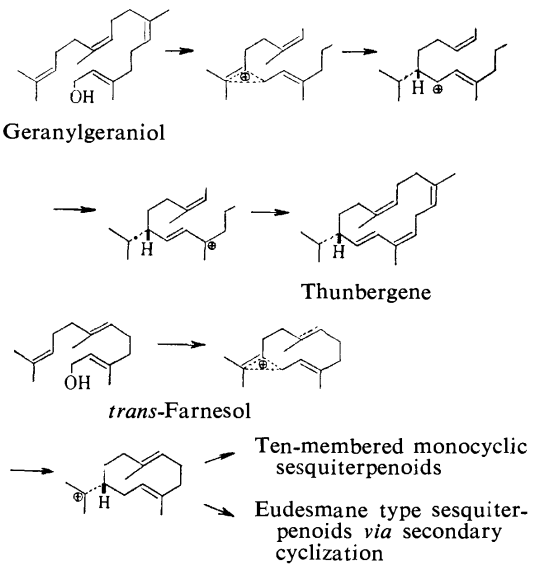

Fig. 4. Hypothetic biogenesis of thunbergene. Comparison with that of sesquiterpenoids proposed by Hendrickson[15].

Structure Ia coincides with that proposed by Dauben[4].

The absolute configuration of the only asymmetric carbon can be directly related to that of (−)-VI, which was confirmed by Fredga[16]. The configuration should be retained throughout the degradation sequence from I to (−)-VI since all the degradation reaction would not affect the asymmetric center.

15) J. B. Hendrickson, *Tetrahedron*, **7**, 82 (1959).
16) A. Fredga and J. Miettinen, *Acta Chem. Scand.*, **1**, 137 (1947).

Thus, Fig. 1 represents the structue of thunbergene (I). This compound is a novel type of diterpene and is the first characterized naturally- occurring fourteen-membered carbon ring compound. It is interesting in connection with the hypothetic biogenesis of I that the absolute configuration of the isopropyl group of I is quite analogous to these found in ten-membered monocyclic sesquiterpenoids or related compounds (Fig. 4).

The stereochemistry of the three trisubstituted double bonds remains to be elucidated. The results of the NMR studies of the stereochemistry of ethylenic double bonds[17] are not considered to be applicable to the elucidation of this problem, because the long-range shielding effect of the double bonds on the methyl groups is difficult to ascertain. Probably the only final solution to the problem will be obtained by the X-ray analysis of a suitable derivative of I.

Experimental[18]

Isolation of Thunbergene (I). — A neutral turpentine oil from the root of *Pinus thunbergii*, *Parl.* was fractionated by distillation under reduced pressure. Thunbergene (I) was separated as a crystalline mass from the fraction boiling at 135～155°C/3 mmHg. The minimum content of I found in the wood turpentine oil was 1% by weight. Repeated recrystallizations from ethanol gave colorless needles melting at 59～60°C, $[\alpha]_D$ +233° (*c* 0.70 in chloroform); molecular weight, 272 (from a parent peak of the mass spectrum of I[19]).

Found: C, 88.14; H, 11.77. Calcd. for $C_{20}H_{32}$: C, 88.16; H, 11.84%.

C-Methyl number: 2.61, 2.64 and 2.54. IR $\tilde{\nu}_{max}$ 1667(w), 1387(s), 1368(s), 963(s), 938, 907 and 837 cm^{-1} (in carbon tetrachloride): UV λ_{max}: 246 mμ (ε, 17100) (in hexane). NMR spectrum[20]: 9.20(3) (doublet, *J* 2.3 c.p.s.) 9.10(3) (doublet, *J* 2.3 c.p.s.), 8.52(3), 8.42(3), 8.22(3), 8.15～7.80 (broad band), 5.30～4.30 (broad band), and 3.95 p.p.m.(1) (doublet, *J* 15 c.p.s.).

18) All melting points were uncorrected and were measured on a Koffer micro hot stage. Elementary analyses were performed by the Service Center of Elementary Analysis of Organic Compounds, Department of Chemistry, Kyushu University. All spectra in the ultraviolet and visible regions were recorded on a Hitachi model EPS-2 spectrophotometer, and in infrared region on a Nippon Koken model DS-301 double-beam spectrophotometer. The authors wish to thank Miss Yasuko Ikejiri for measuring the ultraviolet and visible spectra, and Miss Yuko Tomita for measuring the infrared spectra.

19) The authors are indebted to Dr. Curt Enzell of the Royal Institute of Technology, Stockholm, for the mass spectral datum.

20) The authors are indebted to the staff of the Japan Electron Optics Laboratory, Tokyo, for the NMR spectrum of I. The spectrum was measured in deutrochloroform (an about 20% solution) on a JNM C-60 instrument.

Hydrogenation of I. — Upon catalytic hydrogenation in an ethyl acetate solution (25 ml.) over platinum black, I (1.15 g.) absorbed 502 ml. of hydrogen in the standard state (the calculated amount for 4 mol. of hydrogen, 497 ml.), giving an oily octahydro-derivative (II), n_4^{29} 0.8632, n_D^{29} 1.4730, $[\alpha]_D \pm 0°$ (*c* 7.84 in chloroform), C-methyl number: 2.62.

Found: C, 85.48, 85.35; H, 14.10, 14.30. Calcd. for $C_{20}H_{40}$: C, 85.63; H, 14.37%.

Thunbergene (I) (500 mg.) in ethyl acetate (15 ml.) was hydrogenated with palladium black (100 mg.) until one mole of hydrogen (41 ml. in the standard state) was absorbed. Dihydro-derivative (III) was an oil with the following properties: d_4^{22} 0.890, n_D^{22} 1.5020, $[\alpha]_D$ −2.2° (*c* 8.13 chloroform). UV, λ_{max}: 246 mμ (ε, 355) (in hexane).

Ozonolysis of I. — Ozone was passed through a solution of I (9.8 g.) in methylene chloride (200 ml.) at −70°C until the solution turned purple. The resulting ozonide in methylene chloride was added drop by drop into hot 30% hydrogen peroxide (15 ml.). The solvent was taken off by distillation. After the ozonide in hydrogen peroxide had been refluxed for an hour, manganese dioxide was added to decompose the excess hydrogen peroxide. The resulting mixture was steam-distilled. The residue was acidified and extracted with ether, the ethereal extract giving a non-volatile acid (4.85 g.). The aqueous layer was further extracted with ether for 3 hr. by means of an Asahina continuous extraction apparatus[21]. From the second ethereal extract, levulinic acid (IV) (0.91 g.) was obtained; this gave succinic acid upon being treated with sodium hypobromite at 0°C for 3 hr. The semicarbazone of levulinic acid (IV) melting at 184°C was identified by the comparison of the infrared spectra and the mixed melting point determination with an authentic sample.

The non-volatile acid (2.60 g.) was partition-chromatographed on silica-gel (60 g.) holding 0.5 N sulfuric acid (30 ml.). Eluant was wet ether saturated with 0.5 N sulfuric acid. A keto-acid was isolated from the middle fractions and was purified via semicarbazone (m. p., 138~140°C), which was prepared according to Asahina and Kuwata[22] and was recrystallized from water.

Found: C, 52.30; H, 8.55; N, 18.14. Calcd. for $C_{10}H_{19}N_3O_3$: C, 52.38; H, 8.35; N, 18.33%.

The keto-acid (V) (96 mg.) ($[\alpha]_D$ −30° (*c* 0.56 in chloroform)) was regenerated from the semicarbazone (200 mg.) by heating it together with 25% sulfuric acid (10 ml.) for an hour.

The keto-acid (V) (123 mg.) was oxidized to a dicarboxylic acid (VI) (117 mg.) by treating it for 3 hr. at 0°C with a sodium hypobromite solution. Recrystallization from dilute hydrochloric acid gave a sample (VI) (27 mg.) melting at 92~95°C. Repeated recrystallizations from benzene raised the melting point to 94~95°C, $[\alpha]_D$ −20° (*c* 1.64 in chloroform).

The dicarboxylic acid (VI) was dehydrated by heating it together with acetic anhydride for one and a half hour. The anhydride was separated by distillation under reduced pressure and recrystallized from petroleum ether (b. p. 50~70°C); m. p., 72°C. IR $\bar{\nu}_{max}$ 1810 and 1770 cm^{-1} in carbon tetrachloride.

The degradation products, V, VI and their derivatives, were identified by infrared spectral comparisons in solution with corresponding racemic authentic samples derived from diosphenol[23].

Dehydrogenation of I.—A mixture of I (2.00 g.) and selenium (3.00 g.) was heated at about 300°C for 3 hr. The resulting mixture was washed with 20% aqueous potassium hydroxide and was fractionated by distillation under reduced pressure. Fractions boiling above 180°C/1.5 mmHg (n_D above 1.6025) were combined and chromatographed on alumina. Elution with petroleum ether (b. p. 30~50°C) afforded a fluorescent oil, which gave a picrate (350 mg.) upon treatment with a 6% ethanol solution of picric acid. Repeated recrystallizations from ethanol gave a picrate as orange needles melting at 133.5~134.7°C. From the lower boiling fraction (n_D 1.5832), 50 mg. of the same picrate was obtained.

The aromatic hydrocarbon (VII) was regenerated from the picrate by eluting it from an alumina column using petroleum ether (b. p., 30~50°C)-ethyl ether (1 : 1) as an eluant. The evaporation residue crystallized upon treatment with a small amount of ethanol to give the hydrocarbon (VII) (190 mg.), which was then recrystallized from ethanol; m. p., 77.0~77.8°C. Infrared and ultraviolet spectra were superimposable on these of the authentic sample[14], and the mixed melting point was undepressed.

Found: C, 91.90; H, 8.19. Calcd. for $C_{19}H_{20}$: C, 91.88; H, 8.12%.

UV λ_{max} mμ (log ε): 224 (4.44), 249 (4.48), 257 (5.00), 274 (4.41), 281 (4.37), 288 (4.19), 299 (4.08), 319 (2.46), 328 (2.40), 335 (2.45) (in hexane). NMR spectrum[24]: 1.5, 2.5, 8.0 and 9.0 p.p.m., relative intensities: 2, 5, 6 and 6 respectively.

The chromic acid oxidation of VII and the visible absorption spectroscopy of the oxidation product were performed according to Sugasawa[11].

The authors are indebted to Dr. Shizuo Nagahama for his valuable advice and assistance in the laboratory work.

They also gratefully acknowledge the use of the facilities to obtain the turpentine oil afforded by the Messrs Ogawa Perfumery Co., Ltd., Osaka.

The Structure of Bis(dithizonato)-zinc(II) and -Cadmium(II)

By Yasuo YAMAMOTO, Tetsuo YOSHINAGA* and Shoichiro YAMADA

(Received March 27, 1963)

One of the present authors, (T. Y.) devised a new method for dyeing the zinc ion in tissues[1]. In order to analyze this dyeing mechanism[2], some information about the structure of bis-(dithizonato)zinc(II) became necessary. Though dithizone has been used widely in the field of analytical chemistry and many investigations of the complex compounds with various metals have been carried out[3], information about the structure of metal complexes with dithizone has been very scarce[4,5]. It was thought be interesting and significant to examine various metal complexes with dithizone.

The present paper deals with the preparation methods and structure of bis(dithizonato)-zinc(II) and bis(dithizonato)cadmium(II), in comparison with bis(dithizonato)mercury-(II), whose structure has recently been determined by the X-ray method[5].

Experimental

Preparation of Bis(dithizonato)zinc(II). — Bis-(dithizonato)zinc(II) was prepared according to the method of Pariaud and Archinard[6]. To a solution of zinc acetate (0.5 g.) in aqueous ammonia was added a solution of dithizone (1.7 g.). A dark red precipitate, which formed instantaneously, was filtered off. This precipitate was then dissolved in 30 cc. of chloroform and filtered. The filtrate was evaporated until its volume was reduced by half; then 50 cc. of ethanol was added, and it was evaporated again until crystals began to appear in the solution. This solution was allowed to stand for 3 to 4 hr. Thin plate-like crystals with a green fluorescence were obtained. Recrystallization was made from chloroform-ethanol.

Found: C, 53.16; H, 3.77; N, 19.47. Calcd. for $C_{26}H_{22}N_8S_2Zn$: C, 54.21; H, 3.85; N, 19.43%.

Preparation of Bis(dithizonato)cadmium(II).— Bis(dithizonato)cadmium(II), which had not been isolated as crystals, was prepared by almost the same method as the zinc compound. Here, however, one of two forms of the compound was obtained, depending upon the conditions of the reaction. When a solution of cadmium acetate in aqueous ammonia was poured into a solution of dithizone, a dark red precipitate, which was easily dissolved in chloroform, was formed. By vacuum evaporation of the chloroform solution of this precipitate, however, violet needles which were only slightly soluble in chloroform were obtained. On the other hand, when a solution of dithizone was poured into a solution of cadmium acetate, a dark brown precipitate which was insoluble in chloroform was formed. After this precipitate was thoroughly washed with chloroform, brown powder was obtained. Both forms, the violet and the brown, are soluble in pyridine to give a solution with a strawberry color. After recrystallization from pyridine, both forms yielded a dark red crystalline powder of the same composition.

Found: C, 50.20; H, 3.70; N, 17.69. Calcd. for $C_{26}H_{22}N_8S_2Cd$: C, 50.12; H, 3.56; N, 17.99%.

Elementary analyses of the brown powder and violet needles were also carried out. The results were quite identical with those of the dark red crystalline powder.

Preparation of Bis(dithizonato)mercury(II).—Bis(dithizonato)mercury(II) was prepared by the same method as the zinc compound.

Found: N, 16.02. Calcd. for $C_{26}H_{22}N_8S_2Hg$: N, 15.76%.

Results and Discussion

The analytical results of these metal complexes of dithizone show that the zinc(II) and cadmium(II) compounds, as well as the mercury(II) compound, are composed of one metal ion and two dithizonate ions. The structures of bis(dithizonato)zinc(II) and bis-(dithizonato)cadmium(II) have not yet been determined, but the coordination around these metal ions is regarded as tetrahedral, judging from the stereochemistry of these metal ions and the configuration of dithizone. In the molecules of these metal complexes of dithizone, it may be presumed that dithizonate ions are capable of being coordinated to the metal in eight ways, i. e., in four ways through two nitrogen atoms which do not adjoin each other, and in the other four ways through a

sulfur atom and one of the four nitrogen atoms. The posibility of behaving as a tridentate may be ruled out because of the steric condition.

According to the crystal structure analysis[5], the dithizonate ions in the bis(dithizonato)-mercury(II) molecule are coordinated through its sulfur atoms and nitrogen atoms of the azo radicals to the central metal, as shown in Fig. 1. In fact, the crystal structure analysis was carried out with a pyridinated compound. The nitrogen atoms of the pyridine molecules, however, are not linked with the mercury(II) ions but are connected with nitrogen atoms of imino groups of the dithizonate ion by hydrogen bonds. Therefore, the configurations around the mercury(II) ion in the non-solvated crystals, prepared in the present work, may be assumed to be the same as that in the pyridinated compound.

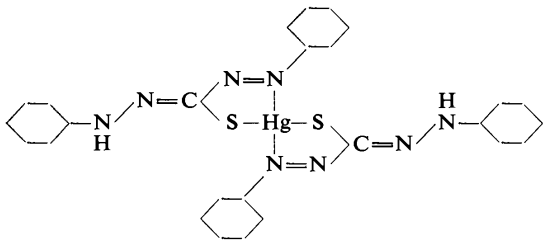

Fig. 1. The structure of bis(dithizonato)-mercury(II).

The infrared spectra of these metal dithizonates and of dithizone itself are shown in Fig. 2. Because the dithizonate ion is coordinated through its sulfur and nitrogen atoms to the mercury(II) ion, the C-S streching and -N=N- stretching absorptions may be shifted to lower frequencies. The N-H stretching vibration was observed by Duncan and Thomas[7] at 3272 cm^{-1} for the mercury(II) compound in carbon tetrachloride. The present measurement, using the KBr method, reveals that the corresponding absorption band appears at 3260, 3235 and 3232 cm^{-1}, respectively, for the mercury(II), cadmium(II) and zinc(II) compounds. However, these characteristic bands of dithizone have not yet been assigned; it is difficult, therefore, to discuss the coordination from these stretching vibrations at the present stage. Nevertheless, some conclusion may be derived by comparing these spectra. If the coordination type of bis(dithizonato)zinc(II) and bis(dithizonato)cadmium(II) is different from that of bis(dithizonato)mercury(II), the configuration of the dithizonate ion in th zinc(II) or cadmium(II) compound is not the same as in the mercury(II) compound. Accordingly, the skeletal vibrations of zinc(II) or cadmium-(II) complexes of dithizone should vary considerably compared with those of the mercury-(II) compound. However, as can be seen in Fig. 2, patterns of skeletal vibrations which are

expected to appear from 1000 cm^{-1} to 1300 cm^{-1}, are very similar, and the peaks for the corresponding vibrations are found to be shifted regularly in the order of the atomic number. It may, therefore, be concluded that the configurations and the mode of the coordination of dithizonate ions are all identical in these metal complexes of dithizone. Consequently dithizonate ions are presumed to be coordinated through the sulfur atom and nitrogen atom of the azo radical to the zinc(II) or the cadmium(II) ion as well as to the mercury(II) ion.

1 Bis(dithizonato)zinc(II)
2 Bis(dithizonato)cadmium(II)
3 Bis(dithizonato)mercury(II)
4 Dithizone
5 Dithizone in aqueous ammonia

The visible and ultraviolet absorption spectra of these complexes in pyridine were determined and are shown in Fig. 3. The spectra of the zinc(II) and mercury(II) complexes in chloroform were found to be almost identical with the spectra of the same complexes in pyridine. As may be seen in Fig. 3, these curves are essentially similar, and maxima of the corresponding bands are shifted to a higher frequency in the order: zinc(II)<cadmium(II)<mercury(II). The order agrees with the current view about the strength of the perturbing effect of the metal ions on the ligand. The rather close similarity of the spectra and the regular shift of the absorption bands seem to be in agreement with the above-mentioned conclusion that the mode of the coordination of dithizonate ions is quite similar among the complexes of the three metal ions.

Summary

Two forms of bis(dithizonato)cadmium(II) have newly been isolated. Upon recrystallization from pyridine, both the forms yielded the same dark red crystalline powder. A comparison of their infrared and ultraviolet spectra shows that the mode of coordination and the configuration of zinc(II) and cadmium(II) are the same as in the mercury(II) complex.

Synthetic Resins Catalyzing the Racemization of Amino Acids. III. Racemization by the Column Procedure

By Koji Toi, Yoshiharu Izumi and Shiro Akabori

(Received March 27, 1963)

In previous papers[1-3], the preparation and activity of the resins catalyzing the racemization of amino acids were described. In the present research, it was found that, on the continuous flow of an amino acid solution containing cupric ion through a column of the resin, racemization of the amino acid was achieved to a degree which was determined by or was dependent on the flow rate. The catalytic resin used was prepared, as has been described in a previous paper[2], by chemical modification of *o*-cresol-phenol-formalin resin. Powdered *o*-cresol-phenol-formalin resin was oxidized with chromium trioxide in a mixture of acetic

3) K. Toi, ibid., **36**, 739 (1963).

anhydride and acetic acid, and the acetal produced was hydrolyzed with 4 N hydrochloric acid. The aldehyde content of the resin was 0.24 mmol. per gram of dry resin.

A column 30 cm. long and 2 cm. in diameter was made with 40 g. of the resin, which had been previously buffered to pH 10.0~10.5 with a borate buffer. The column was fitted with a glass jacket, through which water at 80°C was circulated, and operated at a constant temperature. An aqueous solution of 1.0 M L-alanine containing 0.1 M cupric acetate monohydrate was adjusted to pH 10.0~10.5 with sodium hydroxide. This solution was run through the column, and the effluent was fractionated every 5 ml. Each fraction of five intervals was diluted with two volumes of 6 N hydrochloric acid, and its optical rotation was measured. The racemization reaction during the passage through the column proceeded well, with the decrease in the flow rate shown in Fig. 1. L-Alanine racemized completely at a flow rate of 5 ml. per 13 min.

The amino acid content in the solution used for the optical rotation measurement was determined by the ninhydrin colorimetric method[4]. The loss of the alanine during the passage through the column was below 10%.

Fractions 80 to 120 were combined and made acidic with hydrochloric acid. The acidic solution was treated with hydrogen sulfide to remove the cupric ion. After subsequent treatment of the solution with ion exchange columns to remove the sodium salt, alanine was obtained in a yield of 14 g., which corresponded to 80% recovery. The alanine which recovered was optically inactive. $[\alpha]_D^{15}$ 0.00 (*c* 3, 6 N hydrochloric acid).

*A Simple Digestion Method for the Quantitative Analysis of Metal in Some Organometallic Compounds**

By Shigemi KOHAMA

(Received March 28, 1963)

Metal in organometallic compound can be quantitatively determined as metallic oxide by either the combustion method or the digestion method. Since the latter procedure is simpler than the former, the digestion method has been extensively applied in various ways through the years by many workers[1]. In this digestion, generally, the complete decomposition of organometallic compounds can be achieved by treatment with concentrated sulfuric acid alone or with an accompanying oxidizing agent, such as nitric acid, perchloric acid and hydrogen peroxide.

In a preceding paper[2], the present author has proposed an analytical method in which organosilicon compounds were completely decomposed in a mixture of concentrated sulfuric acid and perchloric acid, silica being left. However, this method was unsuitable for the determination of tin in organotin compounds, since lower analytical values were

* Added in proof: This study was presented at the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

always obtained because of the volatilization of some tin compounds.

For the quantitative analysis of tin in organotin compounds, a procedure[3] has recently been recommended in which the tin compound was first converted into less volatile bromide with bromine in carbon tetrachloride and then digested by the usual way; however, this method disadvantageously requires a long time (about six hours) for a run of analysis.

In order to select a suitable oxidizing agent for tribenzyltin chloride, which is known to be difficult to decompose, digestions were carried out in concentrated sulfuric acid with the usual oxidizing reagents and with ammonium nitrate. The results are shown in Table I.

It is found that ammonium nitrate is superior to other oxidizing reagents in digesting the tin compound. Hence, the author carried out

3) H. Gilman and W. B. King, *J. Am. Chem. Soc.*, **51**, 1213 (1929).

the quantitative estimation of the metal in some organometallic compounds, using ammonium nitrate as an oxidizing reagent. The results on a number of organosilicon compounds, organotin compounds and organotitanium compounds are indicated in Table II; it has thus been found that almost all of the metal in these compounds could be determined accurately.

The values given in Table II are the average of three determinations in most cases.

Thus, the method seems to be a convenient procedure for the determination of the metal in various organometallic compounds. By using ammonium nitrate as a reagent, the loss of the metal salt owing to the volatilization can be completely avoided. There are two further advantages as well; solid ammonium nitrate dissolves uniformly in the solution without forming a separate phase, as in the case of liquid oxidizing agents, and the colorless solution can be obtained by about 30 min. of heating, without any spattering of the sample.

Experimental

All the reagents used were of analytical grade. The organometallic compounds subjected to the tests were partly commercial products and partly compounds which had been synthesized in this Institute. Most of them were further purified according to the methods of the literature.

The Observation of Changes of Tribenzyltin Chloride in Digesting a Solution Containing Perchloric Acid.—A small amount of tribenzyltin chloride was placed in concentrated sulfuric acid containing perchloric acid and then heated to 150~200°C for 5 min., at which time a vigorous reaction started, accompanied with white vapor; this vapor was then passed into dilute aqueous ammonia through a delivery tube. The white precipitate formed in the absorbing solution was identified as tin oxide after ignition.

Analytical Procedure.—About 0.2 g. of a sample is placed in previously-weighed platinum crucible (40 ml.). Then 3 ml. of concentrated sulfuric acid is added, and the mixture is carefully warmed to dissolve the sample. After the mixture has then been cooled somewhat, a spoonful of crystalline ammonium nitrate (about 0.2 g.) is added, with gentle shaking. Gradual oxidation begins as the crystal dissolves into the solution, and the mixture is kept standing for 5 min. In many cases, the content is not yet decolorized, and another spoonful of ammonium nitrate is added, the mixture is then heated carefully so as to avoid spattering. When the mixture is difficult to decolorized, the above procedure is repeated until a colorless solution is obtained. The maximum weight of ammonium nitrate required for the completion of the reaction is about one gram. The contents of the platinum crucible are heated moderately during evaporation and finally ignited intensively until the constant weight of the metallic oxide is attained. The metal is weighed as metallic oxide. The whole procedure takes about 50 min.

Summary

A new, modified digestion method for the quantitative analysis of metal in various organometallic compounds containing silicon, tin and titanium has been developed by the use of ammonium nitrate as a new oxidizing reagent. It has been shown that this method can be carried out more rapidly and more accurately than the other known methods.

The author wishes to express his gratitude to Dr. Sadaomi Fukukawa of this Institute for his advice, and to Professor Shunsuke Murahashi of Osaka University for his kind encouragement and advice throughout this work. He is also grateful to Mr. Toyoji Nakajima, Mr. Manabu Morimoto and Mr. Shoji Suzuki for checking the analysis.

The Electronic Spectra of Aromatic Molecular Crystals. I. Substitued Benzene Molecules

By Jiro TANAKA

(Received February 11, 1963)

Considerable progress has recently been made in the interpretation of the electronic spectra of benzene and the polyacenes[1]. The effect of substituents on the spectrum of benzene has been studied by Nagakura and Tanaka[2], Longuet-Higgins and Murrell[3] and many others[4]. The best way of confirming the theoretical assignments is to measure the polarization of the single crystal absorption band. One such investigation is the study of *p*-dimethoxybenzene by Albrecht and Simpson[5]. They measured the polarization of crystalline absorption and showed that the 280 mμ band of the molecule is polarized perpendicular to the two-fold symmetry axis; hence, the symmetry of the excited level corresponding to the 260 mμ band of benzene is confirmed to be $^1B_{2u}$. In general, monosubstituted benzene molecules have an absorption band corresponding to the 260 mμ band of benzene. When electron-donating substituent groups (such as amino, hydroxyl, methyl and others) are introduced, the 260 mμ band of benzene shifts to the red and increases in intensity. When electron-accepting groups (such as nitro, carbonyl and carboxyl) are substituted, a conspicuous strong, new absorption band appears in the region of 230~360 mμ; this has been interpreted as an intramolecular charge transfer band on the basis of relative energy level locations of benzene and substituent[2]. The direction of the transition moment (polarization) of the latter type of band should be quite different from the former; it may lie on the line connecting the center of the benzene ring and the substituent group.

The primary purpose of this paper is to present a sound basis for the intramolecular charge transfer theory of the spectra of monosubstituted benzenes by measuring the polarization of bands with single crystals. The crystal structures of durene, *p*-nitroaniline, benzoic acid, acetanilide and *trans*-cinnamic acid are known, so the directions of the transition moments can be determined easily by measuring the crystal spectra on the assumption that an oriented gas model is applicable. Owing to a mixing of different excited states and an electron exchange interaction between neighboring molecules, some crystals show noticeable deviations from an oriented gas model, but the crystals of the present investigation show little of this. For this reason it is safe to deduce the direction of the transition moment from the polarization measurement. The possibility of Davydov splitting and of intermolecular charge transfer bands in the crystal has also to be taken into account[6-10].

Experimental

The Spectra of Solutions.—Ultraviolet absorption spectra measurements have been made with a Cary recording spectrophotometer model 14. The spectrophotometer was flushed with dry nitrogen for recording between 220~185 mμ.

Ultraviolet Microspectrophotometer. — For the transmission measurement of aromatic molecular crystals, very thin crystals less than one micron thick are needed because the molar extinction coefficients are 10^4 to 10^5. An ultraviolet microspectrophotometer was used for measuring the spectra of very thin and small crystals.

A schematic diagram of the apparatus is shown in Fig. 1. A double monochromator of the Olympus Optical Co. (A), equipped with synthetic silica prisms and a hydrogen discharge lamp or tungsten lamp (L), has been used. The small diaphragm (B) is set to eliminate the stray light at the exit slit. The light beam is reflected by a mirror (C), is polarized by a Rochon-type polarizer (D) made of natural quartz, and is condensed by

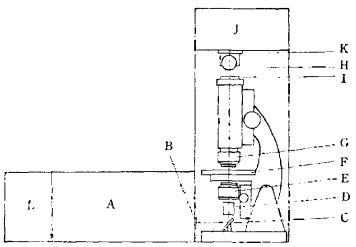

Fig. 1. Ultraviolet microspectrophotometer.

a lens (E) onto the sample. The lenses (E and G) are of Grey's Bausch and Lomb reflecting-refracting type. The numerical aperture of the lens is 0.20~0.72, and the magnification is ×53. The condenser lens (E) is used to collimate the monochromatic light onto the crystal, thereby eliminating the Schwarzschild-Villiger effect[12]. The crystal to be measured is placed between a quartz objective slide 1.0 mm. thick and a 0.18 mm-thick cover glass, and settled on the rotatable table (F). The orientation of the crystal is adjusted, so that one of the crystalline axes is parallel to the direction of the polarization of the light, by the aid of the eyepiece (H) and the cross (I). The iris-diaphragm placed at the top of the microscope is used to cut off the flare light, which disturbs the accurate measurement of the polarization. The shutter (K) is placed in front of an RCA 1p-28 photomultiplier tube, by the use of which, along with that of a direct current amplifier (J), it is possible to measure the light intensity. The effective slit-widths are smaller than 1 mμ, which is sufficient to resolve the broad absorption band of aromatic crystals at room temperature.

The angle of the incident light normal to the plane of the crystal ranges from 12° to 46° because objective and condenser lenses have numerical apertures of 0.20 to 0.72. The polarization of the light is not altered by reflection and refraction at the lens surfaces. In addition, if the transition moments associated with each molecules are parallel to the developed crystalline surface, the intensity of the absorption bands does not depend on the angle of the incident light[13]. However, when the transition moments are vertical to the developed crystalline plane, the absorption may depend greatly on the directional angle of the incident light, and the intensity of absorption has only a qualitative significance.

The stray light of the instrument is estimated to be less than 0.5% of the total light; hence, the measured optical density is reliable up to 2.5. By the use of this microspectrophotometer, the ultraviolet absorption spectra of small single crystals, as small, for example, as $20\mu \times 20\mu \times 0.5\mu$, of aromatic molecules are easily obtained.

p-Nitroaniline

The ultraviolet absorption spectra of *p*-nitroaniline in ethanol and *n*-heptane solutions are shown in Fig. 2. A large solvent effect is observed for this molecule. The first band undergoes a shift from 320 mμ in *n*-heptane to 370 mμ in ethanol. The shift is probably due to a polar solvent effect—the stabilization of the polar-excited state in the polar solvent —or to the hydrogen bonding between the amino group and the oxygen atom of the hydroxyl group of ethanol[14]. One interpretation of this band is that its origin is the 260 mμ band of benzene shifted to the red and intensified by the substituent groups. However, according to Nagakura and Tanaka's theory of intramolecular charge transfer spectra, the 370 mμ band is interpreted by a mechanism

of charge transfer, which takes place from the highest-occupied level of the anilino group to the vacant orbital of the nitro group. Following the former interpretation, the band should be polarized along the short axis of the molecule, while the latter predicts the long axis polarization. By a polarization measurement of the crystalline spectrum, it is easy to eliminate one of these possibilities.

Calculation of the Excited State of *p*-Nitroaniline.—The author[15] has previously calculated the electron affinity of the nitro group and has shown that it behaves as an electron acceptor when conjugated with other π-electron systems, because the group has a large electron affinity. In the present treatment, *p*-nitroaniline is considered to be a composite molecule, consisting of anilino and nitro groups; the electronic interaction between those two groups is calculated by the method of Longuet-Higgins and Murrell[3].

The electronic spectrum of aniline has been studied by Platt and Klevens[16] experimentally and by Murrell[3] theoretically. According to the latter assignment, the ground state and lower excited states configurations are described by a combination of the χ_0, ψ_α, ψ_p, ψ_β, $\psi_{\beta'}$, $\theta^{-1}\varphi_4$ and $\theta^{-1}\varphi_5$ wave functions, where χ_0, ψ_α, ψ_p, ψ_β and $\psi_{\beta'}$ are the wave functions of benzene in its ground state, $^1B_{2u}$, $^1B_{1u}$ and $^1E_{1u}$ are excited states. Functions $\theta^{-1}\varphi_4$ and $\theta^{-1}\varphi_5$ represent, respectively, charge transfer configurations in which a non-bonding electron in the amino nitrogen (denoted by θ) is transferred into the vacant φ_4 and φ_5 orbitals of benzene.

The electron affinity of the nitro group was calculated as -0.40 eV.[15], and the vacant orbital is written as

$$\varphi_w = 0.700\chi_N - 0.502(\chi_0 + \chi_{0'})$$

where χ_N, χ_0 and $\chi_{0'}$ are the $2p\pi$ atomic orbitals of nitrogen and oxygen atoms.

We restrict our attention to the two charge transfer configurations of lowest energy. The highest-occupied orbital of aniline is at -7.70 eV., and the second highest orbital is assumed to be the same as benzene. Next, the configurational interaction between the charge transfer configuration with the locally-excited configurations of aniline is taken into account. The energy of the $\varphi_2{}^{-1}\varphi_w$ and $\varphi_3{}^{-1}\varphi_w$ charge transfer configurations are calculated by the following formula;

$$H_{CT} = I_p - E_A - (\varphi_w\varphi_w \mid \varphi_D\varphi_D) + \sum \delta_{DS}$$

where E_A is the electron affinity of the nitro group, I_p is the ionization potential of the donor orbital in aniline, $(\varphi_w\varphi_w \mid \varphi_D\varphi_D)$ is the electrstatic energy between electrons in φ_w and φ_D orbitals, and the last term, $\sum \delta_{DS}$, denotes the electrostatic energy between the hole in the anilino group with the formal charges on each atom of the substituent nitro group. Taking the numerical values of $E_A = -0.40$ eV., $I_{p_2} = 7.70$ eV., $I_{p_3} = 9.24$ eV., $(\varphi_w\varphi_w \mid \varphi_{D_2}\varphi_{D_2}) = 4.60$ eV., $(\varphi_w\varphi_w \mid \varphi_{D_3}\varphi_{D_3}) = 4.13$ eV., $\sum \delta_{2S} = 0.27$ eV. and $\sum \delta_{3S} = 0.43$ eV., the levels are calculated as 3.77 eV. and 5.94 eV. for the A-type and B-type symmetry states respectively.

The off-diagonal matrix elements are calculated by taking the carbon-nitrogen atom's exchange integral β to fit the calculated value with the observed excitation energies, and the value is selected as -2.30 eV. Then the secular equations for A and B type symmetry levels are given as follows:

A-type symmetry:

$$\begin{array}{c|ccccc} \varphi_0 & -E & 0.93 & 0 & 0 & 0 \\ \varphi_2{}^{-1}\varphi_w & 0.93 & 3.77-E & 0.21 & 0.33 & 0.73 \\ \varphi_{1A} & 0 & 0.21 & 5.27-E & 0 & 0 \\ \varphi_{2A} & 0 & 0.33 & 0 & 6.30-E & 0 \\ \varphi_{3A} & 0 & 0.73 & 0 & 0 & 7.40-E \end{array} \qquad (3)$$

B-type symmetry:

$$\begin{array}{c|cccc} \varphi_{1B} & 4.31-E & 0.51 & 0 & 0 \\ \varphi_3{}^{-1}\varphi_w & 0.51 & 5.94-E & 0.71 & -0.40 \\ \varphi_{2B} & 0 & 0.71 & 6.30-E & 0 \\ \varphi_{3B} & 0 & -0.40 & 0 & 7.40-E \end{array} \qquad (4)$$

where φ_0, φ_{1A}, φ_{2A}, φ_{3A}, φ_{1B}, φ_{2B} and φ_{3B} denote the wave functions of aniline in the ground and excited states as calculated by Murrell, and $\varphi_2{}^{-1}\varphi_w$ and $\varphi_3{}^{-1}\varphi_w$ are the charge transfer configurations described above. The levels belonging to the A-type symmetry group should be active in the long axis, and the B-type symmetry levels, in the short axis of the molecule. The calculated excitation energies are tabulated in Table I, together with the observed values. The agreement between observed and calculated values is generally good, and it is shown that the first strong band at 320mμ in an *n*-heptane solution is predominantly derived from the charge transfer configuration with A-type symmetry. The polarization of this band is deduced to be long-axis, while the next band, at 270 mμ, should be short axis-polarized. The latter band is observed in the crystalline spectrum, but not in *n*-heptane and ethanol solutions, this may be because it borrows intensity from allowed transitions in the crystal. In the region below 220 mμ, there are several transitions belonging to both A- and B-type symmetries; hence, the 220 mμ absorption may consist of two bands, namely, those arising from the transitions between the ground state and the 5.30 eV. and 5.53 eV. states.

The Spectrum of *p*-Nitroaniline Crystal.—The optical properties of *p*-nitroaniline crystal are described by Groth and Winchell as follows[17,18]:

$N_X' = 1.556$, $N_Y = 1.777$, N_Z ?;

Optical plane (010): $2V = 80°(\pm ?)$

The optical axis X is nearly vertical to the (101) plane, and Y=b. This work has been confirmed with the addition of $2V=-80°$. By the use of these values, N_Z is calculated to be 2.005, and the birefringence with (101) plane is estimated to be 0.228. The crystal used for spectral measurement is made by sublimation, and it develops the (101) cleavage plane.

The crystal structure of *p*-nitroaniline has been determined by Abrahams and Robertson and by Donohue and Trueblood[19]. The crystal is monoclinic with the following unit cell dimensions: $a=12.34$, $b=6.02$, $c=8.63$Å and $\beta=91°40'$. The space group is $C_{2h}{}^5-P2_1/n$ with four molecules per unit cell. The projection of the molecules in the unit cell onto the (101) plane, which is the most easily developing face, is shown in Fig. 3(a).

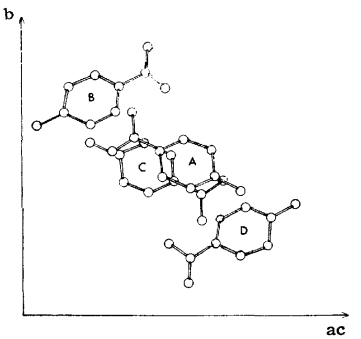

Fig. 3 (a). Projection of *p*-nitroaniline molecules onto the (101) plane.

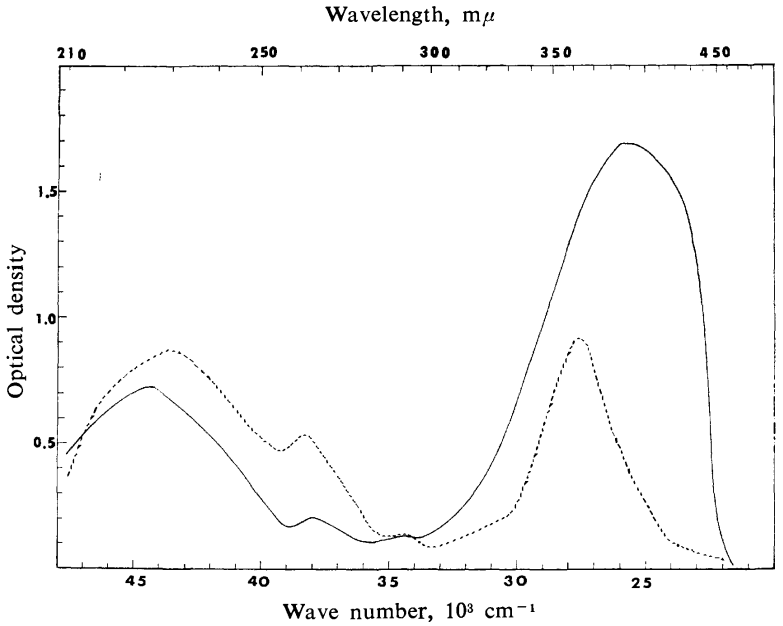

Fig. 3 (b). Polarized absorption spectrum of *p*-nitroaniline crystal.
—— The light polarized parallel to 101 dirrection
---- The light polarized parallel to b-axis

The thickness of the crystal was determined approximately by observing the interference color with a polarizing microscope and by using the relation between the retardation and birefringence; namely $R=d(n_{ac}-n_b)$, where R is the retardation and $n_{ac}-n_b$, the birefringence with the (101) plane, and d, the thickness. For more accurate measurement of crystalline thickness, the "apparent absorption band" in the visible region was measured with the polarized light. This absorption appears as a result of the interference of the beam reflected from the front surface with the beam reflected upon the rear surface[20]. For a wavelength at which the two beams interfere additively upon reflection and at which the transmission is at a maximum, the thickness, d, of the crystal is given by:

$$d=m\lambda/2n, \text{ where } m=3, 4, 5, \cdots\cdots$$

and n is the refractive index at the wavelength of measurement. For a wavelength where the transmission is at a minimum,

$$d=(2m+1)\lambda/4n, \text{ where } m=3, 4, 5, \cdots\cdots$$

In principle we can obtain the crystal thickness accurately by these means, but the dispersion of refractive index is not known, so the accuracy is limited to $\pm 0.03\mu$.

As has been mentioned before, the light falls onto the crystalline surface not at right angles but inclined about 46° to 12°. However, because of the refraction of the light at the crystalline surface, the light passes into the crystal inclined from 22° to 6° normal to the surface plane, and the optical path becomes necessarily large by about 1 to 10 per cent. This correction must be made in considering the optical path and, hence, the intensity of the crystalline absorption. As for the dichroism of the crystal, the transition moments of the molecules are nearly parallel to the (101) plane, so the dichroic ratio may be quite reliable in determining the polarization properties of molecular excited states.

The crystalline spectrum is shown in Fig. 3(b), where the spectrum with the light

20) A. Bree and L. E. Lyons, *J. Chem. Soc.*, **1956**, 2658; E. Edser and C. P. Butler, *Phil. Mag.*, **46**, 207 (1898).

polarized parallel and perpendicular to the b-axis is presented. The thickness of this crystal is estimated to be 0.36 μ. Four absorption bands are seen in the spectrum, three are fairly strong and one very weak. Each band shows a conspicuous dichroism. The observed oscillator strength and dichroic ratios for the 370 mμ and 270 mμ bands are given in Tables II and III, together with the calculated values for the oriented gas model. Comparing the calculated dichroic ratio with the observed value, it is unequivocally determined that the 370 mμ band is polarized parallel to the long axis of the molecule, while the 270 mμ band is directed to the short axis of the molecule. This result is in conformity with the above-mentioned theory, and the strong band appearing at 370 mμ (320 mμ in an *n*-heptane solution) is proved to be an intramolecular charge-transfer absorption. The fact that the 270 mμ band is not observed in solution but appears in the crystal may be explained by a perturbation of other allowed transitions or by a lowering of the symmetry of the excited state in the crystal. Anyway, this transition is shown to have the symmetry of the B type, polarized to the short axis of the molecule, while the wave function in Eq. 6 shows that the state is mainly composed of the $^1B_{2u}$ excited state of benzene. In addition to this band, another very weak absorption band is also observed at 295 mμ only in the crystalline spectrum. This band is not seen in the spectrum of the solution, but Wepster[21] had found a corresponding band in the spectrum of 4-nitro-*N*, *N*-dimethylaniline. Since a very weak transition of this kind would not be expected to appear judging from the results of the calculation of the π-electron system mentioned before, it is most probable that this is an n-π^* transition of the nitro group. The polarization of such a weak band cannot retain its own characteristic directional property of n-π^*, because the intensity mainly comes from the mixing with the allowed π-π^*. Therefore, the polarization of this band cannot be perpendicular to plane of the molecule, and the dichroism may be observed according to the mixing with nearby π-π^* transition.

The band at 220 mμ has a much larger intensity in the ac direction than in the b-axis; however, we cannot say anything conclusive about the polarization of this band, because the calculated energy levels are crowded in this region and a mixing with higher excited levels also easily takes place.

The Calculation of Davydov Splitting.—The crystal of *p*-nitroaniline belongs to a space group of $C_{2h}^5-P2_1/n$, and the molecule A in Fig. 3 (a) is transformed into B by a screw axis rotation parallel to the b-axis, into D by a glide plane vertical to the b-axis, and into C by an inversion. Combining the results of this operation with the character table of the C_{2h}^5 group, we obtain the following excited states wave functions:

$$\left.\begin{aligned}
A_g:&\quad \varphi_\alpha=\frac{1}{2}(\varphi_D'+\varphi_C'+\varphi_A'+\varphi_B')\\
A_u:&\quad \varphi_\beta=\frac{1}{2}(\varphi_D'+\varphi_C'-\varphi_A'-\varphi_B')\\
B_u:&\quad \varphi_\gamma=\frac{1}{2}(\varphi_D'-\varphi_C'+\varphi_A'-\varphi_B')\\
B_g:&\quad \varphi_\delta=\frac{1}{2}(\varphi_D'-\varphi_C'-\varphi_A'+\varphi_B')
\end{aligned}\right\} \quad (7)$$

where φ_A', φ_B', φ_C' and φ_D' denote the excited states wave functions of A, B, C and D site molecules respectively.

The selection rule allows a transition to the A_u excited state polarized along the b-axis and to the B_u state polarized along the a, c-axes. The energies of these levels can be shown to be:

$$\Delta E_\beta=\Delta E_m+D+\varepsilon_\beta$$
$$\Delta E_\gamma=\Delta E_m+D+\varepsilon_\gamma$$
$$\varepsilon_\beta=(\lambda_{AB}-\lambda_{AC}-\lambda_{AD})/2$$
$$\varepsilon_\gamma=(-\lambda_{AB}-\lambda_{AC}+\lambda_{AD})/2$$
$$\lambda_{AB}=\sum_B\int \psi_A^{*\prime}(r_1)\psi_B^*(r_2)\times\frac{e^2}{r_{12}}\psi_A(r_1)\psi_B'(r_2)d\tau_1 d\tau_2$$

where ΔE_m is the excitation energy for a free molecule, D is the whole shift of the center of the crystalline level from that of the free molecule, and λ_{AB} represents the interaction between an excited A molecule ψ_A' with all other excited B site molecules in the crystal.

It is the splitting of the band between b and a, c crystalline directions which is important: $\Delta E_\gamma-\Delta E_\beta$. The calculation of the integrals λ_{AB} and λ_{AD} was carried out using the dipole-dipole approximation, and the summation was taken over a 11 Å radius sphere. The results are shown in Table IV. Comparing them with the experimental value of the splitting $E_b-E_{a,c}=1680\,cm^{-1}$, it is evident that an assignment of the band as long axis polarized gives the better result; the agreement

TABLE IV. THE CALCULATED AND OBSERVED VALUES OF DAVYDOV SPLITTING (E_b-E_{ac})

Assumed polarization	Calculated	Observed
Long axis	1484 cm^{-1}	1680 cm^{-1}
Short axis	76 cm^{-1}	

21) B. M. Wepster, *Rec. trav. chim.*, **76**, 357 (1959).

between the observed and the calculated values is remarkably good. The appearance of such a large splitting means that a strong coupling of resonance energy transfer takes place in the crystal of *p*-nitroaniline.

The Intensity of the Crystalline Absorption.— The intensity of the 370 mμ band decreases greatly in the crystal in both crystalline directions, namely about one-sixth of the expected value of the oriented gas model, as is seen in Table II. One of the reason for the reduction in the intensity of the crystal is that the actual electric field acting upon a molecule has a factor of $(n/\varepsilon(E_e/E))$, where n is the refractive index of the crystal, ε is the static dielectric constant, and E_e and E are the effective field and the average field respectively[22]. The numerical estimation of this factor is a difficult problem. However, an approximate values may be $\sim 1/n$. This accounts in part for the reduction of the intensity, because n is in the range of 2.0~2.5.

Recently Tinocco[23] and Rhodes[24] have presented a formula of the hypochromism of polymeric systems. However, it has not yet been established that their formula explains the results in the crystal of *p*-nitroaniline.

In some other aromatic molecular crystals such as naphthalene, McClure and Schnepp[25] and the present author[26] have found a more pronounced decrease in the intensity from the oriented gas values. This phenomenon is not explained by a simple oriented gas model, neglecting the electronic exchange interaction between neighboring molecules. In order to explain it, we must use another approach, taking into consideration the electronic exchange interaction of the electronic levels of the molecules in the crystal. On the contrary, the crystal of *p*-nitroaniline affords a good example of an appearance of the Davydov splitting; it also presents a successful use of the exciton theory of molecular crystals in explaining the features of the crystalline spectrum except for the anomalous reduction of the absorption intensity.

Abrahams and Robertson[19] have proposed the formation of a self-molecular complex of *p*-nitroaniline, but no absorption was found which could be attributed to the intermolecular charge transfer. Probably the intramolecular charge transfer process is predominant in the molecule itself, and the highest occupied orbital (the donor orbital) of aniline is stabilized by the nitro group, so that no intermolecular charge transfer occurs in the *p*-nitroaniline crystal.

Benzoic Acid

The ultraviolet absorption spectrum of benzoic acid has been measured in an *n*-heptane solution and is shown in Fig. 4. Three absorption bands appear in the region of 185~290 mμ; only the one of the longest wavelength shows some vibrational structures. A theoretical interpretation of the spectrum has been given previously[2], and that of benzaldehyde has been investigated more extensively by the present author[27]. The spectrum of benzaldehyde is very much like that of benzoic acid except that it has an n-π^* transition in the 330 mμ region. According to earlier calculations[27], the 280 mμ band of benzoic acid is assigned to the transition between the $^1A_{1g}$ ground state and the excited state, mainly

composed of the $^1B_{2u}$ excited level of benzene, which has the short-axis polarization. The second excited state, corresponding to the 230 mμ absorption, is assigned to a state having a large component of the intramolecular charge transfer configuration, and the direction of the polarization is calculated to be on the 6.5° line, inclined outward from the Y axis (Fig. 5) to the carbonyl group. Another interpretation of this band is to regard it as derived from the $^1B_{1u}$ excited level of benzene; then the polarization would be along the Y-axis. The measurement of the crystalline spectrum was undertaken in order to decide between the two interpretations.

Spectrum of Benzoic Acid Crystal.—The crystal structure analysis of benzoic acid as carried out by Sim, Robertson and Goodwin[28] showed that the crystal belongs to $C_{2h}^5-P2_1/c$ space group, including four molecules in a unit cell. Based on this finding the projection of molecules onto the (001) plane is pictured in Fig. 6 (a). Thin flakes of crystal are obtained by sublimation and are used for spectral measurement. The developed face is (001). The optical properties of the crystal are as described by Winchell[18], and the axes are easily determined by a polarization microscope. The thickness of the crystal is measured by the interference pattern described in a previous paragraph. The observed crystalline spectrum crystal 0.23 μ thick, is shown in Fig. 6(b). Comparing the integrated intensity of each band when the polarization of light is along the a-axis with that of along the b-axis, the dichroic ratio is estimated to be $D_a : D_b =$ $(10\pm2) : 1$ for the 280 mμ band. In the region between 210~230 mμ there are two bands overlapping each other, and the band near 210 mμ is much stronger along the a-axis than along the b-axis. The 230 mμ band is apparently stronger in the b-axis. In order to estimate the dichroic ratio of the 230 mμ band, we have separated these overlapping bands; the dichroic ratio of the 230 mμ band was thus found to be $D_a : D_b = 1 : (31\pm3)$.

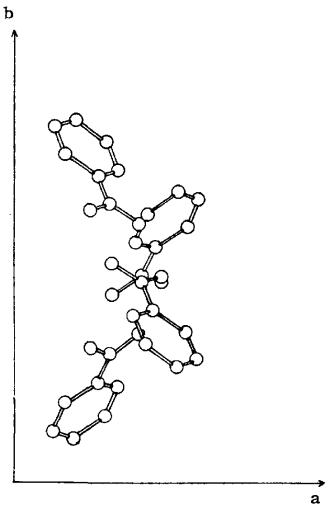

Fig. 6 (a). Projection of benzoic acid molecules onto the (001) plane.

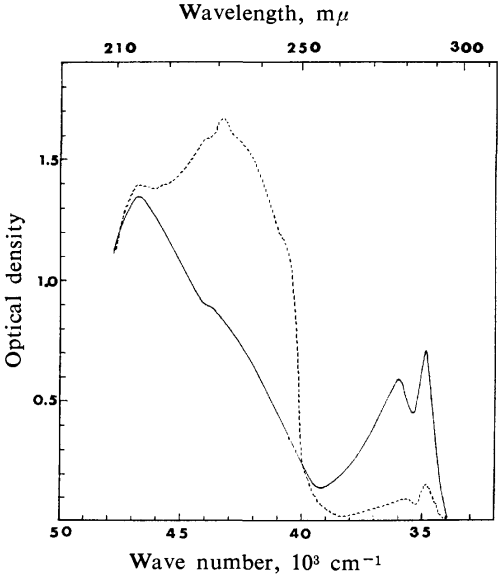

Fig. 6 (b). Polarized absorption spectrum of benzoic acid crystal.
—— The light polarized parallel to the a-axis
---- The light polarized parallel to the b-axis

According to the crystalline structure data, the dichroic ratio is calculated for the short-axis (X-axis in Fig. 5) transition as $D_a : D_b = 12 : 1$; hence, the 280 mμ band is confirmed to be polarized along the X-axis of the molecule, and to be largely a $^1B_{2u}$ transition. As for the 230 mμ band, the ratio is 1 : 30 if we take the direction of the transition moment to lie 6.5° inclined outward to the Y-axis towards the carbonyl group, but it is 1 : 11 if the direction is assumed to be on the Y-axis. Comparing the calculated value with the observed one, it is concluded that the 230 mμ band is polarized 6.5° outward to the Y-axis towards to the carbonyl group. Thus, the 230 mμ band is shown to have a characteristic polarization of an intramolecular charge transfer. The band at 210 mμ is not seen in solution; it may appear as the result of borrowing intensities from the allowed excited states situated in the shorter wavelength region. The polarization of this band seems to be

28) G. A. Sim, J. M. Robertson and T. H. Goodwin, *Acta Cryst.*, 8, 157 (1955).

short-axis, but it cannot be discussed further because the absorption band is not wholly observed.

Finally, as for the intensity of the crystalline absorption bands, the observed value is compared with the calculated value in Table V. The observed intensity of the 278 mμ band is nearly equal to the calculated value, but in the case of the 230 mμ band the observed value is one half the calculated one. In this case the hypochromic effect is again observed in the crystalline spectrum.

Acetanilide

The absorption spectrum of acetanilide measured in an *n*-heptane solution is shown in Fig. 7. Three absorption bands are seen in the region of 290~190 mμ; the long wavelength one is safely regarded by analogy with other substituted benzenes to be an absorption analogous to the 260 mμ band of benzene. In the theoretical interpretation of the spectrum

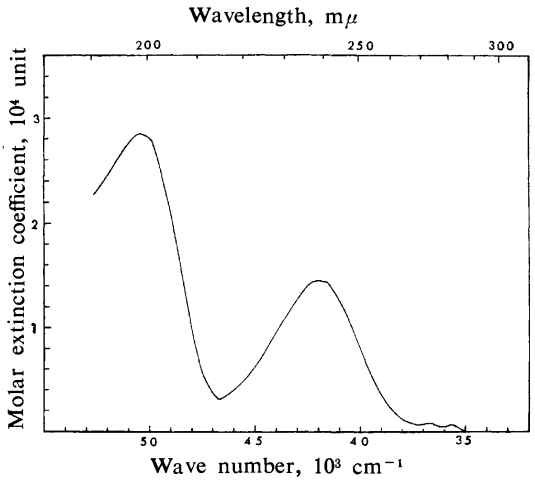

Fig. 7. Ultraviolet absorption spectrum of acetaniline in *n*-heptane solution.

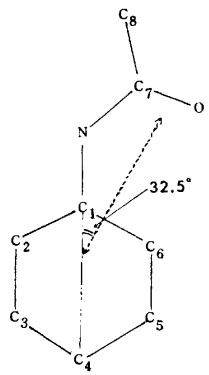

Fig. 8. Direction of the transition moment of the 230 mμ band of acetanilide.

of acetanilide given by Baba and Suzuki[29], it has been shown that the transition moment of the second band at 230 mμ lies 20.5° inclined to the C_1N axis towards the carbonyl group. According to the X-ray crystal structure analysis made by Brown and Corbridge[30], acetanilide is not a planar molecule and the plane of the acetyl group makes an angle of 37°54′ to the plane of the anilino group. The acetyl group can accept electrons from other conjugated systems, and aniline is a good electron donor, so that it is quite probable that an electron transfer takes place from the highest occupied orbital of the anilino group to the vacant orbital of the carbonyl group. If this charge transfer configuration is predominant for the excited state, in this particular transition the polarization should be along the line connecting the center of the highest occupied orbital of the anilino group to that of the vacant orbital of the carbonyl group (the center of the highest occupied orbital is 0.58 Å from the center of the benzene ring in the direction of the amino group, according to the LCAO MO calculations). This direction makes an angle of 32.5° with the C_1C_4 axis (Fig. 8). The 230 mμ band may be considered to have the large character of the charge transfer of this type. However, in order to give an accurate description of the nature of electronic transition, the configurational interaction between the charge transfer state and the locally excited states of aniline and of the carbonyl group must be taken into account. The symmetry of the molecule is less simple than *p*-nitroaniline, and the excited states will be a more complicated mixture of several excited configurations. Anyway, the crystalline spectrum will reveal the direction of the transition moment, and it will be useful for the theoretical assignment of the absorption bands.

The Spectrum of Acetaniline Crystal.—According to Brown and Corbridge[30], the crystal belongs to the space group of Pbca-D_{2h}^{15}, with the unit cell dimensions of $a=19.640$, $b=9.483$ and $c=7.979$ Å, and eight molecules are contained in a unit cell. The crystals for the spectral measurement were made by sublimation, and the (100) or (001) faces develop most easily. Projections of molecules onto these faces are shown in Figs. 9 (a) and 10 (a). The identification of the developed face is made by the use of X-ray rotation photography and the polarization microscope. The crystalline absorption is measured with a (100) face by a light polarized along the b and the

---- The light polarized parallel to the b-axis

c axes and with a (001) face by a light polarized along the a and the b axes, are respectively. The results are shown in Figs. 9(b) and 10(b). From Fig. 10(b), the direction of the transition moment of the 284 mμ band is confirmed to be nearly perpendicular to the C_1N axis, because the observed intensity ratio, $D_b : D_c = 2.90 : 1.0$, is almost in agreement with the calculated value of $D_b : D_c = 2.76 : 1.0$. This result is fairly satisfactory, considering the fact that the 284 mμ band overlaps the 230 mμ band which has a much larger intensity.

The polarization of the next 230 mμ band is determined by both (100) and (001) spectra independently. From the (100) spectrum, the observed intensity ratio is $D_b : D_c = 1.0 : 0.76$,

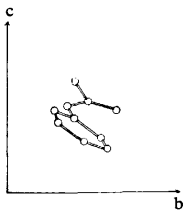

Fig. 10 (a). Projection of acetanilide molecule onto the (100) plane.

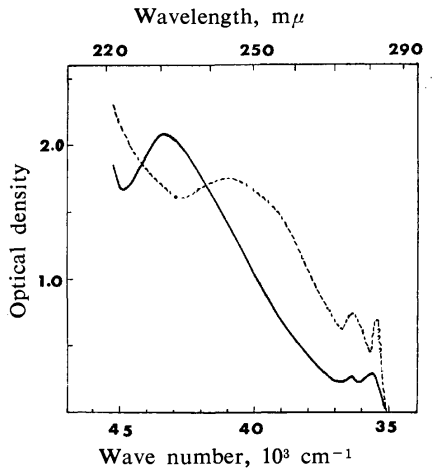

Fig. 10(b). Polarized absorption spectrum of acetanilide crystal through the (100) plane.
—— The light is polarized parallel to the c-axis
---- The light polarized parallel to the b-axis.

while the calculated value is 1.0 : 0.74 if we take the direction of the transition moment on the line inclined 32.1° to the C_1C_4 axis toward the carbonyl group (36.2° to the C_1N axis) (Fig. 8). From the (001) spectrum, the observed intensity ratio $D_a : D_b$ is 4.53 : 1.0, whereas the calculated value is 4.95 : 1.0 if the direction of the transition moment is assumed along the line 33.2° inclined to the C_1C_4 axis (35.4° to the C_1N axis) outward to the carbonyl group. The agreement of these two measurements is quite satisfactory, and the polarization of the 230 mμ band is determined to be along the direction of 32.5±0.5° inclined to the C_1C_4 axis (35.6° to the C_1N axis) outward to the carbonyl group. This direction is the same as the direction of the charge transfer from the highest occupied orbital of the anilino group to the vacant orbital of the carbonyl group, but this coincidence cannot be stressed too much, because the exact description of the excited state must be given by the configurational interaction calculations.

The Davydov splitting of the second absorption is obviously seen in Figs. 9(b) and

10(b); namely, it appears at 243 mμ in the a-axis, at 244 mμ in the b-axis, and at 230 mμ in the c-axis. The splitting was not found with the 282 mμ band, because the dipole-dipole interaction between the excited states is smaller than for the stronger 230 mμ band.

As for the intensity of the 230 mμ band in the crystal, the observed intensity is about one half that of the calculated value, as is shown in Table VI. The hypochromism of crystalline absorption is found again; hence, it seems a common experimental fact that the fairly strong absorption band loses some of its intensity in the crystalline spectrum.

trans-Cinnamic Acid

The electronic absorption spectrum of *trans*-cinnamic acid measured in an *n*-heptane solution is illustrated in Fig. 11. A weak absorption band is seen at 296 mμ as a shoulder of the stronger band at 277 mμ. Another stronger band with vibrational structure is observed near 222 mμ.

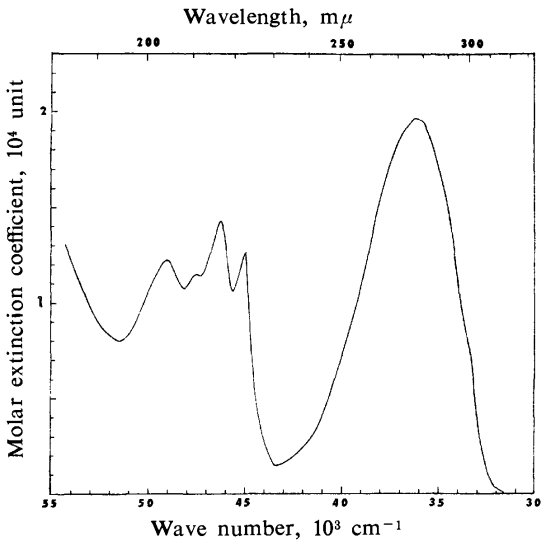

Fig. 11. Ultraviolet absorption spectrum of *trans*-cinnamic acid in *n*-heptane solution.

trans-Cinnamic acid is considered to be a composite, consisting of the electron-donating styryl group and the electron-accepting carboxyl group. The charge transfer from the highest occupied orbital of the styryl group to the vacant orbital of the carboxyl group will take place quite easily, because the ionization potential of styrene is as small as 8.86 eV.[31] and the charge density of the highest occupied orbital of styrene is most dense at the terminal α-carbon atom, where the interaction between the donor and the acceptor group takes place. By this reasoning, the strong absorption band at 277 mμ is regarded as an intramolecular charge transfer band; this is confirmed by a measurement of the crystalline absorption spectrum.

The Crystalline Spectrum of *trans*-Cinnamic Acid.—The crystal structure analysis of *trans*-cinnamic acid is now being carried out by Schmidt and his coworkers[32]. They find two crystalline forms. The α-form belongs to the $P2_1/a$ space group and has lattice constants as follows: $a=8.94$, $b=17.56$, $c=5.51$ Å and $\beta=58°40'$ and $n=4$; the β is found to have cell dimensions of $a=6.05$, $b=4.04$, $c=31.3$ Å, $\beta=90.3°$ and $n=4$. By sublimation, both α and β forms are obtainable, and the α-form develops a (010) face and the β develops a (001) plane. These crystalline faces are confirmed by X-ray rotation photographs. According to the unpublished results of Schmidt et al.[32] the projection of molecules of the α crystal onto a (010) face is shown in Fig. 12(a). The crystalline ultraviolet absorption of the *a*-form as measured through the (010) plane by a light polarized parallel and perpendicular to a-axis is shown in Fig. 12(b). With the β-form, spectrum is taken through the (001) face; the result is shown in Fig. 13. Comparing the spectrum of Fig. 12 (b) with the projections of molecules in Fig. 12 (a), it is easily found that the 270 mμ absorption band

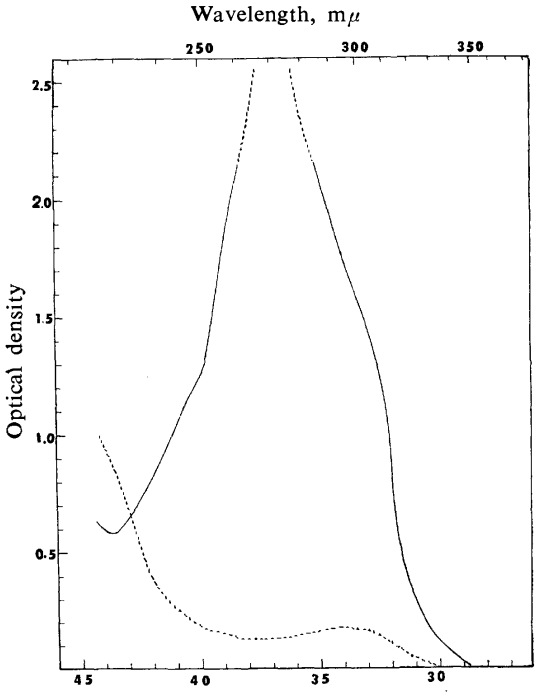

Fig. 12 (b). Polarized absorption spectrum of *trans*-cinnamic acid α-form through the (010) plane.
—— The light polarized parallel to the a-axis
---- The light polarized perpendicular to the a-axis

has a polarization nearly parallel to the a-crystalline axis. The direction of the transition moment is on the line expected from the charge transfer from the styryl group to the vacant orbital of the carboxyl group. In the crystalline spectrum, particularly in the β-form as seen in Fig. 13, the band which is at 277 mμ in an *n*-heptane solution shifts to about 255 mμ. The *trans*-cinnamic acid molecules are supposed to be aligned in pairs by a hydrogen bonding in the crystal. In this situation the transition moments of the pair of molecules are parallel to each other but are in oposite directions, and by a dipole-dipole interaction the excited states split into two, one allowed at a higher energy and the other forbidden at a lower energy. Therefore, the observable band should move to a shorter wavelength region. As a result of this blue shift, the weak absorption band which appears as a little shoulder in a solution at about 296 mμ becomes more evident in the crystalline spectrum. As is seen in Fig. 12 (a), if this absorption corresponds to the 260 mμ band of benzene, it should be observed in directions both parallel and perpendicular to the a-axis

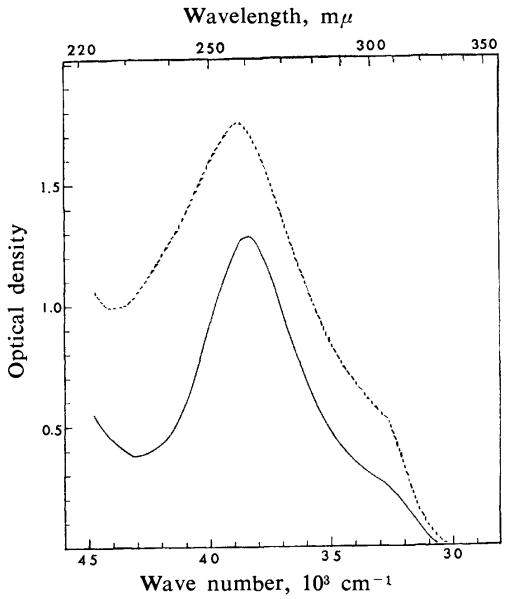

Fig. 13. Polarized absorption spectrum of *trans*-cinnamic acid β-form through the (001) plane.
—— The light polarized parallel to the a-axis
---- The light polarized parallel to the b-axis

because the polarization should be short-axis. In Fig. 12 (b), the 295 mμ band appears both parallel and perpendicular to the a-axis so it is established that the band is derived from the $^1B_{2u}$ excited state of benzene. We cannot discusss further the spectrum shown in Fig. 13 because the crystal structure has not yet been fully analyzed.

Durene

The electronic absorption spectrum of durene is quite similar to that of benzene, and the spectrum in *n*-heptane is illustrated in Fig. 15.

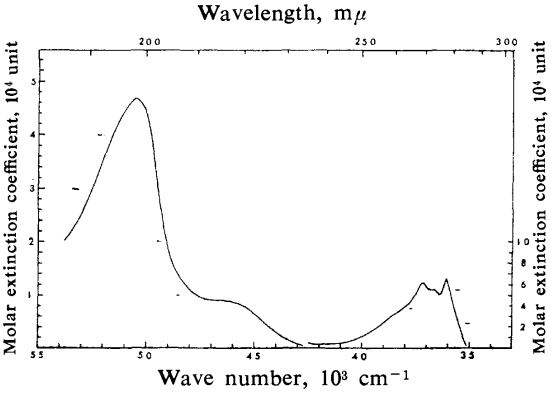

Fig. 14. Ultraviolet absorption spectrum of durene in *n*-heptane solution.

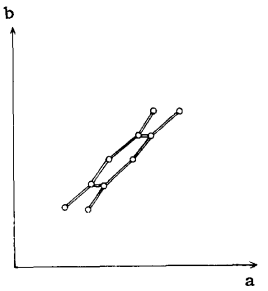

Fig. 15 (a). Projection of durene molecule onto the (001) plane.

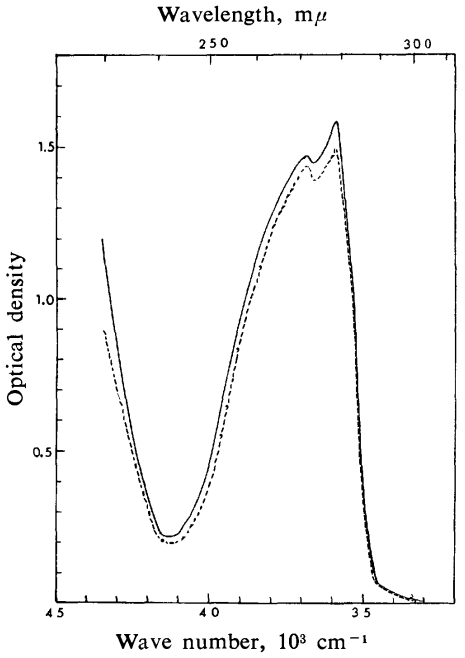

Fig. 15 (b). Polarized absorption spectrum of durene crystal.
—— The light polarized parallel to the a-axis
---- The light polarized parallel to the b-axis

The band near 278 mμ corresponds to the 260 mμ band of benzene ($^1A_{1g} \rightarrow {}^1B_{2u}$), the band around 217 mμ is correlated with 205 mμ band ($^1A_{1g} \rightarrow {}^1B_{1u}$) of benzene, and the strongest one, at 198 mμ, corresponds to the 185 mμ band ($^1A_{1g} \rightarrow {}^1E_{1u}$) of benzene. Following the theory of the spectrum of benzene[1], the first singlet excited state, $^1B_{2u}$, was shown to be polarized perpendicular to the two-fold symmetry axis of the molecule; hence, the polarization of the first band of durene should be perpendicular to the line connecting the two carbon atoms not substituted by methyl groups.

The crystalline absorption spectrum of durene has been studied by Schnepp and McClure[33]. The crystal structure of durene was determined by Robertson[34], and its optical properties were described by Groth[17]. Using Robertson's results, the molecules are projected onto the (001) plane in Fig. 15(a). The crystals measured are obtained by sublimation, and the developed face is easily confirmed as (001) by the aid of a polarization microscope. From Fig. 15(a) it is easy to see that the absorption band should have the same intensity in the a and b axes if the transition moment is parallel to the long axis of the molecule, while it should be stronger along the a-axis than along the b-axis if it is parallel to the short axis. The observed absorption spectrum is shown in Fig. 15 (b). As compared with the results of Schnepp and McClure, the present spectrum is broad and diffuse, because the measuement is made at room temperature. However, the general features of bands are in accordance with their results, and it is confirmed that the intensity ratio of the 280 mμ band is nearly equal in the directions of the a and b crystalline axes. The results show that the polarization of the 278 mμ band is parallel to the long axis of the molecule; hence, the excited level is confirmed to correspond exactly to the $^1B_{2u}$ excited state of benzene. The observed intensity ratio is rather small compared with the oriented gas ratio of $D_a : D_b = 1.0 : 1.3$; this deviation must be explained by the mixing of the $^1B_{2u}$ excited state of a particular molecule with the $^1B_{1u}$ excited state of neighboring molecules[35]. As compared with other substituent groups mentioned before, methyl groups have rather a small influence on the spectrum of benzene, and the polarization of durene's band is in accordance with that of benzene.

Conclusion

The electronic absorption spectra of substituted benzenes are in some way modifications of that of benzene itself. When the substituent group has rather a small influence as in, for instance, the methyl, hydroxyl or chloro groups, the pattern of the benzene spectrum is retained, the absorption peaks being shifted to red and the intensity of the 260 mμ band being strengthened to some extent[4]. A substitution by an amino, *N*, *N*-dimethylamino or ionized hydroxyl group causes the appearance of an additional excited level next to the $^1B_{2u}$

33) O. Schnepp and D. S. McClure, *J. Chem. Phys.*, **30**, 874 (1960).

level of benzene, since a charge transfer takes place in this region because the non-bonding electrons of these groups have relatively low ionization energies[3]. Two charge transfer states are possible, one from the substituent to the vacant orbital symmetrical to the two-fold axis, and the other to the antisymmetrical orbital. The former interacts with the $^1B_{1u}$ state, and the latter mixes with the $^1B_{2u}$ state. However, upon a substitution of the electron-donating groups, there are no serious changes in the polarization properties of each band, because the symmetrical properties of the excited states are not altered in sequence. The $^1B_{2u}$ excited state is the lowest singlet excited state in these substituted benzenes even if the electron-donating power of the substituent is so strong that the lowest state has a large percentage of charge transfer; hence, the longest absorption band is always polarized perpendicular to the two-fold symmetry axis of the molecule. Both the $^1B_{1u}$ excited state and the symmetrical charge transfer state have a polarization parallel to the two-fold axis, so the next band has this polarization in all cases. The results of durene and *p*-dimethoxybenzene[5] confirm the above statement, and such other molecules as aniline and phenol can be treated similarly.

In other substituted benzene molecules, in which the substituents have an electron-accepting property, a different situation arises. Electrophilic substituent groups have vacant orbitals which accept electrons from the benzene ring; as a result of this, new absorption bands often appear in addition to benzen's intrinsic transition[2,19,27]. The 370 mμ band of *p*-nitroaniline, which is the longest absorption band of this molecule, is not an analogous band to the 260 mμ band of benzene but a charge transfer band, and it is polarized along the two-fold symmetry axis of the molecule. In the case of benzoic acid, acetanilide and *trans*-cinnamic acid, charge transfer bands are observed next to the band derived from the $^1B_{2u}$ excited level of benzene. In these molecules, there are also other charge transfer states which interact with the $^1B_{2u}$ state of benzene. In fact, the longest absorption band of nitrosobenzene includes fairly large amounts of this type of charge transfer, together with the $^1B_{2u}$ state of benzene[27]. The sequence of these levels has been determined by the order of the energy levels of the initial states prior to configuration interaction.

Such electrophilic substituent groups as nitro, carbonyl, carboxyl, azo, nitroso are classified by Witt's classical theory as "chromophores"[36]. These groups are characterized by low-lying vacant orbitals which can receive electrons by resonance interaction. When an unsaturated hydrocarbon, which has electronic absorptions in the visible or near-ultraviolet region, is substituted by an electrophilic group, a new strong absorption band is often observed in the visible or the near-ultraviolet region arising from a new charge transfer state in which an electron is transferred from the parent hydrocarbon to the vacant orbital of the substituent. This is a quantum-chemical explanation of Witt's chromophore theory. Witt's "auxochrome" (such substituents as NH_2, NMe_2, OH, OMe, and Cl) may be understood in two ways; it produces bathochromic shifts in the transitions of the parent molecule, and it facilitates the transfer of electrons from the parent system to the electrophilic substituent by decreasing the ionization potential of the parent molecule.

The crystalline ultraviolet absorption spectral measurements are very useful in confirming this theory, because they give information about the directions of the transition moments of the bands and confirm the symmetry properties of excited levels. Moveover, some hidden and ambiguous bands in solution become evident in the crystalline spectra; they are very instructive in ascertaining what kinds of electronic interactions are prevalent in molecular crystals. It turns out that the dipole-dipole interactions of the exciton type are predominant in the case of the crystals studied here.

Summary

The electronic absorption spectra of some substituted benzene molecules *p*-nitroaniline, benzoic acid, acetanilide, *trans*-cinnamic acid, and durene have been measured in ethanol or *n*-heptane solutions and as single crystals, using polarized light. The measurement of the crystalline spectra reveals in many respects the properties of the transitions of substituted benzene molecules. The 277 mμ of durene, which is reasonably regarded as a band analogous to the 260 mμ of benzene, is shown to be polarized perpendicular to the two-fold symmetrical axis of the molecule. Bands of the same type occur at 264 mμ in *p*-nitroaniline (crystal), at 284 mμ in benzoic acid, at 282 mμ in acetanilide and at 299 mμ in *trans*-cinnamic acid. In addition, those molecules in which the benzene ring is substituted by the electron-accepting groups, show a strong band, associated with intramolecular charge transfer, in the near ultraviolet region. The 370 mμ band of *p*-nitroaniline is shown to be

36) A. E. Gilam and E. S. Stern, "Electronic Absorption Spectroscopy", Edward Arnold, Ltd., London (1958).

polarized parallel to the long axis of the molecule, and the 230 mμ band of benzoic acid has a polarization parallel to the line connecting the centers of the benzene ring and the carbonyl group. The directions of the transition moments of the 240 mμ band of acetanilide and the 276 mμ band of *trans*-cinnamic acid are also shown to be on the line connecting the substituents and the benzene ring. Davydov splitting is observed in the crystal of *p*-nitroaniline; this splitting is in good agreement with the values calculated by the exciton theory.

The author thanks Professor Saburo Nagakura for his continued encouragement and Professor Zyun Koana for lending him Bausch and Lomb's lenses. The author's gratitude is also due Dr. G. M. J. Schmidt for his kind communication of his unpublished findings on *trans*-cinnamic acid and also Dr. J. N. Murrell for his valuable discussion and kind hospitality during the author's stay in Sheffield, where some parts of this paper were written.

*The Synthesis of γ,δ-Dimethyl-γ-(2-carboxyethyl)-δ-valerolactone**

By Toshihiro TAKATA, Kazunori SAYAMA, Yukihide FURUTSU and Masahiko TAKIGAWA

(Received March 8, 1963)

The present paper describes a synthesis of γ,δ-dimethyl-γ-(2-carboxyethyl)-δ-valerolactone, through the scheme shown below, from γ-acetyl-γ-methylpimelonitrile derived from ethyl methyl ketone by cyanoethylation with acrylonitrile[1].

The cyanoethylation of ethyl methyl ketone was carried out according to the method of Bruson and Riener[1] to give γ-acetyl-γ-methylpimelonitrile (I), which was then hydrolyzed to γ-acetyl-γ-methyl pimeric acid (II)[1]. Compound II was hydrogenated, in the presence of a Raney-nickel catalyst in an aqueous sodium hydroxide solution, to sodium γ-methyl-γ-(l-hydroxyethyl)-pimelate (III), which was not isolated and which, after treatment with hydrochloric acid, gave γ,δ-dimethyl-γ-(2-carboxyethyl)-δ-valerolactone (IV).

Though δ-valerolactone gives an associated molecule[2], compound IV gives no associated molecule, as was detected by the cryoscopic method.

As another route, compound I was esterified with ethanol, water and sulfuric acid to give diethyl-γ-methyl-γ-acetylpimelate, which was then hydrogenated to γ,δ-dimethyl-γ-(2-carboethoxyethyl)-δ-valerolactone (VII) through diethyl-γ-methyl-γ-(l-hydroxyethyl)-pimelate (VI), which was not isolated.

On the other hand, I was hydrogenated with sodium borohydride to give γ-methyl-γ-(l-hydroxyethyl)-pimelonitrile (VIII). In this procedure the nitrile group was not attacked, but the carbonyl group hydrogenated to the hydroxyl group, as is shown in Fig. 1. The absorption bands at 1095 and 1075 cm^{-1} of compound VII are probably due to the formation of the hydroxyl group, while the absorption band at 1705 cm^{-1}, being due to the carbonyl group of I, is absent in VIII. The band at 2250 cm^{-1}, being due to the nitrile group, is present in both I and VIII.

Then, compound VIII was treated with concentrated sulfuric acid in order to obtain γ-methyl-γ-(l-hydroxyethyl)-pimelic acid diamide

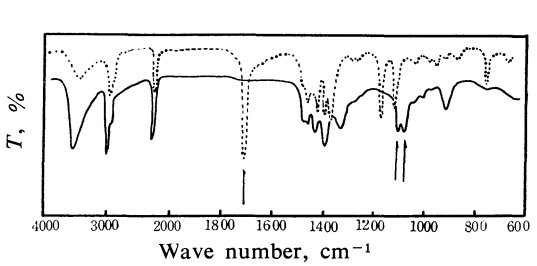

Fig. 1. Infrared absorption spectrum of γ-acetyl-γ-methylpimelonitrile (I) (- - -, KBr disk) and of γ-methyl-γ-(l-hydroxyethyl)-pimelonitrile (VIII) (——, liquid film).

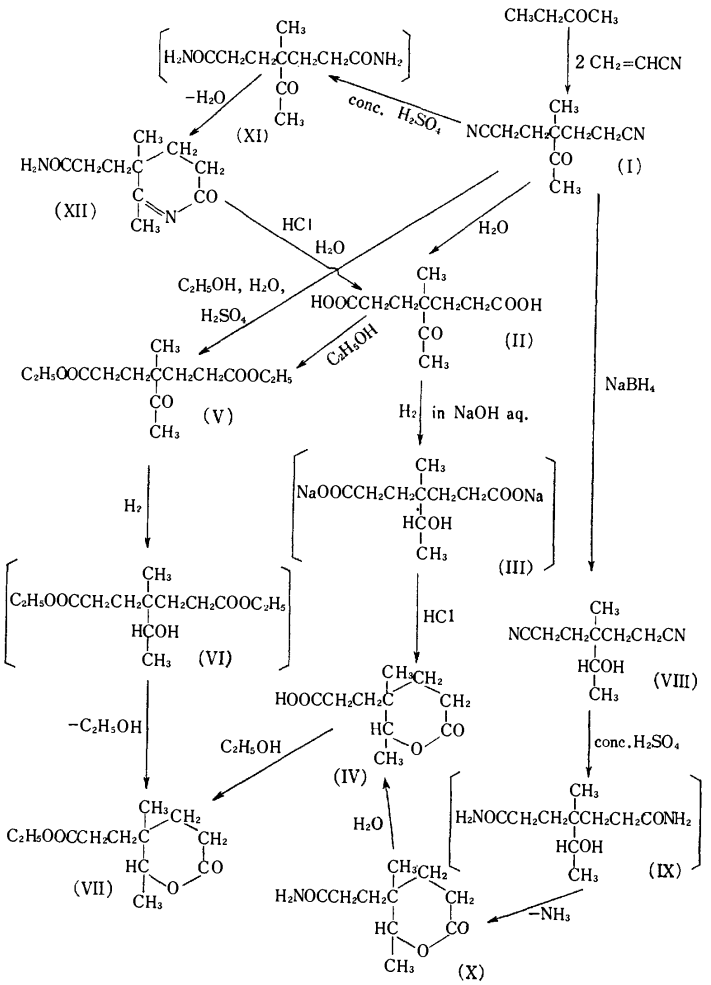
* Reported at the Chūgoku & Shikoku Meeting of the Chemical Society of Japan, Tokushima, August, 1962.

1) H. A. Bruson and T. W. Riener, *J. Am. Chem. Soc.*, **64**, 2850 (1942).

2) K. Sayama, T. Takata and M. Taniyama, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kōgyō Kagaku Zassi*), **58**, 112 (1955).



(IX). However, IX was not obtained, and γ,δ-dimethyl-γ-(2-carbamoylethyl)-δ-valerolactone (X) was obtained; it was converted to IV by hydrolysis. The infrared spectrum of X, shown in Fig. 2, has absorption bands at 1730 cm^{-1} and 1675 cm^{-1}, which are, respectively, due to the structures of the six-membered lactone and of the amide group.

Moreover, compound I was treated with concentrated sulfuric acid in order to obtain γ-methyl-γ-acetylpimelic acid diamide (XI). In this case XI was not obtained, but 2-keto-5, 6-dimethyl-5-(2-carbamoylethyl)-2, 3, 4, 5-tetrahydropyridine (XII) was obtained; it was converted to II by hydrolysis, but it could not be hydrogenated under high hydrogen pressure in the presence of a Raney-nickel catalyst nor by sodium borohydride. The infrared absorption spectrum of XII shown in Fig. 3 has absorption bands at 1685, 1660 and 1640 cm^{-1} which are due to the structures of the carbonyl in the ring, of the double bond between C and N in the ring, and of the amide group in the side chain. Moreover, the ultraviolet absorption spectra shown in Fig. 4 has absorption maxima at 201.5 mμ (ε, 11900) and 282.5 mμ (ε, 5) in water, at 210 mμ (ε, 4067) and 280 mμ (ε, 8) in ethanol, at 202.5 mμ (ε, 20810) and 282.5 mμ (ε, 6) in 0.5 N aqueous sulfuric acid, and at 222 mμ (ε, 2165) and 291 mμ (ε, 6) in 0.5 N aqueous sodium hydroxide. Such a shift of ultraviolet absorption bands according to the pH value of the

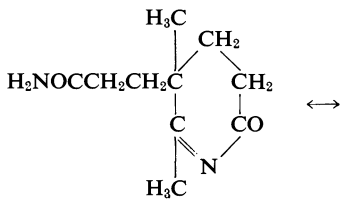
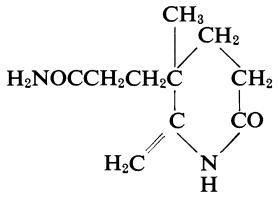
medium suggests the possibility of such tautomerism as the following.



(In an acidic medium or a neutral medium)



(In an alkaline medium)

Further experiments may be necessary to establish this phenomenon completely.

Experimental

γ, δ-Dimethyl-γ-(2-carboxyethyl)-δ-valerolactone (IV).—In a 220 ml. autoclave, compound II (40 g. in 90 g. of a 20% aqueous sodium hydroxide solution) was hydrogenated under about 80 atm. of hydrogen pressure at 104~120°C in the presence of a Raney-nickel catalyst (from 20 g. of Ni-Al alloy 50 : 50) for 4.3 hr. The reaction mixture was evaporated and acidified with concentrated hydrochloric acid, and extracted with ether. From the ether extract IV was obtained as a viscous liquid (b. p., 200~202°C/1 mmHg), which after standing became crystalline; m. p., 60~62°C; yield, 35.2 g. (95.0%).

Found: C, 59.92; H, 8.15; N, 0.00. Calcd. for $C_{10}H_{14}O_4$: C, 59.98; H, 8.06; N, 0.00%.

Neutralization and saponification equivalent, 100.3. Calcd. for IV, 100.1.

Mol. wt., 196.5 (cryoscopic method in acetic acid). Calcd. for IV, 200.2.

Diethyl γ-Methyl-γ-acetylpimelate (V).—Compound I (17.8 g.) was dissolved in a mixture of ethanol (36.8 g.) and concentrated (96%) sulfuric acid (25 6 g.), and the mixture was heated under reflux at a bath temperature of 140~143°C for 3.5 hr. The reaction mixture was washed with water, and the oily layer was extracted with ether, dried with sodium sulfate, and distilled to give V; b. p., 158°C/2 mmHg, d_4^{20} 1.0522, n_D^{20} 1.4562; yield, 20.9 g. (76.7%).

Found: C, 61.88; H, 8.83; O, 28.99. Calcd. for $C_{14}H_{24}O_5$: C, 61.74; H, 8.88; O, 29.38%.

Saponification value, 414.4. Calcd. for V, 412.0.

This compound was obtained in an 82.3% yield by the esterification of II (50 g.) with ethanol (200 g.) in the presence of sulfuric acid (9 g.) at a bath temperature of 130~140°C for 5 hr.

γ, δ-Dimethyl-γ-(2-carboethoxyethyl)-δ-valerolactone (VII).—Compound IV (10 g., in 10 ml. of ethanol) was hydrogenated under about 85 atm. of hydrogen pressure at 140~150°C in the presence of a Raney-nickel catalyst (from 5 g. of Ni-Al alloy 50 : 50) for 2hr. From this reaction mixture VII was obtained by distillation; b. p., 155°C/2 mmHg, d_4^{20} 1.0579, n_D^{20} 1.4640; yield, 6.3 g. (75.2%).

Found: C, 63.07; H, 8.90; O, 27.80. Calcd. for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83; O, 28.04%.

Saponification value, 487.2. Calcd. for VII, 491.2.

This compound was obtained in a 76.3% yield by the esterification of IV (5 g.) with ethanol (50 g.) in the presence of sulfuric acid (2 g.) at a bath temperature of 130~140°C for 5 hr.

γ-Methyl-γ-(1-hydroxyethyl)-pimelonitrile (VIII).—Into a solution of I (90 g.) in methanol (500 ml.) sodium borohydride (9.6 g.) was slowly stirred below 30°C; after it had been left standing for 2.5 hr. at room temperature, this mixture was

neutralized with concentrated hydrochloric acid, evaporated, separated from the precipitate by filtration, and dried in vacuum to give a viscous substance which was identified as VIII by the infrared spectrum shown in Fig. 1 and by elementary analysis as follows. Yield, 90 g. (quantitatively), n_D^{20} 1.4800.

Found: N, 15.48. Calcd. for $C_{10}H_{15}N_2O$: N, 15.55%.

γ, δ-Dimethyl-γ-(2-carbamoylethyl)-δ-valerolactone (X).—A mixture of VIII (10 g.) and 90% sulfuric acid (20 g,) was heated at 60°C for 1 hr., neutralized with concentrated aqueous ammonia while being vigorously stirred and externally cooled, and extracted with chloroform. From this extract after evaporating. X was obtained as a viscous liquid, n_D^{20} 1.4945; yield, 11 g. (99.6%). The infrared spectrum of X is shown in Fig. 2.

Found: N, 7.01. Calcd. for $C_{10}H_{17}NO_3$: N, 7.03%.

The Hydrolysis of X.—Compound X was treated with sodium hydroxide (4 g., in 40 g. of water) on a water bath for 3 hr., acidified with hydrochloric acid, evaporated, and extracted with ether. From the ether extracts IV was obtained; yield 2.2 g. (54.7%).

2-Keto-5, 6-dimethyl-5-(2-carbamoylethyl)-2, 3, 4, 5-terahydropyridine (XII).—By a method similar to that described for X, XII was obtained from I (10 g.) and 90% sulfuric acid (20 g.) in the form of colorless crystals; m. p., 237~238°C (from ethanol); yield, 5.1 g (42.4%). The infrared spectrum of XII is shown in Fig. 3, while the ultraviolet absorption spectra are shown in Fig. 4.

Found: C, 61.64; H, 8.26; N, 14.29. Calcd. for $C_{10}H_{16}N_2O_2$: C, 61.20; H, 8.22; N, 14.28%.

The Hydrolysis of XII.—Compound XII was treated with 20% aqueous hydrochloric acid on a boiling water bath for 2.7 hr. and then extracted with ethylene dichloride. From the ethylene dichloride extract II was obtained; yield, 1.85 g. (84.1%); m. p., 124~125°C (from ethylene dichloride), undepressed on admixture with the authentic specimen derived from I.

Found: C, 55.39; H, 7.33; N, 0.00. Calcd. for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46; N, 0.00%.

The authors are grateful to Mr. Masatomo Kusunose (Manager of the Research Institute, Toho Rayon Co., Ltd.), Dr Minoru Imoto (Professor of Osaka City University), and Dr. Torakichi Yosioka (Professor of Tokushima University) for their valuable advice on the experiments; to Mr. Toshikazu Inoue, Miss Keiko Yano and Miss Akiko Hiroshe for helping them with the elementary analyses, and to Mr. Kiyosumi Kubo for helping them with the infrared and ultraviolet spectral work.

Studies of the Solvent Extraction of Zirconium-95 in the Tribenzylamine-Hydrochloric Acid System

By Takashi OMORI and Nobuo SUZUKI*

(Received December 17, 1962)

In a previous paper[1], the mechanism of the amine extraction of niobium-95 was reported on and the niobium species in a hydrochloric acid solution were estimated. If the zirconium species in the same medium were known, the separation of zirconium and niobium could be carried out successfully. Although a number of investigations have been carried out on the zirconium species in a hydrochloric acid solution, the results reported are not in satisfactory agreement with each other[2-4].

In the present paper, the distribution of carrier-free zirconium-95 between hydrochloric acid and tribenzylamine is investigated.

Experimental

Carrier-free zirconium-95 was prepared from zirconium-niobium-95 by the anion-exchange resin method and was stored in 9 N sulfuric acid. Before being used for each experiment, zirconium-95 was extracted with acetylacetone from an aqueous solution containing hydrogen peroxide[5]. The zirconium-95, being free from niobium-95, was then converted

into the chloride form by back extraction with concentrated hydrochloric acid. The experiments were carried out within four hours to avoid the error due to the growth of niobium-95.

All the other chemicals and the techniques employed were similar to those described in the previous paper[1].

The experiments were carried out at 25±0.5°C unless otherwise stated.

Results and Discussion

The Distribution Mechanism and Some Related Equations.—It has been revealed that the anionic species in the aqueous phase are transferred to the organic phase in the amine extraction through the anion exchange mechanism and that, for the niobium-tribenzylamine system, the metal complexes in the organic phase form the more stable additive compounds with the amine. Thus, the distribution coefficient for zirconium, D_{Zr}, can be represented in terms of activities as follows:

$$D_{Zr}=\frac{\sum_p\sum_q\sum_i(R_{p+q-4}Zr(OH)_pCl_q\cdot iRCl)_o}{\sum_m\sum_n(Zr(OH)_mCl_n^{(4-m-n)+})_a}$$

$$=\frac{(Cl^-)_a^4}{\sum_m\sum_n(\beta_{m,n}(H^+)_a^{-m}(Cl^-)_a^n)}$$

$$\times\sum_p\sum_q\sum_i(K_{p,q}\cdot K_i\cdot\beta_{p,q}(RCl)^{p+q+i-4}$$

$$\times(H^+)_a^{-p}(Cl^-)_a^{-p})$$

$$(5\leq(p+q)\leq8) \qquad (1)$$

where the subscripts a and o denote the aqueous and organic phases respectively, and RCl represent the chloride form of tribenzyl amine (TBA-Cl). $K_{p,q}$, K_i and $\beta_{m,n}$ are defined as follows:

$$K_{p,q}=\frac{(R_{p+q-4}Zr(OH)_pCl_q)_o(Cl^-)_a^{p+q-4}}{(Zr(OH)_pCl_q^{(4-p-q)+})_a(RCl)_o^{p+q-4}} \qquad (2)$$

$$K_i=\frac{(R_{p+q-4}Zr(OH)_pCl_q\cdot iRCl)_o}{(R_{p+q-4}Zr(OH)_pCl_q)_o(RCl_o)^i} \qquad (3)$$

$$\beta_{m,n}=\frac{(Zr(OH)_mCl_n^{(4-m-n)+})_a}{(ZrCl_6^{2-})_a}$$

$$\times(H^+)_a^{-m}(Cl^-)_a^{6-n} \qquad (4)$$

For the sake of simplicity it is assumed in these expressions that only mononuclear complexes exist in solutions. The activities of the species concerned have been employed in a way similar to that reported previously[1].

The Variation of the Distribution Coefficient with Hydrochloric Acid and TBA-Cl Concentrations.—The distribution of zirconium-95 between hydrochloric acid and a TBA-Cl solution in chloroform was determined. As is shown in Fig. 1, the distribution of zirconium-95 increases with an increase in the concentration of hydrochloric acid and TBA-Cl.

The Dependence of the Distribution Coefficient for Zirconium-95 on the Tribenzyl Amine Concentration.—A plot of log D_{Zr} against log$(RCl)_o$ in Fig. 2 gives two straight lines with a slope of 2.8 up to 0.06 M TBA-Cl and of 3.8 above this point, indicating that one molecule of the zirconium complex associates with up to four molecules of TBA-Cl. At a constant acidity and chloride level, Eq. 1 can be written by:

$$D_{Zr}=\frac{\sum K_5\cdot(RCl)_o+\{\sum K_6+\sum(K_5\cdot K_{i=1})\}(RCl)_o^2+\cdots}{F(H,\ Cl)} \qquad (5)$$

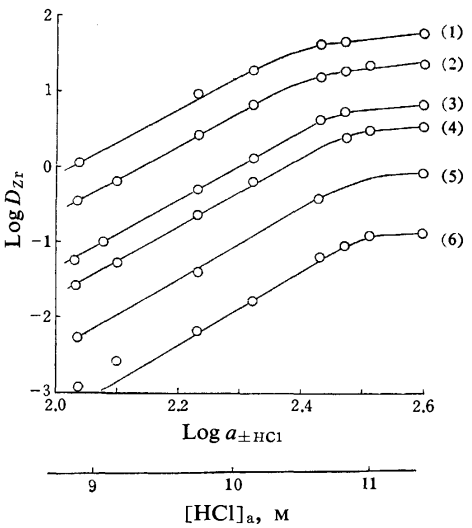

Fig. 1. Distribution of zirconium between hydrochloric acid and TBA-chloroform at 25°C.

	(1)	(2)	(3)	(4)	(5)	(6)
$[RCl]_o$, M:	0.200	0.150	0.100	0.075	0.050	0.025

in which

$$F(\mathrm{H,Cl})=\frac{(\mathrm{Cl^-})_a^4}{\sum\sum\{\beta_{m,n}(\mathrm{H^+})_a^{-m}(\mathrm{Cl^-})_a^{n}\}}$$

$$K_5=K_{p,q(p+q=5)}\beta_{p,q(p+q=5)}\times(\mathrm{H^+})_a^{-p}(\mathrm{Cl^-})_a^{-p} \quad (6)$$

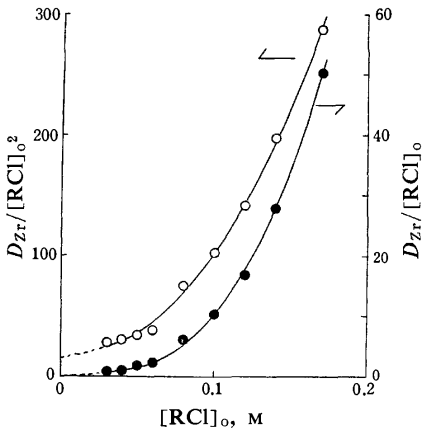

Fig. 3. Plot of $D_{Zr}/[RCl]_o$ and $D_{Zr}/[RCl]_o^2$ vs. $[RCl]_o$ for zirconium.

The plots of $D_{Zr}/(RCl)_o$ and $D_{Zr}/(RCl)_o^2$ against $(RCl)_o$ are given in Fig. 3. The plot of $D_{Zr}/(RCl)_o$ against $(RCl)_o$ provides a curve passing through the point of origin, showing that the values of $K_{p,q(p+q=5)}$ are equal to zero; i.e., the zirconium species with the charge of -1 are not extracted. The value of $\sum K_{p,q(p+q=6)}$ obtained by extrapolation of the plot of $D_{Zr}/(RCl)_o^2$ vs. $(RCl)_o$ to a zero concentration of TBA-Cl is not equal to zero. Thus, one of the charge numbers of the zirconium chloro-complexes extracted is probably -2.

The Dependence on Chloride Ion and Hydrogen Ion Activities.—The dependence of the distribution coefficients on the chloride ion activities is given by the differentiation of Eq. 1 with respect to chloride ion activity at a constant acidity:

$$\frac{\partial \log D_{Zr}}{\partial \log(\mathrm{Cl^-})_a}=4-\bar{p}-\bar{n} \quad (7)$$

In this experiment, the concentration of hydrochloric acid was held at 7.62 M, while the chloride ion activity was varied by the addition of lithium chloride. As is shown in Fig. 4, the distribution coefficients in hydrochloric acid-lithium chloride mixed solutions are lower than those in a hydrochloric acid solution over the range of chloride ion activity investigated, because of the deficiency of the acidity.

The distribution curve has a slope of four at higher chloride ion activities. This suggests,

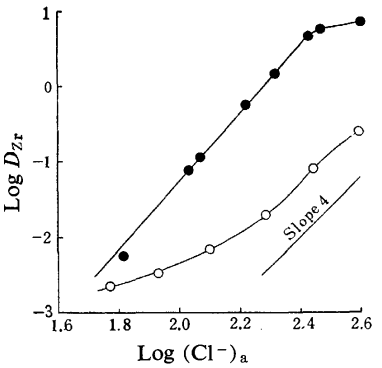

Fig. 4. Chloride dependence of D_{Zr} values for zirconium at 25°C.

○ HCl-LiCl mixture $[H^+]_a=7.62$ M
● Pure HCl

according to Eq. 7, that the zirconium exists as Zr^{4+} in the aqueous phase, i.e., $\bar{p}+\bar{n}=0$, and that $ZrCl_6^{2-}$ (viz., $\bar{p}=0$) is extracted to the organic phase; however, the existence of a zirconyl ion can not be ignored, as will be mentioned later.

Proceeding as above, the following equation can be derived from Eq. 1 at a constant chloride level:

$$\frac{\partial \log D_{Zr}}{\partial \log(\mathrm{H^+})_a}=\bar{m}-\bar{p} \quad (8)$$

By using hydrochloric acid-lithium chloride mixtures, the chloride levels were held at 9.45 and 11.5 M, while the hydrogen ion activity was varied. The plot in Fig. 5 has a slope of ca. 2, i.e., $\bar{m}-\bar{p}=2$, when the chloride level was held at 11.5 M. Since $\bar{p}$ is equal to zero at a high chloride level, even in the region of relatively lower acidity (7.62 M), $\bar{m}$ should be equal to two. These suggest that the extractable species, $ZrCl_6^{2-}$, can be formed by the action of hydrogen ions as follows:

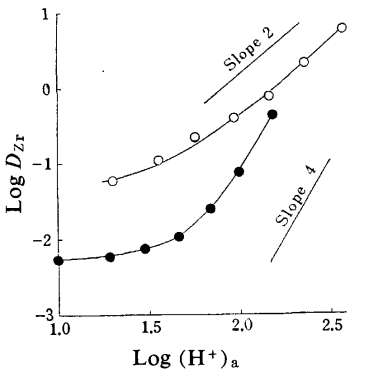

Fig. 5. Acid dependence of D_{Zr} values for zirconium at 25°C.

○ $[Cl^-]_{a,total}=11.5$ M
● $[Cl^-]_{a,total}=9.45$ M

$$Zr(OH)_2Cl_n^{(2-n)+} + 2H^+ + (6-n)Cl^- \rightleftharpoons ZrCl_6^{2-} + 2H_2O \quad (9)$$

Since the slope decreases as the acidity decreases, zirconium-95 may be partly extracted as $Zr(OH)_2Cl_4^{2-}$, which is formed from the zirconyl ion existing predominantly in the aqueous phase.

On the other hand, at a lower chloride level (9.45 M) such a plot shows a curve with a slope of four (Fig. 5), indicating the hydrolysis and/or the polymerization of the zirconium species. Thus, it should be recognized that hydrogen ions play a very important role in the zirconium extraction.

Temperature Effect.—It has been found that the extraction of the niobium with TBA-Cl is fairly much affected by the temperature[1]. Similar studies of the zirconium were carried out at 10±0.5 and 40±0.5°C. These results are shown in Fig. 6. There is an appreciable

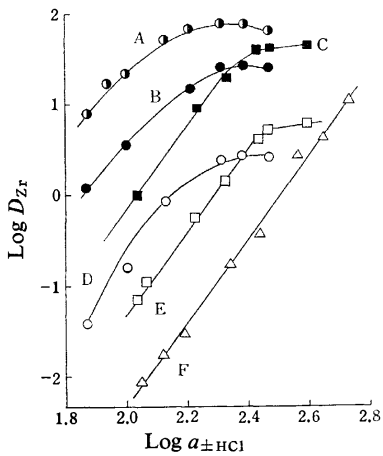

Fig. 6. Temperature dependence of D_{Zr} values for zirconium.

	$[RCl]_0$, M	Temp., °C
A	0.300	40
B	0.200	40
C	0.200	25
D	0.100	40
E	0.100	25
F	0.100	10

difference among the distribution curves obtained at different temperatures. At 40°C the distribution curve has a maximum in the region of higher acidity, whereas at 10°C it shows a straight line over the acidity range investigated. From the slope of the distribution curves in Fig. 6 it is concluded that the reaction expressed in Eq. 9 is promoted with an increase in the temperature.

To judge from the above considerations, the extraction processes of zirconium-95 from hydrochloric acid solutions with tribenzylamine are presumably shown by the following reactions:

$$ZrCl_6^{2-} + 2RCl \rightleftharpoons R_2ZrCl_6 + 2Cl^-$$
$$R_2ZrCl_6 + 2RCl \rightleftharpoons R_2ZrCl_6 \cdot 2RCl \quad (10)$$

and partly

$$Zr(OH)_2Cl_4^{2-} + 2RCl \rightleftharpoons R_2Zr(OH)_2Cl_4 + 2Cl^-$$
$$R_2Zr(OH)_2Cl_4 + 2RCl \rightleftharpoons R_2Zr(OH)_2Cl_4 \cdot 2RCl \quad (11)$$

Although it is considered that the greater part of zirconium is extracted through the process expressed in Eq. 10, the $K_{p=0,q=6}$ value is relatively small in comparison with the $K_{l=2}$ value, as has been shown in the case of the niobium extraction[1]. The formation constants, $\beta_{m,n}$, for the zirconium chloro-complexes and the distribution constants, $k_{p,q}$, can not be obtained because of their complexity, but the authors have drawn up a scheme (Fig. 7) concerning the zirconium species in the chloride system. This includes the most probable species.

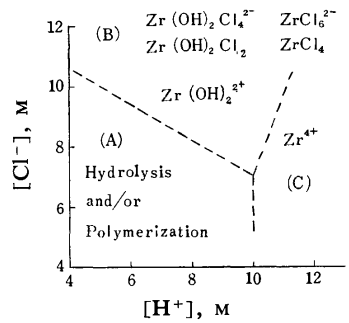

Fig. 7. Zirconium species in hydrochloric acid-lithium chloride solutions at 25°C.

The Possibility of the Mutual Separation of Zirconium-95 and Niobium-95.—In spite of the usefulness of the mutual separation of zirconium-niobium-95 in hydrochloric acid solutions, such a separation has not been carried out completely[6]. However, the more effective separation of zirconium and niobium can be expected, since there is an appreciable difference between the distribution coefficients of the zirconium and niobium with regard to the dependence of the distribution coefficient on the hydrogen ion concentration.

The separation factor, SF, under various conditions of a hydrochloric acid-lithium chloride solution at 25°C are tabulated in Table I. The separation factor increases up to 200 with a 7.6 M hydrochloric acid-0.8 M lithium chloride mixture, whereas it is 110 under optimum conditions for hydrochloric acid alone.

6) E. H. Huffman and R. C. Lilly, *J. Am. Chem. Soc.*, 73, 4474 (1951).

The separation factor as a function of temperature is also given in Table II. The separation factor is remarkably affected by the temperature and, even at 7.6 M hydrochloric acid, has a high value of 400 at 10°C. Since at a lower temperature the reaction expressed in Eq. 9 to zirconium is effectively restricted in comparison with the similar reaction to niobium, the higher separation factor is to be expected at lower temperature under suitable conditions, e.g., 7.5 M hydrochloric acid-1 M lithium chloride.

In the TBA extraction, however, the distribution coefficients for both zirconium and niobium are relatively so small that it is desirable to use other amines, possessing a higher extractability for niobium.

Summary

The extraction process of zirconium-95 from hydrochloric acid solutions tribenzylamine is shown by the following reactions:

$$ZrCl_6^{2-} + 2RCl \rightleftharpoons R_2ZrCl_6 + 2Cl^-$$

followed by the reaction of the above species with TBA-Cl in a chloroform solution:

$$R_2ZrCl_6 + 2RCl \rightleftharpoons R_2ZrCl_6 \cdot 2RCl$$

The main extractable species of zirconium, $ZrCl_6^{2-}$, is formed from the zirconyl ions:

$$Zr(OH)_2Cl_n^{(2-n)+} + 2H^+ + (6-n)Cl^- \rightleftharpoons ZrCl_6^{2-} + 2H_2O$$

On the basis of the present results and of previously reported data on niobium extraction, some information with respect to the optimum conditions for the separation of zirconium and niobium have been given.

The authors wish to express their hearty thanks to Professor Takanobu Shiokawa and Assistant Professor Kunio Seto for their kind suggestions made in the course of this work.

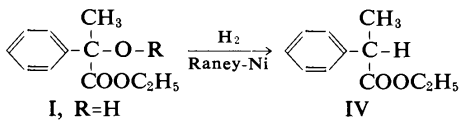
The Stereochemistry and Mechanisms of Catalytic Hydrogenation and Catalytic Hydrogenolysis. II[1]. *The Catalytic Hydrogenolysis of Optically-active Ethyl α-Phenyl-α-aryloxypropionates over Palladium and Nickel Catalysts*[2]

By Sekio MITSUI and Shin IMAIZUMI

(Received March 30, 1963)

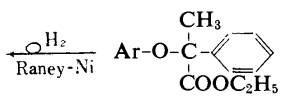
In order to clarify the mechanisms of catalytic hydrogenolysis, hydrogenation, and the exchange reaction of hydrogen on the surface of the catalyst, we have carried out an investigation of the catalytic hydrogenolysis over Raney nickel of optically-active ethyl atrolactate and its derivatives[3] and suggested the mechanisms of both catalytic hydrogenolysis and hydrogenation[1,4].

In the catalytic hydrogenolysis of ethyl atrolactate (I) and its alkyl (II) and aryl ethers (III) over Raney nickel, optically-active ethyl α-phenylpropionate (IV) was obtained with a 90% retention of optical activity. While I and II were hydrogenolyzed with retention of their configurations, III, underwent an apparent Walden inversion.



I, R=H
II, R=alkyl

IV



III Ar=aryl
III$_1$ Ar=C_6H_5-
III$_2$ Ar=p-$CH_3C_6H_4$-
III$_3$ Ar=o-$CH_3C_6H_4$-
III$_4$ Ar=p-$CH_3OC_6H_4$-
III$_5$ Ar=o-$CH_3OC_6H_4$-

In view of these results, we have suggested the following explanation[1,4]. In the cases of I and II, the phenyl, carboethoxy and hydroxy (alkoxy) groups, which are the chemisorption groups on Raney nickel, can be easily adsorbed on the catalyst surface without any steric hindrance (Fig. 1), and the electron or electrons and the proton are transferred from the catalyst surface to the asymmetric carbon of the molecule; accordingly, there results a retention of the configuration (S_{NI} type mechanism on the catalyst). However, owing to steric hindrance by a planar structure of the aryloxy group in III, the three chemisorption groups (phenyl, carboethoxy and aryloxy) can not be so easily adsorbed on the same catalyst surface. Therefore, the aryloxy group is adsorbed on one side of the catalyst surface and the carboethoxy and phenyl groups on the other, thus avoiding steric hindrance and allowing adsorption to proceed smoothly on the catalyst surface (Fig. 2). The asymmetric carbon is then drawn near to the catalyst surface and the electron or electrons and the proton are transferred from the latter, pushing out the aryloxy groups to another catalyst surface (that is, there is a concerted reaction), thereupon allowing the Walden inversion to take place (an S_N2 type reaction on the catalyst).

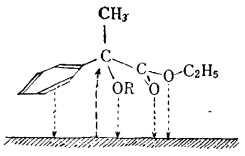


Fig. 1.

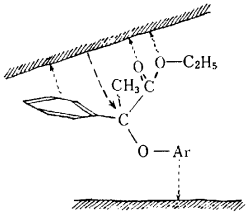

Fig. 2.

Although a molecule has steric hindrance, it can not be chemisorbed on two faces of the catalyst surface unless the catalyst contains suitable pores. It is presumed that the Raney nickel catalyst has a large number of such pores, since it is made by dissolving the aluminum with alkali from the nickel-aluminum alloy.

From the stereochemical viewpoint, it seemed pertinent to investigate hydrogenolysis using a catalyst other than Raney nickel. Therefore, the present paper reports observations on the hydrogenolysis of ethyl α-phenyl-α-aryloxypropionates (III) using palladium and nickel catalysts on some carriers.

Notation a—d) refer to the footnotes of Table II.

Optically-active ethyl α-phenyl-α-aryloxypropionates (III) were prepared according to the process described in the preceding paper[1] and were shaken with 5% palladium on a charcoal catalyst at an ordinary temperature and under hydrogen pressure. These aryl ethers III were hydrogenolyzed to ethyl α-phenylpropionate (IV) and related phenols. As may be seen in Table I, the retention of optical activity and the configuration of IV varied with the structure of the aryl group attached to III. In another series of experiments, ethyl α-phenyl-α-phenoxypropionate (III_1) was hydrogenated by employing various amounts of 5% palladium on a charcoal catalyst. The effects of various amounts of catalyst did not produce appreciable differences in the results, as is shown in Table II. The phenyl ether, III_1, was then hydrogenated over palladium on charcoal catalyst of different palladium concentrations. The configurations of IV produced in each case are shown in Table III.

It may be seen that, with concentrations of palladium on charcoal of 1 and 5%, the retentions of the optical activity of ethyl α-phenylpropionate (IV) with retention of configuration were 65 and 47% respectively. When the palladium concentration on charcoal was increased to 10, 25, 50, 75 and 90%, the retentions of the optical activity of IV with the inversion of the configuration were 6, 18, 30, 49 and 77% respectively. These results show that the percentage of Walden inversion in catalytic hydrogenolysis increases in an orderly fashion with an increase in the concentration of palladium on charcoal. When palladium was used without a carrier, the amount of Walden inversion in the catalytic hydrogenolysis was about the same as that produced with 5% palladium on barium sulfate, but much less than that produced with 75 and 90% palladium on charcoal.

These results lead to the conclusion that, when the palladium concentration on charcoal is low, the catalytic surfaces on which the phenyl ether III_1 can be chemisorbed on the two faces of the catalyst are comparatively small, because the palladium is deposited thinly on the carrier surface, but with an increase in the palladium concentration, the crystals of palladium are deposited on charcoal in such a manner that they create rugged surfaces so that the phenyl ether III_1 can be chemisorbed on the two faces of the catalyst. Thus, the occurrence of the two face-chemisorption of the phenyl ether III_1 is increased, and the proportion of the inverted product IV is likewise increase, because the palladium catalysts are capable of causing a catalytic hydrogenolysis of the phenyl ether III_1 even in a one face-chemisorption state on the catalysts, the proportion of D- and L-forms of IV is principally determined by the quantity of suitable pores in which phenyl ether III_1 can be chemisorbed on the two faces of the catalysts. Of course, besides this fact, the proportion is also related to the reaction rates of both the one face-chemisorption state and the two face-chemisorption state of phenyl ether III_1.

The palladium catalyst without the carrier acted less stereospecifically than 90% palladium on charcoal. This fact seems to account for the existence of fewer suitable pores on the catalyst because of its massive state. Moreover, 5% palladium on barium sulfate acted in the same manner as the palladium catalyst without the carrier. This result may be because the barium sulfate acted merely as a dispersing agent of the palladium, since the adsorptive power of the carrier is comparatively weak.

When alumina instead of charcoal was used as the carrier of the palladium catalyst, the stereospecific hydrogenolysis of the phenyl ether III_1 gave results qualitatively similar to these observed during the course of hydrogenolysis over the palladium on charcoal catalysts, as is shown in Table IV. In the case of palladium on alumina catalysts, however, the extent of the inverted product IV was high, even when 2% palladium on alumina was employed. The reason for this may be that the surface area of alumina is smaller than that of charcoal.

The *p*-anisyl ether III_4 was hydrogenolyzed in the same manner as the phenyl ether III_1 using palladium on charcoal and palladium on alumina catalysts. In these cases, however, the proportion of inverted IV was high, even when 1% palladium on charcoal and 0.2% palladium on alumina catalysts were used, as Table V shows. Therefore, it may be conceived that the hydrogenolysis of the *p*-anisyl ether III_4 in the one face-chemisorption state on the catalyst surface presents some difficulty, since the steric hindrance of the *p*-anisyl ether III_4 in the one face-chemisorption state is more predominant than the corresponding steric hindrance of the phenyl ether III_1, because of a greater chemisorption of the *p*-methoxy group.

The above results prove that not only a small difference in the chemical structure of a molecule but also in the surface structure of the catalyst alters the steric structure of the hydrogenolyzed product. That is, the steric state of a molecule which is being chemisorbed on the catalyst surface is the most important factor in the stereochemistry of the hydrogenolysis.

TABLE IV. STEREOCHEMICAL RELATIONSHIPS IN THE CATALYTIC HYDROGENOLYSIS OF ETHYL D(−)-α-PHENYL-α-PHENOXYPROPIONATE (III_1) OVER PALLADIUM ON ALUMINA CATALYSTS

Weight of III_1 used, 1.4 g.; Optical rotation, absolute configuration and optical purity of III_1, $[\alpha]_D^{27}$ −7.0° (*c* 9.0, absolute ethanol), D, 49.5%; Solvent, absolute ethanol 50 ml.,

Notations a—d) refer to the footnotes of Table II.

e) Stabilized nickel on kieselguhr catalyst (Ni, about 50%); cf. T. Yamanaka et al., *J. Sci. Res. Inst.*, **51**, 168 (1957); **52**, 143 (1958).

f) Stabilized Raney nickel catalyst: cf. ibid.

g) Urushibara nickel-B catalyst: cf. Y. Urushibara and S. Nishimura, This Bulletin, **27**, 480 (1954).

Attention was next paid to the hydrogenolysis of the phenyl ether III_1 over nickel catalysts which had been prepared by different methods. In the cases of these catalysts, the retention of the optical activity of the product IV produced with an inversion of the configuration was almost 100%, as is shown in Table VI.

Since it is not likely that these catalysts, have more pores than are found in an ordinary Raney nickel catalyst, it is presumed to be scarcely possible to hydrogenolyze the phenyl ether III_1 in the one face-chemisorption state. This concept is supported by the fact that larger amounts of these catalysts are essential to complete the hydrogenolysis of the phenyl ether III_1.

Experimental

Optically-active Ethyl α-Phenyl-α-aryloxypropionate (III). — The procedure for preparing the aryl ethers III and their optical purities were reported in the experimental part of the preceding paper[1].

The Catalytic Hydrogenation of Optically-active Ethyl α-Phenyl-α-aryloxypropionate (III). — A mixture of the aryl ether III, 50 ml. of absolute ethanol, and a catalyst was shaken under hydrogen at an ordinary temperature and pressure until the catalyst hydrogen was no longer adsorbed. The catalyst was filtered and rinsed with ethanol, and the solvent was distilled. The residual oil was taken up in ether and extracted with a 5% sodium hydroxide solution. The alkaline insoluble material was dried over anhydrous sodium sulfate, and the solvent was removed. The residual oil was distilled at reduced pressure to give ethyl α-phenylpropionate (IV) (b. p., 103～104°C/12 mmHg).

The alkaline extract was acidified with hydrochloric acid. In the case of phenyl ether III_1, bromine was added to the acidified solution to give tribromophenol (m. p., 94～95°C). The yield was calculated from the weight of the tribromophenol. In the cases of other aryl ethers (III_{2-5}), the resulting oil in the acidified solution was taken up in ether and dried; the solvent was removed by distillation, and the residue was converted to a solid derivative.

It has been established in previous papers[1,3] that (+)-III (absolute ethanol solution) and (−)-IV (neat or absolute ethanol solution) have the same L-form.

These results are described in Tables II-VI and are as follows: Ethyl L(+)-α-phenyl-α-phenoxypropionate (III_1) (b. p., 142～143°C/2.5 mmHg, $[\alpha]_D^6$ +6.2° (*c* 9.0, ethanol), 44.6% optical purity) gave ethyl L-(−)-α-phenylpropionate (IV) ($[\alpha]_D^7$ −15.1° (*c* 8.0, ethanol), 20.9% optical purity) and phenol over 5% palladium on a charcoal catalyst[5], while if gave D(+)-IV ($[\alpha]_D^8$ +29.0° (*c* 5.0, ethanol), 40.2% optical purity) and phenol over a Raney nickel catalyst[6].

Ethyl L(+)-α-phenyl-α-(*p*-cresoxy)propionate (III_2) (b. p., 143～145°C/0.5 mmHg, $[\alpha]_D^3$ +3.5° (*c* 5.4, ethanol), 37.5% optical purity) gave L(−)-IV ($[\alpha]_D^5$ −14.3° (*c* 7.6, ethanol), 19.5% optical purity) and *p*-cresol (its tosylate; m. p., 69～70°C) over 5% palladium on a charcoal catalyst, while it gave D(+)-IV ($[\alpha]_D^8$ +23.3° (*c* 8.8, ethanol), 34.5% optical purity) and *p*-cresol over a Raney nickel catalyst.

Ethyl D(−)-α-phenyl-α-(*o*-cresoxy)propionate (III_3) (b. p., 145～146°C/3 mmHg, $[\alpha]_D^5$ −7.3° (*c* 5.6, ethanol), 45.2% optical purity) gave D(+)-IV ($[\alpha]_D^6$ +15.7° (*c* 9.1, ethanol), 21.7% optical purity) and *o*-cresol (its tosylate; m. p., 54～55°C) over 5% palladium on a charcoal catalyst, while it gave L(−)-IV ($[\alpha]_D^7$ −28.7° (*c* 8.7, ethanol), 39.8% optical purity) and *o*-cresol over a Raney nickel catalyst.

Ethyl L(+)-α-phenyl-α-(*p*-anisoxy)propionate (III_4) (b. p., 170～172°C/3 mmHg, $[\alpha]_D^7$ +10.9° (*c* 8.7, ethanol), 50.3% optical purity) gave D(+)-IV ($[\alpha]_D^9$ +23.2° (*c* 9.6, ethanol), 32.1% optical purity) and *p*-methoxyphenol (m. p., 52～53°C) over 5% palladium on a charcoal catalyst, while it gave D(+)-IV ($[\alpha]_D^8$ +34.0° (*c* 7.4, ethanol), 47.2% optical purity) and *p*-methoxyphenol over a Raney nickel catalyst.

Ethyl L(+)-α-phenyl-α-(*o*-anisoxy)propionate (III_5) (b. p., 158～160°C/2 mmHg, $[\alpha]_D^5$ +13.6° (*c* 4.2, ethanol), 52.5% optical purity) gave D(+)-IV ($[\alpha]_D^6$ +18.5° (*c* 8.5, ethanol), 25.7% optical purity) and guaiacol (*o*-anisoxyacetic acid; m. p., 126～127°C) over 5% palladium on a charcoal catalyst, while it gave D(+)-IV ($[\alpha]_D^5$ +36.0° (*c* 9.2, ethanol), 49.8% optical purity) and guaiacol over a Raney nickel catalyst.

The stereochemical results calculated from the above results are shown in Table I.

Studies on Antibiotics and Related Substances. XVIII. The Synthesis of 5-Methyl-2-methylenecyclopentanone-3-carboxylic Acid, an Antitumor Substance, and Related Mannich Bases

By Mitsuhiro KINOSHITA, Saburo NAKADA and Sumio UMEZAWA

(Received April 6, 1963)

Recent publications[1-2] from this laboratory have described the syntheses and antitumor activities of the methylene derivatives of cyclopentanone-3-carboxylic acid, which are related to Sarkomycin[2], an antitumor antibiotic. The present work is concerned with an extension of this work, and the syntheses and activities of 5-methyl-2-methylenecyclopentanone-3-carboxylic acid and related compounds are described. In addition, we here describe a rare example of the Mannich reaction where the formation of geometrical isomers due to the presence of cyclopentanone ring is demonstrated.

5-Methylcyclopentanone-3-carboxylic acid (I) was prepared by the method of Shemyakin and others[3]. A mixture of 5-methylcyclopentanone-3-carboxylic acid, paraformaldehyde and dimethylamine hydrochloride was fused, and the reaction mixture was treated with absolute ethanol to give 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid hydrochloride (hydrochloride of IIa) with an m. p. of 155°C and an R_f of 0.39 in the solvent system of *n*-butanol-acetic acid-water (4 : 1 : 1); IIa melted at 99~100°C. On being treated with benzaldehyde in the presence of sodium hydroxide, IIa afforded a benzylidene derivative, indicating the presence of an activated methylene group in IIa.

The mother liquor separated from the above product was concentrated and esterified with methanol to give a mixture of Mannich base esters; paper chromatographic study of the mixture (hydrochlorides) showed three spots (R_f 0.54, 0.49 and 0.41) in the solvent system described above. Treatment of the mixture with methyl iodide in ether at about 10°C resulted in the separation of a crystalline methiodide (VIII) of substance with a R_f of 0.54 (VII). The methiodide was hygroscopic and unstable and, when treated with an 10% potassium bicarbonate solution, afforded methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX). The ozonolysis of IX gave formaldehyde (isolated as the methone derivative)

and butane-1, 1, 3-tricarboxylic acid, as expected. Methylsuccinic acid was obtained also, suggesting that the sample of IX is accompanied by methyl 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylate (XI). However, reaction of the methylene compound (IX) with dimethylamine gave, in a 77% yield, methyl 2-(dimethylaminomethyl) -5-methylcyclopentanone-3-carboxylate, which is paper chromatographically identical with VII; this indicated that the sample of IX consists mainly of an exocyclic methylene compound. Additional evidence for this was found in the ultraviolet absorption data; the ultraviolet absorption of a freshly prepared sample of IX showed a strong band at 229 mμ (Fig. 1). However, when the sample was allowed to stand, even at room temperature, the band gradually shifted towards a longer wavelength and also decreased in intensity. On the other hand, we obtained methyl 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylate (XI) by the thermal decomposition of the hydrochloride of VII; the cyclopentenone derivative (XI) could be purified by the hydrolysis of XI, followed by methylation with diazomethane. The cyclopentenone derivative (XI) showed a strong band at 246 mμ (Fig. 1). Thus, it is evident that the above-mentioned shift of band and decrease in the intensity of the band are due to the gradual shift of the double bond into the cyclopentanone ring and to polymerization respectively. Moreover, a significant difference was observed between the infrared spectra of XI and IX; absorptions at 1357, 1100, 1062, 990 and 761 cm^{-1} were observed in the spectrum of XI, but not in that of IX (Fig. 2).

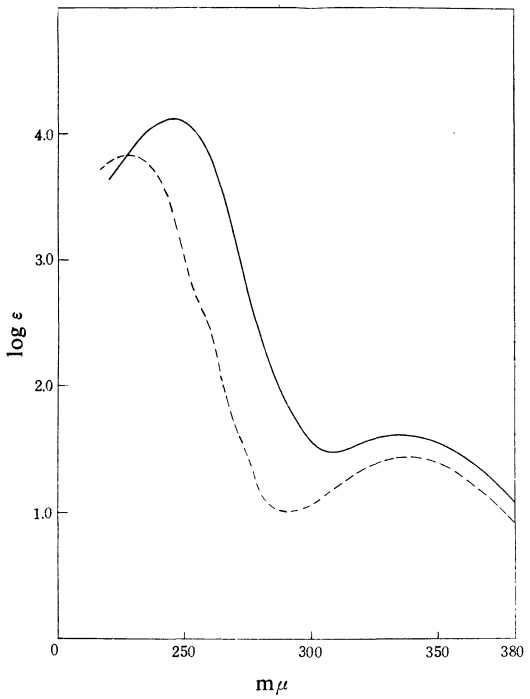

Fig. 1. Ultraviolet absorption spectra of methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX) (----) and methyl 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylate (XI) (——) in methanol.

The mild hydrolysis of IX with dilute sulfuric acid gave a crude product of 5-methyl-2-methylenecyclopentanone-3-carboxylic acid (X), a viscous liquid which polymerized gradually.

Paper chromatographic study of the mother liquor separated from the above-mentioned unstable methiodide (VIII) indicated the presence of a mixture of unchanged Mannich base esters with an R_f of 0.49* and a small quantity of methylene compound (IX). Fortunately, the oxalate of the unchanged Mannich base esters were crystallized from an absolute ether solution. Recrystallization of the oxalate from methanol, followed by treatment with sodium carbonate, gave a single free Mannich base ester (IVb), a colorless liquid. The hydrochloride of IVb melted at 140~141°C (decomp.). The hydrolysis of IVb with barium hydroxide gave the free Mannich base (IIb) (m. p., 124~125°C (decomp.)). IIb and its hydrochloride coincided in analysis with IIa and its hydrochloride respectively. The mixed m. p. of the

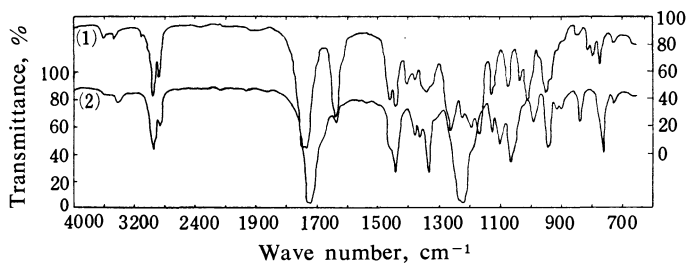

Fig. 2. Infrared absorption spectra of methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX) (1) and methyl 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylate (XI) (2) in liquid film.

* This spot corresponds to the overlap of the two spots of IVa (R_f, 0.51) and IVb (R_f, 0.47).

hydrochloride (m. p. 155~156°C) of IIb with the hydrochloride of IIa showed depression.

On being treated with benzaldehyde in the presence of sodium hydroxide, IIb afforded a benzylidene derivative (IIIb), indicating the presence of an activated methylene group in IIb. The methiodides of IVa and IVb were resistant to treatment[4] with a potassium bicarbonate solution, indicating the absence of hydrogen at the α-carbon atom to which the dimethylaminomethyl group is attached. Moreover, the hydrogenation of methyl ester (IVa) of IIa with an Adams platinum catalyst afforded methyl 3-hydroxy-4-(dimethylaminomethyl)-4-methylcyclopentane-1-carboxylate (V); the resistance of the C-N linkage of IVa to hydrogenolysis also suggested the absence of hydrogen at the α-carbon atom, because, by hydrogenation of methyl 5-(dimethylaminomethyl)cyclopentanone-3-carboxylate, we had obtained methyl 5-methylcyclopentanone-3-carboxylate[1]. Thus it has been clearly established that IIa and IIb are geometrical isomers of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid, although the steric relation therein requires further discussion (vide infra).

Finally, it is noteworthy that the thermal decomposition of the hydrochloride of methyl 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (IVa), followed by hydrolysis, afforded 2,5-dimethyl-2-cyclopenten-1-one-3-carboxylic acid (XII). This finding may be accounted for on the assumption that methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (VII) may conceivably be formed by a rearrangement of the dimethylaminomethyl group through a kind of retrograde Mannich reaction and may then be changed to IX.

Both 5-methyl-2-methylenecyclopentanone-3-carboxylic acid (X) and its methyl ester (IX) were found to possess antitumor and antimicrobial activities; the methyl ester was more potent than the corresponding free acid.

Discussion

On the basis of the data described herein, it is not possible to clearly decide between two structural possibilities for the two racemic geometrical isomers (IIa and IIb) of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid. However, the problem is of interest. The infrared absorption study of IIa and IIb or of their hydrochlorides in KBr did not reveal their steric relation. Similarly, no steric relation was observed between the infrared spectra of IVa and IVb or their hydrochlorides. However, infrared absorptions in chloroform (c, 0.028 M) showed small but real differences (Fig. 3): the dimethylamino frequencies at 2830 and 2780 cm^{-1} and the C=O frequency of the carboxyl group at 1720 cm^{-1} were found in IIa, but IIb showed no absorption at these regions; the N^+-H stretching frequency at 2540~2300 cm^{-1} was found in both IIa and IIb, and the frequency of COO^- at 1603 cm^{-1} was found in both IIa and IIb. These observations led us to the conclusion that IIa exists as a mixture of the XIII and XIV forms, whereas IIb exists as a mixture of the XV and XVI forms.

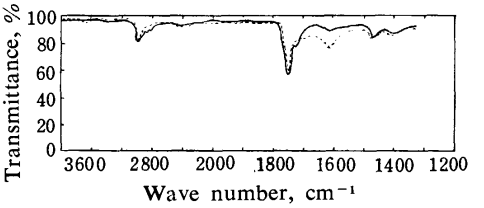

Fig. 3. Infrared absorption spectra of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylc acid (IIa) (——) and its geometrical isomer (IIb) (----) in chloroform solutions: 0.028 M, 0.104 mm. cell.

4) G. Büchi, N. C. Yang, S. R. Emerman and J. Meinwald, *Chem. & Ind.*, 1953, 1063; E. E. van Tamelen and S. R. Bach, *J. Am. Chem. Soc.*, 77, 4683 (1955); cf. Ref. 3.

This suggestion has been supported by the determination of pK_a. IIa had pK_{a_1} 3.60 and pK_{a_2} 8.34, whereas IIb had pK_{a_1} 3.49 and pK_{a_2} 8.66. The effect of hydrogen bonding in IIb may decrease the pK_{a_1} and increase the pK_{a_2}. A comparable effect of hydrogen bonding had been shown by the relation of pK_a values between lysergic acid and isolysergic acid[5].

As to racemic 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid (VI), four geometrical isomers are possible. Recent evidence and discussions[6] have shown that stable conformations of cyclopentanones substituted at the 2- and 3-positions with bulky groups are trans-form. However, it is not possible to state a steric structure in the case of compound VI, which contains acidic and basic groups in ortho-positions.

Experimental

Paper chromatograms of the Mannich bases were run with *n*-butanol-acetic acid-water (4 : 1 : 1) on Toyo Roshi No. 50 papers, using the ascending technique. Spots on paper chromatograms were detected by spraying the chromatograms with Dragendorff's reagent[7]. Paper chromatography of the products obtained by ozonolysis was carried out with xylene-phenol-85% formic acid (7 : 3 : 1)[8], and spots were detected by means of a spray of a 0.1% ethanolic solution of bromophenol blue.

The pK_a values were determined by the method of Parke and Davis[9], except that the titrant was with 0.1 N sodium hydroxide and was delivered by a Gilmont micropipet-buret with a total capacity of 1.0 ml. and with readings to 0.001 ml. on a microgage. The temperature was 22±1°C. The pK_a values were reproducible within a range of ±0.03.

Hydrochloride of 5-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic Acid (IIa).—A mixture of 5-methylcyclopentanone-3-carboxylic acid[10] (I) (8.52 g.) and dimethylamine hydrochloride (4.96 g.) was heated to 75°C. To the resulting melt was added paraformaldehyde (1.80 g.), and the mixture stirred at 78°C for 2 hr. and evaporated in a vacuum to remove moisture. The resulting sirup, which gave three major spots (R_f 0.50, 0.38 and 0.30) on a paper chromatogram, was dissolved in hot absolute ethanol (13 ml.) and filtered. The cooled filtrate was stored in a refrigerator to give crude crystals of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid hydrochloride; yield, 5.40 g. (38.7%); m. p., 150.0~152.5°C (decomp.). Recrystallization from propan-2-ol gave a pure sample of the hydrochloride of IIa as colorless plates, m. p., 155°C (decomp.), R_f 0.39. ν_{max}^{KBr} 2700 ($\overset{+}{N}H$), 1747 (C=O) and 1721 cm^{-1} (COOH). pK_{a_1} 3.60 and pK_{a_2} 8.34.

Found: C, 50.79; H, 7.48; N, 5.74. Calcd. for $C_{10}H_{18}O_3NCl$: C, 50.93; H, 7.70; N, 5.94%.

5-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic Acid (IIa).—A mixture of 114 mg. of free amine ester (IVa) and a 0.45 N barium hydroxide solution (1.23 ml.) was stirred at 25°C for 2.5 hr. The resulting solution was treated with 2.2 N sulfuric acid, and the barium sulfate was removed by centrifuging. The supernatant layer and washings were then combined and subjected to lyophilization. The resulting colorless glass (102 mg.) was dissolved in a small volume of hot propan-2-ol and cooled in a refrigerator overnight to give colorless plates; yield, 76 mg. (71%); m. p., 99~100°C (decomp.). Recrystallization from propan-2-ol afforded an analytical sample; m. p., 99~100°C (decomp.), R_f 0.42, ν_{max}^{KBr} 1720 (C=O) and 1620 cm^{-1} (COO^-); $\nu_{max}^{ClCH_3}$ 2830, 2789 (dimethylamino group), 2415 ($\overset{+}{N}H$) 1745 (C=O), 1720 (COOH) and 1603 cm^{-1} (COO^-) (0.028 M, 0.104 mm.).

Found: C, 60.10; H, 8.65; N, 6.99. Calcd. for $C_{10}H_{17}O_3N$: C, 60.28; H, 8.60; N, 7.03%.

2-Benzylidene-5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic Acid (IIIa).—To a solution of IIa (200 mg.) in 2.5 N sodium hydroxide (1.6 ml.) was added benzaldehyde (100 mg.), and the mixture was stirred at 20°C for 1 hr. The resulting yellow solution was adjusted to pH 3 with 3 N hydrochloric acid and shaken with ether. The water-layer was evaporated to dryness in vacuo and then extracted with absolute ethanol. Evaporation of the ethanol solution afforded a crude hydrochloride of IIIa as hygroscopic yellow amorphous powder; yield, 204 mg. (75%); characteristic, strong absorption in the ultraviolet spectrum at λ_{max}^{MeOH} 308~309 mμ ($E_{1cm}^{1\%}$ 558). To a solution of the crude hydrochloride of IIIa (130 mg.) in methanol (1.5 ml.), picric acid (130 mg.) in hot ethanol (1.5 ml.) was added. Short yellow prisms of picrate of IIIa were obtained; yield, 135 mg. (60% based on the crude hydrochloride of IIIa); m. p., 186~187°C (decomp.). Recrystallization from ethanol-methanol (2 : 1) showed no elevation in the melting point.

Found: C, 53.36; H, 4.70; N, 10.96. Calcd. for $C_{23}H_{24}O_{10}N_4$: C, 53.49; H, 4.68; N, 10.85%.

Hydrochloride of Methyl 5-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (IVa).—A mixture of hydrochloride of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid (IIa) (1.7 g.) and absolute methanol (20 ml.) was saturated with dry hydrogen chloride and allowed to stand overnight. The solvent was removed by

10) 5-Methylcyclopentanone-3-carboxylic acid (I) was prepared by the method of Shemyakin et al.[3]; m. p., 56~58°C; 2,4-dinitrophenylhydrazone (70% yield); m. p., 142~143°C.

distillation in a vacuum, and the residue was dried over phosphorus pentoxide. The crude hydrochloride of methyl ester thus obtained was recrystallized from butanone; yield, 1.6 g. (89%) of short colorless needles; m. p., 160~161°C (decomp.). R_f 0.51. ν_{max}^{KBr} 2690 ($\overset{+}{N}H$) and 1750 (ketone and ester C=O).

Found: C, 53.12; H, 8.23; N, 5.70. Calcd. for $C_{11}H_{20}O_3NCl$: C, 52.90; H, 8.07; N, 5.61%.

Methyl 5-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (IVa).—The hydrochloride of IVa (1.4 g.) in chloroform (10 ml.) was added to a 1.33 N ammonia-methanol solution (4.9 ml.). The chloroform layer was separated from the precipitated ammonium chloride and concentrated under reduced pressure. The resulting yellow oil was distilled without decomposition; b. p., 100~103°C (bath temp.)/0.03 mmHg; yield, 1.03 g. (86%). Repetition of distillation gave an analytical sample as a colorless liquid; b. p., 55°C (bath temp.)/0.001 mmHg, n_D^{27} 1.4609, ν_{max}^{liq} 2870, 2825, 2779 (dimethylamino group), 1747 (ketone and ester C=O) and 1410 cm^{-1} (methylene group in $-CO-CH_2-$).

Found: C, 61.73; H, 9.07; N, 6.70. Calcd. for $C_{11}H_{19}O_3N$: C, 61.94; H, 8.97; N, 6.57%.

The Oxalate of IVa.—To a solution of IVa (214 mg.) in absolute ether was added an ethereal solution of anhydrous oxalic acid (96 mg.), whereupon a thick gum separated; this gum was crystallized by trituration. Filtration followed by washing with ether gave a crude oxalate of IVa (279 mg., 92%) melting at 105~108°C (decomp.). Two recrystallizations from methanol afforded a pure sample as colorless prisms; m. p., 110.5~111°C (decomp.), R_f 0.51.

Found: C, 51.32; H, 7.10; N, 4.72. Calcd. for $C_{11}H_{19}O_3N \cdot C_2H_2O_4$: C, 51.48; H, 6.98; N, 4.62%.

The Methiodide of IVa.—A mixture of IVa and an excess of methyl iodide was allowed to stand for 48 hr. at room temperature. Evaporation of the methyl iodide, followed by washing with ether, gave the methiodide of IVa melting at 213°C (decomp.) in a quantitative yield. Two recrystallizations from methanol gave colorless plates; m. p., 216~217°C (decomp.). ν_{max}^{KBr} 1735 (ketone and ester C=O) and 1412 cm^{-1} (methylene group in $-CO-CH_2-$).

Found: C, 40.54; H, 6.28; N, 4.07. Calcd. for $C_{12}H_{22}O_3NI$: C, 40.57; H, 6.24; N, 3.94%.

Methyl 3-Hydroxy-4-(dimethylaminomethyl)-4-methylcyclopentane-1-carboxylate (V).—A solution of IVa (1.03 g.) in methanol (4 ml.) was shaken with platinum oxide (80 mg.) and hydrogen; 122 ml. (759.2 mmHg, 20.5°C) of hydrogen was absorbed in 1 hr. The reaction mixture was filtered and concentrated in a vacuum and then distilled under reduced pressure to give the title compound (927 mg., 89%) as a colorless viscous oil; b. p., 115~120°C (bath temp.)/0.005 mmHg, $\nu_{max}^{liq.}$ 3400 (OH), 2875, 2823, 2772 (dimethylamino group), and 1737 cm^{-1} (ester C=O).

The Hydrochloride of V.—It was prepared by the addition of a methanolic hydrogen chloride solution to V dissolved in absolute methanol, followed by dilution with absolute ether. Two recrystallizations from absolute methanol-ether gave the specimen with an m. p. of 170~171°C (decomp.).

Found: C, 52.44; H, 9.03; N, 5.88. Calcd. for $C_{11}H_{22}O_3NCl$: C, 52.50; H, 8.81; N, 5.57%.

The 3,5-Dinitrobenzoate of V.—To a solution of V (200 mg.) in chloroform (0.2 ml.) was added a solution of 3,5-dinitrobenzoyl chloride (240 mg.) in chloroform (0.2 ml.), and the mixture was allowed to stand overnight. Dilution with absolute ether gave a viscous oil, which was then triturated with absolute ether to give a crystalline powder (430 mg.). Two recrystallizations from absolute methanol-ether afforded a pure sample of 3,5-dinitrobenzoate hydrochloride of V (273 mg., 66%); m. p., 187~189°C (decomp., sintered at 185°C).

Found: C, 48.35; H, 5.60; N, 9.20. Calcd. for $C_{18}H_{24}O_8N_3Cl$: C, 48.48; H, 5.39; N, 9.22%.

Methyl 5-Methyl-2-methylenecyclopentanone-3-carboxylate (IX).—The mother liquor of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid hydrochloride (5.4 g.) described above was concentrated in a vacuum. The oily residue was dissolved in water (20 ml.), and the solution was extracted with four 15 ml. portions of ethyl acetate to recover the unchanged keto acid (crude 1 g.). The aqueous layer was washed with chloroform several times and evaporated in a vacuum at 40°C. The sirupy residue was dried in a vacuum over phosphorus pentoxide to give a yellow glassy solid (7.6 g.). Paper chromatography showed that the solid consisted of two major components (R_f, 0.50 and 0.37), but a small amount of the hydrochloride of IIa (R_f 0.39) was also found. A mixture of the residue (7.5 g.) and absolute methanol (62 ml.) was saturated with dry hydrogen chloride and allowed to stand for 2 days at room temperature. After evaporation of the solvent in a vacuum, the resulting orange-yellow sirup (8.0 g.) was dissolved in water (11 ml.) while beeing cooled in an ice-water bath, and to the solution was added a 50% aqueous potassium carbonate solution (26 ml.) to separate a viscous oil. The oil was extracted with four 20 ml. portions of ether. After being dried over fused potassium acetate, the ethereal extract was evaporated to give a mixture of free amine esters as an orange-yellow liquid (4.1 g.); paper chromatography of its hydrochloride showed R_f values of 0.54, 0.49 and 0.41. The addition of methyl iodide (9.2 g.) to a solution of the free amino ester in absolute ether (16 ml.) immediately resulted in the crystallization of methiodide. The mixture was allowed to stand for 1 hr. at 9°C and then stored in a refrigerator overnight. The precipitate was collected rapidly on a filter and washed with absolute ether. After drying in vacuo over phosphorus pentoxide, there were obtained 3.4 g. of methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate methiodide (VIII), which was very hygroscopic and which was gradually decomposed by moisture. The crude methiodide (3.4 g.) was dissolved in water (7 ml.) at 10°C, and to this solution was added a 10% aqueous potassium bicarbonate solution (17 ml.). The resulting solution immediately appeared turbid and

separated a colorless oil with a pungent odor. The oil was extracted with ether (10 ml.) while being occasionally shaken for 20 min. at 10°C. After separating the ether layer, the aqueous layer was again extracted with two 10 ml. portions of ether. The combined ethereal extracts were washed with 0.1 N sulfuric acid and then with water. After being dried over fused potassium acetate. the ethereal extract was evaporated at about 0°C to afford a colorless liquid of methyl 5-methyl-2-methylenecyclopentane-3-carboxylate (IX); yield, 882 mg. (54.7% based on the crude methiodide (VIII)), n_D^{16} 1.4775, λ_{max}^{MeOH} 229 (ε, 6580) and 340 mμ (ε, 28). Distillation gave a pure sample; b. p., 43°C (bath temp.)/0.005 mmHg, n_D^{19} 1.4726, λ_{max}^{MeOH} 229 (ε, 6830) and 338 mμ (ε, 28), $\nu_{max}^{liq.}$ 1747, 1733 (ester and ketone C=O), 1640 (C=C), 1400 and 951 cm^{-1} (=CH_2).

Found: C, 64.30; H, 7.02. Calcd. for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

The mother liquor of the methiodide (VIII) was concentrated to give an orange oil intermixed with a small amount of solid. The oily residue was dissolved in ether, and the solution was washed with water. The ether layer was extracted with dilute sulfuric acid until the pH of the aqueous layer became 4.3 and was then washed with water. The ethereal layer was dried and then evaporated to afford a light-yellow oil (110 mg.), which was again distilled to give a sample identical to IX in ultraviolet and infrared spectra.

To the diluted sulfuric acid extract a 50% potassium carbonate solution (4 ml.) was added, and the mixture was extracted with three 7 ml. portions of ether. The ethereal extract dried over potassium acetate was evaporated to recover an unchanged amine ester (1.804 g.) as an orange-yellow oil. The paper chromatogram of its hydrochloride showed an intense spot (R_f 0.49) owing to the overlapping of the two spots (R_f 0.51 and 0.47) and another spot (R_f 0.41), but no spot (R_f 0.54) of the hydrochloride of VII. A mixture of the amine ester (200 mg.) and an excess of methyl iodide was allowed to stand for 48 hr. at room temperature. Evaporation of the excess methyl iodide followed by washing with ether yielded a methiodide (330 mg.) melting at 155~180°C (decomp.). It was found that the methiodide was not decomposed by treatment with a 10% aqueous potassium bicarbonate. Fractional crystallization of the crude methiodide from methanol gave two kinds of methiodides. The less soluble methiodide (67 mg., m. p. 216~217°C (decomp.)) and the more soluble one (60 mg. m. p. 169~171°C (decomp.)) were identical to the methiodide of IVa and to the methiodide of IVb respectively, as was shown by mixed melting points and infrared spectra.

The Formation of Methyl 2-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (VII) from IX.—The methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX) (834 mg.) was added drop by drop to an ice-cooled 32% dimethylamine-methanol solution (816 mg.) while it was being shaken. The solution was allowed to stand at 18°C for 1 hr. and then placed in a refrigerator. After removing the methanol by distillation in a vacuum, the residue was dissolved in ether. The ethereal solution was neutralized with dilute sulfuric acid until the pH in the aqueous layer became 2.3. The aqueous layer was separated and washed twice with ether. From the combined ethereal extracts, an unchanged methylene compound (IX) was recovered (112 mg., λ_{max}^{MeOH} 231 and 336 mμ. To the aqueous layer was added a 50% potassium carbonate solution (2 ml.), and the mixture was extracted with ether repeatedly. The ethereal extract dried over potassium acetate was evaporated to give the methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (VII) as a light yellow liquid (770 mg., 77.2%). The infrared spectrum of the sample showed no peak near 1410 cm^{-1} (methylene group in -CO-CH_2-). The paper chromatogram of its hydrochloride showed a single spot (R_f 0.54).

The Oxalate of VII.—It was prepared by the addition of an ethereal solution of anhydrous oxalic acid (90 mg.) to VII (200 mg.) in ether. The yield. was 267 mg. (94%): m. p., 105~117°C. Two recrystallizations from methanol gave an analytical sample as colorless needles; m. p., 147°C (decomp., sintered at 122~137°C), R_f 0.54.

Found: C, 51.56; H, 7.18; N, 4.75. Calcd. for $C_{11}H_{19}O_3N \cdot C_2H_2O_4$: C, 51.48; H, 6.98; N, 4.62%.

Methyl 2-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate Methiodide (VIII).—To a solution of VII (200 mg.) in absolute ether (1 ml.) methyl iodide (800 mg.) was added at 10°C to give methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate methiodide (VIII) immediately. After the solution has been left standing for 6 hr. at 10°C, the precipitate was rapidly collected and washed with absolute ether by centrifuging; yield: 306 mg. (91.5%) as pale-yellow crystals. This precipitate was very hygroscopic and was easily decomposed by moisture, but it was stable in a vacuum over phosphorus pentoxide at a lower temperature. This methiodide (158 mg.) was treated with a 10% aqueous potassium bicarbonate solution to afford the methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX); yield, 56 mg. (75%). The product was identical with IX in its ultraviolet and infrared spectra.

The Ozonolysis of IX.—A solution of freshly prepared methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX) (400 mg.) in ethyl acetate (20 ml.) was treated with an approximately 2% (by weight) ozone-oxygen mixture at −10°C at a rate of 500 ml./min. for 3 hr. The volume of the reaction mixture was adjusted to 20 ml. by the addition of ethyl acetate. To a 5 ml. aliquot of this solution were added water (5 ml.) and zinc dust (150 mg.), and the mixture was refluxed for 30 min. The reaction mixture was filtered while hot into a solution of methone (150 mg.) in 5 ml. of ethanol. Dilution with water (10 ml.) afforded the needles of formaldehyde methone; yield, 50 mg. (28.7%); m. p., 187~189.5°C. Admixing with an authentic specimen of formaldehyde methone showed no depression of melting point.

The remaining, ozonized solution (15 ml.) was concentrated in a vacuum at a temperature below

10°C to afford a viscous pale-yellow oil, which was then heated with 30% hydrogen peroxide (1.6 ml.) at about 90°C for 1 hr. The colorless solution was evaporated under reduced pressure. The addition of water to the residue, followed by evaporation, was repeated to remove the excess hydrogen peroxide. The final residue (296 mg.) was refluxed with 1.6 N methanolic potassium hydroxide (3.1 ml.) for 1 hr. After removing methanol, the residue was acidified to pH 2.4 with dilute sulfuric acid, saturated with ammonium sulfate, and extracted with ether continuously for 12 hr. The extract was dried over sodium sulfate and distilled to give a residue which immediately crystallized; yield, 186 mg. The paper chromatogram of the product run with xylene-phenol-85% formic acid[8] showed two spots (R_f 0.45 and 0.10). The crystalline mass was pulverized and placed in a sublimation apparatus. The temperature of the bath was gradually raised to about 95°C under about 3 mmHg. A considerable amount sublimed at the bath temperature from 76 to 95°C; sublimation was continued until the bath temperature reached 105°C. The total sublimate weighed 30 mg., m. p., 97~108°C. The paper chromatogram of this material showed one major spot (R_f 0.45) of methylsuccinic acid, but no spot (R_f 0.59) corresponding to α-methylglutaric acid. The material was purified by repetition of the sublimation to afford pure sample of methylsuccinic acid; m. p. and mixed m. p., 109~110°C. The crystals remaining in the sublimator weighed 57 mg.; m. p., 158~160°C (decomp.). The paper chromatogram of the sample showed a single spot (R_f 0.10). Mixed melting point, infrared spectra and paper chromatography showed that this is identical to butane-1, 1, 3-tricarboxylic acid[11].

2, 5-Dimethyl-2-cyclopenten-1-one-3-carboxylic Acid (XII).—2.2 g. of an orange-yellow, viscous sirup (see the preparation of IX) containing methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate hydrochloride was placed in a distillation flask and heated in an oil bath at 150°C for 15 min. The orange-red product was distilled at 150°C (bath temp.)/0.3 mmHg to afford a light-yellow liquid of methyl 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylate (XI), λ_{max}^{MeOH} 243 mμ ($E_{1cm}^{1\%}$ 567). The crude ester (420 mg.) was mixed with a 10% sodium hydroxide solution (1 ml.) and was stirred at room temperature for 2 hr. The orange-yellow solution was acidified to pH 1.8 by the addition of 6 N hydrochloric acid; whereupon a crystalline precipitate of 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylic acid (XII) separated; yield, 240 mg.; m. p., 127~130°C. Two recrystallizations from water followed by vacuum sublimation yielded colorless prisms melting 129~130.5°C, λ_{max}^{MeOH} 245 (ε, 12200) and 334 mμ (ε, 41). $\nu_{max}^{CHCl_3}$ 1720 (COOH), 1707 (C=O) and 1645 cm^{-1} (C=C); ν_{max}^{Nujol} 1722, 1681 and 1640 (SH) cm^{-1}.

Found: C, 62.12; H, 6.66; Neut. eq. 155. Calcd. for $C_8H_{10}O_3$: C, 62.32; H, 6.54%; Neut. eq. 154.1.

The VII was also obtained by the destructive distillation of IVa hydrochloride, followed by saponification in the manner described above. The destructive distilation of IVa hydrochloride (2.0 g.) gave methyl 2, 5-dimethyl-2-cyclopenten-1-one-3-carboxylate (563 mg.). The crude ester (490 mg.) was saponificated to afford XII (156 mg.) melting at 117~123°C. Recrystallization from water followed by vacuum sublimation yielded a pure sample of XII; m. p., 129~130.5°C.

The Ozonolysis of XII.—A solution of XII (71 mg.) in ethyl acetate (5 ml.) was ozonized in the manner described above. The resulting ozonide was decomposed with 30% hydrogen peroxide (0.4 ml.) at about 90°C for 1 hr. to afford a crystalline mass (44 mg.); m. p., 82~97°C. The paper chromatography of the product showed one major spot (R_f 0.45) of methylsuccinic acid. Fractional vacuum sublimation yielded a pure sample of methylsuccinic acid; m. p. and mixed m. p., 109~110°C.

Methyl 2, 5-Dimethyl-2-cyclopenten-1-one-3-carboxylate (XI).—A solution of a pure sample of XII (115 mg.) in ether was treated with a ethereal diazomethane soluion at 0°C. Evaporation of ether, followed by vacuum distillation, gave a colorless liquid of the title compound; yield, 103 mg.; b. p., 73°C (bath temp.)/3 mmHg, n_D^{25} 1.4880, λ_{max}^{MeOH} 246 (ε, 13250) and 336 mμ (ε, 42), ν_{max}^{CCl} 1724 (ester and ketone C=O) and 1640 cm^{-1} (C=C).

Found: C, 64.50; H, 7.19. Calcd. for $C_9H_{12}O_3$: C, 64.27; H, 7.19%.

Semicarbazone of XI.—Colorles needles; m. p., 228°C (decomp.)

Found: C, 53.45; H, 6.75; N, 18.63. Calcd. for $C_{10}H_{15}O_3N_3$: C, 53.32; H, 6.71; N, 18.66%.

5-Methyl-2-methylenecyclopentanone-3-carboxylic Acid (X).—A mixture of freshly prepared methyl 5-methyl-2-methylenecyclopentanone-3-carboxylate (IX) (1.0 g.) and 1.5 N sulfuric acid (20 ml.) was stirred at 30°C for 4.5 hr. and then extracted with three 10 ml. portions of ether. The ethereal extracts were netralized while being shaken with an aqueous sodium bicarbonate solution until the pH value in the aqueous layer became 7.5. The aqueous layer was separated, washed with ether, adjusted to pH 1.8 with 1.5 N sulfuric acid, saturated with ammonium sulfate, and extracted with three 10 ml. protions of ethyl acetate. The extract was dried over sodium sulfate and evaporated in a vacuum at about 0°C to afford a crude 5-methyl-2-methylenecyclopentanone-3-carboxylic acid (X) as a pale-yellow viscous oil; 154 mg. (16.9%), λ_{max}^{MeOH} 233 mμ ($E_{1cm}^{1\%}$ 189), ν_{max}^{liq} 2700~2500 (carboxyl OH), 1740 (carboxyl C=O), 1720 (C=O), 1640 (C=C) and 956 cm^{-1} (=CH_2).

The Oxalate of Methyl 5-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (IVb).—The unchanged mixed Mannich base ester (1.76 g.) recovered from the mother liquor of the methiodide (VIII) was dissolved in absolute ether. To the solution was added an ether solution of anhydrous oxalic acid (0.80 g.), whereupon a gummy solid separated and was crystallized by rubbing. Filtration, followed by washing with ether, gave a crude oxalate (2.56 g.). The crude oxalate was dissolved in absolute methanol at about 50°C. After the solution had cooled and stood at room temperature for 1 hr., the first crop (the oxalate of IVb) was separated and washed with a small quantity of

11) F. Voche, *Z. physiol. Chem.*, **191**, 83 (1930)

methanol and then with methanol-ether (1 : 1); yield, 0.83 g.; m. p. 132~133°C (decomp.). The paper chromatogram of the first crop (IVb oxalate) showed a single spot (R_f 0.47), but no spot (R_f 0.51) corresponding to the oxalate of IVa. To the mother liquor separated from the first crop was added a small quantity of ether to afford a second crop (0.14 g.); m. p., 128~130°C (decomp.). A third crop was obtained by the further addition of ether to the mother liquor of the second crop; yield, 0.45 g.; m. p., 90~105°C. Recrystallizations of the second and third crop from methanol yielded crystals of IVb oxalate melting at 132~133°C (decomp.); the total yield of IVb oxalate was 1.01 g. Recrystallization of the first crop from methanol gave an analytical sample, a colorless plates; m. p., 133~134°C (decomp.).

Found: C, 51.36; H, 7.11; N, 4.78. Calcd. for $C_{11}H_{19}O_3N \cdot C_2H_2O_4$: C, 51.48; H, 6.98; N, 4.62%.

Methyl 5-(Dimethylaminomethyl)-5-methylcylcopentanone-3-carboxylate (IVb).—The oxalate of IVb (347 mg.) was made alkaline with a 10% aqueous sodium carbonate solution while being ice-cooled, and the reaction mixture was extracted with ether. The ether extracts were dried over potassium acetate and evaporated to give free amine ester (IVb) as a pale-yellow liquid; yield, 232 mg. (90.5%). Vacuum distillation afforded an analytical sample, a colorless liquid; b. p., 55°C (bath temp.)/0.001 mmHg, $n_D^{25.5}$ 1.4635, ν_{max}^{liq} 2870, 2825, 2780, (dimethylamino group), 1750, 1745 (ketone and ester C=O) and 1412 cm^{-1} (methylene group in -CO-CH_2-), R_f 0.47 (as hydrochloride).

Found: C, 62.20; H, 9.12; N, 6.73. Calcd. for $C_{11}H_{19}O_3N$: C, 61.94; H, 8.97; N, 6.57%.

The Methiodide of IVb.—A mixture of IVb (35 mg.) and an excess of methyl iodide was allowed to stand for 24 hr. at room temperature. Evaporation of methyl iodide. followed by washing with ether, yielded the methiodide melting at 163~170°C in a quantitative yield. Recrystallization from methanol-ether gave colorless plates (49 mg.); m. p., 171~172°C (decomp.), ν_{max}^{KBr} 1748, 1735 (ketone and ester C=O), and 1412 cm^{-1} (methylene group in -CO-CH_2-).

Found: C, 40.64; H, 6.01; N, 4.0.3. Calcd. for $C_{12}H_{22}O_3NI$: C, 40.57; H, 6.24; N, 3.94%.

The Hydrochloride of IVb.—A solution of IVb in absolute ether was carefully neutralized by the addition of a methanolic solution of hydrochloric acid to afford the crystalline hydrochloride of IVb. Recrystallization from butanone gave a pure sample as colorless plates; m. p., 140~141°C (decomp.), R_f 0.47, ν_{max}^{KBr} 2700~2400 (broad) ($\overset{+}{N}H$) and 1747 cm^{-1} (ketone and ester C=O).

Found: C, 52.76; H, 7.86; N, 5.70. Calcd. for $C_{11}H_{20}O_3NCl$: C, 52.90; H, 8.07; N, 5.61%.

5-(Dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic Acid (IIb).—A mixture of the free amine ester (IVb) (98 mg.) and a 0.45 N barium hydroxide solution (1.05 ml.) was shaken at 26°C for 2.5 hr. The resulting solution was treated with 2.2 N sulfuric acid, and barium sulfate was removed by centrifuging. The supernatant layer and washings were combined and subjected to lyophilization to give a pale-yellow glass which became a hygroscopic crystalline powder by rubbing; yield, 84 mg. (91%); m. p., 118~120°C (decomp.). Two recrystallizations from propan-2-ol gave a pure sample of IIb (46 mg.) as colorless prisms; m. p., 124~125°C (decomp.), R_f 0.40, ν_{max}^{KBr} 1718 (C=O) and 1625 cm^{-1} (COO$^-$): $\nu_{max}^{CHCl_3}$ 2410 ($\overset{+}{N}$-H), 1745 (C=O) and 1603 cm^{-1} (COO$^-$) (0.028 M, 0.104 mm.).

Found: C, 60.00; H, 8.83; N, 6.95. Calcd. for $C_{10}H_{17}O_3N$: C, 60.28; H, 8.60; N, 7.03%.

The Hydrochloride of IIb.—It was at first obtained as a viscous oil by the acidification (pH 1.8) of IIb in metanol with methanolic hydrogen chloride, followed by dilution with absolute ether. However, when the oil was dissolved in propan-2-ol for about one month at room temperature, the crystalline hydrochloride separated. Recrystallization from propan-2-ol afforded a pure sample of IIb hydrochloride as hygroscopic colorless prisms; m. p., 155~156°C (decomp.), R_f 0.37. When admixed with IIa, the hydrochloride showed depression of the melting point. ν_{max}^{KBr} 2730 ($\overset{+}{N}H$), 1745 (C=O) and 1720 cm^{-1} (COOH). pK_{a_1} 3.49 and pK_{a_2} 8.66.

Found: C, 51,19; H, 7.96; N, 5.83. Calcd, for $C_{10}H_{18}O_3NCl$: C, 50.93; H, 7.70; N, 5.94%.

2-Benzylidene-5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic Acid (IIIb).—A mixture of methyl 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (IVb) (90 mg.), benzaldehyde (45 mg.) and 10% sodium hydroxide (0 5 ml.) was stirred at 25°C for 2.5 hr. The orange-yellow solution was processed in the same manner as described in the preparation of IIIa to yield a crude picrate of IIIb (40 mg.) melting at 182°C (decomp.). Recrystallization from methanol afforded a pure sample of the 2-benzylidene-5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid picrate (IIIb) in the form of yellow needles; m. p., 184°C (decomp.). Admixing it with a sample of IIIa picrate melting at 187°C (decomp.) showed a depression of the melting point; mixed m. p., 177°C (decomp.).

Found: C, 53.57; H, 4.87; N, 10.75. Calcd. for $C_{23}H_{24}O_{10}N_4$: C, 53.49; H, 4.68; N, 10.85%.

Bioassays.—Preliminary results indicate that 5-methyl-2-methylenecyclopentanone-3-carboxylic acid (X) and its methyl ester (IX) completely inhibit the growth of *M. pyogenes var. aureus* 209-p in dilutions of 1 : 400 and 1 : 16000 respectively, and inhibit the growth of *Candida albicans* and *Penicillium* 408-701 in dilutions of 1 : 4000 and 1 : 32000 respectively. Moreover, X and IX completely inhibit the growth of *Trichophyton mentagrophytes* in dilutions of 1 : 8000 and 1 : 16000 respectively.

It is interesting that X and IX possess antitumor activity. The minimum necessary concentrations of X and IX for the anti-HeLa cell effect were 125 and 32 mcg./ml.

A detailed report on the biological activity of X and IX will be published elsewhere.

Summary

1) The Mannich reaction of 5-methylcyclopentanone-3-carboxylic acid with formaldehyde

and dimethylamine hydrochloride gave a mixture of 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid (VI) and two kinds of geometrical isomers of 5-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylic acid (IIa and IIb), from which IIa, an unstable methiodide (VII) of methyl ester of VI, and IIb were isolated.

2) Methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate methiodide (VIII) was degraded to give methyl 5-methyl-2-methylencylopentanone-3-carboxylate (IX), which was then hydrolyzed to 5-methyl-2-methyleneclycopentanone-3-carboxylic acid (X), a homolog of sarkomycin.

3) The steric relation between IIa and IIb has been discussed.

4) The destructive distillation of methyl 2-(dimethylaminomethyl)-5-methylcyclopentanone-3-carboxylate (VII), followed by hydrolysis, afforded 2,5-dimethylcyclopenten-1-one-3-carboxylic acid (XII), an isomer of X. It was found that the product was obtained also by the thermal decomposition of the methyl ester hydrochloride of IIa. This fiinding may be accounted for on the assumption that a rearrangement of the dimethylaminomethyl group occurred through a kind of retrograde Mannich reaction.

5) Some derivatives of the above-mentioned Mannich bases were described.

6) Both X and its methyl ester were found to possess antitumor and antibacterial activities.

The authors are indebted to Professor Hamao Umezawa, the National Institute of Health, Tokyo, for the antitumor assays. This work has been supported in part by a cancer reserch grant of the Ministry of Education and by a grant from the Research Society of Microbiological Chemistry, Tokyo, to which the authors thanks are due.

NOTES

Organoborverbindungen. Über die Synthese der höheren Bortrialkyle und ihre Stabilität gegen die Oxydation

Von Seiji KATO, Moriyasu WADA und Yojiro TSUZUKI

(Eingegangen am 25. December, 1962)

Im Anschluss an die Untersuchungen über die Synthese der hochmolekularen borhaltigen Verbindungen haben die Verfasser seit einigen Jahren versucht, die bisher noch nicht beschriebenen Bortrialkyle mit längeren Ketten herzustellen.

Höhere Homologe als die Hexyl-Verbindungen sind noch nicht beschrieben, obwohl eine grosse Anzahl von Bor-Verbindungen mit der Zusammensetzung BR_3 schon bekannt ist[1].

Für die Synthese von Bortrialkylen sind einige Reaktionen recht bekannt, von denen Folgendes am besten verwendet wird.

$$BF_3(\text{Ätherat}) + 3RMgX = BR_3 + 3MgFX$$

In der letzten Zeit ist das Bortrifluorid-Ätherat leicht zugänglich geworden und daher sind das daraus zu bekommende Triäthyl-, Tripropyl- und Tributyl-bor als Katalysatoren verwendet worden[2].

Nun haben die Verfasser nach der obenerwähnten Reaktion die folgenden Bortrialkyle synthetisiert. Die Ergebnisse sind in der Tabelle I zusammengestellt.

Aus den Infrarotspektren von Bortrialkylen, die im NaCl-Bereich mittels Hitachi-EPI-II aufgenommen wurden, zeigten sich die folgenden Wellenzahlen der B–C Bindung. Die Wellenzahlen des Trimethyl-, Triäthyl- und Tributylbors, die ebenfalls im NaCl-Bereich aufgenommen wurden, sind auch in der Tabelle II gezeigt.

TABELLE I. BORTRIALKYLE UND ELEMENTARANALYSE

R_3B	Sdp., °C	Schmp. °C	Ausbeute %	Mol. Gew. Gef.	Mol. Gew. Ber.	Elementaranalyse Gef. C	Gef. H	Gef. B	Ber. C	Ber. H	Ber. B
$(C_5H_{11})_3B$	160～162/30.5 mmHg		60								
$(C_8H_{17})_3B$	189～192/12 mmHg		64	369.8	350.5	82.75	14.89	2.36	82.24	14.64	3.09
$(C_{12}H_{25})_3B$		50.0	74	562.3	518.8	85.13	15.11	1.85	83.25	14.55	2.20
$(C_{18}H_{37})_3B$		66.4～70.0	50	803.1	771.3	84.21	14.61	1.18	84.08	14.52	1.40

TABELLE II. WELLENZAHL DER B-C BINDUNG

R	B-C, cm^{-1}	R	B-C, cm^{-1}
Methyl	1150～1180	*n*-Octyl	1065
Äthyl	1130	Dodecyl	1065
n-Butyl	1080	Stearyl	1065
n-Hexyl	1075		

Die Zuordnung der B-C Bindung im Spektrum wurde schon von einigen Forschern studiert. Lehmann und seine Mitarbeiter[3] beobachteten mit Hilfe vom Deuterium die Bände 1130 und 1180 cm^{-1} als die Wellenzahlen der B-C Bindung des Trimethyl- und Triäthylbors, während Catz[4] für *p*-Vinylphenylborsäure die Wellenzahl 1086 cm^{-1} angab.

Unsere Daten liegen auch im Bereich der Wellenzahl 1060～1080 cm^{-1}, und daraus ersieht man von den Bortrialkylen, dass sich die Wellenzahl der Schwingung der B-C Bindung etwa umso mehr nach dem kleineren Bereich verschiebt, je nachdem die Alkylkette verlängert wird.

Die Stabilität der Bortrialkyle gegen die Oxydation.—Im allgemeinen werden die Bortrialkyle mit den kleineren Alkylgruppen als C_4H_9 leicht oxydiert und sind explosiv in der Luft. Aus dieser Eigenschaft geht hervor, dass die Bortrialkyle, besonders das Triäthyl- und Tributyl-bor als Katalysatoren zur Polymerisation der Vinylmonomeren verwendet werden können, wobei der molekulare Sauerstoff zu dieser Radikalketten-polymerisation eine wichtige Rolle spielt.

Der Mechanismus der Oxydation dieser Bortrialkyle wurde bereits von Johnson[5] beschrieben. Er zeigte, dass die Bortrialkyle dabei zwei Mole molekularen Sauerstoffs, aber in Gegenwart von Wasser nur ein Mole desselben aufnehmen. Später wurde der Reaktionmechanismus auch von Parsons[6] mit der Annahme von Peroxyd-Bildung elektronen-theoretisch erklärt.

Ausserdem hat Abraham[7] durch die ausführliche Untersuchung gezeigt, dass die Aufnahme des Sauerstoffs von Bortrialkylen ausserordentlich gross ist, wenn man sie mit organischen Lösungsmitteln verdünnt.

In der letzten Zeit hat Mirviss[8] an einem kinetischen Versuch gezeigt, dass die erste Bindung zwischen Bor- und Kohlenstoffatomen durch Oxydation leicht gespalten wird, aber die zweite sowie die letzte Bindung etwa beständig ist. Er hat aber sowohl die Geschwindigkeit der Reaktion als auch den Einfluss der Alkylkettenlänge nicht studiert.

Die Verfasser haben nun die Oxydation der Bortrialkyle nach der Methode von Abraham untersucht und beobachtet, dass die Reaktion mit einer monomolekularen Geschwindichkeit verläuft, und dass das Volumen des von diesen Bortrialkylen aufgenommenen Sauerstoffs umso kleiner wird, je länger die Alkylkette wird. Die Versuchsdaten von dem Oxydationsverlauf werden in der Abbildung 1 und 2, und in der Tabelle III gezeigt.

TABELLE III. VERSUCHSDATEN ÜBER DEN OXYDATIONSVERLAUF

R (im R_3B)	Aufgenommener Sauerstoff in Hexan* mol.	Hergestelltes Peroxyd** mol.	k*** 10^{-3} Sek^{-1}
C_2H_5	1.32	0.65	8.54
C_4H_9	1.28	0.42	9.26
C_6H_{13}	0.78	0.26	9.78
C_8H_{17}	0.76	0.06	9.00

* Im Falle der Abwesenheit von Lösungsmitteln ergab es keine günstigeren Resultate.

** Diese Werte wurden als Peroxyd R_2BOOR jodometrisch bestimmt.

*** Bestimmt aus folgender Gleichung

$$k=2.5/t_n\{\log V-\log(V-V_n)\}$$

Hier; k: Geschwindigkeitskonstante

V_n: Das Volumen des aufgenommenen Sauerstoffs am t_n

V: Das Maximalvolumen des aufgenommenen Sauerstoffs

Aus diesen Resultaten kann man sagen, dass die Reaktionsfähigkeit der Bortrialkyle gegenüber Sauerstoff je nach der Länge der Alkylkette abnimmt. So versteht man auch dass,

Abb. 1. Oxydationsverlauf.

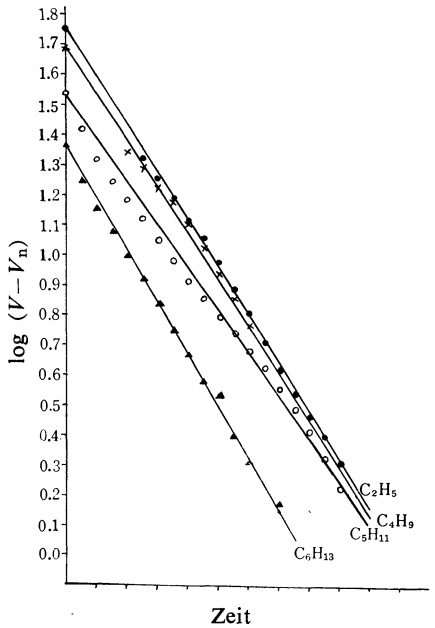

Abb. 2. Verhältnis zwischen der Zeit und Verlauf.

die niedrigen Bortrialkyle tatsächlich als Katalysatoren besser wirken.

Diese Eigenschaften der Bortrialkyle als Polymerisationskatalysator beruhen angeblich auf der Elektronlücke im Boratom, also auf seiner Lewis-Acidität. Daher bilden sie leicht unter Absorption von molekularem Sauerstoff immer Peroxyde, die auch bekanntlich einen Radikal-Charakter zeigen:

$$R_3B + O_2 \rightarrow R_2BOOR \rightarrow R_2BOO\cdot + \cdot R$$

Die Fähigkeit der Peroxydbildung ist umso merklicher, je niedriger die Kettenlänge der Alkylgruppe ist, also hängt die Wirkung der Bortrialkyle als Polymerisationskatalysator namentlich mit der räumlichen Grösse der Alkylgruppe zusammen.

The Reactions of Nitrosobenzene and Some Methylene Compounds

By Hiroyuki NOHIRA, Kenichiro SATO and Teruaki MUKAIYAMA

(Received March 1, 1963)

As part of a study of the dehydration reactions of primary nitroparaffins[1], aldoximes[2,3], and hydroxamic acids[4] by means of such organic reagents as isocyanates, carbodiimides and iminocarbonates[5], the reactions of iminocompounds having carbonyl groups, such as diethyl phenyliminomalonate (I) and phenyliminoacetylacetone (III), have been studied. Although Walker[6] has reported that diethyl phenyliminomalonate (I) (m. p., 113.5°C) was prepared from the reaction of nitrosobenzene and diethyl malonate, it was found by this experiment that the crystalline product is not the iminomalonate, but diethyl dianilinomalonate (II). This is identical with an authentic sample obtained from the reaction of diethyl dibromomalonate with aniline[7]. Iminomalonate I was obtained as a pale brown liquid by distillation (b. p., 108~109°C/0.15 mmHg) in about a 70% yield, when the same reaction was carried out in absolute ethanol in the presence of a catalytic amount of sodium hydroxide. It was further confirmed that, when I was exposed to the moist air, the liquid material I changed gradually to the crystalline substance II.

In order to examine the effect of the water involved in the solvent on the ratio of the products I and II, the experiments in Table I were carried out in aqueous ethanol.

These results suggest that the reaction of nitrosobenzene with diethyl malonate proceeds through the initial formation of I, which is subsequently hydrolyzed to give II and diethyl oxomalonate, if any excess of water is present.

$$C_6H_5\text{-}N{=}O + CH_2\langle^{COOC_2H_5}_{COOC_2H_5} \rightarrow C_6H_5\text{-}N{=}C\langle^{COOC_2H_5}_{COOC_2H_5} + H_2O$$

				H,	5.74	5.70
				N,	14.50	15.34

$$2I + H_2O \rightarrow \underset{C_6H_5NH}{\overset{C_6H_5NH}{\rangle}}C\langle\overset{COOC_2H_5}{COOC_2H_5} \quad \text{(II)} + O{=}C\langle\overset{COOC_2H_5}{COOC_2H_5}$$

Similarly, phenyliminoacetylacetone (III) and ethyl phenyliminoacetoacetate (IV) were prepared by the reaction of nitrosobenzene with acetylacetone or ethyl acetoacetate respectively in absolute ethanol.

$$C_6H_5{-}N{=}C\langle\overset{COCH_3}{COCH_3} \quad \text{(III)} \qquad C_6H_5{-}N{=}C\langle\overset{COOC_2H_5}{COCH_3} \quad \text{(IV)}$$

Next, the reactions of these imino-compounds with various amines were studied. Diethyl phenyliminomalonate (I) or phenyliminoacetylacetone (III) reacts with various primary and secondary amines to give their addition compounds, *gem*-diaminomalonate (V) or *gem*-diaminoacetylacetone (VI). These reactions are accelerated by a catalytic amount of acetic acid.

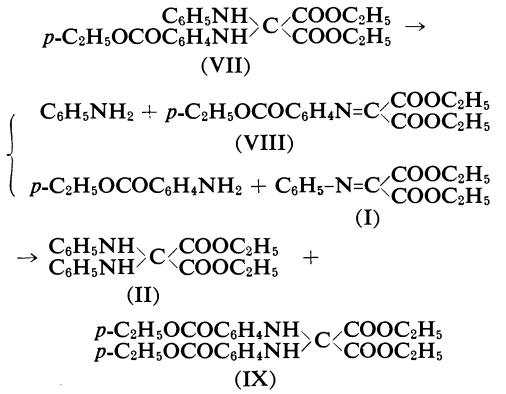
$$C_6H_5{-}N{=}C\langle\overset{COR_1}{COR_1} + R_2{-}NH_2 \rightarrow \underset{R_2NH}{\overset{C_6H_5NH}{\rangle}}C\langle\overset{COR_1}{COR_1}$$

$R_1 = -OC_2H_5$: I — $R_1 = -OC_2H_5$: V

$R_1 = -CH_3$: III — $R_1 = -CH_3$: VI

The yields, melting points and analyses for these adducts are listed in Tables II and III.

These adducts are unstable at an elevated temperature, and when pyrolyzed in a Claisen flask at 150~200°C, they decompose into their components, imino-compounds and amines. For example, when the adduct of diethyl phenyliminomalonate and ethyl *p*-aminobenzoate (VII), which is a viscous liquid and does not crystallize, was pyrolyzed, aniline and diethyl *p*-carbethoxyphenyliminomalonate (VIII) were obtained along with ethyl *p*-aminobenzoate and I. Furthermore, it was confirmed that the asymmetrical adducts like VII are not stable at room temperature but easily undergo a disproportionation reaction to give two symmetrical *gem*-diamino compounds. Thus, in the course of attempts to isolate the above-mentioned adduct (VII), II and IX were isolated.



Experimental

Diethyl Phenyliminomalonate (I).—To a solution of diethyl malonate (23 g.) and nitrosobenzene (15 g.) in 30 ml. of absolute ethanol, an absolute ethanol solution of sodium hydroxide was added slowly, until the green solution of nitrosobenzene changed to pale brown. After the removal of the solvent under reduced pressure, the residual liquid was distilled and 26 g. (72%) (b. p., 108~109°C/0.15 mmHg) of diethyl phenyliminomalonate was obtained. Found: C, 62.19; H, 6.39; N, 5.73. Calcd. for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62%.

Similarly, phenyliminoacetylacetone (III) (b. p., 82°C/0.28 mmHg) (58%). Found: C, 70.09, H, 6.21; N, 7.24. Calcd. for $C_{11}H_{11}NO_2$; C, 69.82; H, 5.86; N, 7.40%, and ethyl phenyliminoacetoacetate (IV) (b. p., 99°C/0.18 mmHg) (64%). Found: C, 65.62; H, 6.47; N, 6.79. Calcd. for $C_{12}H_{13}NO_3$: C, 65.74; H, 5.98; N, 6.39% were prepared from the reaction of nitrosobenzene with acetylacetone or ethyl acetoacetate in absolute ethanol in the presence of triethylamine instead of sodium hydroxide.

The Reaction of I with Varions Amines.—To a mixture of I (2.5 g.) and aniline (0.9 g.), one drop of acetic acid was added. After an exothermic reaction took place, the mixture solidified gradually. It was recrystallized from 95% ethanol, and 3.1 g. (90%) (m. p., 116.5~117.5°C) of diethyl dianilinomalonate (II) was obtained.

Similarly, I reacted with piperidine, *N*, *N*-dimethyl *p*-phenylenediamine and *p*-aminoazobenzene to give the corresponding adducts of type V (Table II). The adducts of I with *p*-toluidine, *p*-anisidine and ethyl *p*-aminobenzoate were viscous liquids and did not solidify.

The adducts VI of phenyliminoacetylacetone (III) with aniline, *p*-anisidine and *p*-amino azobenzene were prepared analogously from the reactions of III with the corresponding amines (Table III).

The Pyrolytic Decomposition of the Adduct (VII).—A viscous liquid of the adduct VII obtained from 5.0 g. of I and 3.2 g. of ethyl *p*-aminobenzoate was decomposed under a reduced pressure in a Claisen flask, and the following three fractions were obtained: aniline, b. p. 43~50°C/2 mmHg; a mixture of I and ethyl *p*-aminobenzoate, b. p. 130~150°C/2 mmHg, and diethyl *p*-carbethoxyphenyliminomalonate (VIII), b. p. 160~170°C/2 mmHg.

This iminomalonate VIII reacted with ethyl *p*-aminobenzoate to give a symmetrical adduct, diethyl di-(*p*-carboethoxyanilino)malonate (IX) (m. p., 135°C. Found: C, 62.19; H, 6.44; N, 5.71. Calcd. for $C_{25}H_{30}N_2O_8$: C, 61.71; H, 6.22; N, 5.76%.)

The same crystalline substance IX was isolated, along with II, in the course of attempts to crystallize the above-mentioned asymmetrical adduct VII.

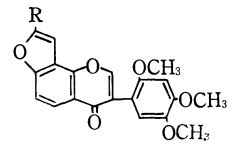
The Synthesis of Elliptol Isoflavone

By Kenji FUKUI, Mitsuru NAKAYAMA and Masayuki HATANAKA

(Received March 15, 1963)

In 1942, elliptol isoflavone (furano(2'', 3'' ; 7, 8)-2', 4', 5'-trimethoxyisoflavone) (I) was prepared by Harper[1] from elliptol methyl ether (II)[2], a degradative fragment of elliptone (III)[3]. As I belongs to the same isoflavone type as Harper's phenol (" toxicarol isoflavone ")[4], which has been isolated from the *Derris elliptica* root along with other rotenoids, I has attracted increasing attention. As described in a previous paper[5], 7-hydroxy-2', 4', 5'-trimethoxyisoflavone (IV) was produced from 2, 4-dihydroxyphenyl 2, 4, 5-trimethoxybenzyl ketone. Now we will describe a total



I R=H
VI R=$CO_2C_2H_5$
VII R=CO_2H

synthesis of I from IV by the same procedure as described in the previous papers[6].

The formylation of IV by the hexamine method gave the 8-formyl compound V, which was converted into 5''-ethoxycarbonyl-furano-(2'', 3''; 7,8)-2',4',5'-trimethoxyisoflavone (VI) by the action of ethyl bromomalonate and potassium carbonate. The alkaline hydrolysis of VI furnished the corresponding acid VII, which was decarboxylated in quinoline into I (m. p., 172~173°C) (reported m. p., 175°C[1]) in a good yield. To confirm the structure of I, the alkaline hydrolysis of I was carried out, giving II as colorless needles (m. p., 135~136°C) (reported m. p., 137°C[2]), which gave a brownish green ferric chloride test in ethanol.

Experimental*

8-Formyl-7-hydroxy-2', 4', 5'-trimethoxyisoflavone (V).—A mixture of IV (10 g.), hexamine (53 g.) and acetic acid (860 ml.) was heated on a steam bath for 8 hr. The hot solution obtained was treated with 1 : 1 hydrochloric acid (168 ml.) and again heated for 15 min.; then the solvent was removed in vacuo until ca. 200 ml. remained. After dilution with water (2000 ml.), the precipitates obtained were collected and crystallized from ethanol. The product was recrystallized from benzene to give V in the form of faintly yellow-colored needles (m. p., 190~191°C), which showed a red ferric chloride test in ethanol; yield, 6.3 g. (58%).

Found: C, 63.75; H, 4.58. Calcd. for $C_{19}H_{16}O_7$: C, 64.04; H, 4.53%.

5''-Ethoxycarbonyl-furano(2'', 3''; 7, 8)-2', 4', 5'-trimethoxyisoflavone (VI).—To a solution of V (6.3 g.) and ethyl bromomalonate in methyl ethyl ketone (500 ml.) potassium carbonate (21 g.) was added; the mixture was then refluxed for 10 hr. on a steam bath. The resulting mixture was filtered from precipitates, and the solvent was distilled off. The residual product was recrystallized from ethyl acetate to give VI in the form of colorless needles (m. p., 185~186°C) with a negative ferric chloride test in ethanol; yield, 5.2 g. (71%). IR: 1735 cm^{-1} (ester), 1650 cm^{-1} (γ-pyrone).

Found: C, 65.22; H, 4.82. Calcd. for $C_{23}H_{20}O_8$: C, 65.09; H, 4.75%.

5''-Carboxy-furano(2'', 3''; 7, 8)-2',4',5'-trimethoxyisoflavone (VII).—A mixture of VI (5.2 g.), acetone (600 ml.) and 10% aqueous potassium carbonate (175 ml.) was heated under reflux on a steam bath for 4 hr. After the acetone had been removed in vacuo, the residue was acidified with dilute hydrochloric acid. The resulting precipitate was recrystallized from ethanol to give VII in the form of colorless microcrystals (m. p., 282~283°C (decomp.)); yield, 2.7 g. (56%). IR: 1719 cm^{-1} (acid), 1648 cm^{-1} (γ-pyrone).

Found: C, 63.35; H, 4.36. Calcd. for $C_{21}H_{16}O_8$: C, 63.63; H, 4.07%.

Elliptol Isoflavone (I).—A mixture of VII (1.2 g.), copper powder (0.6 g.) and quinoline (30 ml.) was heated while being stirred in an atmosphere of nitrogen for 30 min. at 190~210°C until the evolution of carbon dioxide ceased. The solvent was then distilled off by steam distillation from the resulting mixture. The cooled mixture was filtered from precipitates and then extracted with ethyl acetate. After being washed successively with dilute hydrochloric acid, aqueous sodium bicabonate and then water, the solution was dried and evaporated. The residue was recystallized from methanol to give I in the form of colorless needles (m. p., 182~183°C) (reported m. p., 185°C[1]); yield, 0.8 g. (75%). IR: 1640 cm^{-1} (γ-pyrone).

Found: C, 68.28; H, 4.39. Calcd. for $C_{20}H_{16}O_6$: C, 68.18; H, 4.58%.

Elliptol Methyl Ether (II).—A mixture of I (0.3 g.), a 5% aqueous sodium hydroxide solution and ethanol (20 ml.) was refluxed for 3 hr. on a steam bath. After the solvent was evaporated, the residue was extracted with ethyl acetate. The resulting precipitate was recrystallized from methanol to give II in the form of colorless prisms (m. p., 135~136°C) (reported m. p., 137°C[2]), which showed a brownish green ferric chloride test in ethanol; yield, 0.2 g. (69%). IR: 1629 cm^{-1} (ketone).

Found: C, 66.70; H, 4.39. Calcd. for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

prepared by fusion of a mixture of rhodium chloride and chloroplatinic acid with sodium nitrate, is not only highly active, but also very selective as a catalyst in the hydrogenation of various organic compounds. Its high selectivity has already been shown in the hydrogenation of the compounds having C–O linkages liable to hydrogenolysis[1-4,6,7] and in the cis hydrogenation of substituted aromatic compounds[7].

This paper descibes another example of the high selectivity of the rhodium-platinum oxide revealed in the hydrogenation of aniline. Numerous catalysts have been used in the hydrogenation of aniline; of these, cobaltic oxide promoted with calcium oxide and ruthenium dioxide have been shown to give high yields of cyclohexylamine[8,9]. In an acidic medium, platinum catalyzes the hydrogenation even at room temperature, but so much dicyclohexylamine is produced that it is often more dominant than cyclohexylamine[10-12] (see Table I). As has already been reported[5], (7 : 3)rhodium-platinum oxide also catalyzes the hydrogenation in acetic acid at room temperature and gives a better yield of cyclohexylamine than platinum oxide. Table I summarizes the results of further investigations carried out in various solvents at an atmospheric or high pressure of hydrogen. With (7 : 3)rhodium-platinum oxide, aniline is hydrogenated most rapidly in acetic acid, and 16~22% of dicyclohexylamine is obtained with cyclohexylamine as the main product in hydrogenation at room temperature. With ethanol as a solvent, aniline is hydrogenated rather rapidly at 50°C and gives cyclohexylamine exclusively[13]. The addition of a small amount of acetic acid to ethanol causes the formation of dicyclohexylamine to the extent of 12% at 50°C, and a longer time is required for the completion of the hydrogenation than in ethanol. In ethanol and acetic acid in the amount equivalent to that of aniline, the hydrogenation proceeds smoothly at room temperature, and less than half as much dicycloheylamine is formed as in acetic acid. It is obvious from these results that acetic acid greatly promotes the formation of the secondary amine. The high selectivity of cobalt and ruthenium catalysts is probably connected with their use in neutral or alkaline conditions. Figure 1 shows the effect of hydrogen pressure on the rate of the hydrogenation of aniline in

acetic acid. The rate is approximately proportional to $P_{H_2}/(1+bP_{H_2})$, where b is a constant, in the range of 1 to 149 kg./cm^2 of hydrogen pressure, which is indicated by the straight line of P_{H_2}/rate versus P_{H_2} shown in Fig. 1. The rate of the hydrogenation at 149 kg./cm^2 is about thirty times as great as that at atmospheric pressure, but the yield of cyclohexylamine is increased only slightly by increasing the hydrogen pressure. The condensation reaction to give secondary amines seems to be rapid in acetic acid, not a rate-controlling step in the formation of dicyclohexylamine. The use of platinum oxide under high pressures is quite unsatisfatory because of the decrease of the activity during the hydrogenation, as has already been noticed by Baker and Schuetz[12]. The findings on the hydrogenation of various substituted anilines will be published later.

Experimental

The procedure for the preparation of catalysts and the hydrogenation apparatus at high pressure have been described previously[1,7]. Hydrogenations at atmospheric pressure were carried out in a 200 ml. glass bottle shaken at about 300 to 400 oscillations per minute.

The reaction mixture was allowed to stand in order to let most of the catalyst settle, and the upper layer was filtered. The catalyst was washed with acetic acid three times. After the addition of an excess of hydrochloric acid to the filtrate, the solvent was distilled off at reduced pressure. The residual solid was treated with aqueous sodium hydroxide and extracted with ether, and the ethereal solution was dried on solid potassium hydroxide. Distillation at atmospheric pressure followed by distillation at reduced pressure gave cyclohexylamine (b. p., 133~136°C) and dicyclohexylamine (b. p., 129~130°C/20 mmHg).

SHORT COMMUNICATIONS

Paramagnetic Chemical Species of Triphenylmethane and Diphenylamine Formed on the Surface of Several Oxides[1]

By Kozo HIROTA, Yoichi KAGEYAMA and Keiji KUWATA

(Received May 9, 1963)

In a previous communication[2] it was reported that some paramagnetic chemical species were formed if anthracene, naphthalene, benzene and hydroquinone were adsorbed in the presence of air on powdered vanadium pentoxide (V_2O_{5-x}). On the basis of their stabilities and for other reasons, the species were hypothesized to be mainly paramagnetic intermediates in the oxidation process of these aromatic hydrocarbons, e. g. radicals of the semiquinone type, rather than the molecule cations such as have been proposed in the research papers[3] when these hydrocarbons were adsorded on silica-alumina, especially in the absence of air.

In order to confirm the above hypothesis, the research was extended to other adsorbents besides vanadium pentoxide, i. e., cupric oxide, cuprous oxides and alumina. Moreover, instead of aromatic hydrocarbons, triphenylmethane and diphenylamine were used as the adsorbates, because these compounds are known to give radicals by oxidation easily. The experimental procedure and the ESR apparatus used were the same as in the previous paper.

As is shown in Fig. 1, triphenylmethane, when adsorbed on V_2O_{5-x} and heated in air, gave a signal at $g=2.00$ superposed on a broad signal with incompletely resolved hfs of the vanadium ion, in a way similar to that of

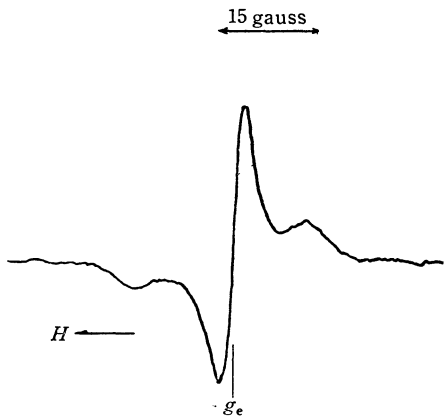

Fig. 3. ESR spectrum of diphenylamine/Cu_2O system heated in air for 15 min. at 200°C.

hydroquinone[4], but it gave no signal when adsorbed on cuprous oxide, cupric oxide, or aluminum oxide. The hfs here observed may be due to the decrease in the number of paramagnetic vanadium ions in the oxide. This finding may be explained by the following process:

$$(C_6H_5)_3CH + 2(\dot{V}) + 2O_2 \rightarrow (C_6H_5)_3C\dot{O}O + (\dot{V})OH + V^{(v)}O \quad (1)$$

occurring in connection with the oxidation of triphenylmethane by air, where $(\dot{V})$ denotes the paramagnetic-valency state of vanadium.

Diphenylamine, however, gave signals at $g=2.00$ for all these oxides. Judging from their shape, all the paramagnetic species produced may not be the same. An interesting point is the splitting of the signal into a triplet of unequal height in the case of cuprous oxide (Fig. 3). This may be brought about by the nuclear spin of ^{14}N of the adsobed species and by the anisotropic effect[5]. A similar tendency was observed, though not so clearly, in the spectrum of diphenylamine adsorbed on V_2O_{5-x} (Fig. 2), while no splitting could be observed in the spectra of cupric oxide and aluminum oxide. From such a difference it may be concluded that the adsorptive power of aluminum oxide is stronger than that of cuprous oxide. The reason why hfs of the adsorbent did not appear can be explained by the constancy in quantity of $(\dot{V})$ during the oxidation, if the following mechanism be assumed in the case of diphenylamine:

$$(C_6H_5)_2NH + (\dot{V}) + O_2 \rightarrow (C_6H_5)_2N\dot{O} + (\dot{V})OH \quad (2)$$

After the ESR measurement had been made, the adsorbates were extracted with carbon disulfide in the cases of triphenylmethane/V_2O_{5-x} and diphenylamine/V_2O_{5-x}. Both extracted substances were found to show ESR signals at $g=2.00$, suggesting the formation of stable radicals by oxidation.

For the sake of comparison, DPPH was similarly adsorbed at room temperature on V_2O_{5-x}; it was found to give no signal. The extract also gave no signal of radicals, suggesting the perfect oxidation of DPPH. Mechanisms (1) and (2) are, therefore, plausible.

Anomalous Conduction across Ion-exchange Membranes

By Manabu SENŌ and Takeo YAMABE

(Received June 12, 1963)

It is extensively shown that a constant electric current passes across ion-exchange membranes under normal conditions, when a constant voltage being applied. Sometimes, however, the anomalous conduction phenomena are observed; that is, non-ohmic conduction and pulse generation[1,2]. The aim of the present communication is to clear the conditions under which the anomalous conduction takes place and to propose a mechanism for pulse generation.

Anomalous conduction is observed in the sample arrangement shown in Fig. 1, which is one of the simplest system for pulse generation. Cellophane diaphragms are used to separate the sample solutions from the electrode solutions; sample solution II is a gel solution of sodium chloride containing agar. Ion-exchange membranes used are Selemion CMG-10 (cation-selective) and AMG-10 (anion-selective) manufactured by Asahi Glass Co., Ltd.

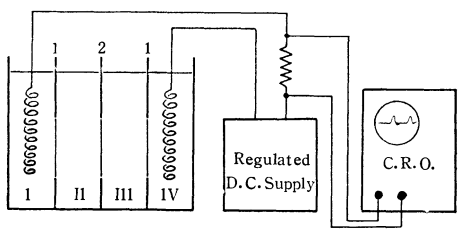

Fig. 1. The sample arrangement for observation of anomalous conduction and the measuring apparatus.
1. Cellophane (Visking) diaphragms
2. Ion-exchange membranes
Electrode solutions I and IV and sample solution III are 0.05 N NaCl solutions and sample solution II is 0.05 N NaCl solution containing agar (1.5 wt%).

The relationship between the voltage applied and the current passed is ohmic at the initial state when the voltage is applied. But, when the membrane is cation-selective and the electrode I is positive, the current decreases with time and reaches a constant value, which is characteristic of the system and independent of the voltage applied. When the polarity of electrode is reversed, such a decrease is not observed.

When higher voltages are applied to the system in the former case, the current no longer decreases and repeated pulses superimposed on the direct current are observed, an example of which is shown in Fig. 2.

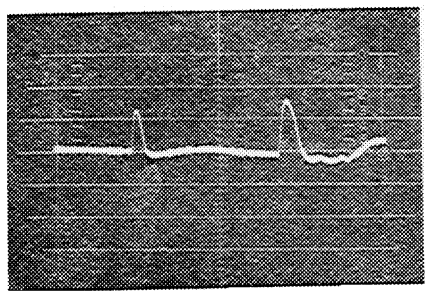

Fig. 2. The pulse train superimposed on the direct current across the ion-exchange membrane in Fig. 1.

The following mechanism is proposed for this anomalous conduction. When the current passes across ion-exchange membranes, the concentration polarization takes place in the diffusion layers (interfaces between solutions and membranes), owing to the difference of transport numbers of ions in the solution and membrane phases. When the limiting current flows, the salt concentration in the salt-depletion diffusion layer, which is built up facing to the anode in the case of cation-selective membranes, becomes zero[3]. When a higher voltage than the critical one is applied to the system, a higher current governed by the ohmic resistance of the system passes initially but, as soon as the salt-depletion layer is built up, a lower and stationary diffusion-controlled current is observed. In this stationary state, the current is independent of the voltage applied, and the electrical potential difference at the salt-depletion layer increases remarkably with the increase of the applied voltage.

When the electrical potential difference becomes higher than a critical value, a sudden increase in current is observed probably because the increasing dissociation of water occurs in the salt-depletion layer. However, such a high current can not pass stationarily, because the salt-depletion layer is built up again in the cource of time. Thus the current passing through this system oscillates along the limit cycle on the voltage-current diagram of the diffusion layer, which is shown in Fig. 3. At the point A the increasing dissociation of water occurs, and the point B is determined by

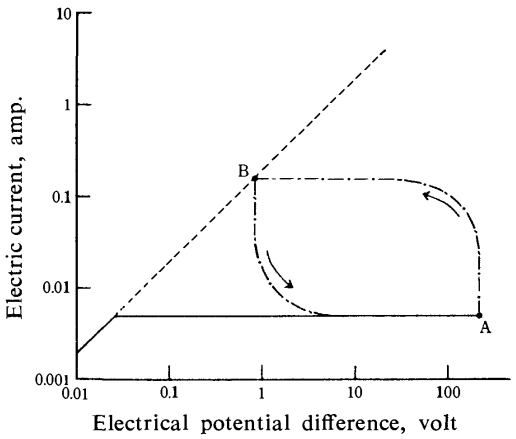

Fig. 3. Log-log plot of electric current against electrical potential difference at the salt-depletion diffusion layer.

the ohmic resistance of the system.

When an aqueous sodium chloride solution is used as the sample solution II, the stationary diffusion-controlled current is not established and the pulse current is not observed. The gel-like structure of agar stabilises mechanically the diffusion layer. Concentrated glycerol-water solutions of sodium chloride can beused as the sample solution for pulse generation.

The same behavior is observed in a double ion-selective membrane, which is made by pressing cation- and anion-selective membranes face to face. In this case, a junction plane between two parts of the membrane plays the same role as the salt-depletion diffusion layer in the case of the single-membrane system.

The rectification effect is also observed in these cases. Further extensive investigations are being made in order to exploire the electric circuit elements with ions as charge carriers and examine its similarity with biological membranes.

The Effects of Stationary Liquids on the Separation of the Isomers of Aromatic Hydrocarbons in Gas Chromatography[*1]

By Takeo ARAKI[*2]

(Received October 17, 1962)

The author has continued gas chromatographic studies of stationary liquids with regard to the separation of xylene isomers[1-4]. Such mixed stationary phases as β-naphthylamine/fluorenone (1 : 1) have been proven to be effective for the separation of xylene isomers containing ethylbenzene[3]. When the separating power of this mixed stationary liquid was compared with that of 7,8-benzoquinoline, which was proposed by Desty et al.[5], there was no appreciable difference between these two stationary phases in the case of the xylene isomers, but when ethylbenzene was present in the isomers, the former one seemed to be rather more suitable[*3,*4].

Of the xylene isomers, the para-isomer can be regarded as the most electronically inactive, its dipole moment is zero. Therefore, *p*-xylene was chosen as the standard isomer in the estimation of the separation factors; the relation of the separation factors to the σ_p values (Jaffé[6]) of the substituents in the aromatic stationary liquids was investigated and discussed in a previous paper[4].

It was found that this relation did not coincide entirely with Hammett's rule, but it had a rather closer relationship. More interesting facts were illustrated by smooth curves, which formed what has been called a "separation diagram"[4].

In connection with the preceding works, there remains the question of whether or not the "separation diagram" of xylenes at 88°C can be applied generally to the gas chromatographic separation of other aromatic hydrocarbon isomers in the same isomeric relation. The present work was undertaken to answer this problem.

Experimental

Apparatus.—The apparatus used was constructed in this laboratory. Some glass chromatographic columns (the dimensions of a unit are 1 m.×6 mm. i. d.) were joined together with copper slender tubes (1 mm. i. d.). A thermal conductivity detector with a tungsten filament was then settled in the apparatus.

Samples.—The ethyltoluene isomers, *o*-, *m*- and *p*-ethyltoluenes and *n*-propylbenzene, were prepared in this laboratory by the preparative methods reported in the literature[7].

Stationary Liquids.—The stationary liquids used were restricted to aromatic compounds. α-Naphthylamine, α-naphthol, benzophenone, 1,3-diphenylbenzene, DOP (dioctylphthalate), dichloronaphthalene and *m*-dinitrobenzene were used as typical of those stationary liquids which showed substituent effects in the separation diagram of a previous paper. TCP (tricresylphosphate), 7,8-benzoquinoline fluorenone, fluorene picrate, α-naphthonitrile and 1,4-dichloro-2-nitrobenzene were used as typical of different stationary liquids which gave results which somewhat deviated from the separation diagram. The inert solid support was coated with these compounds and then packed in glass columns.

Experimental Conditions.—Every effort was made to adjust the many conditions so as to be able to compare the results obtained with ethyltoluenes and xylenes with each other. The experimental conditions for the separation of the ethyltoluene series, together with those of the xylene series, are shown in Table I. The column temperature is setteled at 105°C in this work; it may be assumed

*3 Separation factors are determined as follows: $S_{E,p}$= 0.104, $S_{p,m}$=0.077 on the mixed stationary liquid of β-naphthylamine/fluorenone (1 : 1) and 0.072 and 0.075 on 7,8-benzoquinoline respectively, with a 6 mm.×3 m. column, packed with 17 parts of stationary liquid on 100 parts (w/w) of Celite-545 (60~80 mesh), at 80°C. The separation factors are represented in this paper by the term of S_{12}. in which the suffix 1 denotes the first peak and 2, the second peak. Thus, $S_{E,p}$ is the separation factor between the ethylbenzene and *p*-xylene peaks, and $S_{p,m}$ is that between the *p*- and *m*-xylene peaks.

*4 The separation of *m*- and *p*-xylene by gas chromatography has been developed recently by several investigators: a) G. M. Rouayheb, O. F. Folmer and W. C. Hamilton, *Anal. Chim. Acta*, **26**, 378 (1962); b) J. van Rysselberge and M. van der Stricht, *Nature*, **193**, 1281 (1962).

to be a thermal condition parallel to the previous case of the xylene series at 88°C. The vapor pressures of all these isomers are shown in Table II. The other factors are adjusted so as to be identical in both cases.

Results and Discussion

A Comparison of the Separation Power of Stationary Liquids. — By the separation factor S_{12}*, which was defined by Jones et al.[8], the separation powers of stationary liquids were compared with each other, as had been done in preceding papers. *p*-Ethyltoluene was chosen as a standard isomer for the estimation of the separation factors for the same reasons as *p*-xylene was chosen. It might be interesting to compare the experimental results of the ethyltoluene series directly with those of the xylene series. In the expression of the separation factor given by

$$S_{12}=(t_2-t_1)/t_1 \qquad (1)$$

of either t_1 or t_2, the retention time of the first or the second peak respectively, is always chosen as the retention time of *p*-ethyltoluene.

The relative retention volumes (ethylbenzene=1.000) of the ethyltoluene series on the above-mentioned stationary liquids are tabulated in Table III, while the separation factors estimated from these data are shown in Table IV, in which the separation factors of the xylene series at 88°C on the same stationary liquids are presented for the sake of comparison.

* The $(S_{12}+1)$ value is ordinarily used as the separation factor. In this investigation, however, S_{12} is used as the significant figure of results obtained, because the retention values of these isomers are very close.

Dichloronaphthalene	1.29	(1.46)	0.182	(0.188)	0.021	(0.034)	0.194	(0.293)
m-Dinitrobenzene	1.09	(1.23)**	0.339	(0.364)	0.042	(0.011)	0.240	(0.325)
TCP	0.91	(1.04)	0.100	(0.057)	0.005	(0.035)	0.207	(0.304)
7,8-Benzoquinoline	1.06	(1.22)	0.123	(0.070)	−0.012[b]	(0.070)	0.253	(0.356)
Fluorenone	1.04	(1.22)	0.147	(0.170)	−0.014[b]	(0.056)	0.258	(0.329)
Fluorene picrate	1.06	(1.25)	0.279	(0.334)	0.030	(0.019)	0.288	(0.347)
α-Naphthonitrile	1.09	(1.24)	0.162	(0.147)	0.007	(0.034)	0.227	(0.323)
1,4-Dichloro-2-nitrobenzene	1.19	(1.41)	0.244	(0.290)	0.046	(−0.006)[b]	0.206	(0.281)

a) Suffix T: toluene, E: ethylbenzene, p: *p*-xylene, m: *m*-xylene, Pr: *n*-propylbenzene. p': *p*-ethyltoluene, m': *m*-ethyltoluene, o': *o*-ethyltoluene
For example, $S_{E,p'}$ denotes separation factor between ethylbenzene and *p*-ethyltoluene.
b) Negative sign represents that the order of emergence of two components is inverse to boiling point of these components.
* Values obtained on β-naphthol column (extrapolated from the results of mixed stationary liquid with TCP).
** This value is re-examined; the author reported incorrectly 0.98 in the preceding paper.

Separation Diagrams.—In Fig. 1 of previous paper[4] the separation factors are plotted against the σ_p values (Jaffé) of the substituents in the aromatic stationary liquids. These relationships are interesting, although they are not entirely subject to Hammett's rule. Some discussion of this has already been presented in a previous paper, where the authors pointed out that the diagram of the separation factors against the modified σ_p values of substituents in the stationary liquids was rather effective for practical application to the estimation of the separation of aromatic hydrocarbons in gas chromatography. Figure 2 of this previous paper[4] was obtained when the σ_p values of –OH and $-CO_2R$ radicals were transferred moderately in a negative direction (−0.45 and 0.1 respectively), that of the $-COC_6H_5$ radical, excessively in the same direction (−0.25), and the –X (halogens) radical, in a positive direction (0.35).

Figure 1 illustrates a separation diagram for the ethyltoluene series obtained in a manner analogous to the case of the xylene series; data for the xylene series (88°C) are superposed in broken lines for the sake of comparison. The original points on the horizontal axis indicate the para-isomer.

A parallel relationship between the solid lines and the broken lines is well established in Fig. 1. Only a pair of curves does not show such excellent agreement; they are a solid line for *n*-propylbenzene ($S_{Pr,p'}$) and a broken line for ethylbenzene ($S_{E,p}$). Even in these cases, the inclination of two lines is similar. From the parallel relationship between two series of isomers, it is clear that the results for the xylene series illustrated in Fig. 2 of the previous paper[4] (the separation factors were plotted against the modified σ_p values of the substituents of the aromatic stationary liquids) can be applied to the ethyltoluene series; therefore, the relationship illustrated in Fig. 1 of the previous paper (the separation factors and unmodified σ_p values of the substituents in the aromatic stationary liquids were related to each other by means of Hammett's rule) can also be applied to this series.

It appears certain that the factor which controls the gas chromatographic separation is common in the two isomeric series. For the separation of isomeric aromatic hydrocarbons of *o*-, *m*-, *p*- and *n*-alkylbenzene, these points seem to be important in the selection of the suitable stationary liquids.

A Survey of the Separation Factor, ΔS_{12}.—It can be seen from Fig. 1 that the separation between individual isomers is better in the xylene series than in the ethyltoluene series. The vapor pressures of these isomers at operating column temperature are shown in Table II. The values for the ethyltoluene series (at 105°C) are lower than for the xylene

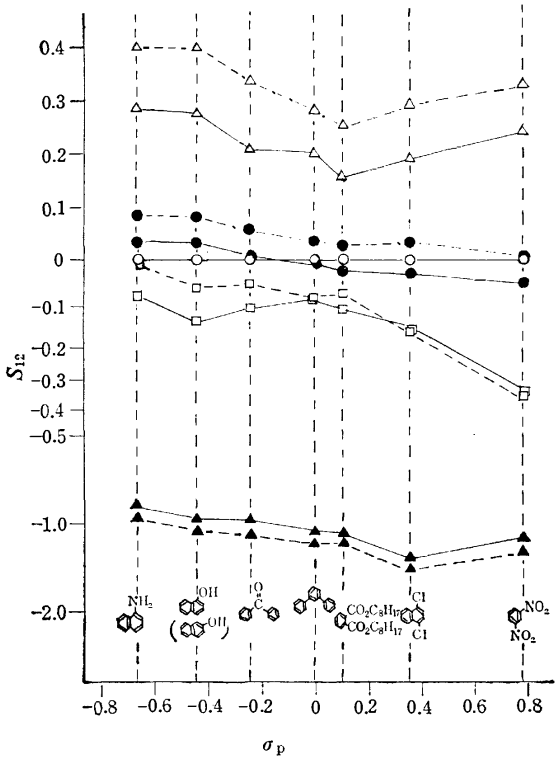

Fig. 1. Comparison of separation diagrams of ethyltoluene series and xylene series.
---- Xylene series (88°C)
—— Ethyltoluene series (105°C)
△ $S_{p,o}$ ● $S_{p,m}$
○ *p*-Xylene and *p*-ethyltoluene
□ $S_{A,p}$ ▲ $S_{A-1,p}$ (cf. Table V)

series (at 88°C). In fact, all ethyltoluenes eluted from the column more rapidly on every stationary liquid used than on corresponding xylenes. This depression of the separation factor (ΔS_{12}) in the ethyltoluene series relative to the xylene series is illustrated in Fig. 1 as roughly uniform on seven liquids, except for the values between $S_{E,p}$ and $S_{Pr,p'}$. ΔS_{12} is defined as follows:

$$\Delta S_{12} = S_{12}(\text{xylenes at } 88°C) - S_{12}(\text{ethyltoluenes at } 105°C) \quad (2)$$

On the other stationary liquids, which show something of a deviation, as has been mentioned above, the ΔS_{12} values likewise fell to roughly constant values (Table V). When an average of thirteen stationary liquids is taken, the values for $\Delta S_{p,o}$, $\Delta S_{p,m}$ and $\Delta S_{A-1,p}$ are 0.094, 0.047 and 0.15 respectively. $\Delta S_{A,p}$ does not, however, show any constant value.

From the other point of view, it is interesting to note that it is possible to predict the separation of these isomeric dialkylbenzenes from the ΔS values, since they do not depend upon sorts of stationary liquids and their polarity character, but rather seem to be dependent only upon the number of carbon atoms in the alkyl groups.

As the S_{12} values of the xylene series are known on many stationary liquids (cf. the literature), if only one set of S_{12} values of given ethyltoluenes is determined on one of these stationary liquids, then the ΔS_{12} value can be readily calculated. It will then be easy to find the suitable stationary liquid by simple

TABLE V. DISCREPANCY OF SEPARATION FACTORS BETWEEN XYLENE ISOMERS AND ETHYLTOLUENE ISOMERS (ΔS_{12})

Stationary liquid	$\Delta S_{A-1,p}$*	$\Delta S_{A,p}$*	$\Delta S_{p,m}$*	$\Delta S_{p,o}$*
α-Naphthylamine	0.086[a)]	−0.073	0.053	0.11
α-Naphthol	0.12	−0.085	0.051	0.13
Benzophenone	0.13	−0.050	0.050	0.12
1,3-Diphenylbenzene	0.16	−0.001	0.034[a)]	0.081
DOP	0.12	−0.028	0.044	0.099
Dichloronaphthalene	0.17	0.006	0.055	0.099
m-Dinitrobenzene	0.15	0.025	0.053	0.085
TCP	0.13	−0.043	0.040	0.097
7,8-Benzoquinoline	0.16	−0.053	0.058	0.10
Fluorenone	0.18	0.023	0.042	0.071
Fluorene picrate	0.19	0.055	0.049	0.059[a)]
α-Naphthonitrile	0.16	−0.015	0.041	0.095
1,4-Dichloro-2-nitrobenzene	0.22	0.046	0.040	0.075
Average value	0.15	—	0.047	0.094

a) The value is seriously deviated from the average.
Suffix p: para-isomers, m: meta-isomers, o: ortho-isomers, A: isomeric *n*-alkylbenzenes, A−1: *n*-alkylbenzenes of lower members than A by one carbon atom.
For example,
$\Delta S_{A,p} = S_{E,p}(88°C) - S_{Pr,p'}(105°C)$ $\Delta S_{A-1,p} = S_{T,p}(88°C) - S_{E,p'}(105°C)$

arithmetic addition or subtraction of the S_{12} value of the xylene series and of the ΔS_{12} values. For example, to separate *m*- and *p*-ethyltoluene isomers, one of the best stationary liquids may be tetrahalogenophthalate, which has been tested for the separation of xylene series by Langer et al.[9] On this stationary liquid, $S_{p,m}$ (xylene) was given as -0.045; therefore, $S_{p',m'}$ (ethyltoluene) will be -0.092 $(-0.045-0.047)$ or in that neighborhood*1.

The Interaction which Controls the Separation Factor Affecting the Gas Chromatographic Separation of Xylene and Ethyltoluene Isomers. —This problem has been considered, but unfortunately, experimental proofs are not satisfactory at present.

In a gas chromatographic column, separation is affected by two sorts of factors. One of these is the vapor pressure of solutes (hydrocarbons), and the other is the solute-solvent interaction of the stationary liquid. This solute-solvent interaction may be represented approximately in the following Eq. 3*2. Because

$$S_{12}(\text{solute-solvent interaction}) = S_{12}(\text{observed}) - S_{12}(\text{vap. press.}) \quad (3)$$

the separation factors of the two series are compared with each other at approximately the same vapor pressures (cf. Table II), and because, furthermore, the operating temperature of each series is kept constant, the inclination of the curves in Fig. 1 may be accepted as the measure of the solute-solvent interaction of the stationary liquids. The absolute value of S_{12} (vap. press.) was calculated from the table of vapor pressures as: $S_{p',o'}$(vap. press. at 105°C) $=0.089$; $S_{m',p'}$(vap. press. at 105°C) $=0.030$; $S_{Pr,p'}$(vap. press. at 105°C) $=0.104$, and $S_{E,p'}$(vap. press. at 105°C) $=1.03$.

In the preceding section, it was shown that the factor which controls the separation is common in both the xylene and the ethyltoluene series. As will be seen in Fig. 1 of a preceding paper[4], $S_{p,m}$ and $S_{A,p}$ curves vary monotonously, while the $S_{p,o}$ curves has a minimum and the $S_{A-1,p}$ curve, a maximum. From the inclination of the $S_{p,m}$ and $S_{A,p}$ curves, the meta-isomer and its isomeric *n*-alkylbenzene (ethylbenzene in the xylene series and *n*-propylbenzene in the ethyltoluene series) appear to interact more weakly with liquids containing electron-withdrawing groups (π-acids) and more strongly with those containing electron-releasing groups (π-bases) than the para-isomer does. The ortho-isomer seems to be independent of the sign of the σ_p values.

The acid strength of the π-acidic stationary liquids will decrease with the σ_p values. Of the stationary liquids used in this study, *m*-dinitrobenzene and 1,4-dichloro-2-nitrobenzene are extremely strong π-acids. These compounds are known as complexing agents, as are picric acid, tetracyanoethylene (TCNE)[10], pyromellitic dianhydride (PMDA)[11] and so on[12], all of which make stable π-complexes (π-π) with xylene isomers.

The order of the relative basicities of the xylene isomers determined from the stabilities of the π-complexes formed with PMDA, for example, was *o*-xylene>*p*-xylene>*m*-xylene〉〉〉ethylbenzene. On gas chromatography, the solute-solvent interaction of *m*-dinitrobenzene was determined at 88°C as follows:

o-Xylene:

$S_{p,o}$(on *m*-dinitrobenzene) $-S_{p,o}$(vap. press. at 88°C)[a] $=0.33-0.23=0.10$

m-Xylene:

$S_{p,m}$(on *m*-dinitrobenzene) $-S_{p,m}$(vap. press. at 88°C) $=0.011-0.040=-0.029$

p-Xylene: 0.000

Ethylbenzene:

$S_{p,E}$[b](on *m*-dinitrobenzene) $-S_{p,E}$ (vap. press. at 88°C) $=-0.36-(-0.07)=-0.29$

9) S. H. Langer, C. Zahn and G. Pantazoplos, *Chem. & Ind.*, **1958**, 1145.

*1 Stronger π-acids appear to be more effective for the separation of these isomers, inverse to the corresponding xylene isomers. The order of boiling points of this pair is opposite to that of the latter; therefore, the stationary liquid of the opposite polarity character will be more effective in this case.

*2 The S_{12} value is represented as follows:

$S_{12} = V_{R2}/V_{R1} - 1 = K_2/K_1 - 1 = \gamma_1^\circ p_1^\circ/\gamma_2^\circ p_2^\circ - 1$

while S_{12}(vap. press.) and S_{12} (solute-solvent interaction) are:

S_{12}(vap. press.) or S_{12} (vap.) $= p_1^\circ/p_2^\circ - 1$

S_{12}(solute-solvent interaction) or S_{12} (int.) $= \gamma_1^\circ/\gamma_2^\circ - 1$

Therefore,

$S_{12} = S_{12}(\text{int.}) \cdot S_{12}(\text{vap.}) + S_{12}(\text{vap.}) + S_{12}(\text{int.})$

In this case, the term $S_{12}(\text{int.}) \cdot S_{12}(\text{vap.})$ is negligibly small and the following approximation is obtained:

$S_{12} \fallingdotseq S_{12}(\text{vap.}) + S_{12}(\text{int.})$

V_R: retention volume corrected by the dead volume of the column; K: partition coefficient; γ°: activity coefficient; p°: vapor pressure of solute at column temperature.

10) R. E. Merrifield and W. D. Phillips, *J. Am. Chem. Soc.*, **80**, 2778 (1958).

11) L. L. Ferstanding, W. G. Toland and C. D. Heaton, ibid., **83**, 1151, 5049 (1961).

12) See, for instance, L. J. Andrews, *Chem. Revs.*, **54**, 713 (1954); R. S. Mulliken, *J. Am. Chem. Soc.*, **74**, 811 (1952); S. P. McGlynn, *Chem. Revs.*, **58**, 1113 (1958).

a) S_{12}(vap. press. at 88°C) is determined from the vapor pressure difference of two isomers at 88°C:

$S_{12}(\text{vap. press.}) = (p_1 - p_2)/p_2$

p_1 denotes a vapor pressure of isomer (i).

b) $S_{p,E} \fallingdotseq -S_{E,p}$

Thus, xylenes are absorbed in *m*-dinitrobenzene in the order of decreasing strength: *o*-xylene > *p*-xylene > *m*-xylene ≫ ethylbenzene, as in the order of the relative basicities in PMDA. This fact suggests a π-complex formation, on gas chromatography, between the aromatic hydrocarbon eluent and π-acidic stationary liquids as Langer et al. and Case have described.

On the other hand, the interaction on the π-basic stationary liquids is ambiguous. Case[13] explained this as dependent upon π-π repulsion between two phases. His interpretation seems to be reasonable, but other theories also appear possible.

When α-naphthylamine was used at 88°C as the stationary liquid of gas chromatographic separation, the following results were obtained:

o-Xylene:

$S_{o,p}$(on α-naphthylamine)
$-S_{p,o}$(vap. press. at 88°C)
$=0.40-0.23=0.17$

m-Xylene:

$S_{p,m}$(on α-naphthylamine)
$-S_{p,m}$(vap. press. at 88°C)
$=0.085-0.040=0.045$

p-Xylene: 0.000

Ethylbenzene:

$S_{p,E}$(on α-naphthylamine)
$-S_{p,E}$(vap. press. at 88°C)
$=-0.011-(-0.071)=0.060$

Thus, the α-naphthylamine absorbs xylenes in the order of decreasing strength: *o*-xylene > ethylbenzene > *m*-xylene > *p*-xylene.

By means of their solubility experiment with hydrogen chloride, Brown and Brady[14] determined the relative basicities of xylenes as follows; *m*-xylene: 1.26; *o*-xylene: 1.13; ethylbenzene: 1.06, and *p*-xylene: 1.00. They concluded that π-complexes were also formed between hydrogen chloride and xylenes. It is generally appreciated that the π-complex formed in this hydrogen chloride system is essentially different from that formed in the π-acid-xylene system, because the orders of the relative basicities of xylenes differ. It may be considered that the π-complex of the former case seems to be largely of the *n*-π type.

13) L. C. Case, *J. Chromatography*, 6, 381 (1961).
14) H. C. Brown and J. D. Brady, *J. Am. Chem. Soc.*, 74, 3570 (1952).

Between the results of our gas chromatographic separation and those obtained by Brown and Brady, no accurate agreement could be observed. However, these two sets of results seem to be essentially identical (*p*-xylene acts as the most acidic compound), and both of them are much different from those of the π-acid system. If π-π repulsion is an effective factor, *o*-xylene should be repulsed most strongly in the π-base system and $S_{p,o}$ curve in Fig. 1 should decline monotonously as the σ_p value decreases.

For the above reason, we may derive a hypothesis that the separation of aromatic hydrocarbons may be affected by π-complex formation with stationary liquids of a π-base as well as of π-acid. In the ethyltoluene series, however, these complex formations will be much weaker than in the xylene series because of the steric effects of the ethyl groups.

Summary

1) The gas chromatographic separation of the isomer of aromatic hydrocarbons has been investigated on the aromatic stationary liquids.

2) It has been established from the experimental results on the xylene series that the $S_{12}-\sigma_p$ diagram of Fig. 1 of the previous paper[4] is applicable to the separation of the ethyltoluene series.

3) ΔS_{12} has been defined, and it has been proven that this value was roughly constant between two series of dialkylbenzenes. Moreover, this value seems to throw a light on the prediction of the separation of the isomers of aromatic hydrocarbons.

4) This separation seems to be affected by π-complex formation between aromatic hydrocarbons and aromatic stationary liquids of both the π-acidic and π-basic types.

The author wishes to thank Professor Ryozo Goto of Kyoto University for many valuable discussions throughout this investigation. He would also like to express his appreciation for the support given his construction of the apparatus by the Yawata Chemical Industry Co. This work was supported in part by a Scientific Research grant-in-aid of the Ministry of Education.

Chromotropic Acid and Its Zirconyl and Thorium Complexes

By Michiaki SAKAGUCHI*, Atsunobu MIZOTE**, Haruo MIYATA and Kyoji TÔEI

(Received November 26, 1962)

Chromotropic acid reacts with some metal ions to form its colored complexes[1], and many kinds of the azo-derivatives are especially sensitive to various metal ions; they are therefore used widely as colorimetric reagents and as metal indicators in chelatometry.

Chromotropic acid has two naphtholic hydroxyl groups, and the first dissociation constant was measured spectrophotometrically.

The composition of zirconyl and thorium chromotropate was determined by the continuous-variation and the mole-ratio methods, while the stability constants of the zirconyl and thorium complexes were measured from their absorbances.

Calculations

The Dissociation Constant of Chromotropic Acid.—Disodium chromotropate (abbr. $H_2Ch\text{-}Na_2$) is dissociated in water as follows:

$$H_2Ch^{2-} \rightleftarrows HCh^{3-} + H^+$$

The first dissociation constant, K_1, is

$$K_1 = [HCh]\,[H] / [H_2Ch]$$

Therefore,

$$pK_1 = pH - \log [HCh] / [H_2Ch]$$

When [HCh] is equal to $[H_2Ch]$, the pH is pK_1. As the concentrations are proportional to the absorbances, pK_1 is obtained by the following equation:

$$pK_1 = pH - \log (E_1 - E)/(E - E_2) \qquad (1)$$

in which E_1 and E_2 are the characteristic absorbances of H_2Ch and HCh respectively at a constant wavelength, and E is an absorbance of their mixed solution at an arbitrary pH value.

The second dissociation constant, however, can not be obtained, because the dissociation occurs above pH 14, and it is too hard to get it under ordinary experimental conditions.

The Stability Constants of the Zirconyl and Thorium Complexes. — K_1 and K_2 are the first and the second dissociation constants of chromotropic acid, and K_{MCh} is the stability constant of the zirconyl or thorium complex.

$$K_1 = [H]\,[HCh] / [H_2Ch] \qquad (2)$$

$$K_2 = [H]\,[Ch] / [HCh] \qquad (3)$$

$$K_{MCh} = [MCh] / [M]\,[Ch] \qquad (4)$$

The total concentration of chromotropic acid C_{Ch}, and the total zirconyl or thorium concentration, C_M, are

$$C_{Ch} = [H_2Ch] + [HCh] + [Ch] + [MCh] \qquad (5)$$

$$C_M = [M] + [MCh] \qquad (6)$$

On the basis of Eqs. 2—6, the stability constant, K_{MCh}, is:

$$K_{MCh} = \frac{[MCh]\{[H]^2/K_1K_2 + [H]/K_2 + 1\}}{\{C_{Ch} - [MCh]\}\{C_M - [MCh]\}} \qquad (7)$$

The apparent stability constant, K'_{MCh}, is:

$$K'_{MCh} = [MCh] / \{C_{Ch} - [MCh]\}\{C_M - [MCh]\} \qquad (8)$$

[MCh] can be obtained from the absorbance of the zirconyl or thorium complex solution.

$$E = \varepsilon_{H_2Ch}[H_2CH] + \varepsilon_{HCh}[HCh] + \varepsilon_{Ch}[Ch] + \varepsilon_{MCh}[MCh]$$

ε_{H_2Ch}, ε_{HCh}, ε_{Ch} and ε_{MCh} are the absorption coefficients of H_2Ch, HCh, Ch and MCh respectively. [Ch] may be neglected below pH 4.

$$E = \varepsilon_{H_2Ch}[H_2Ch] + \varepsilon_{HCh}[HCh] + \varepsilon_{MCh}[MCh] \qquad (9)$$

Therefore, the concentration of [MCh] is

$$[MCh] = \frac{E\{1 + K_1/[H]\} - \varepsilon_{H_2Ch}C_{Ch} - \varepsilon_{HCh}C_{Ch}K_1/[H]}{\varepsilon_{MCh}\{1 + K_1/[H]\} - \varepsilon_{H_2Ch} - \varepsilon_{HCh}K_1/[H]} \qquad (10)$$

By substituting Eq. 10 into Eqs. 7 and 8, K_{MCh} and K'_{MCh} can be calculated.

Experimental and Results

Reagents.—*Disodium Chromotropate.*—The purification of chromotropate is carried out in a dark room. Disodium chromotropate dihydrate (Dôjindo Pharaceutical Co.) is dissolved in water, acidified by concentrated hydrochloric acid, and treated with active carbon by heating. The filtrate is evaporated so as to deposit crystals by a rotary evaporator and

then cooled. The crystals are recrystallized again by the same manner, and then dried over phosphorus pentoxide to obtain the anhydrous compound. The sodium content is found to be quantitative by the use of a flame photometer.

Zirconyl Chloride[2]. — When a saturated solution of zirconyl chloride octahydrate (c. p. grade) is added to an acetone-hydrochloric acid mixture, the flocky octahydrate is precipitated and filtered. After the procedure is repeated twice, the precipitate is washed with acetone and dried in air. Cubic colorless crystals were obtained. The zirconyl content is analyzed gravimetrically by the use of cupferron[3].

Found: ZrO_2, 38.23, 38.26. Calcd. for $ZrOCl_2 \cdot 8H_2O$: ZrO_2, 38.24%.

A 5×10^{-4} M zirconyl chloride solution is prepared by dissolving 16.11 mg. of a zirconyl chloride octahydrate with a 0.1 M potassium chloride solution in a 100 ml.-measuring flask, and it should be used within 20 min.

Thorium Perchlorate.—Thorium nitrate is purified through thorium hydroxy peroxide five or six times[5]. Thorium hydroxide prepared from the purified thorium nitrate is disssolved in perchloric acid, and the concentration is measured gravimetrically by oxalate[4].

Procedure.—All experiments are carried out in a dark room, because chromotropate tends to decompose in daylight, especially at higher pH values.

The Dissociation Constant of Chromotropic Acid. — Five milliliters of a 5×10^{-4} M chromotropate solution and a suitable buffer solution are poured into a 50 ml.-measuring flask, which is then filled up to the mark with 0.2 M sodium perchlorate and water to keep the ionic strength (μ) at 0.1. The spectra are measured with a Hitachi EPS-2 automatic recording spectrophotometer (Fig. 1). The pH values are measured with a Horiba Model M-4 glass electrode pH meter. With an increasing pH, a new absorption maximum appears at 361.5 mμ, and the absorbance is determined by a Shimadzu Model QR-50 spectrophotometer with 1 cm. quartz cell. pK_1 is calculated from Eq. 1, and the average value of six runs is shown in Table I.

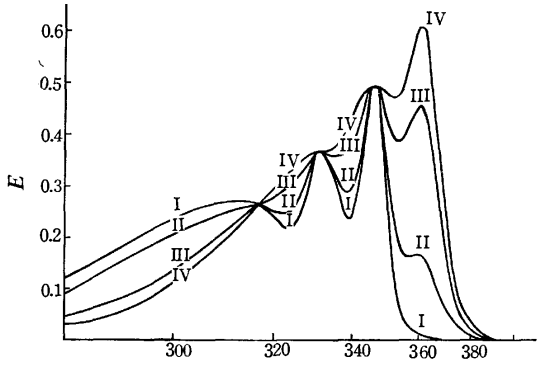

Fig. 1. Absorption curves of chromotropic acid.

TABLE I. pK_1 OF CHROMOTROPIC ACID

The authors	5.44±0.03	(μ=0.1, 16~23°C)
Schwarzenbach et al.[6]	5.36	(μ=0.1, ~20°C)
Zollinger et al.[7]	5.53	(20°C)

Zirconyl Complex. — Each 5 ml. of a 5×10^{-4} M solution of zirconyl and chromotropate is mixed in a 50 ml.-measuring flask containing a suitable amount of hydrochloric acid; the flask is then filled up to the mark with a potassium chloride solution and water to maintain the ionic strength at 0.1.

A new absorption maximum appears at 356.5 mμ. The absorbance reaches its maximum at pH 2 after standing for one hour.

The composition was determined by the continuous variation method (Fig. 2). The composition should be 1 : 1, but the stability of the complex is not very good.

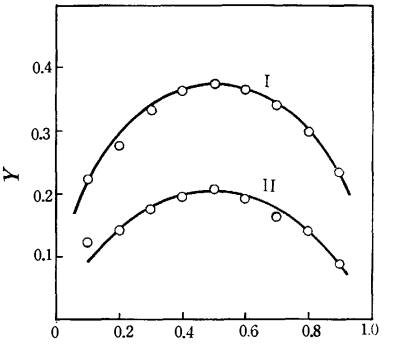

Fig. 2. Continuous variations.
I $[Zr]+[H_2Ch]=2\times10^{-4}$ mol./l.
II $[Zr]+[H_2Ch]=1\times10^{-4}$ mol./l.
pH=2, μ=0.1, at 357.5 mμ

From Eq. 8, the following equation can be obtained.

$$\log K'_{MCh}=\log[MCh]/\{C_{Ch}-[MCh]\} -\log\{C_M-[MCh]\}$$

The values of the first term were plotted against the second term at a constant pH (Fig. 3).

In Fig. 3, straight lines are obtained, and the slope indicates that the ratio of zirconyl to chromotropic acid is 1 to 1; $\log K'_{MCh}$ is 3.6$_3$ at pH 2.0, and 29 at pH 1.2.

Thorium Complex.—Five milliliters of a 5×10^{-4} M chromotropate solution and 5 ml. of a 2.5×10^{-3} M thorium perchlorate solution are poured into a 50 ml.-measuring flask containing a suitable amount

of perchloric acid and then diluted to the mark by a sodium perchlorate solution and water so that the ionic strength is kept at 0.1. The absorption curve has a maximum at 361 mμ. The absorbance at 361 mμ reached its maximum after standing for 90 min., when it was measured. The absorbance is plotted against pH in Fig. 4. As the absorbance decreased above pH 3.6, the following experiment was carried out at pH 3.3~3.5.

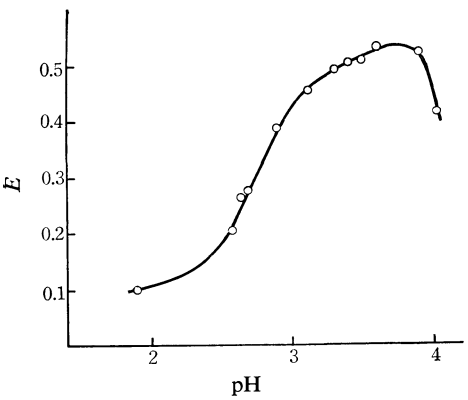

Fig. 4. Effect of pH on the absorbance of the complex.

$\mu=0.1$ at 361 mμ

The Mole-ratio Method.—A plot of the moles of chromotropic acid against the absorbance is given in Fig. 5. The 1 : 1 complex is indicated, being considerably dissociated under the conditions of this experiment.

The Continuous-variation Method.—At pH 3.5, equimolecular solutions of chromotropic acid and thorium perchlorate were mixed in varying proportions, the total number of moles remaining constant. The absorbances of each solution were measured at 361 mμ after they had been left standing for 2.5~3 hr. in a dark room. The values of the absorbances calculated on the assumption of "no reaction" were then substracted from the

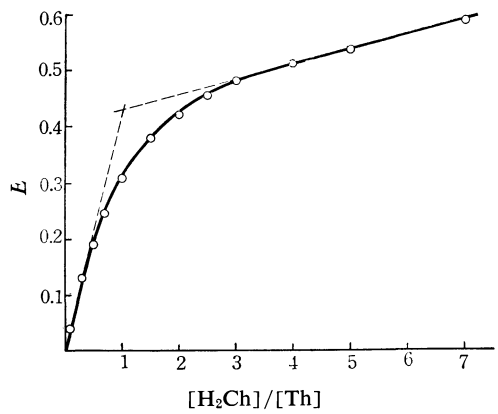

Fig. 5. Mole ratio method.
$C_{Th}=5\times10^{-5}$ M/l. $\mu=0.1$ at 361 mμ

measured absorbances to give what are commonly referred to as Y values (Fig. 6). The ratio of chromotropic acid to thorium was 1 to 1.

Stability Constant.—ε_{H_2Ch}, ε_{HCh} and ε_{MCh} were calculated from the absorbances at 361 mμ; the values were 1.89×10^2, 1.16×10^4 and 1.17×10^4 respectively. The stability constant, K_{MCh}, was calculated from Eqs. 9 and 10 by using $pK_2=15.6$[6]

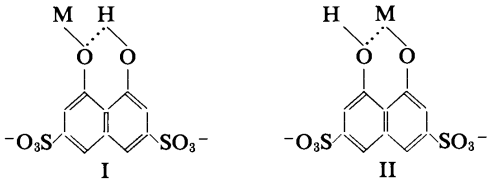
Discussion

The first dissociation constant of chromotrophic acid (pK_1) is 5.4[4], and so, below pH 3.5, chromotropic acid exists predominantly in the form of H_2Ch. It reacts with zirconyl or thorium ions to form its complex. Figures 3 and 8 show that the metal ions react with the acid to replace only one hydrogen ion. There are two possibilities:

$$M + H_2Ch \rightleftarrows MHCh + H^+$$

$$M(OH)_n + H_2Ch \rightleftarrows MCh + H^+ + H_2O$$

In the former case, the following structures of the complex are possible:



Form I is not a chelate but a salt, and by preliminary experiments, 1-naphthol-4-sulfonic acid does not react with the ions under the conditions of this experiment. Therefore, the complex is unlikely to be of Form I.

The second dissociation constant of acid (pK_2) is 15.6[6], because the second hydrogen atom is bridged between two oxygen atoms. The first hydrogen atom is far more exchangeable by the metal ions than the second one. Therefore, it is difficult to consider Form II.

In the latter case, the reaction species of zirconyl or thorium ion can not be detected directly from the absorbance because they have no absorbance at any wavelength.

Zirconium would exist in the form of $Zr(OH)_2^{2+}$ in acidic solutions, but the species has not yet been exactly confirmed[7].

Kraus and Holmberg[8] stated that the hydrolysis of $2.5\times10^{-4}\sim1.5\times10^{-2}$ M thorium ions was negligible below pH 3 and was influenced by the concentration, but that at about pH 3.5 the number of moles of hydroxide attached to thorium was several tenths of the total and that the equilibrium was rapidly established.

In our experiments, the concentration of zirconyl or thorium ions less than 2.5×10^{-4} M and the pH is about 1~2 in zirconyl and about 2~3.5 in thorium. Although the state of the ions has not been studied under the conditions of our experiments and although the reaction species have not been confirmed, zirconyl or thorium ions should have some $M(OH)_n^{4-n}$ ions in acidic solutions. Therefore, the latter equation seems to hold.

The Spectrophotometric Determination of Palladium(II) with Xylenol Orange[1]

By Makoto Otomo

(Received December 14, 1962)

The preceding works in this series of publications on the spectrophotometric determination of metal cations with xylenol orange have dealt with such metals as rare earths[2], vanadium[3], uranium[4] and aluminum[5], all of which react with this reagent in a slightly acidic medium to give red or reddish-violet chelates. Because of the low selectivity of xylenol orange, for the practical determinations in slightly acidic media it was necessary either to mask interfering ions with an appropriate masking agent or preliminarily to separate these ions from the object ion.

In a strongly acidic solution of perchloric acid, however, this reagent reacts selectively with palladous ions, even in the presence of many other cations, to give a bright-red complex with an absorption maximum at 518 mμ.

This paper chiefly presents a spectrophotometric study of the reaction between palladous ion and xylenol orange in a perchloric acid solution. The formation constant is also calculated from the results of the mole ratio method and those of the method of continuous variations.

Experimental

Reagents and Apparatus. — A stock solution of palladium was prepared by dissolving 1.927 g. of palladous chloride in a small amount of nitric acid and then diluting it with water to one liter. The standardization was carried out volumetrically by EDTA titration[6]. A standard working solution was prepared by taking an aliquot of the stock solution and diluting it to the desired concentration.

A 2×10^{-3} M solution of xylenol orange and a 1 : 1 solution of perchloric acid were prepared.

Stock solutions of diverse cations, which were prepared from reagent grade salts, contained approximately 0.1 μ mol. of the ions per ml.

All absorbance measurements were made at 25± 0.5°C with a Hitachi spectrophotometer, Model EPV-2, using 1 cm. glass cells.

Results and Discussion

The Determination of Palladium.—In a preliminary test, it was shown that a red-colored palladium xylenol orange complex was formed in solutions of nitric, sulfuric and perchloric acids, but no color development was obtained in hydrochloric acid or in a solution containing a large number of chloride ions. In a perchloric acid solution, the complex gave the highest absorbance. Perchloric acid was therefore used in further experiments.

Absorption Spectra.—The absorption spectra of xylenol orange and its palladium complex are shown in Fig. 1. The complex has an

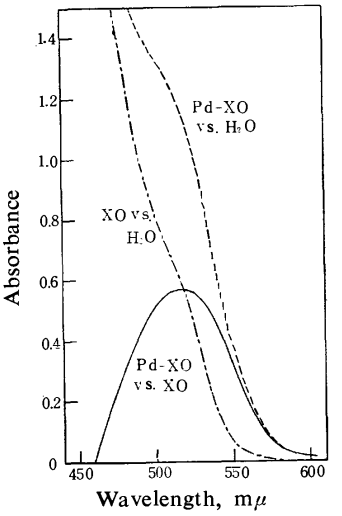

Fig. 1. Absorption spectra of xylenol orange and its palladium complex.
Pd : 57.8 μg. XO : 1.6×10^{-4} M
$HClO_4$: 1.3 N

absorption maximum at 518 mμ. It is of interest to note that the spectrum of xylenol orange has a small shoulder at about 515 mμ and that the position of the absorption peak of the complex is very close to that of the peaks shown by xylenol orange in strongly acidic solutions. For the sake of comparison, the absorption spectra of xylenol orange in sulfuric acid of various concentrations are also shown in Fig. 2.

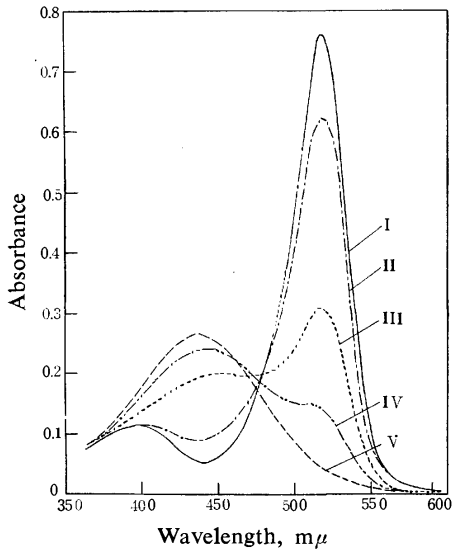

Fig. 2. Absorption spectra of xylenol orange in sulfuric acid of various concentrations.
XO: 2×10^{-5} M
Concentration of sulfuric acid:
I, 21.6 N II, 10.8 N III, 7.2 N
IV, 3.2 N V, 0.7 N

The Effect of the Concentration of Perchloric Acid. — In order to examine the effect of the concentration of perchloric acid, tests were made at varying concentrations of perchloric acid. The maximum and constant absorbance is obtained over the concentration range from 1.1 to 1.7 N in perchloric acid, as is indicated in Fig. 3. Seven to 8 ml. of 1 : 1 perchloric acid in a total volume of 25 ml. is sufficient to maintain the acid concentration within the optimum range.

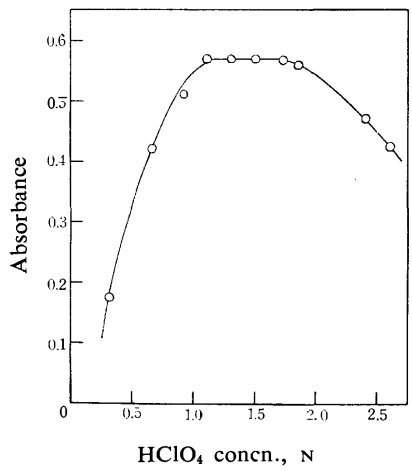

Fig. 3. Effect of concentration of perchloric acid.
Pd: 57.8 μg. XO: 1.6×10^{-4} M
Wavelength: 518 mμ

The Effect of the Concentration of the Reagent. —An excess of xylenol orange must be added, since the absorbance of the complex at 518 mμ is somewhat increased with an increased concentration of the reagent. Two milliliters of a 2×10^{-3} M solution of xylenol orange was found to be a sufficient amount for less than 100 μg. of palladium.

The Effect of Heating Time and the Color Stability. — The maximum color development was reached after about 20 ml. of the sample solution had been kept at boiling temperature for 2 to 3 min. The 20 ml. of solution contained 7 ml. of 1 : 1 perchloric acid and 2 ml. of a 2×10^{-3} M solution of xylenol orange, along with the desired quantity of palladium. After this heating period, the solution was cooled, transferred to a 25 ml. volumetric flask, and diluted to the mark with water. The absorbance of the resultant solution decreased slowly with time for the first 30 min. After this period, however, it remained practically constant for at least 3 hr.

Beer's Law. — Beer's law is obeyed over the concentration range from 0.2 to 4.0 p. p. m. of palladium. The optimum concentration range for the determination of palladium was determined by the method described by Ringbom[7] and was found to be 0.8 to 3.2 p. p. m. The molar extinction coefficient was approximately 26000 at 518 mμ.

Procedure. — To a palladium solution in a 50 ml. Erlenmeyer flask, 7 ml. of 1 : 1 perchloric acid and 2 ml. of a 2×10^{-3} M solution of xylenol orange were added. The volume was made to about 20 ml. with water. After being kept at boiling temperature for 2 to 3 min., the solution was cooled, transferred to a 25 ml. volumetric flask, and diluted to the mark with water. The absorbance of the solution was measured at 518 mμ against the reagent blank. The amount of palladium was then determined from the calibration curve prepared above.

The Effect of Diverse Ions. — The effect of diverse ions on the spectrophotometry was examined. As is shown in Table I, such anions as nitrate, sulfate, oxalate, tartrate and citrate do not interfere, even when as much as 100 μmol. of them are present. However, chloride, nitrilotriacetate and ethylenediaminetetraacetate ions interfere seriously, even when only a small amount is present.

Of the 25 cations which react with xylenol orange in a slightly acidic solution, only zirconium gave a large positive error. However, the interference from less than 200 μg. of zirconium could be effectively removed by

adding 1 to 2 ml. of a 0.01 M fluoride solution. Accordingly, it is possible to say that, in a strongly acidic solution of perchloric acid, xylenol orange is a highly selective color reagent for palladium.

A Comparison with Other Methods. — Several reagents have been used for the spectrophotometric determinations of palladium. The most sensitive reagents have been found to be *p*-nitrosodiphenylamine and *p*-nitrosodimethylaniline, reported by Yoe and Overholser[8,9]. Thioglycolic acid[10], potassium iodide[11], ethylenediaminetetraacetic acid[12] and nitrilotriacetic acid[13] have been used as colorimetric reagents for palladium by König and Cromell, Fraser et al., McNevin and Kriege and Desideri and Pantani respectively. Niesch[14], Cheng[15], Menis and Rains[16] and, recently, Jacobs et al.[17] have described some new reagents for the determination of palladium. The methods using the above reagents, however, in many cases required the extraction of the palladium complexes into such an organic solvent as chloroform or toluene. A method which can be carried out in an aqueous medium and which is rapid, sensitive, selective and relatively free from interference is more desirable.

The present reagent, xylenol orange, has some advantages as a colorimetric reagent for palladium: No extraction of the complex is required, since a palladium-xylenol orange complexes is water soluble; the acid concentration for the maximum color development can easily be controlled; not many cations besides zirconium interfere; and this method is comparable in sensitivity with the β-nitroso-α-naphthol method[15].

Composition and Formation Constant. — The composition of the palladium-xylenol orange complex was determined by the mole ratio method and also by Job's method of continuous variations. The results are presented graphically in Figs. 4 and 5, from which it is evident that only one palladium xylenol orange complex is present and that the mole ratio of xylenol orange to palladium in this complex is 2:1. For the calculation of the formation constant, the absorbance data obtained from the above methods were employed.

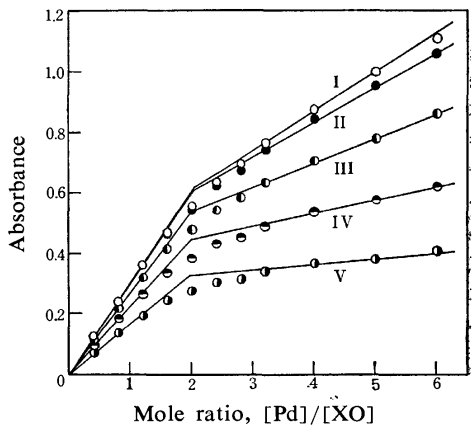

Fig. 4. Mole ratio method.
[Pd] = 2.0×10^{-5} M
Absorbances were measured at:
I, 510 mμ II, 518 mμ III, 530 mμ
IV, 540 mμ V, 550 mμ

Calculation from the Results of the Mole Ratio Method. — Since one part of palladium ions reacts with two parts xylenol orange molecules, the following equilibrium must exist:

$$Pd + 2XO \rightleftarrows Pd(XO)_2$$

$$K = x/(a-x)(b-2x)^2 \qquad (1)$$

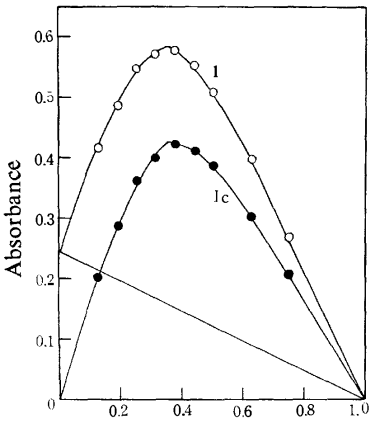

Fig. 5. Method of continuous variations.
[Pd]+[XO]=6.4×10^{-5} M
Wavelength: 518 mμ
I: Uncorrected curve
I_c: Corrected curve

where x is the concentration of the complex at equilibrium, and a and b are the initial concentrations of palladium ion and xylenol orange respectively. In the visible region, the contribution of the palladium ions to the absorbance of the system is negligible. Accordingly, the observed absorbance, D, may be regarded as due to the color of the complex formed and to the free xylenol orange. It is given by:

$$D=\varepsilon_C x+\varepsilon_{XO}(b-2x) \qquad (2)$$

where ε_C and ε_{XO} are the molar extinction coefficients of the complex and xylenol orange respectively. ε_C can be obtained from the equation[18]

$$D'=\varepsilon_C a \qquad (3)$$

where D' is obtained from the absorbance observed by adding xylenol orange in a large excess compared to the concentration of the palladium ions. The values of ε_{XO} and ε_C at various wavelengths are given in Table II. The formation constant, as calculated by combining Eqs. 1, 2 and 3, was found to be 1.4×10^{10} (as an average value at the three wavelengths 510, 518 and 530 mμ).

Table II. Values of ε_{XO} and ε_C at various wavelengths

Wavelength, mμ	ε_{XO}	ε_C
510	5280	36240
518	4660	35320
530	3020	30660
540	1520	23560
550	630	16080
560	250	9440

Calculation from the Results Obtained by Job's Method.—Job's method of continuous variation was then employed for the calculation of the formation constant. At the concentration and the wavelengths investigated, the palladous ion has no absorption. Therefore, the color of the system is due to the free xylenol orange and the complex only. Since xylenol orange has a considerable absorption at the wavelengths investigated, corrections were made. The corrected values are also plotted in Fig. 5. The formation constant, K, was then calculated from the curve, based on the relationships described by Harvey and Manning[19]. It was found to be 2.6×10^{10}.

From the above, therefore, K may reasonably be represented as 2×10^{10}. This value is slightly lower than that of the formation constant for the uranium-xylenol orange complex[4], but it is higher than the values for 1:1 complexes between some metal cations and xylenol orange.

Summary

A new, sensitive spectrophotometric method for the determination of palladium(II) by using xylenol orange as a color reagent has been described. The palladium-xylenol orange complex has an absorption maximum at 518 mμ. The effects of the concentration of perchloric acid and of the reagent have been investigated. In addition, various conditions, including the duration of heating, the stability of the color, and the effect of diverse ions, have been investigated. In a solution of perchloric acid (1.1 to 1.7 N), xylenol orange is a highly selective reagent for palladium, although it reacts with a number of metal cations in a slightly acidic or a neutral solution. Beer's law is obeyed in the range from 0.2 to 4.0 p. p. m. of palladium at 518 mμ. The results of Job's method and of the mole ratio method show a complex consisting of two molecules of the reagent to one palladous ion. The formation constant was calculated to be 2×10^{10}.

The author wishes to express his deep thanks to Professor Kôichi Tonosaki for his kind guidance and encouragement throughout this work. He is also grateful to Dr. Kôyô Aida of Tohoku University for his interest.

*The Radiation-induced Reactions of Benzene with Sulfur and Sulfur Compounds**

By Wataru ANDO, Ken'ichi SUGIMOTO and Shigeru OAE

(Received December 27, 1962)

The radiolysis of the aqueous benzene solution has been studied extensively and is known to give phenol and other minor products[1]. The formation of phenol is known to be increased by the introduction of oxygen into the system. The radiation-induced reaction of benzene has also been studied by many workers[2-6]. According to the reaction mechanisms hitherto suggested, the process of phenol formation involves the initial formation of a hydrogen atom and of a phenyl radical which reacts immediately with dissolved oxygen. We have extended a similar study in the hope of getting thiophenol and other sulfur-containing compounds, since sulfur is also quite an effective radical scavenger[7-9]. Since mercaptans are readily oxidized to their corresponding disulfides under irradiation with X-, beta-, or gamma-rays[10-11], one would expect diphenyl disulfide and hydrogen among the products formed. The present paper deals with the radiation-induced reaction of benzene with sulfur, together with the chemical behavior of thiophenol and hydrogen sulfide in benzene under the irradiation of gamma-rays.

Experimental

Chemicals.— *Benzene.*— Reagent-grade thiophene-free benzene was purified by three successive distillations.

Sulfur.—The sulfur employed was C. P.-grade, large, rhombic crystals, formed from carbon disulfide. The sulfur was again recrystallized from hot, reagent-grade benzene to obtain small, granular, rhombic crystals.

Thiophenol.—C. P.-grade thiophenol was purified by repeated distillations in a nitrogen atmosphere and was vacuum-distilled shortly before use.

The Preparation of the Samples.—Exactly 40 ml. of a benzene solution containing an aliquot amount of sulfur was sealed under vacuum in an ampoule with a glass break-off tip. Air was degassed by freezing and pumping.

The irradiation was carried out with 3800-curie cobalt-60 gamma rays at room temperature. The dosimetry was based on a Fricke dosimeter. The dose rate was approximately 5×10^5 r/hr.

Analysis.—All the analyses of the irradiated samples containing sulfur or thiophenol in benzene were carried out as described below. First, gases were collected from the irradiated samples by the usual repeated freezing evacuation and melting technique[12]. The collected gases were then passed through liquid nitrogen traps. The uncondensed gas was identified as hydrogen, and the gas which passed through a series of dry-ice acetone trap and was condensed at the liquid nitrogen temperature was identified as hydrogen sulfide.

Hydrogen sulfide was absorbed into a solution containing 5% of zinc acetate and 1% sodium acetate. Then, 25 ml. of 10% ammonium molybdate and 5 ml. of phosphoric acid were added to the solution. It was diluted to 50 ml., and the absorption at 670 mμ was observed after one or two days[13].

Thiophenol, which was distilled from irradiated benzene and sulfur at 50°C into a trap cooled by a dry-ice acetone bath, was allowed to react with *p*, *p'*-dinitrodiphenyl disulfide; then, the amount of *p*-nitrobenzenethiol formed was determined by spectrophotometry following the method of Ellman[14]. For each run, 5 ml. of a 0.1 M phosphate buffer at pH 8 and 5 ml. of a saturated acetone solution of *p*, *p'*-dinitrodiphenyl disulfide were added into 20 ml. of the sample and the whole solution was diluted to 100 ml. with acetone. The absorbancy at 470 mμ was measured within one minute after the disulfide had been added.

When a benzene solution of thiophenol was irradiated, both the initial and final amounts of thiophenol was determined by titrating the solution with a solution of silver nitrate in isopropyl

alcohol[15]. The break in the potentiometric curve was found to be between approximately −325 and −175 mV. vs. SCE. The amounts of decreased thiophenol were calculated by subtracting the final values from the initial ones.

Results and Discussion

The Radiolysis of a Benzene Solution of Sulfur.—An aliquot amount of sulfur was dissolved in benzene and was irradiated with gamma-rays. The vacuum technique was employed throughout. The thiophenol and hydrogen sulfide formed were measured. The results obtained at varying concentrations of sulfur and radiation doses are shown in Tables I and II.

TABLE I. THE FORMATION OF THIOPHENOL AT VARIOUS SULFUR CONCENTRATIONS

Sulfur concentration	*G*-Value of thiophenol formed Irradiation dose		
g./100 ml.	1.1×10^7 r	2.5×10^7 r	3.6×10^7 r
2.0	0.056	0.039	0.041
1.5	0.027	0.039	0.037
0.8	0.041	—	0.030
0.25	0.017	0.017	0.013

Dose rate: 5×10^5 r/hr.

TABLE II. THE FORMATION OF HYDROGEN SULFIDE AT VARIOUS SULFUR CONCENTRATIONS

Sulfur concentration	*G*-Value of hydrogen sulfide irradiation dose		
g./100 ml.	1.1×10^7 r	2.5×10^7 r	3.6×10^7 r
2.0	0.047	0.049	0.049
1.5	0.058	0.049	0.040
0.8	0.040	0.040	0.026
0.25	0.003	0.011	0.008

Dose rate: 5×10^5 r/hr.

The formation of thiophenol and hydrogen sulfide showed nearly identical *G*-values, and both are independent of the sulfur concentration and the radiation dose except at an extremely low concentration of sulfur. This means that sulfur cleavage is not the initial step in the formation of these substances and that sulfur reacts at a secondary step of the overall reaction. It appears that the formation of the phenyl radical and of hydrogen atoms from a benzene solution and the reactions of these species with sulfur to form thiophenol and hydrogen sulfide follow.

However, thiophenol, being a very strong hydrogen donor, does not remain unchanged in the solution; rather, a portion is oxidized to diphenyl disulfide. Table II shows a little higher *G*-value of hydrogen sulfide formation than that of thiophenol formation. This seems to suggest that hydrogen sulfide is also produced by the radiolysis of thiophenol, along with the reaction of hydrogen atoms and sulfur.

Radiolysis of Thiophenol in Benzene.—The radiolysis of thiophenol in a benzene solution was carried out under various conditions. Figure 1 shows the relation between the *G*-values and the radiation doses.

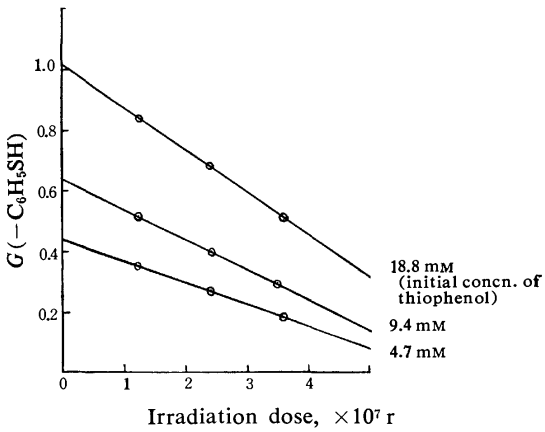

Fig. 1. Relation of *G*-value of decreased thiophenol and irradiation dose on radiolysis of thiophenol in benzene.

The decrease in thiophenol by irradiation was proportional to the initial concentration of thiophenol. This suggests that thiophenol is more susceptible to gamma irradaition than benzene. Therefore, the *G*-value for thiophenol decomposition in benzene could be calculated from the remaining thiophenol concentration.

The variation in *G*-values for different radiation doses and for initial concentrations of thiophenol seems to be caused by the regeneration of thiophenol from the radiolysis of diphenyl disulfide[16], which was found to be the main product in the radiolysis of thiophenol in benzene. In fact, we found that thiophenol was formed by the radiolysis of diphenyl disulfide, as Table III shows.

TABLE III. RADIOLYSIS OF DIPHENYL DISULFIDE IN BENZENE

Disulfide	50 mmol./l.
Irradiation dose	2.8×10^7 r
Found	*G*-Value
Thiophenol	0.024 mM
Hydrogen sulfide	0.001 mM

15) M. W. Tamele and L. B. Ryland, *Ind. Eng. Chem., Anal. Ed.*, **8**, 16 (1936).

16) C. Walling and R. Rabinowitch, *J. Am. Chem. Soc.*, **81**, 1137 (1959).

17) E. C. Truesdale and S. C. Lind, ibid., **54**, 516 (1932).

The formation of hydrogen sulfide increases with an increase in the radiation dose, but at a high radiation dose, the formation of hydrogen sulfide became steady or decreased. This can be explained if one assumes that hydrogen sulfide is slowly decomposed in benzene with an increase in the radiation dose[17].

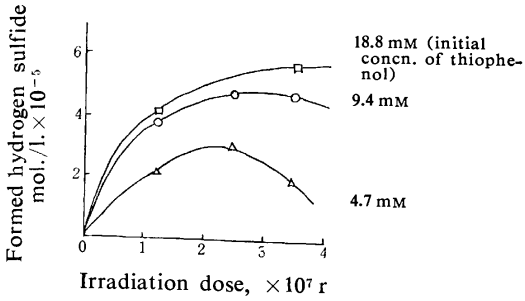

Fig. 2. Relation of hydrogen sulfide formed and irradiation dose on radiolysis of thiophenol in benzene.

This reaction of hydrogen sulfide in a benzene solution will give thiophenol again as a result of the attack of the phenyl radical on hydrogen sulfide. However, this reaction is of minor importance. Therefore, the formation of hydrogen sulfide can probably best be explained as a result of the direct decomposition of thiophenol.

The radiolysis of benzene saturated with hydrogen sulfide was also carried out; the results are shown in Table IV. The amounts of thiophenol formed were similar at various radiation doses, suggesting that more than a certain amount of thiophenol was always converted to diphenyl disulfide.

Table IV. Radiolysis of benzene saturated with hydrogen sulfide

Irradiation dose	Thiophenol formed	*G*-Value
1.2×10^7 r	0.46 mmol./l.	0.046
2.6×10^7 r	0.41 mmol./l.	0.020
3.6×10^7 r	0.42 mmol./l.	0.014

Proposed Mechanisms.—*The Radiolysis of a Benzene Solution of Sulfur.*—The mechanism for the radiolysis of benzene has recently been shown in a number of publications[2-6]. In the formation of the phenyl radical and the hydrogen atom under the irradiation of benzene, they further react with benzene to form polymers :

$$C_6H_6 \xrightarrow{I} C_6H_6^* \quad (1)$$

$$C_6H_6^* \rightarrow C_6H_5 + H \quad (2)$$

However, when elemental sulfur is dissolved in benzene, the phenyl radical and the hydrogen atom formed in the primary step of the radiolysis of benzene react with sulfur to form thiophenol and hydrogen sulfide, as can be seen from the data in Tables I and II.

Since the overall stoichiometry of the *G*-values of the thiophenol and hydrogen sulfide formed is independent both of the radiation dose and the relative concentration of sulfur, the following reaction scheme may be considered :

$$C_6H_5 + S_8 \rightarrow C_6H_5\text{-}S_8 \rightarrow C_6H_5S + S_x \quad (3)$$

$$H + S_8 \rightarrow HS_8 \rightarrow HS + S_x \quad (4)$$

In this case, benzene and sulfur compete for reaction with the phenyl and hydrogen radicals formed in reaction 2. As elemental sulfur is an effective radical scavenger, the phenyl radical and hydrogen atom attack the S-S bonds of sulfur and the open S_8 ring rather than reacting with benzene. Therefore, reactions 3 and 4 take place more readily than the polymer formation.

The incipient open chain polysulfides radicals are quite unstable and immediately decompose to give phenyl, sulfenyl and sulfhydryl radicals[18-20]. These sulfenyl radicals then react with free hydrogen to form the thiophenol. Similarly, the formation of hydrogen sulfide can be written as in reaction 6. Some sulfenyl radicals also recombine to form diphenyl disulfide :

$$C_6H_5S + H \rightarrow C_6H_5SH \quad (5)$$

$$SH + H \rightarrow H_2S \quad (6)$$

$$2C_6H_5S \rightarrow C_6H_5S\text{-}SC_6H_5 \quad (7)$$

The Radiolysis of Thiophenol in Benzene.—The rate of the disappearance of thiophenol was found to depend on the initial concentration of thiophenol and on the radiation dose. This indicates that the main path for the disappearance of thiophenol is not through the following reaction :

$$C_6H_6^* \rightarrow C_6H_5 + H \quad (2)$$

$$C_6H_5 + C_6H_5SH \rightarrow C_6H_6 + C_6H_5S \quad (8)$$

$$2\ C_6H_5S \rightarrow C_6H_5S\text{-}SC_6H_5 \quad (7)$$

Although most of the radiation energy is absorbed into the benzene, the energy absorbed is transferred to thiophenol, which upon the absorption of energy splits into the sulfenyl radical and the hydrogen atom.

$$C_6H_6^* + C_6H_5SH \rightarrow C_6H_6 + C_6H_5SH^* \quad (9)$$

$$C_6H_5SH^* \rightarrow C_6H_5S + H \quad (10)$$

18) P. D. Bartlett and R. E. Davis, ibid., **80**, 2513 (1958).
19) M. Schmidt and C. Talsky, *Ber.*, **90**, 1673 (1957).
20) P. D. Bartlett and G. Maguerian, *J. Am. Chem. Soc.*, **78**, 3710 (1956).

The sulfenyl radicals thus formed mainly recombine, forming diphenyl disulfide, as is shown by 7. Another reaction for the decomposition of thiophenol may be proposed from the formation of hydrogen sulfide[21-23] as follows:

$$C_6H_5SH^* \rightarrow C_6H_5 + SH \quad (11)$$

$$SH + C_6H_5SH \rightarrow C_6H_5S + H_2S \quad (12)$$

$$SH + H \rightarrow H_2S \quad (6)$$

By comparing the yield of hydrogen sulfide with the amount of the decomposition of thiophenol, the relative bond stability of S–H and C–S under the irradiation may be calculated, as is shown in Table V. From these calculations, one finds that reactions 10 and 11 occur in the ratio of about 200 to 1.

TABLE V. THE RATIO OF THE NUMBERS OF BROKEN BONDS S-H/C-S

Irradiation dose	Initial concentration of thiophenol		
	18.8 mM	9.4 mM	4.7 mM
1.2×10^7 r	217	133	189
2.4×10^7 r	—	167	200
3.6×10^7 r	285	175	217
Average	192 S-H/C-S		

The Radiolysis of Diphenyl Disulfide in Benzene.—Sulfenyl radicals are produced from the radiolysis of diphenyl disulfide; these radicals are then converted into thiophenol by reaction with free hydrogen from the radiolysis of benzene:

$$C_6H_5S\text{–}SC_6H_5 \rightarrow 2\ C_6H_5S \quad (13)$$

$$C_6H_5S + H \rightarrow C_6H_5SH \quad (5)$$

The Energy Transfer of Excited Benzene in the Decomposition of Thiophenol.—The *G*-value of decomposition of thiophenol apparently depends on the concentration of thiophenol, the value ranging anywhere 200 to 600 when it is calculated on the basis of the concentration of thiophenol.

The available bond dissociation energy is less than 70 kcal. per mol. for the S–H bond of thiophenol. This means that the *G*-value for the thiophenol decomposition is much larger than the maximum *G*-value obtained when the absorbed energy is used completely for the decomposition of thiophenol.

By assuming the energy transfer from benzene to thiophenol, the overall kinetics for the only favorable conditions of thiophenol decomposition in benzene can be developed by the steady-state approach. Since one may reasonably assume that the direct excitation of thiophenol by gamma rays and the recombination of the sulfenyl radical and the hydrogen atom are small, the *G*-value of the decomposition of thiophenol may be given by the following equation:

$$G(-C_6H_5SH) = \frac{2k_4k_3(M)I}{(k_2+k_4)(k_1+k_3(M))}$$

which may be written in the following convenient form, since k_4 is much larger than k_2:

$$\frac{1}{G} = \frac{1}{2I}\left(1+\frac{k_1}{k_3(M)}\right)$$

where I represents the rate constant for the formation of benzene molecules excited by 100 eV.; k_1 and k_2, the rate constants for the deactivation of excited benzene and thiophenol; k_3 and k_4, the rate constants for Eqs. 9 and 10, and M, the initial concentration of thiophenol.

This equation can be used only for lower concentrations of thoiphenol; at higher concentrations, the direct decomposition of thiophenol by gamma irradiation becomes so large as to obscure the overall assumptions for setting up the equation.

Figure 3 illustrates the relation between the *G*-values at the minimum radiation dose obtained from Fig. 1 and the initial concentrations of thiophenol.

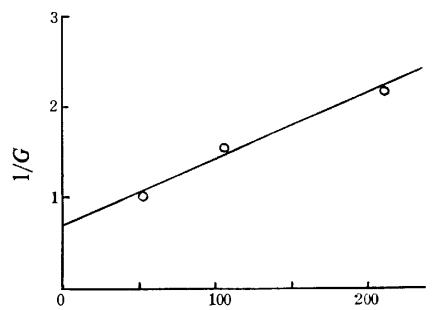

Fig. 3. Relation of *G*-value of decreased thiophenol and its initial concentration on radiolysis thiophenol in benzene.

From Fig. 3, (I) can be obtained by intersecting the slope with the vertical line, and k_1/k_3, from the slope of the line.

The calculation indicates that about 0.7 molecule of excited benzene is formed per 100 eV. of gamma irradiation, and that the ratio of the energy transfer to thiophenol from excited benzene to the deactivation of excited benzene itself is about 100 to 1.

Summary

The irradiation of a benzene solution of sulfur gave thiophenol, diphenyl disulfide, diphenyl sulfide, hydrogen sulfide, hydrogen and some polymers. The formation of thiophenol and of hydrogen sulfide is considered to be initiated by the radiolysis of benzene, which gives phenyl and hydrogen radicals, which in turn combine with sulfur in succeeding steps.

However, the thiophenol formed is oxidized to the disulfide as the radiation energy absorbed in benzene transfers to thiophenol. The effect of the initial concentration of thiophenol and of the radiation dose has been measured. The relative stability of the S–H and C–S bond for radiation was about 1 : 200. The radiolysis of diphenyl disulfide or hydrogen sulfide in benzene were found to form thiophenol. In a kinetical study of the decomposition of thiophenol in benzene, 0.7 benzene molecule is excited by the 100 eV. of gamma rays absorbed, while the ratio between the energy transfer to thiophenol from excited benzene and the deactivation of excited benzene itself is about 100 to 1.

The Syntheses of Polyhydroxybenzene Derivatives from Furfural. II[1]

By Masuo MURAKAMI and Jong-Chen CHEN

(Received January 5, 1963)

It is well-known that poison ivy and Japanese lac urushiol contain a mixture of four components which have the carbon skeleton of 3-pentadecylcatechol. One of these components has a completely reduced side chain (hydrourushiol). The other three contain one, two and three olefinic bonds respectively[2,3]. A number of investigators[1,2,4-6] have synthesized hydrourushiol. The mono-olefinic compound of urushiol and its homologs have also been synthesized by several investigators[1,8,9].

Because of the absence of a general method for the preparation of 3-alkyl catechol and for the other reasons pointed out by Loev and Dawson[9,10], none of di- or tri-olefinic catechols has heretofore been available, either from natural sources or by synthetic means. Consequently, there has been interest in the development of a method of synthesizing such alkenylcatechols. The present paper's method of the syntheses of di- and tri-olefinic catechols (Fig. 1) is based on a route developed earlier[1] by us for syntheses of 3-alkylcatechols. This paper also describes syntheses of 3-alkynylcatechol, as well as of 3-phenylcathechol, neither of which has ever been synthesized before.

Heptadecyl bromide, 1-bromo-8, 11-heptadecadiene and 1-bromo-8, 11, 14-heptadecatriene were prepared by Hunsdiecker reaction from the silver salts of stearic acid, linoleic acid and linolenic acid respectively. It is noteworthy that Hunsdiecker reaction is useful in the preparation of olefinic bromides.

The structures of I, II, III, IV and V were determined from the synthetic process, from analyses, from infrared spectra, and from their reduced products. All of these compounds gave dark blue color with ferric chloride and turned red when dilute aqueous alkali was added.

Hydrolaccol (I)[2,11], one of the components of the Indochina lac tree (*Rhus succedenea*), was also obtained by the reduction of II and 3-(8'-heptadecenyl)catechol[1].

It is known that a latex of the lac tree is polymerized by enzyme laccase on exposure to air at room temperature. A crude laccase, which had a specific activity of 4.1×10^2 at 25°C[12], was isolated from the latex of the Japanese lac tree (*Rhus vernicifera*). To each synthetic 3-alkylcatechol was added a small amount of crude laccase. It was shown that such 3-alkylcatechols as hydrourushiol, hydrolaccol, 3-propylcatechol, and 3-methylcatechol did not solidify as a hard thin film, while 3-olefinic catechol and 3-alkynylcatechol solidified as such a hard thin film when exposed to air at room temperature. The solidification rates are shown in the following comparison:

Latex of the Japanese lac tree<3-allylcatechol<3-(8'-heptadecenyl)catechol< II <III <IV.

Experimental

Heptadecyl Bromide. — This compound was prepared from a pure stearic acid according to the method described in the literature[13].

1-Bromo-8, 11-heptadecadiene.—Into a mixture of 14.0 g. of pure linoleic acid in 300 ml. of hot water and 2.9 g. of potassium hydroxide in 50 ml. of hot water was added 8.5 g. of silver nitrate in 25 ml. of hot water with stirring. The precipitated silver salt was collected on a filter, washed with water and acetone, and dried in a vacuum at room temperature. This material was powdered and then dried in a vacuum at room temperature over phosphorus pentoxide. 37.5 g. (96.6%) of silver linoleate was thus obtained. Into a suspension of 22.8 g. of silver linoleate in 150 ml. of carbon tetrachloride (dried over phosphorus pentoxide) was added dropwise 9.0 g. of dry bromine with stirring at room temperature. After the evolution of carbon dioxide had ceased, the silver bromide was removed by filtration, and the filtrate was washed with a saturated sodium hydrogen carbonate solution and then with water and dried over magnesium sulfate. The carbon tetrachloride was distilled off under reduced pressure. The residue was crude 1-bromo-8, 11-heptadecadiene (a yellowish brown viscous oil) which was pure enough for subsequent purposes. The yield was 9.6 g. (52.0%).

Found: C, 64.03; H, 9.04; Br, 25.00. Calcd. for $C_{17}H_{31}Br$: C, 64.74; H, 9.91; Br, 25.34%.

1-Bromo-8, 11, 14-heptadecatriene. — The silver linoleate (a quantitative yield) was prepared from pure linolenic acid by the method described above for the preparation of the silver linoleate. A yellowish-brown viscous oil of 1-bromo-8, 11, 14-heptadecatriene was prepared from 26.5 g. of silver linoleate and 9.0 g. of dry bromine by the method described above for the preparation of 1-bromo-8, 11-heptadecadiene.

Found: C, 64.40; H, 9.21; Br, 25.78. Calcd. for $C_{17}H_{29}Br$: C, 65.15; H, 9.33; Br, 25.50%.

Hydrolaccol (I), 3-(8', 11'-Heptadecadienyl)-catechol (II), 3-(8', 11', 14'-Heptadecatrienyl)-catechol (III), 3-Propargyl Catechol (IV), and 3-Phenyl Catechol (V). — Each of these compounds was prepared from 1 mol. each of sodium hydride and of *n*-butyl ether in a three-necked flask with a mechanical stirrer, a dropping funnel, and a reflux condenser carrying a soda-lime tube. One mole of ethyl (2, 5-diethoxytetrahydro)-furfuroyl-acetate was added dropwise to the stirred contents of the flask at room temperature for an hour, the corresponding alkyl bromide (iodobenzene was used for the preparation of IV) was added, and the reaction mixture was heated for 8 hr. After the reaction was over, the reaction mixture was acidified with acetic acid, and then *n*-butyl ether was removed by vacuum distillation. The residue was added to 100 ml. of 0.1 N hydrochloric acid and 200 ml. of dioxane and the mixture was allowed to stand at room temperature for a week; the solvent was then removed by vacuum distillation, and the residue was dissolved in ether. The ethereal solution was washed with saturated sodium hydrogen carbonate and with water and dried over magnesium sulfate. The ether was removed by distillation, and the residual oil was dissolved in ethanol and treated with the excess of an ethanolic solution of lead acetate trihydrate. The dense precipitate of lead salt was filtered off and washed with ether. The lead salt was suspended in ethanol and treated with hydrogen sulfide. The lead sulfide was removed by filtration, and the solvent was distilled off from the filtrate. The residual oil was distilled further.

The Reduction of II to Hydrolaccol. — 0.51 g. of II in ethanol was reduced through the use of W-6 Raney nickel[14] at room temperature for 10 hr. The product was then recrystallized from toluene; m. p., 63°C. The yield was 0.505 g. (87% yield).

Compound	Molecular formula	M. p. or b. p.	Yield %	Calcd., %		Found, %	
				C	H	C	H
I	$C_{23}H_{40}O_2$	m. p. 62～63°C	26.4	79.25	11.57	79.28	11.37
II	$C_{23}H_{36}O_2$	212～221°C/0.03 mmHg	15.9	80.18	10.53	80.48	10.64
III	$C_{23}H_{34}O_2$	209～217°C/0.022 mmHg	19.9	80.65	10.01	79.89	9.82
IV	$C_9H_8O_2$	130～136°C/5 mmHg	11.8	72.96	5.44	73.22	5.91
V	$C_{12}H_{10}O_2$	m. p. 57～59°C	7.82	77.40	5.41	77.38	5.40

This product was identified by mixed melting point determination and comparison with the infrared spectra of a sample which had been prepared from ethyl (2,5-diethoxytetrahydro)-furfuroylacetate and heptadecyl bromide.

Laccase. — Crude laccase was isolated from the latex of the Japanese lac tree (*Rhus vernicifera*) according to the method described in the literature[12].

The Action of Laccase. — Into each synthetic 3-alkylcatechol was added a small amount of crude laccase with stirring, the mixture was then spread over a watch glass as thinly as possible at room temperature. A hard thin film adhered to the watch glass when solidification had been completed. The times required for this solidification were then compared.

The Synthesis of Four Optical Isomers of β-Hydroxyaspartic Acid

By Takeo KANEKO and Hakuji KATSURA

(Received January 16, 1963)

In 1904 Skraup[1] suggested that he had found β-hydroxyaspartic acid in the hydrolyzate of casein, but in 1921 Dakin[2] reported that he found none of this amino acid in the hydrolyzate of casein, as compared with the *threo-* and *erythro*-β-hydroxy-DL-aspartic acid synthesized by him. Recently, *erythro*-β-hydroxy-L-aspartic acid ($[\alpha]_D+51°$)[3] has been obtained by the action of a transaminase on dihydroxyfumaric acid and L-glutamic acid. β-Hydroxyaspartic acid has been found in a culture solution of a certain sort of Azotobactor[4], and in a hydrolyzate of Phallicidine[5], a toxic substance isolated from *Amanita phalloides*. Some methods of synthesizing β-hydroxyaspartic acid[6] were reported a few years ago, but the absolute configurations of the optical isomers of this amino acid have never been determined. The present paper deals with the chemical determination of the absolute configurations of these optical isomers by the establishment of the configurational correlation between these isomers and glyceric acid.

Dakin[2] reported that *erythro-* and *threo*-β-hydroxy-DL-aspartic acids (DL-VI and II) were prepared by the ammonolysis of *erythro*-β-chloro-DL-malic acid (DL-IV)*. To determine the stereochemical behavior of this reaction, *cis*-[7] and DL-*trans*-epoxysuccinic acid[8] (I and DL-V) were treated with aqueous ammonia to obtain *threo-* and *erythro*-β-hydroxy-DL-aspartic acids (DL-II and VI) respectively[9]. From D_S-(−)-*trans*-epoxysuccinic acid (D-V)[8] and (−)-*erythro*-β-chloro-D_S-malic acid (D-IV)[8], which were derived from D_S-tartaric acid (III), the same *erythro*-β-hydroxy-L_S-aspartic acid ($[\alpha]_D$ +53°) (L-VI) was obtained. This acid was identical with that given by the enzymatic

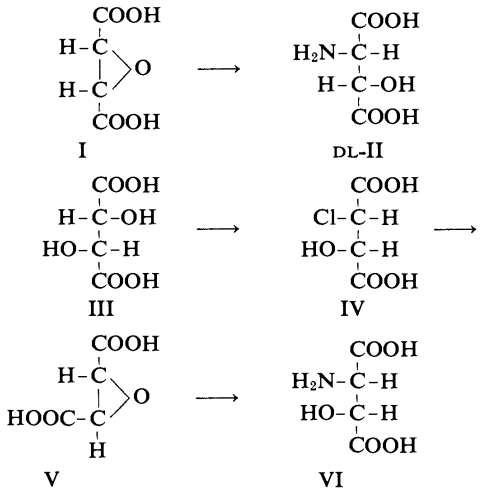
method[3]. These results show that epoxy acid (V) is the intermediate in the ammonolysis of chloromalic acid (IV) to amino acid (VI).



threo-β-Hydroxy-D$_S$-aspartic acid ($[\alpha]_D - 1.2°$) (D-II) was obtained from the oxazolidone derivative (X)[10] of 4, 6-benzylidene-D$_g$-glucosaminic acid hydrochloride (VIII)[11], which was readily derived from D$_g$-glucosamine hydrochloride (VII), by hydrolysis of the benzylidene group and oxidation with periodic acid followed by bromine, and then by the hydrolysis of the oxazolidone ring. From ethyl 4, 6-benzylidene - 2-benzyloxycarbonylamido - 2 - deoxy-D$_g$-gluconate (XI)[11,12], which was derived from VIII, the *threo*-D$_S$-amino acid was also obtained by cyclization to the oxazolidone derivative followed by the oxidation and hydrolysis described above.

TABLE I. THE PHYSICAL AND PHYSIOLOGICAL NATURES OF β-HYDROXYASPARTIC ACID

Configuration	Taste (salty)	Specific rotation $[\alpha]_D$ in N-HCl	Specific rotation $[\alpha]_D$ in water
L-Erythro	Weak	+53.0°	+41.4°
D-Erythro	Very slightly	−49.2°	—
L-Threo	Slightly	+ 1.3°	− 8.9°
D-Threo	Tasteless	− 1.2°	+ 8.9°

threo-β-Hydroxy-L$_S$- and *erythro*-β-hydroxy-D$_S$-aspartic acids (L-II and D-VI) were obtained from *erythro*-β-hydroxy-L$_S$- and *threo*-β-hydroxy-D$_S$-aspartic acids (L-VI and D-II) via their

The physical and physiological natures of optically-active β-hydroxyaspartic acids are summarized in Table I. In this table, it is shown that Lutz-Jirgensons' displacement rule[14] is applicable to these isomers.

The optically active and inactive isomers of β-hydroxyaspartic acid can not be identified by paper chromatography in various solvent systems. The infrared spectra of the isomers prepared in this paper are shown in Fig. 1.

Experimental

***threo*-β-Hydroxy-DL-aspartic Acid (DL-II) from *cis*-Epoxysuccinic Acid (I).**—A solution of 7.0 g. of I[7] in 70 ml. concentrated aqueous ammonia was heated in a sealed tube at 130°C for 18 hr. Crude DL-II was separated from the reaction mixture by concentration and then acidification with acetic acid, and recrystallization from water gave pure amino acid; yield, 8.6 g., 75%.

Found: C, 32.17; H, 4.76; N, 9.66. Calcd. for $C_4H_7O_5N$: C, 32.22; H, 4.73; N, 9.40%.

***erythro*-β-Hydroxy-DL-aspartic acid (DL-VI) from DL-*trans*-Epoxysuccinic Acid (DL-V).**—From 8 g. of DL-V[8], DL-VI was obtained in a similar manner; yield, 5.0 g., 55%.

Found: C, 32.11; H, 4.88; N, 9.03%.

***erythro*-β-Hydroxy-L-aspartic Acid (L-VI).**—*From D-(−)-trans-Epoxysuccinic Acid (D-V).*—From 6.0 g. of D-V[8], L-VI was obtained in a similar manner; yield, 4.9 g., 72%: $[\alpha]_D^{21}$ +53.2° (*c* 2.46,

14) O. Lutz and B. Jirgensons, *Ber.*, **63**, 448 (1930); ibid., **64**, 1221 (1931); ibid., **65**, 784 (1932).

1 N HCl); Found: C, 32.26; H, 4.83; N, 9.46%.

From erythro-β-Chloro-D$_S$-malic Acid (D-IV).—D-Chloromalic acid (D-IV)* was derived from dimethyl *erythro*-β-chloro-D$_S$-malate[15] by hydrolysis with 2.5N hydrochloric acid. A mixture of 10 g. of this acid and aqueous ammonia was heated in a sealed tube for 20 hr. and then concentrated in vacuo. The aqueous solution of this concentrate was treated through a Dowex 2 (OH-form) column and eluted with 2 N acetic acid. Crude L-VI was separated from the concentrate of this eluate and was then recrystallized from water to obtain the pure substance; yield, 5.5 g., 62%: $[\alpha]_D^{21}+53.0°$ (*c* 2.66, 1 N HCl); $[\alpha]_D^{21}+41.4°$ (*c* 2.43, water). Found: C, 32.23; H, 4.73; N, 9.17%. No pure *threo*-amino acid was separated by fractional crystallization from water or by partition chromatography through a Dowex 1 column by elution with 0.03 N formic acid[6b].

4, 6-Benzylidene-2-benzyloxycarbonylamido-2-deoxy-D$_g$-gluconic Acid (IX).—From 3.7 g. of VIII[11], IX was prepared in the usual manner; m. p., 167°C, $[\alpha]_D^{14}-51.0°$ (*c* 3.39, 99% ethanol); yield, 3.4 g., 83%. For analysis, pure substance obtained by recrystallization from ethyl acetate and petroleum ether and dried at 110°C for 22 hr. was used.

Found: C, 60.59; H, 5.52; N, 3.31. Calcd. for $C_{21}H_{23}O_8N$: C, 60.42; H, 5.52; N, 3.36%.

The Oxazolidone Derivative (X) of VIII.—*From IX.*—A mixture of 2.6 g. of IX and 1 g. of sodium hydroxide in 150 ml. of water was stirred continuously below 5°C for 6 hr. After the reaction mixture had been extracted with ether and the aqueous layer acidified with hydrochloric acid, the solution was extracted with ethyl acetate. Crude X (1.2 g., 62%) was separated by concentration of this extract and then recrystallized from ethyl acetate and petroleum ether to obtain the pure substance; m. p. 152°C, $[\alpha]_D^{14}-102.9°$ (*c* 3.15, methanol).

Found: C, 54.25; H, 4.92; N, 4.54. Calcd. for $C_{14}H_{15}O_7N$: C, 54.37; H, 4.89; N, 4.53%.

From VIII.—After a mixture of 25 g. of VIII, 25.5 g. of benzyloxycarbonyl chloride and 25 g. of sodium hydrogen carbonate in 400 ml. of water had been stirred at room temperature for 1 hr., a solution of 5 g. of sodium hydroxide in 20 ml. of water was added to this solution at 5°C and two solutions were stirred continuously together for 6 hr. Crude X (16.4 g., 78%) was obtained from the reaction mixture in a method similar to that described above.

***threo*-β-Hydroxy-D$_s$-aspartic Acid (D-II).**—*From X.*—A mixture of 3.0 g. of X and 30 ml. of 10% aqueous acetic acid was warmed in a boiling water bath for 1 hr.[16], and, on cooling, the reaction mixture was extracted with ether to remove the benzaldehyde. The aqueous layer was evaporated to dryness in vacuo, and the residue was dissolved in water. This solution was treated with 7 g. of a periodic acid dihydrate in 50 ml. of water and allowed to stand overnight at room temperature. The mixture was neutralized with 2 N sodium hydroxide, again set aside overnight, acidified to pH 4 by the addition of hydrochloric acid, and then treated with an aqueous barium chloride solution until no more salts were precipitated. A solution of 10 ml. of bromine in 90 ml. of a 2 N aqueous sodium hydroxide solution was added to the filtered solution. After standing overnight, the reaction mixture was acidified with hydrochloric acid and evaporated to dryness in vacuo. The residue was extracted with 99% ethanol, and the alcoholic extract was concentrated in vacuo. The residual oil was refluxed with 60 ml. of 6 N hydrochloric acid for 6 hr., and the solution was concentrated to dryness in vacuo. When the aqueous solution of the residual oil was treated with a Dowex 2 X8 (OH-form) column, elution with 2 N aqueous acetic acid and subsequent evaporation in vacuo gave crude D-II, yield, 1.1 g., 76%.

From XI.—An ethanolic solution (90 ml.) of 7 g. of XI[11,12] was added dropwise to a solution of 8 g. of sodium hydroxide in 100 ml. of 50% aqueous ethanol in an ice bath, and the mixture was stirred continuously for 7 hr. The reaction mixture was acidified with hydrochloric acid and concentrated to dryness in vacuo, and the residue was extracted with 99% ethanol. The extracts were concentrated in vacuo to a glassy solid (about 5 g.), and this solid was treated with 10% acetic acid, oxidized first with periodic acid, and then with bromine, and then hydrolyzed with hydrochloric acid. The product was isolated by the aid of a Dowex 2 column in the manner described above. The crude D-II weighed 1.5 g. (64%). Recrystallization from water gave the pure substance; $[\alpha]_D^{24}-1.2°$ (*c* 5.16, 1 N HCl), $[\alpha]_D^{28}+8.9°$ (*c* 0.91, water).

Found; C, 31.91; H, 4.71; N, 9.17. Calcd. for $C_4H_7O_5N$; C, 32.22; H, 4.73; N, 9.40%.

Diethyl *erythro*-β-Hydroxy-DL-aspartate Hydrochloride.—A suspension of 4.0 g. of DL-VI in 80 ml. of absolute ethanol was saturated with dry hydrogen chloride, and 125 ml. of dry ether was added. The crude crystals which separated were purified by recrystallization from absolute ethanol; yield, 3.3 g., 51%; m. p., 157~157.5°C (lit.[17]; m. p., 154~156°C).

Found; C, 39.54; H, 6.77; N, 5.52; Cl, 15.14. Calcd. for $C_8H_{16}O_5NCl$; C, 39.76; H, 6.67; N, 5.58; Cl, 14.70%.

Diethyl *N*-Benzoyl-*erythro*-β-hydroxy-DL-aspartate (DL-XII).—From 3.3 g. of the avove-mentioned ester hydrochloride, DL-XII was prepared in the usual manner and recrystallized from benzene and petroleum ether; yield, 3.0 g., 71%; m. p., 84°C.

Found; C, 58.29; H, 6.12; N, 4.46. Calcd. for $C_{15}H_{19}O_6N$: C, 58.24; H, 6.19; N, 4.53%.

Diethyl *N*-Benzoyl-*erythro*-β-hydroxy-L$_s$-aspartate (L-XII).—After 4.1 g. of L-VI had been esterified with absolute ethanol and dry hydrogen chloride, L-XII was obtained from the oily ester in the usual manner and recrystallized from benzene; yield, 5.4 g., 64%; m. p., 99~100°C; $[\alpha]_D^{16}+27.9°$ (*c* 4.52, 99% ethanol). Found: C, 58.52; H, 6.16; N, 4.45%.

Diethyl *N*-Benzoyl-*threo*-β-hydroxy-DL-aspartate (DL-XIV).—From 7.1 g. of DL-II, DL-XIV was

* M. p., 159°C, $[\alpha]_D^{21}$ −28.3° (*c* 3.19, ethyl acetate): literature[8]; m. p., 165~166°C, $[\alpha]_D$ −31°.

15) T. Kaneko and H. Katsura, *Chem. & Ind.*, **1960**, 1188; H. Katsura, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **82**, 98 (1961).

16) Cf. L. V. Vargha, *Ber.*, **68**, 18 (1935).

obtained in a similar manner and was recrystallized from benzene and petroleum ether; yield, 8.3 g., 56%; m. p., 101~102°C. Found: C, 58.55; H, 6.29; N, 4.40%.

Diethyl *N*-Benzoyl-*threo*-β-hydroxy-D$_8$-aspartate (D-XIV).—From 4.8 g. of D-II, D-XIV was obtained in a similar manner and was recrystallized from benzene; yield, 6.6 g., 62%; m. p., 121°C; $[\alpha]_D^{25}$ −21.2° (*c* 3.54, 94% ethanol). Found: C, 58.43; H, 6.17; N, 4.55%.

***threo*-β-Hydroxy-DL-aspartic Acid** (DL-II).—An oily oxazoline derivative[13] (DL-XIII) was obtained from 3.0 g. of DL-XII by the aid of 20 ml. of thionyl chloride. The crude oily DL-XIII was hydrolyzed by refluxing it with 6 N hydrochloric acid for 7 hr. The pure DL-II was obtained by a concentration of the hydrolyzate, followed by recrystallization from water; yield, 0.7 g., 48%. Found: C, 32.05; H, 4.79; N, 9.00. Calcd. for $C_4H_7O_5N$: C, 32.22; H, 4.73; N, 9.40%.

***threo*-β-Hydroxy-L$_8$-aspartic Acid** (L-II).—From 9.0 g. of L-XIII, L-II was obtained in a similar manner via a crude oily oxazoline derivative (L-XIII) and purified by passing it through a Dowex 2 column, followed by recrystallization from water; yield, 3.6 g., 83%: $[\alpha]_D^{27}$ +1.3° (*c* 3.12, 1 N HCl); $[\alpha]_D^{27}$ −8.5° (*c* 1.76, water). Found: C, 32.33; H, 4.87; N, 9.43%.

***erythro*-β-Hydroxy-DL-aspartic Acid** (DL-VI).—A crystalline oxazoline derivative (DL-XV) was obtained from 3.0 g. of DL-XIV by the action of 20 ml. of thionyl chloride; it was purified by the same methods as have been described by Hauptmann[17]; m. p., 99°C (lit.; m. p., 97.5~99°C). Found: C, 62.00; H, 5.97; N, 4.48. Calcd. for $C_{15}H_{17}O_5N$: C, 61.84; H, 5.88; N, 4.81%.

From a crude DL-XV derived from 8.3 g. of DL-XIV, DL-VI was obtained in a similar manner and was recrystallized from water; yield, 1.9 g., 39%. Found: C, 32.26; H, 4.84; N, 9.63. Calcd. for $C_4H_7O_5N$: C, 32.22; H, 4.73; N, 9.40%.

***erythro*-β-Hydroxy-D$_8$-aspartic Acid** (D-VI).—From 6.4 g. of D-XIV, D-VI was obtained in a similar manner via an oily oxazoline derivative (D-XV) and was recrystallized from water; yield 0.7 g., 23%: $[\alpha]_D^{27}$ −49.2° (*c* 1.85, 1 N HCl). Found: C, 32.25; H, 4.70; N, 9.45%.

An Attempt to Convert Glycine Residues to Threonine Residues in Polyglycine

By Toshiyuki FURUYAMA*, Fumio SAKIYAMA and Kozo NARITA

(Received January 24, 1963)

Some attempts have already been made to introduce side chains into the glycine residues of synthetic or naturally-occurring polypeptides[1,2].

Regarding the "fore-protein" formation, for example, Akabori postulated that polyglycine was produced according to the polymerization of aminoacetonitril and that then various side chains were introduced into the glycine residues of polyglycine, thus leading to the fore-protein[3]. In order to prove his hypothesis, Akabori et al. tried to introduce side chains into polyglycine which had been dispersed on the kaolinite surface by means of aldehydes in the presence of some basic catalysts. It was thus shown that small amounts of serine and threonine were formed from the glycine residues in the polymer by reactions with aqueous formaldehyde and acetaldehyde respectively[2].

The present authors have attempted the conversion of the glycine residues in polyglycine to threonine residues by means of acetaldehyde in a non-aqueous medium. Although they were unsuccessful in obtaining polythreonine from polyglycine in the present study, appreciable amounts of threonine could be isolated from the hydrolyzates of the reaction product of polyglycine with acetaldehyde in liquid ammonia. The spatial configuration of the threonine thus formed was also examined by the aid of infrared absorption spectroscopy.

Experimental

Polyglycine. — Polyglycine was prepared by Leuchs' *N*-carboxylic anhydride method[4]. The

average degree of polymerization of the polymer was estimated to be 93~97 by titrating the terminal carboxyl groups[5] with sodium methoxide in dimethylformamide.

The Condensation of Acetaldehyde with Polyglycine and Acid Hydrolysis.—Five hundred milligrams of polyglycine, together with a piece of ferric nitrate crystal, were dispersed in 100 ml. of liquid ammonia in a dry ice-acetone bath. Then, 400 mg. of metallic sodium were added, the mixture was stirred for 80 min., and 50 ml. of freshly distilled acetaldehyde were added dropwise into the above reaction mixture. This was stirred for two hours under cooling and then left overnight at room temperature. During this period, the liquid ammonia evaporated. The residual brown oily substance was dried over concentrated sulfuric acid under reduced pressure. The residue was then hydrolyzed with 6 N hydrochloric acid for 15 hr. at 110°C. The hydrolyzate of the modified polyglycine was evaporated to dryness on a steam bath.

The Isolation of Threonine from the Acid Hydrolyzate of the Modified Polyglycine.—The isolation of threonine was carried out utilizing the O→N acetyl shift reaction[6]. The above-dried hydrolyzate was dissolved in 40 ml. of glacial acetic acid, and dry hydrogen chloride gas was saturated to convert threonine into its *O*-acetyl derivative. The O→N acetyl shift reaction of *O*-acetyl threonine was performed at pH 8 in a pH-stat (Radiometer Co., Demmark) for 4 hr. at 31°C. The reaction mixture was treated with ion exchange resin as in the procedures of Fujiwara et al.[6] One hundred and nine milligrams of crude *N*-acetyl threonine were thus obtained. It was hydrolyzed with 6 N hydrochloric acid. The dried hydrolyzate was dissolved in 5 ml. of methanol, and 0.1 ml. of triethylamine was added; 5.3 mg. of the crystals (m. p., 208~209°C with decomp.) were obtained. The results of paper electrophoresis (500 V., 0.2 mamp./cm., in 1 N acetic acid, pH 2.5) and infrared absorption spectra showed that the material was threonine.

Glycine was recovered from the adsorbed fraction on the resin column, which was used after the O→N acetyl shift reaction for the separation of *N*-acetyl threonine from glycine, by eluting it with 2 N ammonium hydroxide. It was recrystallized from water-ethanol, 410 mg. (m. p., 237°C with decomp. Found: C, 32.08; H, 6.54; N, 18.42. Calcd. for $C_2H_5NO_2$: C, 32.00; H, 6.71; N, 18.66%).

Results and Discussion

As for the formation of the threonine residue from glycine residue in polyglycine, an aldol-type condensation is expected to occur under certain conditions which activate the methylene group in the glycine residue. Akabori et al.[7] found that the formation of a glycine copper chelate complex brought on the activation of the methylene group, and they succeeded in synthesizing threonine by an aldol-type condensation of acetaldehyde. Moreover, they attempted to introduce some side-chain groups into polyglycine which had been dispersed on a clay, kaolinite, and suspended in aqueous alkaline media with formaldehyde or acetaldehyde[2]. In these experiments 0.4~3.1%*1 of glycine residues were shown to be converted to serine and 1.4~1.5%, to threonine residues, but polyglycine which had not been dispersed on kaolinite was not affected under similar conditions.

In the present investigation, it was shown that 7~9%*2 of the glycine residues converted to threonine residues. The analyses were made by means of paper chromatography of their 2,4-dinitrophenyl derivatives after hydrolysis of the modified polymers. Therefore, it seems that the use of liquid ammonia in place of water as a reaction medium is more favorable for this aldol-type condensation reaction[8].

The condensation reaction seemed to occur not only at the *N*- and *C*-terminal glycyl residues in polyglycine but also at the non-terminal residues, since one terminal residue was calculated as being approximately 1% on the basis of the measurement of the average degree of polymerization.

The chromatogram of the 2,4-dinitrophenyl derivatives of the hydrolyzates of the modified polyglycine showed four spots, 2,4-dinitrophenyl (DNP) glycine, DNP-threonine, 2,4-dinitrophenol and one unknown spot which located at the position between threonine and dinitrophenol on a two-dimensional paper chromatogram (*n*-butanol saturated with aqueous ammonia, a 1.5 M phosphate buffer (pH 6)). However, the only amino acids obtained after the isolation procedure are glycine and threonine. Therefore, the amount of an unknown spot on the chromatogram may be insignificant.

It is of interest to examine the spatial configuration of threonine thus obtained from the modified polyglycine. As has already been described, Akabori et al. identified serine and threonine chromatographically from the hydrolyzates of the formaldehyde- and acetaldehyde-treated polyglycine, but they did not isolate the hydroxy amino acids thus formed. In the present studies, liquid ammonia was used as a

reaction medium and the threonine formed was isolated by the use of the O→N acetyl shift reaction[6].

The threonine isolated from the modified polyglycine was examined by infrared absorption spectroscopy. The absorption spectra showed the threonine sample to contain appreciable amounts of allothreonine[9]. Estimation of the amount of contaminated allothreonine was made by the use of characteristic bands at 702 and 619 cm^{-1} [10]. The values of 64.4% for threonine and 35.6% for allothreonine were obtained.

Summary

When polyglycine was reacted with acetaldehyde in liquid ammonia in the presence of metallic sodium, it was observed that 7~9% of the threonine residues were formed from glycine residues. From the hydrolyzate of the modified polyglycine, threonine could be isolated by the aid of the O→N acetyl shift reaction. It was shown that the threonine thus isolated was 35.6% allothreonine.

Consideration on the Q-e Scheme. III. Q-e Factors in Ionic Polymerization

By Nariyoshi KAWABATA, Teiji TSURUTA and Junji FURUKAWA

(Received February 7, 1963)

The reactivity of vinyl compounds in radical copolymerization has been generalized by the *Q-e* scheme proposed by Alfrey and Price[1]. According to the scheme, the rate constant of propagation step, k_p, is expressed by the following equation:

$$k_p = P_R Q_M \exp(-e_R e_M) \quad (1)$$

where P is the reactivity associated with polymer radical, Q is the general reactivity term characteristic of the monomer and e is the polarity term characteristic of the radical and the monomer. In part I of this series[2], a revised pattern of the scheme by assuming the e-value of styrene to be equal to zero was described and a notation e_{RM} was proposed instead of $e_R e_M$ for the polarity term. In part II of this series[3], we tried to give some theoretical background to the scheme. We tried to divide the conjugation-stabilization energy between monomer and attacking radical[4], E_{RM}, into four terms by the following equation:

$$E_{RM} = E_{RoMo} + E_R + E_M + E'_{RM} \quad (2)$$

where E_{RoMo} is the stabilization energy between polyethylene radical and ethylene monomer, E_R and E_M are the increments in the stabilization energy introduced by the substituent of radical and by that of monomer, respectively, E_{RoMo} as standard. E'_{RM} is the surplus increment in the stabilization energy introduced by the substituents of the radical and the monomer. We proposed the relations 3 to 5 for P-, Q- and e-terms.

$$P_R \propto \exp(E_R/RT) \quad (3)$$

$$\ln Q_1 - \ln Q_2 = (E_{M_1} - E_{M_2})/RT \quad (4)$$

$$e_{RM} = -E'_{RM}/RT \quad (5)$$

For ionic copolymerization, however, no such generalization has been established, although several attempts have been made[5]. The most characteristic feature of ionic copolymerization has long been considered to be that the product of monomer reactivity ratios, $r_1 r_2$, is close to unity. Thus,

$$k_{11}/k_{12} \fallingdotseq k_{21}/k_{22} \quad (6)$$

Here, k_{AB} is the propagation rate constant for polymer ion A and monomer B. Landler[5b] and Pepper[6] interpreted the relation 6 in terms of the nearly equal reactivities of polymer ions, i. e.,

$$k_{11} \fallingdotseq k_{21} \quad (7)$$

and

$$k_{12} \fallingdotseq k_{22} \quad (8)$$

However, this assumption has been denied by some experimental results of Okamura et al.[7], who showed that the polymer cation derived from a less reactive monomer had the larger reactivity. The same conclusion was reached in anionic copolymerization by Kuntz and O'Driscoll[8]. The $r_1 r_2 \fallingdotseq 1$ relation was afforded by Okamura et al., who assumed that the rate constant of propagation reaction, k_p, was expressed as a product of the reactivity of ion R_I and that of monomer R_M, i. e.,

$$k_p = R_I R_M \qquad (9)$$

Recently, Szwarc et al.[9,10] have found several anionic copolymerization systems in which the reactivity ratio products determined directly by the use of living polymers are less than unity. Thus, the widely held view that $r_1 r_2$ products for ionic copolymerizations are always nearly equal to unity seems to require some amendment. The authors herewith have tried to give an interpretation of these experimental facts by a logical extention of the Q-e scheme for radical polymerization investigated in previous papers[2,3] to the ionic case. P-, Q- and e-terms were therefore regarded as corresponding to the components of the conjugation-stabilization energy between monomer and attacking ion, much as in the case of radical copolymerization[3].

Method of Calculation

On the basis of Dewar's LCAO MO second-order perturbation method[11], the conjugation-stabilization energy between the attacking

9) C. L. Lee, J. Smid and M. Szwarc, *J. Am. Chem. Soc.*, **83**, 2961 (1961).

11) M. J. S. Dewar, *J. Am. Chem. Soc.*, **74**, 3341 (1952).

polymer ion and the monomer was calculated as the total π-electronic energy difference between the pair of interacting mesomeric systems and the addition product formed by their union. The energy parameters adopted here are those used in the preceding paper[3].

Results and Discussion

***P*-, *Q*- and *e*-Terms in Ionic Polymerization.** —As has been mentioned above, we assume that the activation energy, E_p, in ionic polymerization can be expressed by Eq. 10, as in radical polymerization;

$$E_p = C + \Delta E_\sigma + \Delta E_\pi \qquad (10)$$

where C is a constant, ΔE_σ is the activation energy arising from σ-electrons, and ΔE_π is that arising from π-electrons. We further assume that C and ΔE_σ in Eq. 10 are common throughout all the ion-monomer pairs. According to the view of Fukui et al.[12], ΔE_π is the stabilization energy between the monomer and the attacking polymer ion. Thus,

$$\Delta E_\pi = -E_{CM} \qquad (11)$$

or

$$\Delta E_\pi = -E_{AM} \qquad (12)$$

where E_{CM} is the stabilization energy between monomer and polymer cation and E_{AM} is that between monomer and polymer anion. The stabilization energies recalculated by us are given in Tables I and II*1.

It can be seen in Tables I and II that the relative reactivity of the monomer or the polymer ion is consistent with some experimental results except for the extraordinarily large stabilization energies of the systems of (*p*-methoxystyrene monomer—vinylidene cyanide, acrylonitrile and methyl vinyl ketone cations)*2.

We tried to divide the stabilization energies into four terms by the following equations in

12) T. Yonezawa, T. Higashimura, K. Katagiri, K. Hayashi, S. Okamura and K. Fukui, *J. Polymer Sci.*, 26, 311 (1957).

*1 The conjugation-stabilization energy in ionic copolymerization was calculated by Fukui and others[12]. Our recalculated values of the energy are considerably different from theirs because we used somewhat different values of parameters, the examination of which was described in the preceding paper[3].

*2 In theses, cases, Dewar's second-order perturbation method is inadequate because the energy difference between the lowest vacant level of the polymer cation and highest occupied level of the monomer is too small.

the manner which had been adopted in the preceding paper[3] for radical polymerizations:

$$E_{CM}=E_{CoMo}+E_C+E_M^+ +E'_{CM} \quad (13)$$

$$E_{AM}=E_{AoMo}+E_A+E_M^- +E'_{AM} \quad (14)$$

Here, E_{CoMo} is the stabilization energy between polyethylene cation and ethylene monomer, E_C and E_M^+ are the increments in the stabilization energies of the systems of (substituted polyethylene cation—ethylene monomer) and (polyethylene cation—substituted ethylene monomer) with respect to E_{CoMo} as standard. E'_{CM} is the surplus increment in the stabilization energy of the system of substituted polyethylene cation and substituted ethylene monomer. E_{AoMo}, E_A, E_M^- and E'_{AM} have the significance analogous to E_{CoMo}, E_C, E_M^+ and E'_{CM}, respectively. The values of E_C and E_M^+ are given in Table III; those of E'_{CM}, in Table IV; those of E_A and E_M^-, in Table V; and those of E'_{AM}, in Table VI.

For ionic polymerization, we propose the relations:

$$k_{CM}=P_C^+ Q_M^+ \exp(-e_{CM}^+) \quad (15)$$

$$k_{AM}=P_A^- Q_M^- \exp(-e_{AM}^-) \quad (16)$$

which are just the logical extentions of Eq. 1 to the ionic cases. The terms Q_M^+, P_C^+, e_{CM}^+, Q_M^-, P_A^- and e_{AM}^- will then be given by Eqs. 17 to 22, respectively:

$$\ln Q_{M_1}^+ - \ln Q_{M_2}^+ = (E_{M_1}^+ - E_{M_2}^+)/RT \quad (17)$$

$$P_C^+ \propto \exp(E_C/RT) \quad (18)$$

$$e_{CM}^+ = -E'_{CM}/RT \quad (19)$$

$$\ln Q_{M_1}^- - \ln Q_{M_2}^- = (E_{M_1}^- - E_{M_2}^-)/RT \quad (20)$$

$$P_A^- \propto \exp(E_A/RT) \quad (21)$$

$$e_{AM}^- = -E'_{AM}/RT \quad (22)$$

The Product of Monomer Reactivity Ratios in Ionic Polymerization. — In cationic polymerization, the surplus energy term, E'_{CM}, is negligibly small for most pairs of cations and monomers, as is obvious from Table IV*3. Therefore, Eq. 15 is reduced to Eq. 23.

$$k_{CM} \fallingdotseq P_C{}^+ Q_M{}^+ \qquad (23)$$

That is, Eq. 23, which does not involve the e-factor, is a good approximation of Eq. 15. This result correlates with the experimental finding that $r_1 r_2 \fallingdotseq 1$ for all the cationic copolymerization systems investigated so far. Thus, the experimental finding that $r_1 r_2 \fallingdotseq 1$ seems to be ascribable to the negligible quantity of the surplus energy term. In anionic polymerization, however, the E'_{AM} term often plays a large part in the stabilization energy, E_{AM} (Table VI). Thus, the usual claim that for ionic polymerization the $r_1 r_2$-products are always very close to unity seems not to be of general validity; it seems necessary to amend the generalization to allow for the cases where E'_{AM} is relatively large. Recent experimental findings by Szwarc et al.[9,10] favor our theoretical consideration.

Relative Reactivity toward Carbonium Ions.— According to the above discussion, the relative reactivity of vinyl compounds toward carbonium ions established by Pepper[6] and by Burnett[14] is considered to correspond to the general reactivity term in cationic polymerization, Q^+. In fact, a good linear relationship holds between the logarithm of the relative reactivity and the $E_M{}^+$-value, as is shown in Fig. 1*4.

Overberger et al.[5a] pointed out that when the logarithm of the relative reactivity of substituted styrenes toward α-methylstyrene carbonium ions was plotted against Hammett's substituent constant σ, large deviations of plots from linearity were observed in the cases of the substituents $-OCH_3$ and $-N(CH_3)_2$. Tsuruta (one of the authors) has suggested that linearity was improved when σ^+ was used instead of σ for these substituents[16]. A linear relationship was also observed between σ^+ and $E_M{}^+$.

and polymer ions pointed out by Fukui et al.[12] has been re-examined. The reactivity ratios have been satisfactorily explained in terms of the stabilization energy. The authors have also tried to explain the experimental findings that the r_1r_2 products for all the cationic copolymerization systems so far investigated are nearly equal to unity while those for several anionic copolymerization systems are appreciably smaller than unity. The experimental finding that $r_1r_2 \fallingdotseq 1$ seems to be ascribable to the negligible quantity of the surplus energy term.

In the present paper, the authors have assumed an ideally ionic polymerization in which various energy terms other than the stabilization energy are common throughout all ion-monomer pairs. Ionic polymerizations are sometimes largely affected by the nature of the catalyst, the cocatalyst and the solvent as well as by other experimental conditions[17-19]. In the case of radical polymerization, the reactivity of vinyl compounds can be explained satisfactorily on the basis of the stabilization energy[3,4]. In ionic polymerization, other factors than the stabilization energy, especially the electrostatic interaction between monomer and ion, should also be taken into consideration to explain the reactivity. Other factors than the stabilization energy may then be discussed.

Summary

The authors have tried to divide the conjugation-stabilization energy between monomer and attacking polymer cation, E_{CM}, and that between monomer and attacking polymer anion, E_{AM}, into four terms by means of the equations $E_{CM}=E_{CoMo}+E_C+E_M^+ +E'_{CM}$ and $E_{AM}=E_{AoMo}+E_A+E_M^- +E'_{AM}$, respectively. Here, E_{CoMo} is the stabilization energy between polyethylene cation and ethylene monomer, E_C and E_M^+ are the increments in the stabilization energies of systems of (substituted polyethylene cation —ethylene monomer) and (polyethylene cation —substituted ethylene monomer) with respect to E_{CoMo} as standard. E'_{CM} is the surplus increment in the stabilization energy of the system of substituted polyethylene cation and substituted ethylene monomer. E_{AoMo}, E_A, E_M^- and E'_{AM} have the significance analogous to E_{CoMo}, E_C, E_M^+ and E'_{CM}, respectively. The E'_{CM} values for most cation-monomer pairs have been found to be negligibly small. This result correlates with the experimental findings that the products of r_1r_2 are nearly equal to unity for all the cationic copolymerization systems investigated so far. The equation, $k_{CM}=P_C^+Q_M^+ \exp(-e_{CM}^+)$, is assumed to be applicable to cationic polymerization, the e^+-terms being, however, negligible for any cation-monomer pair. Here, P_C^+ is the reactivity associated with polymer cation, Q_M^+ is the general reactivity term of monomer in cationic polymerization, and e^+ is the corrective term characteristic of polymer cation and monomer. On the other hand, the E'_{AM} values were often found to play a large part in E_{AM}. This result

is consistent with some experimental findings by Szwarc et al. The relative reactivity value of vinyl monomers toward carbonium ions is considered to be the general reactivity term in cationic polymerization, Q^+. A good correspondence of Q^+ with $E_M{}^+$ has been observed.

The authors wish to thank Dr. Takayuki Fueno for his helpful advice and discussion.

Reduction of Hexamminechromium(III) Ions at the Dropping Mercury Electrode

By Nobuyuki TANAKA, Kazuko EBATA and Gen SATÔ*

(Received February 20, 1963)

It has been found that hexamminechromium(III) ions give no well-defined polarographic wave in unbuffered neutral solutions[1], but that, in acetate buffer solutions, they give a two-step wave, the first a well-defined one-electron reduction wave and the second a two-electron reduction wave[2,3]. The previous paper[2] also demonstrated that the first well-defined wave appears only when the solution contains sufficient hydrogen ions to neutralize the six ammonia molecules that the reduced chromium-(II) species liberates.

Friend and Smith[3] observed the half-wave potential of the first wave at -0.83 to -0.84 V. versus a saturated calomel electrode and presumed a reduction mechanism similar to that of hexamminecobalt(III) ions, i. e., an irreversible electron transfer followed by hydrolysis of the divalent species.

Recently, Ichniowski and Clifford[4] investigated the polarographic behavior of hexamminechromium(III) in Divers' liquids and reported the half-wave potential to be -0.972 V. versus the mercury pool anode. From their experimental results, including the slope of the log-plot, they concluded that the electrode process is a reversible one. These results apparently contradict those obtained by Friend and Smith, but comparison of the two seems unreasonable because of the different solvents and reference electrodes used.

In this paper, extensive studies of the nature of the one-electron reduction wave of hexamminechromium(III) ions in aqueous solutions, both neutral and acid, are presented.

Experimental

Hexamminechromium(III) chloride was prepared according to the method of Mori[5]; the chromium and nitrogen contents were determined by the usual methods.

Found: Cr, 19.74%; N, 31.5%. Calcd. for $[Cr(NH_3)_6]Cl_3$: Cr, 19.96%; N, 32.2%.

As the complex is sensitive to light and not very stable in an aqueous solution[6], precautions were taken when it was used. All other chemicals used were of guaranteed reagent grade.

Direct current (d. c.) polarograms were recorded with a Yanagimoto Model PB-4 pen-recording polarograph. A Yanagimoto Y-GR 2 Galvarecorder with an automatic voltage scanner was used for recording alternating current (a. c.) polarograms. The Kalousek circuit used was the same as that

described by Tanaka, Tamamushi and Takahashi[7]. The current-time curves were measured with an apparatus similar to that reported by Tamamushi, Momiyama and Tanaka[8].

The characteristics of the dropping mercury electrodes employed in this study are given in Table I. A saturated calomel electrode (SCE) with a large surface area served as the reference electrode. All measurements were carried out at 25°C unless otherwise stated. All the polarograms presented in this paper have been corrected for the residual current. The half-wave potentials and the log-plots are given after the correction for the *iR*-drop across the electrolysis cell.

Results

The current-potential curves of hexammine-chromium(III) ions, in both neutral and acid media, are given in Fig. 1. The nature of the wave in neutral media was investigated in a 0.1 M potassium chloride solution. Polarograms

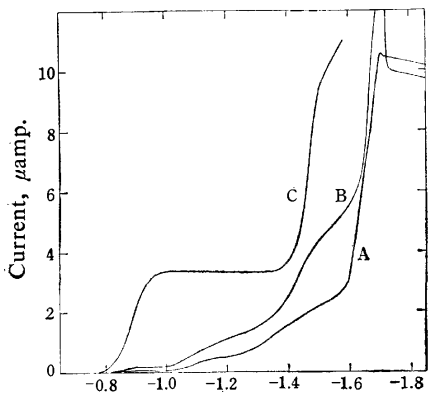

Fig. 1. Polarograms of 1 mM $[Cr(NH_3)_6]Cl_3$, in 0.1 M KCl (A), 0.1 M $NaClO_4$ (B) and in 0.1 M acetate buffer of pH 4.7 (C), in the presence of 0.005% gelatin.

obtained at various concentrations of the complex are shown in Fig. 2. No linear relation was found between the concentration and the current. The plots of $\log h$ (mercury height) versus $\log \bar{i}$ (average current) gave straight lines whose slopes were close to unity at −1.1 V. and −1.2 V. vs. SCE. In Fig. 3, the effect of gelatin on the current-potential curve of hexamminechromium(III) ions in a 0.1 M potassium chloride solution is shown. The current-time curves during the life of a mercury drop were measured at various potentials; those measured at −1.25 V. and −1.30 V. are reproduced in Fig. 4.

In acetic acid-sodium acetate buffer solutions, well-developed waves were observed (see C in Fig. 1). The limiting current was proportional to the concentration of the complex up to 5 mM and to the square root of the height of the mercury reservoir as seen in Table II. No well-defined wave was obtained in the absence of gelatin, while in the presence of gelatin the shape of the wave was affected considerably by the concentration of gelatin. Table III indicates a parallel shift of the wave toward negative potentials observed at lower gelatin concentrations. Diffusion current constants, half-wave potentials, and slopes of the log-plots obtained in various supporting electrolytes and at varied ionic strength are given in Table IV. Measurements were also made at various concentrations of ammonium and

hydrogen ions at a constant ionic strength of 1.0. The results are presented in Tables V and VI. In Table VII, the results obtained at various temperatures are given.

On the a. c. polarogram, a peak was observed at a little more negative potential than the half-wave potential on the corresponding d. c. polarogram. One of the typical Kalousek polarograms of hexamminechromium(III) ions in an acetate buffer solution is reproduced in Fig. 5, where the anodic wave is clearly separated from the cathodic one.

Discussion

In Unbuffered Neutral Solutions.—In a 0.1 M potassium chloride solution, no well-defined wave of hexamminechromium(III) was observed. Upon the addition of hydrochloric acid, a wave began to appear at -0.89 V.; it attained its full development just when the ratio of the flux of hydrogen ions diffusing toward the electrode to that of the complex ions was equal to six. Further addition of the acid made no essential change in the shape of the developed wave[2]. Hydrogen ions seem to play an essential role in the reduction of hexamminechromium(III) to its divalent state. However, as will be mentioned later, hydrogen ions are considered not to be involved in any chemical reaction prior to the electron transfer; they act rather as a neutralizing agent on the ammonia which the divalent chromium species liberates. In an unbuffered neutral solution, the liberated ammonia will make the solution layer near the electrode surface alkaline; it will also cause the divalent chromium species to precipitate as an insoluble film on the surface of the electrode.

This explanation is supported by the following observations. In a 0.1 M potassium chloride solution, the current in the potential region between -0.6 V. and -1.3 V. was almost independent of the concentration of the complex ions (Fig. 2), and the currents at -1.1 V. and -1.2 V. were nearly proportional to the height of the mercury reservoir. The addition of gelatin increased the current between -1.0 V. and -1.35 V., as can be clearly seen in Fig. 3. In addition, further confirmation was obtained by measuring the current-time curve during the life of a mercury drop. Not only did the instantaneous current reach its highest value in the early life of the drop and then decrease with time, but also several sudden breaks were observed in the current (Fig. 4).

It is, therefore, expected that any reagent that can prevent divalent chromium from precipitating will make the one-electron reduction wave of hexamminechromium(III) appear. Figure 6 shows that the wave of hexamminechromium(III) is nearly complete when 1 mM of disodium dihydrogen ethylenediaminetetraacetate (EDTA) was added to a neutral solution of the complex; the divalent chromium is kept in the solution as its EDTA complex.

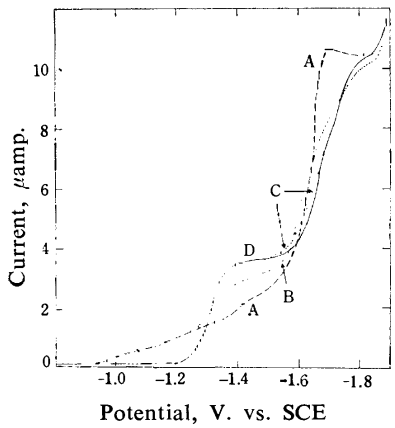

Fig. 6. Polarograms of 1 mM $[Cr(NH_3)_6]Cl_3$ in solutions containing 1 M KCl and 0.005% gelatin without (A) and with 0.52 mM (B), 1.04 mM (C) and 1.56 mM (D) of EDTA. The residual current is not corrected.

That a well-defined one-electron reduction wave does not appear in neutral solutions, though it does in acid media, is a general characteristic of those chromium(III) complexes that have one or more basic ligands, unless the corresponding divalent complexes are stable enough to be maintained in the solution. In fact, the following complex ions gave the one-electron reduction wave in acetate buffer solutions (with 0.005% gelatin added), but not in neutral solutions: $[Cr(H_2O)(NH_3)_5]^{3+}$, $[Cr(en)_3]^{3+}$ (en=ethylenediamine), *trans*-$[Cr(NCS)_2(NH_3)_4]^+$, *trans*-$[Cr(NCS)_2(pn)_2]^+$ (pn=propylenediamine), $[Cr(ox)(en)_2]^+$ (ox=oxalate), and *trans*-$[Cr(NCS)_4(NH_3)_2]^-$. On the other hand, a well-defined reduction wave of chromium(III) to chromium(II) is observed

in potassium chloride or sodium chloride solutions for hexathiocyanatochromate(III), tris-(dipyridyl)chromium(III)[9] and ethylenediaminetetraacetatochromate(III).

In Acid Media.—Every experimental result indicates that the limiting current of the wave in an acetate buffer solution is controlled by diffusion. Assuming the limiting current to correspond to one-electron reduction, the diffusion coefficient of hexamminechromium(III) ions was calculated to be 0.85×10^{-5} cm^2 sec^{-1} at 25°C in an air-free solution containing a 0.1 M acetate buffer, 0.9 M ammonium chloride, and 0.005% gelatin. This value appears to be appropriate for this type of ion[10]. From the change in the limiting current with a change in temperature, the activation energy of diffusion was calculated to be 5.0 kcal./mol.

In most cases, the log-plots gave straight lines whose slopes were 60 to 70 mV. (see Tables IV, V and VI). The values are close to 59 mV. which is to be expected in a reversible one-electron reduction at 25°C. However, as is shown in Fig. 5, the shape of the Kalousek polarogram was that of an irreversible wave, and the peak of an a. c. polarogram was much lower than that expected for a reversible wave. It has been pointed out by Senda, Senda and Tachi[11] that the value of $i_p/(n\,\bar{i}_d\sqrt{t_d})$ represents the degree of polarographic reversibility, where i_p is the peak current in the a. c. polarogram, $\bar{i}_d$, the diffusion current (average) in the corresponding d. c. polarogram, n, the number of electrons involved in the electrode process, and t_d, the drop time. The value for the reduction wave of hexamminechromium(III) ion in acetate buffer solutions was calculated to be 0.009 kΩamp^{-1} sec$^{-1/2}$, which is as small as that for a typical irreversible reduction wave of hydrated nickel(II) ions[12].

The above-mentioned observations can be explained by assuming that the electron transfer between hexamminechromium(III) and the divalent chromium is irreversible with the transfer coefficient close to, or by some chance appearing to be, unity. However, there is the alternative explanation of these observations. The electron transfer process is assumed to proceed reversibly, and the divalent chromium species produced on the surface of the electrode to undergo hydrolysis:

$$[Cr(NH_3)_6]^{3+}+e \rightleftarrows [Cr(NH_3)_6]^{2+} \quad (1)$$

$$[Cr(NH_3)_6]^{2+}+n\,H_2O \rightleftarrows [Cr(H_2O)_n(NH_3)_{6-n}]^{2+}+n\,NH_3 \quad (2)$$

$$NH_3+H^+ \rightleftarrows NH_4^+ \quad (3)$$

If the forward reaction of Reaction 2 is rapid and the backward reaction is extremely slow, the net electrode process will appear to be irreversible in the a. c. and the Kalousek polarogram. Similar mechanisms, viz., mechanisms involving a rapid electron transfer followed by a chemical reaction, have been reported for the oxidation of ascorbic acid[13] and for the reduction of manganese (II) complexes[14]. In these cases, the half-wave potential is dependent on the rate of the following reaction[14,15], as given by

$$E_{1/2}=E_{1/2}^{\circ}+\frac{RT}{nF}\ln 0.89\ (k\,t_d)^{1/2} \quad (4)$$

where $E_{1/2}^{\circ}$ is the half-wave potential with no following reaction and k, the first-order rate constant of the following reaction.

At the moment, it seems impossible to decide, from the experimental results, by which mechanism the reduction of hexamminechromium(III) ions takes place. This is mainly because of insufficient knowledge on the reactivity of chromium(II) complexes.

Table IV shows that in all electrolytes the half-wave potentials shift to more negative potentials with an increase in ionic strength. The shift is much greater than can be expected from the change in the activity coefficients of electroactive species with ionic strength.

The diffusion currents show a slight decrease with increasing ionic strength, but they become almost independent of the ionic strength in the range from 0.1 to 1.0 after the effect of viscosity is corrected for by the equation:

$$I_{corr}=\frac{I}{\sqrt{\eta_{rel}}} \quad (5)$$

where I is the diffusion current constant observed, I_{corr}, that corrected for the viscosity, and η_{rel}, the relative viscosity[16]. The diffusion current constants in ammonium sulfate, however, were found lower by some 10% than those in other electrolytes. This is considered as due to the formation of ion pairs between hexamminechromium(III) ions and anions.

As is seen in Table V, the half-wave potentials vary by no more than a few millivolts when ammonium chloride is replaced by potassium chloride, provided that pH and ionic strength are kept constant. Similarly, the half-wave potential is almost independent of the hydrogen ion concentration of the solution (Table VI). These results indicate definitely

that there is no chemical reaction involving hydrogen ions, ammonium ions or ammonia preceding the electron transfer.

Summary

The reduction of hexamminechromium(III) ion at the dropping mercury electrode has been studied in neutral and acid aqueous solutions. Hexamminechromium(III) ion gives no well-defined d. c. polarographic wave in an unbuffered neutral solution, whereas in an acid solution it gives a well-defined two-step wave, the first wave corresponding to the reduction of chromium(III) to chromium(II) and the second, to that of chromium(II) to chromium-(0).

The first wave of the d. c. polarogram obtained in an acid solution is diffusion-controlled and gives a slope of the log-plot close to that expected for a reversible wave. The a. c. and the Kalousek polarogram, however, are of the irreversible type. No chemical reaction involving hydrogen ions, ammonium ions or ammonia takes place preceding the electron transfer. Considering these results, the following mechanism is temporarily suggested for the reduction of hexamminechromium(III) ions at the dropping mercury electrode:

$$[Cr(NH_3)_6]^{3+} + e \rightleftarrows [Cr(NH_3)_6]^{2+}$$

$$[Cr(NH_3)_6]^{2+} + n\,H_2O \longrightarrow [Cr(H_2O)_n(NH_3)_{6-n}]^{2+} + n\,NH_3$$

$$NH_3 + H^+ \rightleftarrows NH_4^+$$

Ionic Charge Effect on the Reduction Potential of Inert-type Metal Complex

By Nobuyuki TANAKA, Eiki ITABASHI and Eishin KYUNO*

(Received March 19, 1963)

It has been found that there is a relation between the half-wave potentials of polarographic reduction waves and the frequencies of the maxima of the absorption spectra of inert-type metal complexes. In the polarographic study of cobalt(III), chromium(III) and rhodium(III) complexes, Vlček[1] pointed out that the half-wave potentials of the reduction waves of $[MXY_5]$-type complexes were shifted to more positive values with an increasing difference in the position of ligands X and Y in the spectrochemical series, and that the plot of $E_{1/2}$ against $\Delta\nu$ gave a straight line. Maki, Shimura and Tsuchida[2], who studied the polarographic reductions of a number of cobalt(III) complexes, reached the same conclusion.

In the course of our studies of the electrode processes of chromium(III) complexes, we found that the repulsion and attraction between the electrode and the reducible species plays an important role in determining the reduction potential of the species. In contrast with oxalatocobalt(III) complexes[2], the reduction potentials of oxalatochromium(III) complexes were shifted to more negative potentials with an increasing number of oxalates coordinated. In this paper, the study of the polarographic reduction of various oxalatochromium(III) complexes is presented, and the relation of the reduction potential and the ionic charge is discussed.

Experimental

Current-potential curves were obtained with a pen-recording polarograph, Yanagimoto Galvarecorder Model AP-1, with an automatic potential scanner. The dropping mercury electrode used had an m value of 1.499 mg./sec. and a drop time, t_d, of 3.32 sec. as measured in an air-free 1 M potassium nitrate solution at -1.70 V. vs. SCE at 50 cm. of the mercury reservoir. The cell equipment used in this study was the same as has been reported

Results and Discussion

Current-potential curves of the oxalatochromium(III) complexes were obtained in various supporting electrolyte solutions. In acid solutions or acetate buffers only the monooxalato complexes gave a polarographic wave; this is considered to be due to the reduction from chromium(III) to chromium(II). One of the current-potential curves of monooxalatobis(ethylenediamine)chromium(III) is reproduced in Fig. 1. Di- and trioxalato complexes of chromium(III) gave no reduction wave at less negative potentials than the potential of the reduction of hydrogen ions. This is in agreement with the findings of Hamm and Davis[7], who reported that dioxalatodiaquochromate(III) gave no wave in the solution with an ionic strength of 0.3 containing potassium nitrate, nitric acid, 0.1 F potassim oxalate, and 0.005% gelatin.

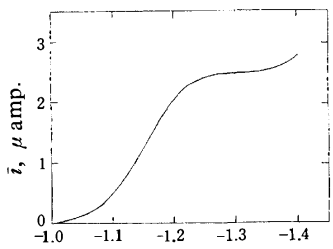

Fig. 1. Current-potential curve of 1.0 mM $[Cr(ox)(en)_2]I$ obtained in the solution containing 0.9 M KCl, 0.1 M acetate buffer and 0.005% gelatin at 25°C.

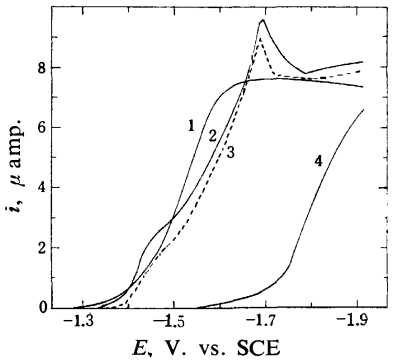

Fig. 2. Current-potential curves of 1.0 mM dioxalatochromate(III) complexes obtained in 0.3 M KCl solutions containing 0.005% gelatin at 25°C: 1, *cis*-$[Cr(ox)_2(H_2O)_2]^-$; 2, *cis*-$[Cr(ox)_2(NH_3)_2]^-$; 3, $[Cr(ox)_2(en)]^-$; 4, *cis*-$[Cr(OH)(ox)_2(H_2O)]^{2-}$.

The reduction waves of dioxalatochromate(III) complexes, therefore, were measured in neutral solutions. The examples shown in Fig. 2 were obtained with 1.0 mM of the complexes in solutions containing 0.3 M potassium chloride and 0.005% gelatin. Dioxalatodiaquochromate(III) gives a well-defined wave, as is shown in Fig. 2.

All attempts to obtain a polarographic wave of trioxalatochromate(III) ions were unsuccessful. No wave was obtained, even in a 0.1 M tetramethylammonium bromide solution. This leads to the conclusion that trioxalatochromate(III) is not reducible at the dropping mercury electrode in the possible range of potential.

Table I gives the potentials at $\bar{i}=\bar{i}_l/10$ (denoted as $\bar{i}_l/10$-potential) on the polarographic waves of mono- and dioxalato complexes. The use of half-wave potentials was avoided because of the irregular polarograms observed with most of the dioxalato complexes. Table I indicates that the monooxalato complexes give the $\bar{i}_l/10$-potential at approximately −1.05 ~ −1.1 V., the dioxalato complexes of univalent anions, at approximately −1.4 ~ −1.45 V., and the dioxalato complexes of divalent anions, at −1.67 V.

In oxalatocobalt(III) complexes, the half-wave potential shifts to more positive potentials with an increasing number of oxalates coordinated[2]; this shift is considered to agree

with the order of the spectrochemical series. In Fig. 3, the half-wave potentials of oxalatocobalt(III) complexes and the $\bar{i}_l/10$-potentials of oxalatochromium(III) complexes are plotted against the frequencies of the absorption band of the cobalt(III)[8] and chromium(III) complexes respectively. The absorption spectra of all the chromium(III) complexes were measured in this laboratory[9] except for that of the hydroxodioxalatoaquochromate(III) complex, which was obtained by Grant and Hamm[10].

It is interesting to note that, in the cobalt(III) and chromium(III) complexes, the absorption bands shift in the same direction with an increasing number of oxalates coordinated, whereas the reduction potentials shift in the opposite directions. The oxalatocobalt(III) complexes are reduced at the positively-charged electrode, whereas the oxalatochromium(III) complexes are reduced at the negatively-charged electrode. This indicates that the electrostatic effect between the reacting species and the electrode is one of the important factors in determining the reduction potential. In the case of chromium(III) complexes, the difference in repulsion between the reacting species and the electrode seems to cancel out the difference in ease with which one electron enters into the reacting chromium(III) species. These observations definitely suggest that the relationship between the reduction potential and the structure of the metal complex can be discussed only when the difference in the electrostatic interaction between the reacting species and the electrode can be disregarded or after an appropriate correction is made for the difference.

Summary

Current-potential curves of various oxalato complexes of chromium(III) were obtained at the dropping mercury electrode in acid or neutral aqueous solutions. The reduction potentials that were defined as potentials at $\bar{i}=\bar{i}_l/10$ were found to shift to more negative potentials with an increasing number of oxalates coordinated. The ionic charge effect on the reduction potentials was discussed in connection with the electrostatic interaction between the reacting species and the electrode.

The authors wish to thank the Japan Society for the Promotion of Science for the financial support granted to one of the authors (E. K.) in this research.

The Dehydrating Cyclization of S-Carboxymethyl-cysteine and N-Acetyl-S-carboxymethyl-cysteine

By Hitoshi OZAWA

(Received March 2, 1963)

It is well known that acidic amino acids and their peptides form ring compounds by dehydration between their β- or γ-carboxyl group and the α-amino group or adjacent imino group of peptide linkage. For instance, glutamic acid and glutamine can be converted to pyrrolidonecarboxylic acid[1]. Aspartyl-ε-lysine can form ε-(amino succinyl)-lysine when treated with concentrated hydrochloric acid. It is to be expected, therefore, that *S*-carboxymethyl-cysteine (SCMC), a reaction product of cysteine with iodoacetic acid, can cyclize in a similar way by dehydration between its amino group and the carboxyl group of the carboxymethyl moiety. This paper describes the formation of 3-oxo-5-carboxyperhydro-1, 4-thiazine (SCMC-lactam) from SCMC and *N*-Ac-SCMC.

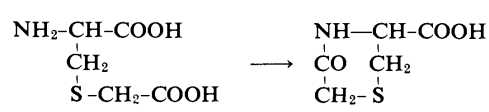
Experimental and Results

The Synthesis of SCMC.—A solution of 1.6 g. of cysteine in 30 ml. of water was neutralized with 1 N ammonium hydroxide. A solution of 2.9 g. of iodoacetic acid in 5.0 ml. of water was adjusted to pH 7.6 with 1 N ammonium hydroxide. Both solutions were mixed and left to stand for one hour. The pH value was kept at 7.6 by adding 1 N ammonium hydroxide occasionally. A small amount of precipitate produced during the reaction was filtered off, and this filtrate was passed through a column (3×15 cm.) of Amberlite IR-120 (hydrogen form) resin which was then washed thoroughly with water. The column was then treated with 1 N ammonium hydroxide. The acidic fraction showing a positive ninhydrin reaction was evaporated to dryness under reduced pressure. About 2 g. of SCMC (free acid) was obtained and recrystallized from water-ethanol. From the last fraction with a positive ninhydrin reaction, about 0.4 g. of the ammonium salt of SCMC was obtained. It was converted to the free acid by absorbing it on a column (4×20 cm.) of Amberlite IR-45 (acetate form) resin and eluting it with 2 N acetic acid. The preparation melted at 196~198°C. The overall yield was 95% of the theoretical.

The Synthesis and Properties of SCMC-lactam.—SCMC (400 mg.) was dissolved in water (5.0 ml.), and the pH brought to 4.8 by the addition of 1 N sodium hydroxide. The solution was then heated in a sealed glass tube at 110°C for 48 hr. and poured onto a column (1.5×15 cm.) of Amberlite IR-120 (hydrogen form) resin which was then washed with water (30 ml.). The filtrate and washings were combined and concentrated under reduced pressure. To a solution of an oily residue in a small amount of glacial acetic acid, ether was added drop by drop. Hexagonal crystals with a melting point of 182~183°C were obtained (about 260 mg., 74% of the theoretical).

Found: C, 37.68; H, 4.65. Calcd. for $C_5H_7O_3NS$: C, 37.26; H, 4.38%.

The compound was acidic and gave a negative ninhydrin reaction. When it was hydrolyzed with 1 N hydrochloric acid at 110°C for 1 hr., SCMC was recovered. The electrophoretic mobility was equal to that of pyrrolidonecarboxylic acid, as is shown in Fig. 3. The infrared absorption spectrum of the preparation is shown in Fig. 1, together with that of SCMC. From these results, it was concluded that SCMC-lactam was obtained as follows:



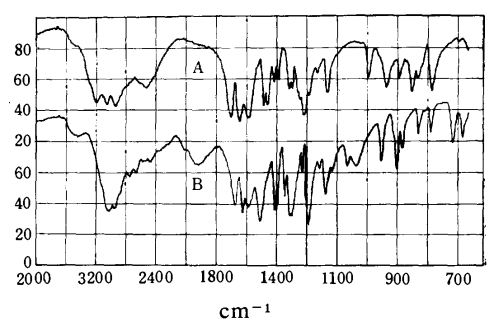


Fig. 1. Infrared absorption spectra of
A *S*-carboxymethyl-cysteine lactam
B *S*-carboxymethyl-cysteine

The Cyclization of SCMC under Various Conditions.—An aqueous solution of SCMC or of its mono sodium salt (1.0 mM) was heated at various temperatures for 1 to 48 hr., and the amount of amino acid remaining was estimated by the ninhydrin method of Yemm and Cocking[3]. The

* The following abbreviations are used: SCMC, *S*-carboxymethyl-cysteine; *N*-Ac-SCMC, *N*-acetyl-*S*-carboxymethyl-cysteine.

1) J. P. Greenstein and M. Winitz, "Chemistry of the Amino Acids", Vol. 3, John Wiley and Sons, Inc., New York (1961), p. 1937.

2) D. L. Swallow and E. P. Abraham, *Biochem. J.*, **70**, 364 (1958).

3) E. W. Yemm and E. C. Cocking, *Analyst*, **80**, 209 (1955).

results are summarized in Fig. 2. When SCMC was heated at 130°C, about 70% of the amino group disappeared in 1 hr., while no measurable reaction occurred at this temperature in the case of glutamic acid, in agreement with the report[4] that the rate of dehydration is very slow under these conditions. The disappearance of the ninhydrin positive substance, however, did not proceed to its completion. The paper chromatogram of the reaction mixture (*n*-butanol : acetic acid : water, 4 : 1 : 2, v/v) gave several ninhydrin positive spots, but no spot of SCMC, indicating that some side-reactions occurred in addition to the main cyclization reaction. When the reaction was carried out at 180°C, only 30% of the amino group disappeared, showing that the side reactions occurred to a larger extent. With SCMC mono sodium salt, the reaction rate was smaller, but the reaction proceeded to its completion. The paper chromatogram of the reaction mixture showed no by-products.

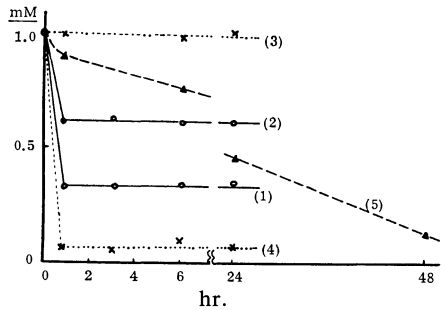

Fig. 2. Disappearance of amino group of *S*-carboxymethyl-cysteine (SCMC) and glutamic acid. Aqueous solution of SCMC (1.0 mM) was heated at (1) 130°C and (2) 180C° for 0 to 24 hr. and tested for ninhydrin reaction. (5) Solution of SCMC-mono sodium salt (1.0 mM) was heated at 110C° for 0 to 48 hr. Solution of glutamic acid (1.0 mM) was treated at (3) 130°C and (4) 180C°.

The Synthesis of *N*-Ac-SCMC.—SCMC (200 mg.) was suspended in water (1 ml.) and dissolved by neutralizing it with sodium hydroxide (4.0 M). Acetic anhydride (0.4 ml.) was added drop by drop to the solution, which was kept about pH 7.0 by adding sodium hydroxide (4.0 M). The reaction mixture, which showed a negative ninhydrin reaction on a filter paper, was diluted with water (20 ml.), passed through a column (1.5×15 cm.) of Amberlite IR-120 (hydrogen form) resin to remove the sodium ion, and evaporated to dryness under reduced pressure. *N*-Ac-SCMC was obtained as an oily residue. The electrophoretic mobility of the compound was similar to that of *N*-acetyl-aspartic acid (Fig. 3). The oily preparation was used as such for further experiments.

The Cyclization Reaction of *N*-Ac-SCMC.—*N*, *N'*-Dicyclohexylcarbodiimide (DCCD) (380 mg.) was added to a suspension of *N*-Ac-SCMC (120 mg.) in ethyl acetate (8.0 ml.) A massy precipitate was produced in ten minutes. After the reaction mixture had been kept at room temperature for two hr., glacial acetic acid (two drops) was added to decompose excess DCCD. Paper chromatography and paper electrophoresis of the reaction mixture showed acidic compounds upon its being sprayed with a 0.05% solution of bromcresol green in ethanol. The spot of the starting material, *N*-Ac-SCMC, was not detected. A large new spot with a somewhat smaller electrophoretic mobility (pyridine : acetic acid : water, 27 : 1 : 142, pH 6.0) and a larger R_f value (0.85 with *n*-butanol : acetic acid : water, 4 : 1 : 2) than SCMC-lactam was detected. Two minor spots with lower electrophoretic mobilities and R_f values were also observed (Fig. 3). The reaction mixture was evaporated to dryness under reduced pressure. The residue was mixed with 2.0 ml. of water, and the pH was adjusted to 9.0 with ammonium hydroxide (1.0 N). After the mixture had been left standing at 37°C for 30 min., the precipitate was centrifuged off and extracted twice with water; then the combined extract was evaporated to dryness in vacuo. The residue gave two spots, together with two other minor spots, by paper chromatography and paper electrophoresis, as is shown in Fig. 3. The main spot had the same electrophoretic mobility and R_f value as SCMC-lactam. The second spot coincided with *N*-Ac-SCMC. The water extract was poured onto a column (1.5×15 cm.) of Amberlite IR-45 (acetate form) resin. After washing with 1.0 N acetic acid (100 ml.), the column was eluted with 0.1 N hydrochloric acid. The crystals of SCMC-lactam were obtained by evaporating the eluate under reduced pressure and were identified by means of the infrared absorption spectrum. The cyclization reaction was also carried out under the following conditions: one mole of *N*-Ac-SCMC was treated (a) with 10 mol. of DCCD at 77°C for 2 hr., (b) with 3 mol. of DCCD at 77°C for 2 hr., or (c) with 10 mol. of DCCD at room temperature for 24 hr. There was no difference in the results.

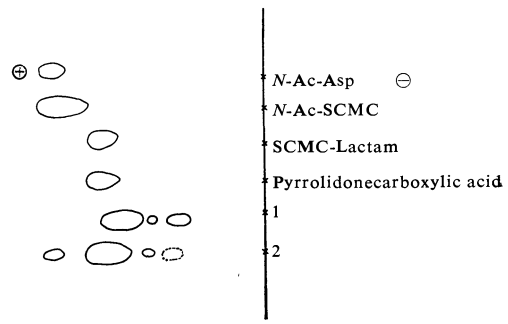

Fig. 3. Drawing of paper electrophoresis of *S*-carboxymethyl-cysteine lactam (SCMC-lactam), *N*-acetyl-SCMC and reaction products of *N*-acetyl-SCMC with *N*, *N'*-dicyclohexylcarbodiimide. 1: Direct dehydration products. 2: After treatment at pH 9.0. Electrophoresis was carried out at pH 6.0, 18 v/cm. for two hr. on Toyo-Roshi filter paper No. 51.

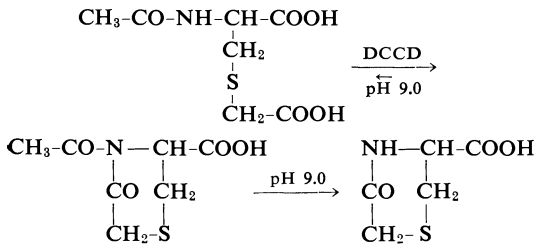
4) H. Wilson and K. Cannan, *J. Biol. Chem.*, **119**, 309 (1937).

SCMC-lactam was not formed when the aqueous solution of *N*-Ac-SCMC was heated at various temperatures (100~180°C) for 10 to 48 hr. Under these conditions, *N*-Ac-SCMC was completely decomposed. No SCMC-lactam was formed either when diethyl ester of *N*-Ac-SCMC was suspended in a 5% sodium hydrogen carbonate solution and heated at 80°C for two hours. The product obtained in this reaction was *N*-Ac-SCMC.

Discussion

SCMC cyclizes easily by dehydration to form 3-oxo-5-carboxy-perhydro-1, 4-thiazine (SCMC-lactam).

The same ring compound was also obtained from *N*-Ac-SCMC when the latter was treated with DCCD at room temperature for two hours and hydrolyzed at pH 9.0. The direct dehydration product of *N*-Ac-SCMC had a larger R_f value and a smaller electrophoretic mobility than SCMC-lactam. The course of the reaction may be explained as follows:



A minor part of the intermediate may be converted to the starting material under hydrolysis at pH 9.0.

An attempt to apply the cyclization reaction to the splitting of cysteine-containing peptides is now in progress.

Summary

S-Carboxymethyl-cysteine (SCMC) cyclizes by dehydration to form 3-oxo-5-carboxy-perhydro-1, 4-thiazine (SCMC-lactam) when the aqueous solution was heated at 110~180°C. SCMC-lactam was also obtained from *N*-acetyl-SCMC when the latter was treated with *N*, *N'*-dicyclohexylcarbodiimide and hydrolyzed subsequently at pH 9.0.

The author wishes to express his gratitude to Professor Nobuo Tamiya of the laboratory for his stimulating discussion and encouragement throughout this work. He is also grateful to Miss Keiko Tanno and Miss Hiroko Arai for their technical assistance.

Synthese von 3, 6-Disubstituierten 2-Oxopiperazinen

Von Mitsuo MASAKI und Masaki OHTA

(Eingegangen am 8. März, 1963)

Die Derivate des 2-Oxopiperazins sind bekanntlich in der Pharmazeutik[1], z. B. als Anticonvulsiva, Antihistaminica, Ataraktica oder Heilmittel auf das Zentralnervensystem brauchbar.

Während die in 3-Stellung substituierten 2-Oxopiperazine durch Umsetzung von Äthylendiamin mit α-Halo-[2], α-Oxy-[1-c] säureestern oder Cyanhydrin[3] hergestellt werden können, ist über die Synthese von 3, 6-disubstituiertem 2-Oxopiperazin noch nicht berichtet worden, mit Ausnahme von Tetrahydrodeoxyaspergillsäure (IV, $R_1 = s\text{-}C_4H_9$, $R_2 = iso\text{-}C_4H_9$), die bei der Reduktion[4] des Antibiotikums Aspergillsäure erhalten wurde.

In dieser Mitteilung wird eine Synthese von 3,6-disubstituierten 2-Oxopiperazinen (IV), die auf der Reduktivcyclisation von dem durch Umsetzung von α-Halo-oxim (I) mit Aminosäureester leicht erhaltenen *N*-(2-Oximinoalkyl)-aminosäureester (II) beruht, beschrieben.

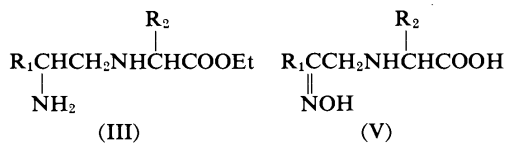
Schon sind die Reaktionen[5,6,7] von α-Chloroximen mit Piperidin und mit tertiären Aminen beschrieben worden, dagegen ist über Reaktion von α-Halo-oxim mit primärem Amin noch nichts berichtet worden.

Die Umsetzung von α-Brom- bzw. α-Chloroxim mit Aminosäureester gelang uns jedoch in Äther bei Raumtemperatur und ergab *N*-(2-Oximino-alkyl)-aminosäureester, aus denen 3-Isobutyl-6-propyl-, 3,6-Diisobutyl-, 3-Isobutyl-6-phenyl- und 3-Benzyl-6-phenyl-2-oxopiperazin synthesiert werden konnten.

Durch die Reduktion von 2-Nitro-1-penten mit Zinn(II)-chlorid in ätherischer Lösung[6] wurde 1-Chlor-2-oximinopentan (I-a) dargestellt, das leicht zersetzlich ist und sich als Piperidino-verbindung charakterisieren liess.

Durch Behandlung des Chlor-oxims (I-a) mit 2 Mol Leucinester in absol. Äther bei Raumtemperatur erhielten wir *N*-(2-Oximino-pentyl)-leucinester (II-a), der als die entsprechende Carbonsäure (V-a) charakterisiert wurde.



(III) (V)

Wenn man dabei als Chlorwasserstoffabspaltungsmittel *N*-Methylmorpholin benutzte, entstand *N*-Methylmorpholiumsalz des Chloroxims quantitativ und wurde Leucinester zurückerhalten, und beim Benutzen des Triäthylamins als dasjenige konnte kein definiertes Produkt erhalten werden.

Durch Reduktion von II-a unter Druck bei Raumtemperatur in Gegenwart von Raney-Nickel konnten wir 3-Isobutyl-6-propyl-2-oxopiperazin synthesieren, dessen Konstitutionsbeweis durch Elementaranalyse und IR-Spektrum erreicht wurde.

Wenn man Rücksicht auf Cyclisation[8] von δ-Amino-*n*-valeriansäure zum Piperidon nimmt, kann es leicht erwarten, dass sich die spontane Cyclisation des als Zwischenprodukt entstehenden *N*-(2-Aminopentyl)-leucinesters (III-a) ohne Erhitzen vollzieht, obgleich Aspinall[2a] beschrieben hat, dass beim Erhitzen auf 200°C der Ringschluss des bei der Umsetzung von Äthylendiamin mit α-Halo-ester als Zwischenprodukt entstandenen Diamino-esters auftritt.

In analoger Weise wie bei II-a liessen sich die Reaktionen von 1-Chlor-2-oximino-isohexan (I-b), das aus 2-Nitro-1-isohexen dargestellt werden kann, und von Phenacylbromid-oxim (I-c) mit Leucinester oder Phenylalaninester erreichen und ergaben *N*-(2-Oximino-isobutyl)-leucinester (II-b), *N*-(2-Phenyl-2-oximinoäthyl)-leucinester (II-c) und *N*-(2-Phenyl-2-oximinoäthyl)-phenylalaninester (II-d), die jeder für sich als die entsprechende Carbonsäure (V) charakterisiert wurden.

Bei der Reduktion lieferte II-b besonders leicht, wie bei II-a erwähnt wurde, das entsprechende 2-Oxopiperazin(IV-b), die Reduktivcyclisation von II-d zum 3-Benzyl-6-phenyl-2-oxopiperazin vollzog sich dagegen beim Erwärmen auf ca. 100°C. Die Effizienz der Reduktivcyclisierungsreaktion nimmt daher mit Austausch von aliphatischen durch aromatische Substituenten ab.

Über die pharmazeutische Aktivität der oben beschriebenen 3,6-disubstituierten 2-Oxopiperazine werden wir bald zusammen mit diejenige der anderen 2-Oxopiperazine berichten.

Beschreibung der Versuche

1-Chlor-2-oximinopentan (I-a).—Die Lösung des Reduktionsmittels liess sich dadurch erhalten, dass man 45 g krist. Zinn(II)-chlorid-dihydrat (96%) in 220 ccm absol. Äther, der 12 g Chlorwasserstoff enthielt, löste.

Eine Lösung von 17.3 g (ca. 0.15 Mol) 2-Nitro-1-penten[9] und 8 g Chlorwasserstoff in 150 ccm Äther wurde unter kräftigem Rühren und Kühlen im Eis/Kochsalz-Bad mit der oben beschriebenen Zinn(II)-chlorid-Lösung im Laufe von 4 Stdn. tropfenweise versetzt. Nach der Zugabe der Lösung des Reduktionsmittels wurde die Mischung noch 2 Stdn. weiter gerührt, dann mit Wasser im Scheidetrichter durchgeschüttelt. Die abgetrennte Ätherschicht wurde dreimal mit 1 N Salzsäure, einmal mit Weinsäure-lösung und anschliessend fünfmal mit Wasser gewaschen und über Natriumsulfat getrocknet. Der nach dem Abdampfen des Äthers verbliebene Rückstand wurde bei 77~86°C/10 mmHg destilliert. Ausb. 13 g (70%). Das bei 78~82°C/7 mmHg redestillierte α-Chlor-oxim ist leicht zersetzlich und scheidet bald farblosen Niederschlag ab.

Bei der Umsetzung mit Piperidin ergibt das Destillat 2-Oximino-1-piperidino-pentan vom Schmp. 66~67°C (aus Petroläther).

***N*-(2-Oximino-pentyl)-*N*-methyl-morpholiumchlorid.**—Dieses wurde bei dem Versuch zur Reaktion von I-a mit Aminosäureester in Gegenwart von *N*-Methylmorpholin als Chlorwasserstoffabspaltungsmittel erhalten.

Eine Lösung von 13.5 g I-a in 40 ccm absol. Äther liess man unter Rühren und Kühlen einer Lösung von 15.9 g L-Leucin-äthylester und 10.1 g *N*-Methylmorpholin in 100 ccm absol. Äther zutropfen, saugte das nach einnächtigem Stehen bei Raumtemperatur ausgeschiedene Salz ab und wusch mit absol. Äther. Farblose Prismen vom Schmp. 169~171°C (aus Äthanol). Ausb. 18 g.

Gef.: N, 11.62. Ber. für $C_{10}H_{21}O_2N_2Cl$: N, 11.89%.

***N*-(2-Oximino-pentyl)-leucin-äthylester (II-a).**—Eine Lösung von 63 g L-Leucin-äthylester in 200 ccm absol. Äther wurde mit einer Lösung von 26 g I-a in 100 ccm absol. Äther unter Kühlen und kräftigem Rühren versetzt und noch 30 min. weitergerührt. Bald begann Leucinesterhydrochlorid langsam sich auszuscheiden, dann wurde die Mischung bei Raumtemperatur (10~20°C) stehengelassen. Nach 8 Tagen filtrierte man das Salz ab, wusch mit absol. Äther, engte die vereinigte ätherische Lösung zu ca. 120 ccm ein, wusch dann mit Wasser und extrahierte dreimal mit je 50 ccm 3 N Salzsäure. Die einmal mit Äther gewaschene und dann mit Kohle behandelte salzsauere Lösung wurde mit Natriumcarbonat neutralisiert und ausgeäthert. Der Ätherextrakt wurde fünfmal mit Wasser gewaschen und über Natriumsulfat getrocknet. Beim Abdampfen des Äthers hinterblieb ein gelbliches Öl, das beim Stehen im Eisschrank erstarrte, doch sich durch weder Umkristallisation noch Destillation reinigen liess. Rohausb. 35 g (70%). Das Produkt wurde durch Verseifung zur freien Carbonsäure (V-c) charakterisiert.

Das Rohprodukt (2 g) wurde in einer Lösung von 2 g Kaliumhydroxyd in 8 ccm Wasser gelöst und über Nacht bei Raumtemperatur belassen. Am anderen Tage wurde die Lösung mit 40~50 ccm Wasser verdünnt, mit Kohle behandelt, filtriert und aus dem Filtrat durch langsames Eintropfen von 20-proz. Essigsäure die Oximino-aminosäure (V-a) in kristalliner Form ausgefällt. Ausb. 1.4 g. Farblose Nädelchen vom Schmp. 192~193°C (aus Methanol).

Gef.: C, 57.43; H, 9.95; N, 12.11. Ber. für $C_{11}H_{22}O_3N_2$: C, 57.36; H, 9.63; N, 12.17%.

3-Isobutyl-6-propyl-2-oxopiperazin (IV-a).—Zur Lösung von 2 g II-a in 60 ccm Äthanol gab man eine Aufschlammung von 1 g Raney-Nickel in 40 ccm Äthanol. Diese Mischung wurde bei Raumtemperatur im Rührautoklav bei 100 atm. Wasserstoff bis zur Druckkonstanz hydriert, dann durch Abfiltrieren vom Katalysator befreit und das Lösungsmittel auf dem Wasserbad unter vermindertem Druck entfernt. Der Rückstand wurde zweimal aus Petroläther umkristallisiert. Ausb. 0.8 g. Farblose Nadeln vom Schmp. 106°C. $[\alpha]_D^{18}$ −50.7° in Äthanol, c=1.06. IR-Spektrum in CCl_4: 3400, 3200, 3080, 1665 und 1470 cm^{-1}.

Gef.: C, 66.70; H, 11.26; N, 14.17. Ber. für $C_{11}H_{22}ON_2$: C, 66.62; H, 11.18; N, 14.13%.

***N*-(2-Oximino-isobutyl)-leucin-äthylester (II-b).**—Eine Lösung von 16.5 g 2-Nitro-1-isohexen[10] und 7 g Chlorwasserstoff in 130 ccm Äther wurde im Laufe von 4 Stdn. mit 38.5 g Zinn(II)-chlorid und 10.5 g Chlorwasserstoff, gelöst in 190 ccm absol. Äther, versetzt und dann analog wie bei I-a aufgearbeitet. 1-Chlor-2-oximino-isohexan (Sdp. 84~89°C/7.5 mmHg) wurde in Ausb. 12.5 g (65%) erhalten, aber nach der Destillation war das Produkt sehr unbeständig und wurde daher direkt weiter verarbeitet.

Die Lösung des erhaltenen Produkts in 80 ccm absol. Äther liess man unter Rühren einer Lösung von 26.5 g L-Leucin-äthylester in 120 ccm absol. Äther zutropfen und bei Raumtemperatur (10~25°C) stehen. Nach 9 Tagen wurde das Gemisch analog wie bei II-a aufgearbeitet und ein gelbliches viskoses Öl erhalten. Rohausb. 12.5 g. Ein Teil des Rohprodukts wurde versuchsweise in Stickstoff-atmosphäre bei 126~128°C/0.02 mmHg destilliert, wobei das gelbe Destillat sofort trübe wurde. IR-Spektrum in CCl_4: 3600, 1650 (-C=N-OH) und 1735, 1180, 1150 cm^{-1} (-$COOC_2H_5$).

Gef.: N, 10.11. Ber. für $C_{14}H_{28}O_3N_2$: N, 10.28%.

Beim analogen Verseifen wie bei II-a lieferte das Rohprodukt (2 g) die entsprechende Carbonsäure (V-b). Ausb. 1.5 g. Farblose Nadeln vom Schmp. 195~197°C.

Gef.: N, 11.42. Ber. für $C_{12}H_{24}O_3N_2$: N, 11.47%.

3,6-Diisobutyl-2-oxopiperazin (IV-b).—Eine Lösung von 4 g II-b in 100 ccm Äthanol wurde unter gleicher Bedingung wie bei IV-a reduziert. Ausb. 1.7 g. Farblose Nadeln vom Schmp. 105.5~106.5°C (aus Petroläther und dann n-Hexan). $[\alpha]_D^{18}$ −50.5° in Äthanol, c=1.00. IR-Spektrum in CCl_4: 3380, 3190, 3070, 1665 und 1465 cm^{-1}.

*Steady-state Studies by the ESR Method of the Photopolymerization of Vinyl Acetate and Methyl Methacrylate**

By Keiji KUWATA, Ko-ichi NISHIKIDA, Hiroshi KAWAZURA** and Kozo HIROTA

(Received March 20, 1963)

In the free radical-initiated photopolymerization of vinyl monomers, free radical intermediates paly an important role as chain initiators or chain carriers or both. In the kinetic studies[1] it has already been shown that both the rate and the degree of polymerization are closely related to steady-state concentration of the radical intermediates. It becomes important, therefore, not only to identify the free radical intermediates, but also to determine their concentration in the course of the reaction.

The use of the ESR method in identifying such radical intermediates in nonsteady-state photopolymerization has given us very useful knowledge about the initiating step[1-4], the propagating step[2-4] and the terminating step[3]. The structures of the decomposition products of initiators and those of both initiating and propagating free radicals formed by the reaction of the primary radical fragment of the initiator with monomers have been investigated.

It has now become possible to determine by the ESR method the rates of initiation, propagation, and termination steps on some plausible assumptions and also to determine the steady-state concentration of the radical chain carriers. Therefore, the steady-state study by the ESR method, as abopted by Piette et al.[5] in the photo-dissociation of some alkyl hydroperoxides, should be very effective in a detailed investigation of the kinetic process of the present photopolymerization.

By a comparison of the steady-state concentration determined experimentally with the one derived by a simple steady-state treatment of the polymerization, it will be possible to

analyze the kinetic data of polymerization. It is particularly important to reconsider the use of an average rate constant for various polymeric chain carriers of different molecular weights. Therefore, we attempted in the present investigation to apply such a steady-state method to the photopolymerization of vinyl acetate and methyl methacrylate, using hydrogen peroxide as the initiator; a reasonable accordance was found to exist between experiment and theory.

Experimental

Materials.—Commercial vinyl acetate and methyl methacrylate were repeatedly distilled and used. Commercial hydrogen peroxide (ca. 30%) was concentrated by vacuum-distillation up to ca. 90%.

Apparatus and Procedure. — To each monomer was added a small amount of enriched hydrogen peroxide so that the latter concentration became ca. 1 mol.%. The sample thus prepared was poured into a quartz tube in which a capillary tube, charged with diphenyl picryl hydrazil (DPPH) or ultramarine of a known spin concentration so as to serve as an analytical internal standard, has been set coaxially. The sample tube thus set up was repeatedly degassed in vacuo and was then sealed off.

Ultraviolet light from a high pressure mercury lamp (1 kW) was focussed with a quartz lens onto the sample tube, which had been inserted into a resonant cavity of a spectrometer. The spectrometer was a high frequency field modulation type, operated at 455 kc. The resonant cavity was a rectangular H_{102} one of the Ingram type and was dipped in a low temperature bath charged with liquid nitrogen as a coolant. The temperature in the cavity was measured with a thermocouple of copper versus constantan, its accuracy being ± 1°K. The temperature in the cavity was adjusted by controlling the level-height of the coolant. The design of this part of the cavity has already been published[6].

The Determination of Rate and Rate Constant. —Before the polymerization reached a steady state, the growth rate of the initiating radical* was measured at such a low temperature (ca. 100°K) that the recombination could be assumed completely quenched. Then, warming the sample up to the temperature where the radical concentration remained constant, i.e., when the steady-state polymerization was realized, the steady-state concentration of the radical was measured, and the rate of decay was determined at the same temperature by cutting off the irradiation source. The temperatures when the steady-state concentration was attained were 115°K for vinyl acetate and 180°K for methyl methacrylate.

The radical concentration was evaluated by comparing the intensity of the absorption of the radical with that of DPPH in the case of vinyl acetate. However, due to the closeness of g-factors between DPPH and the radicals, the two absorption spectra overlapped each other, thus lowering the accuracy of the concentration determination. In the case of methyl methacrylate, therefore, ultramarine ($g=2.030$) was used instead of DPPH.

Results and Discussion

It is shown by Fig. 1 that the initiating radical increases linearly with time in the case of vinyl acetate, though it is not clear if an induction period exists. Similarly, a linear relation was obtained also in the case of methyl methacrylate, as Fig. 2 shows. Assuming the initiation step of the photopolymerization to be of the zeroth order reaction*, the rate of radical growth can be determined from the slope of the curve in Figs. 1 and 2. Stricktly speaking, the radical concentrations

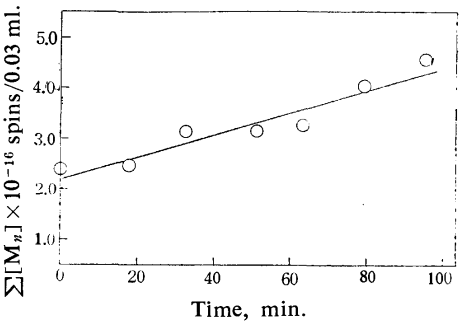

Fig. 1. Radical growth of vinyl acetate against irradiation time at 100°K.

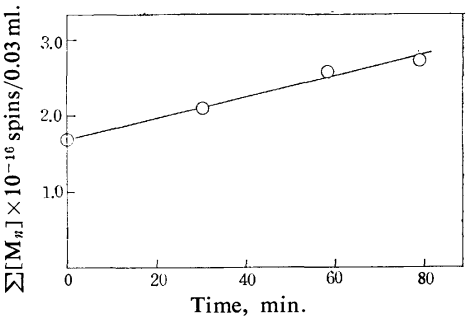

Fig. 2. Radical growth of methyl methacrylate against irradiation at 100°K.

6) K. Kuwata and K. Hirota, This Bulletin, 34, 458 (1961).

* It has been confirmed[4,7] that by irradiating such a system, occluding H_2O_2 at 77°K, an asymmetric signal appears which can be ascribed to the OH or O_2H radical, but if it is kept at 90~100°K, another signal increases its intensity and replaces the first one finally. The initiating radical in the present paper corresponds to the second signal.

7) K. Kuwata, T. Ichikawa and K. Hirota, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), 83, 652 (1962).

* This is due to the fact that the production of $\dot{M}$ is very fast compared with that of $\dot{X}$ in Eq. 1.

TABLE I. RATE CONSTANTS AND STEADY-STATE RADICAL CONCENTRATIONS

		Vinyl acetate	Methyl methacrylate
Rate of radical growth, v_l		$1.2_2\times10^{-5}$ molec./l./min.	$8.3_1\times10^{-6}$ molec./l./min.
Rate constant of radical decay, k_t		$2.7_1\times10$ l./molec./min.	$1.8_1\times10$ l./molec./min.
Steady-state radical concn. $\sum_n[\dot{M}_n]$	Obs.	$1.1_1\times10^{-3}$ molec./l.	$7.2_2\times10^{-4}$ molec./l.
	Calcd.	$6.7_1\times10^{-4}$ molec./l.	$6.7_8\times10^{-4}$ molec./l.
	% dev.	−40%	−8%

thus determined include that of the propagating radicals, but since their amount equals that of the initiating radical which disappeared, the above procedure to determine the rate of radical growth may be said to be justified. The procedure was applied to both monomers, and the rates of radical growth, v_l, obtained are described in Table I.

Next, the rate of the termination step was that determined in a similar manner by assuming the radical concentration decays only by way of the termination reaction of the second order. The rate constants of radical decay, k_t, thus obtained are shown in Table I. The decay rate is shown for vinyl acetate by Figs. 3 and 4, where the open circles denote the experimental values, while the curve is the calculated value. These rate constants correspond to the ones defined by the following reaction scheme:

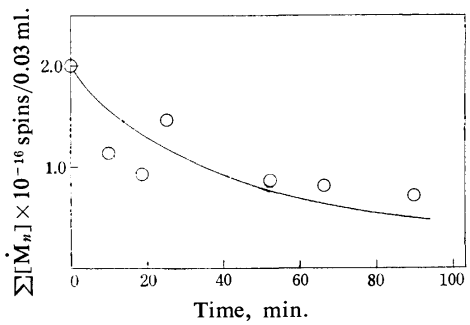

Fig. 3. Radical decay of vinyl acetate at 115°K.

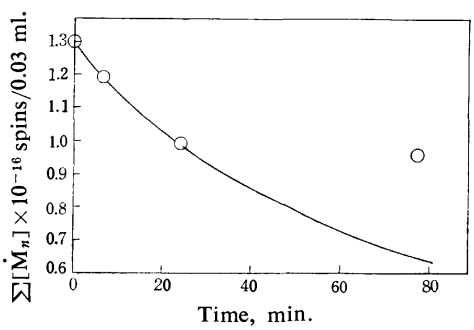

Fig. 4. Radical decay of methyl methacrylate at 180°K.

$$\left.\begin{array}{lll} \text{Initiator} \rightsquigarrow \dot{X} & & v_d=\phi I \\ M+\dot{X} \longrightarrow \dot{M} & & v_l=k_l[M][\dot{X}] \\ \dot{M}_{n-1}+M \longrightarrow \dot{M}_n & & v_p=k_p[M](\sum[\dot{M}_{n-1}]) \\ \dot{M}_n+\dot{M}_m \longrightarrow M_{n+m} & & v_{tc}=k_{tc}(\sum[\dot{M}_n])^2 \\ \dot{M}_n+\dot{M}_m \longrightarrow M_n+M_m & & v_{td}=k_{td}(\sum[\dot{M}_n])^2 \end{array}\right\} \quad (1)$$

Here, I is the light intensity absorbed by the initiator. k_t is defined by a sum of the rate constant of radical recombination, k_{tc}, and that of the disproportionation, k_d, between two propagating radicals $\dot{M}_n$ and $\dot{M}_m$, as shown by reaction scheme 1, i. e.,

$$k_t = k_{td}+k_{tc} \quad (2)$$

In Table I, the steady-state concentrations of the propagating radicals are compared with those calculated by Eq. 3, which employs a simple kinetic treatment[8]:

$$\sum_n[\dot{M}_n] = (v_i/k_t)^{1/2} \quad (3)$$

which exists among the steady-state concentration, $\sum_n[\dot{M}_n]$, of the propagating radical, the rate of radical growth, v_l, and that of termination, k_t.

Table I tells us that the steady-state radical concentrations calculated by Eq. 3 coincide well with those observed in the cases of both vinyl acetate and methyl methacrylate within a factor of two. This agreement seems to be surprisingly good if one considers that the errors occurred in the determination of the radical concentration and the rate of growth. There remains some doubt about the oversimplifications which were worked out in the simple kinetic treatment. In the calculation, only one decay constant is used as an average value for all the polymer radicals of different molecular weights. However, the observed decay curve corresponds to the one superposed by those of individual polymer radicals of different chain lengths. Therefore, the rate constant of radical decay determined on the assumption of simple second order kinetics

8) Cf. Ref. 1, p. 14; J. Laidler, "Chemical Kinetics", McGraw Hill Book Co., Inc., New York (1950), pp. 345—364.

ought not to be used over a wider range of the progress of reaction. Actually, the calculated curve of MMA polymerization (Fig. 4) deviates gradually from the observed values as the polymerization proceeds, i. e., as the chain length of the polymer radical becomes larger. This is probably due to the fact that the reaction rate decreases with the chain length of the polymerizing radicals. A similar tendency seems to occur in the case of VAc as well (Fig. 3), though it cannot be observed so clearly.

There are some modifications of the treatment regarding the direction which will give a more exact feature concerning the radical decay in the case of radical polymerization[9]. However, it can be shown as above that the simple kinetic treatment retains its usefulness in such a limited case of the liquid state photopolymerization at a low temperature as in the present research. One of the reasons why such an accordance was realized seems to be because the error in the determination of the decay rate was canceled out, together with the errors in the determination of the growth rate.

Summary

It has been attempted, by the ESR technique, to study the steady-state photopolymerization of vinyl acetate and methyl methacrylate, using hydrogen peroxide as the initiating substance. The observed steady-state radical concentration has been found to coincide within a factor of two with the calculated value, Eq. 3, derived under the assumption of a simple kinetic treatment. Although, it has been shown that the calculated decay curve deviates from the observed curve in the later period of decay, especially in the case of methyl methacrylate; such a discrepancy seems to be explainable if the reaction rate decreases with the chain length of the polymerizing radicals.

A part of the expense of this research has been defrayed by a special grant given us by the Ministry of Education to which our thanks are due.

The Thermal Annealing of Phosphorus-32 Formed by the Neutron Irradiation of Several Inorganic Phosphorus Compounds

By Hiroshi BABA, Kichizo TANAKA and Kenji YOSHIHARA

(Received April 6, 1963)

The distribution of chemical forms of phosphorus-32 in neutron-irradiated phosphorus compounds has been reported on by several investigators[1-8]. It has been found that these phenomena are very complicated. It seems important to solve the problem that the proportions of the different chemical species of phosphorus-32 appear to depend on various complicated factors: the effect of thermal annealing, which has proceeded during and after the neutron irradiation, the chemical form of the target materials[9], and the circumstances during neutron irradiation[10]. The change in the distribution of phosphorus-32 in various chemical forms after neutron irradiation of phosphorus compounds has been pointed out by Lindner and Harbottle[11] and also by Yoshihara and Yokoshima[12]. They treated the

irradiated salts at room temperature and suggested a specific interpretation of the change in the proportion of the distributed chemical species. Claridge and Maddock[13] have performed thermal annealing experiments using the precipitation method for the separation of chemical species and have suggested an increase in retention and in the threshold temperature as the result of thermal annealing.

Green and Maddock[14] first found that the retention in the Szilard-Chalmers process was increased by the thermal annealing of heating-irradiated chromates. The activation energy for this process has been shown by Harbottle and Sutin[15] to be the energy of the recombination reaction of fragments formed by recoil phenomena. In their treatment for thermal annealing, the term of the change of the retention meant the composite process of change in all the species chemically distributed. In the case of phosphorus recoil chemistry, however, such a treatment of " retention " may give somewhat ambiguous results in the analysis of the given annealing curves.

In a previous communication[16] the present authors pointed out the different behaviour of the different fractions of phosphorus-32 upon thermal annealing. It should be considered that the activation energy of the thermal annealing process of each fraction differs from that of the retention.

In this paper, the authors will describe a detailed study of the thermal-annealing effect of phosphorus-32 in the distributed chemical species with several anhydrous inorganic phosphates and pyrophosphate in crystal, and will report their findings on the activation energies of separated fractions of phosphorus-32.

Experimental

Target Materials.—The sodium dihydrogen phosphate and sodium dihydrogen phosphite used were guaranteed reagents of the Wako Chemicals Co. while the disodium hydrogen phosphate, potassium dihydrogen phosphate, sodium pyrophosphate, and disodium hydrogen phosphite were guaranteed reagents of the Kanto Chemicals Co. Each of these hydrated salts, except potassium dihydrogen phosphate and sodium pyrophosphate, was dehydrated upon heating in a porcelain dish, and evaporating it to near dryness. All salts were dried in vacuo at 100°C for one night over phosphorus pentoxide. Anhydrous trisodium phosphate was prepared from $Na_3PO_4 \cdot 12H_2O$ in the same way. The content of sodium or potassium ions in these salts was determined by flame photometry using a Perkin-Elmer flame photomater. The purity of anions was tested by activation analysis as follows: a small portion of each salt was dissolved in water and was subjected to paper chromatographic separation. Dried paper strips were irradiated in a nuclear reactor, and were cut to pieces 1 cm. in width. The radioactivity was counted by a GM counter 2 weeks after the end of the neutron irradiation. The purity was calculated from the percentage of the radioactivity of the fraction at the corresponding position on the strips. The results are tabulated in Table I.

Table I. Purity of target materials

Target material	Anionic %	Cationic* %
NaH_2PO_4	96	99
Na_2HPO_4	99	99
Na_3PO_4	99	60
$Na_4P_2O_7$	88	99
Na_2HPO_3	98	—
KH_2PO_4	94	—

* Purity as corresponding molecular form.

Neutron Irradiation.—The irradiations were mainly performed in the irradiation hole No. 12 (a vertical hole; thermal neutron flux 4.8×10^{11} n/cm^2·sec.) of JRR-1 (a water boiler reactor operated at 40 kW) for 15 hr. The salts which had been sealed in polyethylene tube in the presence of air were placed in an ambient reactor temperature. After being stored for 1 week at room temperature, the salts were subjected to thermal-annealing experiments. For irradiation and storage, all of the salts were maintained in as constant a condition as possible in order to avoid a change in the initial distribution of phosphorus-32 species.

Thermal-Annealing and Chemical Separation.—The irradiated salts were heated in a quartz boat (size: $10.5 \times 1.2 \times 1.2$ cm^3) which was placed in a thermostatically-controlled electric furnace (a quartz cylinder 2.4 cm. in diameter was used for heating the samples). The samples were inserted at the center of the cylinder, and a Pt-Rh thermostat was operated at the same time. A small portion of the heated samples in the boat was taken into the small water-cooled glass bottle at definite time intervals and was dissolved in a sufficient volume of water.

The separation and identification of the chemical species of phosphorus-32 were accomplished by paper chromatography. Two methods were tried for separation. One of them was that reported previously by one of the present authors, using the Toyoroshi No. 53 (2 cm. × 40 cm.) to separate the polyphosphates and orthophosphate fractions. One drop of the sample solution was put on filter paper (5 cm. from the end of the strip), dried in air, and developed by the one-dimensional ascending method with 2 N nitric acid-saturated *n*-butanol for about 24 hr. Another method was chosen to separate the fraction in such reduced species as phosphite and

—◎— Sodium dihydrogen phosphate at 200°C
—●— Disodium hydrogen phosphate at 150°C
—○— Disodium hydrogen phosphate at 200°C
For trisodium phosphate, sodium pyrophosphate and disodium hydrogen phosphite no change of chemical species is observed by heating at 200°C for 230 hr.

hypophosphite from the bulk of the neutron-irradiated salts. Pretreated filter paper was used in this case; the paper was preliminarily immersed into a solution of dilute hydrochloric acid for 1 day, soaked with redistilled water for another day, washed repeatedly with water, and dried in air; it was then developed with a mixture of 1 N ammonia, dioxane, and *n*-butanol (1 : 1 : 1 volume ratio) for 20 hr.

Counting Procedure.—After developing and drying, the paper was cut into pieces 1 cm. in width. The radioactivity of the pieces was measured by a thin end window-type GM gas flow counter at a constant geometry. Decay curves were drawn for all salts. Counting was started at least 10 days after the end of neutron irradiation in order to avoid errors besed on the radioactivity of sodium-24 or potassium-42. The gamma ray spectra of salts were measured with a NaI scintillation spectrometer in order to verify the absence of other activities.

A Test of the Pyrolysis of the Target Materials.—The target materials, which had not been neutron-irradiated, were heated under the same conditions as in the thermal-annealing experiments but for a comparatively prolonged time. The heated samples were dissolved in water, and the anions were separated by paper chromatography with 2 N nitric acid-saturated *n*-butanol. The strip of paper was dried in air and was subjected to neutron irradiation in a reactor. The radioactivity on the paper was counted with a GM counter 2 weeks after the end of neutron irradiation, and the percentage of the fraction of polyphosphate was estimated. Figure 1 shows the pyrophosphate formed by heating sodium dihydrogen phosphate and disodium hydrogen phosphate at 150~200°C versus the heating time. The formation of neither such higher polyphosphates as tripolyphosphate, tetrapolyphosphate and Grahams' salt, nor such reduction products as phosphite and hypophosphite was detected in any of the salts used here.

Results and Discussion

Figures 2 and 3 are histograms of paper chromatography showing the distribution of phosphorus-32 in various chemical species. The results obtained by development with nitric acid-saturated *n*-butanol are shown in Fig. 2, while those obtained by development with the mixture of 1 N ammonia, dioxane and *n*-butanol are shown in Fig. 3. The several peaks found in the histograms are noted as A, B, C, etc.

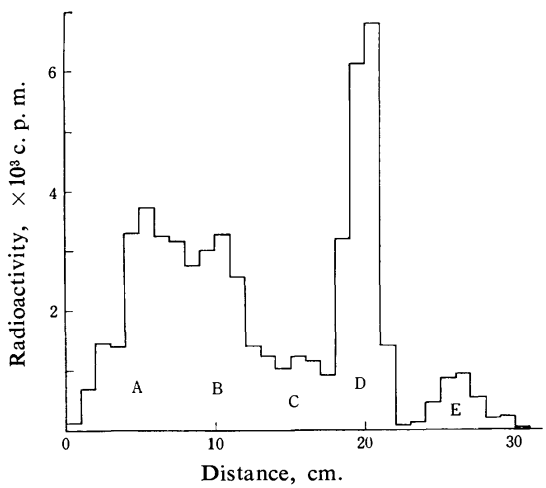

Fig. 2. Chromatographic separation of neutron irradiated disodium hydrogen phosphate with 2 N nitric acid saturated *n*-butanol.

From the R_f value in the chromatograms, it is indicated that the A and B fractions corresponded to the mixture of such higher polyphosphates as tripolyphosphate and polymerized metaphosphates. Pyrophosphate was found in C fractions and orthophosphate, in D fractions. A mixture of phosphite and hypophosphite appeared in E fractions. The separation among A, B and C fractions was not very significant, so the sum of A, B and C was identified as a polyphosphate fraction. In the case of pyrophosphate salt, the sum of the A and B fractions was denoted as a polyphosphate fraction. The E fraction was noted as a reduced species fraction, and D, as an orthophosphate fraction. These assignments were also expected from the results of other experiment[17]. The percentage of the F fraction is equal to the sum of A, B, C and D, the percentage of the E fraction also corresponds to the sum of G and H, while the G fraction can not be identified as phosphite because a low R_f value of the G fraction compared with that of phosphite is obtained. The R_f value of the H fraction is in agreement with that of hypophosphite.

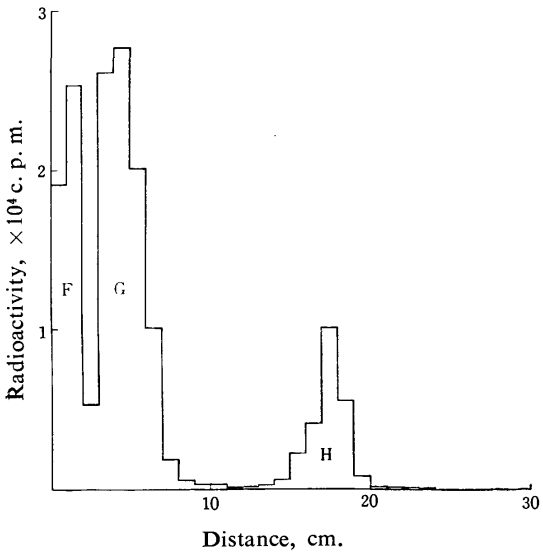

Fig. 3. Chromatographic separation of neutron irradiated disodium hydrogen phosphite with mixed solution (1 : 1 : 1) of 1 N ammonia, dioxane and *n*-butanol.

The samples irradiated in a nuclear reactor were heated in the temperature range of 85~200°C. Similar annealing curves were obtained from all of the orthophosphate salts used. Typical examples of these annealing against the logarithm of time are shown in Figs. 4, 5 and 6. The proportion of phosphorus-32 in the fraction is registered on the ordinate, while on the absissa the heating time is given in minutes. The percentage of the activities in the polyphosphate fraction decreases remarkably, while only a slight decrease is observed in the case of the reduced-species fractions. However, retention as orthophosphate always increases. The annealing curves given from sodium pyrophosphate are very similar to that of orthophosphate salts, but the orthophosphate fraction is a little changed. In the case of sodium phosphite, quite different annealing behavior is observed. Retention as the phosphite fraction increases while an increase in the hypophosphite fraction occurs at the same

time, and only a decrease in the polyphosphate fraction is shown. The composition of the polyphosphate fraction may differ from that of the polyphosphate fraction in phosphate crystals. The results obtained from each of the irradiated salts are shown in Figs. 7 and 8.

For thermal annealing in every salt used here except sodium dihydrogen phosphite, the amount of the increase in retention corresponded to the sum of the decrease in the other fractions. From the results with orthophosphate and pyrophosphate salts, it is found that there is some difference in the annealing behavior between polyphosphate and reduced species. At the initial step, the majority of annealing reaction consists of the reaction of the polyphosphates fraction. This is also found in the case of the phosphite sample. The annealing effect of the reduced species fraction gradually becomes more predominant on prolonged heating.

Fletcher and Brown[18] assumed that the thermal annealing was represented by an expression in which t/τ was the ultimate variable. In this case τ was arbitrarily chosen. In order to obtain a composite annealing curve, the temperature interval was pursued more precisely that of the above experiments. In this treatment we found, that these curves showed the temperature dependency of the annealing behavior. An equivalent annealing curve for 165°C for potassium dihydrogen phosphate is shown in Figs. 9 and 10. These curves show that there might be little difference in the annealing kinetics in this temperature range since a good overlapping of all the curves is to be seen here. The curves given from the change in the proportions of the polyphosphate fraction are each compared with some of different orthophosphate samples in

Fig. 11. On the ordinate the initial proportions of the polyphosphate fraction in irradiated phosphates are plotted as a unity. There are some differences in the annealing curves given from the orthophosphate samples used. However, no definite dependency on the chemical forms of the target materials is found.

It has been found by many investigators that thermal annealing can be described formally by first order kinetics at the initial step of annealing and then followed by second order kinetics. Our results can not accurately be fitted to a definite order of kinetics. For the determination of the activation energy we have adopted Vands' concept[19] as amplified by Primak[20]. If it is assumed that the kinetics can be explained by processes with distributed activation energies, the approximate initial distribution of the activation energy, P_o, for the percentage changes in fractions are given by $(-1/\boldsymbol{k}T)\mathrm{d}p/\mathrm{d}(\ln t)$ vs. $E_o=\boldsymbol{k}T\ln(B_f\,t)$, where E_o is the activation energy in eV., p is the fraction annealed at the time t, B_f is a constant having the dimension of frequency, $\boldsymbol{k}$ is Boltzman's constant, and T is the absolute temperature. This treatment has already been adopted by several authors[15,21,22]. The B_f factor was taken as the best overlapping of successive annealing curves. The estimated values of B_f are described in Table II. The initial distribution of activation energies is plotted in Figs. 12—17. The activation energies of the annealing of the polyphosphate fraction are mostly distributed between 0.60 and 1.0 eV.,

except for the pyrophosphate sample, in which the polyphosphate fraction is annealed with the activation energy distributed between 0.78 and 1.3 eV. Much larger errors are found when the B_f factor is obtained from the annealing of the reduced species fraction because the annealing conditions are limited. However, it is clear that the activation energies of these fractions are distributed higher than that of the polyphosphate fraction. These distribution curves are given in Figs. 13 and 15. The distribution curve starts at 1.4 eV. for disodium hydrogen phosphate and 1.1 eV. for potassium dihydrogen phosphate.

In Fig. 19 the distribution of activation energies for the annealing of the polyphosphate fraction is compared with that of retention as orthophosphate in the case of three kinds of orthophosphate samples. It is found that the distribution curves given from the thermal annealing of retention are very similar to those of the polyphosphate fraction. This means that the distribution curve of activation energy given from the thermal annealing in retention shows only the majority of the fractions annealed, so the annealing behavior seems to be quite different from each particular fraction annealed. Therefore, in the annealing of the phosphate samples used it is possible that the results obtained from the thermal annealing of retention indicate a composite of discrete thermal annealing curves. There would be some advantage in separating the species more elaborately.

The proportions of phosphorus-32 in the polyphosphate fraction show an abnormal increase on prolonged heating at 167 and 200°C in the case of the sodium dihydrogen phosphate and disodium hydrogen phosphate samples. This change is attributed to the formation of pyrophosphate by the pyrolysis of salts shown in Fig. 1. This is confirmed by the activation analysis of chromatographically-separated paper strips after the decaying out of phosphorus-32.

Summary

Thermal annealing curves given from the chemically-distributed phosphorus-32 formed by neuton irradiation in a nuclear reactor were obtained by heating several orthophosphates, sodium pyrophosphate, and disodium hydrogen phosphite samples in crystal. The separation was accomplished by one-dimensional paper chromatography. The amounts of phosphorus-32 in the chemical species different from the parent species decreased upon the heating of the salts, except in the case of sodium dihydrogen phosphite, whereas retention always increased.

By the analysis of thermal annealing curves obtained from the initial distribution of activation energies, it was found that there was a difference between the thermal-annealing behavior of the polyphosphate fraction and that of the reduced species fraction. The activation energies of the polyphosphate fractions were in the range of 0.60 to 1.0 eV., but the pyrophosphate sample showed an exceptionally high value, i. e., 0.78 to 1.3 eV. Higher activation energy values were estimated for the annealing of the reduced species fraction than for those of the polyphosphate fractions.

The authors wish to express their deep gratitude to Dr. Kenjiro Kimura, the Director of this Institute, and to Professor Nobufusa Saito of The University of Tokyo, for their guidance and valuable suggestions. Their thanks are also due to Dr. Nagao Shibata and Dr. Hiroshi Amano for their encouragement throughout this work.

ESR Studies on Negative Ions of Biphenyl Derivatives. I. Electron Spin Resonance Hyperfine Spectra of 4-Methyl Biphenyl and p, p'-Bitolyl Mononegative Ions

By Kazuhiko ISHIZU

(Received January 30, 1963)

The electron-spin resonance spectra of biphenyl mononegative ions have been observed by several investigators[1-3], however, those of the derivatives have not yet been studied extensively. In order to study the effect of methyl-group substitution on the spin densities at biphenyl ring carbons, the author synthesized 2-methyl, 3-methyl, 4-methyl, *o*, *o'*-bitolyl, *m*, *m'*-bitolyl and *p*, *p'*-bitolyl and the electron-spin-resonance hyperfine spectra of these mononegative ions were observed. The findings about the ESR spectra of 4-methyl biphenyl and *p*, *p'*-bitolyl will be presented in this paper.

Experimental

Solvents and Reducing Agents.—Each mononegative ion was made in a solution of either tetrahydrofuran (THF) or dimethoxyethane (DME) by reduction with potassium metal. These solvents were purified by the method described by Deguchi[4].

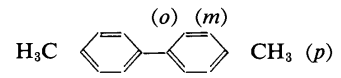
Spectrometer.—The ESR spectrometer employed was a high-resolution apparatus (type JES-3B) constructed by Japan Electron Optics Lab. Co., Ltd; its maximum resolution is about 30 milligauss. The operating frequency of the klystron was about 9470 Mc./sec. The magnetic field was modulated at a frequency of 100 kc./sec. and at a modulation width of about 100 milligauss. An aqueous solution of peroxylamine disulfonate[5] was used as a standard for the *g*-value and the magnetic field.

Overall widths were measured between the points where the resonance signal could just be distinguished from the noise level.

Results

***p, p'*-Bitolyl Mononegative Ion.**—The observed spectra measured in THF and DME are shown in Fig. 1(a) and Fig. 1(b) respectively.

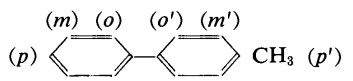
In both cases, the hyperfine structures of these spectra were identical, and the overall width was 46.7 gauss. The *g*-value was 2.0025.



The observed spectra consisted of seventeen groups, each split further into several hyperfine lines. In order to analyze the hyperfine structures of the observed spectrum, we assumed by referring to the spin densities on the carbon atoms of the biphenyl ring as calculated by Hückel's MO treatments (as shown in Fig. 1(d), that the hyperfine splitting coefficients of the six protons in the two methyl groups attached to the para-positions (ΔH_p), these of four-ring protons at the ortho-positions (ΔH_o), and those of four-ring protons at the meta-positions (ΔH_m) were equal to the following values: $\Delta H_p = 5.63$ gauss, $\Delta H_o = 2.66$ gauss, and $\Delta H_m = 0.51$ gauss. Thus, one can explain almost all the hyperfine structures of the observed spectra fairly well. The relative intensities of these hyperfine lines calculated on the basis of this assumption are shown in Fig. 1(c).

The spectra constructed on the basis of calculated spin densities are shown in Fig. 1(d). The observed and calculated spectra were in fairly good agreement in this case.

4-Methyl Biphenyl Mononegative Ion.—The observed spectra measured in THF and DME are shown in Fig. 2(a) and Fig. 2(b) respectively.



Although the shapes of hyperfine structures observed in THF were different from those in DME, inspite of the concentration having been adjusted in a number of ways, the overall width was 33.6 gauss, and the *g*-value was 2.0024 for both samples.

As shown in Fig. 2(a) and Fig. 2(b), the observed spectra consisted of thirteen groups, each of which split alternately into eight or nine hyperfine lines, while the terminal groups split into only a few hyperfine lines.

The line spacing of these hyperfine lines in each group of the spectra was equal to 0.32 gauss. In order to explain the structures of

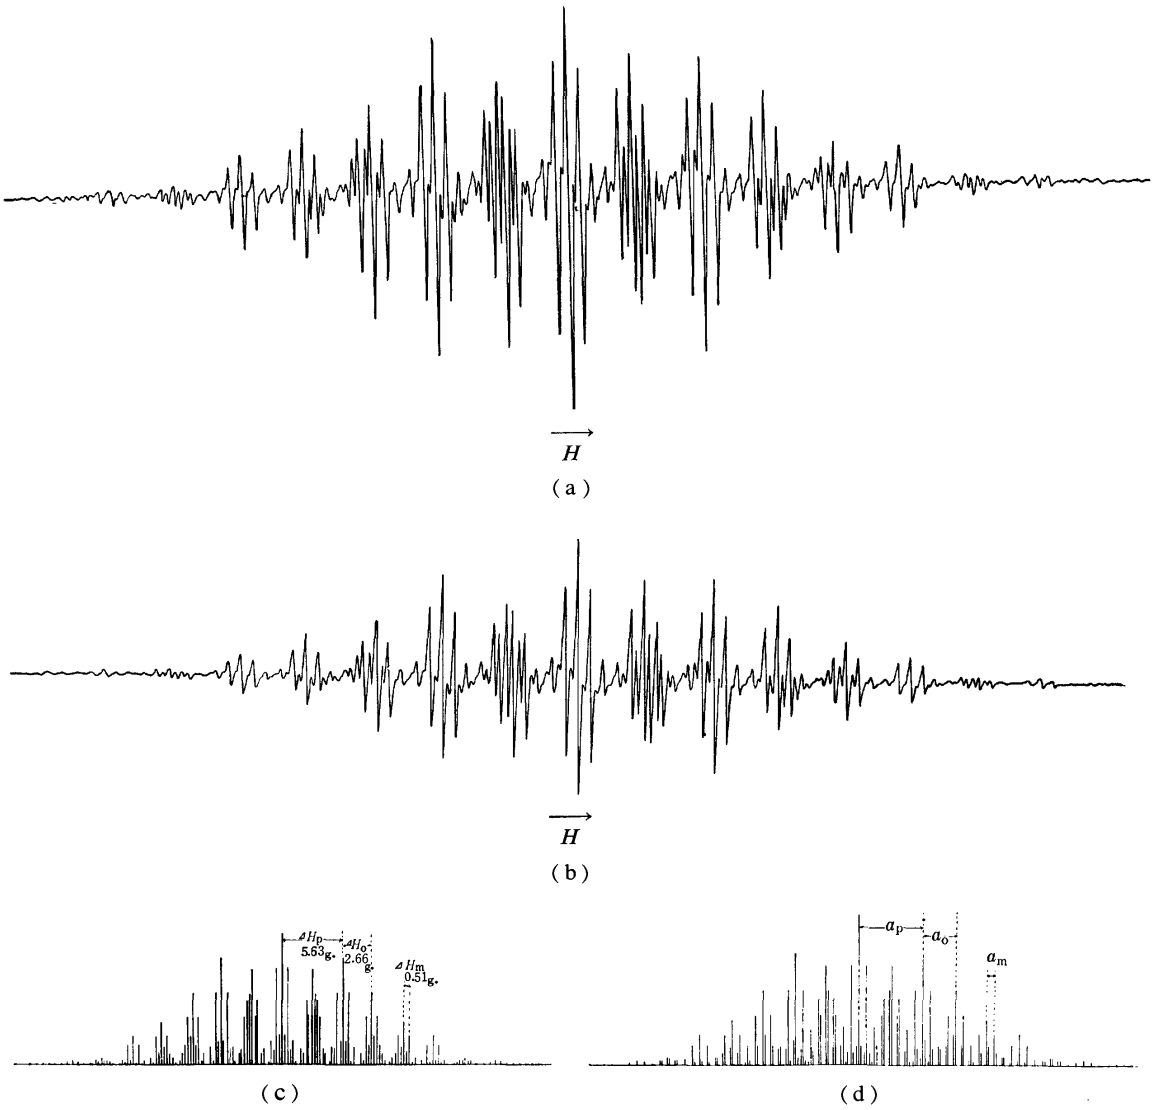

Fig. 1. *p,p'*-Bitolyl mononegative ion.
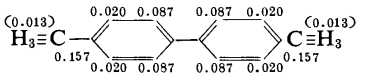
(a) and (b): ESR spectra in THF and DME
(c) and (d): Intensity diagrams constructed based upon experimentally determined and theoretically calculated spin densities



the observed spectra, the author at first assumed, by referring to the spin densities on the carbon atoms of the biphenyl ring as shown in Fig. 2(d) predicted by Hückel's MO calculations, that the splitting coefficients of each methyl proton and of a ring proton at the para-position (ΔH_p, $\Delta H_p'$) were almost equal, and that the splitting coefficient ratios of methyl protons and of each ring proton at the para-, ortho and meta-positions were nearly equal to 8:4:1.

Thus, one can explain that the observed spectra consisted of thirteen groups. In this case, however, it was difficult to explain the details of the hyperfine structures of the observed spectra thoroughly. In order to account for the details of the hyperfine structures, the author paid attention to those of the terminal and the next inner groups of the spectrum, since few overlaps of the hyperfine lines would occur among them. Each of the terminal groups and each of the next inner groups in

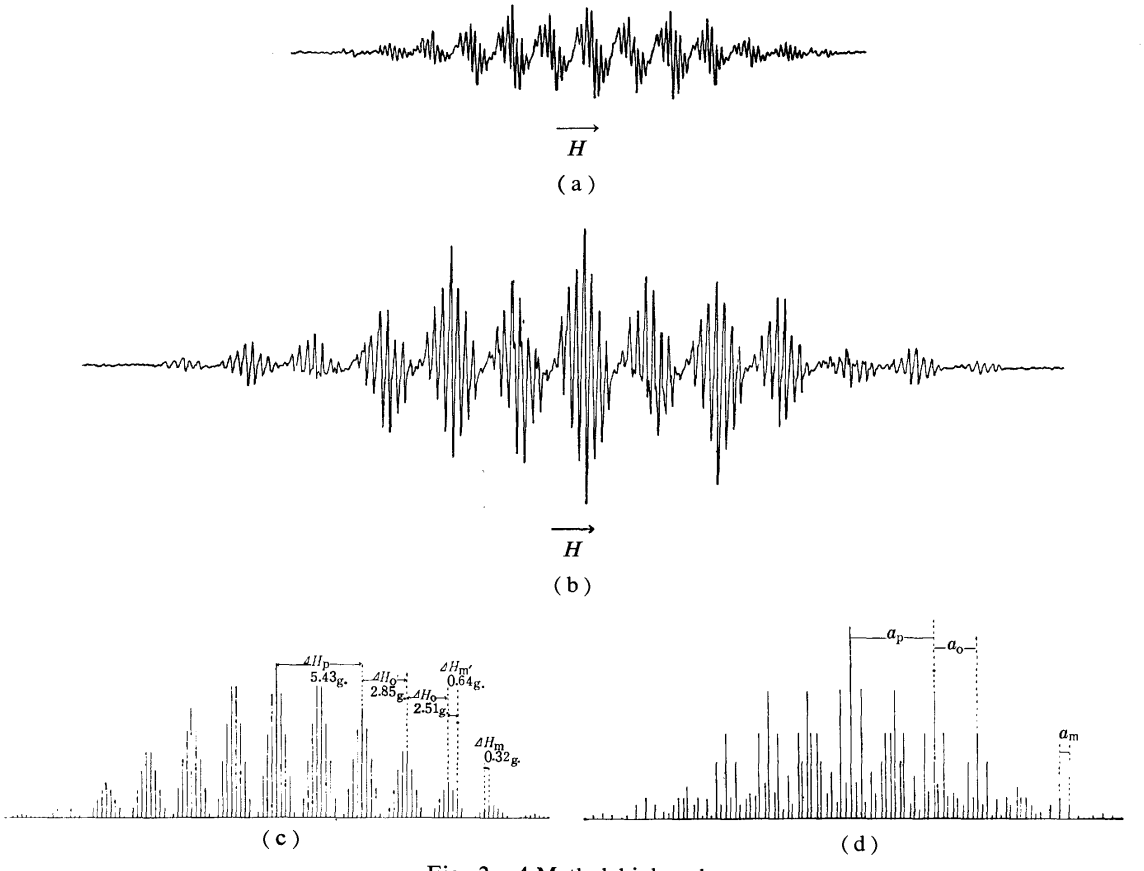


Fig. 2. 4-Methyl biphenyl.
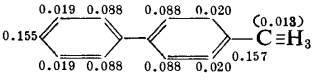
(a) and (b) : ESR spectra in THF and DME
(c) and (d) : Intensity diagrams constructed based upon experimentally determined and theoretically calculated spin densities



the spectra consisted of seven and eight lines respectively, and their relative intensity ratios were 1 : 2 : 3 : 4 : 3 : 2 : 1 and 1 : 3 : 5 : 7 : 7 : 5 : 3 : 1.

On the basis of these relative intensity ratios of the hyperfine lines in the terminal groups, the author assumed that the splitting-coefficient ratio in both pairs of ring protons at the meta-positions ($\Delta H_m' : \Delta H_m$) was equal to 2 : 1. Moreover, since the hyperfine structures of the terminal groups and the next inner groups were different from each other, we assumed finally that the splitting coefficients of both pairs of ring protons at the ortho-position would have different values ($\Delta H_o'$ and ΔH_o) respectively, and that the difference between these values ($\Delta H_o' \sim \Delta H_o$) was equal to 0.32 gauss. Thus one can explain the hyperfine structures of the next inner groups from one end group by considering it as an overlap of two groups of hyperfine lines which have intensity ratios equal to those of the terminal groups.

In this case, one cannot determine which is larger $\Delta H_m'$ or ΔH_m and $\Delta H_o'$ or ΔH_o, but we assumed that $\Delta H_m'$ is larger than ΔH_m, taking into account the results of Hückel's MO calculations, and that $\Delta H_o'$ is larger than ΔH_o, considering the electron inductive effects due to a methyl group.

Putting together these assumptions in the manner described above, the arithmetic ratios of the splitting coefficients, ΔH_s, of each methyl, para, ortho and meta-protons were determined as follows:

$\Delta H_p : \Delta H_o : \Delta H_m' : \Delta H_o : \Delta H_m = 19 : 10 : 9 : 2 : 1$.

The relative intensities of the hyperfine lines thus constructed are shown in Fig. 2(c). The measured values of the splitting coefficients of each proton were as follows:

$\Delta H_p = 5.43$, $\Delta H_o' = 2.85$, $\Delta H_o = 2.51$, $\Delta H_m' = 0.64$, $\Delta H_m = 0.32$ gauss.

On the other hand, the spectrum calculated

by Hückel's MO theory is given in Fig. 2(d). The observed and calculated spectra were not in satisfactory agreement with each other in this case.

Summary

The electron spin resonances of 4-methyl biphenyl and p,p'-bitolyl mononegative ions were observed in either dimethoxyethane or tetrahydrofuran, using potassium metal as a reducing agent. Well-resolved proton hyperfine spectra were observed in each case, and the g-value, the overall width, and the hyperfine splitting coefficients due to the methyl protons and ring protons were determined.

The theoretical spectra were constructed according to the spin densities calculated by Hückel's MO treatment, and these results were compared with the observed spectra.

The author wishes to express his gratitude to Professors Hideo Takaki and Ryozo Goto for giving him the opportunity to use the ESR apparatus and encouraging him during the course of this work. He is also much obliged to Dr. Yasuo Deguchi for his helpful discussions and for his calculation of Hückel's MO treatment.

Studies in the Two Phases System Sodium Formate-Pyridine. Extraction of Nickel and Separation from Chromium

By G. S. DESHMUKH and A. L. J. RAO

(Received February 12, 1963)

Chloroform[1-4] and benzene[5-8] have been widely used for the extraction of nickel and its separation from many elements. A new two phase system sodium formate-pyridine[9] has been reported from these laboratories recently. The behavior of nickel in this system, its quantitative extraction by the batch extraction technique and its estimation in presence of chromium have now been studied.

Experimental

Reagents.—Nickel chloride (B. D. H. AnalaR) sample), sodium formate (Reidel de Haen's recrystallized sample), Baker's analyzed pyridine and sodium chromate (E. Merck's AnalaR sample) are used.

Effect of various factors like the volume of pyridine, molarity of sodium formate, pH and the metal ion concentration on the extraction of nickel have been studied in detail.

Effect of Volume of Pyridine.—Five milliliters of sodium formate containing 1 ml. 0.1 N nickel chloride is taken, various volumes of pyridine are added each time and the amount of nickel extracted into pyridine after equilibration is determined. It is found that with 2 ml. pyridine, both the layers tend to separate but it is not possible to effect a clear separation of the two immiscible phases. The percentage extraction (% E) increased with the volume of pyridine upto 5 ml. and remained constant with a further increase in the volume of pyridine (Fig. 1) and therefore in all the cases 5 ml. of pyridine are used.

Effect of Formate Concentration.—Formate concentration has got very little effect on the amount of metal extracted into the pyridine and its strength need not be rigorously adjusted provided its molarity is above 3 M. At and below 2.3 M formate mixes freely with pyridine and no separation of layers occurs.

Effect of pH.—pH has got a profound influence on the amount of nickel extracted into the pyridine layer. The amount of metal extracted into the organic phase remained constant over a pH range of 7.5~9.2, but on further increase of pH, the percentage extraction decreased markedly. These results are given in Fig. 2.

Effect of Nickel Concentration.—Maintaining optimum conditions of pH, concentration of formate

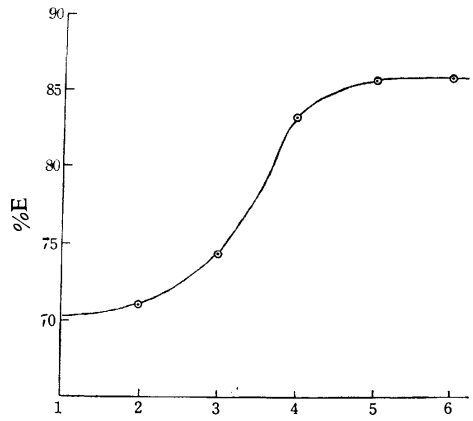

Fig. 1. Effect of volume of pyridine.

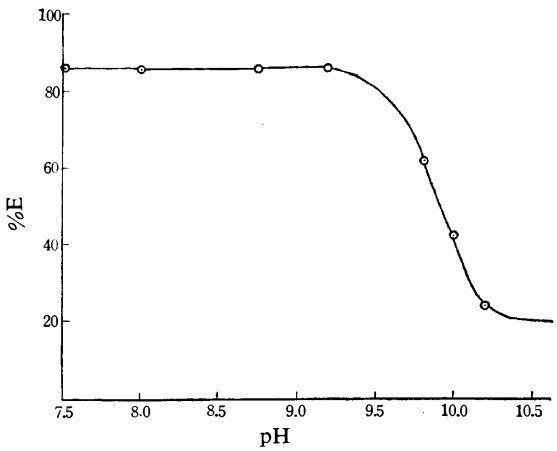

Fig. 2. Effect of pH on nickel extraction.

and pyridine, nickel solution of various concentrations are added each time to the system and the amount extracted into the pyridine is determined in each case. In all the cases the distribution coefficient is found to be constant, thus proving the validity of Nernst's distribution law (Table I).

Table I. Effect of nickel concentration on the extraction

System: 5 ml. of pyridine + 5 ml. 3 M formate containing $NiCl_2$, pH=8

S. No.	Amount of nickel added mg.	Amount of nickel extracted mg.	D
1	0.2	0.172	6.14
2	0.4	0.345	6.27
3	0.6	0.515	6.05
4	0.8	0.690	6.27
5	1.0	0.860	6.14

Procedure for the Extraction of Nickel.—From the study of all the above variables it is concluded that maximum extraction is obtained when the formate concentration is 3 M and 5 ml. of pyridine are used for the extraction, the pH range being 7.5~9.2. To an aliquot of sodium formate (necessary to give 5 ml. of 3 M solution when diluted) nickel chloride solution is added and the volume is made upto 5 ml. in a separating funnel. Five milliliters of pyridine is now added and the whole mixture is equilibrated for 2 min. The formate layer is collected into another separating funnel to which further 5 ml. of pyridine is added to extract some more nickel which remain in the formate during the first extraction. The process is repeated once more so as to get an almost complete extraction of nickel into pyridine. All the pyridine extracts are collected together in 100 ml. conical flask, diluted with a little water and the pyridine is boiled off. The nickel content of this residue is determined polarographically using 1 M ammonium chloride and 0.1 M ammonium hydroxide as the supporting electrolyte[10].

Table II. Analysis of a synthetic mixture of nickel and chromium

Amount of nickel		Amount of chromium	
Taken mg.	Found mg.	Taken mg.	Found mg.
1.45	1.45	1.25	1.243
2.90	2.87	2.50	2.496
4.35	4.34	3.75	3.750
5.80	5.82	5.00	4.926
7.25	7.20	6.25	6.250

Thus a complete extraction of nickel by pyridine from sodium formate is achieved in a three stage batch extraction technique.

Preliminary experiments with chromium under identical experimental conditions showed that it remains completely in the formate layer and is not extracted into pyridine. The observation has been utilized for the separation of nickel and chromium.

Analysis of a Mixture of Nickel and Chromium.—A mixture of nickel and sodium chromate solutions containing various concentrations of nickel and chromium are taken to which the required quantity of sodium formate (necessary to give 5 ml. of 3 M solution) and 5 ml. of pyridine are added and the whole mixture is shaken thoroughly. The formate layer is transferred into another separating funnel and the remaining nickel is re-extracted with a further aliquot of pyridine. For a complete extraction a three stage batch extraction is thus carried out. All the pyridine extracts are mixed together and the nickel content was determined polarographically (vide infra) while the chromium in the formate layer is determined iodometrically[11].

Summary

The distribution of nickel in the two phase system, sodium formate-pyridine is studied in

10) R. G. Menzel and M. L. Jackson, *Anal. Chem.*, 23, 1861 (1951).
11) A. L. Vogel, "A Text Book of Quantitative Inorganic Analysis", Longman Green & Co., New York (1960), p. 350.

detail. The effects of pH, volume of pyridine and molarity of formate are studied and the optimum conditions for the complete extraction are established. The possibility of using this extraction technique for the separation of nickel and chromium has also been worked out and a procedure for the analysis of a synthetic mixture of nickel and chromium is given.

Sincere thanks of the authors are due to Professor G. B. Singh for providing the necessary facilities. The award of a fellowship by the University Grants Commission to one of them (A. L. J. Rao) is also acknowledged.

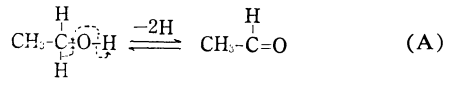
Oxidation of Alcohols by Cerium(IV). I. Oxidation of Methanol by Ceric Perchlorate

By S. S. MUHAMMAD and K. Vijayachander RAO

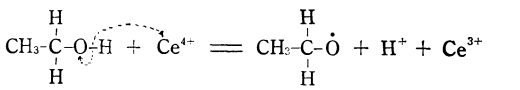
(Received March 12, 1963)

The oxidation of alcohols belongs to the category of reactions in which electron transfer is accompanied by the fission of one or more covalent bond:

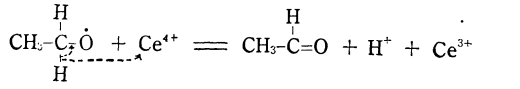


(A)

When the oxidant is a one-electron abstractor such as a ceric or cobaltic ion, these reactions involve the formation of free radicals, as pointed out by Dainton[1] in his Tilden lecture. Thus the work of Bawn and White[2,3] on the oxidation of formic acid, formaldehyde and methanol by cobaltic ions and the work of Mino, Kaizerman and Rasmussen[4] on the oxidation of pinacol by ceric sulfate demonstrated the formation of the free radicals. For example in the oxidation of ethanol by ceric ions the following reactions take place:



(A1)



(A2)

which conform to the observed stoichiometry of 2 ceric ions for one alcohol molecule.

On the basis of his kinetic studies on the trivalent manganese-oxalate reaction[5] and the oxidation[6] of acetone by selenious acid, Duke developed the theory of specific oxidation of glycols and related compounds. He assumed that coordination intermediates[7] are first formed through rapidly established equilibrium between the oxidant and the reductant and thence a slow disproportionation of these complexes occurs. The oxidation of 2, 3-butanediol by nitrato cerate was shown by Duke and Forist[8] to proceed through the disproportionation of a monoglycollated coordination intermediate. Similarly, in their study of the oxidation of meso-2, 3-butanediol (G) by ceric perchlorate, Duke and Bremer[9] noticed the formation of complexes such as $\{Ce\,G(H_2O)_4\}^{4+}$, and $\{Ce\,G_2(H_2O)_2\}^{4+}$ which then decomposed unimolecularly. Later Ardon's[10] investigation of the oxidation of ethanol by ceric ions in perchloric acid showed that the reaction occurred in two consecutive steps, similar to the scheme of Duke. He also established the existence of a 1-1 cerate-alcohol complex independently by a spectrophotometric method. Further, Venkatakrishnan and Santappa[11] found that the oxidation of acetone and methylethyl ketone via the formation of a

complex between the ceric ions and enolic form of acetone.

On the other hand, several studies[12] using ceric sulfate as oxidant in the oxidation of acetone, formaldehyde, alcohols and hydroxy-acids have given no indication of any intermediate complex formation. Hence it appeared of interest to investigate the divergence of behavior of ceric perchlorate and ceric sulfate, using methanol as the substrate under varying conditions of reagent concentration, acidity and temperature.

The first part contains our data on the oxidation of methanol by ceric perchlorate and this will be followed by the results in presence of ceric sulfate in Part II.

Experimental Method and Results

All the chemicals used were analar and of highest purity. Ceric perchlorate was prepared by the anodic oxidation of cerous perchlorate. This was obtained by dissolving the freshly precipitated ceric hydroxide in perchloric acid and reducing the resulting ceric perchlorate by adding concentrated hydrogen peroxide. The colorless solution of cerous perchlorate was electrolyzed with a current of 3 amp. at 4 V., using a platinum hood as the cathode and a platinum wire as the anode, the temperature of the electrolytic bath being maintained at 0°C. The solution of ceric perchlorate obtained had a strength of 0.01 M approximately and could be diluted to desired extent. For each series of experiments, ceric perchlorate was freshly prepared and it was not allowed to age long, as Vickery[13] asserts that aged solutions develop hydrosols and become less reactive.

Methanol was analar reagent grade. The formaldehyde produced was identified and estimated by Schiff's and Schryver's reagents. In the latter case, a photometric calibration curve was constructed with standard solutions of formaldehyde with the Schryver's reagent. All aqueous solutions were prepared with twice distilled water free from oxidizable impurities.

The reaction study was conducted in an all glass quickfit apparatus, having three jointed necks. Through the middle neck passed mercury seal stirrer, the second allowed nitrogen gas in the reacting system, while the third neck was used for the solutions to be put in or taken out by means of a pipette. During reaction, the latter two were closed by ground glass stoppers.

To maintain temperature, a Gallen Kamp thermostat with a toluene regulator was used, the range of fluctuations being ± 0.1°C. For temperatures lower than the room temperature ice cold water was circulated in lead coils in the bath.

The colorimetric estimation of cerium(IV) or formaldehyde was carried out on a Bosh & Lomb's Spectronic 20 type colorimeter, while the complex study was done on a Unicam spectrophotometer, model Sp 500.

The photochemical and thermal oxidation of water by ceric perchlorate is a well established fact[14]. Hence experiments were conducted in a dark room; the reaction vessel was covered with a black cloth. Blank experiments were also done and corrections were applied wherever necessary.

The rate of oxidation was followed by the rate of disappearance of ceric perchlorate, which was measured by adding excess of standardized ferrous ammonium sulfate solution and titrating the unreacted ferrous ion by standard ceric sulfate in presence of methyl red as indicator. Preliminary experiments showed that the volumetric titration was as accurate as the photometric estimation. Besides it was more suitable than the potentiometric titration which took longer time.

Stoichiometry and Order of Reaction.—The reaction mixture containing different proportions of reactants were analyzed after different intervals both for formaldehyde and for ceric perchlorate. The results are given in Table I.

TABLE I. STOICHIOMETRY OF THE REACTION
Temp., 20°C; 1.0 M perchloric acid

MeOH $\times 10^2$ M	Ce^{4+} $\times 10^{+3}$ M	$-\Delta Ce^{4+}$ $\times 10^3$ M per min.	$+\Delta HCHO$ $\times 10^3$ M per min.
2.0	3.55	0.56	0.26
3.0	3.55	0.82	0.40
5.0	3.55	1.32	0.63
6.0	3.55	1.58	0.75
10.0	3.55	2.48	1.20

In each case formaldehyde formed (or methyl alcohol consumed) is nearly half of the ceric ions disappearing in a given time. Hence the stoichiometry is "2 ceric 1 alcohol".

Using different initial amounts of ceric perchlorate with 0.11 M methanol and 1.0 M perchloric acid, the rate of disappearance of ceric ions was found to be directly proportional to ceric ions concentration. Further log Ce^{4+}-time graph was a straight line, confirming the first order dependence of rate on the ceric ion concentration. The latter graph was generally used to derive the rate constants.

Keeping ceric perchlorate at 3.55×10^{-3} M in a molar perchloric acid at 20°C and changing the concentrations of methanol between 0.01 to 0.50 M, it was found that the rate of oxidation rises with increase of methanol concentration, but tends to reach a limiting value at high concentrations of methanol. This is clear from the plot of rate of oxidation vs. methanol concentration shown in Fig. 1a. Figure 1b is the plot of log relative rate against log

a k' vs. (MeOH)
b log rel. k' vs. log rel. (MeOH)

relative methanol concentration and has a slope of 0.77.

Effect of Acid and Ionic Strength.—Experiments at constant ionic strength showed that at low acidities the rate is proportional to acid concentration, but at high acidities, it reaches a maximum value (Table II).

Table II. Effect of acid concentration at constant ionic strength
$Ce^{iv} = 3.55 \times 10^{-3}$ M, methanol = 0.11 M, $\mu = 2.504$ M and $T = 20°C$

$HClO_4$ M	$k' \times 10^2$ min^{-1}	$1/HClO_4$	$1/k'$
0.75	7.37	1.33	13.57
1.00	8.64	1.00	11.58
1.25	9.67	0.80	10.39
1.50	10.36	0.67	9.63
2.00	10.70	0.50	9.35
2.50	11.40	0.40	8.77
3.00	11.60	0.33	8.62

If the reciprocals of the rate constants are plotted against the reciprocals of the acid concentration, a straight line results. But keeping the acid concentration the same and varying the amount of added sodium perchlorate (Table III) it was found that the reaction has a normal salt effect.

The variations of the rate constants in the range 7~27°C are shown in Table IV.

The activation plot yields 14.45 kcal./mol. as the apparent activation energy.

Table III. Influence of ionic strength at constant acidity
$Ce^{iv} = 3.55 \times 10^{-3}$ M, methanol = 0.11 M, $HClO_4 = 1.0$ M and $T = 20°C$

27	0.174, 0.188, 0.164	17.53

Discussion

The present data on the oxidation of methanol are directly in line with the findings of Duke and Bremer[9] and Ardon[10] and may be explained on similar lines. Hence we invoke Duke's mechanism and assume that methanol in perchloric acid medium is oxidized by cerium(IV) only after complex formation:

$$MeOH + Ce^{iv} \rightleftharpoons Ce \leftarrow O\begin{matrix}Me\\H\end{matrix} \quad \text{(complex)} \qquad \text{(B1)}$$

$$Ce \leftarrow O\begin{matrix}Me\\H\end{matrix} \longrightarrow Ce^{iii} + H^+ + \dot{MeO} \quad \text{(methoxy free radical)} \qquad \text{(B2)}$$

These reactions are of course followed by a very fast step in which the methoxyl free radical reacts with another ceric ion:

$$\dot{MeO} + Ce^{iv} \longrightarrow Ce^{iii} + HCHO + H^+ \qquad \text{(C)}$$

which accounts for the observed stoichiometry, 2 ceric: 1 methanol. But the last step being very fast is out side the scope of the present study.

State of Ce^{iv} in Perchloric Acid.—In order to elucidate Duke's mechanism we require a knowledge of (1) the state of Ce^{iv} in perchloric acid, (2) the complex or complexes formed and (3) the disproportionation of these complexes. Hardwick and Robertson[15] have shown that

15) T. J. Hardwick and E. Robertson, *Canad. J. Chem.*, **29**, 818 (1951). See also, E. L. Ring and M. L. Pandow, *J. Am. Chem. Soc.*, **74**, 1966 (1952).

in aqueous perchloric acid solutions of ceric perchlorate three ionic species Ce^{4+}, $CeOH^{3+}$, and $(Ce-O-Ce)^{6+}$ can exist, comprising the reactions:

$$Ce^{4+}+H_2O \rightleftharpoons CeOH^{3+}+H^+ \quad (D)$$

$$CeOH^{3+}+CeOH^{3+} \rightleftharpoons Ce\text{-}O\text{-}Ce^{6+}+H_2O \quad (E)$$

High acidity favors the Ce^{4+} ions, though very high acidities (probably above 4 M) have to be avoided, for according to Vickery[13], autoreduction may occur. In low acidity and dilute solutions, the hydrolyzed form predominates. But increase in total ceric concentration helps the dimerization process and if acidity is also low, Ardon and Stein[16] state that irreversible colloidal polymers are also formed. As the ceric concentration in the present work was of the order of 10^{-3} M, the existence of the binuclear species $Ce\text{-}O\text{-}Ce^{6+}$ may be neglected and we take the reactive species to be unhydrolyzed Ce^{4+} as done by Duke and Bremer[9] and Ardon[10]. Our observation that the rate of oxidation increases though slowly, by rise in perchloric acid concentration in the range 1.0 to 3.5 M, is in conformity with the equilibrium D, in which higher acidity should favor the existence of the unhydrolyzed monomeric species Ce^{4+}. This may actually be the hexahydrated ion $Ce(H_2O)_4^{4+}$, for which the symbol Ce^{4+} will be used in later treatment.

Cerium(IV)-Methanol Complexes. — The coordination complexes between ceric perchlorate and methanol may be formed as a result of the displacement of perchlorate or water. Observed positive salt effect rules out any displacement of perchlorate by alcohol molecules. If the latter were correct, increasing addition of perchlorate would have decreased the rate. Hence it may be concluded that the displacement of coordination water by methanol molecules from Ce^{IV} occurs. The possible complexes would be $\{Ce\,X_5\cdot MeOH\}^{4+}$; $\{Ce\,X_4\,(MeOH)_2\}^{4+}$; $\{Ce\,X_3\,(MeOH_3)_3\}^{4+}$; $\{Ce\,X_2\,(MeOH)_4\}^{4+}$; $\{Ce\,X\,(MeOH)_5\}^{4+}$ and $\{Ce\,(MeOH)_6\}^{4+}$. Further since in solution $Ce\,OH^{3+}$ also exists, complexes such as $\{Ce(OH)X_4MeOH\}^{3+}$; $\{Ce(OH)X_3(MeOH)_2\}^{3+}$; $\{Ce(OH)\,X_2\,(MeOH)_3\}^{3+}$; $\{Ce(OH)\,X\,(MeOH)_4\}^{3+}$ and $\{Ce(OH)\,(MeOH)_5\}^{3+}$ are also possible. But according to Duke and Bremer, the latter type of complexes can not exist in appreciable amount in solution, for the hydrolyzed species has been found to be unimportant in the oxidation reaction.

Complex Formation and Disproportionation.— In the reaction:

$$Ce^{4+}+MeOH \rightleftharpoons \left[Ce \leftarrow O\begin{matrix}Me\\H\end{matrix}\right]^{4+} \quad (F)$$

if the equilibrium concentrations are put as $Ce^{4+}=c-x$; (complex) $=x$; $MeOH=B$ (where methanol being in excess, its initial concentration is supposed to remain unchanged) the equilibrium constant

$$K=\frac{x}{(c-x)B} \quad (1)$$

This gives

$$x=\frac{KBc}{1+KB} \quad (2)$$

or $$(\text{complex})=\frac{K(MeOH)(Ce^{4+})}{1+K(MeOH)} \quad (3)$$

The rate of disproportionation of the complex:

$$Ce \leftarrow O\begin{matrix}Me\\H\end{matrix} \longrightarrow Ce^{3+}+R\dot{O}+H^+ \quad (G)$$

$$\frac{-d\,Ce^{4+}}{dt}=k\ (\text{complex}) \quad (4)$$

But using complex concentration from 3,

$$\frac{-d\,Ce^{4+}}{dt}=\frac{kK(MeOH)(Ce^{4+})}{1+K(MeOH)} \quad (5)$$

This may be written as

$$\frac{-2.303\,d\log Ce^{IV}}{dt}=\frac{kK(MeOH)}{1+K(MeOH)} \quad (6)$$

because the concentration of Ce^{4+} directly depends on total cerium(IV), which is the quantity measured experimentally. It shows that in any given experimental condition, the plot of log Ce(IV) vs. time will be a straight line, the slope of which multiplied by 2.303 gives the first order constant k', which varies with methanol concentration in the manner of Eq. 6. Hence

$$k'=\frac{kK(MeOH)}{1+K(MeOH)} \quad (7)$$

or

$$\frac{1}{k'}=\frac{1+K(MeOH)}{kK(MeOH)}=\frac{1}{k}+\frac{1}{kK(MeOH)} \quad (8)$$

It means that the plot of the reciprocal of the apparent rate constant against the reciprocal of methanol concentration is a straight line with an intercept (Fig. 2). This intercept is equal to $1/k$ and the slope $1/kK$, thus enabling us to evaluate the constants of cerate-methanol complex formation and of its disproportionation in different experimental conditions.

Equation 8 may also be used as an evidence for the formation of an intermediate complex in a reaction. It may be noted here that it

16) M. Ardon and G. Stein, *J. Chem. Soc.*, **1956**, 104.

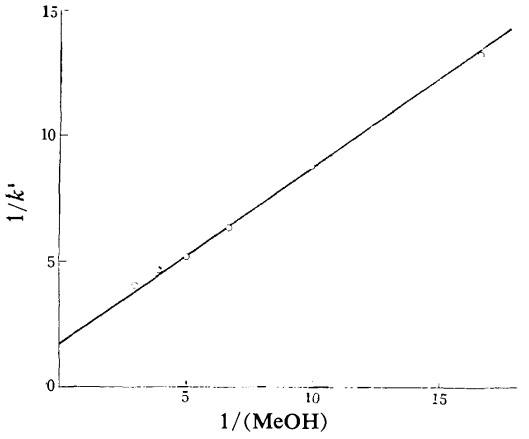

Fig. 2. Evidence for complex formation. Kinetic data.

is similar to Lineweaver and Burke's[17] equation which was a modification of the equation of Michaelis and Menton[18]. In order to explain the widely observed fact that the rate of an enzyme catalyzed reaction increased with the concentration of the substrate as a rectangular hyperbola and eventually levelled off a symptotically (compare Fig. 1), Michaelis and Menton suggested that the substrate combined with the enzyme to form a transient intermediate which then broke down to products:

$$\text{Enzyme}+\text{Substrate} \rightleftarrows \text{Complex} \rightarrow \text{Products}+\text{Enzyme}$$

Hence Lineweaver and Burke showed that in the above case, if the reciprocal of the apparent velocity was plotted against the reciprocal of the concentration of the substrate, then a slope and intercept relation resulted. The graph of Fig. 2 gives 1.36 l. mol^{-1} as the stability constant at 20°C and 1.0 M perchloric acid.

To understand the proposed mechanism, the structure of the cerate-methanol complex should be known. Job's method being unsuitable here, Ardon's optical method based on the spectrophotometric method of Hildebrand and Benesi[20] was employed. In this method the plot of $(1/D-CE_a)$ against 1/(methanol) at 400 mμ gives a straight line with an intercept, provided 1 : 1 complex is formed between ceric and methanol. Here D is the optical density of the equilibrium mixture and C and E_a the concentration and molecular extinction coefficient of the colored species ceric ions. When all the mixtures observed are made to have the same volume, the measured optical density D' of the ceric ions may be used in place of CE_a. Figure 3 shows the graph of $1/(D-D')$ against 1/(methanol). The value of the formation constant is 2.97 at 20°C and 3.0 M acid.

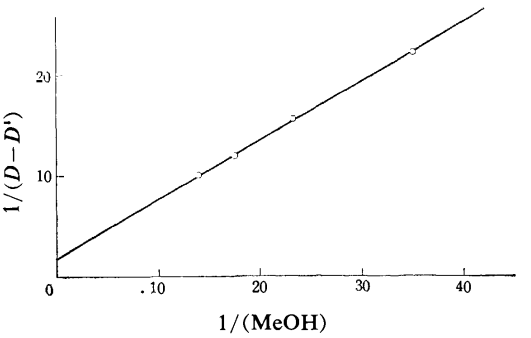

Fig. 3. Spectrophotometric data.

As the method of Ardon is based on the assumption that 1 : 1 complex is formed, it may be concluded that only 1 : 1 cerate-methanol is important in our experimental condition.

Effect of Acid Concentration. — If complex formation is represented by

$$Ce^{IV}+MeOH \rightleftarrows (Ce^{IV}\cdot MeOH)$$

and initial $Ce(IV)=Ce_0(IV)$ and at equilibrium the complex $=X'$, then the equilibrium constant,

$$K=\frac{X'}{(Ce^{IV}-X')(MeOH)} \qquad (10)$$

where it has been assumed that methanol being in excess, its concentration remains unchanged. But the reactive species being Ce^{4+}, the complex formation actually consists of reaction F:

$$Ce^{4+}+MeOH \rightarrow (Ce\cdot MeOH)^{4+} \qquad (F)$$

and the equilibrium constant $\bar{K}$

$$\bar{K}=\frac{X}{(Ce^{4+}-X)(MeOH)} \qquad (11)$$

In this equation Ce^{4+} is not equal to Ce^{IV} and $\bar{K}$ may be called the true stability constant, while K is the apparent stability constant.

In identical conditions of concentrations, acidity and temperature, the quantities X and X' may not be much different and we may assume them to be equal. Hence

$$\frac{\bar{K}}{K}=\frac{Ce^{IV}}{Ce^{4+}} \qquad (12)$$

But $Ce^{IV}(\text{total})=Ce^{4+}+CeOH^{3+}$ in conditions where binuclear species are negligible and

17) H. Lineweaver and D. Burke, *J. Am. Chem. Soc.*, **56**, 81 (1934).
18) L. Michaelis and M. Menton, *Bioch. Zeit.*, **49**, 333 (1913).
19) P. Job, *Ann. chim. (France)*, **9**, 113 (1928).
20) J. H. Hildebrand and H. A. Benesi, *J. Am. Chem. Soc.*, **71**, 2703 (1949).

$$\frac{\bar{K}}{K}=\frac{Ce^{4+}+CeOH^{3+}}{Ce^{4+}}=1+\frac{CeOH^{3+}}{Ce^{4+}}$$

and from equilibrium of Eq. D, $CeOH^{3+}/Ce^{4+}=K_h/H^+$, where K_h is the hydrolysis constant. This gives

$$\frac{\bar{K}}{K}=1+\frac{K_h}{H^+}$$

or

$$\frac{1}{K}=\frac{1}{\bar{K}}+\frac{K_h}{\bar{K}\cdot H^+} \qquad (13)$$

This means that a plot of the reciprocal of the apparent stability constant (derived from Fig. 4) against the reciprocal of the acid concentration, yields a straight line with an intercept $=1/\bar{K}$ and a slope $=K_h/\bar{K}$. Table V incorporates our data on the variation of the rate constants at different acidities by changes of methanol concentration at 20°C and constant cerium(IV) concentration.

TABLE V. VARIATION OF RATE CONSTANTS AT DIFFERENT ACIDITIES BY CHANGING METHANOL AT 20°C

MeOH mol. l.	$k'\times10^2$ min^{-1}	1/MeOH	$1/k'$
		$HClO_4=1.00$ M	
0.03	2.60	33.30	38.42
0.06	4.79	16.67	20.79
0.11	8.68	9.10	11.63
0.24	16.58	4.17	6.03
		$HClO_4=2.00$ M	
0.05	6.70	20.00	14.93
0.06	7.69	16.67	13.00
0.10	11.51	10.00	8.69
0.15	15.76	6.67	6.34
		$HClO_4=3.50$ M	
0.05	9.26	20.00	10.80
0.08	12.74	12.50	7.85
0.15	20.90	6.67	4.79
0.20	26.30	5.00	3.80

The plot of 1/(methanol)-1/(rate constants) is shown in Fig. 4. It is interesting to note from this graph that while apparent stability constants decrease with decreasing acid concentration, the constant of disproportionation remains the same at different hydrogen ion concentrations. This proves that there is only one complex that decomposes.

Figure 5 shows a plot of the reciprocal of the apparent stability constant (as derived from Fig. 4) against the reciprocal of acid concentration. This yields the following values at 20°C:

True stability constant $\bar{K}=6.67$

Hydrolytic constant $K_h=3.75$

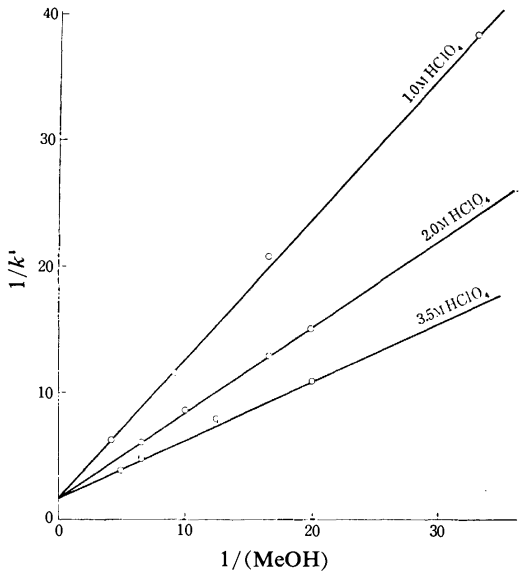

Fig. 4. Rate constants at different acidities at several methanol concentrations.

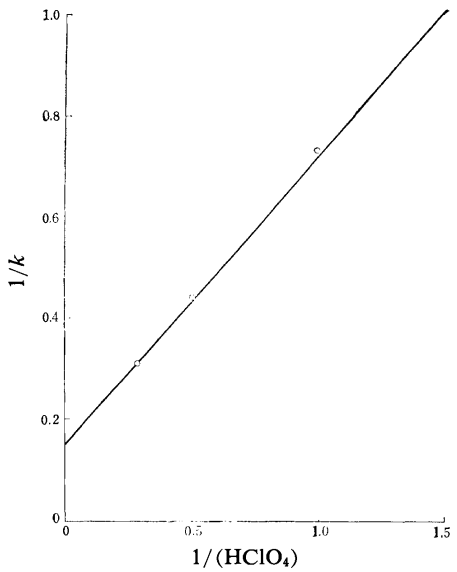

Fig. 5. Evaluation of hydrolytic constant and true formation constant.

The latter value closely agrees with Hardwick and Robertson's value 3.40. It has to be noted that though the apparent formation constant K decreases with decreasing acid concentration, the true formation constant $\bar{K}$ remains unchanged. Measurements at two temperatures yield the following values:

Temp.	K at 2.0 M acid	$\bar{K}$	K_h
13°C	3.74	7.21	1.85
20°C	2.34	6.67	3.57

while the apparent stability constant K has a temperature coefficient of 1.60 (for 7°C rise), that for the true stability constant is only 1.08. The former corresponds to a value of $\Delta H=$ 11.0 kcal. and the latter to about 2.0 kcal. This small heat of formation for the complex $Ce \leftarrow O\begin{matrix}Me\\H\end{matrix}$ again indicates that methanol is replacing only the cordinated water from the hydrated ceric ion, $Ce(H_2O)_6^{4+}$. Similarly the hydrolysis constants derived for 20 and 13°C, indicate the heat of hydrolysis to be 15.6 kcal. in agreement with Hardwick and Robertson's value of 15.3 kcal.

Summary

The oxidation of methyl alcohol by ceric perchlorate in perchloric acid solution was studied at 13, 20 and 26°C. The stoichiometry consisted of two ceric ions for the oxidation of one molecule of methanol. While the rate of disappearance of ceric ions directly depended on the concentration of ceric ions, the dependence on methanol concentration was such as to suggest a 'broken order':

$$\frac{-\mathrm{d}\,Ce^{iv}}{\mathrm{d}t}=\frac{k(Ce^{iv})(MeOH)}{1+k'(MeOH)}$$

This rate also depended on the concentration of perchloric acid in such a way that at high acidity it became independent of it.

These data were explained on the basis of Duke's mechanism for 2, 3-butane diol-ceric perchlorate reaction, i. e. the oxidation of methanol by ceric ions proceeded via an intermediate complex between one Ce^{4+} ion and one methanol molecule. The formation of this complex was also proved independently by a spectrophotometric method. The kinetic data were further used to derive the true heat of formation of the methanol-cerate complex and the heat of hydrolysis of the ceric ions in aqueous perchloric acid.

Oxidation of Alcohols by Cerium(IV). II. Oxidation of Methanol by Ceric Sulfate

By S. S. MUHAMMAD and K. Vijayachander RAO

(Received March 12, 1963)

Benrath and Ruland[1] were the earliest to investigate the oxidizing action of ceric sulfate on several substances, while Lejune[2] studied the oxidizability of alcohols, aldehydes and ketones by potassium permanganate and potassium dichromate. Later Willard and Young[3] observed the unreactivity of formic and acetic acids towards ceric sulfate and complicated kinetics and stoichiometry in the case of tartaric, malonic and other acids. Ross and Swain[4] tried to apply the principle of the concentration cells to kinetic studies on the oxidation of oxalic acid by ceric sulfate. The work of Shorter and Hinshelwood[5] concerned the oxidation of acetone[6] by ceric sulfate in dilute sulfuric acid. They assumed direct reaction between trisulfato-hydroxy cerate ion $\{H_2CeOH(SO_4)_3\}^-$ with enolic form of acetone. Hargreaves and Sutcliffe[7], using rather high concentrations of sulfuric acid, found the rate of oxidation of formaldehyde to depend on the cubic exponent of sulfuric acid concentration, indicating tetra-sulfate ceric acid $H_4Ce\cdot(SO_4)_4$ to be the reactive species. Dodson and Black[8] favored the existence of the trisulfato cerate ions $Ce(SO_4)_3^{2-}$ in soulution and assumed the main reductant to be the bioxalate ion $HC_2O_4^-$. studied the oxidation of methanol, ethanol, isopropanol, *n*- and iso-butanol and benzyl alcohol with potassium permanganate and ceric sulfate and activation energy of these reactions was correlated with dipole moments of the alcohols. Mino, Kaizerman and Rasmussen[10] studied the oxidation of pinacol by ceric sulfate and found no evidence of complexing between the reactants. They also noticed that in presence of acrylamide the primary radicals are captured by it. Krishna and Tewari[11] studied the oxidation of mandelic, *dl*-malic and lactic acids by ceric sulfate.

The present work concerns the study of the kinetics of the oxidation of methanol by ceric sulfate and activation data for the oxidation of methanol, ethanol and *n*-propanol.

Experimental Results

The ceric ammonium sulfate was of Merck's analar. It was dissolved in standardized sulfuric acid of highest purity and was assayed with ferrous ammonium sulfate. Other experimental details remain the same as given in Part I. Ceric sulfate solutions are much more stable as compared to ceric perchlorate. They do not decompose or undergo dimerization. Hence the rates could be followed in ordinary daylight.

The stoichiometry of reaction proves to be 2 ceric sulfate for each methanol molecule, the same as found with ceric perchlorate-methanol reaction.

Effect of Added Bisulfate Ion on Methanol-Ceric Perchlorate Reaction.—Addition of potassium hydrogen sulfate causes large retardation in the oxidation of methanol by ceric perchlorate. Thus using 3.55×10^{-3} M ceric perchlorate and 0.15 M methanol at 20°C, we get the data of Table I.

TABLE I. EFFECT OF ADDED BISULFATE IONS

$KHSO_4$ added g.	0	0.10	0.20	0.30	0.40	0.50
Apparent rate constant x $\times10^2$ min^{-1}	8.60	5.07	3.80	3.38	3.03	2.82

Methanol-Ceric Sulfate Reaction in Perchloric Acid.—The log-time plots showed the order to be one with respect to cerium(IV). Using differential method, the value of the exponent

$$n=\frac{\log(k_2/k_1)}{\log(C_2/C_1)}$$

was found to be one, where k_2 and k_1 are first order constants with methanol concentrations C_2 and C_1 in identical conditions.

The effect of perchloric acid was similar to ceric perchlorate-methanol reaction and the reciprocals of rates versus reciprocals of acid concentration, gave a straight line. Further the sodium perchlorate added results in a positive salt effect. But the search for complex formation led to negative result as the plot of $1/k'$ against 1/(MeOH) gave a straight line without an intercept (similar to Fig. 4). Hence it may be concluded that methanol and ceric sulfate in perchloric acid react without the prior formation of a complex.

Methanol-Ceric Sulfate Reaction in Sulfuric Acid.—The rate of oxidation depends directly on the concentrations of ceric sulfate and methanol. The plots of log titre value against time gave a straight line. The first order

character with respect to ceric sulfate continues till half of ceric sulfate is consumed, after which the rate falls off. The plot of log rel. (methanol) versus log rel. (first order constant), gave a straight line with a slope of unity. These data are contained in Table II. Hence the dependence of oxidation on methanol is of first order and the overall order of this reaction is two. This was varified by plotting $\log\{(a-x)/(b-x)\}$ against time (Fig. 1), using a = (ceric sulfate) = 6.75×10^{-3} M, b = (methanol) = 1.5 M and (sulfuric acid) = 1.0 M at temperature 55°C.

Effect of Sulfuric Acid and Ionic Strength.—Keeping the ionic strength constant at 2.53 M at 55°C the solutions containing 1.5 M methanol and 4.2×10^{-3} M ceric sulfate were made 0.5 M to 2.0 M with respect to surfuric acid. The plot of initial rate against molarity of sulfuric acid is shown in Fig. 2. This shows direct dependence of rate on the concentration of the

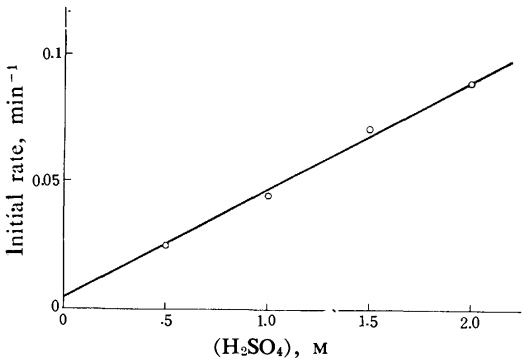

Fig. 2. Effect of acidity.

acid. But when the ionic strength is not maintained constant, the rate decreases directly with increase of sulfuric acid concentration. Besides, when the sulfuric acid concentration is maintained constant the plot of log of initial rate against (ionic strength)$^{1/2}$ shows a negative salt effect (Fig. 3).

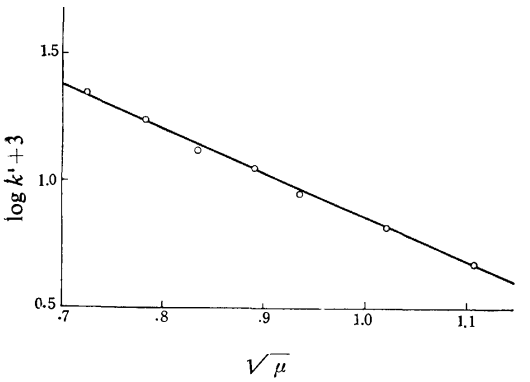

Fig. 3. Effect of ionic strength.

Effect of Temperature.—Using mixtures of 2.0 M methanol, 1.5 M sulfuric acid and 4.2×10^{-3} M ceric sulfate, the first order rate constants were determined at different temperatures and are given in Table III. The Arrhenius plot gives the value of 26300 cal. mol^{-1} for the activation energy.

Table III. Variation of rate constants with temperature

Temp. °K	First order rate constant $\times10^3$ min^{-1} (each is a mean of 3 expts.)	Mean k $\times10^3$ min^{-1}
313.2	2.50, 2.32, 2.61	2.48
318.2	4.64, 4.39, 4.48	4.50
323.2	8.68, 8.47, 8.27	8.47
328.2	14.15, 15.76, 14.76	14.88
333.2	32.53, 32.24, 32.20	32.32
338.2	56.56, 57.01, 55.51	56.36

Search for Complex Formation.—The plot of $1/k'$ against 1/(MeOH) (Fig. 4) is a straight line passing through the origin. Similarly the plot of $1/(D-D')$ against 1/(MeOH) is a straight line passing through the origin. Both facts show that the complex is not formed during oxidation.

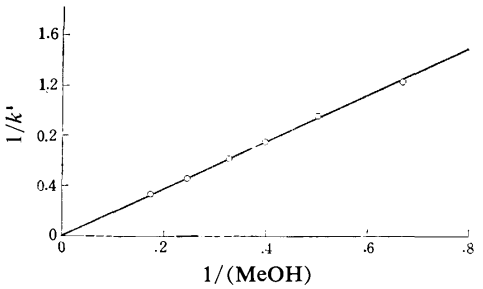

Fig. 4. Search for complex formation.

Discussion

The oxidation of methanol by ceric sulfate exhibits the same stoichiometry as the reaction of alcohols with ceric perchlorate, indicating that this also consists of two stages—the first being the slow reaction:

$$Ce^{IV} + CH_3OH \rightarrow Ce^{III} + CH_3\dot{O} + H^+ \quad (1)$$

followed by the very fast step:

$$Ce^{IV} + CH_3\dot{O} \rightarrow Ce^{III} + HCHO + H^+ \quad (2)$$

But the fact that in sulfuric acid medium, oxidation of alcohols does not involve the formation of a complex implies a difference between the mode of oxidation in the two media. This might be due to the difference in the state of Ce^{IV} in the two media.

The stability of ceric sulfate solutions compared to easy decomposition of ceric perchlorate and the fact that addition of alcohol to ceric sulfate does not change its color[12] are suggestive of covalent bonding between cerium(IV) and sulfate. While ion migration studies by Jones and Soper[13] and spectrophotometric studies by Hardwick and Robertson[14] support this, they do not agree about the species existing in solution[15]. Similarly, as shown in the introduction, different authors have assumed the existence of diffenent complexes to explain their kinetic data. It has to be admitted that in aqueous sulfuric acid solutions of ceric sulfate, several complexes can exist depending on the concentration of ceric sulfate and sulfurid acid such as

$\{Ce(SO_4)\}^{2+}$, $\{Ce(OH)SO_4\}^{1+}$, $\{Ce(SO_4)_2\}$, $\{Ce(SO_4)_3\}^{2-}$, $\{HCe(SO_4)_3\}^{1-}$, $\{H_2Ce(SO_4)_4\}^{2-}$ and $\{Ce(SO_4)_4\}^{4-}$

The choice of the right species is difficult. But our observation that the rate of oxidation of methanol by ceric perchlorate is retarded by added sulfuric acid and also the observation that the oxidation of methanol by ceric sulfate decreases on the addition of sulfuric acid point to the fact that the relative species should be the covalent by bond ceric sulfate $Ce(SO_4)_2$.

Mechanism of Waters.—Admitting that the reactive participants are the neutral ceric sulfate and methanol, the course of reaction may be assumed to be analogous to that proposed by Waters and Levesley[16] for the oxidation of α-hydroxy acids by manganese pyrophosphate. Earlier this mechanism was adopted by Krishna and Tiwari[11] to explain the kinetics of the oxidation of mandelic and *dl*-malic and lactic acids.

Hence we assumed that ceric sulfate and methanol react to form a transition complex which decomposes to produce a free radical, a hydrogen ion and cerous sulfate complex. The free radical then picks up another ceric sulfate (as in the case of ceric perchlorate-methanol reaction) and quickly produces the final products of reaction:

$$Ce(SO_4)_2 + CH_3OH \rightarrow \underset{\text{transition state}}{Ce(SO_4)_2\cdots\cdots CH_3OH} \rightarrow Ce^{III}(SO_4)_2 + H^+ + CH_3\dot{O} \quad (3)$$

$$Ce(SO_4)_2 + CH_3\dot{O} \xrightarrow{\text{very fast}} Ce^{III}(SO_4)_2 + H^+ HCHO \quad (4)$$

The retarding action of bisulfate ions at constant acidity can be explained as due to the removal of ceric sulfate by the reaction

$$Ce(SO_4)_2 + HSO_4^- \rightleftharpoons HCe(SO_4)_3^- \quad (5)$$

while the accelerating effect of hydrogen ions at constant ionic strength might be due to the reactions:

$$Ce(SO_4)_2 \rightleftharpoons Ce(SO_4)^{2+} + SO_4^{2-} \quad (6)$$

$$Ce(SO_4)^{2+} + H_2O \rightleftharpoons Ce(OH)SO_4^- + H^+$$

According to reaction 3, the rate of disappearance of ceric sulfate

$$\frac{-d(Ce(SO_4)_2)}{dt} = k''[Ce(SO_4)_2][CH_3OH] \quad (a)$$

and the rate is first order with respect to both reagents and the overall order is 2. Hence the bimolecular constant can be calculated by

$$k'' = \frac{2.303}{t(a-x)} \log \frac{b(a-x)}{a(b-x)} \quad (b)$$

where $a>b$ and x is the quantity of cerium(IV) disappearing in the time interval t.

From Eq. 5,

$$[C(SO_4)_2] = \frac{[HCe(SO_4)_3^-]}{K[HSO_4^-]}$$

$$\frac{-d\,(Ce(SO_4)_2)}{dt} = \frac{k''[HCe(SO_4)_3^-][MeOH]}{K[HSO_4^-]} \quad (c)$$

Assuming that ceric sulfate in sulfuric acid exists largely as $HCe(SO_4)_3^-$, the concentration of the latter is proportional to that of cerium(IV) and $HSO_4^- \propto H_2SO_4$, we arrive at the rate equation:

$$\frac{-d\,Ce^{IV}}{dt} = \frac{k'[MeOH][Ce^{IV}]}{[H_2SO_4]} \quad (d)$$

Evidence for the Proposed Mechanism.—The proposed mechanism is also supported by the behavior of methanol-ceric sulfate in perchloric acid medium. The reaction between methanol and ceric sulfate is very fast due to the absence of the bisulfate ions which slow down the reaction by removing ceric sulfate in the form of the complex ion $HCe(SO_4)_3^-$. Further the hydrogen ions of the perchloric acid stop the hydrolysis and degradation of the ceric sulfate (as shown in Eqs. 6 and 7).

TABLE IV. RELATION BETWEEN $(1/E)^{1/2}$ AND $\log PZ$ FOR OXIDATION OF ALCOHOLS BY Ce^{iv}

	Reaction system	Medium	E, cal. mol^{-1}	$\sqrt{1/E}\times10^3$	$\log PZ$
1	Methanol-ceric sulfate	Sulfuric acid	21850	6.76	10.74
2	Ethanol-ceric sulfate	Sulfuric acid	18800	7.59	9.10
3	*n*-Propanol-ceric sulfate	Sulfuric acid	13860	8.50	6.32
4	Methanol-ceric sulfate	Perchloric acid	12210	9.05	6.08

Data obtained with $Ce^{iv}=3.55\times10^{-3}$ M, $H_2SO_4=1.0$ M and rate constants derived from Eq. d

in a series of related reactions, the relation between $(1/E)^{1/2}$ and $\log PZ$ should be linear. In Table IV are recorded the values of the activation energy E, the square root of its reciprocal $(1/E)^{1/2}$ and the logarithm of the product of steric fator P and the collision number Z for the reactions of the three alcohols, methanol, ethanol and *n*-propanol with ceric sulfate as obtained in the present study:

Figure 5 is the graphical representation of

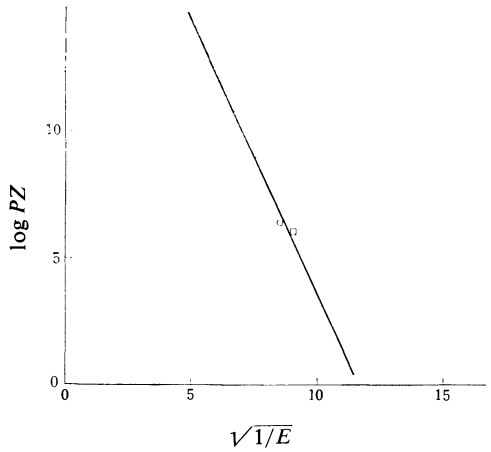

Fig. 5. Relation between $(1/E)^{1/2}$ and $\log PZ$.

$\log PZ$ against $(1/E)^{1/2}$. The four systems lie on a smooth line with a slope -2.16×10^3. This value of slope, according to Hinshelwood, is a characteristic of many bimolecular reactions.

Summary

The oxidation of methanol by ceric sulfate in sulfuric acid solutions was studied in the temperature range 40~70°C. The rate of oxidation depended directly on the concentration of cerium(IV) and methanol. At constant ionic strength the rate was directly dependent on the concentration of sulfuric acid. But when the ionic strength is not maintained, the rate changes inversely with sulfuric acid. At constant acid concentration, a negative salt effect is observed. The reaction occurs without the intermediate formation of a complex. The activation energy was derived to be 26300 cal. mol^{-1}. It has been shown that the mechanism of Waters for the oxidation of α-hydroxy-acids by manganese pyrophosphate can be used to explain the present data.

The Hydration of Some Organic Compounds in an Aqueous Solution. I. Studies of Aliphatic Aldehydes by Raman-effect Observation

By Michiko MATSUSHIMA

(Received March 22, 1963)

It has long been recognized that acetaldehyde is partly hydrated in an aqueous solution to the $CH_3CH(OH)_2$ molecule; Bell and his co-workers have summarized this evidence[1] and have reported kinetic measurements[2] of the reversible hydration process. The hydrate in question could not be isolated except for those from chloro-substituted aldehydes, and such a structure as $=C(OH)_2$ is often mentioned as a reactive intermediate in the organic reactions. It is, therefore, of interest to examine the species existing only in solution from the spectral point of view. Moreover, it seems worthwhile to pay attention to the infinite solubility with which formaldehyde and acetaldehyde dissolve, in water as well as in organic solvents. Since the formation of hydrates obviously helps their solubility, to obtain hydration energy is also of interest. The present paper aims at obtaining the molecular vibrational spectra characteristic of the hydrated structure; it also aims at elucidating molecular interactions through measurement of the changes in the relative intensities of suitable Raman lines produced by changes in temperature.

In the case of formaldehyde, an interesting phenomenon was observed by Hibben[3] in the Raman spectrum in an aqueous solution. The spectrum in solution has a relatively close similarity to that of glycol: $CH_2O+H_2O \rightleftharpoons CH_2(OH)_2$. The simplicity of the Raman spectrum of water led us to hope that the Raman effect technique would prove useful in detecting the species existing in an aqueous solution. Further, it seemed reasonable to expect that each spectrum corresponding to aldehyde and its hydrate would change in intensity as the temperature changed. In the present paper, the Raman spectra of acetaldehyde and its solutions in light and heavy water are studied. At the same time, those of dimethylacetal, chloral and chloral hydrate are recorded as related compounds useful for the sake of comparison.

Experimental

Materials.—Pure acetaldehyde was obtained from its trimer compound, which was depolimerized with a drop of concentrated sulfuric acid. The fraction below 27°C of the distillate was redistilled to get acetaldehyde, boiling at 20~20.5°C. The dimethylacetal synthesized[4] was purified by distillation over metallic sodium. Fractional distillation was repeated until the boiling point was constant at 64.3°C. Chloral and the chloral hydrate of E. P. grade (Tokyo Kasei) were used without further purification. Water purified through ion exchange resins was used as a solvent. The isotope content in the deuterium oxide used was 99%.

Measurements.—*The Raman Spectra of Liquids.*— A Cary Raman spectrophotometer, model 81, was used to measure the Raman spectra of pure liquids and solutions. Measurements were usually carried out at ordinary temperatures in a mercury lamp compartment (35~40°C), a sealed glass cell (O. D. 7 mm.) 4.5 ml. in volume being used. For the purpose of recording a spectrum at various points of equilibrium, the temperature of the Raman cell was kept almost constant by circulating water of a desired temperature through the tube jacket. The jacket was specially fitted to the space between the filter cylinder and the cell, as is illustrated in Fig. 1.

recorded at 60°C in the melted phase by using the tube jacket mentioned above.

The Irradiation of Polarized Lights.—The exciting light was polarized by surrounding a Raman tube with a polaroid cylinder, the transmitted electric vector of which was either parallel or perpendicular to the axis of the Raman tube. Baffles were not used to get a parallel exciting light, nor were the observed depolarization ratios corrected for the convergence error, so the results should be treated only as a measure of the true ratios.

Results (Part I)

The Raman Spectra of Acetaldehyde and Its Solutions in Light and Heavy Water. — The results obtained are summarized in Table I, together with the relative intensities. The spectra shown in Figs. 2, 3, and 4 were recorded at ordinary temperatures; Fig. 5 shows the spectrum of pure water. In a heavy water solution, the exchange reaction of deuterium with hydrogen in aldehyde might occur following the instantaneous hydration process. It was, however, observed that there

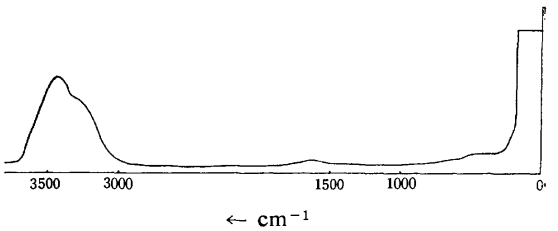

Fig. 5. Raman spectrum of pure water.

are no visible changes in intensity for the lines arising from C–H vibrations, and no visible new lines corresponding to C–D vibrations either. Since the rate of the exchange reaction is much less than that of the hydration process, it is not necessary to take account of the effect of the former reaction within the period of time employed for recording the Raman spectra.

In practice, the spectra of solutions are different from that of pure aldehyde, although in Figs. 3 and 4 the difference is not clearly shown. Arrows are given to show the position of each new line as it was acertained from observations at various temperatures and concentrations. (See Results, Part II.)

The spectra shown below, in Figs. 7 and 8, obviously indicate the effect of the temperature and concentration on the intensities of certain new lines; these factors cause at the same time compensative changes in the intensities of lines for aldehyde. Spectral lines corresponding to the new species may be distinguished from those for the original aldehyde when the lines of the latter are subtracted from all those observed in solution, at least with the exception of some overlapping lines. Generally, lines for aldehyde itself are not substantially shifted, even in solution, nor do they change their shapes except for the line around 900 cm^{-1}. This line is very broad, and its center shifts to a higher frequency in the case of a solution. It seems, however, very reasonable to interpret this change by regarding the broad line as the superposition of a couple of lines which might have their peaks within this range. The decrease in intensity of the lower frequency peak resulted in showing the higher frequency peak to be stronger. The change about 900 cm^{-1} can be interpreted thus, and not as the result of solvent shift of the broad line.

Concerning C–H vibrations, one of the noticeable changes is the appearance of a strong new line at 1449 cm^{-1} with the decrease in intensity of the line at 1430 cm^{-1} for aldehyde. The line at 2919 cm^{-1} (aldehyde) produces a strong line at 2939 cm^{-1} as it decreases. A similar change is observed on the new lines at 2874 and 2996 cm^{-1}.

For the O–H stretching region, it is obvious that the stronger of the two broad peaks, around 3275 and 3425 cm^{-1} in pure water, shifts towards a frequency higher by 50 in the unit of cm^{-1} and that the separation becomes unclear. There may be a new broad line centered about 3400 cm^{-1} which would lead to the general broadening in this region.

The Raman Spectra of Related Compounds.—The results obtained with chloral, chloral hydrate and dimethylacetal are listed in Table II. The difficulty in the purification of chloral hydrate caused the superposing on the spectrum of a main impurity, chloral. The lines showing the same frequencies as Raman lines belonging to chloral are marked with (?) in the Table. The spectrum for dimethylacetal is shown in Fig. 6.

An Analysis of the Spectrum for the Hydrated Molecule.—Since $CH_3CH(OH)_2$ involves ten atoms, twenty-four normal vibrations are expected. Assuming that the hydrate molecule takes a symmetric configuration belonging to the point group C_s, all the modes of normal vibrations expected are listed in Table III.

TABLE III. THE NUMBER OF THE NORMAL MODES FOR THE HYDRATE

	A′	A″		A′	A″
C–H stretching	1	0	C–C stretching	1	0
C–H deformation	1	1	$O\diagup C\diagdown O$ stretching (sym. & asym.)	1	1
CH_3 stretching					
symmetric	1	0	$O\diagup C\diagdown O$ scissoring	1	0
degenerate	1	1	$O\diagup C\diagdown O$ skeletal deformation	1	1
CH_3 sym. def.	1	0			
deg. def.	1	1	O–H stretching	2	0
CH_3 rocking	1	1	O–H deformation (in- and out-of-plane)	2	2
CH_3 torsion	0	1			

As both A′ and A″ species of vibrations are active in the Raman effect, all of those modes of vibration are observable. Six of them, such as the C–H and O–H stretching modes, are expected in the region above 2500 cm^{-1}; another six, including skeletal deformation, CH_3 torsion and O–H out-of-plane deformation, are below 700 cm^{-1}, and the remaining twelve are between 700 and 1500 cm^{-1}.

Tentative Assignments.—First, in the region below 700 cm^{-1}, all the lines except 420 cm^{-1} are assigned as follows. The line at 325 cm^{-1} in an aqueous solution is remarkable among new lines. This could be most reliably assigned to the skeletal deformation vibration (A′) in the $C-C\langle^{O}_{O}$ structure. Also, the line at 322 cm^{-1} in a heavy water solution seems to correspond to the mode in its lower frequency and sharpness. This assignment is supported by the fact that the line at 292 cm^{-1} for dimethylacetal is due to the skeletal deformation vibration, which shows a similar property in its shape. Those wave numbers are reasonable, considering their mass difference. The out-of-plane vibrations of O–H are also expected in this region. The line at 567 cm^{-1} in an aqueous solution is attributed to it because no line is observed in a heavy water solution near the frequency and because the line at 410 cm^{-1} in the heavy water solution could be regarded as the corresponding one from the product rule. The rather higher frequency of this vibration is explained by the fact that the hydrogen bonding in water could shift a frequency of this mode to a higher frequency than usual. The line at 480 cm^{-1} in the aqueous solution is assigned to $O\diagup C\diagdown O$ scissoring (A′), the line at 473 cm^{-1} in the heavy water solution corresponding to it. This scissoring mode (A′) is more reasonable than that other skeletal deformation vibration (A″) which is the only mode left among the skeletal deformation vibrations. Since a mode belonging to the A″ species can not usually show a stronger intensity than that for A′ species in a Raman spectrum, we can not attribute the observed line in question to a mode belonging to the A″ species when no suitable line for the remaining mode is observed.

Moreover, such an assignment is unacceptable because the scissoring mode is probable for the frequencies left in this region. All the assignments stated above being relatively consistent with each other, the broad band at 420 cm^{-1} in an aqueous solution is the only line in this region on which no comment can be made at present.

In the region between 700 and 1500 cm^{-1}, skeletal stretching vibrations and $C-H_n$ and O–H (in-plane) deformation vibrations are expected. No clear conclusion on some of them can be obtained at present, mainly because couplings between similar modes should be considered, especially in the region between 700 and 1200 cm^{-1}. The following attempt is focused on the modes of vibration related to the O–H group. The most distinguishable line, at 857 cm^{-1}, was assigned to the symmetric stretching vibration of $C\langle^{O}_{O}$ in the structure of $C-C\langle^{O}_{O}$. At the same time, it was observed that the new line at 845 cm^{-1} in the heavy water solution is also sharp, equivalent in its intensity and with the same order of depolarization ratio. The assignment is decisively supported by the existence of the line at 808 cm^{-1} in dimethylacetal, which has features similar to those mentioned above and has been attributed to the symmetric skeletal stretching vibration. The asymmetric stretching vibration seems to be at 920 cm^{-1} in the aqueous solution and around 918 cm^{-1} in the heavy water solution.

The features of the broad line centered at 918 cm^{-1} imply the superposing of another line, which line may well be assigned to O–D (in-plane) deformation since it is a reasonable position evaluated from the product rule if we suppose either the line at 1095 cm^{-1} or the line at 1156 cm^{-1} to be an O–H (in-plane) deformation vibration. It might be one coupled with a CH_3 rocking vibration. The reasons why we should suppose either of those lines to be an O–H deformation vibration are, one, that no lines are observed in the same frequency region in heavy water, which implies a large frequency shift due to the change of mass from H to D, and, two, that those frequencies are probable for O–H (in-plane) deformations. This assignment, as well as those for such vibrations as C–C stretching, C–H deformation (A′) and CH_3 rocking (A′ and A″), will be discussed elsewhere with extensive further data.

The lines at 1353, 1400 and 1449 cm^{-1} are due to C–H deformation (A″), CH_3 symmetric deformation, and CH_3 degenerate deformation respectively. The assignment for the first one, (A″), is supported by the value of its depolarization ratio and by the existence of the line at 1348 cm^{-1} in the chloral hydrate. The new line at 1449 cm^{-1} changes in intensity in compensation for the intensity at 1430 cm^{-1} for aldehyde. Moreover, it keeps the same frequency in a heavy water solution. The depolarization ratio implies the superposition of the A′ and A″ species of vibration. In

the spectrum of dimethylacetal, the equivalent line is found at 1448 cm^{-1}.

In the region of C–H stretching vibrations, one C–H stretching (A'), one CH_3 symmetric, and one CH_3 degenerate stretching vibration are to be expected. As a result of the investigation of their relative intensities and degrees of depolarization, the line at 2995 cm^{-1} is attributed to the CH_3 degenerate stretching mode, the one at 2940 cm^{-1} to the CH_3 symmetric stretching mode, and the other, at 2874 cm^{-1}, to the C–H stretching vibration. This conclusion is not consistent with that obtained for the CH_3 symmetric stretching frequencies of formals, acetals and related compounds.[4] For these, however, it has been suggested that the CH_3 symmetric stretching frequencies of OCH_3 groups split into two frequencies as a result of the Fermi resonance, with overtones of the CH_3 asymmetric deformation frequencies of OCH_3 groups. The splitting of the symmetric stretching frequency under the influence of an overtone frequency was not introduced here. Those frequencies remain in deuterated compounds, also. The fact that the frequency for a tertiary C–H stretching mode varies rather widely from hydrates to acetals may indicate a strong dependency of this frequency upon the groups attached to the tertiary carbon atom.

Thus, assignments have been carried out tentatively for as many observed lines as possible on the basis of the data presented here. The assignments described above are shown in Table IV.

As has been discussed above, reliable lines characteristic of hydrated molecules which exist only in solution can be used for spectroscopic investigation of reactive intermediates having two hydroxy groups on one and the same carbon atom.

Since changes in an aqueous solution are closely connected with a skeletal structure, further precise analysis of the relative intensities for new and original lines and a complete knowledge of acetaldehyde would provide us with assignments in more detail, especially for the region where complicated lines are produced out of couplings with skeletal vibrations.

TABLE IV. THE ASSIGNMENT OF THE RAMAN LINES FOR THE HYDRATE AND DEUTERATE OF ACETALDEHYDE

$CH_3CH(OH)_2$	$CH_3CH(OD)_2$	Mode
325	322	Skeletal deformation (A')
480	473	$O\diagup C\diagdown O$ scissoring
567	410	O–H or O–D out-of-plane deformation
857	845	$O\diagup C\diagdown O$ sym. stretching
920	918	$O\diagup C\diagdown O$ asym. stretching
1095 or 1156	918~	O–H or O–D in-plane deformation
1353	1358	C–H deformation (A'')
1400	1400	CH_3 sym. deformation
1449	1449	CH_3 deg. deformation
2874	2873	C–H stretching
2939	2941	CH_3 sym. stretching
2996	2996	CH_3 deg. stretching

Results (Part II)

Observation of the Spectra at Various Temperatures and in Various Concentrations.—The spectra for solutions were recorded at various temperatures from 0 through 60°C, some of which are shown in Figs. 7 and 8. The ratios of the intensities for new lines to those of original lines increase as the temperature and

the concentration of aldehyde decrease. At 60°C only a few stronger lines are observable. Their compensative changes with the lines for aldehyde have been described in Results (Part I) of this paper. This observation was quite helpful in attributing the observed lines to the species present in a solution.

The reproducibility of their intensities upon a change in temperature is good enough to prove this hydration process to be reversible.

Evaluation of Raman Intensities.—For the purpose of quantitative measurements, working curves were drawn for various temperatures by using mixtures of acetaldehyde and *n*-hexane. The carbonyl frequency, 1720 cm^{-1}, in this solution does not undergo any significant changes due to intermolecular interaction, but retains the same shape as in a pure liquid. We have, therefore, used the peak height of this line as a measure of the concentration of acetaldehyde in order to obtain each working curve at different temperatures. Using these working curves, we can eliminate several basic factors which must be taken into account in intensity measurement[5,6]. We, however, have still had trouble in an aqueous solution in estimating the peak heights of a carbonyl frequency at a lower temperature, trouble such as a lifting-up of

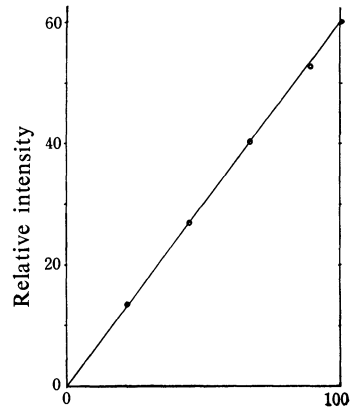

Fig. 9. The working curve for carbonyl band in solution.
$\nu_{C=O}$: 1720 cm^{-1}
at 0°C, in *n*-hexane solution

a base line and a variation in the shape. The specific causes of these phenomena have not yet been elucidated. Therefore, the values calculated of the basis on this observation could give only a measure of the true values. One of the working curves is shown in Fig. 9.

Equilibrium Constants and Calculation of the Hydration Energy. — The equilibrium constant is written as

$$K=\frac{(X)}{(a-X)(b-X)}$$

where a and b denote the initial concentrations of aldehyde and water respectively and X, the concentration of the hydrated species. The concentration of aldehyde remaining at an equilibrium point was determined from the spectrum recorded after keeping the sample tube at a desired temperature for more than one hour[7]. K's were obtained since the values of a and b were known.

The hydration energy can be determined from a plot of $\log K$ against $1/T$, as is obvious in the following equation:

$$K=A\exp(-\Delta H^{h}/RT)$$

The equilibrium constants and the calculated hydration energy are: $K^{273}=0.029$, $K^{313}=0.0040$ (mol^{-1}), and $\Delta H^{h}=-8.7$ kcal./mol., and the initial concentrations: $a=12.1$, and $b=18.5$ mol./l. Fig. 10 shows the experimental results from which the value of the hydration energy was calculated.

Bell and Clunie[7] made an attempt to separate the instantaneous heat of solution from that of the subsequent hydration process, and

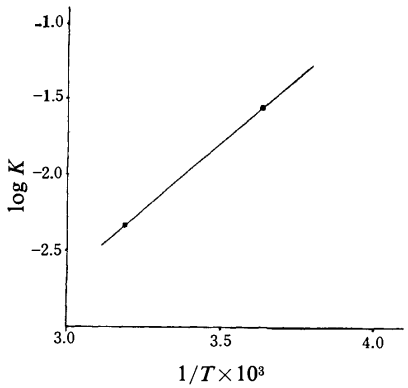

Fig. 10. The plot of $\log K$ against $1/T$.

reported, by combining calorimetric and ultraviolet absorption measurements, that the heat of hydration in question is -5.10 kcal./mol. for a very dilute solution. The value obtained here seems to be a little larger than those given by others. We have to notice, however, that there is confusion in the literature regarding the equilibrium constants and the heat of hydration. Our experiments concerned a very concentrated solution. Most others have investigated rather dilute solutions, and no consideration has been paid to the form of the equation for equilibrium constants. Since water molecules are apt to associate with each other, they are also at an equilibrium between aggregate water and isolated water, in which we should mention various extents of aggregation. Moreover, the isolated form might be a reactive form. Therefore, the effective concentration of water, for instance, must be varied according to the initial concentration as well as to the temperature range investigated. This could be introduced as a correction for use in determining the actual equation for this hydration equilibrium in an effort to obtain constant values. Generally speaking, a very delicate balance between the hydration process and the dissociation of aggregate water molecules might be shown in changes of the value of K depending on the initial concentration of components. This will be discussed elsewhere[8] through the precise measurement of the proton magnetic resonance.

Summary

The Raman spectra of acetaldehyde, its aqueous solution and its heavy water solution have been recorded at various temperatures and in various concentrations in order to find the Raman frequencies characteristic of the hydrated species and in order to investigate the reversible hydration process. Almost all the lines have been assigned tentatively on the assumption that the hydrate molecule has C_s symmetry. The lines at 325, 480, 567, 1353, 1440, 1449, 2874, 2939 and 2996 cm^{-1} can be referred to as the lines characteristic of the hydrate. Supporting data have also been obtained for the related compounds for the sake of comparison. Moreover, through the intensity measurements, equilibrium constants, as well as the heat of hydration, have been evaluated as the basis for a discussion of the hydration process.

The author would like to express her deepest appreciation to Dr. Yo-ichiro Mashiko, Dr. Shinnosuke Saeki, and Dr. Kenkichi Nukada for their helpful discussions.

*Syntheses and Structures of Acetylformoin and Its Related Compounds. III. Isobutyrylformoin**

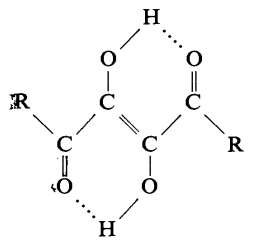
By Yō Miyagi and Ryozo Goto

(Received April 16, 1963)

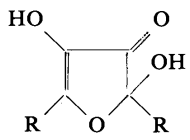
In previous papers, the chemistry of acetyl-[1], benzoyl-[1] and neopentoyl-formoin[2] was reported on. These formoins were synthesized by the acyloin condensation of methyl-, phenyl- and *t*-butyl-glyoxal; the possible structures for these formoins are I—III. The structures of acetyl-, benzoyl- and neopentoyl-formoin in the crystalline state were established as I (R=CH_3), II (R=C_6H_5) and II (R=$C(CH_3)_3$) respectively.

The present report is concerned with isobutyrylformoin, which was also synthesized by the acyloin condensation of isopropylglyoxal:

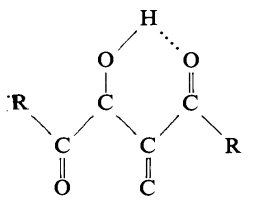
$$2\ (CH_3)_2CHCOCHO \rightarrow (CH_3)_2CHCOCH(OH)COCOCH(CH_2)_3$$



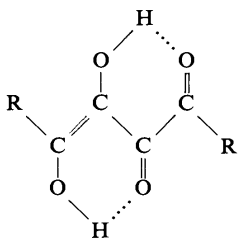
I



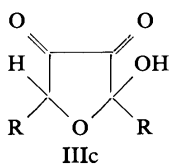
II



IIIa



IIIb

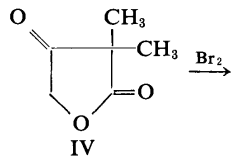


IIIc

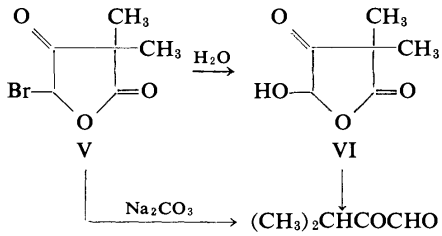
Results and Discussion

The Preparation of Isopropylglyoxal.—Conrad and Gast[3] first synthesized isopropylglyoxal by the following sequence of reactions:

$$CH_3COCH_2COOC_2H_5 \xrightarrow[Na]{CH_3I} CH_3COC(CH_3)_2COOC_2H_5 \xrightarrow{Br_2} BrCH_2COC(CH_3)_2COOC_2H_5 \xrightarrow{AcOK} CH_3COOCH_2COC(CH_3)_2COOC_2H_5 \xrightarrow{H_2SO_4}$$



IV



V VI

$$\xrightarrow{Na_2CO_3} (CH_3)_2CHCOCHO$$

They obtained isopropylglyoxal by the decarboxylation of 5-oxy-3, 3-dimethyltetronic acid VI, which had been prepared by the hydrolysis of 5-bromo-3, 3-dimethyltetronic acid V. They isolated the latter compound as an oily products, but we found it a white solid melting at 52.5~54°C. Reid, Fortenbaugh and Patterson[4] prepared isopropylglyoxal by the steam distillation of 5-bromo-3,3-dimethyltetronic acid V in a 20% yield. We are of opinion that the low yield may be due to the decomposition of isopropylglyoxal by hydrogen bromide, which is produced by the hydrolysis of V.

We succeeded in obtaining isopropylglyoxal directly from the bromide V by suspending it in an aqueous solution of enough amount of sodium carbonate to neutralize the acid produced and then by heating the entire mixture.

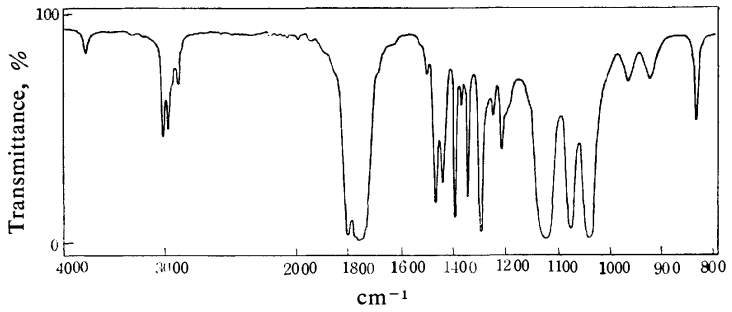

Fig. 1. Infrared spectrum of 3,3-dimethyltetronic acid (IV) in carbon tetrachloride.

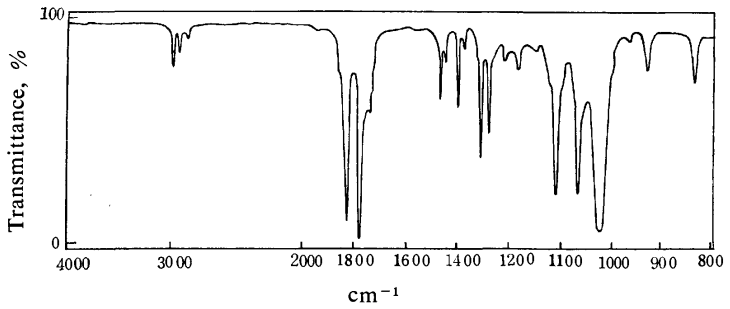

Fig. 2. Infrared spectrum of 5-bromo-3,3-dimethyltetronic acid (V) in carbon tetrachloride.

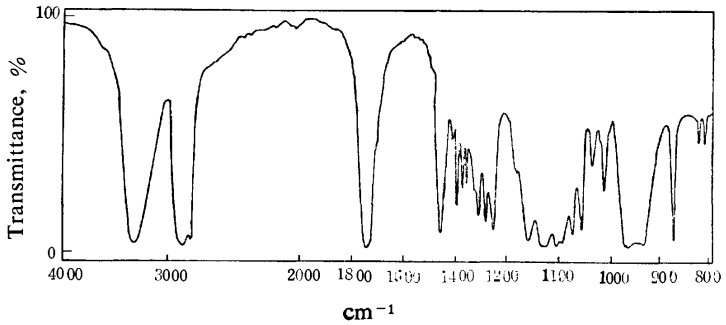

Fig. 3. Infrared spectrum of 5-oxy-3,3-dimethyltetronic acid (VI) in Nujol.

Figures 1, 2 and 3 show the infrared spectra of compounds IV, V and VI respectively. Compound IV shows a broad band of the C=O stretching absorption between 1740 and 1810 cm^{-1} in carbon tetrachloride. Similarly, compound VI absorbs at 1740~1770 cm^{-1} in Nujol. These broad bands may be overlapping bands of ring ketones and γ-lactones; five-membered ketones are said to absorb at around 1750 cm^{-1} [5-7], and γ-lactones absorb at around 1770 cm^{-1} [8,9]. The C=O stretching absorption band of compound VI arises at 1760~1800 cm^{-1} in tetrahydrofuran. Compound V shows two separated bands, at 1825 and 1773 cm^{-1}. The absorption bands of α-bromoketones are usually shifted to a higher frequency by about 20 cm^{-1}. Thus, in compound V, the absorption band of the ring ketone may be considered to arise at a higher frequency, 1825 cm^{-1}, separated from the lactone band at 1773 cm^{-1}.

Isobutyrylformoin.—The reaction product of isopropylglyoxal with sodium cyainde is a white solid, which was proved by elementary analysis and by molecular weight determination to be a condensation product of the two molecules of isopropylglyoxal.

The infrared absorption bands of isobutyrylformoin in the regions of C=O, C=C and OH stretching absorption are listed in Table I. The

TABLE I. INFRARED ABSORPTION BANDS, cm^{-1}

Formoin	Phase					
Benzoyl-	Nujol	3500	3270	1685	1608	1595
Neopentoyl-	Nujol	3330	3180	1690	1605	
Isobutyryl-	Nujol	3340	3100	1690	1598	
	Tetrahydrofuran	3290		1705	1635	
	Chloroform	weak and broad 3700~2600		1635		
Acetyl-	Nujol, Chloroform	weak and broad 3600~2800		1625		

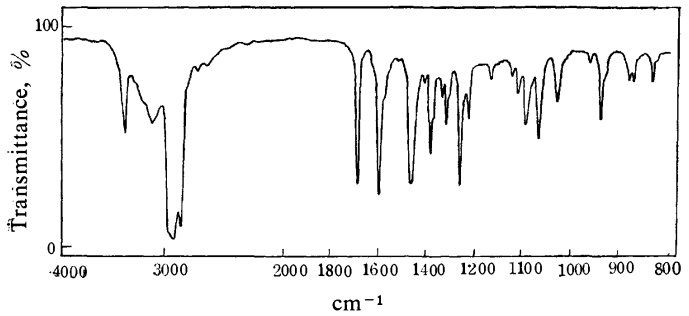

Fig. 4. Infrared spectrum of isobutyrylformoin in Nujol.

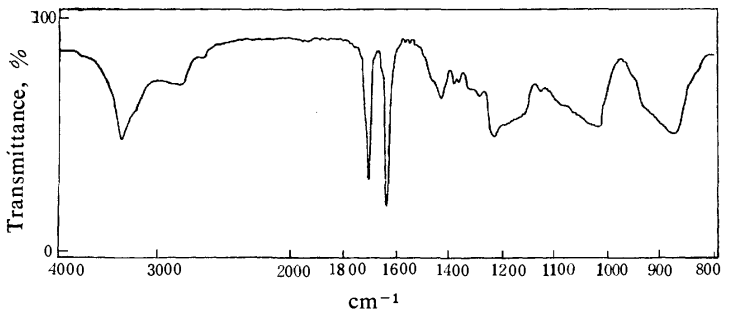

Fig. 5. Infrared spectrum of isobutyrylformoin in tetrahydrofuran.

infrared spectrum of isobutyrylformoin in Nujol (Fig. 4) is very similar to those of benzoylformoin and neopentoylformoin, the structures of which were both established as II ($R=C_6H_5$ and CMe_3)[1,2]. Thus, the structure of isobutyrylformoin also seems to be II ($R=CHMe_2$). The absorption band at 1598 cm^{-1} and that at 1690 cm^{-1} are attributable to the C=C and C=O stretching absorption respectively. This assignment seems probable, in spite of the lack of spectral data on furanones, because conjugated ketones usually absorb at 1690~1680 cm^{-1}, and olefinic linkages do at around 1600 cm^{-1}.

The spectrum in tetrahydrofuran (Fig. 5) resembles that in Nujol, except that the former shows only one band of the OH stretching absorption at 3290 cm^{-1}, while the latter shows two bands, at 3340 and 3100 cm^{-1}. Therefore, isobutyrylformoin may be considered to have structure II in tetrahydrofuran. The difference in the hydroxyl bands between the solid state and the solution does not suggest that isobutyrylformoin would have a structure other than II in tetrahydrofuran, because the position of the OH stretching absorption band is easily shifted with the strength of hydrogen bondings, which may be different in the solid state and in the solution. Moreover, the spectrum can not be explained on the basis of structures I, IIIa, IIIb and IIIc for reasons similar to those discussed in a previous paper[1].

The spectrum of isobutyrylformoin in chloroform (Fig. 6) is remarkably different from those in tetrahydrofuran and Nujol; it is, however, very similar to that of acetylformoin in chloroform or Nujol. There is only a broad, weak absorption band extending from 2600 cm^{-1}

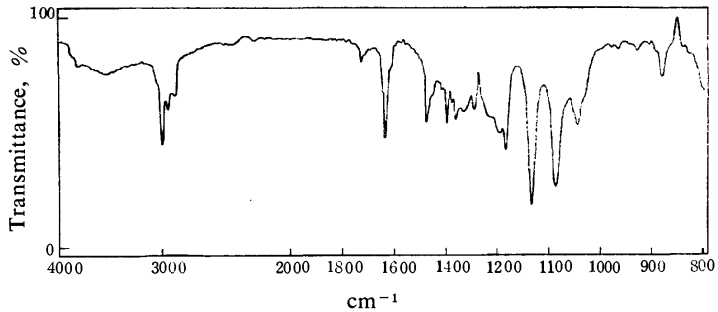

Fig. 6. Infrared spectrum of isobutyrylformoin in chloroform.

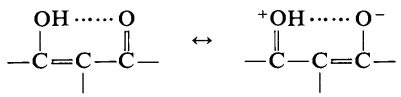
beyond over 3700 cm^{-1} instead of distinct bands at 3340 and 3100 cm^{-1} in Nujol or at 3290 cm^{-1} in tetrahydrofuran. The C=O stretching absorption band is widely shifted to 1635 cm^{-1}. This type of spectra has been said to be characteristic of the enol form of β-diketones and has been attributed to the resonance structures[10]:



Structure I (R=$CHMe_2$) is most compatible with these observations, as in the case of acetylformoin. Any further explanation and exclusion of the other structures, II, IIIa, IIIb and IIIc, would be the same as have been given in a previous paper[1].

A similar tendency is observed in the ultraviolet absorption spectra. In tetrahydrofuran, the absorption maximum is attained at 305 mμ with ε_{max}, 7350. On the other hand, in chloroform it is shifted to 360 mμ, with a great enhancement of its intensity (ε_{max}=14200). Thus, the absorption at 360 mμ is attributable to the enediol structure I and that at 305 mμ, to the furanone structure II.

Experimental

Ethyl α,α-Dimethylacetoacetate. — This compound was prepared by the method of Marshall and Cannon[11]; 51%; b. p. 96~98°C/40 mmHg; n_D^{25} 1.4180.

Found: C, 60.99; H, 8.96. Calcd. for $C_8H_{11}O_3$: C, 60.74; H, 8.92%.

Ethyl γ-Bromo-α,α-dimethylacetoacetate.—This compound was prepared by the method of Conrad and Gast[3,12]: 70%; b. p. 109~111°C/10 mmHg; n_D^{25} 1.4682.

Found: C, 40.62; H, 5.50; Br, 33.68. Calcd. for $C_8H_{13}O_3Br$: C, 40.55; H, 5.49; Br, 33.42%.

Ethyl γ-Acetoxy-α,α-dimethylacetoacetate. — This compound was also prepared by the method of Conrad and Ggast[3,12]: 55%; b. p. 91~92°C/1 mmHg; n_D^{25} 1.4339.

Found: C, 55.32; H, 7.22. Calcd. for $C_{10}H_{21}O_5$: C, 55.54; H, 7.46%.

3, 3-Dimethyltetronic Acid.—This compound was prepared by the method of Cannon and Jones[12]: 70%; b. p. 70~72°C/3 mmHg; n_D^{25} 1.4475.

Found: C, 56.30; H, 6.52. Calcd. for $C_6H_8O_3$: C, 56.24; H, 6.29%.

5-Bromo-3, 3-dimethyltetronic Acid.—A solution of 16 g. of 3,3-dimethyltetronic acid in 30 ml. of carbon tetrachloride was warmed at 60°C, and then 20 g. of bromine was added with stirring. The solvent was evaporated off under reduced pressure. Upon the cooling with ice-water, all the residue was solidified. The product was washed with cold water, dried in vacuo over potassium hydroxide, and recrystallized from ether; 92%; m. p. 52.5~54°C (decomp.).

Found: C, 34.75; H, 3.68; Br, 42.02. Calcd. for $C_6H_7O_3Br$: C, 34.78; H, 3.38; Br, 41.88%.

5-Oxy-3, 3-dimethyltetronic Acid[3].—A suspension of 5-bromo-3, 3-dimethyltetronic acid in water was stored in a refrigerator for over a month. The solid product was recrystallized from methanol; m. p. 137°C.

11) R. J. Marshall and W. N. Cannon, *J. Org. Chem.*, 21, 245 (1956).

12) W. N. Cannon and R. G. Jones, ibid., 23, 126 (1958).

Found: C, 49.89; H, 5.72. Calcd. for $C_6H_8O_4$: C, 50.00; H, 5.60%.

Isopropylglyoxal. — Five grams of pulverized 5-bromo-3,3-dimethyltetronic acid was suspended in an aqueous solution of 1.3 g. of sodium carbonate in 50 ml. of water. The entire mixture was whirled. The evolusion of carbon dioxide began immediately, and after about half an hour the characteristic odor of isopropylglyoxal could be smelled. The entire mixture was stored in a refrigerator. After a few hours, most of the solid disappeared, but after standing overnight many white needles were deposited. The entire mixture was then gradually heated to 90°C. The needles dissolved in the solution, and a steady evolution of gas took place. After its end, the solution was cooled with ice-water. The long white needles which were deposited were collected by filtration. The purification was effected by vacuum sublimation; yield, 85%; m. p. 95~96.5°C.

Found: C, 59.80; H, 8.07. Calcd. for $C_5H_8O_2$: C, 60.00; H, 8.00%.

Isobutyrylformoin.—Into a solution of 4.5 g. of isopropylglyoxal in 150 ml. of 90% aqueous alcohol, a solution of 0.2 g. sodium cyanide in 5 ml. of water was added under a nitrogen stream. The entire solution was then cooled at 0°C for about twenty minutes. After the addition of a few drops of phosphoric acid, the solvent was evaporated off under reduced pressure. The faint-colored crystals which appeared were washed with about 50 ml. of cold water, then dissolved in a minimum amount of alcohol and crystallized by the addition of water: yield, 68%; m. p. 88~93°C.

Found: C, 59.78; H, 7.75; mol. wt. (Rast), 186. Calcd. for $C_{10}H_{16}O_4$: C, 60.00; H, 8.00%; mol. wt., 200.

Spectra. — The infrared spectra were recorded with a Koken model DS-301 spectrophotometer. The ultraviolet spectra were recorded with a Shimadzu model QR-50 spectrophotometer.

The Determination of the Water Content of the Low Polymers of Formaldehyde by the Karl Fischer Method. I. The Determination of the Adsorbed Water and Bound Water Formed by the Pyrolysis of the Polymer

By Kaname MUROI and Kunihiko OGAWA

(Received April 20, 1963)

The difficulty in determining the water content in the low polymers of formaldehyde by the vacuum-drying method is that the content of bound water produced by the pyrolysis of the polymer via the reaction,

$$HO-(CH_2O)_n-H \rightleftharpoons nCH_2O+H_2O \quad (1)$$

and also the content of water physically adsorbed on the polymer are determined at the same time[1]. The determination of the adsorbed water with a high degree of accuracy is, therefore, difficult in this method. The authors have found a new method to determine these two kinds of water separately by using the Karl Fischer method.

Experimental

Materials.—Both commercial grade and a special-class reagent of paraformaldehyde were used without further purification. α-Polyoxymethylene was supplied by our laboratory. Methanol was dried by magnesium metal. Ethylene glycol, butylene glycol and propylene glycol were dried by boiling. The Karl Fischer reagent SS "Mitsubishi", free from methanol supplied by the Mitsubishi Chemical Industries, was used (titer: 0.5 mg. H_2O/ml. and 3.0 mg. H_2O/ml.).

Apparatus.—The Karl Fischer electrometric titration apparatus, operating by the dead stop method, was manufactured by the Tsutsui Chemical Instrument Co. The apparatus is illustrated in Fig. 1. A is the container of anhydrous methanol prepared by adding the Karl Fischer reagent drop by drop to the end point. The methanol was used for the extraction of the adsorbed water. The polyethylene bag, H, filled with dry nitrogen was used to keep the titration flask from moisture in the air. The titration flasks J and K were used for the determination of the adsorbed water, and L, for the bound water, in polymers. Figure 2 illustrates the Ward-type automatic buret which was used as the container and the pipet of dry propylene glycol. Dry propylene glycol was treated

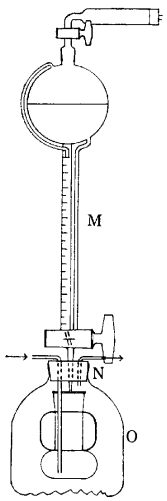

Fig. 2. Automatic buret of propylene glycol.

M: Ward-type automatic buret, 1000 ml.
N: Rubber stopper
O: Polyethylene bag

in the polyethylene bag, O, filled with dry nitrogen.

Procedure.—*The Determination of the Adsorbed Water.—Undried Sample:* The titration flask, J, was attached to E and filled with 25 ml. of anhydrous methanol as exactly measured by the buret, C. After adding the Karl Fischer reagent to the dead stop end point, an exactly-weighed polymer sample was added through a side-arm; the methanol solution was then stored about 10 min. The percentage of adsorbed water, *a* %, is calculated from the titration value of the Karl Fischer reagent (titer 3 mg. H_2O/ml.) for this solution.

Dried Sample: The flask K, containing about 10 g. of a carefully dried sample, was attached to E in bag, H, filled with dried nitrogen. Fifty milliliters of anhydrous methanol was added, and the solution was stored about 10 min. The water content, *a* %, was calculated from the titration value of the Karl Fischer reagent (titer 0.5 mg. H_2O/ml.) for this solution, from which the blank value obtained by the control experiments for a methanol solvent had been subtracted.

The Determination of the Bound Water.—Undried Sample: The titration flask, L, attached to the automatic buret, M, was flushed with dry nitrogen so as to completely remove the adsorbed water from the wall. An exactly weighed sample was added to 25 ml. of propylene glycol in the flask, L, and heated at 160°C about 5 to 10 min., while the jacket around the flask, L, was cooled. The sample was completely dissolved into propylene glycol in this condition. The flask, L, was carefully attached to E so as not to come in contact with moisture in the air by using a dry nitrogen-filled bag, H. The water content in the solution, *b* %, was calculated from the titration value with the Karl Fischer reagent of the titer of 3 mg. H_2O/ml., from which the value for control experiment had been subtracted.

Dried Sample: About 5 g. of a weighed sample in the flask, L, was carefully dried in a vacuum desiccator. The flask, L, was attached to the automatic buret, M, via the joint, N, in a completely dry condition by using the polyethylene bag, O, filled with dry nitrogen. Fifty milliliters of propylene glycol was added to the sample. Again the sample was dissolved into propylene glycol after 5 to 10 min. heating at 160°C. The water content, *b* %, was calculated by the method previously described for the undrid sample. The content of bound water, *c* %, was given by the difference between *b* and *a*; i.e. $c(\%) = b(\%) - a(\%)$.

Results and Discussion

The Elimination of the Effect of Moisture in the Air.—The interference of moisture in the air with the Karl Fischer method and a method of eliminating this interference have been discussed in detail by Bastin et al.[2] and by Loveland and Wester[3]. In the course of the present work, the authors found that the Karl Fischer reagent had a great sensitivity to the moisture in the air and that the water adsorbed on the wall of the flask caused a big error in the determination of a

0.43	−0.02	4.99	−0.09	
average	0.45±0.05	5.08	±0.10	+4.63

small amount of water. Table I lists the amount of adsorbed water for the dried sample and the range of error in two cases, one, for the experiment carefully conducted in a dry nitrogen atmosphere and the other, in air. It is obvious that, in the latter case, moisture in the air and the water adsorbed on the glass wall yield much larger values and errors. To eliminate this interference, the authors propose the following two methods:

1) To flush dry nitrogen through a titration flask about 20 min.

2) In the case of the determination of a small amount of water adsorbed on a dried sample, in order to eliminate the repetition of control experiments and also to prevent moisture from entering a flask during the sampling, anhydrous methanol which had been prepared by adding a Karl Fischer reagent to the dead stop point was added to the sample from columns A and C. It would be more effective to put the whole apparatus in a dry box or in a low-humidity room, but in the present work the authors have reported a convenient method for use in an ordinary laboratory.

The Determination of the Adsorbed Water.—Various conditions of the extraction of adsorbed water by dry methanol were studied using the special class reagent paraformaldehyde as a sample. Table II lists the experimental conditions and observed values of water content. It is concluded that the adsorbed water was easily extracted by 25 ml. of methanol after storing the solution for 10 min. Table III lists the values of water content in the various dried samples. An excellent reproducibility is obtained.

The Determination of the Summed Amount of Bound Water and Adsorbed Water.—Iliceto and Bezzi discovered the reaction of formaldehyde with methanol and suggested the use of the Karl Fischer reagent after changing formaldehyde to cyanohydrine by treating it with hydrogen cyanide[4]. The authors have tried to find a better solvent than methanol. Dimethylformamide, *o*-chlorophenol, dioxane, *m*-cresol and ethylene glycol, propylene glycol, and butylene glycol were used as solvents. First, the solubility of samples in these solvents was studied. The samples had low solubility in dimethylformamide, *o*-chlorophenol, *m*-cresol and diethylene glycol, even at 120°C. They had a high solubility in hot dioxane, but a low value at room temperature. It was concluded from the solubility tests that ethylene glycol, propylene glycol and butylene glycol were good solvents. Formaldehyde reacts readily with glycols and yields water in the presence of acid catalysis or at a high temperature via the reaction:

$$\begin{matrix} CH_2OH \\ | \\ CH_2OH \end{matrix} + HCHO \rightarrow \begin{matrix} CH_2O \\ | \\ CH_2O \end{matrix}\!\!>CH_2 + H_2O \quad (2)$$

The water thus formed might interfere with the determination of water by the pyrolysis method.

Table IV lists the variation in water content of paraformaldehyde at various conditions of pyrolysis in dry ethylene glycol. The sample is insoluble below 60°C, when only the

4) A. Iliceto and S. Bezzi, *La Chimica e l'Industria*. 42, 728 (1960).

adsorbed water was extracted. The water content reached a constant value in the temperature region 120~150°C within 10 minutes heating. At 170°C the same constant value was obtained in 3 minutes heating. At 150°C, the water content increased with the heating period, which suggests the occurrence of reaction 2. The reaction of formaldehyde with propylene glycol and butylene glycol was also studied, because it is well known that the rate of esterification decreases in the order of primary, secondary and tertiary alcohols. Figure 3 illustrates the results. It is concluded that propylene glycol is the best solvent because it gives an almost constant value of water content during the heating period studied. The dependence of the value of water content on the ratio of the amount of propylene glycol to that of sample was studied. Table V lists the value of water content with various amounts of sample and solvent. It is suggested that about 5 g. of a sample in 25 ml. of propylene glycol is suitable for conducting experiments. Table VI lists the value of the summed content of adsorbed water and bound water in various types of low polymers of formaldehyde determined by the pyrolysis method in dry propylene glycol. Table VII lists the value of adsorbed water content for the samples determined by the methanol extraction method. The difference in values corresponds to the content of bound water in the polymers. The average degree of polymerization was calculated from the content of bound water.

The determination of the degree of polymerization of the low polymer of formaldehyde is rather difficult, and only a few methods have been reported[5,6]. Recently, Iliceto and Bezzi[4] have determined the degree of polymerization from the water content by the Karl Fischer method, but they have not determined bound water and adsorbed water separately, as the present authors have now done. In the other works, since the calculation was based on the summed amount of bound and adsorbed water, the accuracy of

the determination of the degree of polymerization was not very high. The method reported in the present work can be used for the determination of the degree of polymerization of formaldehyde with a high degree of accuracy. To verify the accuracy of the determination of bound water, formaldehyde and methanol in polymer were determined independently. The former was determined by the sodium sulfite method, and the latter, by gas chromatography. Table VIII lists the percentage of formaldehyde and methanol thus determined, together with that of bound water. The sum of these three components is almost 100%, thus establishing the accuracy of this method.

Summary

The adsorbed water of the low polymer of formaldehyde was determined by extraction with dry methanol and Karl Fischer titration. The sum of the adsorbed water and the water formed by the pyrolysis of the sample was determined by titration with the specially prepared Karl Fischer reagent SS, after the sample had been dissolved in propylene glycol by heating. The method of the separation and the determination of the two kinds of water was thus established. When the average numerical degree of polymerization of the polymers was calculated from the content of bound water determined by this method, satisfactory results were obtained. To verify the accuracy of the determination of water content, formaldehyde and methanol were determined independently; their sum was found to be almost 100%.

The authors wish to thank Mr. Daikichiro Nishikawa of the High Polymer Research Department, for the samples used in this study and Mr. Hisakazu Araki, Manager of the Analytical Research Department, for his kind advice.

Studies of Acenaphthene Derivatives. IX[1]. *The Reaction of Acenaphthenequinone with Ammonia*

By Otohiko Tsuge and Masashi Tashiro

(Received April 22, 1963)

In the course of the investigation of the reaction of acenaphthenequinone (I) with various amines, the reaction of I with ammonia was studied.

Many years ago, Graebe and Gfeller[2] found that the treatment of I with aqueous ammonia at 100°C in a sealed tube afforded red crystals (II) (m. p. over 300°C) with the formula $C_{24}H_{12}ON_2$, for which acenaphthenequinoneimide anhydride (IIa) was assumed. Later, Schönberg and Nedzati[3] suggested that acenaphthazine (IIb) (m. p. 400°C (decomp.)), with the formula $C_{24}H_{12}N_2$ for II, would be more reasonable than IIa because of its formation by the reduction of acenaphthenequinone dioxime (III) with a very poor yield and its having properties similar to those of phenanthrazine as well as because of the elemental analyses. In a similar manner, Charrier and Ghigi[4] obtained naphthalimide in addition to II, whose structure was not reexamined.

Furthermore, Schiedt[5] reported that IIb (m. p. 438°C) was produced by the heating of I with formamide in the presence of glacial acetic acid at 170°C. However, its structure was not characterized.

Although the structure of acenaphthazine for II seemed to be reasonable, the authors were doubtful about the reduction procedure of III and the purification method of II carried out by Schönberg and Nedzati[3]. They recognized that IIb was formed by the condensation of 1,2-diaminoacenaphthene (IV) and I, which had been produced by the reduction, accompanied by the simultaneous hydrolysis of III, as is depicted in Chart 1. However, it can also be considered that this product was formed by the reaction of I produced by hydrolysis with ammonia, since they treated the reaction mixture with aqueous ammonia for a long time. Further, even if I reacted with IV, IIb was not the only possible product. Furthermore, the purification of II was carried out by sublimation with iron powder.

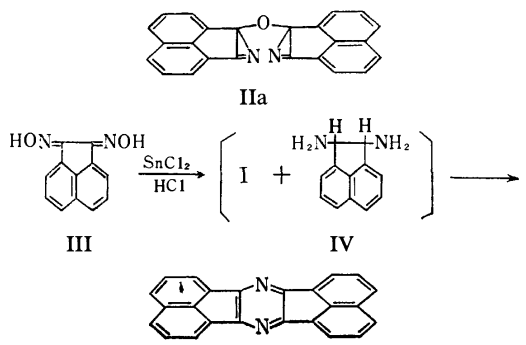

Chart 1

This paper deals with the results of a reexamination of the structure of II and of the reaction of I with ammonia under various conditions.

Results and Discussion

Reaction by Graebe's Procedure.—The reaction of I with 21% aqueous ammonia at 100°C in a sealed tube according to Graebe's procedure afforded red crystals (II) (m. p. 382°C), naphthalimide (V), and a new colorless compound (VI) (m. p. 286~287°C).

The elemental analytical data of II was in agreement with the formula $C_{24}H_{12}ON_2$ given by Graebe and Gfeller[2] but not with Schönberg's formula, $C_{24}H_{12}N_2$[3]. Its infrared spectrum exhibited the sharp bands at 1704 and 1616 cm^{-1} ascribed to the carbonyl group[6] and the C=N bond respectively, but it did not reveal any bands for the amino group (Fig. 1.). Also, the infrared spectrum of the compound purified by sublimation was exactly the same as that of the original substance. As no suitable solvent of II could be found, its molecular weight was not determined.

In order to elucidate the structure of II more clearly, the following experiments were carried out. It is obvious that II contains two acenaphthene rings in the molecule, because the oxidation of II (1 mol. as $C_{24}H_{12}ON_2$) with sodium dichromate in glacial acetic acid

—— In hexachlorobutadiene mull
------ In Nujol mull

afforded naphthalimide (V) (ca. 1.5 mol.) and naphthalic anhydride (VII) (ca. 0.5 mol.) (Chart 2). The reduction of II with zinc dust in acetic acid gave a labile orange substance which was purified as the picrate. In the infrared spectrum of the orange product just after the reduction, there was no band due to the carbonyl group, but there were two bands, at 3120 and 1618 cm^{-1}, which may be ascribed to the hydroxyl group and the C=N bond respectively. However, this compound could not be identified.

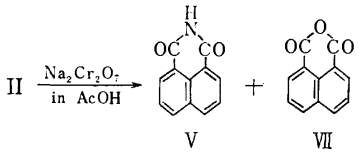

Chart 2

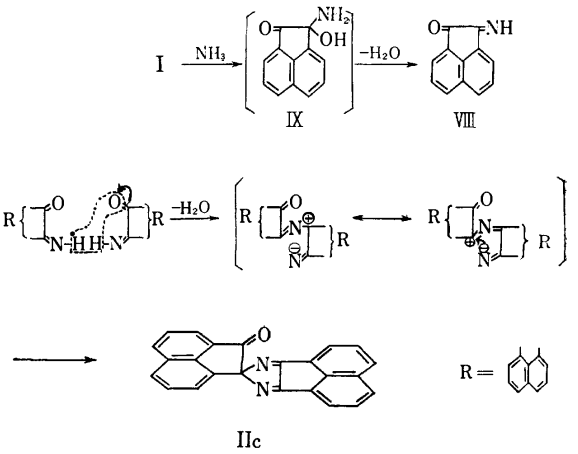
In addition, II was obtained quantitatively by the heating of the acenaphthenequinone monoimine (VIII) which had been obtained by the reaction of I with ammonia in ethanol, as will be described below.

Weiss[7] discovered that the reaction of benzil with ammonium acetate in the presence of acetic acid resulted in isoimidazole derivatives.

7) M. Weiss, *J. Am. Chem. Soc.*, 74, 5193 (1952).

Accordingly, these observations are accommodated much better by the structure of acenaphtho[1,2-b]isoimidazole-2-spiro-2'-acenaphthenone (IIc) than by IIa or IIb. IIc is assumed to be formed by the self-condensation of the VIII which was produced by the dehydration of the ammonia-adduct (IX) of I as depicted in Chart 3.

On the other hand, VI accorded with the formula $C_{24}H_{13}O_3N$, which is the result of the



IIc

Chart 3

elemental analysis and the molecular weight measurement. The infrared spectrum of VI showed the absorption bands at 1721 or 1698 and 1658 cm^{-1} assigned to the carbonyl group or the amide I band respectively. The bands at 3077 cm^{-1} for the aromatic C-H bond and at 2933 cm^{-1} ascribed to the aliphatic C-H bond were also observed[8] (Fig. 2.). Its ultraviolet spectrum is very similar to that of *N*-phenylnaphthalimide, as is shown in Fig. 3.

These observations indicate that this compound is *N*-(2-oxo-acenaphthenyl)naphthalimide (VI).

It has previously been well-known that the treatment of I with alkali gives naphthaldehyde and naphthalic acid[9]. Consequently, VI is assumed to be formed by the condensation of the ammonia-adduct (IX) and naphthaldehyde, as is depicted in Chart 4.

Furthermore, the formation of V and VII can be illustrated naturally, as Chart 4 shows. The effect of the reaction time on the yields of these compounds was examined. The results are listed in Table I.

As is shown in Table I, IIc was formed as

8) The infrared spectrum of IIc did not show any absorption due to the aliphatic bonds, but it did show a band at 3030 cm^{-1} for the aromatic C-H bond. Also, *N*-phenylnaphthalimide exhibited the bands at 1701 and 1664 cm^{-1} assigned as the amide I bands in its infrared spectrum.

the main product, accompanied by a considerably large amount of VI. The yields of these compounds were nearly constant, even if the reaction time was longer than 3 hr.

The Reaction with Ammonia in Water or Ethanol.—Ammonia gas was violently passed through the suspension of I in either water or ethanol. The results are shown in Tables II and III.

In the case of the reaction of I with ammonia gas in water, also, IIc, V and VI were obtained, as is shown in Table II. However, more V was formed than VI, and the rate of the formation of IIc was slower than in Graebe's procedure mentioned above.

The reaction of I with ammonia gas in ethanol gave V as the main product, accompanied by IIc and an unknown compound

(VIII) (m. p. 343°C (decomp.)) in almost identical yields. As the heating of VIII gave IIc in a quantitative yield, it seems reasonable to assume that VIII is the intermediate of IIc.

Zincke[10] reported long ago that the reaction of phenanthrenequinone with ammonia afforded phenanthrenequinone monoimine, which in turn yields a red substance upon being heated. In addition, the infrared spectrum of VIII, which corresponds to the formula $C_{12}H_7ON$, revealed absorption bands at 3128 and 1605 or 1681 cm^{-1} for the -C=NH or the carbonyl group respectively[11].

On the basis of these facts, this compound is considered to be acenaphthenequinone monoimine (VIII) formed as shown in Chart 3. The observed shifts of these bands to a longer wavelength region seem to be due to the intermolecular chelation of VIII.

10) Th. Zincke, *Ber.*, 12, 1641 (1879).
11) Phenanthrenequinone monoimine prepared by the reaction of phenanthrenequinone with ammonia showed the infrared absorption bands at 3215 and 1605 or 1678 cm^{-1} due to the -C=NH or the carbonyl group respectively.

The reaction of I with ethanolic ammonia in a closed vessel at room temperature for ten days afforded IIc, VI and VIII in about 10, 35 and 45% yields respectively. Another reaction with liquid ammonia gave IIc, VI and naphthalic acid.

The Reaction of I with Ammonium Carbonate in Glacial Acetic Acid.—The treatment of I with ammonium carbonate in boiling glacial acetic acid gave IIc and V. The effect of reaction conditions on the yields of these compounds is summarized in Table IV. As is shown in Table IV, this simple procedure seems to be the most promising route to IIc.

Furthermore, the heating of I with formamide and glacial acetic acid at 170~180°C afforded a red substance which was confirmed to be identical with IIc by a comparison of their infrared spectra. Also, another reaction of 2, 2-dichloroacenaphthenone with ammonium carbonate in glacial acetic acid afforded IIc.

Experimental[12,13]

The infrared spectra of all compounds were measured in hexachlorobutadiene mull. Acenaphthenequinone (I) was prepared by the oxidation of acenaphthene[14] in the form of yellow needles (m. p. 244~245°C).

The Reaction of I with Aqueous Ammonia by Graebe's Procedure.—A mixture of I (5.0 g.) and 21% aqueous ammonia (50 ml.) was heated in a sealed tube at 100°C for 1 hr. After it had cooled, the reaction mixture was poured into water and the precipitate was extracted by boiling acetic acid (100 ml.), leaving red crystals. Those red crystals were washed with ethanol and dried to give 1.78 g. (m. p. 375~376°C). Recrystallization from pyridine or sublimation afforded acenaphtho[1, 2-b]-isoimidazole-2-spiro-2'-acenaphthenone (IIc) as red needles (m. p., 382°C).

Found: C, 83.61; H, 3.56; N, 8.42. Calcd. for $C_{24}H_{12}ON_2$: C, 83.71; H, 3.51; N, 8.13%.

The precipitate obtained by the pouring of the extract and washings into water was heated with 40% sodium bisulfite (200 ml.) for 10 min. The hot solution was then filtered by suction. The filtrate was treated with concentrated sulfuric acid as usual to recover I (2.0 g.). The sodium bisulfite solution-insoluble residue was washed with hot water and ethanol, and then dried to afford 0.95 g. of colorless crystals melting at 260~270°C. On the fractional recrystallization of the colorless crystals from acetic acid, two compounds were obtained: one with an m. p. of 300°C and the other with an m. p. of 286~287°C. The former was in a trace amount and was proved to be identical with naphthalimide (V) by the admixed melting point with an authentic sample. The latter was *N*-(2-oxo-acenaphthenyl)naphthalimide (VI) as colorless prisms in a large amount.

12) All melting points are uncorrected.
13) The microanalyses were carried ont by M. Shidō of Kyushu University, to whom the authors are indebted.
14) "Organic Syntheses", 24, 1 (1944).

Found: C, 79.43; H, 3.69; N, 3.82; mol. wt. (Rast), 362.5. Calcd. for $C_{24}H_{13}O_3N$: C, 79.32; H, 3.61; N, 3.85%; mol. wt., 363.35.

$\lambda_{max}^{Dioxane}$ mμ (log ε): 231 (4.69), 330 (4.23)[15].

The effect of reaction conditions on the yields of these products is shown in Table I.

The Oxidation of IIc.—Sodium dichromate (6.0 g.) was added slowly to a suspension of IIc (2.0 g., 5.8 mmol.) in glacial acetic acid (50 ml.) at 80°C.

After being refluxed for 1 hr., the reaction mixture was poured into water and allowed to stand overnight. The precipitate was then collected and extracted with a 10% aqueous sodium carbonate solution. The insoluble residue was washed with water and dried to afford 1.7 g. (8.6 mmol.) of colorless crystals (m. p. 287~279°C). On recrystallization of these crystals from acetic acid, colorless needles (m. p., 300°C) were obtained and proved to be identical with V. The sodium carbonate-extract was acidified with dilute hydrochloric acid, and the deposited precipitate was collected, washed with water, and dried to give 0.62 g. (3.1 mmol.) of a white solid (m. p. 267~269°C). Recrystallization of this from concentrated nitric acid gave colorless needles (m. p. 274°C) which were identical with naphthalic anhydride.

The Reduction of IIc.—A suspension of IIc (0.5 g.) and zinc dust (1.0 g.) in a mixture of acetic anhydride (20 ml.) and glacial acetic acid (6 ml.) was heated under reflux for 20 min.; additional zinc dust (1.0 g.) was then added to the reaction mixture and it was refluxed for another 30 min. The hot solution was filtered by suction, and the filtrate was poured into water to give a labile orange precipitate which tended to decompose on heating.

Purification of the orange substance was accomplished through its picrate. This picrate was obtained (0.45 g.) as a yellow solid (m. p. 270°C (decomp.)) which, on recrystallization from dioxane, gave a yellow crystalline powder (m. p. 275°C (decomp.)). (Found: C, 63.90; H, 3.73; N, 12.51%). This compound could not be identified.

The Reaction of I with Ammonia Gas in Water.—Ammonia gas was violently passed through a suspension of I (5.0 g.) in water (50 ml.) at 70~80°C for 6 hr. The reaction mixture was poured into water, and the precipitate was collected. The same treatment as in Graebe's procedure gave the starting material, I (1.5 g.), IIc (1.79 g.), V (0.64 g.) and VI in a small amount. The results of other experiments, along with various reaction conditions, are listed in Table II.

The Reaction of I with Ammonia Gas in Ethanol.—a) Ammonia gas was violently passed through a suspension of I (5.0 g.) in boiling ethanol (50 ml.) for 4 hr. The same treatment as in the above-mentioned procedure gave the starting material, I (0.8 g.). The sodium carbonate-insoluble residue was extracted with hot glacial acetic acid and then with hot chloroform[16], (40 ml.×2) remaining a white solid (0.67 g.; m. p. over 300°C). (Recrystallization from pyridine gave acenaphthene monoimine (VIII) as colorless prisms (m. p. 343°C (decomp.)).

Found: C, 79.69; H, 4.16; N, 7.75. Calcd. for $C_{12}H_7ON$: C, 79.54; H, 3.89; N, 7.73%. Hydrochloride of VIII, Found: N, 6.99. Calcd. for $C_{12}H_8ONCl$: N, 6.43%.

The acetic acid-extract was concentrated in vacuo to afford V (2.69 g.), and from the chloroform-extract IIc (0.66 g.) was obtained. The results of other reactions in ethanol are shown in Table III.

b) A mixture of I (2.0 g.) and ethanol (50 ml.) containing ammonia (ca. 0.4 g.) was stirred in a closed vessel at room temperature for ten days.

After the reaction mixture had been poured into water, the precipitate was collected, washed with water, dried, and extracted with hot chloroform (50 ml.×2). The recrystallization of the insoluble white solid (0.9 g.) (m. p. 343°C (decomp.)) whose infrared spectrum was superimposed on that of VIII obtained above was undertaken. The chloroform-extract was evaporated, and the residue was further extracted with hot glacial acetic acid to give insoluble red crystals IIc (0.17 g.) and soluble colorless prisms VI (0.8 g.). The structures of these compounds were confirmed to be as described above.

The Reaction of I with Ammonium Carbonate in Glacial Acetic Acid.—The refluxing of a mixture of (1.0 g.) and ammonium carbonate (13.0 g.) in glacial acetic acid (30 ml.) resulted in the precipitation of red crystals within a few minutes. After the mixture had been refluxed for 1 hr., filtration gave red crystals (0.37 g.) (m. p. 377~378°C), the infrared spectrum of which was exactly the same as that of IIc. The filtrate was poured into water, and the precipitate was treated, as usual, with a 40% sodium bisulfite solution (50 ml.) to give I in a small amount. The sodium bisulfite-insoluble residue was washed with hot water and dried to give colorless crystals (0.53 g.), which were found to be identical with V from the admixed m. p. and infrared spectrum. The findings on the effect of reaction conditions on the yields of these compounds are summarized in Table IV.

The Reaction of I with Liquid Ammonia.—A mixture of I (10.0 g.) and liquid ammonia (120 ml.) was shaken in a dry ice-methanol bath for 7 hr.

After the ammonia had been removed at room temperature, the residue was washed well with water. The washings were acidified with dilute hydrochloric acid and dried to afford white crystals (3.0 g.) (m. p. 268~272°C) which, on recrystallization from concentrated nitric acid, gave colorless needles (m. p., 274°C). This compound was identical with VII. The treatment of the insoluble residue with a 40% sodium bisulfite solution, and then with hot acetic acid, as mentioned above, gave I (3.2 g.), IIc (2.0 g.), and VI (1.0 g.).

The Reaction of I with Formamide in the Presence of Acetic Acid.—A mixture of I (2.5 g.), formamide (40 ml.) and glacial acetic acid (1 ml.) was heated at 170~180°C in an oil bath for 20 min.

After being cooled, the mixture separated out crystals. Filtration gave red crystals (1.5 g.) (m. p.

15) *N*-Phenylnaphthalimide: $\lambda_{max}^{Dioxane}$ mμ (log ε); 231 (4.59), 329 (4.17).

16) IIc was soluble in boiling chloroform.

over 300°C) which, on recrystallization from pyridine, showed an m. p. of 382°C. The infrared spectrum and elemental analytical values were in agreement with those of IIc. (Found: C, 83.83; H, 3.60; N, 8.48%.)

The Reaction of 2, 2-Dichloroacenaphthenone with Ammonium Carbonate in Glacial Acetic Acid. —A mixture of 2, 2-dichloroacenaphthenone[17] (1.0 g.) and ammonium carbonate (26.0 g.) in glacial acetic acid (30 ml.) was refluxed for 30 min. After the mixture had been cooled, filtration afforded red crystals (0.4 g.) (m. p. 360~363°C) which, on recrystallization from pyridine, gave red needles (m. p. 382°C), the infrared spectrum of which was superimposed on that of IIc. The filtrate was not examined.

17) 2, 2-Dichloroacenaphthenone was prepared by the reaction of I with PCl_5. (A. I. Tochilkin, *Zhur. Vsesoynz. Khim., Obshchestva im. D. I. Mendeleeva*, **6**, 591 (1961).)

The authors wish to express their deep gratitude to Dr. Takashi Yoshida of the Yawata Chem. Co. for contributing acenaphthene used in this study.

*Ionic Hydration in an Aqueous Electrolyte Solution and Its Parameter**

By Kiyoshi TAMURA** and Tsunetaka SASAKI

(Received April 8, 1963)

It is well-known that ion-solvent interaction in aqueous solutions plays an important rôle in various properties and phenomena[1-4], such as the adsorption, surface tension, mobility, viscosity, diffusion, compressibility and activity coefficient, as well as the swelling, salting-out and other lyotropic phenomena. A concept of ionic hydration has been introduced as an important factor in attempting to explain these phenomena, and the amount or the intensity of hydration has been determined by various methods, such as measurements of the compressibility[5-8], the activity[9-11], the diffusion[12] and the dielectric constant[13,14]. All these quantities measure in some way the ion-solvent interaction or the hydration properties, but each of these different methods measures a different extent of ionic hydration. It is desirable, therefore, to establish a common and basic parameter concerning ionic hydration.

The dissolution of an electrolyte in water causes a volume contraction and a decrease in compressibility due to the interaction between the ions and water molecules. The magnitude of these changes can, therefore, be used as a measure of the hydration. We have already noticed[8,15,16] that the volume contraction is proportional to the amount of hydration water calculated from the compressibility data and that the proportionality constant is independent of the temperature and the nature of the electrolyte. For the explanation of this fact, we can refer to the studies of Webb[17] and Bernal and Fowler[18], who have calculated the mutual interaction between water molecules and ions. However, the lack of data necessary for calculation, especially the lack of knowledge about the hydrostatic pressure in the immediate vicinity of an ion in an aqueous solution, made a similar calculation impossible in the present case. Therefore, we adopted another method of calculation, one similar to

Harned and Owen's[19] and based upon the empirical equation of Tait, which gives the compressibility of water under pressure. Thus we obtained the quantity which may be proposed as a common parameter of hydration.

Tait's Equation and its Applicability to Water. —Tait's equation is applicable to many pure liquids in either of the form:

$$\beta_1^{(p)}V_1^{(p)} \equiv -(\partial V_1^{(p)}/\partial P)_T = 0.4343C/(B+P) \quad (1)$$

or in its integrated form:

$$V_1^{(p_0)} - V_1^{(p)} = C\log\{(B+P)/(B+P_0)\} \quad (2)$$

where β_1 is the isothermal compressibility; V_1, the molar volume of water (solvent); P, the pressure; T, the absolute temperature, and B and C, constants dependent only upon the temperature and the nature of the liquid. The superscript (p) indicates the properties under the external pressure, P, and P_0 is the standard pressure, which may be taken as one bar.

According to Carl[20] and Gibson[21], Eq. 1 is applicable to water up to about $P=10000$ bar; the former author has also shown that the value of $0.4343C/V_1^{(p_0)}$ is independent of the temperature. The values of B, C and $0.4343C/V_1^{(p_0)}$ for water at temperatures ranging from 20 to 50°C, calculated from Bridgman's data[22] by the present authors, are shown in Table I. The average value of $0.4343C/V_1^{(p_0)}$ is somewhat different from the value obtained by Carl (0.1243)[20] and that obtained by Gibson (0.1368)[23].

		Average	0.1338

The Molar Volume of the Solute in a Solution.—The molar volume of the solute was calculated by a method similar to that of Harned and Owen[19]. According to Tammann[24], water in an electrolyte solution behaves like a substance under a constant effective pressure which is higher than the atmospheric one by P_e. This state is called electrostriction by Nernst[25]. The volume contraction and the decrease in the compressibility of a solution produced by the addition of an electrolyte to it are ascribed exclusively to the changes in the respective properties of the solvent water. The volume, $\varphi_1^{(p)}$, occupied by one mole of water in an electrolyte solution under an external pressure, P, is, therefore, the molar volume of pure water under the pressure $(P+P_e)$. Thus, from Eq. 2 we obtain:

$$V_1^{(p)} - \varphi_1^{(p)} = C\log\{(B+P+P_e)/(B+P)\} \quad (3)$$

A solution containing n_1 mol. of water and one mole of solute has the volume

$$V^{(p)} = n_1\varphi_1^{(p)} + \varphi_2^{(p)} \quad (4)$$

where $\varphi_2^{(p)}$ is the contribution to the volume of the solution made by one mole of solute in the state of solution.

From Eqs. 2, 3 and 4, we obtain

$$V^{(p)} = n_1V_1^{(p_0)} - n_1C \times\log\{(B+P+P_e)/(B+P_0)\} + \varphi_2^{(p)} \quad (5)$$

Putting $P=P_0$, we get

$$V^{(p_0)} = n_1V_1^{(p_0)} - n_1C \times\log\{(B+P_0+P_e)/(B+P_0)\} + \varphi_2^{(p_0)} \quad (6)$$

By the differentiation of Eq. 5 with respect to pressure at a constant temperature and composition, we obtain:

$$\beta^{(p)}V^{(p)} \equiv -(\partial V^{(p)}/\partial P)_T = 0.4343Cn_1/(B+P+P_e) - (\partial\varphi_2^{(p)}/\partial P)_T \quad (7)$$

where β is the isothermal compressibility of the solution.

As the last term of Eq. 7 is negligible at moderate pressures and concentrations for an electrolyte solution[21], we obtain from Eqs. 1 and 7:

$$(B+P_0+P_e)/(B+P_0) = n_1\beta_1^{(p_0)}V_1^{(p_0)}/\beta^{(p_0)}V^{(p_0)} \quad (8)$$

and from Eqs. 6 and 8:

$$\varphi_2^{(p_0)} = V^{(p_0)} - n_1V_1^{(p_0)} + n_1C\log(n_1\beta_1^{(p_0)}V_1^{(p_0)}/\beta^{(p_0)}V^{(p_0)}) \quad (9)$$

By Eq. 9 we can calculate $\varphi_2^{(p_0)}$ from the isothermal compressibilities and the densities of both solution and solvent water. The isothermal compressibility can be determined by the sound velocity measurement[7].

T-S: Present authors

The values of $\varphi_2^{(p)}$ obtained were nearly independent of the concentration. The values at an infinite dilution are shown in Table II as $[\varphi_2^{(p)}]$. According to the view that the solute merely melts on going into a solution and occupies the same volume as that of the super-cooled liquid[21], the molar volume of a molten electrolyte at a high temperature was calculated and was extrapolated to the temperatures corresponding to those at which $[\varphi_2^{(p)}]$ was calculated. The values obtained are listed in the third column of Table II as V_2. The two values, obtained from independent methods, exhibit a satisfactory agreement except for a few cases which require further study. This result strongly supports the view that the solute in a solution behaves as a super-cooled liquid so far as its contribution to the volume of the solution is concerned. This means that the aqueous electolyte solution behaves ideally when we use as the molar volume of water the value under the pressure (P_0+P_e) instead of that under P_0.

27) E. B. Freyer, *J. Am. Chem. Soc.*, **53**, 1313 (1931).

Rosen[28] also calculated the molar volume of alkali halides in the solution state from the density of the solution on a principle similar to, but by using an equation of state different from ours. Thus he obtained the same result as did Scott[29], who actually calculated the value by the extrapolation of the apparent molar volume. Both of these authors have given values slightly smaller than ours.

The Parameter of Hydration

Before we discuss the common parameter of hydration, it is pertinent to list some useful quantities relating to the amount of hydration, which will itself be discussed in a later section.

Effective Pressure. — Following Tammann's principle[24] mentioned above, Eucken[30] has calculated the "Hydratationsdruck" the measure of the intensity of solute-solvent interaction for some electrolytes and non-electrolytes such as alcohol and sugar, by comparing the effects of pressure and solute on the specific volume of the solvent water. However, the effective pressure, P_e, or electrostriction, which can be calculated by Eq. 8, expresses more clearly the intensity of the ionic hydration. P_e is further correlated with the molar concentration of water (C_1) and solute (C_2) in a solution in a manner similar to van der Waals' cohesive pressure in gases as follows[31]:

$$P_e = LC_1C_2 \qquad (10)$$

where L is a constant representing the electrostriction or electrostatic attraction under unit concentration.

Volume Contraction. — A number of investigators have examined the volume change which takes place when a solute dissolves into a solvent[1,2,15,17]. This is also one of the simplest quantities representing the intensity of hydration and is directly related to the effective pressure mentioned above. The present authors define the volume contraction of the system, ΔV, due to the dissolution of one mole of solute by

$$\Delta V \equiv n_1 V_1^{(p_0)} + \varphi_2^{(p_0)} - V^{(p)} \qquad (11)$$

From Eqs. 6 and 11, we obtain

$$\Delta V = n_1 C \log \{(B+P_0+P_e)/(B+P_0)\} \qquad (12)$$

Eq. 12 enables the calculation of ΔV from the value of P_e. Here the volume contraction is ascribed exclusively to the change in the volume of the solvent water.

The Amount of Hydration Water.—An entirely different method has been adopted to give a parameter of hydration based on the incompressible hydration shell model[5-8].

If we assume, as is usual with inorganic ions, that the hydration shells, together with the central solute ions, are incompressible, the volume of water, V_h, bound to one mole of solute in solution, reduced to the atmosphere pressure of P_0, is given by

$$V_h = (n_1\beta_1^{(p_0)}V_1^{(p)} - \beta^{(p_0)}V^{(p_0)})/\beta_1^{(p_0)} = -K_2/\beta_1^{(p_0)} \quad (13)$$

where K_2 is the apparent molal compressibility of the solute. The value of V_h may be calculated from the compressibility and density data. We can also give the average hydration number of water molecules for a pair of solute ions by

$$h = V_h/V_1^{(p_0)} \quad (14)$$

The evaluation of V_h and h has been attempted by several authors[5-8,15,16].

The Correlation between L, ΔV and V_h, and the Parameter of Hydration

In order to discuss the correlation between the above three quantities, L, ΔV and V_h, the

* Same as in the footnote of Table II.

density, $d^{(p)}$ and the isothermal compressibility, $\beta^{(p)}$, of a dilute solution at atmospheric pressure are expressed as follows:

$$d^{(p_0)}=d_1^{(p_0)}+aC_2 \quad \text{and} \quad \beta^{(p_0)}=\beta_1^{(p_0)}+bC_2$$

where a and b are constants characteristic of the electrolyte and where the higher terms of concentration are disregarded. Putting these relations into Eqs. 10, 12 and 13, and extrapolating C_2 to zero, we get the following relations:

$$[L]=(B+P_0)(V_1^{(p_0)}/1000)^2[h] \quad (15)$$

$$[\Delta V]=0.4343C[h] \quad (16)$$

$$[V_h]=-[K_2]/\beta_1^{(p_0)}=V_1^{(p_0)}[h] \quad (17)$$

where $[L]$, $[\Delta V]$, $[V_h]$, $[K_2]$ and $[h]$ denote L, ΔV, V_h, K_2 and h at an infinite dilution respectively, and

$$[h]=(1000d_1^{(p_0)}/M_1)(a/d_1^{(p_0)}-b/\beta_1^{(p_0)})-M_2/M_1 \quad (18)$$

where M_1 and M_2 are the molecular weights of the solvent and of the solute respectively. It is noticeable that each of the three quantities contains a common factor $[h]$ multiplied by a different coefficient which depends only upon the nature of water. Therefore, they vary proportionally to each other and to $[h]$; namely, they change proportionally with the change in the nature of the solute provided that the solvent and temperature are kept unchanged. It is quite legitimate, therefore, to take the quantity $[h]$ as a common parameter of hydration. The quantities of $[\Delta V]$, $[V_h]$ and $[h]$ for several electrolytes are listed in Table III.

An important conclusion evidently follows from Eqs. 16 and 17; that is,

$$[\Delta V]/[V_h]=0.4343C/V_1^{(p_0)} \quad (19)$$

As is seen in Table I, the values of $0.4343C/V_1^{(p_0)}$ for water are independent of the temperature, their average being 0.1338. This, together with Eq. 19, explains the previously-mentioned facts[8,15,16] that the volume contraction due to the dissolution of the electrolyte is about 10% of the volume of hydration water for the same electrolyte and that this value does not change with the temperature or the nature of the solute. There, the volume of hydration water (called V_h^*) was calculated from the data of adiabatic compressibility instead of from those of isothermal compressibility in Eq. 13, and the volume contraction (called ΔV^*) was calculated by using V_2 instead of $\varphi_2^{(p_0)}$ in Eq. 11. Figure 1 shows the plots of $[\Delta V^*]$ against $[V_h]$, together with the theoretical straight line of Eq. 19. Agreement is satisfactory.

It is further noticed in Table III that the value of $[h]$ decreases with the increase in

The numbers in bracket indicate temperature (°C) and solid line expresses Eq. 19.

temperature, as can be seen in the case of barium chloride. A similar temperature change was found for sodium chloride in the temperature range from 0 to 60°C[8]. The hydration reaction proves, therefore, to be exothermic in nature.

Stokes and Robinson[9] and Miller[11] modified the Debye-Hückel equation for the activity in a solution of strong electrolytes and expressed the effect of ion-solvent interaction by the term "hydration number". Though their numerical values agree as a whole with ours, their results are not staisfactory in that the hydration numbers increase with the increasing size of the anion and in that the law of the additive contribution of individual ions to the total hydration number does not hold.

Glueckauf[10] calculated hydration numbers with a model similar to that of Stokes and Robinson by means of volume fraction instead of mole fraction statistics; he found values about half as large as those of Stokes and Robinson. In his results, the anomalies of anions are less remarkable, and the additivity law holds fairly well. However, since his hydration numbers for anions are relatively small and since the variation among anions is not so distinct, it does not fully explain the difference in the contribution of each anion to the various phenomena involved in hydration. The superiority of the $[h]$ parameter in comparison with the hydration

numbers cited above is shown by the fact that it varies significantly among ions and is directly proportional to such quantities as $[L]$, $[\Delta V]$ and $[V_h]$.

The values of $[V_h^*]$ are somewhat greater than those of $[V_h]$, and the ratio $[V_h^*]/[V_h]$ is roughly constant, being 1.08 ± 0.14 for the electrolytes listed in Table III. The former can, therefore, be used in place of the latter after due precautions. This is rather fortunate, since the accurate data necessary for the calculation of isothermal from adiabatic compressibility are often lacking. Conventional hydration numbers, $[h^*]$, calculated from the value of $[V_h^*]$ are also listed in the fifth column of Table III.

Summary

Tait's equation for water and Harned and Owen's treatment of an electrolyte solution, together with sound velocity data, enabled the calculation of the molar volume of electrolytes in the solution state. The results agreed fairly well with the molar volume of the super-cooled molten electrolyte extrapolated to room temperature.

The concentration coefficient of electrostrictive pressure, $L=P_e/C_1C_2$, the volume contraction due to the dissolution of one mole of solute, ΔV, and the volume of hydration water per mole of solute, V_h, as an incompressible part of water have been evaluated. We have found a common variable, $[h]$, for L, ΔV and V_h, and it has been proposed that this variable can be used as a parameter of hydration expressing the mole number of hydration water per mole of electrolyte. A conventional hydration number, $[h^*]$, was also proposed.

The authors wish to express their hearty thanks to the Ministry of Education for the Scientific Research Grant given to Tsunetaka Sasaki.

Influence of Substituent Groups on Nuclear Reactivity in the Formation of Substituted Biphenyls by Reaction of Aromatic Diazo and Related Compounds with Aromatic Liquids. VI. p-Chlorophenylation

By Toshihiko MIGITA, Naotake MORIKAWA and Osamu SIMAMURA

(Received May 10, 1963)

In a previous paper[1] the determination has been reported of the partial rate factors of nitrobenzene in *p*-methoxyphenylation by the *p*-methoxyphenyl radical derived from *N*-nitroso-*p*-acetanisidide. In order further to examine the effect of the substituent in the attacking radical in the homolytic arylation, competitive *p*-chlorophenylations of nitrobenzene, chlorobenzene, anisole, and toluene using benzene as a reference substrate have been carried out, with *N*-nitroso-*p*-chloro(^{36}Cl)acetanilide as a source of the *p*-chlorophenyl radical, and the products have been analyzed by isotope dilution analysis. We now report the results of this study.

Table I lists the values for the partial rate factor and the relative rate calculated from the relative amounts in which 4-chlorobiphenyl and the three isomeric substituted 4-chlorobiphenyls were formed in the competitive *p*-chlorophenylation. Because of difficulty in isolating radiochemically pure 3,4′-dichlorobiphenyl from the reaction mixture with chlorobenzene, we could not determine the partial rate factor for the meta position of chlorobenzene by means of isotope dilution analysis. The value of 0.87 given in Table I for this partial rate factor was estimated from the value of the partial rate factor for the ortho position obtained by this method and the molar ratio, as determined by means of infrared-spectrophotometry, in which 2,4′- and 3,4′-dichlorobiphenyl were formed by the reaction of non-labelled *N*-nitroso-*p*-chloroacetanilide with chlorobenzene.

Inspection of the table shows that the ortho- and para positions are more reactive than the meta position for all aromatic compounds,

	Mean	2.97	1.07	1.32	1.56

* Reaction temperature was 18°C. ** See text.

k, k_o, k_m, and k_p denote the rate constants on one nuclear position of benzene and the ortho, meta, and para position of the substituted benzene, respectively.

$k_x=2k_o+2k_m+k_p$ and $k_H=6k$

and that all substituents, regardless of their polar nature, activate the aromatic ring, especially at the ortho and the para position. This substitution pattern is in keeping with what is already known to be typical of the homolytic aromatic phenylation[2] and is quite different from that found in the electrophilic substitution. Qualitative consideration of the substitution pattern would therefore suggest that the polar influence due to the chlorine atom in the attacking radical is of minor, if any, importance in the chlorophenylation.

It has been reported in Part III[1] that no polar influence has been detected in the *p*-methoxyphenylation of nitrobenzene. The effect of the polarized aryl radical, however, was soon after recognized by Dannley and Sternfeld[3], who examined the isomer distribution of the products from the reactions of *p*-chlorobenzoyl and of *p*-nitrobenzoyl peroxide with benzotrichloride, and by Cadogan, Hey, and Williams[4], who measured the relative rates of the *p*-chlorophenylation of chlorobenzene and of nitrobenzene by means of *p*-chlorobenzoyl peroxide, and subsequently by Chang, Hey and Williams[5], who determined the partial rate factors in the same reaction. In the present study of chlorophenylation, although no simple correlation is apparent between the partial rate factor for the ortho or the para position and the electronic nature of the substituents on the substrates, the partial rate factor of the meta position was found to diminish in the order: toluene>benzene, anisole>chlorobenzene>nitrobenzene, and this order appears to represent the electronic effect of the substituent. Indeed, a plot of the logarithm of the partial rate factor against Hammett's substituent constant for the meta position falls on a straight line with a slope of −0.27, as shown in Fig. 1. This fact, more convincingly than anything else, demonstrates that the *p*-chlorophenyl radical has a measure of electrophilic character due to the polar nature of the chlorine atom.

The homolytic aromatic arylation is considered[2] to proceed through the rate-determining step of the addition of an aryl radical to

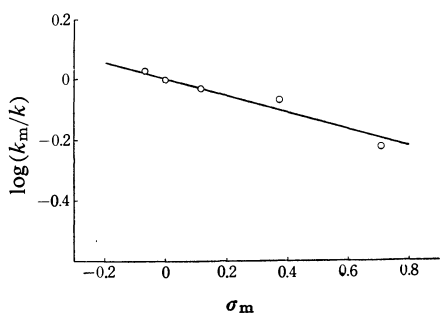

Fig. 1. The Hammett plot for the *p*-chlorophenylation.

an aromatic ring, giving an arylcyclohexadienyl radical. The generally observed ortho-para orientation suggests that the major factor controlling the orientation of the entering group is the degree of stabilization of the transition state due to the delocalization of the odd electron. Thus, when the addition occurs at the ortho or the para position to a substituent, the odd electron, in the transition state, can conjugate with the substituent group through the π-electron system of the aromatic nucleus; consequently, the substituent contributes to the stabilization of the transition state. In substitution at the meta position, however, it is obvious that no such conjugation, and hence no such stabilization, is possible, with the result that all substituents direct the homolytic substitution mainly to the ortho and the para position.

In the *p*-chlorophenylation at the ortho and the para position, the subtle influence of the polar character of the radical is masked by the foregoing major factor, that is, the conjugative effect; it is consequently not revealed in the variation of either the partial rate factor or the relative rate. On the other hand, when the addition occurs at the meta position, the odd electron, in the transition state, conjugates only with the π-electrons on the aromatic ring, and the conjugation does not, to the first approximation, extend further into the substituent group. The stabilization due to the conjugative effect therefore will have nearly equal magnitude for every monosubstituted benzene, and the effect of the polar nature of the attacking radical will become significant enough to be reflected in the sequence of the reactivity of the meta position of aromatic compounds, as has actually been observed.

Experimental

Melting points are uncorrected.

Solvents. — Thiophene-free benzene was purified by repeated fractional distillations through a Vigreux column, b. p. 79.5°C. Nitrobenzene was purified by heating commercial material with an aqueous solution of potassium bichromate, distilling it in steam and then under reduced pressure, and finally freezing it fractionally, m. p. 5.9°C. Toluene was purified by shaking it with concentrated sulphuric acid and then fractionating through a Vigreux column, b. p. 109°C. Anisole was prepared from purified phenol and dimethyl sulphate and was purified by distilling it through a Vigreux column, b. p. 153°C. Commercial chlorobenzene was purified by fractionating it through a Vigreux column, b. p. 131°C.

4-Chlorobiphenyls.—A variety of substituted 4-chlorobiphenyls, including several new compounds, which were used as carriers in the isotope dilution analysis were prepared as follows:

4-Chlorobiphenyl was prepared by reaction of *N*-nitroso-*p*-chloroacetanilide with benzene, m. p. 78.5°C (from methanol).

4-Chloro-2'- and -4'-nitrobiphenyl were prepared by the nitration[6] of the above 4-chlorobiphenyl and were purified by chromatography on alumina in petroleum ether-benzene and then by recrystallization from methanol or ethanol; they had the melting points of 69°C and 146°C, respectively.

4-Chloro-3'-nitrobiphenyl was prepared by the chlorination of 3-nitrobiphenyl according to the method described by Blakey and Scarborough[7], m. p. 94°C (from methanol).

4-Chloro-2'- and -4'-methoxybiphenyl were prepared by reaction of *N*-nitroso-*p*-chloroacetanilide with anisole. After removal of anisole from the reaction mixture, the residue was distilled with superheated steam, and the distillate was treated with stannous chloride and concentrated hydrochloric acid in methanol to free it from coloured material. Fractional distillation of the mixture, followed by chromatography on alumina in petroleum ether-benzene, gave the 2'-isomer, m. p. 58°C (from methanol) (Found: Cl, 16.17. Calcd. for $C_{13}H_{11}ClO$: Cl, 16.21%), and the 4'-isomer, m. p. 116°C (from ethanol). The structure of the 2'-isomer was established by demethylation by heating it with pyridine hydrochloride[8] into the known 4-chloro-2'-hydroxybiphenyl[9], m. p. 53°C. The 4'-isomer was also prepared by the Ullmann reaction from *p*-iodoanisole and *p*-chloroiodobenzene.

4-Chloro-3'-methoxybiphenyl was prepared by heating a mixture of *m*-iodoanisole and *p*-chloroiodobenzene with copper powder at 230°C for 11 hr. The oily material extracted from the reaction mixture with benzene was fractionally distilled under reduced pressure. The crystals of 4,4'-dichlorobiphenyl which deposited from the cooled distillate (b. p. 197~212°C/27 mmHg) were filtered off, and then the filtrate was heated with pyridine hydrochloride at 210°C for 7 hr. The phenolic fraction was separated and fractionated by chromatography on alumina in benzene, giving 4-chloro-3'-hydroxybiphenyl[10], m. p. 84°C. This was methylated with dimethyl sulphate and aqueous alkali to yield 4-chloro-3'-methoxybiphenyl, m. p. 36~37°C (from methanol) (Found: Cl, 16.02. Calcd. for $C_{13}H_{11}ClO$: Cl, 16.21%).

4-Chloro-2'-, -3'- and -4'-methylbiphenyl were prepared by the *p*-chlorophenylation of toluene with *N*-nitroso-*p*-chloroacetanilide. After removal of the toluene, distillation with superheated steam gave an oily material, which was then fractionally distilled three times under reduced pressure. In each distillation, some 4-chloro-4'-methylbiphenyl (m. p. 124°C) was separated from the after-run in the

form of crystals, which were collected and recrystallized from methanol. Cooling a methanolic solution of the first fraction (b. p. 101~105°C/2 mmHg) in a dry ice-ethanol bath yielded crystals (m. p. 27°C), which were purified by chromatography on alumina in petroleum ether to afford 4-chloro-2'-methylbiphenyl (Found: Cl, 17.29. Calcd. for $C_{13}H_{11}Cl$: Cl, 17.48%), m. p. 29.5~30.5°C (from methanol). Similarly, the second fraction (b. p. 105~115°C/2 mmHg) gave 4-chloro-3'-methylbiphenyl (Found: Cl, 17.40. Calcd. for $C_{13}H_{11}Cl$: Cl, 17.48%), m. p. 36~37°C (from methanol). The structure of this compound is evident, since it was found to be identical with the unsymmetrically substituted biphenyl obtained from *p*-chloroiodobenzene and *m*-iodotoluene by the Ullmann reaction, and consequently the structure of the 2'-methyl isomer is also established. Incidentally, Otto and Smith[11] prepared this isomer by a similar method and described it as an oil.

2,4'-Dichlorobiphenyl was prepared by the Sandmeyer reaction from 2-amino-4'-chlorobiphenyl[6]. To a stirred solution of 2-nitro-4'-chlorobiphenyl (5 g.) in benzene (200 ml.), dry iron powder (50 g.) activated by treatment with concentrated hydrochloric acid (10 ml.) was added[12]. After refluxing the mixture for 1 hr., 10 ml. of water was added over a period of 5 hr. under refluxing. The benzene layer was separated from the cooled reaction mixture, and passage of dry hydrogen chloride to the dried benzene solution yielded 4.8 g. of 2-amino-4'-chlorobiphenyl hydrochloride, which was then hydrolysed to 2-amino-4'-chlorobiphenyl (m. p. 43~43.5°C). The amine hydrochloride (14.5 g.) was diazotized by 42 g. of sodium nitrite in aqueous hydrochloric acid. The diazotized solution was filtered quickly and added to a wet precipitate of cuprous chloride prepared from cupric sulphate (19.5 g.) and sodium chloride (6 g.) by reduction with an alkaline solution of sodium bisulphite (4.2 g.). The reaction mixture was left to stand overnight and then distilled with steam. The 2,4'-dichlorobiphenyl thus isolated was purified by chromatography on alumina in petroleum ether, m. p. 44.5°C (from methanol) (Found: Cl, 31.66. Calcd. for $C_{12}H_8Cl_2$: Cl, 31.78%).

3,4'-Dichlorobiphenyl was prepared by a similar method from 4-chloro-3'-nitrobiphenyl. The product was purified by chromatography on alumina in petroleum ether and distillation under reduced pressure, b. p. 125°C/1 mmHg (Found: Cl, 31.55. Calcd. for $C_{12}H_8Cl_2$: Cl, 31.78%).

4,4'-Dichlorobiphenyl was prepared by the Ullmann reaction from *p*-chloroiodobenzene and was purified by chromatography on alumina in benzene, m. p. 147~148°C (from ethanol).

p-Chloro(^{36}Cl)acetanilide.—This was prepared by chlorination of acetanilide with chlorine-36, which had been obtained by oxidation of silver chloride-(^{36}Cl) precipitated from hydrochloric-(^{36}Cl) acid (4.06 mc./mol.). The detailed procedure is described elsewhere[13].

N-Nitroso-p-chloro(^{36}Cl)acetanilide.—To an ice-cooled, stirred mixture of *p*-chloro(^{36}Cl)acetanilide (0.371 g.), fused potassium acetate (0.9 g.), acetic acid (3.2 ml.), acetic anhydride (0.8 ml.), and a trace of phosphorus pentoxide, 4 ml. of an 11.8% solution of nitrosyl chloride in acetic anhydride was added over a period of 18 min. The mixture was kept in ice-water for a further 30 min. and then poured into ice-water to precipitate the *N*-nitroso compound, which was collected, washed with water, and dried in a vacuum desiccator (m. p. 75°C; yield, 0.358 g.).

Decomposition of N-Nitroso-p-chloro(^{36}Cl)acetanilide. — *N*-Nitroso-*p*-chloro(^{36}Cl)acetanilide was allowed to decompose in an equimolar binary or ternary mixture of aromatic solvents, each containing benzene as one component (see Table II). The reaction vessel was immersed in a thermostat kept at 20.0°C and let stand for two days. In experiments 1 and 2, which were carried out at 18°C, at the end of two days the volume of nitrogen evolved reached final values of 77% and 80% of theory, respectively.

General Procedure for Isotope Dilution Analysis.—The reaction mixture was diluted with benzene to a volume of 50 or 100 ml., and the resulting solution was weighed and divided into several weighed portions. To each portion an accurately known amount of each of the biaryls to be assayed was added as a carrier; the solvent was then driven off at atmospheric pressure through a Vigreux column 15 cm. in length and, if necessary, further under reduced pressure. From the residue the labelled biaryl diluted with the carrier was recovered by chromatography on activated alumina in benzene-petroleum ether. The crystalline material thus recovered was purified by repeated crystallization from methanol or ethanol. The purification was considered to be complete when the specific activity of a specimen remained constant on further crystallization.

Since the dilution was made with a large excess of carriers, the molecular ratio in which two labelled biaryls (A and B) were formed in this reaction is given by the ratio $(f_B M_A C_A / f_A M_B C_B)$, where f_A and f_B denote the ratios to the total reaction mixture of the portions used for the determination of A and B, respectively; C_A and C_B, the specific activities in counts per minute of recovered A and B, and M_A and M_B, the amounts of non-labelled A and B added as carriers. All the numerical results are listed in Table II.

Measurement of Radioactivity.—The radioactivity of ^{36}Cl-labelled compounds was determined by a method described elsewhere[14], which comprises decomposition of the labelled compounds with sodium in boiling isopropyl alcohol, precipitation of the liberated chloride ions as mercurous chloride, and counting the radioactivity of the chloride on an "infinitely thick" layer with an end-window Geiger-Müller counter.

Determination of the Partial Rate Factor for the Meta Position of Chlorobenzene.—*N*-Nitroso-*p*-chloroacetanilide (9.86 g.) was dissolved in 509 g.

* Indicated deviations are probable errors.

of chlorobenzene and allowed to decompose at 20.0°C. After removal of most of chlorobenzene through a Vigreux column (60 cm.), 2 ml. of nitrobenzene was added to the residue. By fractionating the mixture through a concentric column, all the chlorobenzene retained in the mixture and 0.3 ml. of nitrobenzene were driven off. The residue was dissolved in benzene, and the solution was passed through a column of alumina and then treated with 50 g. of iron activated by treatment with hydrochloric acid[12] and 10 ml. of water for reduction of the nitrobenzene contained in the solution. The benzene layer was washed with diluted hydrochloric acid and then with water and dried over calcium chloride. The reddish-brown material obtained by removal of the benzene was fractionated by chromatography on an alumina column using a mixture of ether and petroleum ether (1 : 1) as an eluant into the following fractions: the first fraction (a light yellow oil and a small amount of a crystalline

material): a mixture of 2,4'- and 3,4'-dichlorobiphenyl; the second fraction (a yellowish crystalline material): 4,4'-dichlorobiphenyl; the third fraction: traces of reddish crystals; and the succeeding fractions: traces of crystals and reddish impurities. The first and the second fraction were combined, and the mixture was analyzed for three isomeric dichlorobiphenyls by infrared spectrophotometry in carbon disulphide with a Perkin Elmer-21 spectrophotometer, using absorptions at 883 cm^{-1}, 730 cm^{-1}, and 810 cm^{-1} for 2,4'-, 3,4'- and 4,4'-dichlorobiphenyl, respectively. It was found that the foregoing mixture consisted of 65, 21 and 12% of the respective isomers, giving 3.1 as the molar ratio of the 2,4'- and the 3,4'-isomer formed. This value, in conjunction with the value of the partial rate factor for the ortho position determined by the isotope dilution analysis, leads to the partial rate factor of 0.87 for the meta position, while the value is 1.16 when the molar ratio of the 4,4'-isomer to the 3,4'-isomer is used. The former value is considered to be more reliable for the following reason. From the spectrophotometric result, the ratio of the reactivity of the *o*-position to that of the *p*-position of chlorobenzene towards *p*-chlorophenylation is calculated to be 2.7, which is rather too large when compared with the corresponding value, 2.0, calculated from the results of the isotope dilution analysis. This discrepancy is most probably due to the method of preparing the sample subjected to the spectrophotometric analysis, in which the third fraction containing a little of the least elutable 4,4'-dichlorobiphenyl was discarded to avoid contamination of the sample by any coloured impurities.

Summary

N-Nitroso-*p*-chloro(^{36}Cl)acetanilide has been decomposed in mixtures of benzene and monosubstituted benzene C_6H_5X (X=NO_2, Cl, OCH_3, and CH_3), and the reaction products have been analyzed for 4-chlorobiphenyl and isomeric 4-$ClC_6H_4C_6H_4X$ by the isotope dilution method. On the basis of these results, the partial rate factors for the *p*-chlorophenylation have been calculated to be, for nitrobenzene: *o*, 4.35; *m*, 0.61; *p*, 6.18; for chlorobenzene: *o*, 2.70; *m*, 0.87; *p*, 1.33; for anisole: *o*, 3.93; *m*, 0.94; *p*, 1.54 and for toluene: *o*, 2.97; *m*, 1.07; *p*, 1.32.

The values of the partial rate factor for the meta position give a satisfactory Hammett plot with a slope of −0.27. This fact demonstrates that the *p*-chlorophenyl radical shows a measure of electrophilic character in the homolytic aromatic substitution.

Influence of Substituent Groups on Nuclear Reactivity in the Formation of Substituted Biphenyls by Reaction of Aromatic Diazo and Related Compounds with Aromatic Liquids. VII. p-Nitrophenylation and p-Methoxyphenylation

By Ryôichi Itô, Toshihiko Migita, Naotake Morikawa, Morihiko Ōkuni and Osamu Simamura

(Received May 10, 1963)

In the preceding paper[1], the partial rate factors for the *p*-chlorophenylation of monosubstituted benzenes by the *p*-chlorophenyl radical derived from *N*-nitroso-*p*-chloroacetanilide have been reported. The variation of the reactivity of the meta position with the nature of the substituent has suggested that the attacking *p*-chlorophenyl radical has a somewhat electrophilic nature due to the presence of a chlorine atom. The study has now been extended to include *p*-nitrophenylation and *p*-methoxyphenylation, the former being expected to be more electrophilic than *p*-chlorophenylation and the latter to be rather nucleophilic because of the electron-releasing nature of the *p*-methoxy group in the radical.

N-Nitroso-*p*-nitroacet(anilide-^{14}C) and *N*-nitroso-*p*-methoxyacet(anilide-^{14}C) were used as sources of the *p*-nitrophenyl and the *p*-methoxyphenyl radical, respectively, and the arylated products were analyzed by isotope

dilution analysis. The results are summarized in Tables I and II.

The partial rate factors for the *p*-methoxyphenylation of nitrobenzene had previously been determined to be 7.24, 0, and 8.95 for the *o*-, *m*-, and *p*-position, respectively, the product analysis being done by means of column chromatography[2]. The more accurate results obtained in the present work have shown that the meta-substituted product is actually formed. Probably the meta isomer could not be separated from the ortho isomer by the chromatographical method used in the previous experiments.

It is apparent from Table I that the relative rate of a monosubstituted benzene in *p*-nitrophenylation decreases in the order: anisole > toluene > benzene > chlorobenzene > nitrobenzene. This trend, which is parallel to the order of reactivity towards electrophilic reagents, has not been observed in the case of *p*-chlorophenylation[1]. This shows that the *p*-nitrophenyl radical is decidedly more electrophilic than the *p*-chlorophenyl radical. It has been shown[1] that in *p*-chlorophenylation the major factor controlling the rate is the stabilization of the transition state due to the delocalization of an odd electron, that is, the conjugative effect, and that the polar character of the attacking radical is of subordinate importance. In the *p*-nitrophenylation, however, it has now turned out that the polar effect of the *p*-nitrophenyl radical is strong enough to compete with the foregoing major

2) O. Simamura and T. Migita, This Bulletin, 27, 228 (1954).

factor, with the result that the relative rate sequence resembles that observed in electrophilic substitutions. The electrophilic nature of the *p*-nitrophenyl radical becomes even more evident when the reactivity is compared at the meta position, where the conjugative effect of the substituent group in the substrate may be regarded as negligible. Thus, the reactivity of the meta position of monosubstituted benzenes in the *p*-nitrophenylation decreases in the order: toluene>benzene> anisole > chlorobenzene > nitrobenzene. The same trend is observed in the *p*-chlorophenylation[1], but the variation is much more conspicuous in the *p*-nitrophenylation. Figure 1 shows the relation between the partial rate factor for the meta position of a substituted benzene and the Hammett substituent constant for the substituent at the meta position. From the slope of the line, the reaction constant for the *p*-nitrophenylation is found to be −0.81, while the corresponding value of the *p*-chlorophenylation is −0.27[1]. It is evident from a comparison of these values that the electrophilic nature of the *p*-nitrophenylation is more pronounced than that of the *p*-chlorophenylation because of the much stronger electron-withdrawing effect of the nitro group.

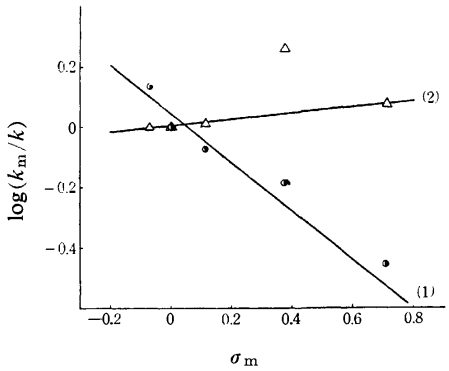

Fig. 1. The Hammett plots for the *p*-nitro-(1) and the *p*-methoxy-(2) phenylation.

In the *p*-methoxyphenylation, on the other hand, Table II shows that all substituents increase the nuclear reactivity of the aromatic nucleus, and that, except for chlorobenzene, the meta position is less reactive than the ortho and the para position, as has been observed in the *p*-chlorophenylation. Except for chlorobenzene, the partial rate factor for the meta position of every compound is approximately unity, so that the reactivity of the meta position of a monosubstituted benzene is close to that of a single position of benzene itself. This finding suggests that the *p*-methoxyphenyl radical has little, if any, polar character. The reaction constant of the Hammett relation between $\log(k_m/k)$ and σ_m is +0.09; this value might indicate a very slight, if any, nucleophilic nature for the *p*-methoxyphenylation. The partial rate factor of 1.82 for the meta position of chlorobenzene seems to be anomalously high; the Hammett plot would predict it to be 1.08. It is not clear whether the value is true or erroneous owing to some unknown experimental difficulty in the analysis of 3-chloro-4′-methoxybiphenyl.

Recently, Hambling, Hey, and Williams[3] have observed that the relative reactivity of nitrobenzene towards the arylations by aroyl peroxides increases in the order: *p*-nitrophenylation < *p*-chlorophenylation < *p*-methoxyphenylation < phenylation. On the basis of this tendency, which has also been recognized in the present study, and of its parallelism to the dipole moment values of the compounds corresponding to the aryl radicals which cause these arylations, they have concluded that the *p*-methoxyphenyl radical has rather an electrophilic character compared with the phenyl radical. The disagreement between their view and ours seems to be attributable to the fact that, in their deduction, a comparison has been made between the relative rates of *p*-methoxyphenylation and of phenylation of nitrobenzene, using benzene as the reference substrate in both cases.

Experimental

Melting points are uncorrected.

Solvents.—Nitrobenzene, chlorobenzene, anisole, toluene and benzene were purified as described in Part VI[1].

Substituted Biphenyls Used as Carriers in Isotope Dilution Analysis. — 4-Nitrobiphenyl was prepared by nitration of biphenyl according to Maki and Ôbayashi's method[4], m. p. 112.8～113°C (from methannol).

4-Methoxybiphenyl was prepared by reaction of *N*-nitrosoaceto-*p*-anisidide[5] with benzene and was purified by recrystallization from methanol, m. p. 90°C.

2,4′- and 4,4′-Dinitrobiphenyl were prepared by the nitration of *p*-nitrobiphenyl according to Maki and Ôbayashi's method[4]. The 2,4′-isomer was recrystallized from ethanol, m. p. 93.5～94°C, and the 4,4′-isomer from acetone, m. p. 237°C.

3,4′-Dinitrobiphenyl was prepared as follows: To a cooled solution of 3-nitrobiphenyl[6] (15 g.) in acetic anhydride (20 ml.), a mixture of fuming nitric acid (*d*, 1.54; 6.8 ml.), acetic anhydride

4) T. Maki and K. Ôbayashi, *J. Chem. Soc. Japan, Ind. Chem. Sec.* (*Kōgyō Kagaku Zassi*), **54**, 375 (1951).
5) J. W. Haworth and D. H. Hey, *J. Chem. Soc.*, **1940**, 361.
6) H. France, I. M. Heilbron and D. H. Hey, ibid., **1940**, 369.

(3.4 ml.) and urea (0.2 g.) was added over a period of 15 min., and the mixture was heated on a steam bath. After being cooled, the mixture was poured into water to give a precipitate (17 g.), which was then collected, washed with water, and dried. The product was purified by chromatography on alumina in benzene-acetone (4 : 1) to give 3,4'-dinitrobiphenyl, m. p. 189°C (from ethanol).

2-Chloro-4'-nitrobiphenyl was prepared by reaction of *N*-nitroso-*p*-nitroacetanilide[6] with chlorobenzene. The product, which was isolated by removal of chlorobenzene under reduced pressure followed by distillation with superheated steam, was purified by chromatography on alumina in petroleum ether-benzene (4 : 1), m. p. 79~80°C (from methanol).

3-Chloro-4'-nitrobiphenyl was obtained by nitration of 3-chlorobiphenyl[7]. The procedure for the nitration was analogous to that used for preparation of 3,4'-dinitrobiphenyl. The brown oily product was fractionated by distillation under reduced pressure (b. p. 157~158°C/1 mmHg) and then by chromatography on alumina in petroleum ether-benzene (4 : 1), m. p. 93~94°C (from methanol).

The preparation and purification of 4-chloro-4'-nitrobiphenyl were described in Part VI[1].

2-Methoxy-4'-nitrobiphenyl was prepared from *N*-nitroso-*p*-nitroacetanilide and anisole and was purified by chromatography and recrystallization from methanol, m. p. 63~64°C.

3-Methoxy-4'-nitrobiphenyl was prepared from diazotized *m*-anisidine and nitrobenzene by the Gomberg reaction. After removal of the solvent from the reaction mixture, the residue was distilled with superheated steam to afford a crystalline distillate, which was then fractionated by chromatography on alumina in petroleum ether-benzene (1 : 1), m. p. 90~91°C (from methanol).

4-Methoxy-4'-nitrobiphenyl was prepared as described in Part III[2].

Methyl-4'-nitrobiphenyls were prepared as follows: *N*-Nitroso-*p*-nitroacetanilide (35 g.) was dissolved in 1 l. of toluene and left to stand for two days. After removal of the toluene, the residue was distilled with superheated steam and the distillate was fractionated by chromatography on alumina in petroleum ether-benzene into three parts: (i) an oily material which contained 3-methyl-4'-nitrobiphenyl (see below), (ii) 2-methyl-4'-nitrobiphenyl (6 g.), m. p. 102.5~103°C, and (iii) 4-methyl-4'-nitrobiphenyl (1.5 g.), m. p. 139~140°C. Fraction (ii) was further purified by similar chromatography, m. p. 102.5~103°C (from methanol). Distillation of fraction (i) under reduced pressure gave nitrobenzene (2 g.) and the residue, which chromatographed on alumina in petroleum ether-benzene (10 : 1) yielded, besides a small amount of 2-methyl-4'-nitrobiphenyl, 3-methyl-4'-nitrobiphenyl (0.5 g.), m. p. 60°C. The structure of this compound was established by the following preparation. Nitrosation of *m*-acetotoluidide (33 g.) by nitrous fumes in a mixture of acetic acid and acetic anhydride yielded oily *N*-nitroso-*m*-acetotoluidide, which was allowed to decompose in nitrobenzene. The products were isolated as usual and chromatographed on alumina to give the same methylnitrobiphenyl (2.5 g.), m. p. 60°C. 3-Methyl-4'-nitrobiphenyl was further purified by chromatography, m. p. 61.5°C (from methanol) (Found: C, 73.10; H, 5.21; N, 6.65. Calcd. for $C_{13}H_{11}NO_2$: C, 73.22; H, 5.20; N, 6.57%). 4-Methyl-4'-nitrobiphenyl was also prepared by nitration of 4-methylbiphenyl according to Grieve and Hey's method[8]. The product was combined with fraction (iii) obtained above and purified by recrystallization from ethanol, m. p. 141°C.

4-Methoxy-2'-nitrobiphenyl was prepared as described in Part III[2], m. p. 62.5~63°C.

4-Methoxy-3'-nitrobiphenyl was prepared by reaction of *N*-nitroso-*m*-nitroacetanilide[9] with anisole and was purified by distillation and chromatography on alumina in petroleum ether-benzene (4 : 1), m. p. 78~79°C (from methanol).

2-Chloro-4'-methoxybiphenyl was prepared as follows: 2-Nitro-4'-methoxybiphenyl (5 g.) was reduced with activated iron powder and water[10] to 2-amino-4'-methoxybiphenyl, which was then diazotized and allowed to react with cuprous chloride in a manner similar to the preparation of 2,4'-dichlorobiphenyl described in a previous paper[1], giving 2-chloro-4'-methoxybiphenyl (0.5 g.), m. p. 24~24.5°C. In another preparation *N*-nitroso-*p*-acetoanisidide (50 g.) was allowed to decompose in 700 ml. of chlorobenzene. The isolated product was treated with a little stannous chloride and concentrated hydrochloric acid in methanol and then distilled under reduced pressure. The distillate (b. p. 135~141°C/1 mmHg, 3.1 g.) was purified by chromatography on alumina in petroleum ether, yielding 2-chloro-4'-methoxybiphenyl (3.5 g.), m. p. 24~24.5°C. Specimens from both preparations were combined and purified by recrystallization from methanol, m. p. 24~24.5°C (Found: Cl, 16.18. Calcd. for $C_{13}H_{11}ClO$: Cl, 16.21%).

3-Chloro-4'-methoxybiphenyl was prepared by heating *m*-chloroiodobenzene (25 g.), *p*-iodoanisole (73.3 g.), and copper powder (100 g.) at 250°C for 8 hr. and purified by distillation under reduced pressure (b. p. 130~140°C/1.3 mmHg; yield, 13.1 g.) followed by chromatography on alumina in petroleum ether, m. p. 56~57°C (from methanol) (Found: Cl, 16.08. Calcd. for $C_{13}H_{11}ClO$: Cl, 16.21%).

4-Chloro-4'-methoxybiphenyl was prepared and purified as described in Part VI[1].

2,4'-Dimethoxybiphenyl was prepared by the method described by Dunstan and Hughes[11] and was purified by recrystallization from methanol, m. p. 71.5°C.

3,4'-Dimethoxybiphenyl was prepared by the Ullmann reaction of *p*-iodoanisole (70 g.) and *m*-iodoanisole (25 g.), m. p. 60~61°C (yield, 7 g.) (Found: C, 78.64; H, 6.63. Calcd. for $C_{14}H_{14}O_2$:

give two main distillates, b. p. 118~128°C/1 mmHg and b. p. 153°C/1 mmHg. The latter solidified to give 4-methoxy-4'-methylbiphenyl, m. p. 111°C (from methanol). The former was chromatographed on alumina in petroleum ether and distilled under reduced pressure to yield an oily material (b. p. 136~138°C/5 mmHg). The oil was heated with picoline hydrochloride at 220~230°C for 8 hr. After being cooled, the reaction mixture was poured into water, and the phenolic product was isolated and purified by chromatography on alumina in benzene to give 4-hydroxy-2'-methylbiphenyl (m. p. 80~81°C). The structure of this compound was evident from its preparation by the Ullmann reaction of *p*-iodoanisole and *o*-iodotoluene in the presence of copper powder at 200~220°C, followed by demethylation with picoline hydrochloride at 220~230°C for 8 hr. 4-Hydroxy-2'-methylbiphenyl

was methylated with dimethyl sulphate in aqueous alkali to afford 4-methoxy-2'-methylbiphenyl, b. p. 140~141.5°C/13 mmHg (Found: C, 85.06; H, 7.28. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%).

4-Methoxy-3'-methylbiphenyl was prepared by the Ullmann reaction from *p*-iodoanisole (110 g.) and *m*-iodotoluene (40 g.) and was purified by chromatography on alumina in petroleum ether (yield, 12 g.), m. p. 53~54°C (from methanol) (Found: C, 84.84; H, 7.21. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%).

Preparation of Labelled Compounds.—The preparations of *p*-nitroacet(anilide-^{14}C) and *p*-methoxyacet(anilide-^{14}C) from benzene-^{14}C have been described elsewhere[14,15]. The detailed procedure for nitrosation of these substituted acetanilide-^{14}C was analogous to that of *p*-chloro(^{36}Cl)acetanilide described in a previous paper[1]. Nitrosation of *p*-nitroacet(anilide-^{14}C) (specific activity, 61.2±0.5 mc./mol., 0.506 g.) with 7 ml. of a 10% solution of nitrosyl chloride in acetic anhydride in a mixture of acetic acid (5.2 ml.) and acetic anhydride (1.3 ml.) in the presence of fused potassium acetate (1.7 g.) and a trace of phosphorus pentoxide yielded 0.475 g. of *N*-nitroso-*p*-nitroacet(anilide-^{14}C). A mixture of *p*-methoxyacet(anilide-^{14}C) (specific activity, 27.4±0.2 mc./mol., 0.941 g.), fused potassium acetate (1.2 g.), acetic acid (4.5 ml.), acetic anhydride (1.1 ml.) and a trace of phosphorus pentoxide, treated with 4.5 g. of a similar solution of nitrosyl chloride, gave 0.992 g. of *N*-nitroso-*p*-methoxyacet(anilide-^{14}C).

Decomposition of Labelled *N*-Nitroso Compounds and Isotope Dilution Analysis. — The reaction was carried out in an equimolar binary or ternary mixture of aromatic solvents at 20.0°C in a manner similar to the *p*-chlorophenylation[1] (see Table III). The general procedure for the analysis of the products was analogous to that described in a previous paper[1]. The 4-methoxy-2'-methylbiphenyl recovered from the reaction mixture in the *p*-methoxyphenylation was demethylated by heating it with picoline hydrochloride to crystalline 4-hydroxy-2'-methylbiphenyl, which was then chromatographed on alumina in benzene, recrystallized from a mixture of benzene and petroleum ether, and assayed for carbon-14. 4,4'-Dinitrobiphenyl was purified by chromatography in acetone and by recrystallization from a mixture of ethanol and acetone. 3,4'-Dinitrobiphenyl, 4-methoxy-4'-nitrobiphenyl, and 4-methyl-4'-nitrobiphenyl were purified by chromatography in benzene and by recrystallization from ethanol. The other biaryls recovered were normally purified by chromatography on alumina in a mixture of benzene and petroleum ether and by recrystallization from methanol or ethanol. Carbon-14 determination was carried out as described in Part V[16]. The numerical results are summarized in Tables III and IV.

Summary

N-Nitroso-*p*-nitroacet(anilide-^{14}C) and *N*-nitroso-*p*-methoxyacet(anilide-^{14}C) have been decomposed at 20.0°C in mixtures of benzene and monosubstituted benzenes C_6H_5X (X=NO_2, Cl, OCH_3, and CH_3), and the reaction products have been analyzed for 4-nitro-and 4-methoxybiphenyl and isomeric 4-$NO_2C_6H_4C_6H_4X$ and 4-$CH_3OC_6H_4C_6H_4X$ by the isotope dilution method.

From the results of these competitive experiments, the partial rate factors for the *p*-nitrophenylation and *p*-methoxyphenylation have been calculated (Tables I and II).

The values of the partial rate factor for the meta position give a satisfactory Hammett plot with a slope of −0.81 for the *p*-nitrophenylation and one with a slope of +0.09 for the *p*-methoxyphenylation, showing that the *p*-nitrophenyl radical has a pronounced electrophilic character while the *p*-methoxyphenyl radical has little, if any, nucleophilic character.

Influence of Substituent Groups on Nuclear Reactivity in the Formation of Substituted Biphenyls by Reaction of Aromatic Diazo and Related Compounds with Aromatic Liquids. VIII. Phenylation and p-Methylphenylation. The Separation of the Polar and the Conjugative Effect

By Ryôichi Itô, Toshihiko Migita, Naotake Morikawa and Osamu Simamura

(Received May 10, 1963)

The results of our study of the influence of some substituent groups, viz., the *p*-methoxy, *p*-chloro, and *p*-nitro group, in the attacking aryl radical on the homolytic arylation of monosubstituted benzenes have been reported in Parts III,[1] VI,[2] and VII[3]. The present paper deals with the phenylation and *p*-methylphenylation, in which *N*-nitrosoacet-(anilide-^{14}C) and *N*-nitroso-(*p*-methyl-^{14}C)-acetanilide have been used as the sources of the phenyl and the *p*-methylphenyl radical, and the arylated products have been analyzed by isotope dilution analysis. The partial rate factors and relative rates are listed in Tables I and II; the values for the phenylation obtained previously[4] by the same method are also included in Table I.

The tables show that all substituents in the aromatic substrate make the aromatic ring more reactive at the ortho and the para than at the meta position or at a nuclear position of benzene itself, and that they consequently direct the phenylation and *p*-methylphenylation preferentially to the ortho and para positions. This observation is in keeping with the already known results[5] concerning the orientation in the homolytic phenylation which were mainly obtained by the study of the decomposition of benzoyl peroxide, and it corroborates the view already adumbrated on the basis of the previous findings[2,3] that the invariable ortho-para orientation is characteristic of the homolytic aromatic arylation, irrespective of the nature of the attacking aryl radical.

As with the *p*-methoxyphenylation[3], the partial rate factors for the phenylation and *p*-methylphenylation of the meta position of aromatic compounds are all very close to unity. This fact suggests that the *p*-methylphenyl radical has little, if any, measure of polar character. Satisfactory Hammett plots are obtained for both the phenylation and *p*-methylphenylation, as shown in Fig. 1, between the logarithm of the partial rate factor for the meta position and the substituent constant, σ_m. The values for the Hammett reaction constant, ρ, together with those for *p*-nitro-[3], *p*-chloro-[2], and *p*-methoxy-phenylation[3], all obtained by the least squares method, are listed in Table III. The negative ρ values for the *p*-chloro- and *p*-nitro-phenylation indicate the electrophilic character of the *p*-chloro- and the *p*-nitrophenyl radical, as has already been discussed in Parts VI and VII. The polar character of these radicals is obviously attributable to the electron-withdrawing nature of their substitituent groups.

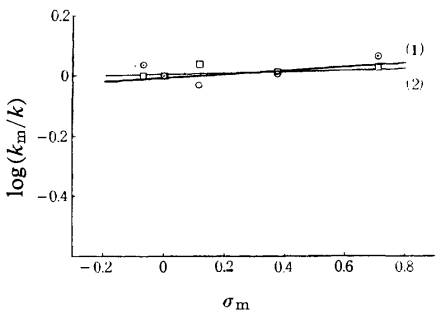

Fig. 1. The Hammett plots for the phenylation (1) and the *p*-methylphenylation (2).

The Hammett substituent constants, σ_p, which are shown in Table III for purposes of comparison, may be taken more or less to represent the electronic influence of the substituent groups in the aryl radicals upon the carbon atom on which the odd electron is located. Therefore, it is plausible to suppose that the σ_p value may show some correlation with the polar nature of arylation. In fact, in the *p*-nitro- and *p*-chloro-phenylation and in phenylation

* Results by Inukai, Kobayashi and Simamura[4].

** Simamura and Inukai (This Bulletin, **28**, 445 (1955)) reported the partial rate factors of 3.7, 0.9 and 1.1 for the *o*-, *m*-, and *p*-position, as determined by infrared spectrophotometry.

TABLE II. PARTIAL RATE FACTORS AND RELATIVE RATES IN *p*-METHYLPHENYLATION OF MONOSUBSTITUTED BENZENES AT 20.0°C

Compound	Exp. No.	Partial rate factor			Relative rate
		k_o/k	k_m/k	k_p/k	k_X/k_H
$C_6H_5NO_2$	3	10.73	1.07	8.93	5.50
C_6H_5Cl	3	3.10	1.04	1.16	1.57
$C_6H_5OCH_3$	4	3.69	1.09	1.52	1.85
$C_6H_5CH_3$	5	3.27	1.00	1.33	1.65

TABLE III. POLAR NATURE OF ARYL RADICALS IN ARYLATION

Aryl radical	Hammett's reaction constant, ρ	Substituent constant		
		σ_p	σ_p^n	σ_p^o
p-Nitrophenyl	−0.81	0.778	0.78	0.73
p-Chlorophenyl	−0.27	0.227	0.24	0.27
Phenyl	0.05	0	0	0
p-Methylphenyl	0.03	−0.170	−0.13	−0.15
p-Methoxyphenyl	0.09	−0.268	−0.11	−0.16

the numerical magnitudes of ρ and σ_p approximately coincide with each other. Although no theoretical significance can be attached to this numerical coincidence, if this correlation should hold throughout the entire range of σ_p values, it would predict much larger ρ values for the *p*-methyl- and *p*-methoxy-phenylation than have actually been found. In fact, the values for these arylations are practically indistinguishable from that for the phenylation. If, for purposes of comparison, we take σ_p^n [6] or σ_p^o [7] as a measure of the polar influence of a substituent, the parallelism becomes much better. This fact evidently indicates that the influence on the arylation reaction exerted by a substituent group in the attacking radical is purely inductive in nature, since both σ_p^n and σ_p^o are thought to represent the inductive polar effect for the para-substituted phenyl group, including the conjugative interaction between the substituent and the benzene ring. This view seems quite reasonable in view of the nature of the orbital occupied by the odd electron, for that orbital does not allow the electron to conjugate with the π-elctronic system of the substituted phenyl group.

The value of ρ should be dependent, at least partly, on the reactivity of the attacking radical as well; the more reactive an attacking radical is, the more difficult it is for this radical to discriminate differently substituted substrates, and, consequently, the lower will be the absolute value of ρ. Such an effect ought to be observed in the arylations by substituted phenyl radicals, which simple molecular orbital calculations have shown to be more reactive than the phenyl radical itself. This effect, however, does not seem important in view of the simple correlation between the ρ value and the inductive substituent constant.

No simple correlation can be found of the effect of the polar substituent in the substrate on the partial rate factors of the para and

c) See Table IV.

ortho position, since the conjugative effect of the substituent is overwhelming at these positions. In fact, the Hammett relation does not hold for the para position. For this position, however, the following equation has now been found to give a very noteworthy correlation with regard to the effect of the substituent:

$$\log (k_p/k) = \rho\sigma_p + \tau_p \qquad (1)$$

where k_p/k is the partial rate factor of the para position of a substituted benzene in an arylation; ρ, the Hammett reaction constant for this arylation as determined from the Hammett plot of the partial rate factors of the meta position; and σ_p, the Hammett substituent constant for the para position. As shown in Table IV, the value for τ_p may be regarded as tolerably constant for each substituted benzene irrespective of the nature of the attacking radical and decreases in the order: $NO_2 \gg Cl$, $MeO > Me$. Since the term $\rho\sigma_p$ obviously represents the polar effect consisting of the inductive and the conjugative or electromeric response in the presence of a polar attacking radical, τ_p may be considered to represent that part of the conjugative effect of the substituent which is independent of the polar nature of the attacking radical. It is therefore natural that τ_p should have been found to be a constant quantity characteristic of the nature of the substituent group, in so far as such a treatment, in which the substituent effect is divided into several independent components, is valid[8]. Thus, τ_p or, expressed in energy term, $2.30 \times RT\tau_p$ may be identified with the difference in extra resonance energy, that is, the additional stabilization due to the conjugation of the substituent group with the π-electronic system, between the transition state and the initial state. The value of 0.90 found for τ_p for the nitro group corresponds to 1.2 kcal./mol. Since the extra resonance energy in nitrobenzene is estimated at 8.5 kcal./mol.[9], that in the transition state will be 9.7 kcal./mol.

Although the exact structure of the transition state is unknown, we may identify it with the structure of the phenylcyclohexadienyl radical[10] (II). The odd electron occupies its non-bonding molecular orbital, and the presence of a substituent group in the radical may be thought to cause the perturbational lowering of the energy of the system. This effect will be greatest for the nitro group, with its comparatively low-lying vacant orbital, resulting in its having the greatest extra resonance energy, in accordance with the observed sequence of the conjugative effect, whereas such an effect becomes much less important for the substituents: chlorine, methoxy and

8) Such division of the electronic effect of a substituent into independent contributions from the inductive and the conjugative effect has first been suggested by Branch and Calvin ("The Theory of Organic Chemistry", Prentice-Hall, Inc., New York (1941), p. 193) for the effect on acid strength and has extensively been applied by Taft ("Steric Effects in Organic Chemistry," Ed. by M. S. Newman, John Wiley & Sons, Inc., New York (1956), p. 577; *J. Am. Chem. Soc.*, **80**, 2436 (1958)) to the consideration of the substituent effect in reaction rates as well.

9) The authors are indebted to Prof. S. Nagakura for this value.

10) Ref. 5, p. 17.

methyl, since these groups are able to contribute only a filled orbital for conjugation. This view is supported by the following consideration based upon the molecular orbital theory. The extra resonance energies in substituted bezenes have been evaluated by Matsen[11] by means of a perturbational treatment with simple molecular orbitals, and those for substituted cyclohexadienyls have now been estimated by the same method as in Matsen's treatment. The results are shown in Table V, which also includes the values similarly calculated for the nitro group, it being assumed that the perturbing vacant molecular orbital of the nitro group has the energy $\alpha+\delta\beta$ ($\delta=-0.5$ or -0.2)[12], and that the coefficient of the atomic orbital of the nitrogen atom constituting the molecular orbital is $1/\sqrt{2}$. The trend seen in the differences in the calculated extra resonance energy between the substrate and the substituted cyclohexadienyl radical shown in the fourth column is in satisfactory agreement with that in the τ_p values, considering the approximate nature of this molecular orbital method.
