Other *o*-(1-alkenyl)phenols were prepared similarly. The physical constants and the analytical data are collected in Table I.

The methyl ethers of the phenols were prepared by the methylation of the corresponding phenols with sodium hydroxide and dimethyl sulfate, or by the dehydration of dialkyl-*o*-methoxyphenylcarbinol. The physical constants and the analytical data are listed in Table II.

2, 4-Dimethyl-3-(2-methoxyphenyl)-3-pentanol.—This was an unknown compound and was prepared from methyl 2-methoxybenzoate and isopropylmagnesium bromide. It was a colorless oil boiling at 124—126°C/4 mmHg and was obtained in a 72% yield.

Found: C, 75.36; H, 9.73%. Calcd. for $C_{14}H_{22}O_2$: C, 75.63; H, 9.98%.

Results and Discussion

The apparent ν_{O-H} absorption curves at around 3600 cm^{-1} are shown in Figs. 1, 2 and 3. In Table III are listed the ν_{O-H} maxima, the apparent half band widths ($\Delta\nu^a_{1/2}$), the integrated intensities, the shifts ($\Delta\nu_{max}$) of the interacting ν_{O-H} (ν_i) from the corresponding free ν_{O-H} (ν_f) and the ratios of A_i to A_f.

Although the phenols vary widely, there always appears an absorption of a certain intensity at about 3610 cm^{-1} in each phenol examined. Since phenol itself absorbs in this region in its monomeric state, it is reasonable to assign the absorption which appears here to the free ν_{O-H} band of the phenols.

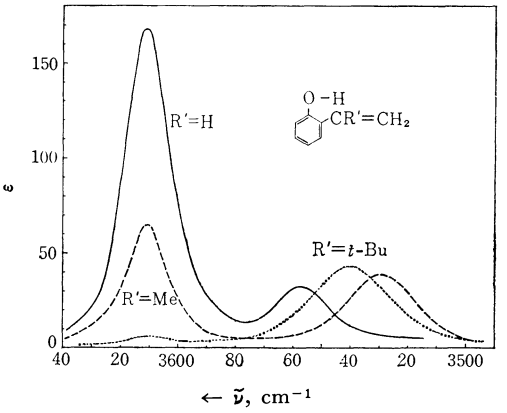

Fig. 1. ν_{O-H} absorptions of I, II and III.

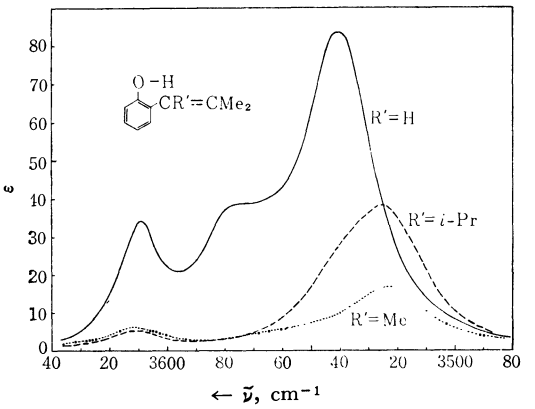

Fig. 2. ν_{O-H} absorptions of IV, V and VI.

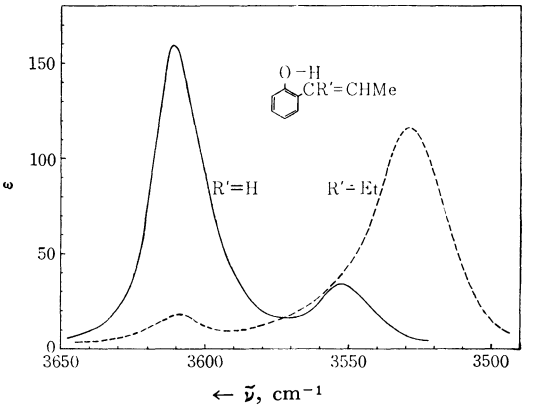

Fig. 3. ν_{O-H} absorptions of VII and VIII.

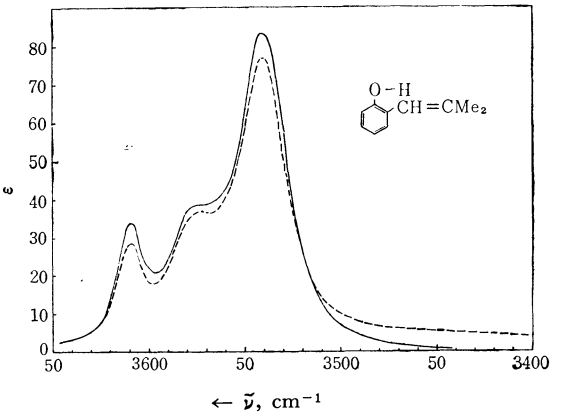

Fig. 4. Variation in ν_{O-H} absorption of *o*-isobutenylphenol (IV) with concentration.
—— 0.00154 mol./l. - - - 0.113 mol./l.

Some of the ν_{O-H} curves are very unusual in shape; this complexity can be interpreted only when the curves are assumed to be overlaps of at least three symmetric curves, each expressed

in terms of the Lorentz function.[8] It has first been confirmed through dilution study that all these ν_{O-H} bands belong to the monomeric molecules of the phenols. Over a wide range of concentration, ν_{O-H} curves hardly change at all in any spectral properties, as is shown in Fig. 4. Secondly, the possibility of the incidental occurrence of the overtone or the combination bands in the midst of the ν_{O-H} region was discarded as a result of a deuterium-substitution experiment in the hydroxyl group. As is shown in Fig. 5, with the example of *o*-(2-methyl-1-propenyl)-phenol-*O*-d, the ν_{O-D} curve appears in the expected region of the lower frequency, with almost the same band shape as the original ν_{O-H} curve. Three absorptions in this case have the same ν_{O-H} to ν_{O-D} ratio of 1.35. It is quite natural that the anharmonicity of ν_{O-H} would not vary significantly after the O–H···π interaction, since it is suggested that ν_{O-H} is of normal anharmonicity or is possibly slightly more harmonic after the hydrogen bond formation.[16] Therefore, the lower ν_{O-H} bands appearing below 3600 cm^{-1} were all thought to result from the hydroxyl group interacting somehow with π-electrons in the vinyl group intramolecularly.

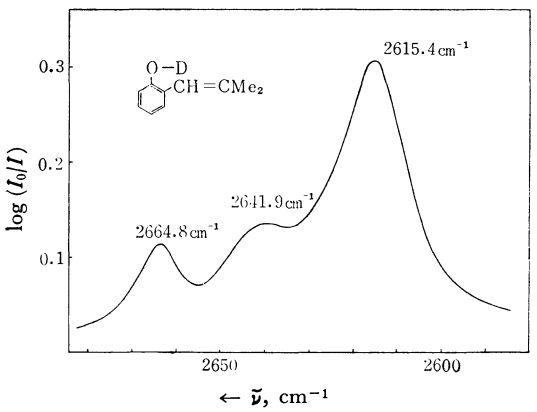

Fig. 5. ν_{O-D} absorption curve of *o*-isobutenyl-phenol-*O*-d.

By assigning in these ways, the remarkable effects of the substituents on the apparent absorption curves can be summarized as follows.

a) It is obvious from Figs. 1, 2 and 3, and also from the last column of Table III, that the degree of the interaction increases as the α-substituent on the vinyl group varies from methyl to ethyl, isopropyl and to *t*-butyl, because the intensity of the free ν_{O-H} band decreases, while the relative intensity of the interacting ν_{O-H} to the free one increases, in this descending order of substituents.

b) The phenols with a sterically-crowded alkenyl group show a rather less total intensity of the ν_{O-H} band.

c) In some instances, two or more kinds of ν_{O-H} bands appear interacting with π-electrons. This suggests the possible presence of more than one kind of interacting forms of a comparable stabilization.

d) The ν_{O-H} shifts following the interaction, which may be reagrded as corresponding to the

16) C. C. Pimentel and A. L. McClellan, "The Hydrogen Bond," W. H. Freeman and Co., San Francisco and London (1960), p. 114.

energy of the interaction, are not always in the order of the degree of the interaction, A_t/A_f.

Before ascribing these effects mainly to the steric factors and discussing them further, it would be more instructive to inspect here the configuration of the molecules with reference to the ultraviolet absorption spectra, together with the corresponding anisoles which lack the O–H···π interaction. Figure 6 illustrates the ultraviolet absorption curves of the selected examples in the region from 215 to 350 mμ, the numerical data of these, together with other phenols, being tabulated in Tables IV and V.

The absorption bands may be classified into two groups. The first, appearing in the 240—250 mμ region with a greater intensity, can only include the samples without a rather bulky group in the α-position of the vinyl group; the K-band of styrene chromophore[17] is characteristic. Styrene has been shown to be planar and, according to the thermochemical data,[18] to be stabilized through conjugation between the benzene ring and the vinyl group by 1.5 kcal./mol. Though no direct data is available for *o*-vinylphenol, it is not unreasonable to regard the molecule as planar, since the K-band is actually observed and there is no benefit in the non-planar structure with a loss of the resonance energy. The α-methyl substituent is not enough to make this conjugation band vanish and so retains it as a shoulder. The second bands appear in the 270—300 mμ region, with the maximum molar absorptivity in the neighborhood of $2-3\times10^3$. This is assigned to the B-band of the benzene derivatives with an oxygen function, such as phenol and anisole.[19]

Those homologs with a rather bulky α-substituent have only the latter absorption; it is, in addition, very akin to that of phenol itself in its shape and in the location of the absorption peak. There is no conjugation between the vinyl group and the benzene ring in these cases. It is most probable that the loss of the conjugation is due to the non-bonded repulsion between the group(s) on the vinyl group on the one hand and the hydroxyl group (the methoxyl group, in the case of anisoles) and the hydrogen atom of the benzene ring ortho to the alkenyl group on the other, and that it arises from the rotation of the alkenyl group around the bond through which it is connected to the benzene ring and from the consequent non-coplanarity between the two planar systems concerned. As the angle between them increases by way of a change in the α-substituents from methyl to ethyl, isopropyl, and to *t*-butyl, the non-bonded repulsive energy is relieved at the expense of the resonance energy. The compromise is attained at a certain angle of twist; thus, the conformation of the *o*-(1-alkenyl)phenols is determined. Since their

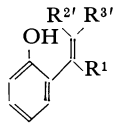
ultraviolet absorptions are, with one exception to be discussed later, very similar to the corresponding anisoles, it may be concluded that a third effect, that of the intramolecular interaction between the hydroxyl group and π-electrons on the conformation of the molecule, is a minor one and that the interaction takes place in a steric environment determined mainly by the resonance and the steric hindrance of the alkenyl group.

The trend mentioned in a) can now be explained. As the angle between the planes made by the benzene ring and the vinyl group increases, the localization of the π-electrons on the vinyl group commences to reduce their ionization potential, and so the strength as the electron donor of the π-electron system increases. This tendency is in the same direction as the inductive electron-donating ability of the alkyl groups, and it must be a factor in the observed substituent effect. In addition, the increased rotation of the plane of the vinyl group from that of the benzene ring is sure to produce a more favorable overlap between the π- and O–H orbitals, because the directional O–H anti-bonding orbital can approach the highest-occupied π-orbital in the vinyl group from the upper side of the electron cloud. Thus, the following order of the $\Delta\nu_{max}$ values is reasonable: II>I; III>I; V>IV; VIII>VII. It must be a reflection of the electronic effect that V and VII have greater $\Delta\nu_{max}$ than II and I, respectively. Nevertheless, the orders, II>III and V>VI, which are obtained by assuming that the $\Delta\nu_{max}$ values are direct measures of the strength of the interaction, can not be explained satisfactorily by the above interpretation. An inspection of the molecular models suggests that, when the α-substituents are greater than the methyl group, the dihedral angle made by the planes of the vinyl group and the benzene ring becomes great enough to make the hydroxyl and the vinyl groups overlap in the desired direction, but that the distance between the two groups increases a little, thus resulting in a reduction of their overlap. Thus, if the energy of the interaction is expressed by $\Delta\nu_{max}$, then methyl group as an α-substituent seems to afford the optimum among the two opposing steric effects, in addition to the favorable electronic effect.

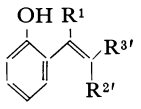
The steric effect may be an attractive means of interpreting of the decrease in the total intensity of the phenols with a rather sterically-crowded alkenyl group, since the bulky alkenyl group may dislocate the hydrogen atom of the hydroxyl group out of the benzene ring, thus giving a lower absorption intensity, from the analogy of comparison of the intensities of phenols and alcohols. However, this is not the case for sterically-hindered phenols. Ingold and Taylor[20] have reported that, among the homologous series of alkyl- or alkenyl-substituted phenols, the molar absorptivity did not change significantly. The present authors are tentatively inclined to attribute this phenomenon to the electronic effect of the substituent. That is, the vinyl group withdraws the electron, thus increasing the molar absorptivity of the ν_{O-H}, unless the steric effect is operating. When the steric effect forces the vinyl group to rotate out of the plane of the benzene ring, the vinyl group which is carrying some alkyl groups now acts as an electron-releasing group to lessen the molar absorptivity. We have to await further investigations to confirm this hypothesis, but the authors are postulating this on the basis that the compound V gives the least total intensity, whereas the second least is that of the compound VI, and the third least, that of the compound III.

As has been discussed above, the ultraviolet spectra indicate that I and VII are planar. If the molecule is perfectly planar, however, even the conformation IX cannot show the O–H···π interaction, because the hydroxyl group is pointing to the node of the π-orbitals on the vinyl group. A slight rotation around the bond which connects the vinyl group with the benzene ring will not lose the resonance energy materially, while the overlap between the O–H and π-orbitals may become possible; this must be the case in I.

The free ν_{O-H} in I is practically symmetric under the resolution of the present spectrometer. In VII, on the contrary, the band at the higher frequency is asymmetric. The tailing on the lower frequency side is reminiscent of the second absorption at 3601 cm^{-1}. Since it is shifted only 10 cm^{-1} from the free ν_{O-H}, the band is in its nature free. In this latter case, the basicity of the



IX



X

π-electron system as the proton acceptor is enriched by the β-alkyl substitution, and the hydroxyl group in the conformation X may be perturbed a little. Since the energy gained by the O–H···π interaction is not enough to compensate for the loss in the resonance energy in X, X cannot be a form which has a strongly interacting ν_{O-H}; it shows only a perturbed free ν_{O-H}.

When $R^{2'}$ is methyl, the vinyl group must be buttressed out of the plane of the benzene ring by the hydrogen at the 3-position with respect to the hydroxyl group, and some overlap between the hydroxyl group and the π-orbital becomes possible in X, giving an interacting ν_{O-H} curve different from that in IX. This must be the reason for the doublet interacting ν_{O-H} bands

20) K. U. Ingold and D. R. Taylor, *Can. J. Chem.*, **39**, 471 (1961).

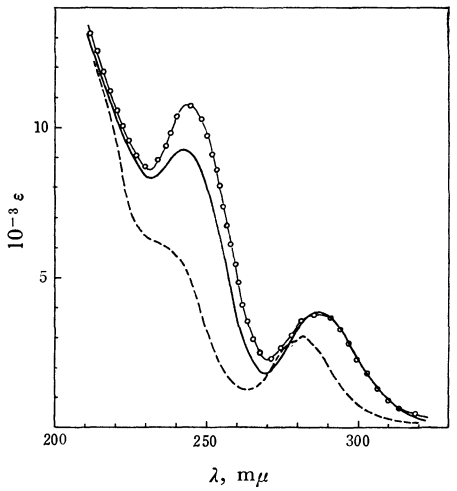


Fig. 7. The effect of solvents on the ultraviolet absorptions of *o*-isobutenylphenol (IV) and its methyl ether.

——— IV in 95% ethanol (A)

—○— IV methyl ether in A and H

in IV and IV'. This explanation has already been adopted by Baker and Shulgin[4] for the ν_{O-H} curves of IV and *o*-(*cis*-1-propenyl)phenol.

In this connection, it should be mentioned that the solvents and *O*-methylation have marked effects on the ultraviolet spectra of IV. Figure 7 shows the ultraviolet absorptions of IV in 95% aqueous ethanol and in *n*-heptane. The corresponding methyl ether has, in both solvents, the same absorption pattern as that of IV in ethanol, the data of which can be seen in Tables IV and V. Since the ether exhibits the K-band characteristic of the styrene chromophore, the molecule can be assumed to have a fairly planar structure. This must hold true in IV in ethanol. It is only in IV in *n*-heptane that the intramolecular interaction between the hydroxyl group and the π-electrons of the vinyl group takes place in this system. From the fact that it is only under these conditions that the K-band is weakened, it may be concluded that, when the interaction is possible, the angle made by the planes of the isobutenyl group and the benzene ring increases, thus producing better overlap of the orbitals of the hydroxyl group and the π-cloud on the isobutenyl group. This is the first observation of the effect of the intramolecular O–H$\cdots\pi$ interaction on the ultraviolet absorption spectra.

As regards the remaining assignment, concerning which of the two bands, at 3576 and 3539 cm^{-1}, should correspond to the conformations represented by IX and X, it is effective to compare the $\Delta\nu_{max}$ value of IV with those of I and VII. Since the $\Delta\nu_{max}$ values of 53.9 and 58.9 cm^{-1} of I and VII respectively, can be regarded as originating from the conformation IX, this form of IV must have a greater $\Delta\nu_{max}$ value because the basicity of the π-electrons is increased by one more methyl substitution. It is the band at 3539 cm^{-1} which conforms to this requirement; therefore, it may rather safely be concluded that the bands at 3576 and 3539 cm^{-1} should be assigned to the interacting hydroxyl groups in X and IX respectively.

A confirmative support of this assignment is now being investigated; it will be presented in a forthcoming paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 476—480 (1966)

The Absorption Spectra of Dyes. X.[1] Note on the Configuration of the Component Molecules in the Complex State*

By Toshihiko Hoshi and Yoshié Tanizaki

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received June 22, 1965)

The configuration of the component molecules in the complexes formed between Chrysophenine G (G) and the direct dyes (P), such as Chlorazol Sky Blue FF, has been discussed qualitatively with respect to the relation between the steric structure of the individual P molecules and the enthalpy or the entropy changes in the complex formations. The electrons to be transferred from

1) Part IX of this series: T. Hoshi, Y. Tanizaki and N. Ando, This Bulletin, 38, 725 (1965).

* Presented at the 7th Discussions on Dyeing Chemistry (May, 1965) held by the Chemical Society of Japan and the Society of Fiber Sience and Technology, Japan.

the partner (P) to the G molecule are the π electrons of the functional (hydroxy) groups and are those of the inner-side groups when the respective coupling components of the dye have more than one functional group. The larger the charge density of such an effective functional group becomes, the more the enthalpy change ($-\Delta H$) is increased. It may be said with certainty that there must exist a certain configuration of the component molecules peculiar to the complex formation. Such a configuration may be seen for the combination of G and ND (NW-acid←dianisidine→NW-acid). For other combinations of which the partner of G is more deformed in free than ND state, the shifts of equilibrium to the configuration for the complex state are almost due to an entropy change ($-\Delta S$) which increases in proportion to the magnitude of the deformation.

Hitherto in this series, the complex formation between the disazo direct dyes and Chrysophenine G has been studied.[1-4] According to the conclusion reached on the complex state, the component molecules are arranged side by side when the charge transfer from the partner (to be abbreviated as P) to the G molecule (Chrysophenine G) occurs[1,3]; that is, the π electron on the functional group of the P molecule transfers to the lowest vacant MO (π_G^*) of G.[1] Since the charge transfer, as is well known, plays an important role in the intermolecular force, the enthalpy change ($-\Delta H$) for the complex formation should be directly affected by the π electron density of the functional group. Moreover, as the π electron possesses the directional property, there may exist a certain configuration of P and G suitable for a charge transfer. The shifts to such a peculiar configuration of the component molecules must be reflected in the entropy change ($-\Delta S$).

The purpose of the present study is therefore to consider the thermodynamic quantities qualitatively and in connection with the configuration. At the same time, a supplement to the previous discussion will be given, on the basis of the experimental results accumulated so far, regarding the configuration of the complexes formed.

Experimental

The experimental procedure and the treatment of the data obtained were the same as have been described before.[4]

The dyes used here were the symmetric disazo dyes prepared in the usual way from the following diazo and the coupling components, which will hereforth be called by the notations indicated in parentheses; benzidine (B), tolidine (T), dianisidine (D) and 3, 3'-dichlorobenzidine (Cl), and NW-acid (N), J-acid (J), SS-acid (S), H-acid (H) and chromotropic acid (C). A dye, for example, NW-acid←benzidine→NW-acid, will be represented by NB. CT and CCl were excluded because they could not be obtained in a pure enough form to indicate only one spot on the paper chromatograph. The other dyes, when combined with G, showed the spectral change corresponding to the 1 : 1 and 1 : 2 complex formations. However, there were some combinations for which the equilibrium constants for the complex formations could not be estimated for several reasons; some dyes with the first absorption peaks at 530 mμ or at shorter wavelengths were affected by the absorption tail of G at its higher concentrations; others when combined with G did not indicate large enough spectral changes at the isosbestic points for reliable equilibrium constants to be calculated, and so on. The estimated thermodynamic quantities are shown in Table I, in which 1 : 1 means the complex

* Taken from Ref. 4.

a) The isosbestic points due to the influence of the tail of G did not appear because the first absorption peaks of P's were at too short wavelengths (530 mμ).

b) The equilibrium constants could not be calculated because the spectral change corresponding to the 1 : 2 complex formation did not retain well-defined isosbestic points.

c) In spite of the indication of the well-defined isosbestic points due to the complex formations, the spectral changes corresponding to the 1 : 1 and the 1 : 2 complex formations at the 1 : 2 and the 1 : 1 isosbestic points respectively were too small for the equilibrium constants to be calculated.

d) The sample could not be purified so as to provide only one spot on the paper chromatograph as the other samples could.

e) The spectral change due to the 1 : 2 complex formation at the 1 : 1 isosbestic point was too small for K_2 to be calculated.

f) The spectral change due to the 1 : 1 complex formation at the 1 : 2 isosbestic point was too small for K_1 to be calculated.

g) The values obtained were extensively dispersed; for example, the $-\Delta H$ values were dispersed from −18 to −23.

formation of the P+G→PG type, and 1 : 2, that of the PG+G→GPG type.

Results and Discussion

The thermodynamic quantities for the complex formations of 1 : 1 (P+G→PG) and 1 : 2 (P+2G →GPG) are summarized in Tables II and III for the D and the H series respectively. There can be discussed by means of the data in Table II the effect of the structural differences for the coupling components, and, by means of the data in Table III, that for the diazo components.

The Enthalpy Change.—It has been clarified that the lone pair electrons on the amino group of SS-acid (S) cannot conjugate to the naphthalene link due to the intramolecular hydrogen bond formation of the N···H–O type, as is shown in Fig. 1.[5] The π electrons of the hydroxyl groups must, therefore, be alone responsible for the SD→G charge transfer, provided the SD molecule allows of the above-mentioned situation for S. On the other hand, all the amino and/or the hydroxyl groups of H and C have π type lone pair electrons, because of the hydrogen bond formation in the N–H···O or O–H···O form respectively (Fig. 1).[5] That is, the HD and the CD molecule have twice as many functional groups with π type lone pair electrons as the SD molecule. According to Table II, however, the ΔH's of SD, HS and CD are nearly in the same order. This suggests strongly that only the π electrons of the internal functional groups (the hydroxyl groups) of P are responsible for the charge transfer. The reason why the π electrons on the end functional groups attached to the outside ring of naphthalene are ineffective could not be found. At any rate, the internal hydroxyl groups will be discussed with the above facts in mind.

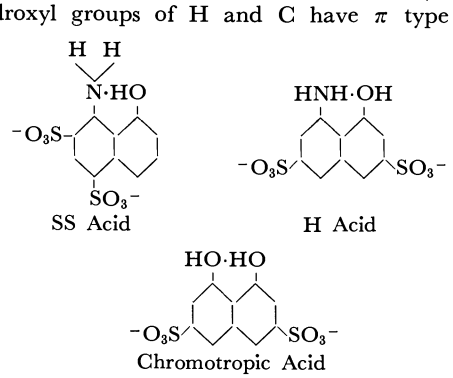

Fig. 1. The type of the hydrogen bonding of SS acid, H acid and chromotropic acid.

The effective functional groups of the P dyes used here are, therefore, just the hydroxyl groups. According to the findings described above, it ought to be possible to explain the relative magnitude of $-\Delta H$ in connection with the π electron densities of such hydroxyl groups. The relative π electron density will be comparable with that of the total charge density in the usual sense. It can be said that the larger the charge density of the hydroxyl group, the more the difficulty of the proton dissociation of the group. The order of the starting pH value for the dissociation of the hydroxyl groups has been found to be C(4.2)<J(5.6)<N(6.2)<S(8.0)≒H(8.4), where the figures in parentheses indicate the approximate pH values.[5] As the solvent water used here had a pH value of 6, nearly a half of C and also a small amount of J could be dissociated in the solution. Accordingly, the plausible order of the charge density is N<J≒S<H<C in the solution. If it is assumed that the condition of the hydroxyl groups is preserved because of the same coupling positions of the components,* the charge densities of the hydroxyl groups of the P dyes in the D series may plausibly be arranged in the same order as that of the coupling components, i. e., (ND)<JD<SD≒HD≒CD. Indeed, the order just mentioned corresponds well—including ND—with that of the magnitude of the $-\Delta H$'s in Table II.

In the H series, the coupling component, H-acid, is the common ingredient; therefore, the kinds of substituents at the 3,3′ positions of the biphenyl skeleton must be correlated with the charge density on the hydroxyl groups. The resonance effect of the substituent will hinder the electron of the hydroxyl group from migrating to the inner conjugate system. If this is the case, the π electron density of the hydroxyl group

5) Y. Tanizaki, H. Inoué and N. Ando, This Bulletin, **38**, 1419 (1965).

* This assumption is adequate except in the case of ND, because, as will be shown in the following section, all of the dyes in the D series but ND are affected by some steric effects and, consequently, the relative situation of the charge densities of the hydroxyl groups could not be altered. At present, however, no reason can be found for arranging ND on the left side as above.

will be larger in the case of HD and HCl than in that of HB and HT. Consequently, the transition probability of P→G in the former case will become larger than in the latter. In fact, the order of the magnitude of $-\Delta H$'s in Table III comes up to this expectation.

The above consideration can equally be applied to both the PG (1 : 1) and the GPG (1 : 2) complexes.

In the 1 : 2 complex state, the two G molecules have been considered to be equivalent to one another.[1,2] This is not inconsistent with the magnitude of the ΔH values obtained here, because, for all cases, the $-2\Delta H_1 > -\Delta H_2$ relation is always maintained.

Entropy Change.—First of all, concerning the ΔS value, it is interesting to notice the following relations which appear in Table II;

for the ND–G system: $\Delta S_1 \fallingdotseq \Delta S_2 \fallingdotseq 0$ (1)

for the JD–G and SD–G systems:

$$2\Delta S_1 \fallingdotseq \Delta S_2 \quad (2)$$

for the HD–G and CD–G systems:

$$-2\Delta S_1 < -\Delta S_2 \quad (3)$$

and for both ΔS_1 and ΔS_2 :

$$0 \fallingdotseq -\Delta S(\mathrm{ND}) < -\Delta S(\mathrm{JD}) < -\Delta S(\mathrm{SD}) < -\Delta S(\mathrm{HD}) \fallingdotseq -\Delta S(\mathrm{CD}) \quad (4)$$

Relation 1 implies that ND and G have not been suffered from any structural restriction by the complex formation; Relation 2, that the amount of deformation is equally distributed to the first (P+G →PG) and the second process (PG+G→GPG), and Relation 3, that the deformation is larger in the first process than in the second.

In order to enable the charge transfer to take place, the π_P orbital of the hydroxyl groups of P and the π_G^* orbital of G must overlap with each other. Besides, the π_P orbital originally has a directional property, as has been described above. For that reason, both of the component molecules are required to change the configuration into that suitable for the above conditions.

Though all of the P dyes take similar chemical structures, some differences may be seen in the three-dimensional structures between them, i. e., the differences in the torsional angles about the bonds shown in Fig. 2, as R_0, R_1 and R_2 are dependent on the sort of coupling components, though R_0 and R_1 may be almost independent. In the case of ND (see Fig. 2), the hydrogen bond formation is possible ($R_2=0°$), while in HD the electrostatic repulsion between the negative charge on the sulfonic group and the lone-pair electrons of the azo group exceeds the sum of the hydrogen bonding force and the resonance force of the C–N bond, $R_2=50$—$60°$.[6] That to is say, the $R_2(\mathrm{ND}) \ll R_2(\mathrm{HD})$ relation can

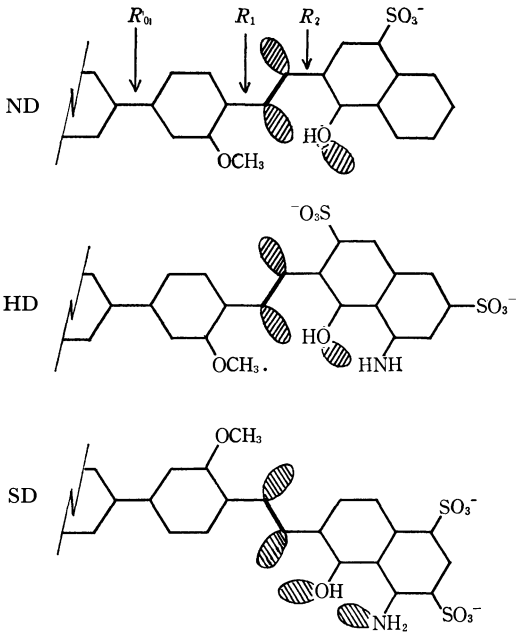

Fig. 2. Steric structures of ND, HD and SD; shadings indicate the σ type lone pair electrons.

well be correlated to the $-\Delta S(\mathrm{ND}) \ll -\Delta S(\mathrm{HD})$ relation. Therefore, it may be expected that a parallelism exists between the order of the tortional angle, R_2, in the free state and that of the entropy change.

Let us assume here that the ND molecule keeps the ideal conformation for the complex formation, because it can form the complexes without any entropy change. According to this assumption, the other P dyes have to become somewhat deformed in order to approach such an ideal conformation.

JD and CD have previously been considered to have nearly the same order of R_2 as HD.[6] However, JD has amino groups at the end β positions of the naphthalene links, while HD has these at the end α positions. The resonance effect of the amino group of J slightly increases the charge density at the opposite β position to be coupled with the diazo component, while that of the amino group of H cannot do that.[7] In the case of JD, therefore, the amino group could increase the resonance force of the C–N bond (R_2) and could also increase the charge density of the azo-nitrogen atom adjacent to biphenyl. For that reason, the R_2 angle of JD may become smaller than that of HD. The order of the torsion angles is considered to be as follows (R_2(SD) will not be considered here):

$$0° \fallingdotseq R_2(\mathrm{ND}) < R_2(\mathrm{JD}) < R_2(\mathrm{HD}) \fallingdotseq R_2(\mathrm{CD}) \quad (5)$$

Relation 5 coincides with Relation 4 except for

6) T. Kobayashi, Y. Tanizaki and N. Ando, ibid., **33**, 913 (1960).

7) H. Baba and S. Suzuki, ibid., **34**, 82 (1961).

SD. If Relations 4 and 5 are parallel, it must be said that R_2(SD) can be positioned between R_2(JD) and R_2(HD), indicating that the R_2 of SD is also fairly large. This, together with the drawing of SD in Fig. 2, implies the existence of some repulsive force acting between the σ type lone-pair electrons of the hydroxyl group and those of the azo-nitrogen atom. The fact of the steric structure of SD just mentioned must be emphasized, because the conventional image of the SD molecule has been one in which an intramolecular hydrogen bond is formed like the ND molecule shown in Fig. 2, that, i. e., the R_2 angle of SD is zero.[6]

In the H series, since R_0 and R_2 can be assumed to be invariant because of the common coupling components, the difference in the entropy change of Table III may be attributed to the difference in R_1 values. As may be seen from the drawing of HD in Fig. 2, the torsion of R_1 is mainly due to the electrostatic repulsion or the steric hindrance of the methoxy group in relation to the σ type lone-pair electrons of the azo-nitrogen atom. Also, in the case of HCl, a similar situation involving the chlorine atom can be taken into consideration. Such substituent effects may be larger for HD and HCl than for HB and perhaps for HT as well. The corresponding torsion angles R_1 for the former class will, therefore, become larger than those for the latter. Thus, the entropy change difference appearing in the two classes, (HB, HT) and (HD, HCl), can reasonably be explained.

One of the present authors (T. H.) wishes to express his hearty thanks to Dr. Harutada Negoro, Sankyo Co., Ltd., for his encouragement and advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 480—484 (1966)

The Synthesis of α, ω-Disubstituted Higher Alkanes from $\alpha, \alpha, \alpha, \omega$-Tetrachloroalkanes

By Kazuo SAOTOME, Hiroshi KOMOTO and Toshiaki YAMAZAKI

Technical Research Laboratory, Asahi Chemical Industry Co., Itabashi-ku, Tokyo

(Received June 22, 1965)

Higher ω-chloroalkanoic acids than ω-chlorooctanoic acid were prepared in good yields (over 90%) by improved methods of the hydrolysis of $\alpha, \alpha, \alpha, \omega$-tetrachloroalkanes. The reactions were carried out in fuming nitric acid, with the addition of nitrogen dioxide during the reaction or in the presence of a small amount of phosphoric anhydride. α, ω-Dichloroalkanes were derived from the ω-chloroalkanoic acids by the Kolbe electrolytic synthesis. Various other novel α, ω-disubstituted alkanes with very long methylene chains, such as glycols, dinitriles, dicarboxylic acids, and diamines, were also prepared starting from the tetrachloroalkanes.

Many kinds of bifunctional derivatives have been prepared by several Russian authors[1] from $\alpha, \alpha, \alpha, \omega$-tetrachloroalkanes which had been obtained by the telomerization of ethylene with carbon tetrachloride. Some of the lone-chained derivatives have also been synthesized. For example, α, ω-dodecanedioic and α,ω-hexadecanedioic acids were obtained through the dimeric compounds produced by the catalytic hydrogenation of these tetrachloroalkanes:[2]

$$Cl(CH_2)_nCCl_3 \rightarrow [Cl(CH_2)_nCCl_2\text{-}]_2 \rightarrow$$
$$Cl(CH_2)_{2n+2}Cl \rightarrow HOOC(CH_2)_{2n+2}COOH$$

In the present work, α, ω-disubstituted derivatives with a long methylene chain have been prepared by the Kolbe electrolytic synthesis of the ω-substituted alkanoic acids derived from $\alpha, \alpha, \alpha, \omega$-tetrachloroalkanes.

The preparation of lower ω-chloroalkanoic acids from the tetrachloroalkanes with sulfuric acid was also well investigated by the previously-mentioned authors. Freidlina et al.[3] obtained higher ω-chloroalkanoic acids (C_9—C_{13}) in yields of 60—70% by treating the tetrachloroalkanes with fuming nitric acid. A careful hydrolysis of these higher tetrachloroalkanes in concentrated sulfuric acid also gave the acids in nearly the same yields.[4]

We have found that the yield of these higher ω-chloroalkanoic acids (C_9–C_{15}) is remarkably affected by the density of fuming nitric acid, and that the

Table I. The preparation of higher ω-chloroalkanoic acids

$Cl(CH_2)_nCCl_3$		HNO_3	$Cl(CH_2)_nCCl_3$		$Cl(CH_2)_nCOOH$	
			Recovered	Conversion		
n	g.	g.	g.	%	g.	Yield, %*
8	130	350	6.0	95.5	87.0	96.0
10	120	400	19.0	84.0	74.0	97.5
12	120	450	31.0	74.0	66.5	96.5
14	100	450	30.0	70.0	51.0	92.0

* The yield was calculated by taking the recovered tetrachloroalkane into account.

yield is much improved to over 90% by adding nitrogen dioxide to the reaction mixture during the course of the reaction. The yield has also been found to increase when the reaction is carried out in a fuming nitric acid solution containing a small amount of phosphoric anhydride. ω-Chloroalkanoic and ω-hydroxyalkanoic acids derived from the tetrachloroalkanes were subjected to the Kolbe electrolysis to afford α, ω-disubstituted long alkanes according to the following scheme;

$$\begin{array}{l} Cl(CH_2)_nCCl_3 \\ \downarrow \\ Cl(CH_2)_nCOOH \rightarrow HO(CH_2)_nCOOH \\ \downarrow \quad \text{Kolbe electrolysis} \quad \downarrow \\ Cl(CH_2)_{2n}Cl \qquad HO(CH_2)_{2n}OH \\ \downarrow \\ CN(CH_2)_{2n}CN \rightarrow H_2N(CH_2)_{2n+2}NH_2 \\ \downarrow \\ HOOC(CH_2)_{2n}COOH \end{array}$$

The Kolbe electrolytic syntheses of some ω-chloroalkanoic[5] and ω-hydroxyalkanoic[6] acids have been reported.[7] In this work, however, very long α, ω-dichloroalkanes (up to α, ω-dichlorotetracosane) were prepared. Dinitriles, dicarboxylic acids, and diamines were also derived from these long α, ω-dichloroalkanes.

Experimental and Results

δ-Chlorovaleric, ω-chloroenanthic and ω-chloropelargonic acids were prepared by hydrolyzing the corresponding tetrachloroalkanes in sulfuric acid according to the method in the literatures.[8]

The Preparation of Higher ω-Chloroalkanoic Acids in Fuming Nitric Acid with Nitrogen Dioxide Added.—A mixture of $\alpha, \alpha, \alpha, \omega$-tetrachloroalkane and fuming nitric acid (d=1.52) was stirred in a water bath. The reaction started at about 40°C with the generation of gas. When the initial generation of gas stopped (at 45—50°C, after 2—2.5 hr.), a stream of an excess of nitrogen dioxide was passed through the solution. Then the temperature was gradually raised to 70°C until the gas genaration practically ceased. 2—2.5 hr. were needed to complete the reaction under the flow of nitrogen dioxide. The reaction was carried out for about 5 hr. in all. A crystalline product was precipitated by adding ice-water to the reaction mixture. The precipitate was then filtered and washed several times with water. White crystals were obtained after recrystallization from ether - petroleum ether. From the mother liquor, the unreacted tetrachloroalkane was recovered by distillation under reduced pressure. The repeated recrystallization of the crystals from the same solvents afforded the following specimens: ω-chloropelargonic acid (a fraction of b. p. 140—143°C/2 mmHg was recrystallized), m. p. 30°C (lit. 30°C); ω-chloroundecanoic acid, m. p. 42°C (lit. 42°C); ω-chlorotridecanoic acid, m. p. 53°C (lit. 52°C); and ω-chloropentadecanoic acid, m. p. 62°C (lit. 62°C).

The details of the reaction are shown in Table I.

The Preparation of Higher ω-Chloroalkanoic Acids in Fuming Nitric Acid Containing Phosphoric Anhydride.—1) A mixture consisting of 55 g. of 1, 1, 1, 9-tetrachlorononane, 150 g. of fuming nitric acid (d=1.52) and 6 g. of phosphoric anhydride was stirred. The reaction started at 40°C with the generation of gas. The temperature was then gradually raised to 70°C as the reaction proceeded. After a 3 hr. reaction, the mixture was treated as above. Distillation under reduced pressure afforded a crystalline product without the unreacted tetrachloroalkane. Yield, 38.5 g. (96.5%).

2) A mixture consisting of 60 g. of 1,1,1,11-tetrachloroundecane, 180 g. of fuming nitric acid and 4 g. of phosphoric anhydride was treated as above. The reaction was carried out at temperatures between 40—60°C for 5 hr. Recrystallization from ether - petroleum ether gave white crystals. From the mother liquor, 3.5 g. of the unreacted tetrachloroalkane was recovered; conversion, 94%. Yield, 37.5 g. (89%).

The Preparation of ω-Hydroxyalkanoic Acids.—A mixture of ω-chloroalkanoic acid and its two moles of sodium hydroxide (a 5% aqueous solution) was refluxed for 6 hr. The solution was

then acidified with sulfuric acid while being cooled with ice-water in order to separate the product. The precipitate was filtered, washed with water, and dissolved in ether - petroleum ether. The crystals which were separated after the evaporation of a large part of the solvents were again recrystallized from ethyl acetate. The following ω-hydroxyalkanoic acids were thus obtained: ω-hydroxypelargonic acid, m. p. 51°C (lit. 51.5°C); yield 86%; ω-hydroxyundecanoic acid, m. p. 69°C (lit. 70°C); yield 89%; ω-hydroxyundecanoic acid, m. p. 69°C (lit. 70°C); yield 89%; ω-hydroxytridecanoic acid, m. p. 79°C (lit. 79°C); yield 83%; and ω-hydroxypentadecanoic acid, m. p. 82°C (lit. 82°C); yield 78%.

The Kolbe Electrolysis of ω-Substituted Alkanoic Acids.—The apparatus used for the electrolysis was as follows. In a glass cell ($10\times10\times1$ cm^3), electrodes of titanium plates plated with platinum ($8\times8\times0.3$ cm^3) were settled 2 mm. apart. The cell was then placed in a cooling bath, and a sample solution was vigorously circulated through it. Commercial absolute methanol was used as the solvent, and small amounts of metallic sodium were added. The current density was maintained between 0.10 and 0.12 amp./sq. cm. throughout the reaction. The temperature in the cell was controlled below 50°C (30—40°C), while the solution outside the cell was cooled with ice-water in order to deposit crystalline products. A glass filter was placed between the outer section and the cell in order to protect the circulation pump from the solid precipitate. The reaction was continued until the solution was just alkaline to litmus; the time needed for this to occur was usually 100—150% longer than that calculated. The product, after being acidified with hydrochloric acid, was condensed almost to dryness, then the residue was extracted with ether. The ether extract was washed with a dilute solution of sodium carbonate in order to remove the unreacted acid, and then dried. The product which was obtained after the evaporation of the ether was recrystallized from ethanol. In the cases of α, ω-dichloroalkanes, in which carbon atoms in a molecule are less than 16, however, the products were purified by distillation under reduced pressure.

The details of the reaction and the characteristics of the products are shown in Tables II and III.

The Preparation of Dinitriles from α, ω-Dichloroalkanes.—α, ω-Dicyanoalkanes were prepared by treating these dichloroalkanes with potassium cyanide in the solvent of dimethylformamide (DMF). The reaction products were filtered to remove precipitated potassium chloride, and the filtrates were condensed by heating under reduced

pressure in order to evaporate the solvent. The lower dinitriles were separated and purified by distillation under reduced pressure, while the higher ones were obtained as white crystals after repeated recrystallizations from ethanol. The yields in Table IV are the values after the first distillation or recrystallization. The characteristics and the analytical results are shown in Table V.

The Preparation of α,ω-Alkanedioic Acids.—1) The oxidation of ω-hydroxyalkanoic acids. ω-Hydroxyundecanoic, ω-hydroxytridecanoic and ω-hydroxypentadecanoic acids were oxidized with nitric acid. For example, a mixture of 11 g. of ω-hydroxytridecanoic acid and 150 g. of nitric acid (98%) was stirred at room temperature for 1.5 hr. Then the temperature was gradually raised to 60°C over a 1-hr. period and then maintained between 60 and 70°C for 5 more hours. The mixture was diluted with water, and a crystalline product was filtered, washed with water and recrystallized from ethyl acetate. The pure crystals were obtained after repeated recrystallization from benzene.

2) The oxidation of glycols. Hexadecamethylene and eicosamethylene glycols were oxidized with potassium permanganate in acetone-water. For example, 5 g. of hexadecamethylene glycol was added to a solution of acetone (200 ml.) and water (20 ml.) containing 10 g. of potassium permanganate. The mixture was then heated at 70°C for 8 hr. while being stirred. After being allowed to stand overnight, the mixture was acidified with hydrochloric acid; then an aqueous solution of sodium hydrogen sulfite was added in order to dissolve precipitated manganese dioxide. The separation and the purification of a crystalline product were carried out as above.

3) The hydrolysis of dinitriles. Into a mixture consisting of 25 ml. of sulfuric acid (96%), 20 ml. of water and to 80 ml. of acetic anhydride, 25 g. of the dinitrile shown in Table V was added and the mixture was then refluxed for 15 hr. The reaction mixture was cooled and diluted with water to afford a crystalline precipitate, which was then separated and purified much above.

The yields and the melting points of these dicarboxylic acids are shown in Table VI.

The Preparation of Diamines.—The dinitriles shown in Table V were hydrogenated in the presence of the Raney cobalt or nickel (recipe W-7) under hydrogen pressures of 110—130 atm. The reaction was carried out for 2 hr. in 200 ml. of methanol containing 20 g. of ammonia. The absorption of hydrogen generally reached the theoretical amount after 1 hr. From the reaction mixture, the catalyst was filtered off, and the filtrate

was condensed by evaporating the solvent and ammonia. A fraction with a higher boiling point was again distilled under reduced pressure to give a product with a constant boiling point.

The details of the reaction and the products are summarized in Table VII.

Discussion

In the hydrolysis of the higher tetrachloroalkanes in fuming nitric acid, the yields of ω-chloroalkanoic acids were much improved by the addition of either nitrogen dioxide or phosphoric anhydride. The hydrolysis of the trichloromethyl group is denoted by:

$$RCl_3 + 2H_2O \rightarrow RCOOH + 3HCl$$

The hydrogen chloride produced is immediately oxidized by an attack of nitric acid to give 3 mol. of water:

$$3HCl + 3HNO_3 \rightarrow 3NO_2 + 3/2Cl_2 + 3H_2O$$

As a matter of fact, the gas generated from the reaction mixture is a mixture of nitrogen dioxide and chlorine. The actual reactions taking place in the nitric acid solution may be summarized as:

$$RCCl_3 + 3HNO_3 = RCOOH + 3NO_2 + 3/2Cl_2 + H_2O$$

According to the above equation, one mole of water is produced to dilute the nitric acid when one mole of the tetrachloroalkane is converted. The facts that the yield is greatly affected by the density of the fuming nitric acid and that relatively poor yields are obtained in a simple treatment with fuming nitric acid, reveal the prohibiting effect of dilution by the produced water. Moreover, the reaction is actually interrupted by the small addition of water into the system. It is obvious that the nitrogen dioxide and the phosphoric anhydride in the reaction mixture catch the water, thus maintaining the system free from the dilution. The characteristic feature of these acidic media with regard to the progress of the reaction is much affected by the dilution with water. The remarkable improvements in the yields of the higher ω-chloroalkanoic acids in these experiments may be explained by the above explanation.

On the other hand, the hydrolysis of the lower tetrachloroalkanes ($<C_9$) in fuming nitric acid proceeds smoothly enough to give a high conversion even without the addition of these dehydrating agents. The products, however, are somewhat yellow, and this color could not be removed even by repeated distillations. The infrared spectra of the colored products denote the presence of some nitro-compounds as impurities.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 485—489 (1966)

The Synthesis of Novel α, ω-Oxaalkanedioic Acids with Long Methylene Chain Units

By Kazuo SAOTOME and Kenichiro SATO

Technical Research Laboratory, Asahi Chemical Industry Co., Nakadai, Itabashi-ku, Tokyo

(Recieved June 22, 1965)

α, ω-Oxaalkanedioic acids with the general formula $HOOC(CH_2)_mO(CH_2)_nCOOH$ (m, n= 3—10, but in unsymmetric structures m=3 or 4) were synthesized. The symmetric acids were prepared by the catalytic dehydration of ω-hydroxyalkanoic acids or by the condensation of ω-chloroalkanoic acids in the presence of alkali hydroxide. The unsymmetric acids (m=3 or 4) were prepared by the reaction of γ-butyrolactone or δ-valerolactone with alkali alcoholates of ω-hydroxyalkanoic acids. The reaction mechanisms were also discussed. In the plots of the melting points of the two unsymmetric series (m=3, 4 in m/n) against the carbon atoms in a molecule, the minimum melting points are found at 3/5 and 4/5 respectively.

The synthesis of some α, ω-oxaalkanedioic acids with a formula $O[(CH_2)_nCOOH]_2$ (n= 2—5) has been reported hitherto.

Alexander and Schniepp[1] prepared 6-oxaundecanedioic acid from bis(4-chlorobutyl)ether through its biscyano derivative. 7-Oxatridecanedioic acid was also derived from bis(4-bromobutyl)-ether by malonic ester synthesis.[2] Reppe et al.[3] prepared 5-oxaazelaic acid by treating γ-butyrolactone with alkali hydroxide at temperatures above 200°C.[4-6] The conversion of β-propiolactone to 4-oxapimelic acid proceeds easily in the presence of water at about 100°C.[7,8]

In the present work, the authors will report on the synthesis of α, ω-oxaalkanedioic acids with the general formula of $HOOC(CH_2)_mO(CH_2)_n$ COOH, in which m and n are integers from 3 to 10 respectively, although m is 3 or 4 in unsymmetric structures. In the synthesis of the above α, ω-oxaalkanedioic acids, the ω-carboxyalkyl groups of C_4 and C_5 are derived from γ-butyrolactone and δ-valerolactone as raw materials in each case. The reaction between γ-butyrolactone and alkali alcoholates to form γ-carboxypropyl derivatives was precisely investigated by Reppe et al.[3] The reaction is considered to proceed through alkyl-fission in the γ-butyrolactone ring. On the other hand, the reactivities of δ-valerolactone have been little studied.

The synthesis and the polymerization of δ-valerolactone were reported on in previous papers.[9,10] During the course of the investigation of the reactivities of δ-valerolactone in comparison with those of γ-butyrolactone, it was found that δ-valerolactone reacts with alkali alcoholates in the same manner as γ-butyrolactone to afford δ-carboxybutyl derivatives.

For example, a mixture of sodium phenolate and δ-valerolactone gives δ-phenoxyvaleric acid in a good yield.[11] The preparation of 6-oxaundecanedioic acid from δ-valerolactone was carried out by three different methods, in which the formation of the ether linkage was effected through the following processes: 1) the dehydration of alkali δ-hydroxyvalerate in the presence of alumina as the catalyst, 2) the reaction between δ-valerolactone and the alkali alcoholate of sodium δ-hydroxyvalerate, and 3) the reaction of δ-valerolactone with sodium carbonate. By the second type of reaction, unsymmetric 5-oxasebacic acid was also found to be produced by the reaction between γ-butyrolactone and the sodium alcoholate of sodium δ-hydroxyvalerate, which had been prepared by heating a mixture of δ-valerolactone and two times as many moles of sodium hydroxide under reduced pressure. The reactions of the first two types were investigated using various lactones, ω-hydroxyalkanoic and ω-chloroalkanoic acids; novel α, ω-oxaalkanedioic acids with both symmetric and unsymmetric structures were thus obtained. It was found that δ-valerolactone reacted with alkali alcoholates of ω-hydroxyalkanoic salts in the same manner as γ-butyrolactone to give both symmetric and unsymmetric α, ω-oxaalkanedioic acids. ε-Caprolactone, however, did not react with the

alcoholates as above; rather, a resinous product was obtained under severe conditions. The symmetric α, ω-oxaalkanedioic acids with longer methylene chain units than C_4 were prepared either by the condensation of ω-hydroxyalkanoic salts in the presence of the dehydration catalyst or by the treatment of ω-chloroalkanoic acids with potassium hydroxide. We tried to obtain unsymmetric α, ω-oxaalkanedioic acids of which had methylene chain units longer than C_4, by the reaction between ω-chloroalkanoic acids and the alkali alcoholates of ω-hydroxyalkanoic salts with carbon numbers different from those of the chloro-acids. However, the reaction products seemed to be mixtures of symmetric and unsymmetric α, ω-oxaalaknedioic acids, each with the ω-carboxy-alkyl group of the starting compounds. It was difficult to separate the individual α, ω-oxa-alkanedioic acids from the reaction mixtures.

The mechanisms of these condensation reactions will be discussed.

Experimental

Materials.—δ-Valerolactone was prepared according to the method described in a previous paper.[9] ω-Chloroalkanoic and ω-hydroxyalkanoic acids were also prepared from the telomers of ethylene with carbon tetrachloride. The characteristics of these intermediates agreed with those in the literature.[12]

6-Oxaundecanedioic Acid.—1) A mixture of 50 g. of δ-valerolactone and 20 g. of sodium hydroxide was heated at about 200°C in order to make a homogeneous solution. Then, 10 g. of activated alumina (grains) was added to the solution, and the temperature was gradually raised to 260—265°C over a 3 hr. period. During this period, a vigorous foaming due to the dehydration reaction was observed. After the reaction mixture had been kept at that temperature for a further 6 hr., the product was cooled and dissolved in 500 ml. of water. The aqueous solution was acidified by adding sulfuric acid a little over the neutral point of methyl orange. The precipitate and the solution were extracted with ether. After the evaporation of the ether, the residue was distilled under reduced pressure. The recrystallization of a fraction (b. p. 200—230°C/1 mmHg) from ethyl acetate afforded white crystals; m. p. 89.5—90°C (lit.[1] 88.5—89°C). Yield, 29 g. (53%).

A mixture of 25 g. of δ-valerolactone and 14 g. of potassium hydroxide was treated as above, but the reaction was carried out at temperatures of 255—260°C for 4 hr. White crystals of the same melting point were obtained. Yield, 19 g. (70%).

Found: C, 55.13; H, 8.29; mol. wt. (titration), 219. Calcd. for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31%; mol. wt., 218.3.

2) A solution of 42 g. of sodium hydroxide dissolved in 50 ml. of water was gradually added to 50 g. of δ-valerolactone under cooling. After the evaporation of water with an aspirator, the mixture was heated to 220°C under the reduced pressure of 1 mmHg for 3 hr. until the water in the system was completely removed. Then, 60 g. of δ-valerolactone was added, and the mixture was refluxed under the atmosphere of nitrogen. When the mixture became homogeneous after several minutes, the temperature was raised to 255—260°C and kept there for a further 8 hr. When the product was treated as above, 88 g. (74%)

12) A. N. Nesmeyanov, R. Kh. Freidlina and L. I. Zakharkin, *Quart. Rev.*, **10**, 330 (1956).

of 6-oxaundecanedioic acid was obtained.

3) A mixture of 25 g. of δ-valerolactone and 14 g. of sodium carbonate was refluxed. The temperature was gradually raised to 260°C over a 1.5 hr. period and then maintained at that point for 3 hr. During this period, the generation of 2.5 l. of carbon dioxide (nearly theoretical) was observed. When the reaction product was treated as above, 14 g. (51%) of 6-oxaundecanedioic acid was obtained.

5-Oxaazelaic Acid.—The preparation of this acid from γ-butyrolactone has already been reported in the cited articles. In these experiments, however, the reaction was carried out under somewhat different conditions; γ-butyrolactone was treated with potassium hydroxide and sodium carbonate under conditions similar to those in the cases of δ-valerolactone described above. No large difference in the yields between the two lactones was observed in either case, and the melting point of the obtained crystals agreed with that of the literature (81°C).

5-Oxasebacic Acid.—From a mixture of 50 g. of δ-valerolactone and 42 g. of sodium hydroxide in 60 ml. of water, the water was completely removed by heating it to 250°C for 3 hr. under the reduced pressure of 1 mmHg. Then 60 g. of γ-butyrolactone was added, and the mixture was heated at 250—260°C for 8 hr. under nitrogen. Just before the end of the reaction, the unreacted lactone was recovered by distillation under reduced pressure. The treatment of the product was carried out much as in the case of 6-oxaundecanedioic acid. From the ether extract, a fraction with a b. p. of 180—210°C/2 mmHg was separated by distillation. Recrystallization from ether-petroleum ether afforded white crystals; m. p. 67°C. Yield based on δ-valerolactone, 72 g. (71%).

Found: C, 53.00; H, 8.06; mol. wt. (titration), 206. Calcd. for $C_9H_{16}O_5$: C, 52.93; H, 7.90%; mol. wt., 204.2.

A mixture of 43 g. of γ-butyrolactone and 42 g. of sodium hydroxide was treated as above. Then 60 g. of δ-valerolactone was added, and the mixture was heated similarly. Crystals identical with the above product were separated. Yield based on γ-butyrolactone, 62 g. (61%). The infrared spectrum is shown in Fig. 1.

5-Oxaundecanedioic Acid.—A mixture of 28 g. of ε-caprolactone and 32 g. of potassium hydroxide in 50 ml. of water was treated as in the case of 6-oxaundecanedioic acid (2). Then 25 g. of γ-butyrolactone was added, and the mixture was treated similarly. A fraction with a b. p. of 200—215°C/1 mmHg was distilled from the ether extract. Recrystallization from ether - petroleum ether gave white crystals; m. p. 34—35°C. Yield based on ε-caprolactone, 38 g. (71%).

Found: C, 54.96; H, 8.07; mol. wt. (titration), 220. Calcd. for $C_{10}H_{18}O_5$: C, 55.03; H, 8.31%; mol. wt., 218.3.

5-Oxadodecanedioic Acid.—A mixture of 55 g. of ω-chloroenanthic acid and 64 g. of potassium hydroxide in 150 ml. of water was refluxed for 4 hr. After the complete evaporation of the water from the mixture according to the above procedure, 35 g. of γ-butyrolactone was added; and the mixture was then treated similarly. The recrystallization of a fraction with a b. p. of 200—220°C/1 mmHg with ether - petroleum ether afforded white crystals; m. p. 57.5—58°C. Yield based on ω-chloroenanthic acid, 45 g. (58%).

Found: C, 56.72; H, 8.52; mol. wt. (titration), 229. Calcd. for $C_{11}H_{20}O_5$: C, 56.88; H, 8.68%; mol. wt., 232.3.

5-Oxatetradecanedioic Acid.—Into a solution of 9.2 g. of metallic sodium dissolved in 100 ml. of dry methanol, 35 g. of crystalline ω-hydroxypelargonic acid was added. The methanol was completely removed from the mixture by heating it to 220°C over a 3 hr. period under the reduced pressure of 1 mmHg. To the residue 20 g. of γ-butyrolactone was then added, and the mixture was refluxed for 2 hr. Then the excess γ-butyrolactone was recovered by distillation under reduced pressure. The reaction was continued for a further 6 hr. at temperatures of 250—260°C. The product was treated as above. The recrystallization of a fraction with a b. p. of 220—250°C/0.4—0.8 mmHg with ether - petroleum ether afforded white crystals; m. p. 64.5—65°C. Yield based on ω-hydroxypelargonic acid, 31 g. (59%).

Found: C, 59.82; H, 9.35; mol. wt. (titration), 264. Calcd. for $C_{13}H_{24}O_5$: C, 59.98; H, 9.29%; mol. wt., 260.3.

The infrared spectrum is shown in Fig. 1.

5-Oxahexadecanedioic Acid.—The reaction was carried out under conditions similar to those above. Thus 35 g. of ω-hydroxyundecanoic acid was treated with 8.0 g. of metallic sodium and 20 g. of γ-butyrolactone. A crystalline product was obtained after the evaporation of ether from the extract. Recrystallization from an ether - petroleum ether solution afforded white crystals; m. p. 74—74.5°C. Yield based on ω-hydroxyundecanoic acid, 26 g. (52%).

Found: C, 62.39; H, 9.67; mol. wt. (titration), 286. Calcd. for $C_{15}H_{28}O_5$: C, 62.47; H, 9.79%; mol. wt., 288.4.

6-Oxadodecanedioic Acid.—The reaction was carried out under conditions similar to those in the case of 5-oxaundecanedioic acid. The intermediate product from 28 g. of ε-caprolactone and 32 g. of potassium hydroxide was treated with 29 g. of δ-valerolactone. The recrystallization of a fraction with a b.p. of 200—220°C/1mmHg from an ether - petroleum ether solution afforded white crystals; m. p. 52.5—53°C. Yield based on ε-caprolactone, 37 g. (65%).

Found: C, 56.91; H, 8.58; mol wt. (titration), 234. Calcd. for $C_{11}H_{20}O_5$: C, 56.88; H, 8.68%; mol. wt., 232.3.

6-Oxatridecanedioic Acid.—The reaction was carried out under conditions similar to those in the case of 5-oxadodecanedioic acid. The intermediate product from 55 g. of ω-chloroenanthic acid and 64 g. of potassium hydroxide was treated with 41 g. of δ-valerolactone. The recrystallization of a fraction with a b. p. of 200—225°C/1 mmHg with ether-petroleum ether afforded white crystals; m. p. 57.5—58°C. Yield based on ω-chloroenanthic acid, 56 g. (68%).

Found: C, 58.17; H, 8.94; mol. wt., (titration), 249. Calcd. for $C_{12}H_{22}O_5$: C, 58.51; H, 9.00%; mol. wt., 246.3.

The infrared spectrum is shown in Fig. 1.

6-Oxapentadecanedioic Acid.—The reaction was carried out under conditions similar to those in the case of 5-oxatetradecanedioic acid. The intermediate product from 35 g. of ω-hydroxypelargonic acid and

9.2 g. of metallic sodium was treated with 24 g. of δ-valerolactone. The recrystallization of a fraction with a b. p. of 210—240°C/0.5—1 mmHg from ether-petroleum ether afforded white crystals; m. p. 64.5—65°C. Yield based on ω-hydroxypelargonic acid, 34 g. (62%).

Found: C, 62.89; H, 9.10; mol. wt. (titration), 277. Calcd. for $C_{14}H_{26}O_5$: C, 62.91; H, 9.15%; mol. wt., 274.3.

6-Oxaheptadecanedioic Acid.—The reaction was carried out under conditions similar to those in the case of 5-oxahexadecanedioic acid. The intermediate product from 35 g. of ω-hydroxyundecanoic acid and 8.0 g. of metallic sodium was treated with 24 g. of δ-valerolactone. A crystalline product was obtained after the evaporation of ether from the extract. Recrystallization from ether-petroleum ether afforded white crystals; m. p. 84.5—85°C. Yield based on ω-hydroxyundecanoic acid, 33 g. (63%).

Found: C, 63.36; H, 9.70; mol. wt. (titration), 304. Calcd. for $C_{16}H_{30}O_5$: C, 63.54; H, 10.00%; mol. wt., 302.4.

7-Oxatridecanedioic Acid.—A mixture of 28 g. of ε-caprolactone and 15 g. of potassium hydroxide in 20 ml. of water was treated much as in the case of 6-oxaundecanedioic acid (1). The recrystallization of a fraction with a b. p. of 210—250°C/1 mmHg from water-ethanol afforded white crystals; m. p. 90—91°C, (lit. 91°C). Yield, 16 g. (53%).

Found: C, 58.49; H, 8.90; mol. wt. (titration), 245. Calcd. for $C_{12}H_{22}O_5$: C, 58.51; H, 9.00%; mol. wt., 246.3.

8-Oxapentadecanedioic Acid.—From a mixture of 55 g. of ω-chloroenanthic acid and 39 g. of potassium hydroxide in 40 ml. of water, the water was rapidly removed (within 20 min.) by heating the mixture to 240°C under reduced pressure. After the evaporation of the water, the mixture was kept at temperatures of 250—260°C for 8 hr. under the reduced pressure of 1 mmHg. The product was then treated as above. The recrystallization of a fraction with a b. p. of 210—250°C/0.5—1 mmHg from water-ethanol afforded white crystals; m. p. 95.5—96°C. Yield, 28 g. (61%).

Found: C, 61.19; H, 9.50; mol. wt. (titration), 271. Calcd. for $C_{14}H_{26}O_5$: C, 61.29; H, 9.55%; mol. wt., 274.3.

10-Oxanonadecanedioic Acid.—A mixture of 48 g. of ω-chloropelargonic acid and 29 g. of potassium hydroxide was treated much as above. A crystalline product was obtained after the evaporation of ether from the extract. Recrystallization from toluene afforded white crystals; m. p. 99—99.5°C. Yield, 21 g. (51%).

Found: C, 65.56; H, 10.08; mol. wt. (titration), 327. Calcd. for $C_{18}H_{34}O_5$: C, 65.45; H, 10.30%; mol. wt., 330.4.

The infrared spectra of some of these novel α, ω-oxaalkanedioic acids are shown in Fig. 1. The characteristic band at 1110—1125 cm^{-1} due to the ether linkages of these α, ω-oxaalkanedioic acids is observed in every chart.

The melting points of these dicarboxylic acids are plotted against the carbon numbers of the oxaalkylene groups in Fig. 2.

Discussion

The synthetic processes for the preparation of these α, ω-oxaalkanedioic acids may be classified into the following four types. During every course of the reaction, the carboxyl groups are protected as alkali salts.

1) The catalytic dehydration of ω-hydroxyalkanoic acids:

$$2HO(CH_2)_nCOOM \xrightarrow[-H_2O]{} MOOC(CH_2)_nO(CH_2)_nCOOM$$

where M denotes sodium or potassium.

2) The addition of γ-butyrolactone or δ-valerolactone to the alkali alcoholates of ω-hydroxyalkanoic acids:

$$\left[O(CH_2)_mCO\ (m=3 \text{ or } 4)\right] + MO(CH_2)_nCOOM \rightarrow MOOC(CH_2)_mO(CH_2)_nCOOM$$

3) The reaction of γ-butyrolactone or δ-valerolactone with sodium carbonate:

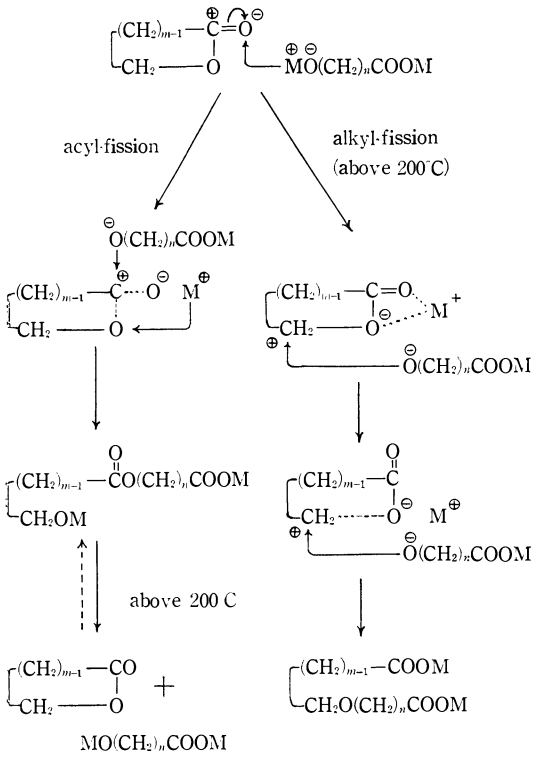
$$2\left[O(CH_2)_mCO\right] + Na_2CO_3 \rightarrow NaOOC(CH_2)_mO(CH_2)_mCOONa + CO_2$$

4) The condensation of ω-chloroalkanoic acids with alkali hydroxide:

$$2\,Cl(CH_2)_nCOOH + 4MOH \xrightarrow[-3\,H_2O]{} MOOC(CH_2)_nO(CH_2)_nCOOM + 2MCl$$

The unsymmetric α, ω-oxaalkanedioic acids, in which one of the methylene chain units interrupted by an ether linkage consists of 3 or 4 methylene units, can be prepared through the Type 2 process. In the synthesis of 5-oxasebacic acid, it is interesting that no symmetric dicarboxylic acid (neither 5-oxaazelaic nor 6-oxaundecanedioic acid) was found in the product. Moreover, the same product was obtained in similar yields whichever of the two lactones had been treated with sodium hydroxide first. These facts indicate that no interchange reaction between these lactones

and the alcoholates occurs. The mechanisms of the addition of γ-butyrolactone and δ-valerolactone to the alkali alcoholates of ω-hydroxyalkanoic salts may thus be presented as follows:



The acyl-fission is considered to occur more smoothly than the alkyl-fission in the ring opening of these lactones under these experimental conditions. In the polymerization of δ-valerolactone initiated with sodium alcoholate, the acyl-fission mechanism is supported by the presence of the end hydroxyl groups in a polyvalerolactone molecule.[10] The ester intermediate of δ-valerolactone formed by the acyl-fission is unstable at elevated temperatures, and δ-valerolactone is recovered almost quantitatively by distillation under reduced pressure. In the case of γ-butyrolactone, which can not usually be polymerized, the ester intermediate is supposed to be far more unstable and to be dissociated into the monomeric lactone immediately. Therefore, the acyl-fission can be disregarded for these reaction mechanisms. In the case of ε-caprolactone, however, the ester intermediate is stable enough, and the lactone can not be recovered, even at elevated temperatures. No large difference is observed in the tendencies toward the acyl-fission between γ-butyrolactone and δ-valerolactone, because the yields of the corresponding α, ω-oxaalkanedioic acids are much alike under similar conditions.

In the Type 4 process, the chlorine atom may be considered to be eliminated, thus forming ω-hydroxyalkanoic salts at the initial stage of the reaction. However, large differences between the Type 1 and Type 4 reactions are observed. When ω-hydroxyenanthic and ω-hydroxypelargonic acids were treated according to the directions for the Type 1 process, only poor yields of the corresponding dicarboxylic acids were obtained, even in the presence of relatively large amounts of alumina. Therefore, the reaction mechanism in the Type 4 process is considered to be differed from that of Type 1. The eminent depression of yields was actually observed when the water was evaporated slowly (for one hour or more) in the preparation of 8-oxapentadecanedioic and 10-oxanonadecanedioic acids. Moreover, when ω-chloroalkanoic acids of which carbon atoms in a molecule are less than 6 were subjected to this process, only poor yields of the dicarboxylic acids were obtained. Perhaps the rapid hydrolysis of the chloride due to the formation of lactonic rings prevented the progress of the reaction of this type. In an experiment in which an equimolar mixture of ω-chloroenanthic and ω-hydroxypelargonic acids was treated with potassium hydroxide according to the procedure for the preparation of 8-oxapentadecanedioic acid, a crystalline product was separated from a water-ethanol solution. From the molecular weight and the elementary analysis, this product was estimated to be a mixture consisting of three α, ω-oxaalkanedioic acids: 8-oxaheptadecanedioic, 8-oxapentadecanedioic, and a small amount of 10-oxanonadecanedioic acids.

From these experimental results, the reaction of the following mechanism is considered to take place dominantly for the formation of the ether linkage:

$$Cl(CH_2)_nCOOM + MO(CH_2)_nCOOM \rightarrow MOOC(CH_2)_nO(CH_2)_nCOOM + MCl$$

In the relations between the melting points of the dicarboxylic acids of two types—$HOOC(CH_2)_3O(CH_2)_nCOOH$ and $HOOC(CH_2)_4O(CH_2)_nCOOH$—and their carbon atoms in a molecule, shown in Fig. 2, the minimum melting points are observed at 3/5 and 4/5 respectively. The remarkable depression of melting point around these minimum points may be attributed to the decrease in the symmetry in the configuration, in other words, the increase in the entropy of fusion (ΔS_m).

Polyamides from these α, ω-oxaalkanedioic acids have also been prepared. They will be reported in detail in the near future.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 490—497 (1966)

The Chemistry of Protactinium. I. The Preparation of Protactinium-233 and the Purification of Protactinium-231

By Shin SUZUKI and Yasushi INOUE

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received June 22, 1965)

Many methods, such as the co-precipitation method, the solvent extraction method and the ion exchange method, had previously been proposed for the separation and the purification of protactinium. However, these methods have some defects for the separation of Pa-233 produced by the thermal neutron irradiation of thorium dioxide and the purification of commercial Pa-231, when an attempt is made to study the chemistry of protactinium. From the above point of view, a combined method of solvent extraction and anion exchange was investigated. In the present paper, the detailed conditions for the TBP extraction of protactinium from a hydrochloric acid solution and the method for its final purification by anion exchange were described. The present method is comparatively simple and rapid, and chemically- and radiochemically-pure protactinium can thus be obtained.

Although protactinium has been known for a long time, its chemical properties are still far from having been thoroughly investigated; this is because of its comparative natural scarcity, its lack of usefulness, and the difficulties involved in its separation due to the remarkable similarity of its chemical properties to such Vb elements as niobium and tantalum, which usually accompany protactinium. This backwardness in the investigation is also attributable to its unstability in an aqueous solution; that is, it has a strong tendency to hydrolyze and to precipitate, even in a relatively strong acid solution. Recently, however, the chemistry of protactinium has become of interest in nuclear reactor technology because one of its isotopes, ^{233}Pa, is an intermediate in the thorium-uranium breeding cycle, being the parent of the fissionable isotope ^{233}U. Some investigations have therefore been carried out on the chemistry of protactinium.[1-3] However, the results are not always acceptable because the unstability in aqueous solution has resulted in some confusion in published works. Therefore, we have attempted to study its chemistry exhaustively, using the various methods available.

In this paper simple and relatively rapid methods will be described for the preparation of ^{233}Pa and for the purification of commerical ^{231}Pa.

Protactinium-233 can be produced by the ^{232}Th(n, γ) ^{233}Th $\xrightarrow[\beta^-]{}$ ^{233}Pa reaction. Many methods for the separation of protactinium from neutron-irradiated thorium have been proposed, but they are not satisfactory because of the necessity for the special reagents or because of the complexity of the procedures. Among these, the ion exchange method is excellent in this respect, but it is generally most useful in the treatment of a microamount of materials, so that its direct application to the complete separation of a large amount of materials will make for a cumbersome procedure. Therefore, it is desirable to use a preliminary separation method before ion exchange. For this purpose, McCormack and his co-workers[4] used diisopropylcarbinol extraction from a nitric acid solution, but this reagent is not easily available. Will[5] used diisopropyl ketone after the ion exchange separation and finally purified ^{233}Pa by the use of another small anion exchange column. His procedure, however, is complicated.

In this experiment, tri-*n*-butyl phosphate was chosen for its easy availability, its ease of handling and its powerful extractability. This reagent was used for the separation of thorium, protactinium and uranium by the countercurrent extraction method from a hydrochloric acid solution;[6] its behavior toward the accompanying fission products will not be given. In this paper the conditions for the TBP extraction of ^{233}Pa from a hydrochloric acid solution and the method for its final purification by anion exchange will be described in detail.

For the purification of commercial ^{231}Pa, this anion exchange method was modified on the basis of its chemical and radiochemical purity.

^{233}Pa	Prepared by this method		

and the methods of pretreatment are shown in Table I. Their radiochemical purities were certified by γ-ray and α-ray spectrometries, or by analyses of their β-ray absorption curves, before use.

Ion Exchanger.—A strong basic anion exchange resin, Dowex-1, 100—200 mesh, was used. It was conditioned in the usual manner and converted to the chloride form before use.

Solvent.—Highest purity-grade TBP was washed with a diluted sodium hydroxide solution and then with distilled water in order to remove any hydrolysis product. Immediately before use, it was then equilibrated with the aqueous solution to be used.

The other chemicals, such as thorium dioxide, hydrochloric acid and hydrofluoric acid, were of highest purity grade.

Apparatus.—The β- and γ-rays were measured by a Hitachi G. M. counter and a Hitachi well-type scintillation counter respectively. A Kobe-Kogyo Model PS-400 well-type scintillation probe and a Osaka-Dempa Model 4 gridded ionization chamber, both of them connected to a TMC-400 channel pulse height analyzer, Model 406-6, were used for the measurements of the γ- and α-ray spectra respectively. For the solvent extraction procedures, a Iwaki universal mechanical shaker, Model V-S, was used. The ion exchange column, the separatory funnel and the centrifuge cone were made of polyethylene in order to minimize the adsorption of protactinium on the wall.

Procedures.—The experimental procedure was as follows unless otherwise stated.

Solvent Extraction.—Ten-milliliter portions of the aqueous phase which had been adjusted to the desired condition and of the organic phase were mixed for 10 min. with a mechanical shaker. After the two phases had been completely separated, an aliquot of each phase was taken for the measurement of its gamma radioactivity by the use of a scintillation counter. Each value given is the average of the results of at least two determinations. Care was taken to check the material balance in each case.

Ion Exchange.—The column was prepared as follows. Ten milliliters of an exchanger immersed in distilled water was poured into a polyethylene column, 9 mm. in internal diameter, using finely-cut polyethylene cloth as a column support. The column thus prepared had a height of about 150 mm. After that, the column was treated passing through 30 ml. of the solution to be used at the flow rate of 0.2—0.3 ml./min. When the level of the solution reached the top of the exchanger bed, the sample solution was introduced and ion exchange separation was started. The flow rate of the influent was kept nearly constant, 0.2—0.3 ml./min., throughout this experiment.

For making elution curves, effluents were received in polyethylene test tubes for every suitable aliquot; their radioactivities were measured with the well-type scintillation counter.

The Preparation of the Sample for the Measurement of the α-Ray Spectra.—The method recommended by Kirby[7] was used: An aliquot of a diluted acidic sample solution was transferred to a stainless-steel disk coated with a thin collodion film. The solution was then evaporated to dryness under an infrared lamp, with the plate tilted as necessary to retain the solution in the center of the plate. The plate was then cooled, and the residue was covered with one milliliter of 0.1 N nitric acid. One drop of concentrated ammonium hydroxide solution was added, and the solution was again evaporated to dryness. The position of the lamp was lowered sufficiently to drive off all the ammonium nitrate, and then the plate was ignited over a flame until the organic coating had burned off. This was used for the measurement of the α-ray spectrum.

The Determination of Thorium and Uranium.—The thorium and uranium were determined by the neothorone[8] and the peroxide methods[9] respectively.

Results

I. The Preparation of Protactinium-233.—The Irradiation and Dissolution of the Target.—Two-tenths grams of thorium dioxide, sealed in a quartz ampoule under reduced pressure, was irradiated with thermal neutrons for 20 min. in the

8) M. Ishibashi and S. Higashi, *Japan Analyst* (*Bunsekikagaku*). **4**, 14 (1955).
9) Y. Inoue, S. Suzuki and H. Gotô, This Bulletin, **37**, 1547 (1964).

pneumatic tube of the JRR-2 atomic pile (total flux; 6.4×10^{13}) of the Japan Atomic Energy Research Institute, or, if circumstances did not permit, this 2 g. of thorium dioxide, sealed in a polyethylene bag, was irradiated with thermal neutrons for 2 hr. in the pneumatic tube of the JRR-1 atomic pile (total flux; 3×10^{11}). The sample was allowed to decay for one day for the complete conversion of ^{233}Th into ^{233}Pa, and then dissolved by heating it with a concentrated hydrochloric acid solution containing several drops of diluted hydrofluoric acid (1 : 30) as a catalyst. Care must be taken not to add excess hydrofluoric acid solution, because too much fluoride ions prevent the complete dissolution of the target.

Conditions for the TBP Extraction.—*The Effect of the Shaking Time.*—The effect of the shaking time on the extraction of protactinium from a 6 N hydrochloric acid solution was investigated. It was found that 10 min. shaking is sufficient, therefore, extraction will hereafter be performed by shaking for 10 min.

The Effect of the Hydrochloric Acid Concentration.—The effect of the hydrochloric acid concentration on the extraction of protactinium was also investigated. It is apparent from Fig. 1 that the extraction is almost complete at hydrochloric acid concentration above 5 N.

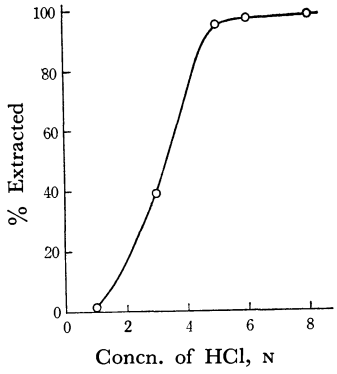

Fig. 1. The effect of hydrochloric acid concentration on the extraction of protactinium.
Shaking time: 10 min.

The Effect of the Hydrofluoric Acid Concentration.—The effect of the hydrofluoric acid concentration on the stripping of protactinium was investigated at a hydrochloric acid concentration of 6 N. The results presented in Fig. 2 show that the extraction percentage is constant over a hydrofluoric acid concentration of 0.4 N, so a 6 N HCl - 0.5 N HF solution is sufficient for the stripping of ^{233}Pa.

The Effect of the Thorium Concentration.—The effect of thorium on the extraction of protactinium was investigated at a hydrochloric acid concentration of 6 N, as is shown in Table II. With the

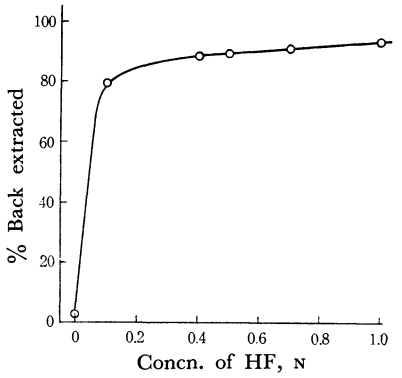

Fig. 2. The effect of hydrofluoric acid concentration on the stripping of protactinium.

None	97.1
400	95.4
800	94.4

increase in the concentration of thorium, the extraction of protactinium was somewhat decreased, but the effect was not very great.

The Masking of Fluoride Ions by Means of Aluminium Chloride.—If re-extraction is needed, it is essential to mask the fluoride ions added for the back extraction of protactinium. Aluminum chloride and boric acid are efficient for this purpose. In this experiment aluminum chloride was chosen, and the effect of its concentration was examined. The experiments were performed by the addition of a 3 M aluminium chloride solution to 10 ml.

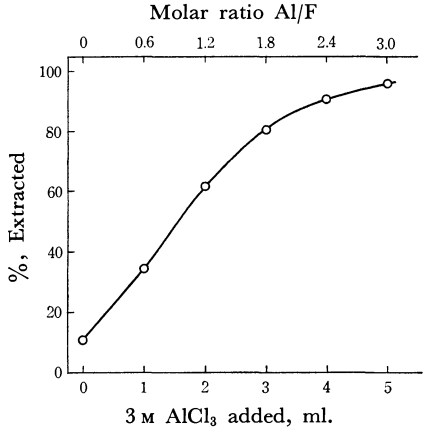

Fig. 3. The masking of fluoride ion with aluminum chloride.
Shaking time: 10 min.
Acidity: 6 N HCl - 0.5 N HF

of an aqueous solution which had the same composition as the stripping solution, 6 N HCl - 0.5 N HF. As is clearly shown in Fig. 3, the addition of 5 ml. or more of the aluminum chloride solution was needed for the complete extraction of protactinium from the stripping solution. This corresponds to the aluminum to fluoride molar ratio of 3.0.

The Extraction of Ions to Co-exist.—The main impurities in the irradiated thorium dioxide are considered to be ^{233}U and long-lived fission products; ^{95}Zr-^{95}Nb, ^{137}Cs, ^{106}Ru, ^{90}Sr-^{90}Y and rare earths (mainly ^{144}Ce). The separation of them from protactinium by the TBP extraction was examined, with the results shown in Table III. It is clear from the table that ^{137}Cs, ^{90}Sr-^{90}Y and ^{144}Ce can be separated from protactinium in the forward extraction, and uranium, in the backward one. The separation of ^{95}Zr-^{95}Nb and ^{106}Ru, was, however, incomplete. For their decontaminations, it is necessary to use other separation techniques.

Table IIIa. Extraction of long-lived fission products

Nuclide	Condition	Per cent extracted
^{95}Zr-^{95}Nb	6 N HCl	68.2
^{137}Cs	6 N HCl	1.40
^{106}Ru	6 N HCl	70.8
^{90}Sr-^{90}Y	6 N HCl	0.91
^{144}Ce	6 N HCl	0.73

^{106}Ru	6 N HCl - 0.5 N HF	67.2
^{90}Sr-^{90}Y	6 N HCl - 0.5 N HF	0.21
^{144}Ce	6 N HCl - 0.5 N HF	0.10

Table IIIb. Extraction of thorium and uranium

Element	Added mg.	Condition	Per cent extracted
Th	400	6 N HCl	0.0
Th	800	6 N HCl	7.8
Th	1.6	6 N HCl	0.0
Th	1.6	6 N HCl-0.5 N HF	91.9
U	2.38	6 N HCl	98.7
U	2.38	6 N HCl-0.5 N HF	98.7

Anion Exchange Separation.—Referring to Moore's method[10] the anion exchange method was investigated. After protactinium was adsorbed on the resin bed, elution was performed with a 9 N HCl-0.004 N HF solution and then a 9 N HCl - 0.2 N HF solutions. At the same time, the behaviour of ^{95}Zr-^{95}Nb and of ^{106}Ru was investigated under the same conditions as for protactinium. These results are presented in Fig. 4. ^{95}Zr-^{95}Nb could be separated quantitatively, but the separation of ruthenium was not complete. The removal of ruthenium, however, can be more easily and completely attained by the distillation from a perchloric acid solution[11] than by ion exchange, so no further experiments were conducted. It may be assumed from the investigation by Kraus[12] that the ions, which are almost all removed by solvent extraction, will not be adsorbed on the exchanger bed from a 10 N hydrochloric acid solution except uranium. Uranium, however, cannot be eluted by the eluant at all. Therefore, these elements may be separated again by this procedure, and so the decontamination factor may be extremely high. As is shown in Fig. 4a the elution curve of protactinium shows some tailing and a large volume of eluant is necessary for the complete recovery of protactinium. When the yield of fission products is considered to be extremely low, as in this case,[2] the use of an eluant with a higher fluoride concentration, such as 9 N HCl - 1 N HF, is convenient, because it hardly affects the behavior of any of the ions except zirconium and niobium, while the elution curve of protactinium becomes sharp, with a resultant decrease in the volume of eluant necessary for protactinium.

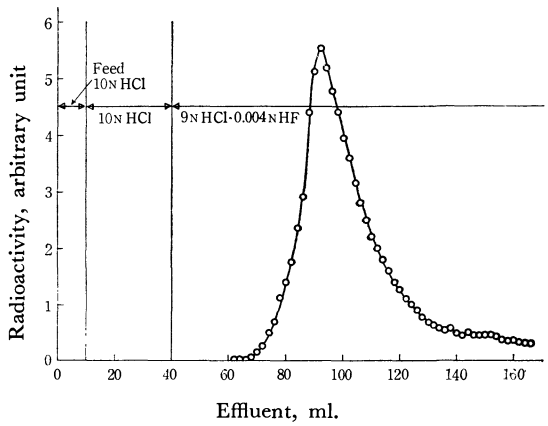

Fig. 4a. Elution of protactinium.

Recommended Procedure for the Separation of ^{233}Pa from Neutron-irradiated Thorium.—By putting the above results together, the best conditions for the separation of protactinium from thorium dioxide were decided upon. The irradiated thorium dioxide was dissolved by heating it in a platinum dish with concentrated hydrochloric acid containing several drops of a diluted hydrofluoric acid solution (1 : 30) to serve as a catalyst. This solution was initially evaporated almost to dryness, on a hot plate and then on a water bath. The residue was dissolved in possibly a small amount of a concentrated hydrochloric acid solution and

○: ^{95}Zr-^{95}Nb △: ^{106}Ru

again evaporated to dryness in the same manner. This was repeated a few times in order to eliminate the hydrofluoric acid completely. Then the residue was dissolved in 10 ml. of 6 N hydrochloric acid, and the solution was transferred to a separatory funnel. Ten milliliters of TBP was added, and the funnel was shaken mechanically for 10 min. After the two phases had separated, the aqueous layer (the lower) was run off and discarded. The TBP layer was then scrubbed with 10 ml. of a 6 N hydrochloric acid solution and its aqueous layer discarded. Then 10 ml. of a 6 N HCl - 0.5 N HF solution was added to the TBP extract, and the mixture was shaken mechanically for 10 min. The aqueous layer was run into another separatory funnel and scrubbed with fresh TBP. The aqueous layer was then transferred into another separatory funnel and washed with 10 ml. of distilled benzene in order to remove the remaining TBP. The aqueous layer was then placed in a platinum dish and heated almost to dryness, initially on a hot plate and finally on a water bath. After it had been cooled, 10 ml. of 10 N hydrochloric acid was added; the solution was heated in order to dissolve the residue and then poured into an ion exchanger bed; when the level of the solution reached the top of the exchanger bed, 50 ml. of a 10 N hydrochloric acid solution and 30 ml. of a 10 N HCl - 1.0 N HF solution were passed through the column successively. The protactinium-233 obtained in a 10 N HCl - 1.0 N HF solution was not only free from any thorium but also free from any solid materials. To make sure of its radiochemical purity, the γ-ray spectrum was measured. As is shown in Fig. 5, the spectrum completely coincided with the published data.[1]

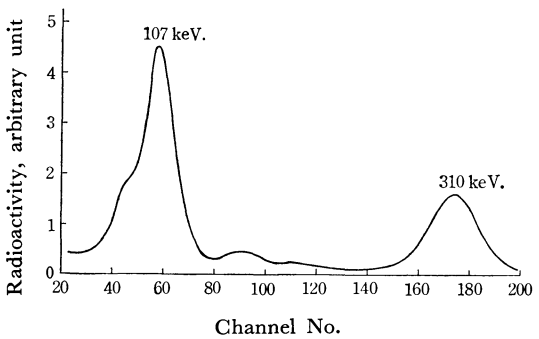

Fig. 5. γ-Ray spectrum of ^{233}Pa.

II. The Purification of Protactinium-231. —Basic considerations and Preliminary Experiments.—As is shown in Table I, ^{231}Pa was purchased in the form of protactinium pentoxide from the Radiochemical Center, Amersham, England. To check its chemical purity, emission spectrographic analysis was performed; a little niobium was detected in some cases. Although it was difficult to detect rare earths, they, as well as niobium, should be considered as chemical impurities. As to radiochemical impurities, it is assumed that ^{227}Ac, ^{227}Th and ^{233}Ra, the daughters of ^{231}Pa, are important enough to take consideration of their half lives. All the impurities listed above except niobium were considered not to be adsorbed on the anion exchange column from the concentrated hydrochloric acid solution, so the separation of niobium and protactinium was the main problem. The separation seems to be possible by means of the above-mentioned anion exchange procedures, but in the treatment of macro-amounts of protactinium, the hydrofluoric acid concentration of 0.004 N is so small that tailing may

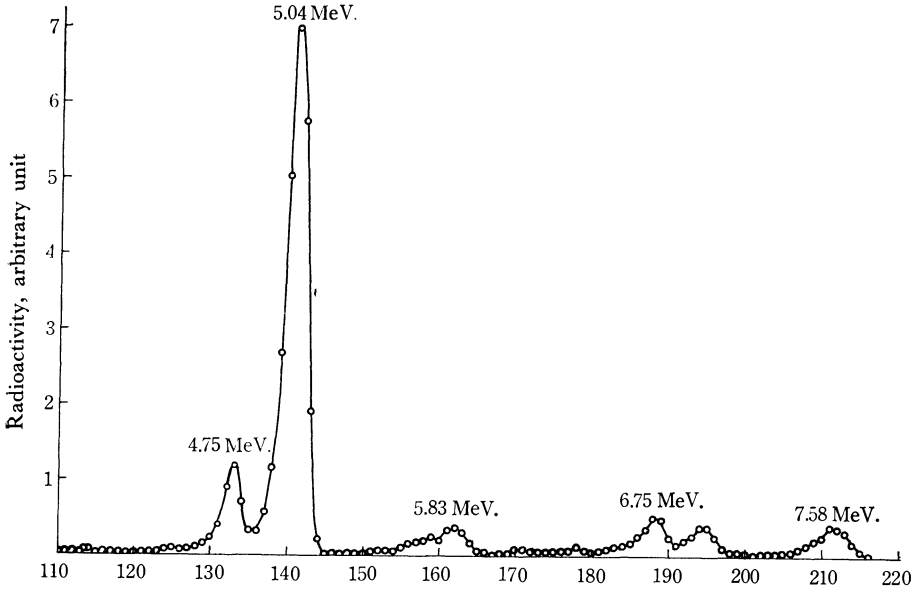

Fig. 6a. α-Ray spectrum of commercial ^{231}Pa.

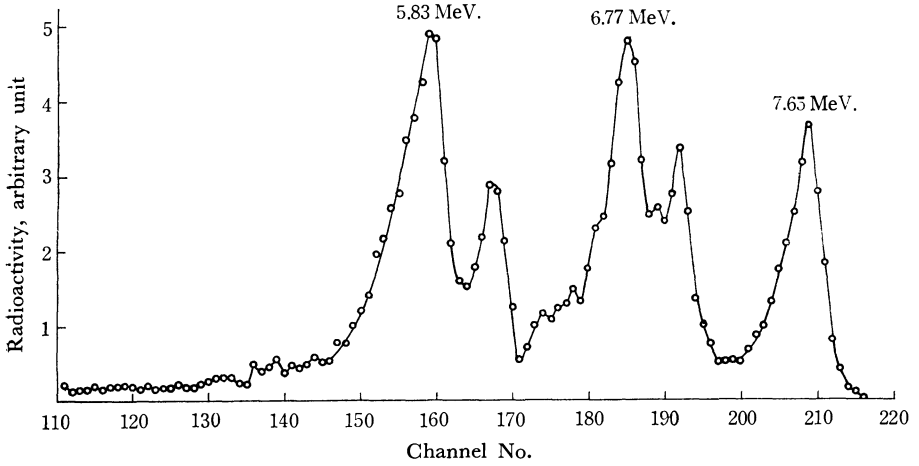

Fig. 6b. α-Ray spectrum of HCl washings.

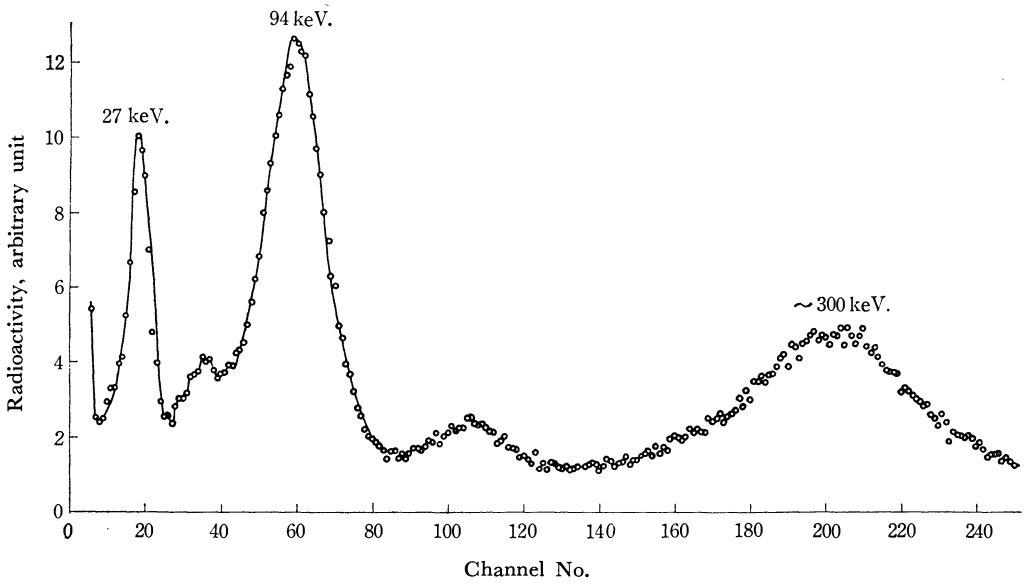

Fig. 7a. γ-Ray spectrum of commercial ^{231}Pa.

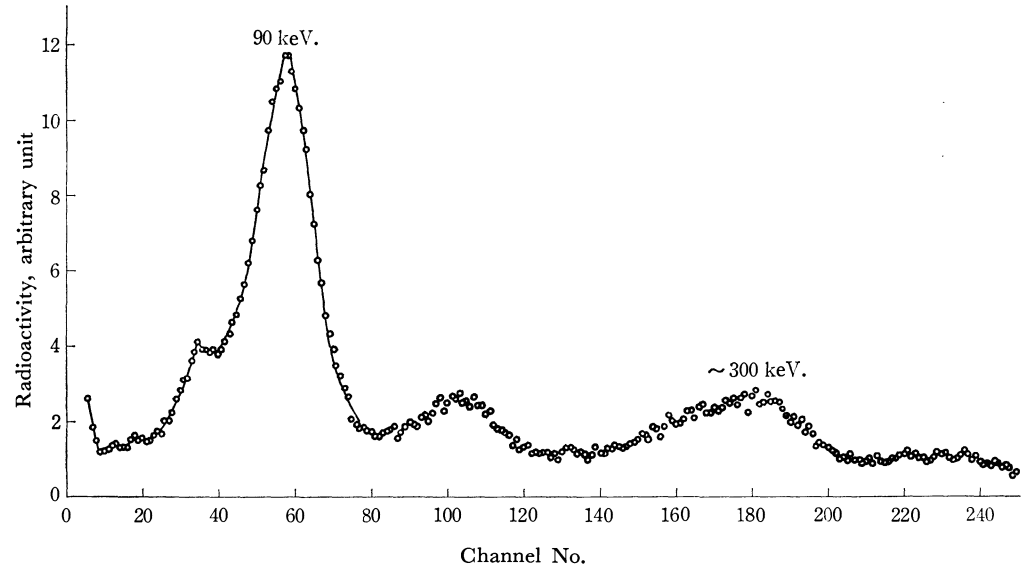

Fig. 7b. γ-Ray spectrum of HCl washings.

increase markedly. Furthermore, the ion exchange capacity should be large because a good separation is desired. Therefore, a high concentration of hydrofluoric acid and a large column are necessary for this purpose. Bearing this in mind, the preliminary separation of ^{95}Nb and ^{233}Pa was performed using 20 ml. of anion exchange resin and a 9 N HCl - 0.1 N HF solution as an eluant. In this case, niobium began to elute after 40 ml. of eluant had passed through. The elution of protactinium was complete before 30 ml. of eluant had passed through, so the complete mutual separation of these elements seemed possible.

Recommended Procedure for the Purification of Commercial Protactinium-231. — Putting the above results together, the recommended procedure for the purification of commercial protactinium was decided upon.

Protactinium pentoxide was dissolved in concentrated hydrochloric acid, containing possibly a small amount of hydrofluoric acid, in a platinum dish, the solution was then evaporated almost to dryness. This process was repeated until the hydrofluoric acid was completely expelled. The residue was dissolved in concentrated hydrochloric acid and diluted to 9 N with distilled water. This

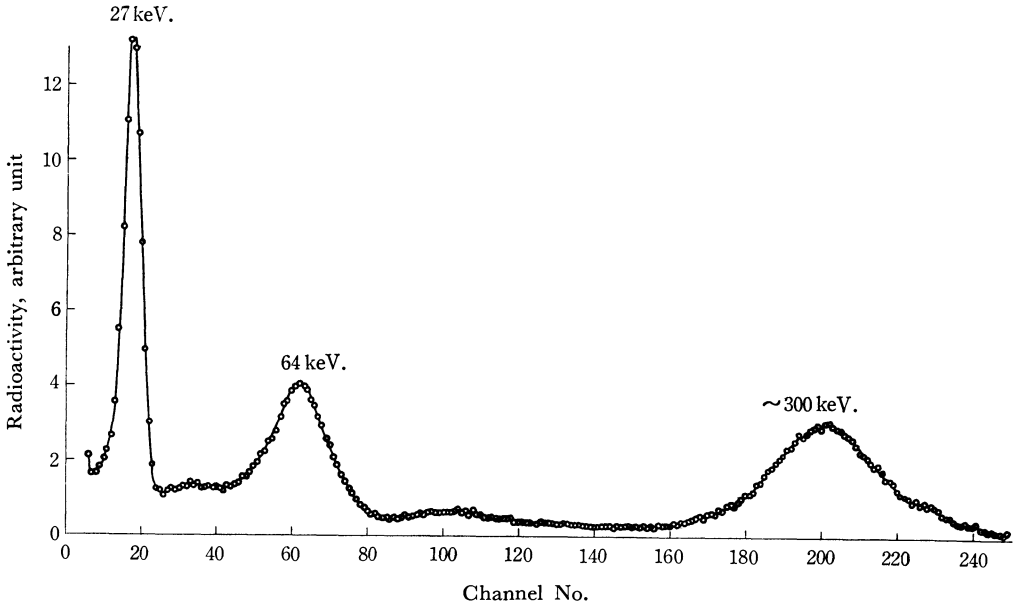

Fig. 7c. γ-Ray spectrum of purified ^{231}Pa.

sclution was percolated into the ion exchange column; when the level of the solution reached the top of the exchanger bed, 20 ml. of a 9 N hydrochloric acid solution was introduced in order to remove any radiochemical impurities. Then protactinium was eluted with 30 ml. of a 9 N HCl - 0.1 N HF solution. Care must be taken to check the characteristic γ-ray of 27 keV. throughout the ion exchange process in order to prevent any accidental loss due to the incomplete elimination of fluoride ions from the sample solution. The protactinium solution thus prepared was then evaporated almost to dryness and diluted with distilled water, and enough ammonium hydroxide solution was added to precipitate protactinium hydroxide. This precipitate was filtered, washed thoroughly, and ignited in a platinum crucible in the usual manner. For example, 29.8 mg. of pure protactinium pentoxide was obtained from 35.0 mg. of the crude sample. To check its radiochemical purity and to see the course of purification, the α- and γ-ray spectra of the original sample, the hydrochloric acid washings and the purified sample were measured, as is shown in Figs. 6 and 7. In Fig. 6 α-ray peaks more energetic than 5 MeV. are observed in the original sample. They have their origin in the decay products of ^{231}Pa. The α-ray spectrum of the hydrochloric acid washings shows no peaks of protactinium except those of daughters. On the contrary, the purified sample shows no peaks above 5 MeV., so it can be considered to be completely pure. In the γ-ray spectra, the circumstances are not as clear as in the α-ray spectra because of the complex overlapping of peaks, but the characteristic peak of ^{231}Pa (27 keV.) is not observed in the spectrum of hydrochloric acid washings, and that of the purified sample shows good agreement with the standard one.[1] Moreover, no niobium was detected in the purified sample by emission spectrographic analysis.

Summary

The methods for the separation of the ^{233}Pa produced by the thermal-neutron irradiation of thorium dioxide and the purification of commercial ^{231}Pa have been investigated. The separation of ^{233}Pa has been achieved by the combination of TBP extraction from a hydrochloric acid solution and anion exchange separation by a hydrochloric acid - hydrofluoric acid eluant. ^{231}Pa has been purified by a modification of the above anion exchange. Both processes can be conducted comparatively simply and rapidly, with the result that both isotopes are chemically and radiochemically pure enough for research work.

A part of the expense has been defrayed by a grant-in-aid by the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 498—503 (1966)

An MO-Theoretical Illumination for the Principle of Stereoselection

By Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 23, 1965)

The principle of the stereoselection in organic chemistry has been discussed from the point of view of the molecular orbital theory. The stereoselectivity in the stereospecific ring-closure of conjugated polyenes and the stereospecific ring-cleavage of unsaturated carbon cycles, *trans*-1,2-noncycloadditions, *cis*-1,2-additions and *cis*-1,3-dipolar additions have been accounted for with a qualitative generalization. In many cases the symmetry relationship of certain particular molecular orbitals ("frontier orbitals") plays a conspicuously significant role in the steric control of stereochemical processes. This may be put in contrast with the role of the frontier electron density in the orientation process in organic reactions.

The purpose of the present paper is to make an attempt to furnish organic stereochemistry with a theoretical strategy. In view of the multifariousness noticed in the accumulation of recent stereochemical studies, it is hoped that a guiding principle to unravel the entanglements involved will appear. In order to be of practical applicability, such a guiding principle must first of all possess generality and simplicity. Therefore, the molecular orbital (MO) theory seems suitable.

The recent experimental information on the stereoselectivity in several cyclic reactions of unsaturated compounds[1] has been an incentive to start an MO-theoretical attack.[2-4] All these papers pointed out the importance of the symmetry of particular MO's in discussing the problem in question. These particular MO's were the highest-occupied MO (HO) and the lowest vacant MO (LV) of the ground state molecule. Oosterhoff[2] has suggested that the difference in stereochemical behavior between thermal and photo-induced reactions may be attributed to the symmetry characteristics of HO and LV. The important role of HO and LV (the frontier orbitals) in the course of the chemical interaction of organic compounds was early well established in the frontier electron theory,[5,6] and the symmetry of the frontier orbitals was also duly employed for the elucidation of Diels-Alder reactivity.[7]

However, it should be noted that the discrimination of the frontier orbitals from the other MO's should be based upon a proper comprehension of the theoretical grounds. Woodward and Hoffmann[3] discussed, in their elegant generalization of the problem of stereoselectivity, the ring-closure of conjugated olefins, and suggested that the steric course should be determined by the symmetry of HO only. However, this is evidently an "over-discrimination" of HO, since the overlap stabilization between two π atomic orbitals in a single conjugated system should be evaluated as the sum of the contributions from all occupied MO's.[4] The mere coincidence of the results does not justify such improper or less authentic neglect of the other MO's.

The basic idea, used throughout the present paper, for discussing the steric course in a consistent manner is to determine, from the MO perturbation calculation of the energy change of interaction, the direction of the overlap stabilization between interacting atomic orbitals; this will lead to the most likely correct steric course. The details will be illustrated by examples.

The Ring-Closure of Conjugated Polyenes. —Consider a linear conjugated polyene with k π electrons. So-called Hückel MO's of the simplest type are given by[8]:

$$\phi_j = \sum_{r=1}^{k} C_r^j \phi_r = \left(\frac{2}{k+1}\right)^{1/2} \sum_{r=1}^{k} \phi_r \sin\frac{jr\pi}{k+1} \qquad (j=1,\ 2,\cdots k)$$

where ϕ_r is rth carbon $2p\pi$ atomic orbital (AO), and C_r^j is the coefficient of ϕ_r in jth MO. These MO's are obtained by solving the usual secular equations, which yield the secular determinant:

$$\Delta(\varepsilon)=\begin{vmatrix} -\varepsilon & \beta & \cdots & 0 & 0 \\ \beta & -\varepsilon & \cdots & 0 & 0 \\ \cdots & \cdots & \cdots & \cdots & \cdots \\ 0 & 0 & \cdots & -\varepsilon & \beta \\ 0 & 0 & \cdots & \beta & -\varepsilon \end{vmatrix} = \beta^k \frac{\sin(k+1)\theta}{\sin\theta} \quad (1)$$

$(\varepsilon=-2\beta\cos\theta)$

(k rows and k columns)

where the zero point of the energy, ε, is taken as equal to the Coulomb integral of carbon $2p\pi$ AO, β being the resonance integral between two adjacent $2p\pi$ AO's.

The change in the π-electronic energy in the case of the overlapping of the first and kth AO's is clearly approximated by:

$$\Delta E = 2\sum_{j=1}^{k} \nu_j C_1^j C_k^j \gamma = 2P_{1k}\gamma \quad (2)$$

by the first-order perturbation calculation, where ν_j is the number of π electrons occupying the jth MO, while γ is the resonance integral between ϕ_1 and ϕ_k in the case of the σ-like overlapping of these two orbitals in the distorted π electron system. The sign of γ is obvious, as is indicated by the scheme of Fig. 1.

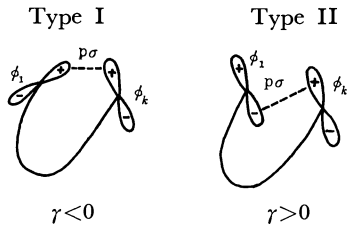

Fig. 1. Two types of overlap stabilization.

The quantity, P_{1k}, has the same form as that defined as the well-known "bond order," but in the present case it serves to determine the stability due to the overlapping of two π orbitals; it may thus appropriately be tentatively named the "overlap stabilization." If this quantity is positive, the overlapping of Type I is preferred, while if it is negative, Type II is more preferable, in the case of cyclization.

For the ground state of linear conjugated polyenes, P_{1k} is known to be easily expressed in an integral representation[9] as:

$$P_{1k} = \frac{\beta^{k-1}}{\pi}\int_{-\infty}^{+\infty}\frac{dy}{\Delta(iy)} = 4(-1)^{k/2+1}\frac{1}{\pi} \times \int_0^{\infty}\frac{\cosh^2\varphi d\varphi}{\cosh(k+1)\varphi} \quad (3)$$

$(y=-2\beta\sinh\varphi)$

which is immediately convertible into the form:

$$P_{1k} = \frac{(-1)^{k/2+1}}{k+1}\left(1+\frac{1}{\cos(\pi/(k+1))}\right) \quad (4)$$

Therefore, it follows clearly that, when $k=4m+2$, P_{1k} is positive, so that the cyclization of Type I occurs, while when $k=4m$, P_{1k} is negative, so that a Type II cyclization results; this is consistent with experimental facts in the case of $k=6$.[1]

This relationship is not limited to the cyclization due to the bonding between two termini. It is likewise very easy to prove mathematically that P_{rs} is positive in the cyclization forming a $(4m+2)$-membered ring, leading to a Type I course, whereas the cyclization forming a $4m$-membered ring would follow a Type II course. The discussion of this sort has already been made by numerical calculations more comprehensively and also more elaborately in connection with the theory of aromaticity by Fukui et al.[10]

A reverse relation holds in the first excited state, in which we assume the jumping of one π electron of HO into LV. In the present simple treatment, both the triplet and the singlet states will be discussed in terms of the same theoretical quantity. The overlap stabilization, which is in this case denoted by P_{1k}^*, is easily represented by:

$$P_{1k}^* = \frac{(-1)^{k/2}}{k+1}\frac{\cos(\pi/(k+1))+1}{\cos(\pi/(k+1))} \times\left(2\cos\frac{\pi}{k+1}-1\right) \quad (5)$$

Therefore, it is positive when $k=4m$, and negative when $k=4m+2$, provided $k\geqq 4$. Photo-induced cyclizations are known experimentally to take place by the Type II course when $k=6$.[1]

The steroselection in polyene cyclization, whether Type I or Type II, may thus be understood to be governed by the following rule:

	Thermal reaction	Photo-induced reaction
$k=4m$	Type II	Type I
$k=4m+2$	Type I	Type II

The steric courses, Type I and Type II, were named by Woodward and Hoffmann[3] "disrotatory" and "conrotatory" processes respectively, in their first generalization of this interesting cyclic conversion.

The Ring-Opening of Cyclic Olefins.— The reverse process to the above-mentioned cyclization have also been studied and found to follow the same stereoselection rule;[1] these reactions in two opposite directions were explained *en bloc* by Woodward and Hoffmann by emphasizing the symmetry of HO and LV.[3] This sort of ring-opening reaction is, however, supposed to

8) See, for instance, A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, New York (1961), p. 50.

9) C. A. Coulson and H. C. Longuet-Higgins, *Proc. Roy. Soc.*, **A191**, 39 (1947); **A192**, 16 (1947).

10) K. Fukui, A. Imamura, T. Yonezawa and C. Nagata, This Bulletin, **33**, 1591 (1960).

be governed essentially by a sigma-pi interaction between a part of the π-electron system and the σ bond to be broken. A more plausible, separate explanation must be given on the basis of the direction of stabilization in this sigma-pi interaction.

The electrons to be taken into account are two σ-bonding electrons in the a—b bond to be broken and $(k\text{-}2)$ π electrons in the conjugated part of the ring, r-t-s in Fig. 2.

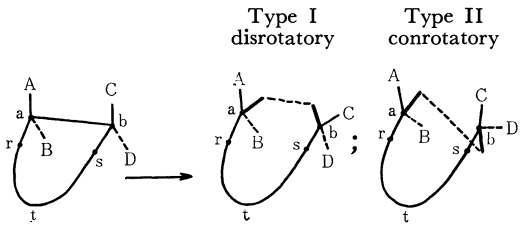

Fig. 2. Two types of interaction in the ring-cleavage.

The open-chain polyene to be produced has k π electrons. At the initial stage, the sigma and pi parts evidently have no appreciable interconjugation. As soon as the ring-cleavage begins to proceed, however, a π-like conjugation will take place between each of the two "incipient" orbitals appearing at the carbon atoms, a and b, and each end of the conjugated part, r-t-s.

The components of the two incipient orbitals perpendicular to the plane of the conjugated part are parallel and antiparallel to each other in the interactions of Type I and Type II respectively.[11]

The change in the energy of the system, ΔE, may be evaluated most simply by a perturbation treatment as a second-order term, if we regard the above-mentioned π-like conjugation as a small perturbation. The result is[12]:

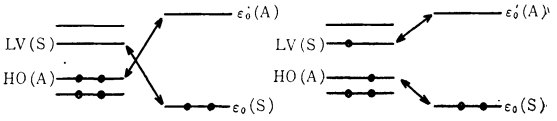
$$\Delta E = \text{const.} + \left\{\sum_j \nu_j \frac{(C_r^j C_a'\gamma_a + C_s^j C_b'\gamma_b)^2}{\varepsilon_j - \varepsilon_0'} - \sum_j (2-\nu_j)\frac{C_r^j C_a\gamma_a + C_s^j C_b\gamma_b)^2}{\varepsilon_j - \varepsilon_0}\right\} + 0(\gamma^4) \quad (6)$$

where (1) ε_0 and ε_0' are the energies of a—b bonding and antibonding orbitals, which are denoted by $\chi = C_a\varphi_a + C_b\varphi_b$ and $\chi = C_a'\varphi_a + C_b'\varphi_b$ respectively, in which φ_a and φ_b are the initially-existing, carbon sp^3 hybridized orbitals of the a—b bond: (2) ε_j is the energy of the jth MO of the $(k-2)$ π electron system, which is written as $\varphi_j = \sum_t C_t^j \phi_t$, where ϕ_t is tth atomic orbital; (3) ν_j is the number of electrons occupying the jth MO; (4) γ_a and γ_b are the "resonance" integrals (although this terminology may be inadequate for their positive value) between each of the two incipient orbitals appearing at the carbon atoms, a and b, with the adjacent $2p\pi$ orbital at the carbon atoms, r or s; and (5) the term const. signifies the term which is involved almost always in both Type I and Type II interactions.

As may clearly be understood from the illustration, the sign, γ_a and γ_b which favors the minimization of ΔE will control the direction of the steric course. The same sign of γ_a and γ_b means the interaction of Type I, whereas Type II corresponds to γ_a and γ_b with opposite signs.

In the light of our knowledge about the parameters used in the MO treatment of σ electron systems developed by Fukui et al.,[13] the chief contributing terms on the right side of Eq. 6 are demonstrated to be those associated with HO and LV. Figure 3 indicates an example for the case of $k=6$. The charge transfer interaction of an HO electron with the a—b antibonding orbital will drive the σ bond into cleavage so as to cause a narrowing of the separation of ε_0' and ε_0, resulting in a stronger and stronger interaction.

If we take into account, for the sake of simplicity, only the most dominant term in each summation of the right side, Eq. 6 may be reduced to the following form:



(S: symmetric; A: antisymmetric)

Fig. 3. Relation of energy levels occupied by interacting electrons in the ring-cleavage ($k=6$).

(a) For the case of the ground-state π electron system:

$$\Delta E \sim \text{const.} - 2\left\{\frac{(C_r^{HO}C_a'\gamma_a + C_s^{HO}C_b'\gamma_b)^2}{\varepsilon_0' - \varepsilon_{HO}} + \frac{(C_r^{LV}C_a\gamma_a + C_s^{LV}C_b\gamma_b)^2}{\varepsilon_{LV} - \varepsilon_0}\right\} \quad (7)$$

(b) For the case of the first-excited-state π electron system:

$$\Delta E \sim \text{const.} - \left\{\frac{(C_r^{LV}C_a'\gamma_a + C_s^{LV}C_b'\gamma_b)^2}{\varepsilon_0' - \varepsilon_{LV}} + \frac{(C_r^{HO}C_a\gamma_a + C_s^{HO}C_b\gamma_b)^2}{\varepsilon_{HO} - \varepsilon_0}\right\} \quad (8)$$

where the super- and subscript HO's and LV's signify the highest occupied and the lowest vacant MO's in the ground state.

11) The description of line 9, page 3 of Ref. 4 should be reversed with regard to "conrotatory" and "disrotatory" processes.

12) K. Fukui, C. Nagata, T. Yonezawa, H. Kato and K. Morokuma, *J. Chem. Phys.*, **31**, 287 (1959); also see Ref. 7.

13) K. Fukui, H. Kato and T. Yonezawa, This Bulletin, **33**, 1198 (1960); also see Ref. 6a).

The orbital symmetry[14] of HO is antisymmetric (A) when $k-2=4m$, and symmetric (S) when $k-2=4m-2$, while LV is S when $k-2=4m$ and A when $k-2=4m-2$. The symmetry of the ε_0 level is, of course, S, and ε_0' is A. Therefore, in order for ΔE to be minimized,

(a) For the ground state: γ_a and γ_b should have opposite signs when $k=4m$, and the same sign when $k=4m+2$;

(b) For the first excited state: γ_a and γ_b should have the same sign when $k=4m$, and opposite signs when $k=4m+2$.

Hence we are led to the following stereoselection rule, which has already been pointed out by Woodward and Hoffmann,[3] in accordance with the experimental results[1,3]:

	Thermal reaction	Photo-induced reaction
$k=4m$	Type II, conrotatory	Type I, disrotatory
$k=4m+2$	Type I, disrotatory	Type II, conrotatory

It should be noted that the orbital symmetry of HO and LV plays an essential role in determining the steric course. The discrimination of the "frontier orbitals" is thus justified in this case. This may be put in contrast with the fact that the "frontier electron density" plays an important role in determining the intramolecular orientation.

The *trans*-1, 2-Noncycloadditions. — The predominance of noncyclic *trans*-1, 2-additions in olefins has been well established in many experimental results in both ionic and radical additions.[15] It therefore appears appropriate to discuss the problem by dividing it into two items:

i) In the case in which the attacking reagent, XY, is used in highly dissociative conditions, the *trans*-selectivity may be attributed to the well-discussed symmetrical adduct of X to the ethylenic bond, which is supposed to be formed in the first stage.[16] No further, new way of explanation seems to be necessary in such a case, except a consideration of the orbital symmetry relation of X and the ethylenic bond which creates the possibility of forming such a symmetrical adduct. This point will be discussed in detail in the next section, on *cis*-1, 2-additions.

ii) For the case of almost simultaneous noncyclic additions, however, there seems to be a more plausible explanation than the existing ones if we consider the relationship of the orbital symmetry[14] between the reagent and the olefin. The direction of the approach of the reagent is supposed to be perpendicular to the plane of the ethylenic molecule.[17] The characteristic feature of the noncyclic addition of XY may be specified as the unfavorable square-form interaction of XY with the C-C double bond in the course of approach. For instance, a non-dissociated Br_2 molecule does not have any MO with a symmetry suitable for entering into square-form conjugation with ethylenic π orbitals. Its lowest vacant MO is antisymmetric, so that the interaction with ethylenic π electrons could be facilitated only by orbital overlapping in opposite directions at two terminals, as is illustrated in Fig. 4.[18] The formulation of this relation is in essence identical to the treatment of Eqs. 1—4 (Fig. 4(a)); it is also possible to apply Eq. 7 for the same purpose (Fig. 4(b)). The electron transfer from the π bond to the X-Y antibonding MO will give rise to the dissociation of XY, leading to the stage

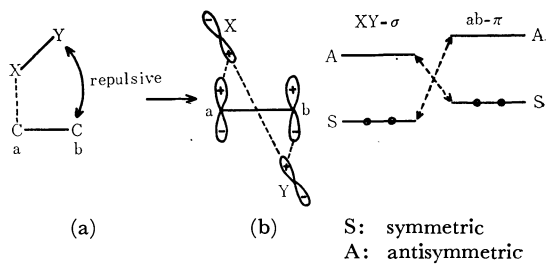


Fig. 4. The mode of initial interaction of the attacking reagent with an ethylenic bond.

indicated by (b) in Fig. 4. The explanation mentioned above may lead to a presumption of 1, 2-*cis*-noncycloaddition in the photo-excited state under suitable conditions.

No experimental results seem to be available for the stereoselectivity in noncyclic additions more distant than to 1, 2-positions of conjugated

14) More generally, it is, of course, not required to be exactly symmetric or antisymmetric. Only the relation between the signs of the coefficients in Eq. 7 is essential.

15) See, for instance, a) E. S. Gould, "Mechanism and Structure in Organic Chemistry," Henry Holt & Co., New York (1959), p. 514, 733 ff.; b) B. A. Bohm and P. I. Abell, *Chem. Revs.*, **62**, 599 (1962).

16) Evidence has been given early for the two-step additions (A. W. Francis, *J. Am. Chem. Soc.*, **47**, 2340 (1925)).

17) The opinion of Bader et al. (A. R. Bader, R. P. Buckley, F. Leavitt and M. Szwarc, *J. Am. Chem. Soc.*, **79**, 5621 (1957)) that the approach of the methyl radical in the additions to olefins was along the double bond axis was later corrected (M. Matsuoka and H. Szwarc, ibid., **83**, (1961)).

18) The author does not intend to reject the assumption of a bridged intermediate like the cyclic bromonium ion. Depending on conditions, we might have to take into account the interaction of X and C_b in addition to that of X and C_a. The essential point of the present discussion lies in pointing out the possibility of a mechanism with which we need no further, too-far-fetched views.

19) It should be noted that the terms "1, 4-" or "1, 6-addition" are used here in a purely mechanistic sense. They do not include a reaction composed of a series of successive processes. Hence, it is desirable that the starting conjugated polyene have a specific favorable structure: i. e., the *cis*-butadiene form for 1, 4-addition and the *cis-cis*-hexatriene form for 1, 6-addition. Also, we have to avoid confusion due to the term "*trans*-1, 4-addition," by which e. g., the following reaction is meant:

Butadiene + Cl_2 → *trans*-1, 2-Bischloromethyl ethylene

The term "*cis*-1, 4-addition" employed above signifies an addition of XY by the attack of X and Y from the same side of the molecular plane of conjugation.

olefins. Discussions similar to those for 1, 2-additions are possible if we make a consideration analogous to that of Fig. 4. The conclusion is that 1, 4-noncycloaddition should be *cis*, 1, 6-, *trans*, and so forth.[19]

The *cis*-1,2-Additions.—The *cis*-1,2-addition to an ethylenic bond can take place when the reagent has a vacant MO (of course, preferably LV, for the reason understood through Eq. 6), of a symmetry that is advantageous for interaction with the occupied MO of the ethylenic π bond. For this reason the reagents which have the LV orbital symmetrical with respect to the middle of their two reaction centers are qualified as having a possibility of *cis*-addition. The formation of the intermediates considered in the two-step mechanism of stereospecific *trans*-additions, such as the bridged cation of protonated ethylene, may clearly be understood by the fact that the reagent ion has a symmetrical LV orbital. The other reagents which can satisfy this symmetry requirement are the phenyl cation in the phenonium ion,[20] the oxygen atom in epoxidation, carbenes in their singlet-state adducts to olefins,[21] the permanganate ion,[22] osmium tetroxide,[23] dienes in the Diels-Alder addition, and so on. Among these the symmetry of LV in various dienes has already been investigated by numerical calculations.[7] With respect to the other species, it is also easy to show by an appropriate MO treatment that their LV satisfies the symmetry conditions mentioned above.

The *cis*-1, 2-addition in hydroboration is well known. The result of an extended Hückel calculation by Kato et al. for boron compounds[24] may be useful in comprehending how borane can add to the *cis* positions. The LV of the BH_3 molecule is completely localized at the central boron $2p\pi$ AO, so that a strong charge-transfer interaction is possible with bonding π electrons of the C-C double bond (Fig. 5). As the $p\sigma$-overlapping proceeds, the bond populations of B-H sigma as well as of C_a-C_b pi are seriously reduced, so as to repel the hydrogen atom and force it to combine with the C_b carbon. Thus, a square-form interaction[25] is performed to give rise to *cis*-addition. From this explanation it is easy to realize that the hydroboration is a reaction of an electrophilic nature.

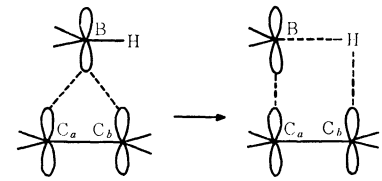

Fig. 5. The square-form interaction of BH_3 with C-C double bond.

Under these circumstances it is interesting that the easiness of the photo-induced cyclodimerization of olefins[26] in comparison with thermal reactions is also intimately connected with the symmetry relationship of HO and LV orbitals. In such cases, the *cis*-addition is geometrically desirable in order for the cyclodimerization to take place. Consequently, the orbital symmetry must be favorable for the square form interaction. As may easily be understood from the illustration in Fig. 6, in which acenaphthylene is chosen as an example, Eqs. 7 and 8 show that the square form interaction is thus facilitated in *excited-state* reactions.[27] The relation of the opposite symmetries of HO and LV in the ground state also holds as a general rule in alternant hydrocarbons, such as anthracene and pentacene, whose photodimerization has been well studied.

We have to remember that these circumstances must be similar in the case of the strong charge-transfer interaction in which one electron jumps from the olefin into the reagent orbital. The orbital symmetry requirement for a square-form

20) S. Winstein, E. Grunwald and L. L. Ingraham, *J. Am. Chem. Soc.*, **70**, 821 (1948); D. J. Cram, ibid., **71**, 3863 (1949); as regards the MO-theory, see Ref. 8, p. 382; the LV orbital of the phenyl cation is localized at the sp^2-like sigma orbital on the attached carbon atom (K. Fukui, H. Kato and T. Yonezawa, This Bulletin, **35**, 1475 (1962); K. Morokuma, S. Ohnishi, T. Masuda and K. Fukui, ibid., **36**, 1228 (1963)), which is, therefore, symmetrical with respect to the bisecting plane of the C-C double bond in the phenonium cation.

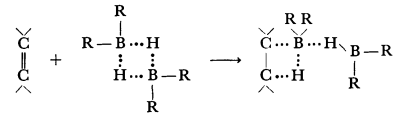
25) Some alkyl borane compounds are known to react as a dimeric form. In such cases, the mode of interaction would resemble that of the S_N2 reaction of the halogen anion with alkyl halide.



Thus, the structure near the transition state may be more or less similar to the square form.

26) E. L. Bowen and J. D. F. Marsh, *J. Chem. Soc.*, **1947**, 109; as regards the MO theory, see K. Fukui, K. Morokuma and T. Yonezawa, This Bulletin, **34**, 1178 (1960); A Schönberg and A. Mustafa, *J. Chem. Soc.*, **1948**, 2126; A. Mustafa, *Chem. Revs.*, **51**, 1 (1952); O_2 *cis*-addition is also described in G. O. Schenck and K. Ziegler, *Naturwissenschaften*, **32**, 157 (1944).

27) The perturbation theory is modified in case b where the second-order term in Eq. 8 should be replaced by the first-order term,

$$\{|C_r^{LV}C_{r'}^{LV}\gamma_a+C_s^{LV}C_{s'}^{LV}\gamma_b|^2 + |C_r^{HO}C_{r'}^{HO}\gamma_a+C_s^{HO}C_{s'}^{HO}\gamma_b|^2\}^{1/2}$$

where rs and $r's'$ are the two pairs of the reaction centers of the M and M′ molecules respectively.

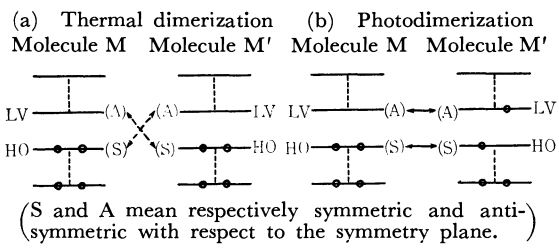


Fig. 6. The symmetry relationship of OH and LV of acenaphthylene in connection with dimerization reactivity.

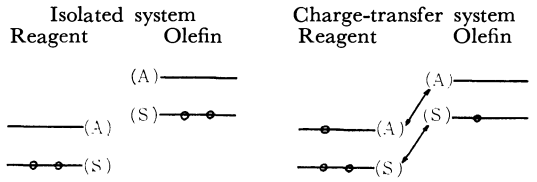

Fig. 7. The relation of orbital symmetry with charge-transfer interaction.

interaction, which the isolated systems are unable to fulfil, will then be satisfied. An instance for such a case is indicated in Fig. 7.

Here we should make reference to the recent finding in the field of polymerization chemistry that several stereospecific ionic polymerizations are thought to occur through successive *cis*-openings of the monomer double bond.[28] An interpretation of this fact has been given from a purely sterical point of view.[29] However, in view of the reasons above set forth it seems likely that the orbital symmetry of the system, including the growing chain end and the counter ion or catalyst part, should be examined after reliable information on the catalyst structure has been obtained. Also, whether or not circumstances like those in Fig. 7 might be realized in these cases is a matter of deep interest. We hope to re-examine the working mechanism of stereomodifiers in stereospecific vinyl polymerizations from the point of view of orbital symmetry. In addition, we may have to consider the participation of the neighboring group in the activated complex influencing the orbital symmetry when the monomer has any conspicuously influential group in the molecule. On this point, we shall present a report in the near future.

The 1, 3-Dipolar Additions.—The addition of 1, 3-dipoles to olefins occurs at positions *cis* with respect to both reactants.[30] Although various species of 1, 3-dipoles are known, the essential structure under reactive conditions may be characterized by the conjugated system which is indicated in Fig. 8.

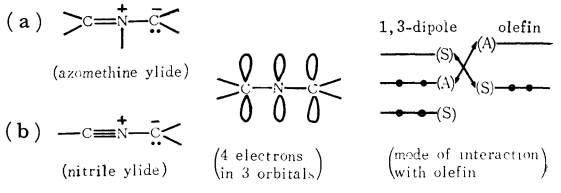

Fig. 8. The schematic representation of 1, 3-dipoles.

The LV orbital of 1, 3-dipoles is symmetric with respect to the two side AO's, so *cis*-interaction with olefin may be made favorable.

Other interesting problems, like the *trans*-1, 2-additions and the *endo*- and *exo*-additions in Diels-Alder reactions, as well as the stable conformations of organic molecular skeletons and the problem of *trans*-β-elimination, are left untouched in the present paper; they will be considered in several separate papers later.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 504—506 (1966)

The Infrared Absorption Spectra of the Condensation Products of Formaldehyde with Hydrazine

By Mitsuo MASHIMA

Department of Literature and Science, Saga University, Saga

(Received June 24, 1965)

The infrared absorption spectra of tetraformaltrisazine and formalazine have been obtained in the solid state. From a tentative assignment of the bands observed, it has been shown that a molecule of tetraformaltrisazine has the bicyclic structure proposed by Hofmann and Storm, while formalazine is a polymer with a four-membered heterocyclic ring.

Pulvermacher[1] first obtained a condensation product of formaldehyde with hydrazine hydrate. This compound, which is completely insoluble in water, has been designated as formalazine. Another water-soluble formaldehyde derivative of hydrazine, tetraformaltrisazine, was obtained by Hofmann and Storm.[2] On the basis of the results of molecular weight measurements and elemental analyses, they have proposed a bicyclic structure for this product.

In the present studies, the condensation products of formaldehyde with hydrazine were reexamined spectroscopically.

Experimental

Tetraformaltrisazine.—This compound was prepared by the gradual addition of 0.8 mol. of formaldehyde (ca. 37% solution) to one mole of hydrazine hydrate (ca. a 80% solution) under cooling.[2] The solution obtained was evaporated on a water bath, and then a great quantity of ethanol was added to the concentrated solution; the precipitate thus obtained was collected by suction filtration. When the precipitate was repeatedly dissolved in water and separated with ethanol, fine crystals were obtained. When heated, this compound begins to decompose partly over 200°C and then decomposes rapidly at 218°C (lit.[2] 225°C). The infrared spectra of this compound and its *N*-deuterated derivative were studied from 650 to 4000 cm^{-1} in the solid state.

Found: C, 33.09; H, 8.51; N, 58.11. Calcd. for $C_4N_6H_{12}$: C, 33.32; H, 8.39; N, 58.29%.

Formalazine.—This compound was prepared the by drop by drop addition of hydrazine hydrate (1 mol.) to formaldehyde (2 mol.) in a 37% solution. The precipitate obtained was washed with a large quantity of water and then dried; a white amorphous compound was obtained. This compound begins to decompose and turn brown at 265°C. The infrared spectra of this compound was studied in the solid state.

Found: C, 40.46; H, 7.51; N, 46.59. Calcd, for $C_{10}N_{10}H_{22}O$: C, 40.26; H, 7.38; N, 46.97%.

Measurements of the Infrared Spectra.—The infrared spectra were measured by using a double-beam Hitachi infrared spectrophotometer, type EPI-2, equipped with rock salt prisms. Potassium bromide disks were used to obtain the solid spectra.

Results and Discussion

Tetraformaltrisazine.—Hofmann and Storm[2] have proposed the molecular structure for this compound shown in Fig. 1. The spectroscopic

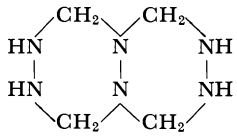

Fig. 1.

observations were also in agreement with this structure. The infrared spectra obtained are shown in Fig. 2: a solid curve shows the spectrum of this compound, and a dotted curve, the spectrum of its *N*-deuterated derivative.

The CH_2 group gives rise to bands corresponding to the C–H stretching vibrations and the CH_2 deformation vibrations. As may be seen from Fig. 2, the four bands at 2980, 2935, 2885, and 2830 cm^{-1} are scarcely changed in frequency on *N*-deuteration; they may be safely assigned to the CH_2 stretching vibrations. The CH_2 bending vibration gives rise to a band around 1465 cm^{-1} in *n*-paraffins. In cycloalkanes, there is a decrease in the CH_2 bending frequency; e. g., cyclopentane shows the corresponding band at 1455 cm^{-1}. Tetraformaltrisazine has two bands, at 1452 and 1437 cm^{-1}, which are little changed in frequency on *N*-deuteration. Consequently, they may be ascribed to the CH_2 bending vibration. The CH_2 twisting and wagging vibrations occur in the 1300—1200 cm^{-1} region. In *n*-paraffins a band near 1305 cm^{-1} has been assigned to the CH_2 wagging vibration. The present compound shows weak or moderately strong bands at 1379, 1349, 1303, and 1279 cm^{-1}; its *N*-deuterated derivative has bands corresponding to them at 1378, 1349, 1306, and 1275 cm^{-1}. These bands may be ascribed to

2) K. A. Hofmann and D. Storm, ibid., **45**, 1725 (1912).

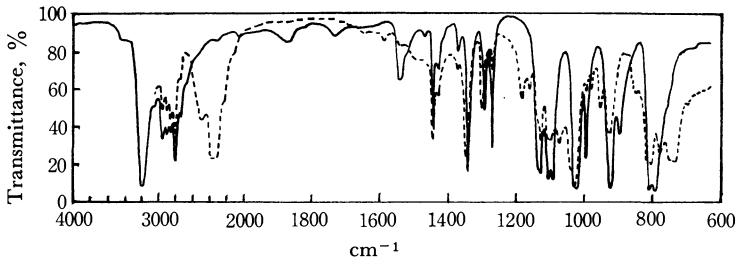

Fig. 2. Infrared spectra of tetraformaltrisazine (solid curve) and its *N*-deuterated derivative (dashed curve) in KBr disks.

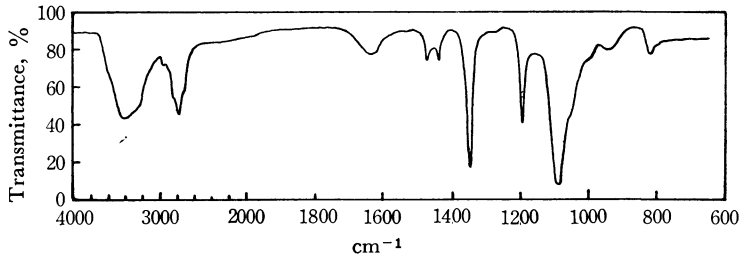

Fig. 3. Infrared spectrum of formalazine in KBr disks.

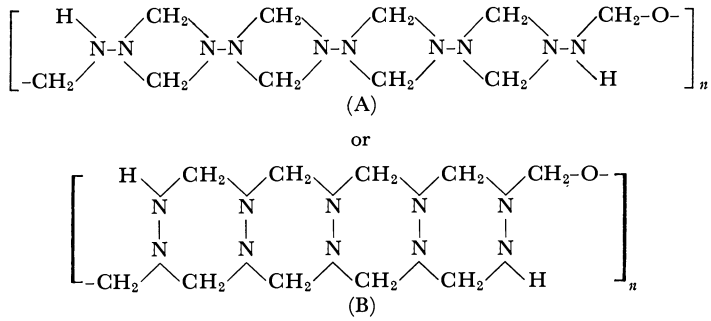

Fig. 4.

the CH_2 wagging and twisting vibrations. The CH_2 rocking vibration occurs near 720 cm^{-1} in *n*-paraffins, but this band is seen only when the number of the methylene group is more than two.[3] Tetraformaltrisazine has four CH_2 groups, which are isolated from each other; this compound shows no band in the 720 cm^{-1} region. Thus, the identification of the CH_2 rocking vibration is not easy.

Tetraformaltrisazine shows a strong band at 3220 cm^{-1}; it is displaced by a band at 2360 cm^{-1} on *N*-deuteration. Therefore, this band may safely be ascribed to the NH stretching vibration. In secondary amines, the NH deformation absorption usually occurs in the 1650—1550 cm^{-1} region. Tetraformaltrisazine shows a weak band at 1552 cm^{-1}, which falls in the range indicated above. This band is displaced by bands at 1186 and 1166 cm^{-1} on *N*-deuteration. Consequently, the 1552 cm^{-1} band may be ascribed to the NH deformation vibration.

In the 1150—800 cm^{-1} region, tetraformaltrisazine shows several strong or moderately strong bands; they are considered to be due to the C–N and N–N stretching vibrations. *N*-Deuterated tetraformaltrisazine shows new bands at 783 and 745 cm^{-1}. Therefore, it may surely be considered that the NH deformation vibration contributes to absorptions in this region. However, a detailed assignment of the above-indicated bands is not easy. The observed frequencies and some tentative assignments of them are summarized in Table I.

Formalazine.—The results of elemental analyses are in agreement with the structure shown in Fig. 4, but the results are inconsistent with the formula $(CH_2{=}N{-}N{=}CH_2)_x$ proposed by Pulvermacher.[1] The infrared absorption spectrum is shown in Fig. 3. As may be seen from Fig. 3, the number of absorption bands observed is not large. Consequently, it may be expected that at least the structural unit of molecules is relatively

simple. Since this compound is almost completely insoluble in water, we could not examine the effect of *N*-deuteration on the absorption spectrum. The observed frequencies were tentatively assigned by a comparison of the spectrum of this compound with that of tetraformaltrisazine (Fig. 2).

In the CH-stretching frequency range, this compound shows moderately strong or weak bands at 2960, 2860, and 2780 cm^{-1}. These bands may be assigned to the CH stretching vibration. The three bands at 1477, 1442, and 1349 cm^{-1} correspond in frequency to the 1452, 1437, and 1349 cm^{-1} bands of tetraformaltrisazine. Therefore, the 1477 and 1442 cm^{-1} bands were assigned to the CH_2 bending vibration, while the 1349 cm^{-1} band was assigned to the CH_2 wagging vibration. A sharp, moderately strong band at 1196 cm^{-1} may be considered to be due to the CH_2 twisting vibration. From these assignments of the observed bands, it may be concluded that a molecule of this compound contains the methylene group.

If this compound contains ether linkages, as is shown in Fig. 4, the intense absorption band will be shown in the 1150—1060 cm^{-1} range. For the identification of ether linkages in aliphatic ethers we have to depend upon the presence of intense bands within the range indicated above. Formalazine shows an intense band at 1088 cm^{-1}; this band has no partner band in the spectrum of tetraformaltrisazine. Therefore, the 1088 cm^{-1} band may be acribed to the CH_2–O–CH_2 stretching vibration.

In tetraformaltrisazine, which contains a ten-membered heterocyclic ring, several strong bands were observed in the 1150—800 cm^{-1} region. On the other hand, in formalazine no band corresponding to them was found. Therefore, out of the two structures indicated in Fig. 4, the former A is considered to be prefereable to B.

The broad band with its peak near 3400 cm^{-1} is considered to be due to the NH strecthing vibration.

The author is grateful to Professor Yoshiya Kanda of Kyushu University for letting him use the spectrophotometer. Thanks are also due to Mr. Michio Sido and Miss Takeko Tahara of the Centre of Elementary Analyses, Kyushu University, for their analyses of the C, H, and N contents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 507—511 (1966)

A New Synthesis of Polyhydroxydihydroflavonols*

By Taichiro OYAMADA and Hajime BABA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata

(Received June 25, 1965)

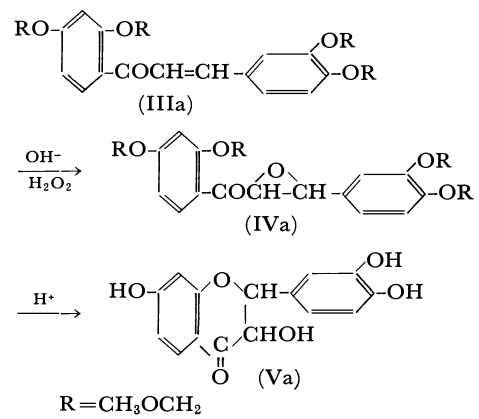
An alkaline hydrogen peroxide oxidation of chalcones with methoxymethoxyl groups in the 2'-position and in other positions gave the corresponding poly(methoxymethoxy)chalcone oxides; these were then, in turn, easily converted into polyhydroxydihydroflavonols, with a simultaneous splitting of all the *O*-methoxymethyl groups, by warming with acid. The general applicability of the new method was illustrated by the synthesis of the following hydroxydihydroflavonols: 3, 7-dihydroxy- (m. p. 170—171°C), 3, 4'-dihydroxy- (m. p. 214—216°C), 3, 4'-dihydroxy-3'-methoxy- (m. p. 217—218°C), 3, 4', 7-trihydroxy- (m. p. 214—215°C), and 3, 3', 4', 7-tetrahydroxyflavanone (*dl*-fustin, m. p. 217—218°C). The first four new compounds were identified by converting them into known methyl ethers, while the last one was identified by comparing it with natural *dl*-fustin. Their structures were also confirmed by infrared and ultraviolet spectra.

The action of alkaline hydrogen peroxide on 2'-hydroxychalcones results in the formation of flavonols (3-hydroxyflavones)[1] or dihydroflavonols (3-hydroxyflavanones)[2], depending on the conditions employed. The course and mechanism of these reactions have been postulated by Geissman et al.[3] to involve an intermediary formation of the corresponding epoxides, which are immediately transformed into dihydroflavonols or aurones by the nucleophilic attack of the hydroxide or phenolate ions. The dihydroflavonols thus formed are readily oxidized in alkaline media into flavonols (the so-called Algar-Flynn-Oyamada reaction[4]); hence, the isolation of the former may be accomplished only under the appropriate conditions. Particularly polyhydroxychalcones, which carry one or more hydroxyl groups besides the 2'-hydroxyl group, often fail to give hydroxydihydroflavonols because of a further oxidation. Thus, only a few examples of the formation have been reported.[5]

The present authors have found that, from polyhydroxychalcones bearing one or more hydroxyl groups besides the 2'-hydroxyl one, the corresponding expoxides can be prepared by protecting all the hydroxyl groups by methoxymethylation during the course of the alkaline peroxide oxidation, and that the resulting poly(methoxymethoxy)chalcone oxides, when warmed with acid, readily cyclize to polyhydroxydihydroflavonols, with the simultaneous splitting of all *O*-methoxymethyl groups.

The general applicability of the new method will be illustrated by demonstrating the syntheses of the following hydroxydihydroflavonols: 3,3',4',7-tetrahydroxyflavanone (Va), 3,4',7-trihydroxyflavanone (Vb), 3,4'-dihydroxy-3'-methoxyflavanone (Vc), 3,7'-dihydroxyflavanone(Vd), and 3,4'-dihydroxyflavanone (Ve).

The synthetic scheme of Va (*dl*-fustin), for example, is:



Of the above-mentioned compounds, the first one was identified by comparing it with the natural *dl*-fustin[6] obtained from the wood of *Rhus succedanea L.*, while the remaining four new compounds were identified by converting them into the known methyl ethers.[7-9] Their structures were also confirmed by infrared and ultraviolet spectra. Furthermore, these compounds gave a color reaction

a Inflection

characteristic of flavonoid compounds when they were reduced with magnesium or zinc and hydrochloric acid, and they were readily oxidized, by air in the presence of alkali or acid, into the corresponding flavonols. This facile dehydrogenation is a common feature of dihydroflavonols with trans-configurations. The stereochemistry of these dihydroflavonols and the steric course of this reaction will be discussed elsewhere.

In Table I are collected the infrared spectral data of the carbonyl group in the hydroxydihydroflavonols and the corresponding flavanones bearing no 3-hydroxyl groups, along with their ultraviolet absorption maxima. An examination of the infrared spectra will indicate that the introduction of a 3-hydroxyl group in the flavanones results in a rise in the carbonyl frequency, due probably to an inductive effect of the hydroxyl group. On the other hand, as might be expected, the ultraviolet absorption maxima of the dihydroflavonols and the corresponding flavanones are essentially identical.

Experimental

All melting points are uncorrected.

2′-(Methoxymethoxy)acetophenone (Ia).—A mixture of sodium salt of 2′-hydroxyacetophenone (30.0 g.), monochlorodimethyl ether (15.3 g.), calcium oxide (10.5 g.), and dioxane (240 cc.) was heated while being stirred at 40—45°C for 3 hr. The mixture was then filtered, and the filtrate was poured into water. The ether extract of the oily product was washed with 2% aqueous sodium hydroxide, dried over anhydrous sodium sulfate, and evaporated to yield 35.0 g. (89%) of a colorless liquid (Ia); b. p. 114—116°C/8 mmHg (lit. b. p. 139—140°C/12.5 mmHg[10]); n_D^{24} 1.5144. IR liquid film): 2990(sh), 2950, 2910(sh), 2830, 2780, 1082, 923 (CH_3OCH_2O); 1676 (CO); 1362 cm^{-1} (CH_3CO). (Found: C, 66.64; H, 6.91. Calcd. for $C_{10}H_{12}O_3$: C, 66.65; H, 6.71%).

2′,4′-Bis(methoxymethoxy)acetophenone (Ib).—To a solution of resacetophenone (37.5 g.) in absolute ethanol (150 cc.) containing sodium ethoxide (metallic sodium: 12.0 g.) there was added, drop by drop, monochlorodimethyl ether (40.0 g.) under cooling; the mixture was then stirred at room temperature (20°C) for 20 min. After the solvent had been removed, the residue was poured into water. The ether extract of the oily product was washed with 2% aqueous sodium hydroxide, dried over anhydrous sodium sulfate, and evaporated to yield 20.0 g. (33%) of a colorless liquid (Ib); b. p. 184°C/12 mmHg (lit. b. p. 140—150°C/0.2 mmHg[11]); n_D^{15} 1.5274. IR (liquid film): 2990(sh), 2960, 2900, 2835, 2775(sh), 1084, 924 (CH_3OCH_2O); 1669 (CO); 1363 cm^{-1} (CH_3CO). (Found: C, 59.89; H, 6.74. Calcd. for $C_{12}H_{16}O_5$: C, 59.99; H, 6.71%).

4-(Methoxymethoxy)benzaldehyde (IIa).—To a stirred suspension of a finely-divided sodium (3.4 g.) in toluene (90 cc.), a solution of 4-hydroxybenzaldehyde (18.0 g.) in absolute ethanol (20 cc.) was added; the mixture was then refluxed with stirring in order to complete the salt-formation. After the alcohol had been removed by fractional distillation the suspension of the sodium salt in toluene was treated with monochlorodimethyl ether (120.0 g.) under cooling the precipitate disappeared. The resulting solution was washed with 2% aqueous sodium hydroxide, dried over anhydrous sodium sulfate, and evaporated to yield 12.5 g. (86%) of a colorless liquid (IIa); b. p. 147—149°C/22 mmHg

11) A. Bellini and P. Venturella, *Ann. chim. (Rome)*, **48**, 111-24 (1948); *Chem. Abstr.*, **52**, 1641 (1958).

(lit. b. p. 152—153°C/21 mmHg[12]): n_D^{15} 1.5434. IR (liquid film): 2960, 2910, 2840, 2740, 1082, 923 (CH_3OCH_2O); 2840, 2740, 1962 cm^{-1} (CHO). (Found: C, 65.04; H, 6.10. Calcd. for $C_9H_{10}O_3$: C, 65.05; H, 6.07%).

3, 4-Bis(methoxymethoxy)benzaldehyde (IIb).—This product was obtained from protocatechualdehyde by the procedure used for Ib; yield, 46%; m. p. 59—60°C (lit. m. p. 60°C[12]). IR (KBr): 2980(sh), 2940, 2840, 2740, 1083, 918 (CH_3OCH_2O); 2840, 2740, 1676 cm^{-1} (CHO). (Found: C, 58.66; H, 6.41. Calcd. for $C_{11}H_{14}O_5$: C, 58.40; H, 6.24%).

3-Methoxy-4-(methoxymethoxy)benzaldehyde (IIc).—To a solution of the sodium salt of vanillin (15.3 g.) in dioxane (76 cc.), chlorodimethyl ether (5.6 g.) was added, drop by drop, under ice-cooling; the mixture was then heated at 70—80°C for 1.5 hr. and poured into water. The toluene extract of the product was washed with 2% aqueous sodium hydroxide, dried over anhydrous sodium sulfate, and evaporated to yield an oily residue which crystallized on standing. Recrystallization from ether gave 10.0 g. (49%) of colorless plates (IIc); m. p. 39.5—41.5°C (lit m. p. 39—40°C[13]). IR (liquid film): 2990(sh), 2950, 2900, 2830, 2740, 1083, 924 (CH_3OCH_2O): 2830, 2740, 1685 cm^{-1} (CHO).

2', 3, 4, 4'-Tetrakis(methoxymethoxy)chalcone (IIIa).—To a solution of Ib (3.2 g.) and IIb (3.0 g.) in methanol (40 cc.) 50% aqueous sodium hydroxide (25.0 g.) was added; the mixture was then allowed to stand at room temperature overnight. The reaction mixture was poured into water, and the precipitate formed was collected and recrystallized from ligroin to give 3.0 g. (50%) of pale yellow needles (IIIa); m. p. 69—70°C. IR(KBr): 2990(sh), 2930(sh), 2900, 2830, 2800(sh), 1072, 918 (CH_3OCH_2O); 1640 cm^{-1} (CO).

Found: C, 61.98; H, 6.51. Calcd. for $C_{23}H_{28}O_9$: C, 61.59; H, 9.30%.

The Hydrolysis of IIIa with Hydrochloric Acid.—To a solution of IIIa (1.0 g.) in ethanol (20 cc.), 12 N hydrochloric acid (10 cc.) was added; the solution was then left at room temperature for 40 min. The reaction mixture was poured into water and the precipitate was collected and recrystallized from ethanol to give 0.15 g. of yellow crystals, m. p. 215—216°C. No depression of the melting point was observed on admixture with an authentic sample of butin.

2', 4, 4'-Tris(methoxymethoxy)chalcone (IIIb).—IIIb was obtained from Ib and IIa by the procedure described above. Yield, 90%; pale yellow needles; m. p. 47—48°C (*n*-hexane-carbon tetrachloride). IR (KBr): 2990, 2960, 2900, 2830, 2795(sh), 1077, 928 (CH_3OCH_2O); 1650 cm^{-1} (CO).

Found: C, 64.69; H, 6.38. Calcd. for $C_{21}H_{24}O_7$; C, 64.93: H, 6.24%.

2', 4-Bis(methoxymethoxy)-3-methoxychalcone (IIIc).—IIIc was obtained from Ia and IIc by the procedure described above. Yield, 67%; colorless needles; m. p. 64—64.5°C. IR(KBr): 2965, 2910, 2825, 2790(sh), 1080, 917 (CH_3OCH_2O); 1648 cm^{-1} (CO).

Found: C, 67.03; H, 6.34. Calcd. for $C_{20}H_{22}O_6$: C, 67.02; H, 6.20%.

2', 4'-Bis(methoxymethoxy)chalcone (IIId).—IIId was obtained from Ib and benzaldehyde by the procedure described above, except that the oily product was extracted with ether. The removal of the ether gave a pale yellow oil (IIId), which was used in the subsequent epoxidation without further purification. Yield, 80%; pale yellow liquid: n_D^{18} 1.5978. IR (liquid film): 3005, 2950, 2900, 2830, 2780(sh), 1080, 926 (CH_3OCH_2O); 1662 cm^{-1} (CO).

2', 4-Bis(methoxymethoxy)chalcone (IIIe).—IIIe was obtained from Ia and IIa by the procedure used for making IIId. Yield, 95%; pale yellow liquid; n_D^{13} 1.6067. This was used without further purification. IR (liquid film): 2990, 2940, 2900, 2835, 2780(sh), 1082, 924 (CH_3OCH_2O); 1660—1640 cm^{-1} (doublet) (CO).

2', 3, 4, 4'-Tetrakis(methoxymethoxy)chalcone Oxide (IVa).—To a solution of IIIa (3.0 g.) in methanol (160 cc.) there were adedd 15% aqueous hydrogen peroxide (9 cc.) and then 16% aqueous sodium hydroxide (15.0 g.) under cooling. The mixture was then allowed to stand in a refrigerator over night. The colorless precipitate formed was collected by filtration and recrystallized from carbon tetrachloride to give 1.5 g. (48%) of colorless needles (IVa), m. p. 77—79°C. A further amount (about 1.1 g.) of this compound was recovered from the filtrate by diluting it with water. IR (KBr): 2970, 2945, 2920, 2830, 2805, 1071, 924 (CH_3OCH_2O); 1678 (CO); 896 cm^{-1} (C(O)C—O).

Found: C, 59,74; H, 6.19; Calcd. for $C_{23}H_{28}O_{10}$: C, 59.47; H, 6.09%.

2', 4, 4'-Tris(methoxymethoxy)chalcone Oxide (IVb), 2', 4-Bis(methoxymethoxy)-3-methoxychalcone Oxide (IVc), 2', 4'-Bis(methoxymethoxy)-chalcone Oxide (IVd), and 2', 4-Bis(methoxymethoxy)chalcone Oxide (IVe).—IVb, IVc, IVd, and IVe were obtained from IIIb, IIIc, IIId, and IIIe respectively by the procedure described above for IVa.

IVb.—Yield, 76%; colorless needles; m. p. 95—96°C (carbon tetrachloride). IR (KBr): 3000, 2960, 2930(sh), 2830, 2800(sh), 1076, 910 (CH_3OCH_2O); 1681 (CO); 889 cm^{-1} (C(O)C—C).

Found: C, 62.67; H, 5.65. Calcd. for $C_{21}H_{24}O_8$: C, 62.36; H, 5.99%.

IVc.—Yield, 67%; liquid, n_D^{15} 1.6633. Attempts to crystallize the oily product (IVc) were unsuccessful. Thus, its elementary analysis gave no satisfactory results, although the infrared spectrum exhibited the expected bands as follows: IR (liquid film): 2990(sh), 2960, 2900(sh), 2820, 2780(sh), 1084, 924 (CH_3OCH_2O); 1679 (CO); 898 cm^{-1} (C(O)C—C).

IVd.—Yield, 68%; colorless needles; m.p. 61.5—62°C (carbon tetrachloride). IR(KBr): 2960, 2900, 2830, 2780(sh), 1086, 926 (CH_3OCH_2O); 1675 (CO); 898 cm^{-1} (C(O)C—C).

Found: C, 66.01; H, 5.93. Calcd, for $C_{19}H_{20}O_6$: C, 66.26; H, 5.86%.

IVe.—Yield, 79%; colorless prisms; m. p. 59—60°C (carbon tetrachloride). IR(KBr): 2991, 2970(sh), 2825(sh), 2785, 1084, 927 (CH_3OCH_2O); 1686 (CO); 890 cm^{-1} (C(O)C—C).

Found: C, 66.24; H, 6.29. Calcd. for $C_{19}H_{20}O_6$: C, 66.26; H, 5.86%.

3, 3', 4', 7-Tetrahydroxyflavanone (Va, *dl*-fustin).—A mixture of IVa (1.0 g.), methanol (10 cc.) and 12 N

12) H. Baum, D. R. Pat. 209608 (1909).
13) K. Freudenberg and H. G. Müller, *Ann.*, **584**, 40 (1953).

hydrochloric acid (3 cc.) was refluxed for 5 min. The reaction mixture was then diluted with water (about 20 cc.), and the methanol was removed at a temperature below 40°C in vacuo. The precipitate which had separated on cooling was collected and recrystallized from water to give 0.5 g. (80%) of colorless plates (Va), m. p. 217—218°C; this substance showed no melting point depression on admixture with an authentic sample of *dl*-fustin.[6] The infrared and ultraviolet spectra of Va were identical with those of the natural substance

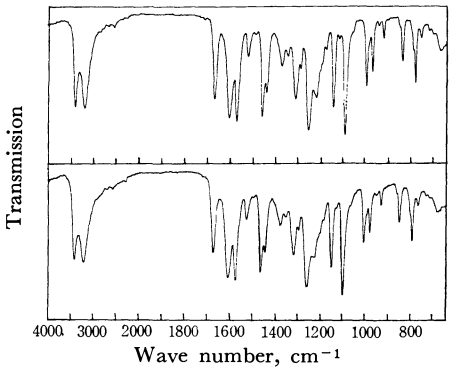

Fig. 1. The infrared spectra of natural (upper) and synthetic fustin (Va) (lower).

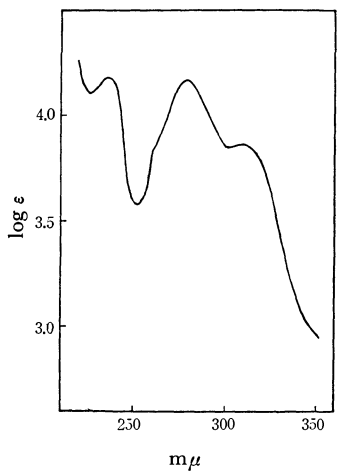

Fig. 2. The ultraviolet spectrum of synthetic fustin (Va) in ethanol.

(Figs. 1 and 2). Color reactions: magnesium - hydrochloric acid, orange red; zinc — hydrochloric acid, orange red; ferric chloride, green. IR(KBr): 3400, 3200, 1018 (OH); 1674 cm^{-1} (CO). UV λ_{max}^{EtOH} mμ (log ε): 235 (4.19), 279 (4.17), 310 (3.84). (Found: C, 62.61; H, 4.38. Calcd. for $C_{15}H_{12}O_6$: C, 62.50; H, 4.16%).

Tetraacetate: m. p. 148—149°C (lit. m. p. 150—151°C[6]). IR (KBr): 1752 (acetate CO); 1707 cm^{-1} (CO).

3', 4', 7-Trimethyl Ether: m. p. 140—140.5°C (lit. m. p. 143—144°C[6]). IR(KBr): 3450, 998 (OH); 3000—2900 (triplet), 2835 (CH_3O); 1679 cm^{-1} (CO).

3, 4', 7-Trihydroxyflavanone (Vb), 3, 4'-Dihydroxy-3'-methoxyflavanone (Vc), 3, 7-Dihydroxyflavanone (Vd), and 3, 4'-Dihydroxyflavanone (Ve). —Vb, Vc, Vd, and Ve were prepared from IVb, IVc, IVd, and IVe respectively by a slight modification of the procedure described above. The precipitate which had separated on the addition of water was collected and recrystallized from the appropriate solvents.

Vb.—Yield, 63%; colorless fine crystals; m. p. 214—215°C (ethanol). Color reactions: magnesium - hydrochloric acid, reddish violet; zinc - hydrochloric acid, reddish violet; phloroglucinol - hydrochloric acid, reddish violet; ferric chloride, none. IR (KBr): 3250 (broad), 1005 (OH); 1660 cm^{-1} (CO). UV λ_{max}^{EtOH} mμ (log ε): 232 (4.19), 275 (4.13), 310 (3.83).

Found: C, 66.17; H, 4.78. Calcd. for $C_{15}H_{12}O_5$: C, 66.17; H, 4.44%.

Triacetate: m. p. 149—150.5°C. IR (KBr): 1750 (acetate CO); 1707 cm^{-1} (CO).

Found: C, 63.19; H, 4.75. Calcd. for $C_{21}H_{18}O_8$: C, 63.31; H, 4.56%.

4', 7-Dimethyl Ether: m. p. 130—131°C (lit. m. p. 124—126°C[8]). IR (KBr): 3450, 1007 (OH); 3000—2900 (triplet), 2840 (CH_3O); 1683 cm^{-1} (CO).

The Oxidation of Vb to 3, 4', 7-Trihydroxyflavone (VIb). —A mixture of Vb (0.1 g.), 16% aqueous sodium hydroxide (4 cc.), and methanol (3 cc.) was warmed on a water bath for 10 min. The reaction mixture was then poured into water, and the precipitate formed was collected and recrystallized from ethanol to give VIb as yellow crystals, m. p. 296—297°C (lit. m. p. 302°C[14]).

Vc.—Yield, 45%; colorless needles; m. p. 217—218°C (ethyl acetate). Color reactions: magnesium - hydrochloric acid, reddish orange; zinc - hydrochloric acid, reddish orange; phloroglucinol - hydrochloric acid, violet; ferric chloride, none. IR(KBr): 3460, 1009 (OH); 1677 cm^{-1} (CO). UV λ_{max}^{EtOH} mμ (log ε): 232[a](4.06), 250(3.95), 281(3.58), 315(3.51).

Found: C, 67.10; H, 4.99. Calcd. for $C_{16}H_{14}O_5$: C, 67.12; H, 4.94%.

Diacetate: m. p. 144—145°C. IR (KBr): 1750 (acetate CO): 1699 cm^{-1} (CO).

Found: C, 65.07; H, 5.19. Calcd. for $C_{20}H_{18}O_7$: C, 64.85; H, 4.91%.

3', 4'-Dimethyl Ether: m. p. 155—157°C (lit. m. p. 155—157°C[8]). IR (KBr): 3450, 1005 (OH); 3000—2900 (triplet), 2840 (CH_3O); 1692 cm^{-1} (CO).

Vd.—Yield, 75%; colorless needles; m. p. 170—171°C (ethanol). Color reactions: magnesium - hydrochloric acid, reddish orange; zinc - hydrochloric acid, red; phloroglucinol - hydrochloric acid, orange; ferric chloride, none. IR(KBr): 3395, 3165, 1010 (OH); 1677 cm^{-1} (CO). UV λ_{max}^{EtOH} mμ (log ε): 234[a](3.92), 277-(4.07), 308(3.88).

Found: C, 69.66; H, 5.06. Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.73%.

Diacetate: m. p. 129.5—130°C. IR (KBr): 1752 (acetate CO); 1700 cm^{-1} (CO).

Found: C, 66.95; H, 4.99. Calcd. for $C_{19}H_{16}O_6$: C, 67.04; H, 4.75%.

7-Methyl Ether: m. p. 148—149°C (lit. m. p. 146—147°C,[9] 149—150°C[10]). IR(KBr): 3450, 1012 (OH); 3000—2900 (triplet), 2840 (CH_3O); 1682 cm^{-1} (CO).

The Oxidation of Vd to 3, 7-Dihydroxyflavone (VId).—A

14) S. Yamaguchi, *J. Chem. Soc. Japan, Pure Chem. Sec.* (*Nippon Kagaku Zasshi*), **84**, 148 (1963).

mixture of Vd (0.05 g.), 2 N sulfuric acid (5 cc.), and methanol (2 cc.) was heated on a water bath for 15 hr. under reflux, while a gentle stream of air was passed into the flask. The work-up of the reaction product gave VId as pale yellow crystals, m. p. 251—252°C, which was identical with the sample prepared from 2', 4'-dihydroxychalcone by the Algar-Flynn-Oyamada method.

Ve.—Yield, 45%; colorless needles; m. p. 214—216°C (methanol). Color reactions: magnesium - hydrochloric acid, red; zinc - hydrochloric acid, reddish orange; phloroglucinol - hydrochloric acid, red; ferric chloride, none. IR(KBr): 3390, 1006 (OH); 1688 cm^{-1} (CO). UV λ_{max}^{EtOH} mμ (log ε): 230[a](4.21), 253(4.10), 317(3.65).

Found: C, 70.03; H, 5.03. Calcd. for $C_{15}H_{12}O_4$: C, 70.30; H, 4.73%.

Diacetate: m. p. 164.5—165.5°C. IR(KBr): 1742 (acetate CO); 1694 cm^{-1} (CO).

Found: C, 67.29; H, 4.99. Calcd. for $C_{19}H_{16}O_6$: C, 67.04; H, 4.75%.

4'-Methyl Ether: m. p. 171—172°C (lit. m. p. 172—174°C[7]). IR(KBr): 3450, 1003 (OH); 3000—2900 (triplet), 2840 (CH_3O); 1690 cm^{-1} (CO).

The Oxidation of Ve to 3, 4'-Dihydroxyflavone (VIe).—This oxidation was effected essentially by the method described above for Va. VIe was obtained as yellow needles, m. p. 266—268°C; it was identical with the sample prepared from 2', 4-dihydroxychalcone by the Algar-Flynn-Oyamada method.

As has been described above, except for *dl*-fustin, the hydroxydihydroflavonols obtained here, which contain a free 4'-, 7-hydroxyl, or 4', 7-dihydroxyl grouping, gave no color reaction with ferric chloride (carried out by the addition of aqueous ferric chloride to aqueous alcohol solutions of these compounds). This is not too surprising, for this observation is in agreement with that made by Briggs and Locker[15] in hydroxyflavones containing a similar hydroxyl grouping.

All of the above acetates were prepared by treating them with acetic anhydride and pyridine; all of the above methyl ethers were prepared by refluxing them with dimethyl sulfate and anhydrous potassium carbonate in an acetone solution.

The authors are indebted to Mr. Toru Sato, Mr. Yusuke Inoguchi, Mr. Masaki Kikuchi, and Mr. Kazuyuki Mori for their technical assistance, and to Miss Toshiko Koyama and Miss Yoshi Yamawaki for the ultraviolet and infrared spectral measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 511—516 (1966)

A Geochemical Study of the Fumarolic Bismuthinite from Showashinzan

By Yoshihiko MIZUTANI

The Institute of Earth Sciences, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received June 30, 1965)

In an active fumarole on the dome of the Showashinzan volcano, Hokkaido, Japan, a crystalline sublimate was found. It is lead grey, with a metallic luster, and forms loose clusters of acicular crystals. X-Ray diffraction, spectrographic and micro-chemical analyses have been made of the sublimate. The results indicate that the sublimate consists of bismuthinite Bi_2S_3, with traces of lead, zinc, aluminum, copper, iron and titanium. A colorimetric determination has also been made of the bismuth in the fumarolic gases from Showashinzan. The variation in the bismuth content of the gases with the gas temperature suggests that, when the temperature falls to about 500°C, bismuth compounds lose their volatility in the gases and are precipitated to form a sublimate. On the assumption that the chemical equilibrium is established in the gases, the stability of bismuth minerals and a possible reaction for the formation of bismuthinite in the gases have been discussed, and it has been suggested that the bismuthinite is formed by the $2BiCl_3 + 3H_2S = Bi_2S_3 + 6HCl$ reaction in the gases.

Showashinzan, Hokkaido, Japan, is an active volcano formed during the period from 1943 to 1945. It is composed of a platform-shaped mountain with a dome on it. The dome consists of new lava, hyperthene dacite. Fumarolic activity still persists on and around the dome, with the emission of large amounts of high-temperature volcanic gases.

Recently, Mizutani[1] has made chemical and mineralogical investigations of volcanic sublimates from Showashinzan. His results show that many primary volcanic sublimates, such as crystobalite, hematite, thenardite, glaserite, sal ammoniac, and sassolite, are deposited in the fumaroles of

1) Y. Mizutani, *J. Earth Sciences, Nagoya Univ.*, **10**, 149 (1962).

Showashinzan.

In the present research, a volcanic sublimate from fumarole B-1b (Mizutani's notation[2]) of Showashinzan was subjected to X-ray diffraction, spectrographic and micro-chemical analyses in order to clarify its mineralogical composition. An attempt was also made to explain the formation of the volcanic sublimate through a gas phase reaction.

Occurrence

The sublimate was found at fumarole B-1b (Fig. 1), about 10 cm. inside the opening of the fumarole. It had been developed on the inner wall of the fissure vent and had formed loose clusters of acicular crystals. The crystals are lead-grey

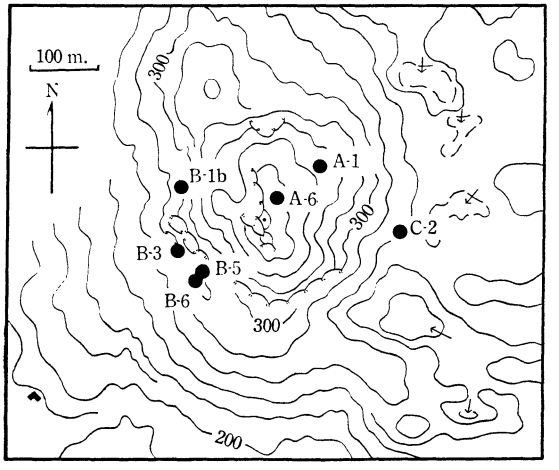

Fig. 1. Location of sampling.

with a metallic luster. Individual crystals reach a length of about 5 mm., but they are extremely thin. About 40 mg. of the sublimate was collected in 1960, and about 10 mg. in 1961, from the same place in the fumarole.

The vent of fumarole B-1b was 1—5 cm. wide and several meters long, running upwards on the slope of the dome. The surface of the inner wall of the fumarole was partly coated with a very thin film of a brown material, possibly hematite, but the inside of the wall rock, brecciated new lava, showed little evidence of having been attacked by fumarolic gases. From the fissure vent, gases with a temperature higher than 200°C were emitted at a rather low pressure, perhaps close to 1 atm. The temperature and chemical composition of the gases, determined at the same time as the sublimate was collected, are given in Table I.

Experimental

Identification.—A carefully-selected sample of the sublimate was subjected to qualitative spectrographic analysis and micro-chemical tests in order to get a provisional idea of its composition. The results showed that the sublimate consisted of bismuth sulfide, with trace amounts of lead, zinc, aluminum, copper, iron and titanium.

An X-ray powder pattern was prepared with a Norelco X-ray diffractometer using nickel-filtered copper radiation. The results obtained are given in Table II, together with the X-ray powder data of some bismuth minerals reported by ASTM,[3] Harcourt[4] and Graham et al.[5] The X-ray powder pattern of the sample is very similar to that of bismuthinite given by ASTM. Although they are identical in *d*-value, however, they are different in the intensities of some lines. The X-ray pattern of the bismuthinite given by Harcourt is also similar to that of the sample, though they differ slightly in the intensities and *d*-values of some lines. On the other hand, the X-ray patterns of the galenobismutite and cannizzarite given by ASTM and Graham et al. respectively are distinctly different from that of the sample.

The present identification is incomplete in the absence of quantitative chemical data, but it is thought to be sufficiently significant to prove that the sublimate examined consists of bismuthinite (Bi_2S_3).

The Determination of the Bismuth Content of Fumarolic Gases.—In order to discuss the formation of fumarolic bismuthinite throuhg a gas phase reaction, the bismuth content of the gases of Showashinzan was determined as follows.

Fumarolic gases were drawn into a cold trap containing a small amount of concentrated nitric acid by using a syringe through a silica tube inserted into the fumarole. By this process, the water vapor in the gases was condensed in the trap and bismuth compounds in the gases were completely dissolved in the condensed water. The nitric acid prevents the precipitation of bismuth as sulfide. The condensed water was then subjected to the following chemical analysis.

Two hundred and fifty milliliters of the condensed water was placed in a dish and concentrated to about 20 ml. Bismuth was separated from the solution as bismuth dithizonate in chloroform by Sandell's dithizone extraction method.[6] After the chloroform solution of bismuth dithizonate had been shaken with sulfuric acid (1 : 300), the aqueous phase was transferred to a small beaker and boiled gently until the odor of chloroform disappeared. Then the solution was subjected to Goto's colorimetric method.[7] The results obtained are given in Table III, together with the observed temperatures of the gases.

Discussion

The Behavior of the Bismuth in the Fumarolic Gases.—As may be seen from Table III, there is a notable decrease in the bismuth content at a temperature of about 500°C. This implies that, when the temperature falls to about 500°C, bismuth compounds lose their volatility in the gases

and are precipitated to form volcanic sublimate. Therefore, it is suggested that the occurrence of the bismuth mineral may be common in low-temperature fumaroles of Showashinzan. The difficulty of finding fumarolic bismuth minerals may be attributable to the fact that the rate of the accumulation of the minerals in a fumarole is very small, as may be expected from the observed bismuth contents of the gases.

Stable Bismuth Minerals under Fumarolic Conditions.—Three minerals are considered: the metal itself, the sulfide and the oxide. Stability relationships among these minerals may be expressed as a function of the temperature and the chemical compositon of the gaseous phase in equilibrium with the minerals.

The reactions considered are:

$$2/3\,Bi + H_2O = 1/3\,Bi_2O_3 + H_2 \quad (1)$$

and

$$1/3\,Bi_2S_3 + H_2 = 2/3\,Bi + H_2S \quad (2)$$

The values of the free energy change, ΔG, for these reactions were obtained from the thermodynamic data given by Kubaschewski and Evans[8] and by Rossini et al.,[9] and the equilibrium constant of the reaction, K, was calculated from the $\Delta G = -RT\ln K$ relation, where R is the gas-law constant and T is the absolute temperature of the system. The equations of K thus obtained are: for Reaction 1,

($T<271$°C)

$$\log K_1 = -8.961 + 2.323\log T - 2.98\times10^{-4}T - 2320T^{-1} \quad (3)$$

($T>271$°C)

$$\log K_1 = -7.950 + 1.650\log T + 0.963\times10^{-4}T - 1973T^{-1} \quad (4)$$

$$K_1 = \frac{P_{H_2}}{P_{H_2O}}$$

and for Reaction 2:

($T<271$°C)

$$\log K = 8.36 - 2.02\log T - 1790\,T^{-1} \quad (5)$$

($T>271$°C)

$$\log K_2 = 7.35 - 1.35\log T - 0.394\times10^{-3}T - 2120\,T^{-1} \quad (6)$$

$$K_2 = \frac{P_{H_2S}}{P_{H_2}}$$

The stability relationships obtained from these equations are shown in Figs. 2 and 3. The observed values of P_{H_2}/P_{H_2O} and P_{H_2S}/P_{H_2} in fumarolic gases of Showashinzan[2,10] are also plotted in Figs. 2 and 3 respectively.

It may be seen from these figures that the equilibrium ratio, P_{H_2}/P_{H_2O}, is far below the ratios observed in the fumarolic gases, so the metal is more stable in the gases than is the oxide (Fig. 2), and similarly, that the sulfide is stable at temperatures below about 230°C with repect to the

metal, but unstable at temperatures above 230°C (Fig. 3). Thus, in fumarolic gases of Showashinzan, bismuth, if present in an amount sufficient to form a solid, must exist as the sulfide or native metal.

A Possible Reaction to Form Bi_2S_3. — Theoretical evidence for the transportation of bismuth in magmatic vapor as chloride was adduced in Krauskopf's thermodynamic calculations[11] of the heavy metal content of magmatic vapor. His calculations suggest that high temperature magmatic vapor containing an appreciable amount of hydrogen chloride may transport bismuth in the form of bismuth chloride. On the basis of this theory, the following reaction may be offerred to account for the formation of bismuthinite under fumarolic conditions:

$$2\,BiCl_3 + 3\,H_2S = Bi_2S_3 + 6HCl \qquad (7)$$

This reaction may also be expressed as:

$$K_3 = \frac{X^6_{HCl} \cdot P}{X^2_{BiCl_3} \cdot X^3_{H_2S}} \qquad (8)$$

where K is the equilibrium constant, X is the molar fraction of the gaseous components in the system, and P is the total pressure on the system.

On the assumption that chemical equilibrium is attained in fumarolic gases of Showashinzan, the bismuth content of the gases may be estimated from the above relation if the equilibrium constant of the reaction, the chemical composition and pressure of the gases are given. The equilibrium constant for the reaction may be calculated in the way described above. The equation of the equilibrium constant thus obtained is:

$$\log K_3 = -17.23 + 5.34 \log T + 1.18 \times 10^{-3}\, T + 5190\, T^{-1} \qquad (9)$$

With respect to the chemical composition of the gases, Mizutani[2] showed that the variation in the hydrogen chloride and hydrogen sulfide contants of the fumarolic gases of Showashinzan could be approximately expressed as a function of the temperature. Thus the following relations, which are obtained from the analytical data of the fumarolic gases[2,12] by using the method of least squares, may be used for the estimation of the equilibrium bismuth chloride content of the gases:

$$C_{HCl} = 0.77 \times 10^{-3}\, T - 0.25 \qquad (10)$$

$$C_{H_2S} = -0.19 \times 10^{-3}\, T + 0.21 \qquad (11)$$

where C is the content of the chemical components in fumarolic gases in l./1000 l. and T is the temperature of fumarolic gases in °K. For the pressure it is assumed that the static pressure of fumarolic gases near the outlet is 1 atm. The result obtained is illustrated graphically in Fig. 4,

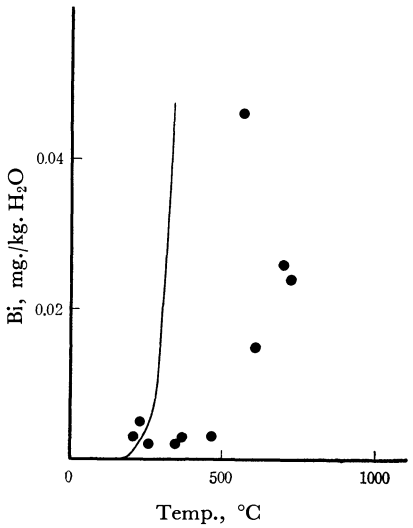

Fig. 4. Theoretical bismuth content in fumarolic gases of Showashinzan in equilibrium with Bi_2S_3 as a function of temperature at a total pressure of 1 atm., solid line.

● : observed bismuth content of fumarolic gases of Showashinzan
(0.01 mg. Bi/kg. $H_2O = 8.6 \times 10^{-4}$ ml. $BiCl_3$/1000 l. water vapor)

together with the observed bismuth contents of fumarolic gases.

Figure 4 indicates that the fumarolic gases are capable of forming bismuth sulfide when the temperature falls to about 250°C. This temperature of the formation of bismuth sulfide is in good agreement with that obtained by the field observations. This agreement suggests that the major part of the bismuth that is volatilized out of Showashinzan magma is transported as bismuth chloride and that the bismuthinite is formed by Reaction 7 in the fumarolic gases as the temperature falls. A problem, however, arises about the decrease in the actual bismuth content observed at a temperature of about 500°C. As is shown in Fig. 4, the theoretical curve deviates significantly from the observed bismuth contents at temperatures above 250°. This discrepancy may be due to uncertainties in the thermodynamic estimation or to the formation of bismuth minerals other than bismuthinite which are more stable in the fumarolic gases with temperatures between 250 and 500°C than is bismuthinite. This problem, however, remains unsolved, because available data are not enough to make discussion significant. Thus, it is necessary to find other bismuth minerals in fumaroles with gas temperatures between 250 and 500°C and to have more thermodynamic data on various bismuth compounds in order to be able to extend the discussions concerning the formation of fumarolic bismuth minerals.

Summary

A volcanic sublimate from fumarole B-1b of Showashinzan has been subjected to X-ray diffraction spectrographic and micro-chemical analyses. These analyses indicate that the sublimate consists of bismuthinite with trace amounts of lead, zinc, aluminum, copper and other substances. A possible reaction for the formation of bismuthinite in fumaroles of Showashinzan has been discussed by using the results of the analyses of fumarolic gases. It has been suggested that the bismuthinite is formed by the 2 $BiCl_3 + 3H_2S = Bi_2S_3 + 6HCl$ reaction in the fumarole.

The author wishes to express his deep appreciation to Professor Shinya Oana for his encouragement throughout this study. He is also indebted to Dr. Yoshiro Tsuzuki for his help in carrying out the preparation of the X-ray powder pattern, to Dr. Chuzo Iida for his spectrographic analysis, and to Mr. Tsutomu Sugiura for his help in the collection of samples.

Free Radical Reactions in Organic Electrode Processes. II. The Anodic Aroyloxylation of Anisole*

By Kikuhiko KOYAMA, Kunihisa YOSHIDA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received July 1, 1965)

Electrolyses of an acetonitrile solution of benzoic acid containing triethylamine have been carried out in the presence of anisole by the use of a platinum anode in an undivided cylindrical glass cell under various conditions. The electrolysis with benzoic acid at 15—23°C gave *o*- and *p*-methoxyphenyl benzoates (60%) as the main products, but the *m*-isomer could not be detected. The ratio of the isomers was 2 (*ortho*) : 1 (*para*). The other products identified in this experiment were carbon dioxide and biphenyl. The yield of the benzoates decreased when the electrolysis temperature was raised. The peaks of carbon dioxide and biphenyl on the vapor phase chromatograms in the experiment at 84°C, on the contrary, were relatively large compared with that observed in the low temperature electrolysis. Analogous products were obtained from the electrolysis of both *p*-toluic and *p*-anisic acids. These results have been compared with those obtained from the thermal decomposition of diaroyl peroxide in anisole. The mechanism of this anodic aroyloxylation of anisole has also been discussed.

It has been widely accepted that the anodic oxidation of carboxylate anions, generally known as the Kolbe electrolysis, proceeds via the direct formation of free radicals by the discharge of the carboxylate anions:[1,2]

$$RCOO^- \rightarrow RCOO\cdot + e \quad (1)$$

$$RCOO\cdot \rightarrow R\cdot + CO_2 \quad (2)$$

$$2R\cdot \rightarrow R\text{-}R \quad (3)$$

As a characteristic reaction of free radicals, the above sequence involves only the radical decomposition (Eq. 2) and the coupling reaction (Eq. 3). One might, however, expect that, when suitable conditions are employed, these intermediate radicals would react through the more varied processes observed in the other free radica reactions.[3] Indeed, this expectation has been partially realized in some studies.

It has already been suggested that the formation of some non-dimeric hydrocarbons could arise from either disproportionation or hydrogen abstraction from a solvent.[4] Evidence that the electrolysis of some carboxylates affords products which might be formed through a rearrangement of intermediate radicals has been provided by several groups of workers.[5,6]

Recently, Corey and his co-workers[7] have shown that electrolytically-generated aliphatic radicals readily undergo further oxidation to carbonium

ions, which then attack the solvent.

In addition to the findings described above, the free radicals produced in the Kolbe electrolysis are capable of attacking organic substrates, giving rise to either an addition to double bonds or a substitution on aromatic nuclei. Interesting attempts to use the Kolbe electrolysis as a source of free radicals for the additive dimerization of dienes and for the polymerization of vinyl monomers have been made by many investigators.[8-11] The anodic acetoxylation and methylation of aromatic compounds, which takes place when acetate anions are subjected to electrolysis in the presence of the aromatic compounds, have previously been reported,[12-14] even though further attention has not yet been devoted to these substitutions.

On the other hand, analogous aromatic substitutions occur during the course of the decomposition of diacyl peroxides in aromatic solvents, the thermal decomposition of some lead tetracarboxylates in aromatic compounds, and the reaction of the complexes formed from a dry silver salt of a carboxylic acid and a halogen, with aromatic compounds, and it is well recognized that these compounds could readily undergo breakdown into acyloxy and hydrocarbon radicals, which then participate in aromatic substitutions.[15]

It thus becomes desirable to compare the products of the Kolbe electrolysis, which was carried out in the presence of an aromatic compound, with those of the decomposition of the corresponding diacyl peroxides in the aromatic solvent; we can thus extend our knowledge of the characteristics of the electrochemically-generated free radicals.

The present investigation will deal with the electrolysis of a salt of some aromatic acids in the presence of anisole, not merely because of the high availability of data on the decomposition of dibenzoyl peroxide in anisole, but also because of the paucity of information on the electrochemical behavior of aromatic acids.

Results and Discussion

The electrolyses which will now be reported on were carried out under various conditions in a mixture of anisole and acetonitrile containing triethylamine. Two platinum foil electrodes were used; a detailed description of the apparatus was given in a previous paper.[13]

In all cases, the mixtures became brownish, and a sticky non-conducting polymer was frequently deposited on the anode. The current, therefore, was gradually decreased until the end of the electrolysis.

The gaseous products evolved during these electrolyses were analyzed by vapor-phase chromatography, while the liquid products were generally treated as will be described below. After the electrolyzed mixtures were worked up to remove the solvents and recover the acids, the oils remaining were distilled under reduced pressure, and the distillates were chromatographed on alumina and/or treated with alcoholic potassium hydroxide. Qualitative and quantitative determinations of phenolic isomers and neutral fractions obtained from the hydrolysis products were carried out by vapor-phase chromatography, and the acidic fractions were characterized by mixed-melting-point measurements. The crystals isolated by column chromatography were identified as the esters

themselves by the usual methods.

The results obtained with benzoic, *p*-toluic and *p*-anisic acids are summarized in Table I. Percentage yields, based on the amount of the acid not recovered at the end of the electrolysis, are given for those products which were isolated quantitatively.

As has been indicated above (Table I), the major products in each experiment were *o*- and *p*-methoxyphenol esters of the corresponding aromatic acids; no *m*-isomers could be detected. The proportions of the isomers were nearly 2(*ortho*) to 1(*para*) with benzoic acid, and 3(*ortho*) to 2(*para*) with *p*-toluic and *p*-anisic acids.

From the results of the experiment with benzoic acid, it is evident that the extent of such anodic benzoyloxylation decreases when the temperature is raised to 84°C even though the value for the isomer distribution still remains constant. It might be expected that benzene, biphenyl, methoxybiphenyls and/or phenyl benzoate would be formed, either by the attack of phenyl radicals on the anisole or by the radical-recombination reaction. There was, however, no evidence for the presence of these products, except for the biphenyl, in our present studies with benzoic acid. In addition to the above observations, the formation of 1, 2-diphenoxyethane and phenoxymethylanisoles could not be observed in these electrolyses.

The gases evolved from these electrolyses consisted of hydrogen, accompanied by a trace of carbon dioxide.

The peak of carbon dioxide on the vapor phase chromatogram in the experiment with benzoic acid at 84°C, was relatively large compared with that observed in low temperature electrolysis.

The results thus obtained indicate that the high temperature electrolysis led to the decomposition of benzoyloxy radicals into carbon dioxide and phenyl radicals, which subsequently dimerized to give biphenyl as a normal Kolbe product.

In all cases, a considerable amount of polymeric residues was obtained. Although further treatment of the residues was unsuccessful because of their low solubility in usual organic solvents, their infrared spectra indicated the presence of both methoxyl and phenyl groups.

Results similar to those with benzoic acid were obtained in the experiments with *p*-toluic and *p*-anisic acids, except that both the yield of the esters and the value for the isomer distribution slightly varied. However, the differences in the isomer distribution are insignificant since the figures based on the peak area on the vapor-phase chromatograms admit some allowances in their calculations.

The results described herein exhibit a striking contrast to those obtained from the decomposition of dibenzoyl peroxide in anisole.[16-19] It may be suggested, in principle, that the radicals from dibenzoyl peroxide, both benzoyloxy and phenyl radicals, attack the aromatic substrates, giving rise to either the benzoyloxylation or the phenylation of aromatic nuclei. Both reactions, as a matter of course, have been observed in the homolytic aromatic substitutions. However, the extent of benzoyloxylation is generally small, especially with simple and monosubstituted aromatic compounds, since benzoyloxy radicals appear to be considerably less reactive entities than phenyl radicals in aromatic substitution.

Recently, Lynch and Moore[19] have found that the homolytic benzoyloxylation of anisole with dibenzoyl peroxide, which had been neglected in previous works, occurred to an appreciable extent at 80°C, even though phenylation still proceeded as the main reaction.

The predominance of benzoyloxylation over the phenylation in our experiment clearly indicates the characteristics of the anodically-generated benzoyloxy radical. An explanation for such an anomalous stability of benzoyloxy radicals is provided by the facts that this radical is generated at the anode, at a comparatively low temperature, and that biphenyl is only product which was formed with phenyl radicals by their coupling reaction. These facts imply that the anodically-produced benzoyloxy radicals are stabilized and suppressed to undergo their rapid decarboxylation by adsorption on the electrode surface, and that their subsequent reactions take place only on the electrode surface.

If free benzoyloxy radicals existed in a bulk solution during these electrolyses, a considerable amount of methoxybiphenyls would be produced through the spontaneous decomposition of the benzoyloxy radicals.

Furthermore, it may be assumed that the formation of biphenyl arose from the coupling of the phenyl radicals which were adsorbed on the electrode or which existed in the original solvent cage, since it seems that biphenyl and phenyl benzoate are formed by the "cage" recombination reaction of the radicals generated by the decomposition of dibenzoyl peroxides.[20]

The question may be raised, then, of how such stabilized benzoyloxy radicals react with anisole to afford methoxyphenyl benzoates. The recent work by Zweig et al.[21] has indicated that anisole can also be polarographically oxidized, with the

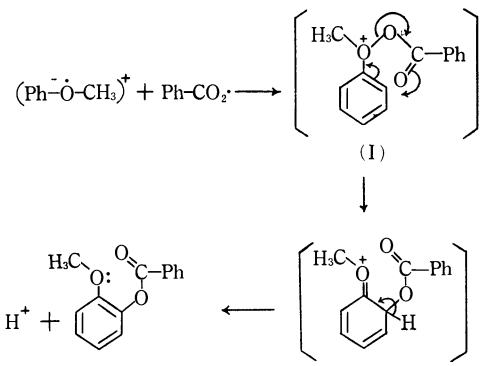
values of +1.76 V. (vs. SCE) and 19.4 μamp./mmole for the half-wave potential and the diffusion current respectively, to produce its cation radical in acetonitrile. Their finding will help provide an explanation of this question. It may suggest that the occurrence of the simultaneous oxidation of anisole molecules with benzoate anions would result in the facile attack of adsorbed benzoyloxy radicals on anisole cation radicals, which are produced by the loss of an electron from anisole at the anode, leading to the predominant formation of methoxyphenyl benzoates.

There is, as yet, an unsolved problem concerning the isomer distribution. The observed isomer distribution in this reaction is analogous to those in the anodic acetoxylation of anisole[12] and the benzoyloxylation with dibenzoyl peroxide,[19] in which no *m*-isomer could be detected and *ortho-para* orientation has been observed to be preferred. The predominance of *o*- and *p*- positions in this anodic substitution appears to be partly due to the polar character of the benzoyloxy radicals. The benzoyloxy radical, that is, seems to be an electrophilic species, it may thus be expected to attack preferentially the points of high electron density in the anisole.

However, a more satisfactory explanation for the orientation in this substitution will be given by the assumption that the coupling reaction of a benzoyloxy radical with an anisole cation radical will occur at the positions of high spin density in the cation radical. Lynch and Moore have already proposed the analogous coupling for the ortho benzoyloxylation of anisole with dibenzoyl peroxide[19]; i. e.:



Furthermore, Zweig's calculation[21] of the spin densities for the ring and oxygen positions of the anisole cation radical affords abundant evidence in support of our assumption. The values of the spin density for each position are shown in Fig. 1.

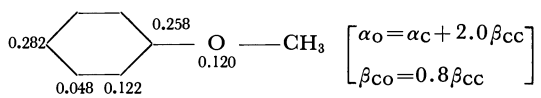


Fig. 1. The spin densities of the anisole cation radical.[21]

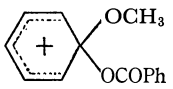
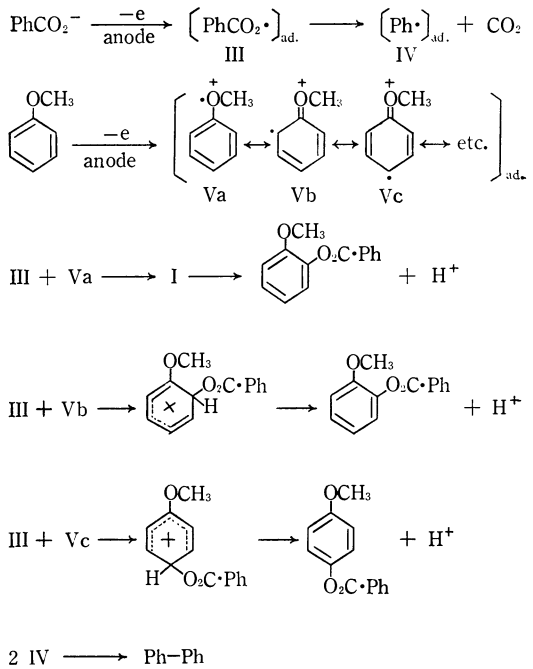
Although a high spin density on the substituted carbon atom in the benzene ring appears in their calculation, the possibility of the coupling at this position is very small because of the unfavorable steric requirement of this coupling or because of the low stability of a σ-complex (II) if one is formed in the transition state for this reaction.

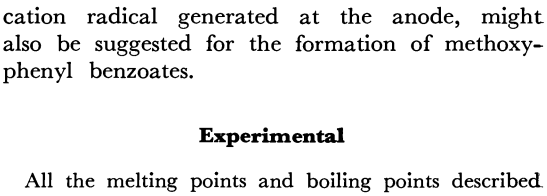


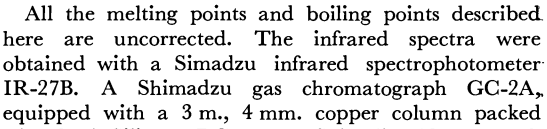
(II)

Accordingly, *o*- and *p*-methoxyphenyl benzoates would be formed by either process, a direct attack of benzoate radicals on *o*- and *p*-positions of the cation radical or a cyclic rearrangement of the indirect coupling intermediate (I), as has been suggested by Lynch et al.

On the basis of the argument described above, the most probable scheme for this anodic aromatic substitution may be shown thus:







However, another mechanism, one involving the reaction of a benzoate anion with an anisole cation radical generated at the anode, might also be suggested for the formation of methoxyphenyl benzoates.

Experimental

All the melting points and boiling points described here are uncorrected. The infrared spectra were obtained with a Simadzu infrared spectrophotometer IR-27B. A Shimadzu gas chromatograph GC-2A, equipped with a 3 m., 4 mm. copper column packed with 25% Silicone DC-550 on Shimalite (Chromosorb P) was employed for the analysis of the phenolic and

neutral fractions; it was operated at 180°C, using hydrogen as a carrier gas. A vapor-phase chromatogram of the gaseous products was also obtained on the same instrument equipped with a 0.5 m., 4 mm. silica gel column, which was operated at 13°C. The carrier gas was nitrogen.

Electrolyses were carried out in a cylindrical cell fitted with a condenser; two platinum foil electrodes (3×2 cm.; gap about 5 mm.) were also used. During the electrolyses, the cell was cooled in a bath of cold water containing ice to control the temperature, and the contents were stirred magnetically.

Materials.—Commercially-available aetonitrile was dried over anhydrous magnesium sulfate and distilled (b. p. 81°C). Triethylamine was dried over potassium hydroxide and distilled. Anisole was washed with a 10% aqueous sodium hydroxide soultion and then with water, dried over calcium chloride, and distilled before use (b. p. 155°C). Benzoic, *p*-toluic and *p*-anisic acids were obtained commercially and used without further purification.

The Electrolysis of the Ammonium Salt of Benzoic Acid in the Presence of Anisole.—A solution of benzoic acid (9.2 g., 0.075 mol.) and anisole (50 ml., 0.46 mol.) in acetonitrile (30 ml.) containing triethylamine (1.5 ml.) was electrolyzed at 15—23°C, with an applied potential of 83—100V. for 41.5 hr. at a current of 0.33—0.05 amp.; the solution thus became slightly alkaline. The current was gradually decreased from 0.33 to 0.05 amp.; 0.47 faraday had been passed through the solution by the end of the electrolysis.

The acetonitrile was removed from the electrolyzed solution under reduced pressure, and the residue was dissolved in ether. The ethereal solution was then extracted with a saturated aqueous sodium hydrogen carbonate solution, washed with 10% hydrochloric acid and then with water, dried over anhydrous magnesium sulfate, filtered, and evaporated to yield 54.3 g. of a brownish residual oil.

When the aqueous solution was acidified with 10% hydrochloric acid, 0.3 g. of the unchanged benzoic acid was recovered. The residual oil, distilled under reduced pressure, gave the following fractions:

Fraction I: b. p. 58°C/15 mmHg, 30.8 g.

Fraction II: b. p. 148—154°C/2.5 mmHg, 10.3 g.

Residue: 10.2 g.

Fraction I consisted of anisole, which was identified by vapor-phase chromatography.

The infrared spectrum of Fraction II indicated the presence of benzoates. Thus, a portion (5 g.) of Fraction II was heated under reflux with 5% potassium hydroxide in ethanol for 16 hr. After the ethanol had been removed, the residue was acidified and extracted twice with ether. The combined extracts were worked up in the usual manner in order to separate them into acidic, phenolic and neutral fractions.

From the acidic fraction, 2.3 g. of the crude benzoic acid was obtained and recrystallized from benzene. The acid melted at 119.5—121°C (lit.[22] m. p. 122.4°C); the melting point was undepressed on admixture with an authentic sample. Moreover, the infrared spectrum of the acid (KBr disk) was essentially identical with that of authentic benzoic acid.

The phenolic fraction (2.4 g.) displayed two peaks with the same retention times as those of authentic *o*- and *p*-methoxyphenols on a vapor phase chromatogram; the ratio of the isomers was determined by an internal standard method to be 2 (*ortho*): 1(*para*). Moreover, the infrared spectrum of this fraction (liquid film) exhibited absorption bands at 733, 745, 825, 1022, 1037, 1105, 1150, 1175, 1220, 1260, 1300, 1380, 1440, 1450, 1510, 1600 and 3400 cm^{-1}. These absorption bands can easily be assigned to the *o*- and *p*-methoxyphenols respectively. If the phenolic fraction contained the *m*-isomer, it should show the additional absorption bands at 690, 770, 1160, 1200, 1290, 1500 and 1600 cm^{-1} in its infrared spectrum.

The neutral fraction (0.2 g.) obtained from the hydrolysis product of Fraction II displayed three peaks on a vapor-phase chromatogram. One of them had the same retention time as biphenyl, but this peak was relatively small compared to the other ones. No further attempts were made to determine the products which correspond to the other peaks. It is, however, evident that 1, 2-diphenoxyethane, phenoxymethylanisoles and methoxybiphenyls were not major constituents of this fraction. The fraction, however, displayed major absorption peaks in the infrared spectrum at 700, 755, 1025, 1228, 1450, 1600, 2860 and 3200 cm^{-1} (liquid film).

The remaining portion (5.3 g.) of Fraction II was chromatographed on alumina and eluted with benzene to afford two crude solids after the solvent had been removed. The solid rapidly eluted was recrystallized from ethanol and gave a white crystal (2.3 g.; m. p. 57—58°C, undepressed by admixture with *o*-methoxyphenyl benzoate prepared by an entirely different method). The infrared specturm (KBr disk) was essentially identical with that of an authentic sample.

Found: C, 73.63; H, 5.14. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

The recrystallization of the slowly-eluted solid from ethanol gave a white crystal (1.5 g.), m. p. 87.5—88.1°C; the melting point of this crystal was not depressed on admixture with *p*-methoxyphenyl benzoate. The infrared spectrum (KBr disk) was identical with that of an authentic sample.

Found: C, 73.62; H, 5.64. Calcd. for $C_{14}H_{12}O_3$: C, 73.67; H, 5.30%.

The brownish polymeric residue was insoluble in ether and ethanol, but slightly soluble in acetone and benzene. The infrared spectrum exhibited characteristic absorption bands which could be assigned to the methoxyl group and to the aromatic ring.

A vapor-phase chromatographic analysis indicated that the gaseous product consisted mainly of hydrogen, plus a trace of carbon dioxide.

The Electrolysis of the Benzoate Anion in the Presence of Anisole at a High Temperature.—The electrolysis was carried out at 84°C, with an applied potential of 55—98 V., at a current of 0.1—0.3 amp., for 59 hr. The results obtained from this electrolysis are summarized in Table I.

The peaks of carbon dioxide and biphenyl on the vapor-phase chromatograms were relatively large compared with those observed in a low-temperature electrolysis.

The Electrolysis of the Triethylammonium Salt of *p*-Toluic Acid in the Presence of Anisole.—A solution of *p*-toluic acid (10.2 g., 0.075 mol.) and

22) "The Merck Index" (seventh edition), Merck & Co., Inc., New Jersey (1960), p. 133.

anisole (50 ml., 0.46 mol.) in acetonitrile (30 ml.) containing triethylamine (1.5 ml.) was electrolyzed at 10°C, for 66 hr. A current of 0.1 amp. was maintained, while the voltage was varied from 50 to 99 V. By the end of electrolysis, about 0.25 faraday had been passed through the solution.

The procedure used for the isolation and the identification of the product was identical with that described in the experiment with benzoic acid.

After the work-up of the electrolyzed mixture, 2.6 g. of *p*-toluic acid was recovered. The distillation of the remaining oil under reduced pressure gave unreacted anisole (ca. 24.3 g.), a fraction (4.7 g.), b. p. 160—166°C/2.7 mmHg, and a residue.

The hydrolysis of 3.5 g. of the high-boiling fraction with 5% potassium hydroxide in ethanol for 20 hr. afforded an acid (1.7 g.), phenols (1.6 g.) and neutral substances (0.3 g.). The acid was characterized as *p*-toluic acid, m. p. 179—180.5°C, undepressed on admixture with an authentic sample. The infrared spectrum of the acid was identical with that of the authentic sample. The phenols were shown to be *o*- and *p*-methoxyphenols by vapor-phase chromatography; the ratio of these isomers was found to be 3 (*ortho*): 2 (*para*).

In addition, two crystals were isolated by chromatography; they were identified as *o*- and *p*-methoxyphenyl *p*-toluates.

The melting point of *o*-methoxyphenyl *p*-toluate was 75—76°C; infrared spectrum (KBr disk): 750, 835, 1020—1035 (2 bands), 1065, 1100, 1160, 1265, 1450, 1490, 1600 and 1710 cm^{-1}.

Found: C, 74.03; H, 5.91. Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.83%.

The infrared spectrum of *p*-methoxyphenyl *p*-toluate, m. p. 95.5—96.5°C, exhibited characteristic bands at 835, 1025, 1035, 1065, 1100, 1165, 1200, 1265, 1450, 1500, 1600 and 1715 cm^{-1} (KBr disk).

Found: C, 74.27; H, 6.08. Calcd. for $C_{15}H_{14}O_3$: C, 74.36; H, 5.83%.

The Electrolysis of the Triethylammonium Salt of *p*-Anisic Acid in the Presence of Anisole. —A solution of *p*-anisic acid (11.4 g., 0.075 mol.) and anisole (50 ml., 0.46 mol.) in acetonitrile (30 ml.) containing triethylamine (4 ml.) was electrolyzed at 8—12°C, for 100 hr. The current was maintained at 0.1 amp., while the voltage was increased from 40 to 95 V.

After the electrolysis, unchanged anisic acid (3.1 g.) was recovered. The residual oil was distilled under reduced pressure to give the following fractions:

Fraction I: b. p. 46°C/11 mmHg, 23.4 g.

Fraction II: b. p. 92—181°C/3 mmHg, 2.1 g.

Residue: 9.4 g.

Fraction I was shown by vapor-phase chromatography to consist of anisole. A portion (0.8 g.) of Fraction II was submitted to hydrolysis. An acidic fraction obtained from the hydrolysis product consisted of *p*-anisic acid (0.4 g.), m. p. and m. m. p. 184°C. The infrared spectrum was identical with that of an authentic sample.

The phenolic fraction (0.4 g.) was found to be a mixture of *o*- and *p*-methoxyphenols (3 : 2 ratio).

Seven peaks were indicated on the vapor-phase chromatogram of the neutral fraction (0.1 g.) separated from the hydrolysis product, but this fraction could not be further identifed.

The Preparation of Authentic Samples. — Methoxybiphenyls were prepared by Gomberg's method,[23] and *o*- and *p*-methoxyphenyl benzoates were prepared by the reaction of benzoyl chloride with the corresponding methoxyphenols. 1, 2-Diphenoxyethane was prepared according to the directions of Drahowzal et al.[24] The syntheses of authentic phenoxymethylanisoles were carried out by the method of Claisen.[25]

The Temperature Dependence of the Radio-Frequency Polarographic Wave Height

By Tomihito KAMBARA and Shogo WATARAI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received July 1, 1965)

When the radio-frequency polarographic current, i_{RF}, is regarded approximately as the difference between the Fournier current and the ordinary DC polarographic current, i_{DC}, one can elucidate the temperature dependence of i_{RF}. It may be theoretically predicted that the relative temperature coefficient of i_{RF} for the completely-reversible system is less by 0.66% than that of i_{DC}. The plot of log $(i_{RF} \cdot T^2)$ against $1/T$, where T is the absolute temperature, gives two straight lines which join each other at a knick, coresponding to the transition from a completly reversible process to a less reversible one. Experiments with thallium(I) and zinc(II) ions in various supporting electrolytes reveal the essential validity of the present theory.

It was reported in our previous study[1] that the AC polarographic peak heights of the zinc ion in various supporting electrolytes, therefore with varying reversibilities, show different temperature dependencies. In the present study the effect of the temperature on the radio-frequency (R-F) polarographic wave heights observed with various redox systems will be investigated.

Theoretical

The R-F polarographic method developed by Barker[2,3] and the theoretical treatment of the Faradaic rectification developed by several authors[4-9] offer many complicated problems. Because of the mathematically-complicated expression for the R-F polarographic process, we will here employ the simplified concept suggested by Yasumori[10] that, during the half-period of R-F modulation, the electrolytic current observed is the Fournier current,[11] while the signal recorded in R-F polarography is the Fournier current minus the ordinary DC polarographic current, i_{DC}, as is illustrated in Fig. 1.

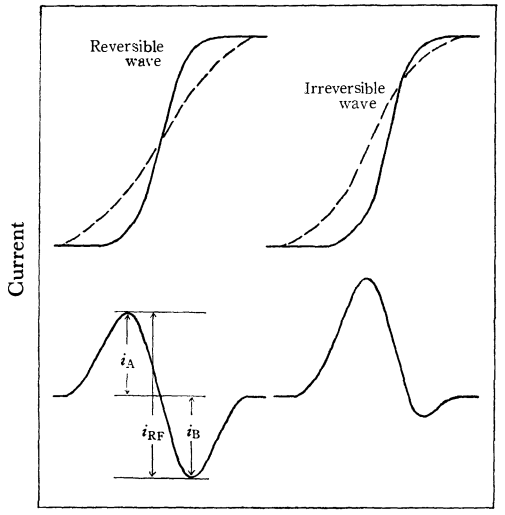

Fig. 1. Relation between the ordinary DC polarographic wave (full line), the Fournier polarogram (dashed line) and the R-F polarogram. (The construction method for evaluating the R-F wave heights, i.e. i_A, i_B and i_{RF}, are also schematically illustrated.)

Applying the Senda-Tachi[12] theory for the Fournier polarogram, one can derive the following expressions for a reversible system:

$$i_{DC} = j_0 i_d = \frac{i_d}{2}(1-\tanh x) \tag{1}$$

$$x = \frac{nF(E-E_{1/2})}{2RT} \tag{2}$$

$$i_F = i_{DC} + \frac{i_d}{4}\left(\frac{nF}{2RT}\right)^2 \frac{d^2 j_0}{dx^2} \Delta E^2 \tag{3}$$

$$i_{RF} = i_F - i_{DC} = \frac{i_d}{4}\left(\frac{nF}{2RT}\right)^2 \frac{d^2 j_0}{dx^2} \Delta E^2$$

$$= \frac{i_d}{4}\left(\frac{nF}{2RT}\right)^2 \Delta E^2 \frac{\sinh x}{\cosh^3 x} \tag{4}$$

In these equations, i_d is the DC diffusion current and ΔE the amplitude of the R-F voltage; the other symbols have their usual meanings.

The maximum and minimum in the R-F polarogram are obtained by solving $di_{RF}/dE = 0$ at:

$$x = \pm\frac{1}{2}\ln(2+\sqrt{3}) = \pm 0.6584 \tag{5}$$

Thus, it is found that:

$$i_{RF} = k \cdot i_d \cdot T^{-2} \cdot \Delta E^2 \tag{6}$$

where k is the proportionality factor. On the other hand, one has:

$$i_d \propto D^{1/2} \tag{7}$$

$$D = D_0 \cdot \exp\frac{-\Delta H_D}{RT} \tag{8}$$

where ΔH_D is the activation heat of diffusion.

Hence, it may be seen that:

$$\frac{1}{i_{RF}} \cdot \frac{di_{RF}}{dT} = \frac{1}{i_d} \cdot \frac{di_d}{dT} + \frac{2}{T} \tag{9}$$

It is thus expected that, for the completely reversible electrode process the R-F wave height would have a relative temperature coefficient less by 0.66% than that of the ordinary DC step height. Further, the plot of $\log(i_{RF}T^2)$ vs. $1/T$ would give a straight line in the reversible region.

Experimental

A Yanagimoto polarograph, type PF-500, was used; the radio frequency was 455 kC, and the square-wave frequency was 200 c. p. s.

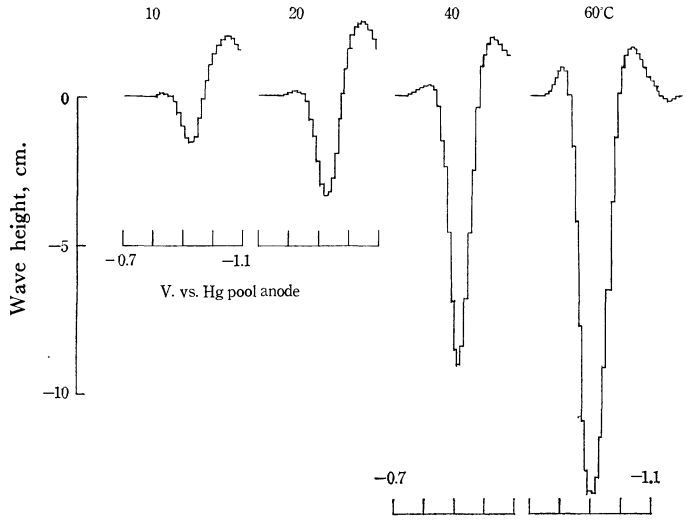

Fig. 2. R-F polarograms of 10^{-4} M Zn^{2+} in 1 M KCl at various temperatures.

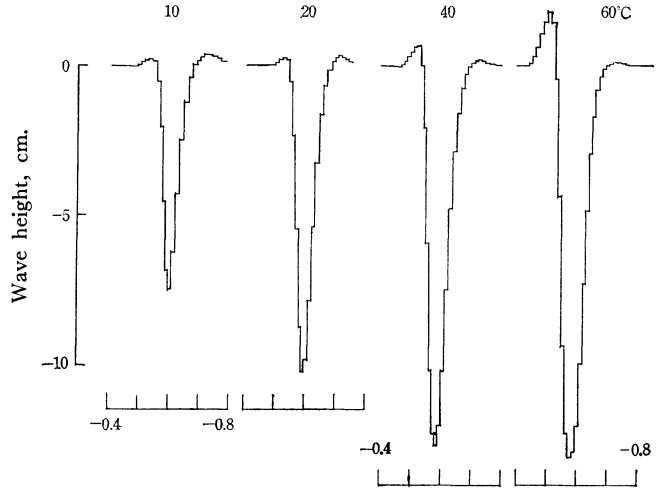

Fig. 3. R-F polarograms of 5×10^{-5} M Zn^{2+} in 1 M KI at various temperatures.

Table I. Relative temperature coefficient of the R-F polarographic wave height in percent

Absolute temp. T°K	10^{-4} M Zn^{2+} in 1 M KCl	10^{-4} M Zn^{2+} in 1 M KBr	5×10^{-5} M Zn^{2+} in 1 M KI	10^{-4} M Tl^{+} in 1 M KCl
283	7.6	6.5	3.9	4.3
293	6.4	5.9	2.1	2.6
303	5.0	4.1	1.2	1.8
313	4.2	1.7	0.6	1.1
323	1.7	0.6	0.5	0.6
333	1.0	0.3	0.3	0.4

The drop time was controlled to about 4 sec. at a constant mercury level, and the low frequency current was gated to a time interval from 2 to 3 sec. for each drop. The R-F voltage was 5 V., and the amplifier and recorder sensitivities were kept to 0.1.

Results

Figures 2 and 3 show some examples of the R-F polarograms recorded. The wave hieghts are plotted against the temperature in Fig. 4; the temperature coefficient is summarized in Table I. In Fig. 5 $\log(i_{RF}T^2)$ is plotted against the reciprocal of the absolute temperature.

Discussion

The temperature corresponding to the knick in the plot of $\log(i_{RF}T^2)$ vs. $1/T$ would indicate the transition of the rate-determining step from diffusion to electron-transfer. The transition temperature, as evaluated with AC peak heights

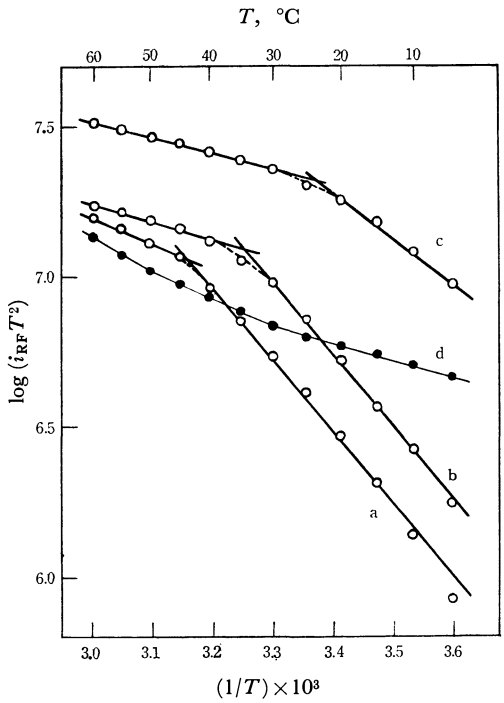

Fig. 5. log ($i_{RF}T^2$) vs. $1/T$.

a Zn^{2+} in KCl; b Zn^{2+} in KBr; c Zn^{2+} in KI; d Tl^{+} in KCl. In curve c i_{RF} was doubled for purposes of comparison.

in our previous study,[1] coincides well with that obtained by the present R-F method.

As for the R-F wave height of thallium(I), it may be safe to say that, in the temperature region higher than 35°C, another mechanism plays a role and that the temperature coefficient increases more rapidly than expected with an assumption of complete reversibility.

Summary

On the simplified model that the R-F polarographic current is the difference between the Fournier current and the ordinary DC polarographic current, one can clear up the temperature dependence of the R-F wave height. It has been concluded that, in the reversible case, the temperature coefficient of the R-F wave height is less by 0.66% than that of the DC step height. Further, a new method, in which the logarithm of the product of the R-F wave height and the square of the absolute temperature is plotted against the reciprocal of the absolute temperature, has been introduced and examined. In the reversible region the above plot gives a straight line, the slope of which corresponds to that of log i_{DC} plotted against $1/T$. At lower temperatures the reversibility decreases and the above plot shows a break, indicating the transition from a reversible electrode process to an irreversible one.

Further Study of Syntheses of *dl*-2, 3-Dicarboxycyclopentylacetic Acids

By Kazu KUROSAWA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Heitaro OBARA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa

(Received July 2, 1965)

The assignment of the configuration of racemic *trans-trans* and *cis-cis*-2, 3-dicarboxycyclopentylacetic acid previously proposed has been confirmed by the syntheses of these compounds through other unambiguous reaction sequences. The *trans-cis*-isomer has been prepared by the epimerization of the 3-carboxyl group of the *cis-cis*-isomer, but the attempt to synthesize the fourth isomer (*cis-trans*) has been unsuccessful.

It has been reported that the chromic acid oxidation of tetrahydroanhydrodesoxyaucubigenin (I) gives the optically active *cis-cis*-2, 3-dicarboxycyclopentylacetic acid (IIa) as the key compound for determining the carbon framework of aucubin; from this the *trans-trans* (IIb) and *trans-cis** isomer (IIc) can be derived by the epimerization of either one of two carboxyl groups attached to the cyclopentane ring. Moreover, the stereochemistry of each isomer has been established, along with the chemical properties and the course of formation.[1]

The synthesis of *dl-trans-trans*-tricarboxylic acid (IIb), on the other hand, has been accomplished by one of the present authors[2] starting from the Michael condensation of dimethyl Δ^2-cyclopentene-1, 2-dicarboxylate (III) with diethyl malonate.[3] IIb was transformed to the isomer, the configuration of which has been presumed to be a *cis-cis* relation (IIa) because of its identity with the natural IIa (see below).

The present paper will describe the syntheses of IIa and IIb according to alternative reaction sequences[4] and the isomerization of IIa to IIc.

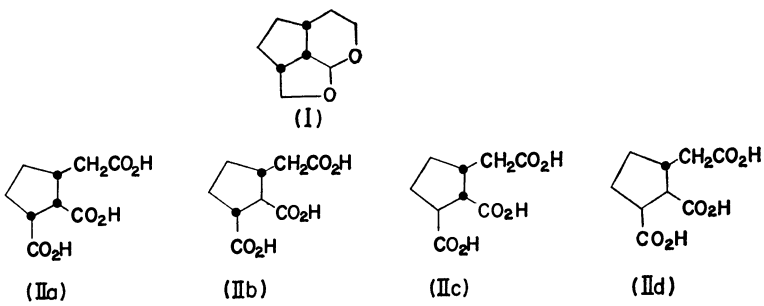

Fig. 1

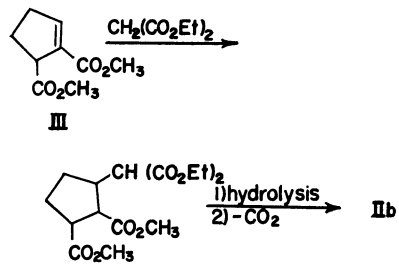

Fig. 2

* In this and other designations in this paper the relationship between two carboxyl groups attached to the cyclopentane ring is given first, and that between the carboxymethyl group and the adjacent carboxyl group, second.

1) a) S. Fujise, H. Obara and H. Uda, *Chem. & Ind.*, **1960**, 289; *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **81**, 677 (1960). b) H. Uda, ibid., **81**, 1865 (1960).

2) H. Obara, ibid., **81**, 1871 (1960).

3) J. Grimshaw and H. R. Juneja (*Chem. & Ind.*, **1960**, 656) stated, without any evidence, that the migration of the double bond in III took place, giving the Δ^1-isomer, before the addition of diethyl malonate, and that, therefore, the final product was apparently 1, 2-dicarboxycyclopentylacetic acid (IV), not IIb. This possibility, however had already been excluded by the synthesis of IV through an unambiguous route,[2] and unlike III, the Δ^1-isomer undergoes the Michael addition accompanied by a migration of the double bond to the Δ^2-position, giving the same adduct as from III.[2]

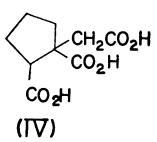

Fig. 3

4) An attempt to prepare IIa by the Dieckmann cyclization of diethyl 3-ethoxycarbonylmethyladipate was unsuccessful. S. Fujise, H. Obara and K. Kurosawa, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **82**, 370 (1961).

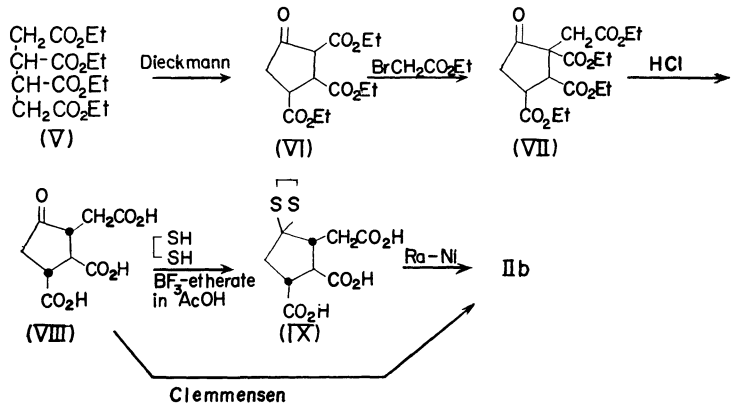

Fig. 4

2, 3, 4 - Triethoxycarbonylcyclopentanone (VI), which appeared to be the most satisfactory precursor for the synthesis of IIb, was prepared from tetraethyl butane-1, 2, 3, 4-tetracarboxylate (V) by the Dieckmann cyclization in a good yield. The condensation of the sodio derivative of VI with ethyl bromoacetate afforded a keto tetraester (VII), b. p. 195—210°C/2 mmHg; then VII was hydrolyzed and decarboxylated to yield 2, 3-dicarboxy-5-oxo-cyclopentylacetic acid (VIII), m.p. 215—216°C, by refluxing it with 6 N hydrochloric acid. The conversion of VIII into IIb was achieved by transforming it into a thioketal (IX) and then subjecting the IX to desulfurization with Raney nickel or directly by the Clemmensen reduction. The IIb thus obtained, m. p. 160°C, was identical with a sample of IIb which had been prepared from III, as has been mentioned above; this was determined by a comparison of the infrared spectra and by a mixed melting point determination. Since three substituents of VIII or of the Michael addition product of III will be preferentially oriented towards sterically less hindered (in another words, thermodynamically more stable) directions in such a strongly basic reaction condition, IIb must have the expected *trans-trans* arrangement.

In a series of experiments on the naturally-derived compounds, the *trans-trans* isomer (IIb), prepared by the epimerization of the triester of the *cis-cis*-tricarboxylic acid (IIa), produced the same dimeric trianhydride (X) as that obtained from IIa, involving the anomalous isomerization of one carboxyl group towards the sterically

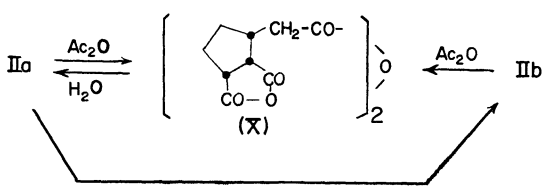

Fig. 5

unfavorable side, upon being treated with boiling acetic anhydride; X returned to IIa on hydrolysis.[1b] This process has been applied to the racemic IIb, giving an isomer.[2] However, there has been no definite evidence about the stereochemistry of this isomer; the assignment of *cis-cis* relationship as in the natural IIa has been tentatively made only on the basis of the course of formation and its identity with the natural IIa. In order to clarify this point, an alternative synthesis of IIa was carried out. The catalytic hydrogenation of the unsaturated lactone ester (XI) afforded the corresponding saturated compound, *cis-cis*-2-(2'-hydroxyethyl)-5-carboxycyclopentylcarboxylic acid δ-lactone (XII), resulting from the *cis* attack of hydrogen on the double bond from the side opposite an allylic substituent.[5] The chromic acid oxidation of XII gave the desired *cis-cis* isomer (IIa), m. p. 176—177°C,[5,6] which was identical with a sample of IIa derived from IIb via the dimeric trianhydride (X) as shown by a study of the infrared spectra and by a mixed melting point determination. These results provide convincing evidence for the correctness of the assumed reaction course from IIb to IIa via X and for the stereochemistry of IIa.

The procedure which was employed in the conversion of the natural IIa to another isomer, IIc,[1b] appeared to be most suitable for the synthesis of the third isomer, *trans-cis*-tricarboxylic acid (IIc). Upon being heated over its melting point, IIa was converted into an anhydride carboxylic acid (XIII) with a loss of water; it was then esterified with diazomethane to yield an anhydride ester (XIV). The methanolysis of XIV, followed by the epimerization of the resulting diester carboxylic acid (XV, R=CH_3), without purification, with sodium methoxide in boiling methanol,

5) For a preliminary communication, see K. Kurosawa and S. Fujise, *Chem. & Ind.*, **1963**, 1688; for a full publication, see K. Kurosawa, H. Obara and H. Uda, This Bulletin, **39**, 530 (1966).

6) The reported melting point of IIa is 161—162°C.[2] A further purified sample melts at 173—174°C.

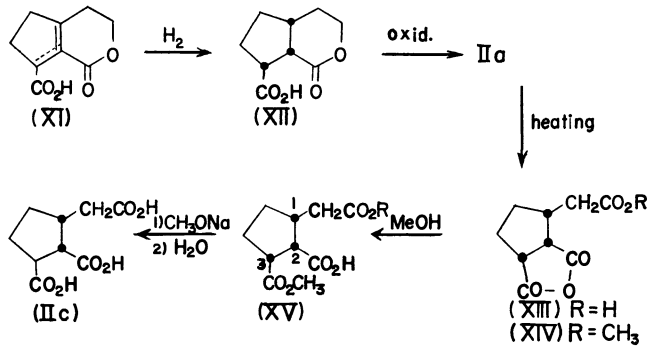

Fig. 6

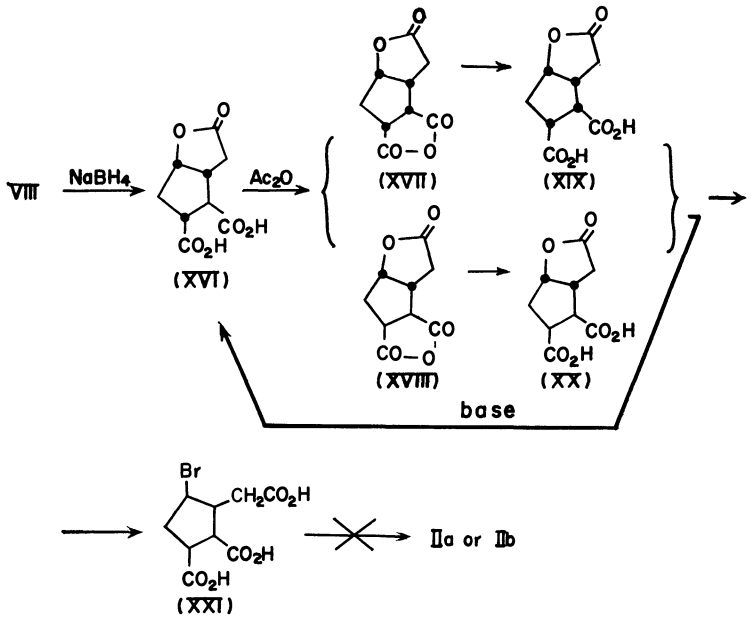

Fig. 7

and then the hydrolysis by addition of water produced the desired isomer (IIc) m. p. 156—157°C.[7] The method of synthesis and the chemical behavior[8] indicate that IIc must have a *trans-cis* configuration.

The following is an approach to the synthesis of the remaining *cis-trans* enantiomer (IId). The reduction of the keto tricarboxylic acid (VIII) with sodium borohydride afforded predominantly a lactone dicarboxylic acid (XVI), m. p. 192—193°C. The treatment of XVI with boiling acetic anhydride produced a single lactone anhydride, m. p. 164—165°C, accompanied by the rearrangement of one carboxyl group, the infrared spectrum of which manifested both succinic-type anhydride and γ-lactone carbonyl absorption (1850 and 1769 cm^{-1} [9] respectively). This compound is represented as the formula XVII or XVIII, according to the isomerization of either one of the two carboxyl groups. Thus, a lactone dicarboxylic acid, m. p. 198—199°C, isomeric with XVI and obtained by hydrolysis, possesses the structure XIX or XX respectively; this isomeric lactone carboxylic acid could be isomerized back to the starting material (XVI) on treatment with

7) The facts that the XV (R=H) naturally derived from XIII could undergo intramolecular anhydride (glutaric-type) formation, without isomerization, with hot acetic anhydride and that, after epimerization, the yield of the *trans-trans* isomer (IIb), evidently produced through the esterification of the C-2 carboxyl group,[1b] was very low prove the preferential ester-formation of the C-3 carboxyl group of the anhydride group in XIV on methanolysis and also indicate that the exclusive epimerization of the ester group takes place.

8) In addition to the glutaric-type anhydride formation in XV (R=H),[7] the thermostability of the natural IIc (no change upon heating) confirms the relative configuration of the three substituents of IIc to be *trans-cis*, since, if the configuration of the C-2 and C-3 carboxyl groups is *cis*, they must easily produce a succinic-type anhydride like IIa → XIII.[1b]

9) A succinic-type anhydride usually shows two carbonyl absorption bands, near 1855 and 1775 cm^{-1}. The latter hand in this compound presumably overlap with the lactone absorption.

base. Supposing that the epimerization of a carboxyl group takes place in the same mode as in the case of IIb→X during anhydride formation, the isomeric lactone dicarboxylic acid must be XIX with a *cis-syn-cis* configuration, whereas the epimerization of the other carboxyl group gives the alternative *cis-anti-cis* isomer (XX). The latter possibility seems to be sterically more favorable and has not, therefore, been eliminated. If this compound is actually XX, the expected *cis-trans* isomer (IId) would be obtained by the displacement of the hydroxyl group with hydrogen. The reaction of the compound (XIX or XX) with hydrogen bromide in anhydrous ethanol yielded a non-crystalline substance, which was supposed to be a bromotricarboxylic acid (XXI) because of the disappearance of lactone carbonyl absorption in its infrared spectrum. Successive attempts to reduce XXI to IIa or IId by means of zinc - hydrochloric acid or by means of catalytic hydrogenation under various conditions were all unsuccessful. Consequently, the preparation of IId or even the confirmation of the stereochemistry of the isomerized lactone dicarboxylic acid (XIX or XX) have not yet been accomplished.

Finally, a few remarks regarding the characterization of the Δ^1- and Δ^2-cyclopentene-1, 2-dicarboxylic acids, XXII and XXIII, used for the synthetic work[2] would be appropriate. The Δ^2- compound (XXIII), m. p. 144—145°C, has been obtained

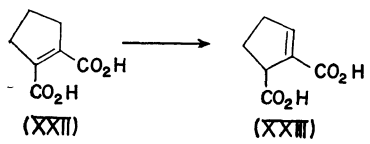

Fig. 8

from the Δ^1-isomer (XXII), m. p. 177—178°C, by treatment with boiling concentrated aqueous potassium hydroxide, involving a double-bond migration.[2,10] The further purification of this isomerized substance, m. p. 144—145°C, indicated that it was still a mixture of Δ^1- (XXII) and Δ^2-isomers (XXIII), which could be separated in the pure state. The structures of XXII and XXIII were verified beyond doubt by infrared and nuclear magnetic resonance spectroscopy. The former (XXII): 179—180°C, ν^{KBr}: 1685, 1620, 1585 and 1550 cm^{-1}, δ[11] = 2.97 (triplet, 4H, $-CH_2-C=$) and 1.67 (quintet, 2H, $-CH_2-$), pK_a : 3.36 and 7.18. The latter (XXIII): m. p. 178—179°C, ν^{KBr}: 1700, 1672 and 1636 cm^{-1}, δ = 4.12 (diffused singlet, 1H, $-CH=$) and 2.48 (multiplet, 5H, $-CH_2-$ and $-CH-$), pK_a: 4.03 and 5.92 respectively.

11) Measured in a pyridine solution at 60 Mc. Chemical shifts are given in p.p.m. units, using tetramethylsilane as an internal standard.

Experimental

Tetraethyl Butane-1, 2, 3, 4-tetracarboxylate (V). —Commercial *cis*-Δ^4-cyclohexene-1, 2-dicarboxylic acid anhydride (100 g.) was dissolved into a solution of 75 g. of sodium carbonate, 2 kg. of cracked ice and 3 l. of water. To this solution 500 g. of well pulverized potassium permanganate was added portion by portion with efficient stirring; then the reaction mixture was stirred for 10 hr. with the temperature kept below 50°C. The precipitated manganese dioxide was filtered off, and the light brown filtrate was acidified (Congo red) with concentrated hydrochloric acid and evaporated to dryness. The residual solid was dried in vacuo over sulfuric acid and then extracted with boiling acetone three times; the acetone extracts were concentrated to a small volume, giving 55 g. of crude crystals. The second crop (21 g.) was obtained from the mother liquor. Recrystallization from acetone yielded 60 g. (39%) of pure butanetetracarboxylic acid, m. p. 188—189°C.

A solution of 380 g. of the above tetracarboxylic acid in 1.5 l. of ethanol containing 1 ml. of concentrated sulfuric acid was refluxed for 15 hr. The ethanol was removed by distillation, and the residue was again esterified with fresh ethanol by refluxing for an additional 15 hr. The ethanol was distilled off, and the residual oil was allowed to distill in vacuo. Tetraester (V), b. p. 178—183°C/1.0 mmHg; 395 g., 70%, was thus obtained.

2, 3, 4-Triethoxycarbonylcyclopentanone (VI).— To a suspension of 2.5 g. (0.11 g.atom) of finely-granulated sodium metal in 150 ml. of hot toluene there was carefully added 38 g. (0.11 mol.) of the tetraester (V) with vigorous stirring, so as to maintain a gentle refluxing and continuous evolution of hydrogen; after the addition of sodium, the stirring was continued for 2 hr. under refluxing. Then the cooled reaction mixture was poured into ice water containing an almost equimolar amount of acetic acid or hydrochloric acid with vigorous stirring. The water layer was separated and extracted with toluene two times. The combined toluene extracts were washed with water, dried over anhydrous sodium sulfate, and freed from toluene. The residual liquid was distilled in vacuo to give 25.5 g. of triethoxycarbonylcyclopentanone (VI), b. p. 175—182°C/2—3 mmHg (a slight decomposition was observed).

2, 3, 4-Triethoxycarbonyl-2-ethoxycarbonylmethylcyclopentanone (VII). — The sodio-derivative of VI was prepared from 85 g. (0.29 mol.) of VI and 7 g. (0.30 g.atom) of well-granulated metallic sodium in 400 ml. of anhydrous toluene in the usual manner. To this solution there was added dropwise 62 g. of ethyl bromoacetate with stirring and water-cooling, and the reaction mixture was heated under reflux for 6 hr. Then the mixture was poured into ice water, and the water layer was extracted with the same solvent three times. The combined toluene extracts were washed with dilute sodium bicarbonate solution and water, and then dried over anhydrous sodium sulfate and freed from toluene to give viscous liquid. Distillation in vacuo afforded 84 g. (76%) of 2, 3, 4,-triethoxycarbonyl- 2 -ethoxycarbonylmethylcyclopentanone (VII), b. p. 195—210°C/2.0 mmHg, ν^{neat} 1760 and 1733 cm^{-1}. The additional absorption bands at

1685 and 1638 cm^{-1} can be attributed to an *O*-alkylated by-product.

2, 3 - Dicarboxy - 5 - oxo-cyclopentylacetic Acid (VIII).—The mixture of VII and *O*-alkylated by-product from the preceding experiment (5 g.) was refluxed with 50 ml. of 6 N hydrochloric acid for 6 hr.; then the solvent was removed under reduced pressure. The residual viscous material crystallized when treated with ethyl acetate, and recrystallization from ethyl acetate gave 1.8 g. (47%) of a pure keto tricarboxylic acid (VIII), m. p. 215—216°C, ν^{KBr} 1747 (cyclopentanone) and 1700 cm^{-1} (carboxyl).

Found: C, 47.21; H, 4.45. Calcd. for $C_9H_{10}O_7$: C, 46.96; H, 4.38%. pK_{a_1} 3.32, pK_{a_2} 4.76, pK_{a_3} 5.92.

***trans - trans* - 2, 3 - Dicarboxycyclopentylacetic Acid (IIb).**—Keto tricarboxylic acid (VIII) (1.0 g.) was treated with 1.5 ml. of ethane dithiol and 1.5 ml. of boron trifluoride etherate, and then the mixture was allowed to stand at room temperature for 24 hr. The separated amorphous solid was collected by filtration, yielding 1 g., m. p. 190°C (decomp.) (no ketonic band in infrared); this was then subjected to desulfurization without purification. The above thioketal was refluxed with Raney nickel, prepared from 30 g. of alloy, in 100 ml. of 70% aqueous ethanol for 4 hr. Removal of the catalyst, followed by acidification and then evaporation of the solvent, gave crude crystals. Pure *trans-trans*-2,3-dicarboxycyclopentylacetic acid (IIb), 0.1 g., m. p. 160°C, was obtained by recrystallization from ethyl acetate, and showed an infrared spectrum completely identical with that of a sample prepared by the previously-reported procedure, starting from the Michael addition of dimethyl Δ^2-cyclopentene-1, 2-dicarboxylate (III) and diethyl malonate,[2] and there was no depression in a mixed melting point determination.

***cis-cis*-2,3-Dicarboxycyclopentylacetic Acid (IIa).**—A solution of *cis-cis*-2-(2'-hydroxyethyl)-5-carboxycyclopentylcarboxylic acid δ-lactone (XII)[5] (1.5 g.) in 250 ml. of glacial acetic acid was treated with a solution of 2.0 g. of chromium trioxide and 3.5 ml. of concentrated sulfuric acid in 7 ml. of water; the oxidation was then allowed to proceed at room temperature for three days. The excess oxidant was decomposed by addition of methanol, almost all of the acetic aicd was removed by distillation under reduced pressure with the aid of water, and then the solution was neutralized with a minimum amount of solid sodium bicarbonate, keeping the Congo red acidity. The resulting solution was saturated with sodium chloride and extracted continuously with ether for 65 hr. Evaporation of the ether extract gave 0.9 g. (51%) of *cis-cis*-2, 3-dicarboxycyclopentylacetic acid (IIa). The pure sample recrystallized from ethyl acetate had a melting point of 176—177°C.

Found: C, 50.00; H, 5.63. Calcd. for $C_9H_{12}O_6$: C, 50.00; H, 5.60%.

The infrared spectrum of this substance was completely indistinguishable from that of the sample obtained from IIb by isomerization via dimeric trianhydride (X),[2] and the mixed melting point of these samples was not depressed.

***trans-cis*-2, 3-Dicarboxycyclopentylacetic Acid (IIc)**—The *cis-cis* isomer (IIa) was heated over its melting point in a sublimation apparatus for half an hour and then distilled under diminished pressure. The resulting anhydride carboxylic acid (XIII) was treated with excess ethereal diazomethane. The anhydride methyl ester (XIV) (0.4 g.) thus obtained was refluxed in 4 ml. of anhydrous methanol for 1 hr., and, after removal of the methanol, a methanolic solution of sodium methoxide freshly prepared from 0.2 g. of metallic sodium and 10 ml. of anhydrous methanol was added and refluxing was continued for 2 hr. After water (3 ml.) had then been added, the reaction mixture was again refluxed for 30 min. to complete hydrolysis. The hydrolysate was worked up in the usual manner, i. e., evaporation of the methanol, dilution with water, acidification with mineral acid, and finally extraction with ethyl acetate, to give 0.25 g. of a crude product, m. p. 127—144°C. Recrystallization from ethyl acetate yielded pure *trans-cis*-2, 3-dicarboxycyclopentylacetic acid (IIc), m. p. 156—157°C, which revealed a different infrared spectrum from that of either IIa or IIb.

Found: C, 49.66; H, 5.56. Calcd. for $C_9H_{12}O_6$: C, 50.00; H, 5.60%.

2, 3-Dicarboxy-5-hydroxycyclopentylacetic Acid γ-Lactone (XVI).—To a solution of 0.2 g. of VIII in 5 ml. of water containing 0.15 g. of sodium hydroxide, there was added 0.1 g. of sodium borohydride; the reaction mixtrure was then stirred at 80°C for 2 hr. After acidification with concentrated hydrochloric acid, the solution was evaporated to dryness. The residual solid was treated with ethyl acetate, and then, after removal of the insoluble inorganic material by filtration, the filtrate was passed through a column of silica gel. Evaporation of the ethyl acetate gave 0.04 g. of a lactone dicarboxylic acid (XVI), m. p. 192—193°C, ν^{KBr} 1769 and 1685 cm^{-1}, pK_{a_1} 3.34, pK_{a_2} 5.51.

Found: C, 50.18: H, 4.82. Calcd. for $C_9H_{10}O_6$: C, 50.47; H, 4.71%.

2, 3-Dicarboxy-5-hydroxycyclopentylacetic Acid Anhydride γ-Lactone (XVII or XVIII).—A solution of 0.17 g. of XVI in 20 ml. of acetic anhydride was refluxed for 2 hr. After removal of the acetic anhydride under reduced pressure, the residual viscous liquid was distilled in vacuo using a sublimation apparatus and then treated with ethyl acetate to give a crystalline product. Recrystallization from ethyl acetate yielded 0.02 g. of pure anhydride lactone (XVII or XVIII), m. p. 164—165°C, ν^{KBr} 1850 and 1769 cm^{-1}.

Found: C, 55.25; H, 4.20. Calcd. for $C_9H_8O_5$: C, 55.10; H, 4.11%.

Isomeric 2, 3 - Dicarboxy-5-hydroxycyclopentylacetic Acid γ-Lactone (XIX or XX).—The anhydride lactone from the preceding experiment (0.17 g.) was treated with 5 ml. of water at 100°C for 30 min. and then dried up and recrystallized from ethyl acetate to give 0.13 g. (68%) of the isomeric lactone dicarboxylic acid (XIX or XX), m. p. 198—199°C, ν^{KBr} 1730 and 1692 cm^{-1}, pK_{a_1} 3.91, pK_{a_2} 5.92.

Found: C, 50.86; H, 4.69. Calcd. for $C_9H_{10}O_6$: C, 50.47; H, 4.71%.

Ethyl Diethoxycarbonyl - 5 - bromocyclopentylacetate (XXI).—The isomeric lactone dicarboxylic acid was treated overnight with anhydrous ethanol saturated with hydrogen bromide at room temperature. The hydrogen bromide and ethanol were then removed under reduced pressure to give a bromoester (XXI) (the lactone absorption disappeared) which,

without further purification or characterization, was then subjected to reduction. However, the reduction of XXI with zinc - hydrochloric acid or with hydrogen catalytically under various conditions failed to produce any crystalline product.

The authors wish to express their deep gratitude for the help of the late Professor Emeritus Shin-ichiro Fujise and of Professor Koji Nakanishi; they are also grateful to Mr. Hiroshi Honda for his technical assistance.

(Received July 2, 1965)

The racemic tetrahydroanhydrodesoxyaucubigenin, one of the derivatives from a glycoside, aucubin, has been synthesized using *cis-cis*-2-(2'-hydroxyethyl)-5-methoxycarbonylcyclopentanecarboxylic acid δ-lactone as an intermediate. 6, 7-Dimethoxycarbonyl-2-oxa-bicyclo[3.3.0]-octane has also been synthesized, and the mechanism of the base-catalyzed rearrangement of the naturally-derived tetrahydroanhydroaucubigenin *p*-toluenesulfonate has been elucidated.

The recent achievement of the synthesis of a number of cyclic acetals fused to a five- or six-membered ring, for example, 1-ethoxyoctahydrocyclopenta[c]pyran,[1] has prompted the present authors to attempt the synthesis of tetrahydroanhydrodesoxyaucubigenin (II),[2] one of the most important derivatives from a glycoside, aucubin (I),[2a,3] and one with a unique tricyclic acetal-ring system.

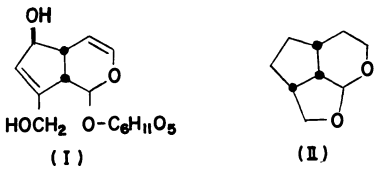

Fig. 1

In view of the previous findings,[1] an unsaturated lactone ester (X) appeared to be one of the most satisfactory intermediates for the synthesis of II, since the steric requirement (*cis-cis*) with respect to the three substituents on the cyclopentane ring in the precursor (XI) of II would be settled beyond difficulty by means of the catalytic hydrogenation of X; undoubtedly hydrogens add *cis* to the double bond from the side opposite to an allylic substituent, producing a *cis-cis* orientation. The most important and difficult problem, however, arises in the final step; that is, the lithium aluminum hydride reduction of XI must proceed selectively so as to reduce the ester group exhaustively to a primary alcohol, while reducing the lactone partially to an acetal. A controlled operation of this reduction has now been accomplished, resulting in the synthesis of racemic tetrahydroanhydrodesoxyaucubigenin (II), although in a low yield.[4] This paper will describe these results in detail, and also the syntheses of the related compounds.

The reaction of the sodio-derivative of 2-ethoxycarbonylcyclopentanone (III) with 2-iodoethyl methyl ether afforded a mixture (b. p. 130—135°C/5 mmHg) of the desired *C*-alkylated product (IV) and an undesired *O*-alkylated one (V) in a ratio of 3 : 1 (by v. p. c. analysis); the infrared spectrum showed absorption bands at 1748 and 1722 cm^{-1} due to IV and one at 1548 cm^{-1} due to V. Upon the treatment of the mixture with a boiling 0.1 molar-equivalent solution of sodium ethoxide in ethanol, the β-keto ester, a *C*-alkylated product (IV), underwent "acid-cleavage" to give diethyl 2-(2'-methoxyethyl)-adipate (VI), whereas V did not change; VI,

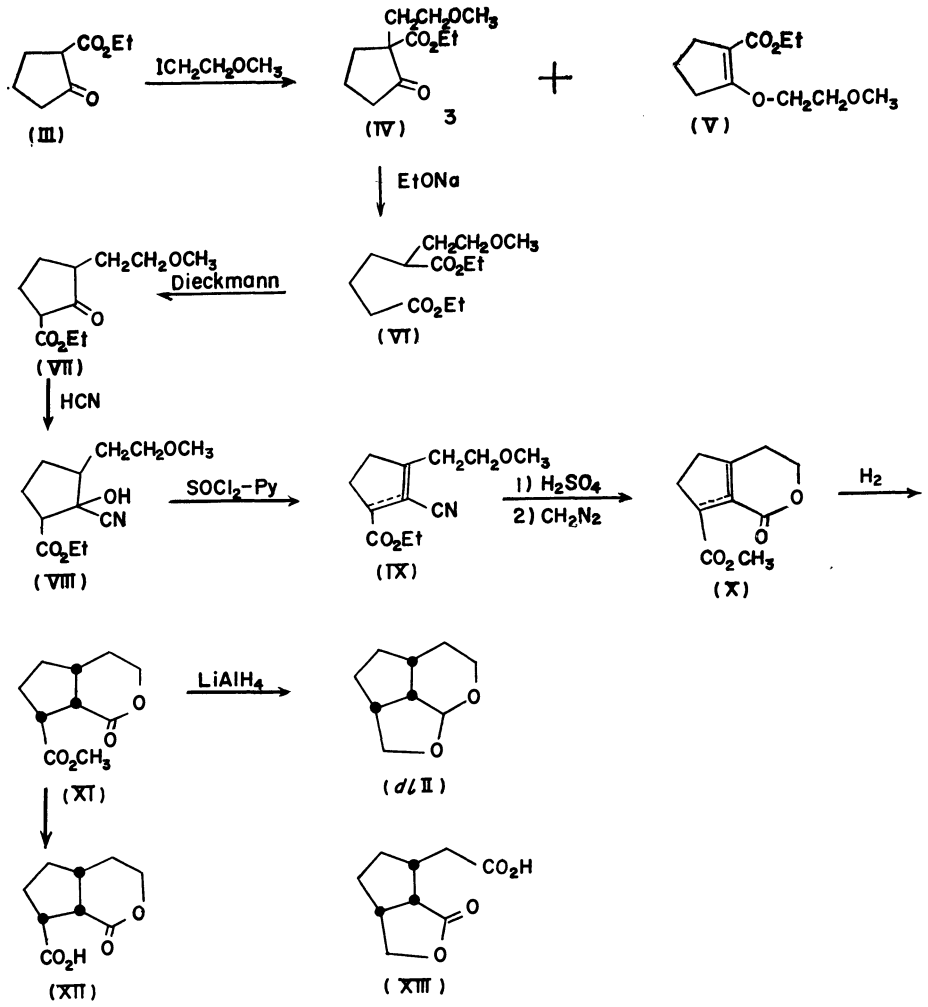

Fig. 2

b. p. 136—139°C/1 mmHg, was separated from V (distilled as a forerun) by fractional distillation through a 1 m. helix-packed column.[5] The Dieckmann cyclization of VI gave predominantly 5-ethoxycarbonyl - 2 - (2′ - methoxyethyl)cyclopentanone (VII), b. p. 155—162°C/3 mmHg, as expected, this was characterized by typical enol absorption bands at 1658 and 1625 cm^{-1} and a positive color test with ferric chloride. This was transformed readily into a cyanohydrin (VIII), b. p. 139—140°C/4.5 mmHg, by reaction with liquid hydrogen cyanide in the presence of a small amount of 50% potassium hydroxide; then the dehydration of VIII with thionyl chloride - pyridine gave an unsaturated nitrile ester (IX), b. p. 130—140°C/4.5 mmHg. The conversion to the desired intermediate, 2-(2′-hydroxyethyl)-5-methoxycarbonyl-Δ^1-(or Δ^5-)cyclopentenecarboxylic acid δ-lactone (X), was achieved by the hydrolysis of IX with boiling sulfuric acid - acetic acid - water, followed by the esterification of the resulting unsaturated lactone carboxylic acid with diazomethane. The pure X, obtained in a 29% yield,[6] b. p. 164—168°C/5 mmHg, ν^{neat} 1730 cm^{-1} (δ-lactone

5) 2-(2′-Acetoxyethyl) - 2 - ethoxycarbonylcyclopentanone (i)[1b] was also subjected to "acid-cleavage" reaction as one of the preliminary experiments on the introduction of the 2′-hydroxyethyl function; the product, however, was not the expected adipic acid derivative (iii), but rather an α-substituted butyrolactone derivative (ii, R = C_2H_5), b. p. 146—154°C/1.2 mmHg, ν(neat) 1768 and 1728 cm^{-1}, and the free acid (ii, R = H), m. p. 84—85°C, ν(KBr) 1760 and 1700 cm^{-1}.

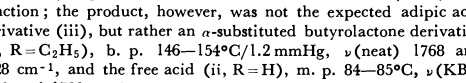

Fig. 3

6) A considerable amount of a by-product (as a low boiling fraction; b. p. 143—153°C/5 mmHg) was also isolated; it had the molecular formula of $C_{11}H_{18}O_5$ and neither a double bond nor a hydroxyl group, as was shown by infrared spectroscopy. The hydrolysis of this material gave a free carboxylic acid, $C_9H_{12}O_5$, m. p. 160—161°C. The analytical and spectral data of these compounds show the former to be the dimethyl ester of the latter, dicarboxylic acid, which possesses an oxygen-containing heterocyclic ring, but their structures have not been investigated further.

and ester) and 1648 cm^{-1} (double bond), was hydrogenated to the corresponding saturated lactone ester (XI), m. p. 72—73°C, using a platinum oxide catalyst in acetic acid, in which the stereochemistry of the three substituents on the cyclopentane ring must be *cis-cis*, as has been mentioned above.

In the final step, it is necessary to control the reduction of XI so as to discriminate each functional group to a reducing agent, lithium aluminum hydride; the ester group must be reduced exhaustively to a primary alcohol, and the lactone, partially to an acetal, in order to achieve the synthesis of II. Considering the environment of both functional groups in XI, it is obvious that the lactone would be more slowly reduced than the ester because of the steric obstruction of the ester and the hydroxyethyl moiety of the lactone ring; the ester is open to the approach of the reagent. In order to enhance this selectivity on reduction, a modified procedure was employed in which there was quite a slow reverse addition of a theoretical amount (0.75 mol.) of lithium aluminum hydride at a low temperature. Thus a mobile liquid, b. p. 112—120°C/20 mmHg, was obtained in a 10% yield; this synthetic material was identical with a sample of natural tetrahydroanhydrodesoxyaucubigenin (II) as determined by a comparison of their infrared spectra and their vapor-phase chromatographic behavior.

In addition to the above results, a few remarks regarding a comparison of synthetic lactone carboxylic acid (XII), m. p. 123—124°C, with a naturally-derived lactone carboxylic acid are appropriate. A δ-lactone structure, as XII, has been assigned on the basis of the lactone absorption band at 1755 cm^{-1} to the lactone carboxylic acid derived from the natural II by potassium permanganate oxidation in an acidic medium.[2a] The infrared spectra of the synthetic lactone carboxylic acid (XII) and its methyl ester (XI) are, however, completely different from those of the naturally-derived compounds, including the lactone carbonyl absorption which is at 1715 in XII and at 1725 cm^{-1} in XI, whereas it is at 1755 and 1766 cm^{-1} in the natural lactone carboxylic acid and methyl ester respectively. Consequently, the structure of the natural lactone carboxylic acid should be revised to the formula XIII with γ-lactone.[7]

7) The nuclear magnetic resonance spectrum of the natural lactone carboxylic acid also supports the structure XIII. Private communication of Dr. W. H. Tallent, G. D. Searle and Co. Two protons, H_A and H_B, attached to the carbon atom bearing lactone hydroxyl show a AB-type quartet at ca. $\delta = 4.2$ p.p.m., each peak of which is further split into a doublet by coupling with an adjacent proton, H_C ($J_{AB}=10$, $J_{AC}=9$—10, and $J_{BC}=3$—4 c.p.s.).

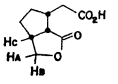

Fig. 4

Finally, as a part of the synthetic work on the aucubin derivative, the synthesis of 6, 7-dimethoxycarbonyl-2-oxa-bicyclo[3.3.0]octane (XXIII) should be mentioned.

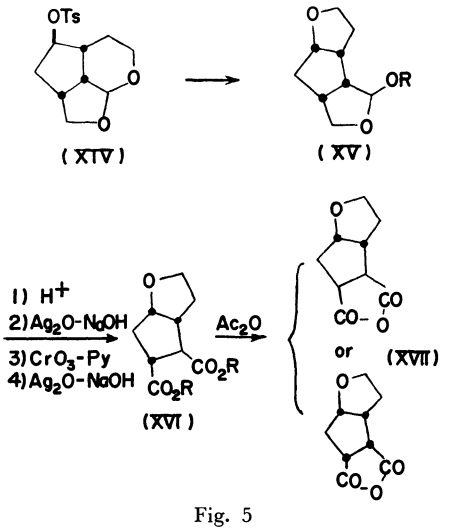

Fig. 5

It has been also reported that tetrahydroanhydroaucubigenin *p*-toluenesulfonate (XIV), when treated with alcoholic potassium hydroxide or sodium ethoxide, underwent acetal ring opening and a new oxygen-containing ring formation to give a compound XV, the structure of which was assumed to be that of a 2-oxa-bicyclo[3.3.0]octane derivative according to the successive transformation of XV into a succinic-type anhydride[8] (XVII), as is shown in Fig. 5; this unusual rearrangement has been explained in terms of the back-side attack of the ring-oxygen atom in the six-membered ring of XIV on the *p*-toluenesulfonyloxy group, facilitated by the attack of the hydroxy or ethoxy anion on the acetal carbon atom.[3b,9] It appeared, however, that the previous results were not sufficient to lead to a definite conclusion concerning the mechanism of rearrangement and the structure of product; hence, the final confirmation should be made by the synthesis of either compound from XV to XVII.

8) For the same type of epimerization involving one carboxyl group in the *trans*-cyclopentane-1, 2-dicarboxylic acid derivative during anhydride formation, see R. B. Bates, E. J. Eisenbraun and S. M. McElvain, *J. Am. Chem. Soc.*, **80**, 3413 (1958), and Refs. 2a and 10.

9) The alternative mechanism, in which another oxygen atom (in the five-membered ring) participates in this reaction, giving a bridged compound (iv), has been excluded because a dicarboxylic acid corresponding to XVI (R=H) would have to form a glutaric-type anhydride (v).

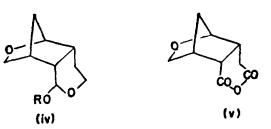

Fig. 6

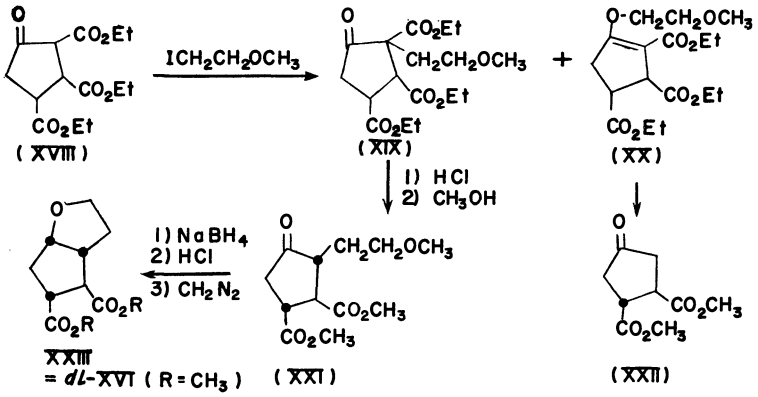

Fig. 7

The condensation of the sodio-derivative of 2, 3, 4-triethoxycarbonylcyclopentanone (XVIII)[10] with 2-iodoethyl methyl ether afforded a mixture of a *C*-alkylated (XIX) and an *O*-alkylated product (XX), in roughly equal amounts (as determined by v. p. c. analysis). The hydrolysis of them with boiling 6 N hydrochloric acid, followed by the esterification of the resulting carboxylic acid using methanol, gave a mixture of the desired compound (XXI) and a keto diester (XXII); these were readily separated by fractional distillation. XXI, b. p. 145—155°C/1.5 mmHg, was characterized by the formation of 2, 4-dinitrophenylhydrazone, $C_{18}H_{22}O_9N_4$, m. p. 123—124°C, and the relative configuration of three substituents must be a thermodynamically more stable or sterically more favorable *trans-trans* arrangement.

The reduction of XXI with sodium borohydride proceeded stereospecifically to produce a single hydroxy diester with *cis* hydroxyl to the adjacent methoxyethyl side chain, which was then transformed into a dicarboxylic acid (XXIII, R=H), accompanied by a simultaneous ring closure, by being refluxed in concentrated hydrochloric acid; subsequent esterification with diazomethane furnished 6, 7-dimethoxycarbonyl-2-oxa-bicyclo[3.3.0]-octane (XXIII, R=CH_3). The synthetic material (XXIII, R=CH_3) was identical with a sample of natural diester (XVI, R=CH_3) as was shown by vapor-phase chromatography and infrared spectroscopy. These results provide convincing evidence of the correctness of the proposed mechanism of transformation from XIV to XV, and also of the assigned structure for XVI; XVI must have a *trans-anti-cis*[11] configuration, and the epimerization of the acetal substituent in XV must take place during the oxidation sequence to XVI.

11) In this designation the relationship of the two carboxyl groups attached to the cyclopentane ring is given first.

Experimental

2-Chloroethyl Methyl Ether.—To a mixture of 500 g. (6.6 mol.) of ethylene glycol monomethyl ether and 500 ml. of pyridine, there was added 1 kg. (8.4 mol.) of thionyl chloride dropwise with stirring and ice cooling; after the mixture had been allowed to stand at room temperature for 48 hr., 500 ml. of water was added. The resulting mixture was extracted with ether three times, and the combined extracts were washed with 10% aqueous sodium hydroxide, dried over calcium chloride, and freed from ether. The residual liquid was distilled through a short fractional column to give 498 g. (80%) of 2-chloroethyl methyl ether, b. p. 89—90°C.

2-Iodoethyl Methyl Ether.—A solution of 438 g. of 2-chloroethyl methyl ether and 1 kg. of sodium iodide in 1 l. of dry acetone was refluxed for 50 hr.; the reaction mixture was then poured into ice water and extracted with ether. The extract was successively washed with aqueous sodium thiosulfate, water, and saturated sodium chloride solution, dried over calcium chloride, and freed from ether. Distillation of the residual liquid gave 782 g. (90%) of 2-iodoethyl methyl ether, b. p. 103—105°C.

Condensation of 2-Ethoxycarbonylcyclopentanone (III) with 2-Iodoethyl Methyl Ether.—To a suspension of 29 g. of finely-granulated sodium metal in 1 l. of anhydrous toluene was added 190 g. of 2-ethoxycarbonylcyclopentanone (III) dropwise with vigorous stirring; the mixture was then heated on an oil bath, while being continuously stirred, until all of the sodium was consumed, after about 5 hr. Then 323 g. of 2-iodoethyl methyl ether was added to the above jelly-like solution of the sodio-derivative of III, and the reaction mixture was refluxed for 10 hr. After cooling, the mixture was worked up by dilution with water, acidification with hydrochloric acid, and extraction in the usual manner to give a crude condensation product. Distillation in vacuo gave 218 g. (84%) of a mixture of two products, b. p. 130—135°C/5 mmHg. The mixture consisted of a *C*-alkylated (IV) and an *O*-alkylated product (V) in the ratio of about 3 : 1, as was determined by v. p. c. on a 3 m. silicone DC 550 column, there were two peaks at retention times of 25 min. (major) and 46 min. (minor) (200°C;

hydrogen flow 80 ml./min.). The major product (IV) gave 2, 4-dinitrophenylhydroazone, m. p. 69.5—70.5°C (from dilute ethanol), according to the usual procedure.

Found: C, 51.54; H, 5.62; N, 13.69. Calcd. for $C_{17}H_{22}O_7N_4$: C, 51.77; H, 5.62; N, 14.21%.

Diethyl 2-(2'-Methoxyethyl)adipate (VI).—The mixture of IV and V from the preceding experiment (624 g.) was treated with a sodium ethoxide solution prepared from 6.7 g. of metallic sodium and 1 l. of anhydrous ethanol; the resulting mixture was refluxed for 6 hr. The mixture was then neutralized with ethanolic hydrogen chloride and heated again for an additional 2 hr. The ethanol was removed by distillation, and the residual oil was poured into ice water and extracted with ether three times. The combined ether extracts were washed with water, dried over anhydrous sodium sulfate, and freed from ether to give 467 g. of the crude material. Fractional distillation in vacuo through a 1 m. helix-packed column gave, after a forerun of ca. 40 g., 425 g. (57%) of pure diethyl 2-(2'-methoxyethyl)-adipate (VI), b. p. 136—139°C/1 mmHg, n_D^{20} 1.4471, d_4^{20} 1.024, M. R. Obs.: 67.95; Calcd.: 67.19.

Found: C, 60.15; H, 9.55. Calcd. for $C_{13}H_{24}O_5$: C, 59.95; H, 9.29%.

5-Ethoxycarbonyl-2-(2'-methoxyethyl)cyclopentanone (VII).—To a suspension of 39 g. of finely-granulated sodium metal in 1 l. of dry benzene was added 425 g. of VI dropwise with efficient stirring; the reaction mixture was then warmed at 80°C for 2 hr., poured into cold 10% aqueous acetic acid, and extracted with benzene. The organic layer was thoroughly washed with saturated brine, dried over anhydrous sodium sulfate, and freed from benzene. The residual liquid was distilled in vacuo to give 227 g. (62%) of β-keto ester (VII), b. p. 155—162°C/3 mmHg, n_D^{18} 1.4600, d_4^{18} 1.073, M. R. Obs.: 54.58; Calcd.: 54.11, which gave a purple color with ferric chloride.

Found: C, 61.11; H, 8.55. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%.

VII (5 g.) was hydrolyzed and decarboxylated by refluxing with 10% sulfuric acid; it thus gave 2.2 g. (67%) of 2-(2'-methoxyethyl)cyclopentanone, b. p. 104—108°C/24 mmHg, ν^{neat} 1755 cm^{-1}, n_D^{31} 1.4964, d_4^{31} 0.9799, M. R. Obs.: 38.37; Calcd.: 38.59, which in turn gave 2, 4-dinitrophenylhydrazone, m. p. 123—124°C.

Found: C, 52.31; H, 5.82; N, 17.37. Calcd. for $C_{14}H_{18}O_5N_4$: C, 52.17; H, 5.63; N, 17.38%.

This 2-(2'-methoxyethyl)cyclopentanone was also obtained from IV by hydrolysis and decarboxylation.

2-(2'-Methoxyethyl)-5-ethoxycarbonylcyclopentenylnitrile (IX).—Freshly-prepared liquid hydrogen cyanide (25 ml.) and a few drops of a 50% potassium hydroxide solution were added to 20 g. of the β-keto ester (VII) with ice cooling and vigorous stirring, and the reaction mixture was stored at 0°C for 20 hr. and carefully acidified with 80% phosphoric acid. The excess hydrogen cyanide was expelled under reduced pressure. Distillation of the residual liquid gave 18 g. of 5-ethoxycarbonyl-2-(2'-methoxyethyl)cyclopentanone cyanohydrin (VIII), b. p. 139—140°C/4.5 mmHg.

The above cyanohydrin (VIII) (18 g.) was dissolved in 20 ml. portions of anhydrous pyridine and benzene and treated with 18.5 g. (11 ml.) of thionyl chloride at 0°C. The reaction mixture was then allowed to stand at the same temperature for 20 hr., poured into ice water, and extracted with benzene. The benzene extracts were washed successively with dilute hydrochloric acid, sodium bicarbonate solution, and water, dried over anhydrous sodium sulfate, and freed from benzene to give a crude product. Distillation in vacuo gave 13.2 g. (79%) of an unsaturated nitrile ester (IX), b. p. 130—140°C/4.5 mmHg, n_D^{18} 1.4799, d_4^{18} 1.075, M. R. Obs.: 58.32. Calcd.: 58.06.

Found: C, 63.71 (low); H, 7.51; N, 6.47. Calcd. for $C_{12}H_{17}O_3N$: C, 64.55; H, 7.68; N, 6.27%.

2-(2'-Hydroxyethyl)-5-methoxycarbonylcyclopentenylcarboxylic Acid Lactone (X).—The unsaturated nitrile ester (IX) (13.2 g.) was dissolved in a solution of 23 ml. of concentrated sulfuric acid, 70 ml. of acetic acid, and 35 ml. of water, and the reaction mixture was refluxed for 15 hr. After cooling, the reaction mixture was diluted with ca. 130 ml. of water and extracted with ether. The ether extract was evaporated to dryness under reduced pressure; then the residual oil was dissolved in a dilute sodium hydroxide solution prepared from 20 g. of sodium hydroxide and 160 ml. of water. This solution was refluxed for 3 hr., acidified with concentrated hydrochloric acid, evaporated to dryness, and finally extracted with ethyl acetate. The ethyl acetate extract was treated with excess diazomethane in ether. The solvent was removed by distillation, and the residual liquid was fractionally distilled in vacuo through a short fractional column. After a forerun of 7 g. (b. p. 143—153°C/5 mmHg), the fraction (5.5 g.) was collected at b. p. 164—168°C/5 mmHg. This fraction consisted mainly of the desired unsaturated lactone ester (X). n_D^9 1.5042.

Found: C, 60.30 (low); H, 6.22. Calcd. for $C_{10}H_{12}O_4$: C, 61.21; H, 6.17%.

The forerun showed the following physical properties: n_D^{13} 1.4775, d_4^{13} 1.290, M. R. Obs.: 54.29; Calcd.: 53.55.

Found: C, 57.51; H, 7.29. Calcd. for $C_{11}H_{16}O_5$: C, 57.88; H, 7.01%.

The hydrolysis of this material with boiling dilute hydrochloric acid gave a crystalline substance, which was then recrystallized from chloroform. M. p. 160—161°C. There was neither hydroxy nor double bond absorption in the infrared spectrum.

Found: C, 53.61; H, 6.07. Calcd. for $C_9H_{12}O_5$: C, 53.99; H, 6.04%.

2-(2'-Hydroxyethyl)-5-methoxycarbonylcyclopentylcarboxylic Acid Lactone (XI).—The unsaturated lactone ester (X) (3.8 g.) in 25 ml. of acetic acid was hydrogenated using a platinum oxide catalyst at atomospheric pressure. A total of 375 ml. (70% of the theoretical amount) of hydrogen was absorbed. Filtration of the catalyst, followed by evaporation of the acetic acid to dryness, afforded a viscous liquid which was then distilled in vacuo to give 2.5 g. (65%) of a saturated lactone ester (XI), b. p. 163—167°C/3.5 mmHg, n_D^{13} 1.4886, d_4^{13} 1.220, M. R. Obs.: 46.87. Calcd.: 47.29. This distilled material gradually crystallized upon standing; it was recrystallized from ethyl acetate-petroleum ether to give pure XI, m. p. 72—73°C.

Found: C, 60.49; H, 7.48. Calcd. for $C_{10}H_{14}O_4$: C, 60.59; H, 7.12%.

***dl*-Tetrahydroanhydrodesoxyaucubigenin (II).**—A solution of 0.303 g. (7.95 mmol.) of lithium aluminum hydride in 20 ml. of anhydrous ether was added dropwise at −15 to −18°C to a stirred solution of 2.1 g. (10.6 mmol.) of the crystalline saturated lactone ester (XI) in 20 ml. of anhydrous ether; the reaction mixture was

then stored at 0°C overnight. Dilute sulfuric acid (10%) was slowly added to the reaction mixture with cooling and stirring until the solution became slightly acidic (Congo red); the organic layer was separated, and the water layer was extracted with ether three times. The combined ether extracts were then washed with water, dried over anhydrous sodium sulfate, and freed from ether. Distillation of the residual liquid in vacuo gave 0.15 g. (10%) of colorless *dl*-tetrahydroanhydrodesoxyaucubigenin (II), b. p. 112—120°C/15 mmHg, n_D^{19} 1.4987, d_4^{19} 1.124 (the reported values for the natural II: n_D^{20} 1.4961, d_4^{20} 1.1249),[2b] M. R. Obs.: 40.30. Calcd.: 40.43. Analysis by v. p. c. using a silicone DC 550 column indicated that this product was essentially pure; its behavior on this column (at 150°C) exactly matched that of pure natural tetrahydroanhydrodesoxyaucubigenin. The infrared spectrum of a sample of the synthetic product was completely indistinguishable from that of the authentic natural product II.

Found: C, 70.66; H, 9.59. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15%.

2-(2′-Hydroxyethyl)-5-carboxycyclopentylcarboxylic Acid (XII).—The saturated lactone ester (XI) (4 g.) was hydrolyzed by refluxing with 30 ml. of 1.2 N hydrochloric acid for 3 hr.; the solution was then evaporated. The separated crystalline solid was collected and recrystallized from ethyl acetate-petroleum ether to give 1.5 g. (40%) of a lactone carboxylic acid (XII), m. p. 123—124°C.

Found: C, 59.03; H, 6.64. Calcd. for $C_9H_{12}O_4$: C, 58.69; H, 6.54%.

The infrared spectrum of this material was completely different from that of the lactone carboxylic acid derived from the natural II.

2-(3′-Ethoxycarbonylpropyl)butyrolactone (ii, R=C_2H_5) and the Free Acid (ii, R=H).—A solution of 24 g. of 2-(2′-acetoxyethyl)-2-ethoxycarbonylcyclopentanone (i)[1b] in 30 ml. of anhydrous ethanol containing 1.5 g. of sodium ethoxide was refluxed for 2 hr. The ethanol was then removed by distillation, and the residue was poured into ice water and extracted with ether. The ether extract was then washed with water, dried over anhydrous sodium sulfate, and freed from ether. Distillation of the residual liquid in vacuo gave 16 g. of a butyrolactone derivative (ii, R=C_2H_5), b. p. 146—154°C/1.2 mmHg, n_D^{12} 1.4574, d_4^{12} 1.087, M. R. Obs.: 49.25. Calcd.: 49.49.

Found: C, 59.88; H, 8.04. Calcd. for $C_{10}H_{16}O_4$: C, 59.98; H, 8.04%.

Hydrolysis of 2 g. of this material by refluxing with 30 ml. of 4 N hydrochloric acid, followed by recrystallization of the resulting semi-solid product from benzene, afforded 1.1 g. (64%) of 2-(2′-hydroxyethyl)adipic acid γ-lactone (ii, R=H), m. p. 84—85°C.

Found: C, 55.24; H, 6.92. Calcd. for $C_8H_{12}O_4$: C, 55.80; H, 7.03%.

Condensation of 2, 3, 4-Triethoxycarbonylcyclopentanone (XVIII) with 2-Iodoethyl Methyl Ether.—The sodio-derivative of XVIII was prepared from 21.5 g. of keto triester (XVIII)[10] and 3.5 g. of finely-granulated sodium metal in 150 ml. of dry xylene according to the usual procedure. To this solution there was added dropwise 30 g. of 2-iodoethyl methyl ether with stirring; the reaction mixture was then refluxed for 10 hr., and worked up in the usual manner, using benzene for extraction of the product to give 20 g. of a mixture of a *C*-alkylated and an *O*-alkylated product (XIX and XX) in roughly equal amount (as determined by v. p. c. analysis on a silicone DC 550 column), b. p. 160—195°C/2.0 mmHg.

3, 4-Dimethoxycarbonyl-2-(2′-methoxyethyl)cyclopentanone (XXI).—The mixture of XIX and XX obtained from the preceding experiment (20 g.) was hydrolyzed by boiling it in 150 ml. of 6 N hydrochloric acid for 4 hr. After removal of the hydrochloric acid and almost all of the water under reduced pressure, the oily residue was dissolved in anhydrous methanol containing a small amount of hydrogen chloride; the resulting solution was then refluxed for 36 hr. The methanol was removed by distillation, and the residual liquid was distilled in vacuo. After a forerun of 6 g. (major fraction, b. p. 122—129°C/1.5 mmHg), which consisted mainly of 3, 4-dimethoxycarbonylcyclopentanone (XXII), the minor fraction (2.5 g.) was collected at a boiling point of 145—155°C/1.5 mmHg. This fraction was the essentially-pure desired compound, 3, 4-dimethoxycarbonyl-2-(2′-methoxyethyl)cyclopentanone (XXI), as was shown by v. p. c. on a silicone DC 550 column. The 2, 4-dinitrophenylhydrazone of this material was prepared in the usual manner in a good yield. It had a melting point of 123—124°C.

Found: C, 49.83; H, 5.04; N, 12.59. Calcd. for $C_{18}H_{22}O_9N_4$: C, 49.31; H, 5.06; N, 12.78%.

***trans-anti-cis*[11]-6, 7-Dimethoxycarbonyl-2-oxabicyclo[3. 3. 0]octane (XXIII, R=CH_3) (*dl*-XVI, R=CH_3).**—A solution of 1.0 g. of XXI in a small amount of methanol was added to a solution of 0.55 g. of sodium borohydride in 4 ml. of methanol containing a trace of sodium hydroxide; the mixture was then refluxed for 4 hr. After the methanol had been removed, the residual solid was warmed with 5 ml. of concentrated hydrochloric acid on a steam bath for 2 hr., and then dried up to give a paste-like dicarboxylic acid (XXIII, R=H). This material, without further purification, was dissolved in a small amount of ethyl acetate and treated with excess ethereal diazomethane. The solvents were removed by distillation, and the residual liquid was distilled in vacuo to give 0.25 g. (30%) of the diester (XIII, R=CH_3), b. p. 123—125°C/1.0 mmHg. The infrared spectrum of a sample of the product collected by v. p. c. using a silicone DC 550 column was completely identical with that of a specimen of the naturally-derived diester (XVI, R=CH_3), and the v. p. c. behaviors of the two samples were also identical. An analytical sample was prepared by v. p. c.

Found: C, 57.56; H, 7.21. Calcd. for $C_{11}H_{16}O_5$: C, 57.88; H, 7.07%.

The authors are greatly indebted to the late Professor Emeritus Shin-ichiro Fujise and Professor Koji Nakanishi, Tohoku University, for their valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 536—537 (1966)

Vinylpolymerisation. CXXIX. Pfropfung von Methylmethacrylat auf Naturkautschuk in Abwesenheit von Initiatoren*

Von Mitsuru KONDO,† Kuniyoshi YAMADA,†† Kiichi TAKEMOTO und Minoru IMOTO

Abteilung der Angewandten Chemie, Technische Fakultät der Städtischen Universität Osaka, Sumiyoshi-ku, Osaka

(Eingegangen am 2. Juli, 1965)

The graft polymerization of methyl methacrylate on natural rubber was studied in an aqueous suspension at 90°C, in the absence of initiators. It was found that methyl methacrylate could be grafted fairly smoothly on uncured natural rubber crepe and latex, both of which had previously been extracted with acetone.

Die Pfropfung von Methylmethacrylat (abgekürzt MMA) auf Naturkautschuk in Anwesenheit von Initiatoren wurde bereits ausführlich untersucht,[1,2] und das Pfropfpolymerisat ist unter dem Handelsnamen Heveaplus MG bekannt. Neuerdings haben Imoto und seine Mitarbeiter gefunden, dass MMA in wässriger Emulsion ohne Hilfe von Initiatoren leicht auf Stärke, Dialdehydstärke und Maltose,[3] und ferner auf verschiedene Natur- und Kunstfasern, vor allem beträchtlich auf Seide und Cellulosefasern[4] gepfropft werden kann.

Im Zusammenhang mit einer Reihe von unseren Untersuchungen erschien es interessant, die Pfropfung von MMA auch auf Naturkautschuk unter analogen Bedingungen zu studieren. Es ist uns nun gelungen, MMA in Abwesenheit von Initiatoren auch auf nichtvulkanisierten Naturkautschuk mit höherem Umsatz zu pfropfen. Im folgenden sollen die Resultate der Versuche beschrieben werden.

Experimentelle Ergebnisse und Diskussion

Da die Pfropfung von Vinylmonomeren auf Stärke und einige Fasern am besten mit MMA gelingt, wurde auch in diesen Versuchen MMA als das zu pfropfende Monomere gewählt. Die Ergebnisse einer Reihe von Versuchen sind in Tabelle I zusammengestellt.

Wie aus dieser Tabelle ersichtlich, entsteht in Abwesenheit von Kautschuken (Vers. B) nur wenig Polymerisat. Während die Gewichtszunahme der Kautschuke in Anwesenheit vom Kunstkautschuk (Vers. K) und von vulkanisiertem Kautschuk (Vers. v. K.) nicht bemerkbar ist, verläuft die Polymerisation von Methylmethacrylat in Anwesenheit von nichtvulkanisierten Naturkautschuken glatt (Vers. C-2, 3, 4 und L-2, 3, 4). Bei den Versuchen, bei denen das gebildete Polymerisat nicht mit Aceton, sondern mit Methyläthylketon (abgekürzt MÄK)/Methanol-gemisch (10 : 1) extrahiert wurde (C-1 und L-1), beträgt die Gewichtszunahme wesentlich weniger; das beruht möglicherweise darauf, dass bei diesen Fällen sogar auch das Pfropfpolymerisat durch MÄK extrahiert worden ist. Im Unterschied zu den Versuchen in Anwesenheit von vorher nicht gereinigten Kautschuksproben ist zu beachten, dass MMA mit höherer Ausbeute auf die vorher mit Aceton extrahierte Kautschuksproben gepfropft werden kann (Vers. C-3, 4 und L-3, 4), während aber die Pfropfpolymerisation kaum an deproteiniertem Kautschuk eintritt (Vers. L-5). Aus der Beobachtung, dass die Pfropfpolymerisation beim Kunstkautschuk nicht eintritt, wird nahegelegt, dass die Pfropfpolymerisation durch die eigentlich im Naturkautschuk befindliche Proteine verursacht werken kann.

Hinzuzufügen ist, dass Luft den Pfropfungsumsatz fast gar nicht beeinflusst.

Zusammenfassend kann festgestellt werden, dass MMA unter den beschriebenen Bedingungen ähnlich wie auf Stärke und einige Fasern auch leicht auf nichtvulkanisierten Naturkautschuk gepfropft werden kann.

Experimenteller Teil

Reagenzien.—Der handelsübliche Krepp wurde 16 Stunden mit Aceton extrahiert. Der konz. Naturkautschukslatex wurde zuerst bei 70°C getrocknet, bis er durchsichtig wurde und ein konstantes Gewicht erreichte, und dann 16 Stunden mit Aceton extrahiert. Beide Proben wurden weiter im Vakuum bei Raumtemperatur getrocknet; die von den mit Aceton extrahierte Fraktionen betrugen 2.2% bzw. 2.4%. Der protein-

a) Die Kautschuke wurden vorher mit Aceton extrahiert.
b) Das Gewicht des Festkörperteils wurde als 62.7% (gemessener Wert) genommen.
c) Die gewonnenen Pfropfpolymerisate wurden mit MÄK/Methanol-gemisch (10 : 1) extrahiert. (Die anderen wurden alle mit Aceton extrahiert.)
d) Der Latex wurde durch Alkalibehandelung proteinfrei gemacht.
e) Vulkanisierter Kautschuk.
f) Kunstkautschuk (Polyisopren IR-305; Shell Chem. AG.)

freie Latex wurde nach der Methode von Pummerer[5] durch Alkalibehandlung des Latexkautschuks gewonnen. Als vulkanisierter Naturkautschuk wurde die handelsübliche Platte von ca. 2 mm Dicke gebraucht. Alle Kautschukproben wurden schliesslich im Vakuum bei Raumtemperatur über Calciumchlorid getrocknet. MMA wurde mit wassriger Natriumbisulfitlösung, 5% iger Natronlauge und dann mit 20% iger Natriumchloridlösung je dreimal gewaschen, über Natriumsulfat getrocknet, und anschliessend durch dreimalige Destillation im Vakuum unter Leitung von Stickstoffstrom gereinigt: Kp. 43°C (90 mmHg). Als Emulgator diente Emulgen 106 (Polyäthylenoxydderivat der Firma Kaô Sekken).

Pfropfpolymerisation.—4.68 g frisch destilliertes MMA wurden mit 0.15 g. Emulgator in 60 ml. Wasser suspendiert und die angegebene Menge von Kautschuk in kleinen Stückchen zugegeben. Das Reaktionsgemisch wurde unter ständigem Rühren 2 Stunden bei 90°C gehalten. Nach Abkühlen auf Raumtemperatur wurde das Reaktionsgemisch in überschüssiges Methanol eingegossen. Um das Homopolymere abzutrennen, wurde das Produkt nach dem Trocknen im Soxhlet-Apparat mit Aceton oder MÄK/Methanol-gemisch (10 : 1) extrahiert. Nach 18 bis 24 stündiger Extraktion war der Rückstand homopolymerfrei; er wird als Pfropfpolymerisat betrachtet. Pfropfungsumsatz, Pfropfungswirkungsgrad usw. ergeben sich aus folgenden Gleichungen:

$$\text{Gewichtszunahme des Kautschuks} = \frac{\text{Gew. des gepfropften Kautschuks} - \text{Gew. des Kautschuks}}{\text{Gew. des Kautschuks}} \cdot 100(\%)$$

$$\text{Polymerisationsumsatz} = \frac{\text{Gesamtausbeute} - \text{Gew. des Kautschuks}}{\text{Gew. des eingesetzten Monomeren}} \cdot 100(\%)$$

$$\text{Pfropfungsumsatz} = \frac{\text{Gew. des gepfropften Kautschuks} - \text{Gew. des Kautschuks}}{\text{Gew. des eingesetzten Monomeren}} \cdot 100(\%)$$

$$\text{Pfropfungswirkungsgrad} = \frac{\text{Gew. des gepfropften Kautschuks} - \text{Gew. des Kautschuks}}{\text{Gesamtausbeute} - \text{Gew. des Kautschuks}} \cdot 100(\%)$$

Zusammenfassung

Die Pfropfpolymerisation von Methylmethacrylat auf Naturkautschuk wurde in wässriger Suspension in Abwesenheit von Initiatoren bei 90°C untersucht. Es ergab sich, dass Methylmethacrylat ziemlich glatt auf die nichtvulkanisierten, vorher mit Aceton extrahierten Naturkautschukskrepp und -latex gepfropft werden kann.

Herrn Dr. A. Kogure von Japan Synthetic Rubber Co., Ltd. danken wir verbindlich für die Lieferung der Kunstkautschuksproben.

The Mass Spectra of Chalcones, Flavones and Isoflavones*

By Yasuhiro ITAGAKI, Tadashi KUROKAWA and Shin-ichi SASAKI

Department of Chemistry, Tohoku University, Sendai

and

Chin-Te CHANG and Fa-Ching CHEN

Department of Chemistry, National Taiwan University, Taipei, Republic of China

(Received July 2, 1965)

The fragmentation of flavonoid compounds by electron impact has been studied and the following results described: 1) Chalcones gave the usual fragmentation pattern; however, 2'-hydroxy chalcones showed complex spectra according to the isomerization of chalcone to flavanone. 2) The fragmentation pathways of flavones were decided by comparison with many kinds of halogen-substituted flavones. 3) Isoflavone gave the M-1 ion as the base peak, and no loss of CO was observed.

A few reports on the mass spectral investigation of flavonoids have been published.[1] However, the fragmentation pathways of these compounds on electron impact have not always been established. The mass spectra of flavone and halogen-substituted flavones have been recorded; the natural isotopic abundance of halogen made the structures of most fragment ions clear. 2'-Hydroxychalcone and 2'-hydroxyhalochalcones give complex spectra because of the isomerization of chalcone to flavanone in the spectrometer. Furthermore, the mass spectra of isoflavones have been determined; in them M-1 ions are always characteristic base peaks and no loss of CO is observed, unlike as in flavones.

Experimental

All the mass spectra were obtained with an Hitachi RMU-6D Mass Spectrometer. Mass spectra were recorded with 70 V. electron energy and an 80 μamp. ionizing current. The temperature of the ion source was 250°C. All the samples were synthesized according to the known procedure.[2]

Results and Discussion

Chalcones.—The mass spectra of 4'-methoxychalcone (I) and 4-methoxychalcone (II) have been determined (Fig. 1). Both I and II give the molecular ion (a, a') (*m/e* 238), the M-1 ion (b, b') (*m/e* 237) and the M-CH_3 ion (c, c') (*m/e* 223) as common fragments. The peaks at *m/e* 103 (e) and *m/e* 131 (f) in I are shifted to *m/e* 133 (e') and *m/e* 161 (f') in II respectively; moreover, the peaks at *m/e* 105 (d') and *m/e* 77 (g') in II are shifted to *m/e* 135 (d) and *m/e* 107 (g) in I respectively. The difference between the two compounds is the location of the methoxyl group, that is, 30 mass units.

The spectra of the two compounds are very similar, but the process of cleavage is not fully identical; for instance, the phenyl cation (g') (*m/e* 77) in II is due to the loss of CO from the benzoyl cation (d') which was formed by the fragmentation of the methyl radical from the molecular ion (a') followed by the cleavage of the c' cation. However, an abnormally abundant phenyl cation (h) in I arises from the methoxyphenyl cation (g) and the styryl cation (e). All these pathways are ascertained by means of the presence of metastable ions (Table I). Furthermore, the supposition that the (h) ion deos not arise by the simple

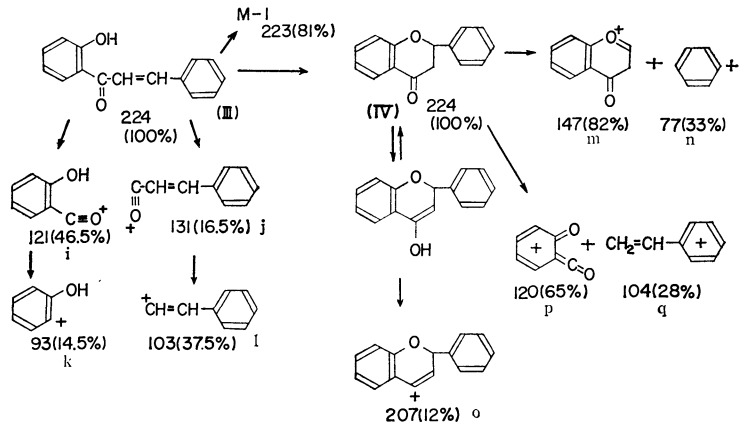

Fig. 2. Fragmentation of 2'-hydroxychalcone (III).

cleavage of the molecular ion (a) is supported by the fact that no CH_3O- -$COCH{=}CH^+$ ion appears in the spectrum of I.

The spectrum of 2'-hydroxychalcone (III) is interpreted in the same way as in the case of either I or II (Fig 2. Table II). The peaks at *m/e* 121 (i), *m/e* 131 (j), *m/e* 93 (k) and *m/e* 103 (l) must arise from 2'-hydroxychalcone itself. However, that the chalcone gives rise to the M–C_6H_5 ion (m) and the M–OH ion (o) is not conceivable; these cations, m and o, most probably arise from the loss of the phenyl radical and the hydroxyl radical respectively from the heat-isomerization product of the chalcone,

	(95)	(100)	(50)	(10)	(30)
	M	M-42	M-42-1	R=OH	$R=CH_3$
2-Methyl-7-acetoxy-isoflavone (IV)	294	252	251	136	116
	(13)	(81)	(100)	(2)	(8)

that is, flavanone (IV). Other peaks at *m/e* 120 (p) and *m/e* 104 (q) which are never observed in the spectrum of chalcone without a hydroxyl group at C-2', are also well-explained through the isomerization of III to IV.

The spectra of the following 2'-hydroxyhalochalcones have been determined (Table II): 2'-hydroxy-3-chloro-(V), 2'-hydroxy-4-chloro-(VI), 2'-hydroxy-3-bromo - (VII), 2'-hydroxy-4'-bromo-(VIII), 2'-hydroxy-5'-bromo-(IX) and 2'-hydroxy-5'-chlorochalcone (X). In all cases these hydroxyhalochalcones give molecular ions as the base peaks and M-X ions as the characteristic peaks. They also show both fragments from hydroxyhalochalcones (V-X) and the corresponding flavanones, as in the case of 2'-hydroxychalcone itself.

Flavones.—Barnes et al. reported that flavone (I) itself gives the molecular ion (*m/e* 222) as the base peak and shows the substantial loss of one hydrogen, thus giving an ion (*m/e* 221); one oxygen is readily eliminated as CO, but more readily by the retro-Diels-Alder fission of the heterocyclic ring, thus giving two ions, one with a quinonoid (*m/e* 120) (b), and the other a phenylacetylene

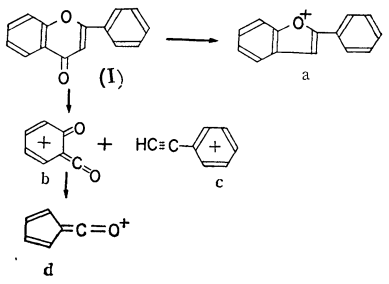

Fig. 3. Fragmentation of flavone.

(*m/e* 102) (c) structure. The d ion (*m/e* 92) arises from the loss of CO from the b ion (Fig. 3).

The spectra of 6-chloro- (II), 7-chloro- (III), 8-chloro- (IV), 4'-chloro- (V), 6-bromo- (VI), 7-bromo- (VII), 8-bromo- (VIII), 6-iodo- (IX), 7-iodo- (X) and 4'-iodoflavone (XI) have also been determined. All the characteristic peaks arise from the haloflavones correspond to the peaks of the molecular ion, the M-1 ion, and to the a, b, c and d of flavone itself. Therefore, the breakdown process of flavone proposed by Barnes may be regarded as quite reasonable (Table III).

Isoflavones.—It has been reported[1a] that the spectrum of daidzein dimethyl ether (I) shows a peak at *m/e* 282 (molecular ion) as the base peak, other peaks at *m/e* 150 (a) and *m/e* 132 (b), and no M-CO ion (Fig. 4).

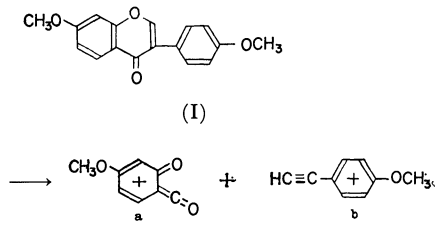

Fig. 4. Fragmentation of daidzein dimethyl ether.

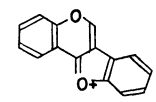

However, according to our determination of isoflavone (II) and 7-methoxyisoflavone (III), M-1 ions appear as the base peaks. In the case of 2-methyl-7-acetoxyisoflavone (IV), the ion loses a ketene molecule from the molecular ion; then it loses one hydrogen radical, which appears as the base peak. The structure of the M-1 ion is probably an oxonium ion (c) results from the

fragmentation of a hydrogen radical at C-2′ of the molecular ion. Because of the stability of the ion, no further fragmentation or loss of CO occurs, unlike as in flavones (Table IV).

Summary

The mass spectra of chalcones, flavones and isoflavones have been studied. From the metastable peaks or from a comparison with halogen-substituted compounds, the main fragmentation paths of chalcones and flavones on electron impact have been elucidated. The fragmentation of isoflavones, which give characteristic M-1 ions as base peaks has also been studied.

The authors wish to express their hearty thanks to Professor Koji Nakanishi for his encouragement throughout the course of this work.

The Interaction of Cumulene Systems with Organometallic π-Complexes. IV.[1] Novel π-Allyl Complexes Obtained from the Reactions of Allene with Iron and Cobalt Carbonyls

By Akira NAKAMURA*1

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received July 2, 1965)

2, 2'-Bi-π-allylene(hexacarbonyl)di-iron, $[(OC)_3Fe]\cdot\begin{matrix}CH_2\\CH_2\end{matrix}\!\!>\!C\!-\!C\!<\!\!\begin{matrix}CH_2\\CH_2\end{matrix}\cdot[Fe(CO)_3]$, was found to be a product of the reaction of allene with $Fe_3(CO)_{12}$. A study of the NMR spectrum, however, showed that a rapid valence tautomerisation takes place, even at −10°C between the 2, 2'-bi-π-allylene structure and the related butadiene-type structure. In the presence of an excess of $Co_2(CO)_8$, allene yielded the $[(C_3H_4)Co(CO)_3]_2$ complex. The structure of this complex in which a $\begin{matrix}CH_2\\CH_2\end{matrix}\!\!>\!C\!-\!C\!<\!\!\begin{matrix}O\\\end{matrix}$ skeleton was bound to two $Co(CO)_2$ groups via π-allyl and acyl groups, was suggested.

In a previous paper,[2] we have described the interaction of cumulene systems with organometallic π-complexes such as iron carbonyls to give a variety of stable π-complexes. As the first member of the cumulene system, allenic systems were examined for their ability to form π-complexes. Tetraphenylallene gave a stable iron tricarbonyl complex, $(Ph_4C_3)Fe(CO)_3$ and a cobalt complex, $(C_5H_5)Co(CO)(Ph_4C_3)$. Unsubstituted allene gave complexes of the compositions $[(C_3H_4)Fe(CO)_3]_2$ (I) and $[(C_3H_4)_2Fe(CO)_3]_{1-2}$. The structure of these complexes was not, however, clear. In this report, an investigation of the structure of the complex I will be described. A novel complex obtained from the reaction of allene with dicobalt octacarbonyl will also be reported.

Results and Discussion

The reaction of unsubstituted allene with tri-iron dodecacarbonyl at 120°C under pressure has been described in the previous paper.[2] The same reaction at atmospheric pressure in *n*-hexane, using an excess of tri-iron dodecacarbonyl gave a similar product, except that in this case the amount of the complex I increased and a new red compound was isolated in a small amount. When iron pentacarbonyl was used under the pressure of carbon monoxide at 140°C, no reaction was observed. In order to get a clue about the skeletal structure of the complexed organic part of complex I, the bromination of complex I was studied.*2 It gave colorless crystals upon bromination at room temperature. The crystal exhibited a reaction typical of allylic bromide, but it did not add another molecule of bromine. The presence of a double bond was shown by the permanganate test. The infrared spectrum of the crystals was found to be superimposable upon that of the authentic 2, 3-bis(bromomethyl)-1, 4-dibromobutene-2 prepared by the literature method.[3] If no coupling

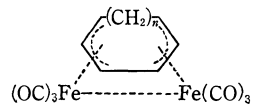
of the C_3H_4 moiety occurs during the bromination, the structure of the bromination product suggests that the skeletal structure of the organic part is $\begin{matrix} C \\ C \end{matrix}\!\!>\!C\!-\!C\!<\!\!\begin{matrix} C \\ C \end{matrix}$. Therefore, the 2, 2-bi-π-allylene structure may be present in I.*3 The infrared spectrum of I had strong maxima at 2068, 2030, 2003 and 1990 cm^{-1}, indicating the presence of terminal metal carbonyl groups. The infrared spectrum as a whole supported the π-allyl type structure. Recently, Emmerson et al.[4] reported the preparation of cyclic bi-π-allylene type iron carbonyl complexes such as are shown below.



$n=1, 2$

These complexes can be regarded as derivatives of unknown 1, 1'-bi-π-allylene(hexacarbonyl)diiron. 2, 2'-Bis-π-allylenemetal complexes also have been unknown. If one assumes the 2, 2'-bi-π-allylene structure for I, the NMR spectrum would have two singlets, with a separation of ca. 1. p.p.m., corresponding to the syn and anti protons of the π-allylic group. The actual NMR spectrum in carbon tetrachloride at 35°C had two peaks, separated by only 0.07 p.p.m. and centered at 8.34 τ. The separation became smaller when the temperature was lowered, until finally the two peaks condensed into a sharp singlet at −10°C. This NMR behavior can be understood on the assumption that the following valence tautomerism occurs rapidly, even at −10°C in the solution. This rapid tautomerism averages out all the protons, and the NMR spectrum will have a single peak. The τ-value can be calculated approximately as follows on the assumption of this tautomerism. The calculation, which involves averaging out all the τ-values[5] of the terminal protons of butadiene(tricarbonyl)iron and the hypothetical τ-values for π-allyl(tricarbonyl)iron, results in a value of 8.35 τ. π-Allyl(tricarbonyl)iron is reported to be paramagnetic in a solution, and the NMR spectrum can not be obtained.[6] The hypothetical τ-value was calculated by averaging the known τ-values of the terminal protons in π-allyl(tetracarbonyl)-manganese and in π-allyl(tricarbonyl)cobalt.[7]

At much lower temperature, e. g., at −55°C in chloroform, the compound I showed three broad signals centered at about 8.3 τ; these may correspond to the tautomers slowly exchanging at the temperature. At higher temperatures, such as at 65°C, two peaks are observed. However, the oxidative degradation of the compounds I was occurring during the measurement by the solvent, carbon tetrachloride, and no satisfactorily accurate result could be obtained. These two NMR peaks at higher temperatures appeared to us to arise from

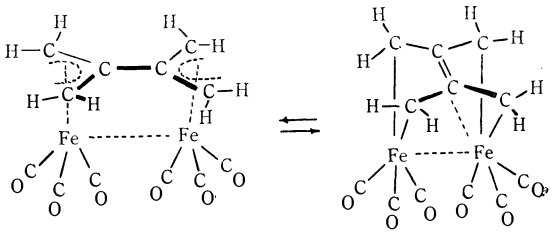


Fig. 1

the π-allylic tautomer (A). This fact suggests that the π-allylic form might be predominant at higher temperatures. The possible intervention of the π-allylic complex at higher temperatures has already been suggested in the deuterium exchange study[8] of polymethylcyclopentanes using such metal catalysts as palladium. Therefore, the predominance of the π-allylic form at higher temperatures is not unreasonable.

Rapid valence tautomerism has been postulated in the interpretation of the NMR spectra of some cyclic polyene-metal carbonyl complexes. For example, cyclooctatetraene(tricarbonyl)iron has only one sharp NMR signal.[9] This NMR behavior was once taken as evidence for the planar structure and aromaticity of the cyclooctatetraene ring on π-complex formation.[9a] X-ray structure analysis[10] of the compound, however, has shown that the ring is not planar in the crystalline state. The appearance of only one NMR signal has been understood as due to rapid valence tautomerism in the solution. More recently, two other similar examples[11] have been added to this type of tautomerism. It is of interest to regard compound I as the first example of rapid tautomerism occurring in the chain structure. Valence tautomerism now

*3 The author at first called this system "2, 2'-bis-π-allyl" to indicate two π-allyl systems connected at the center carbon atoms. However, it was later recommended that the system be called "2, 2'-bi-π-allylene" because of its bifunctional character. A confusion may indeed arise because allylene is a common name for 1-propyne. The author nevertheless prefers to use the latter nomenclature for the system, as he used it in the preliminary note.

seems to be possible not only in the cyclic polyene ligand, but also in the chain structure.

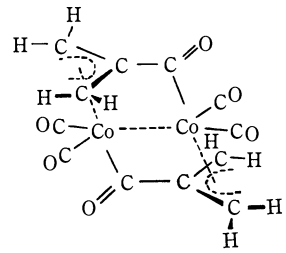
Our investigation suggests that a comparison of the thermodynamic stability between the π-allylic form (A) and the π-complexed butadiene form (B) is possible by means of the measurement of the NMR spectrum.

The 2, 2'-bi-π-allylene structure may yield compounds with many other transition metals, and other interesting properties may be found. We therefore intend to explore the chemistry of 2, 2'-bi-π-allylene complexes and related compounds further.

The Allene Complex of Cobalt Carbonyl.— The polymerization of allenic compounds by dicobalt octacarbonyl at room temperature was first reported by Greenfield et al.[12] The presence of metal carbonyl stretching bands in the infrared spectrum of the polymer attracted our interest. So far, only the formation of rather unstable diene-cobalt carbonyl complexes has been reported. However, the considerable stability of the metal carbonyl species in the allene polymer prepared by means of the cobalt carbonyl catalyst suggests the possibility of the formation of a stable allene complex of cobalt carbonyl. Thus, allene was slowly bubbled into a solution of dicobalt octacarbonyl in benzene at room temperature. A slight change in color to reddish brown and an evolution of heat was observed.

The sublimation of the reaction mixture gave air-sensitive yellow and black crystals. The black crystals were identified as tetracoblat dodecacarbonyl by means of their infrared spectrum. The yellow crystals were further purified and found to have the composition: $[(C_3H_4)Co(CO)_3]_2$ (II). A well-crystallized pure sample was stable in air for a few days, but the solution in organic solvents was unstable. Decomposition usually begins after the solution has stood in air at room temperature for about 10 min. The infrared spectrum showed two very strong bands at 2050 and 2010 cm^{-1}, indicating the presence of terminal metal carbonyl groups. The presence of a strong band at 1620 cm^{-1} suggests the presence of a keto carbonyl with an unusually low stretching frequency. This keto carbonyl may be of the acyl cobalt type. The NMR spectrum in carbon tetrachloride showed two singlets, at 6.39 and 7.72 τ, of equal intensity. The position of the peaks may be well accounted for by assuming the presence of a π-allyl group with an electro-negative group at the 2-position. For example, π-allyl cobalt tricarbonyl shows its NMR peak at 6.93 and 7.85 τ.[7] The peak at 6.93 τ has been assigned to the syn proton and the one at 7.85 τ, to the anti protons. The chemical shifts of the syn and anti protons in the known π-allyl cobalt tricarbonyl are, therefore, similar to those observed for the complex, except for the presence of a shift towards a lower field, which is probably due to an electron-withdrawing substituent at the 2-position.

The structure of the complex was investigated by bromination. The action of bromine at room temperature in carbon tetrachloride evolved 4 mol. of carbon monoxide. The composition of the complex indicates that six carbon monoxide groups are incorporated into the structure. Therefore, two carbon monoxide groups are bound to the organic part, and four such groups are present as terminal metal carbonyl groups. The bromination product was a complicated one. It contained an acid bromide of an unknown structure and other materials. The bromination in methanol at about 15°C gave a colorless crystals in a good yield. The elemental analysis and the molecular weight measurement, together with the infrared evidence, favor a diketone structure: $(BrCH_2)_2$-C–CO–CO–C$(BrCH_2)_2$. The bromination in methanol at higher temperatures resulted in a reduced yield of the diketone and in a mixture of bromoesters. The bromination product suggests that the skeletal structure of the organic part is $\begin{matrix}C\\C\end{matrix}\!>\!C\text{–}C\!<\!^{O}$. In addition, the presence of an acyl cobalt linkage is indicated by the isolation of an acid bromide, and also by the infrared band of II at 1620 cm^{-1}. The accumulated evidence suggests the following π-allyl-acyl cobalt carbonyl structure for the complex.



(II)

Fig. 2

A dimeric structure with a Co–Co bond, as indicated by its molecular weight, is necessary in explaining the diamagnetism of the compound. An alternative structure, in which one cobalt atom is bound to the π-allyl and the acyl groups simultaneously, is possible. However, this structure might allow dissociation in the solution, as in the case of the π-allyl-(tricarbonyl)iron dimer.[6] The considerable stability of the complex in solution and its diamagnetism in carbon tetrachloride makes the latter structural possibility less probable.

The reaction of II with triphenylphosphine occurred readily when the solution of the reactants was warmed in benzene; orange air-stable crystals

12) a) H. Greenfield and I. Wender and J. H. Wotiz, *J. Org. Chem.*, **21**, 875 (1956); b) I. W. Stolz, G. R. Dobson and R. K. Sheline, *Inorg. Chem.*, **2**, 1264 (1963).

were thus obtained. The crystals have strong infrared bands at 2002 cm^{-1} and at 1964 cm^{-1} and its NMR peaks mainly in the phenyl proton range. The composition was nearly $(C_3H_4)_2$-$Co_2(CO)_2(Ph_3P)_3$. The structure of the phosphine derivative is not clear at present.

The isolation of the iron and cobalt compounds is closely connected with the known polymerization[13] and carbonylation[14] of allene by organometallic catalysts. The π-allylic iron carbonyl compound (I) can be regarded as the stabilized form of the initiation step of the allene polymerization. The importance of π-allyl complexes of nickel and cobalt in the polymerization of butadiene and allene has already been shown.[13] In the reaction with allene, iron(0) in the iron carbonyl group ($Fe(CO)_3$) forms a stable complex, as has been described above, whereas nickel(0) does not. Possibly for this reason, nickel(0) complexes polymerize allene to a 1, 2-polymer with a very regular structure at room temperature.[13] The isolation of a stable complex of cobalt carbonyl with the $\overset{C}{C}\!>\!C\!-\!C\!<\!\overset{}{O}$ skeletal structure shows that this form might be the stabilized initial step of the carbonylation of allene. The catalytic carbonylation[14] of allene has been reported using a ruthenium(II) or a platinous chloride-stannic chloride system. In all cases, carbon monoxide adds to the central carbon atom of the allene system. The close similarity of the structure shows that the carbonylation of allene may be possible by means of a cobalt carbonyl catalyst.

The Interaction of Allene with Other Metal π-Complexes.—The interaction of allene with molybdenum hexacarbonyl with ultraviolet irradiation formed an orange solution under nitrogen. The attempt to isolate the allene complex failed, however, because of its instability. The orange complex may be stable only in the solution. We regard it as similar to the unstable olefin and acetylene complexes reported by Sheline et al.[12] No reaction of allene was observed in the thermal reaction with molybdenum hexacarbonyl at 70°C at atmospheric pressure or with dimanganese decacarbonyl at 150—160°C under pressure. No stable π-complexes have been isolated from the photochemical reaction of allene with cyclopentadienyl vanadium tetracarbonyl or with cyclopentadienyl manganese tricarbonyl. The polymerization of allene was observed, in the thermal reaction with nickelocene at 150—200°C to give a polymer with an irregular structure, together with a small amount of an unstable red compound. Tetraphenylallene was recovered unchanged in the reaction with nickelocene at 140°C.

Experimental

All melting points are uncorrected and were measured by a micro-melting point apparatus Yanagimoto Model MP-S2. The melting points and decomposition points in nitrogen were measured in a sealed capillary filled with nitrogen. The infrared spectra were obtained by a Hitachi Model EPI-2 and a Jasco Model DS-402G grating spectrometer. The NMR spectra were recorded by a Varian Model A-60 instrument and a Jeol JNM 4H-100 instrument using tetramethylsilane as an internal standard. The elemental analysis for carbon and hydrogen was performed by Mr. Shibano of this Institute. The molecular weights were measured in a bezene solution using a Mechrolab Vapor Pressure Osmometer, Model 301A.

Materials.—Allene was prepared by the debromination of 2, 3-dibromo-propene-1 with zinc dust. Tri-iron dodecacarbonyl and dicobalt octacarbonyl were prepared by the literature method.[15]

The Preparation of I.—a) The preparation of I in an autoclave under an autogeneous pressure of allene has been described in a previous paper.

b) In a 100 ml. round-bottomed flask, tri-iron dodecacarbonyl (1.5 g.) and a *n*-hexane solution of allene (1 ml. in 30 ml.) were placed. The mixture was then refluxed by stirring it for 3 hr. under nitrogen, using a condenser cooled with dry ice - acetone. At all times there was an excess of iron carbonyl. When the reaction mixture was treated in a way similar to that described previously, about 70 mg. of I was obtained. In addition to this I, a small amount of orange oil and red crystals were obtained.

The Bromination of I.—In a carbon tetrachloride solution of I (0.1 g. in 5 ml.), an excess of bromine (1 ml.) in carbon tetrachloride was slowly added at room temperature in air. An instant reaction occurred, with the evolution of a gas. The ferric bromide formed was removed by an addition of water, and the product was obtained after the evaporation of the solution. The crude product was purified by sublimation at 70°C/3 mmHg, followed by washing with *n*-hexane, to give 0.1 g. of colorless crystals. M. p. 174°C (in sealed tube).

The Preparation of II.—Into a solution of di-cobalt octacarbonyl (3.0 g.) in benzene (50 ml.), 1 ml. of liquid allene was slowly introduced in the gaseous state with stirring at 40°C during a 30 min. period under nitrogen. The evolution of a gas and slight heat was observed. After the reaction mixture had stood for 2 hr., then the solvent was evaporated under reduced pressure. A dark brown solid containing a yellow solid was thus obtained. The crude product was obtained by slow sublimation at 80°C/3 mmHg under nitrogen. The sublimate was a mixture of dark brown and yellow crystals. The dark brown sublimate consisted of di-cobalt octacarbonyl and teracobalt dodecacarbonyl and was sensitive towards air. The sublimate was stored under nitrogen for several days. During this period, the di-cobalt octacarbonyl decomposed. The product was then extracted with benzene.

14) a) T. J. Kealy and R. E. Benson, *J. Org. Chem.*, **26**, 3126 (1961); b) E. L. Jenner and R. V. Lindsey, Jr., U. S. Pat. 2876254 (1959).

15) a) R. B. King and F. G. A. Stone, "Inorganic Syntheses," Vol. 7, McGraw Hill, New York (1963), p. 193; b) I. Wender, ibid., Vol. 5, McGraw Hill, New York (1959), p. 190.

The evaporation of the solvent under nitrogen, followed by sublimation, gave pure II as yellow crystals. The purified crystals were stable in air for a few days, and a slight decomposition was observed when it was stored in air for a longer period. The solution of II in benzene or in carbon tetrachloride began to decompose in air in 10—20 min.

The preparation of II can be performed under the pressure of carbon monoxide. A cooled *n*-hexane solution (20 ml.) of allene in an ampoule and dicobalt octacarbonyl in benzene (20 ml.) were placed in an autoclave at about 10°C. The carbon monoxide pressure was raised to 50 atm., and then the contents of the ampoule and the cobalt carbonyl solution were mixed. The autoclave was heated with rocking to 50—60°C for 1 hr. The product (0.7 g.) was isolated in this case by the evaporation of the solvent, followed by extraction with *n*-hexane and recrystallization. The purification of the product could be achieved by alumina chromatography under nitrogen.

Found: C, 39.76; H, 2.29. Calcd. for $[C_6H_4CoO_3]_2$: C, 39.37; H, 2.20%. mol. wt. 322: calcd. 366.

The Bromination of II.—a) In methanol: A suspension of II in methanol was mixed slowly with a solution of bromine in carbon tetrachloride at 10—15°C until the bromine was in excess. Water was then added to separate the cobaltous bromide formed, and the carbon tetrachloride layer was extracted with benzene. The evaporation of the solvent gave crude colorless crystals, which were further purified by recrystallization; m. p. 130—132°C in a sealed capillary.

Found: C, 15.6; H, 2.1. Calcd. for $C_4H_4Br_3O$: C, 15.60; H, 1.3%. mol. wt. 556. calcd. 615. infrared max., 1720cm^{-1} (strong, –CO–CO–).

The vicinal bromide structure was shown by the reaction with potassium iodide in acetone to give iodine.

b) In carbon tetrachloride: A solution of II in carbon tetrachloride was mixed with a solution of bromine at room temperature. The reaction occurred immediately. The product was isolated by distillation on a small scale and gave a colorless liquid. The characteristic smell and acidity of the liquid suggested the presence of an acid bromide. The presence of strong infrared band at 1780 cm^{-1} showed this compound to be acid bromide. The product hydrolyzed in air, and analysis was impossible. Another bromination, in a mixture of ethanol and carbon tetrachloride, gave a mixture of bromoesters (b. p. 100°C/3 mmHg), as evidenced by the presence of 1735 cm^{-1} band in the infrared spectrum.

Summary

The product with the $[C_3H_4Fe(CO)_3]_2$ composition obtained from the reaction of allene with tri-iron dodecacarbonyl has been found to be the first metal complex with a 2, 2'-bi-π-allylene structure. A study of the NMR spectrum has, however, shown an extensive valence tautomerism occurring, even at -10°C between the bi-π-allylene structure and the related butadiene-type structure. The reaction of allene with an excess of dicobalt octacarbonyl gave yellow crystals with the $[(C_3H)_4$-$Co(CO)_3]_2$ composition. A structure has been proposed in which a $\begin{matrix}CH_2\\CH_2\end{matrix}\!\!>\!C\text{–}C\!\!\begin{matrix}\diagup\!\!\!\!\diagup O\\\diagdown\end{matrix}$ skeleton is bound to cobalt atoms via π-allyl and acyl groups. The relation between the structures of these complexes and the catalytic reaction of allene have been discussed.

The author is grateful to Professor Nobue Hagihara for his invaluable discussions and encouragement during this study. He also wishes to express his appreciation of the advice and cooperation of Professor Sei Otsuka in the preparation of this report.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 547—551 (1966)

The Crystal Structure of the Pyrene-Tetracyanoethylene Complex

By Haruo KURODA, Isao IKEMOTO and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received July 3, 1965)

The crystal structure of the pyrene-tetracyanoethylene (TCNE) complex has been determined by the two-dimensional Fourier method. The monoclinic unit cell dimensions are: $a=14.58$, $b=7.34$, $c=8.09$ Å and $\beta=92.4°$. The space group is $P2_1/a$. Two pyrene and two TCNE molecules are contained in a unit cell. Pyrene and TCNE molecules are stacked alternately along the c-axis direction, making their molecular planes parallel to each other. The center of a TCNE molecule is not directly above that of the neighboring pyrene molecule, but is displaced considerably along the long axis of pyrene. The mean separation of the molecular plane is 3.32 Å.

The crystal of the charge-transfer complex involving pyrene as the electron donor and tetracyanoethylene (TCNE) as the electron acceptor is an organic semiconductor, the resistivity of

which is about $10^{12}\Omega$·cm. at room temperature with an energy gap of 1.6 eV.[1] Interestingly, this complex exhibits a relatively high photoconductivity, which enables us to determine the drift mobilities of charge carriers.[2] Further investigation is going on in our laboratory in order to elucidate the nature of the electronic conduction. The determination of the crystal structure was undertaken, in the first place, in connection with these studies. There is, however, another point of interest in its crystal structure. The pyrene and the TCNE molecules are nonpolar and planar molecules, similar in shape and size to each other. In this case, the intermolecular forces other than the charge-transfer one do not seem to depend strongly on the relative orientation of the symmetry axes of the pyrene molecule to those of TCNE in so far as they are stacked face-to-face. One may, therefore, presume that the relative orientation is mainly determined by the charge-transfer interaction. It would be interesting to see if the orientation of the molecules in the crystal is the one expected from the charge-transfer theory.

Experimental

The dark purple crystals of a lath shape elongated in the c-axis direction, or of a square, thin plate with a (100) face, were obtained by slowly evaporating the solvent from the chloroform solution containing equimolar amounts of pyrene and TCNE. The mole ratio of pyrene and TCNE in the crystal was determined to be 1 : 1 by chemical analysis. The crystal is stable if it is kept in an atmosphere saturated with vapors of pyrene and TCNE, but it decomposes gradually in air. Thus, the crystal was sealed in a glass capillary with a very thin wall during the X-ray experiments.

The crystal data are as follows:

Pyrene-TCNE complex: $C_{16}H_{10}\cdot C_6N_4$

Monoclinic

$a=14.58\pm0.05$ Å

$b=7.34\pm0.03$ Å

$c=8.09\pm0.03$ Å

$\beta=92.4°$

Volume of the unit cell: 864.4 Å^3

Absent spectra: $h0l$ when h is odd, $0k0$ when k is odd.

Space group: $P2_1/a$ (C_{2h}^5)

Assuming that two molecules of pyrene and two molecules of TCNE are in a unit cell, the density is calculated to be 1.28 g.cm^{-3} (the density observed by the floatation method is 1.3 ± 0.02 g.cm^{-3}).

The intensities of $h0l$ and $hk0$ reflexions were measured visually from multiple-film Weissenberg photographs with Cu$K\alpha$ radiation. The number of the measured reflexions is 80 for $h0l$ and 92 for $hk0$. No correction was made for the absorption, while the corrections for the Lorentz and polarization factors were made in the usual way.

The Determination of the Crystal Structure

The crystal shows a marked dichroism.[3] It is known that the strong band at 830 mμ in the absorption spectrum of the crystal is the charge-transfer band, which is distinctly polarized in the c-axis direction. This fact indicates that the donor and the acceptor molecules are stacked alternately along the c-axis making their molecular planes parallel to each other, so as to give a large overlap between their molecular orbitals. From the consideration of the symmetry of the molecules and the space group of the crystal structure, one can fix the positions of the centers of two pyrene and two TCNE molecules in the unit cell as follows:

Pyrene: 0, 0, 0; 1/2, 1/2, 0

TCNE: 0, 0, 1/2; 1/2, 1/2, 1/2

Assuming the known bond distances from the crystal structures of pyrene[4] and TCNE[5] respectively, several trial structures were deduced; then the structure factors were calculated on each trial structure. The one that gives the best agreement between the calculated and the observed structure factors was chosen and refined by means of two-dimensional Fourier syntheses on ($h0l$) and ($hk0$). The calculation of the structure factors and the Fourier syntheses were repeated several times, and then the (F_o-F_c) syntheses were applied to correct the atomic coordinates. The temperature factors were assumed to be the same for all atoms, the values being 4.00 for ($h0l$) and 4.79 for ($hk0$).

The electron density projection along the b-axis and that along the c-axis are shown in Fig. 1 and Fig. 2 respectively. The atomic coordinates of the final structure are given in Table I, for

Description and Discussion of the Structure

The arrangement of molecules in the crystal is shown in Fig. 3. The donor and the acceptor molecules are stacked alternately along the c-axis. The molecules can be considered planar. The equations of the mean planes of pyrene and TCNE are:

$$-1.3361x+0.6639y+1.4371z=0$$

and

$$-1.6990x+0.8630y+2.0000z=1$$

respectively.

The departures of the atoms from the mean planes are less than 0.02 Å. The molecular planes of pyrene and TCNE are almost parallel to each other, the deviation from parallelism being about 2°. The average separation between the planes is 3.32 Å, which is smaller than the usual van der

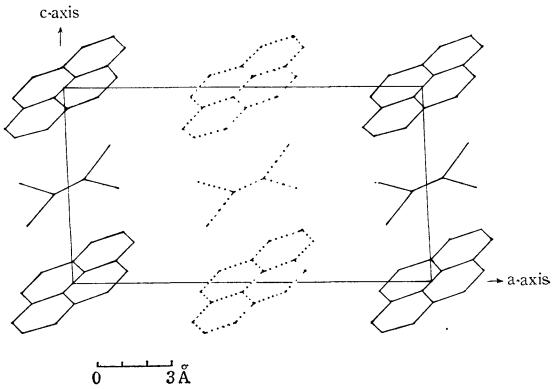

Fig. 3. Projection of the molecular arrangement on the (010) plane.

Waals separation. The distances between the atoms of the nearest neighbor pyrene and TCNE molecules are shown in Fig. 4, where the shortest one is 3.30 Å. Such close contact between the donor and the acceptor molecules suggests the presence of a strong intermolecular interaction between them.

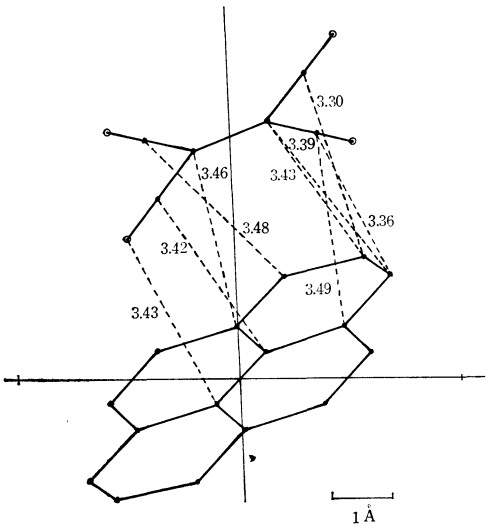

Fig. 4. Distances between atoms of the nearest neighbor pyrene and TCNE.

It is known that TCNE behaves as a very strong electron acceptor. There is reason to believe that nearly half of the binding energy between pyrene and TCNE is associated with the charge-transfer interaction in the case of the 1 : 1 complex formed in the solution. According to the charge-transfer theory, the donor molecule is supposed to take an orientation relative to the acceptor molecule, so as to give the largest overlap between the highest occupied orbital of the donor and the lowest vacant orbital of the acceptor, provided that the former is the donating orbital and the latter is the accepting one. This rule, known as

the orientation and overlap principle, leads to the following structural model for the 1 : 1 complex of pyrene and TCNE: pyrene and TCNE molecules are stacked face-to-face, so that their molecular centers are directly over each other and the central double bond of TCNE is parallel to the short axis of pyrene. The relative orientation of pyrene to TCNE found in the crystal is, however, considerably different from the model described above, as is shown in Fig. 5. Naturally there can be several factors affecting the relative orientation of molecules in the crystal other than the charge-transfer interaction between the donor and the acceptor which are the nearest neighbors. Therefore, it is possible that the orientation in the crystal is not identical with the stable orientation for the 1 : 1 complex. It seems worthwhile, however, to examine the theoretical bases of the model for the 1 : 1 complex described previously.

According to the charge-transfer theory, the ground state of the complex is expressed by the resonance hybrid between the no-bond structure and the dative structure, or the charge-transfer state. Usually it is regarded enough for the first approximation to take as the dative structure merely the lowest charge-transfer state where

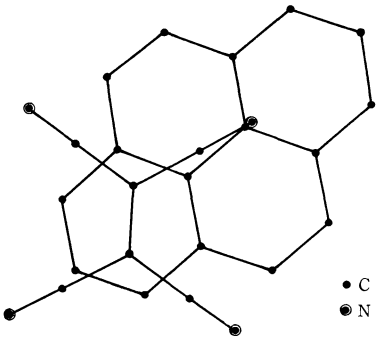

Fig. 5. Relative orientation of pyrene to TCNE found in the crystal.

an electron has been transferred from the highest occupied orbital of the donor to the acceptor. We have found, however, that the pyrene-TCNE complex shows two charge-transfer bands in the crystalline state as well as in the solution. The charge-transfer bands of the crystal are at 830 mμ and 510 mμ, and both of them are polarized in the c-axis direction. The first band is associated with the charge-transfer from the highest occupied orbital of pyrene to the lowest vacant orbital of TCNE, while the second one is associated with the charge transfer from the second highest occupied orbital of pyrene. The intensities of the two charge-transfer bands are comparable to each other. This can not be explained unless the charge-transfer state associated with the second band is as important a resonance structure as that of the lowest charge-transfer state. These facts suggest that the approximation neglecting the interactions of the charge-transfer states other than the lowest one is not satisfactory for the pyrene-TCNE complex. If such is the case, the orientation deduced from this approximation may not be the most stable structure, even for the 1 : 1 complex, since the overlap between the second highest occupied orbital of pyrene and the lowest vacant orbital of TCNE is largest when the central double bond of TCNE is parallel to the long axis, not the short axis, of pyrene. It is likely that the interactions of other charge-transfer states also make significant contributions to the binding energy. Further theoretical investigation seems to be necessary in this respect. Presumably the stable orientation for the 1 : 1 complex in solution will be similar, if not identical, to the one found in the crystal. Since there is a strong intermolecular interaction between pyrene and TCNE, we could expect deformations in the molecular structures. The bond distances determined at the present stage are, however, not accurate enough for us to determine conclusively if the molecules have been deformed by the complex formation or not. In order to solve this problem, refinements of the atomic coordinates as well as of the temperature factors are now in progress by means of three-dimensional analysis.

The authors wish to express their thanks to Professor Yōichi Iitaka, who has kindly allowed us to use the computer programs for the two-dimensional Fourier analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 551—555 (1966)

Vulcanized Aniline Black. Its Electrical Conductivity and Catalysis upon the Decomposition of Hydrogen Peroxide*1,*2

By Hiroo INOUE, Yasuji KIDA and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, The University of Osaka Prefecture, Sakai, Osaka

(Received July 5, 1965)

New semiconductive polymers have been prepared by the vulcanization of the oxidative condensation products of aniline. The polymers vulcanized are infusible black or black-violet powders insoluble in any organic solvent. The spin concentrations of the polymer vulcanized are about 1.5—2.5 $\times 10^{19}$ spins/g., about ten as much as those of the oxidative condensation products of aniline. The electrical conductivity increases with the increase in the sulfur content; the electrical resistivity at 20°C is 10^6—10^9 ohm-cm., and the activation energy is 0.68—1.18 eV. The polymers vulcanized have catalytic effects on the decomposition of hydrogen peroxide at 30°C. The catalytic effects of phenothiazine and the oxidative condensation products of aniline are, however, extremely slight. The catalytic ability depends not only on the structure of the polymer vulcanized, but also to some extent on its electrical conductivity.

*1 Part II of a series of studies of organic catalysts. The previous paper, also presented in This Bulletin (37, 326 (1964)), will be referred to as Part I of this series.

*2 Presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

The catalytic action of organic semiconductors on chemical reactions has received little attention. In a previous paper,[1] however, we have shown that some organic dyes catalyze the photo-oxidation of isopropyl alcohol in the liquid phase, and that the dyes classified as *p*-type organic semiconductors are more effective in catalytic activity than those classified as *n*-type organic semiconductors. Dawans, Gallard, Jeyssie and Traynard[2] have recently reported that the semiconductive polymers containing free radicals have catalytic activities on the decomposition of nitrous oxide, the dehydration of cyclohexanol and the isomerization of 1-butene.

In this paper we will describe how a new semiconductive polymer (shown as PAS in Fig. 1) synthesized by the vulcanization of the oxidative condensation product of aniline (shown as PA in Fig. 1) catalyses the decomposition of hydrogen peroxide at room temperature; the correlation between the catalytic activities of the polymer and their semiconductive properties will also be discussed.

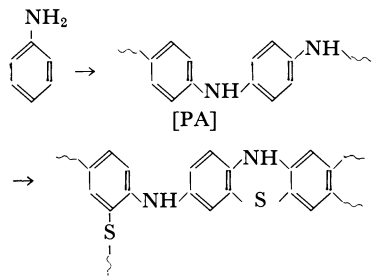

Fig. 1

Experimental

The Preparation of the Semiconductive Polymers.—*a) The Oxidative Condensation Product of Aniline (PA).*—A mixture of 50 ml. of 7.5% hydrogen peroxide and 0.25 g. of ferrous sulfate was gradually added to 5 g. of aniline at 60°C; the mixture was then allowed to stand overnight. The black precipitate obtained by filtration was poured into 100 ml. of 2 N sulfuric acid at 50°C. After the mixture had been filtered, the precipitate was washed with a boiling aqueous solution of ammonium hydroxide and then with water. When the washed precipitate was dried over calcium chloride at room temperature under the reduced pressure of 1 mmHg for a day, about 1.3 g. of black powder was obtained, m. p. 115—137°C.

Found: N, 13.68%.

b) The Oxidative Condensation Product of Aniline Hydrochloride (PA-Cl).—A mixture of 13.5 g. of concentrated hydrochloric acid, 38 ml. of 5% hydrogen peroxide and 0.9 g. of ferrous sulfate was gradually added to 4.66 g. of aniline dispersed in 200 ml. of water at 0°C; the mixture was stirred at 0°C for an hour, and then at room temperature for 44 hr. To this mixture 20 ml. of ammonium hydroxide was added, and the precipitate obtained was washed thoroughly with water and then dried over calcium chloride in the same way as has been described in the case of a). The yield of the product was 2.5 g.

c) The Vulcanized Product (PAS).—The vulcanization of PA or PA-Cl was carried out under the various conditions shown in Table I. Here the synthetic procedure of PAS, in which the molar ratio of sulfur to aniline unit was 2.1, will be described in detail as an example. A mixture of 0.56 g. of PA, 1.18 g. of sulfur and 0.08 g. of iodine was heated at 200—210°C for about 10 hr. under a nitrogen stream. During the course of the reaction, the evolution of hydrogen sulfide was observed. The solidified product was pulverized, and then extracted with carbon disulfide using a Soxhlet apparatus for a day in order to remove excess sulfur and low-molecular-weight compounds. With this extraction process, 0.91 g. of a mixture of sulfur and the black powder consisting of low-molecular-weight compounds was obtained. The traces of sulfur and iodine which remained in the extracted residue were removed by sublimation at about 120°C under the reduced pressure of 1—2 mmHg for 8 hr. About 0.78 g. of the infusible black powders was obtained. The results of the elementary analysis of nitrogen or sulfur for the black powders are shown in Table I.

Table I. The contents of nitrogen and sulfur in PAS

Starting material	S/-NHC_6H_4-*	PAS		
		N%	S%	r_s

PA	8	8.35	35.05	1.84
PA	20	6.90	37.74	2.39
PA-Cl	0	—	—	—
PA-Cl	6	—	32.98	—

* S/-NHC_6H_4- is the molar ratio of sulfur to aniline unit for the starting material.
** PA was vulcanized at 300°C.

Electrical Conductivities.—The d. c. resistivities of the polymers obtained were measured under a pressure of 1.0×10^3 kg./cm^2 at an applied electric field of 100—200 V./cm. according to the methods described in the preceding papers.[3] The current-voltage relationship was shown to be ohmic up to 10^4—10^5 V./cm. The electrical resistivity (ρ) at an ascending temperature was identical with that at a descending temperature, and a linear relationship between log ρ and $1/T$ was observed. The resistivity of all the polymers obtained fit the following equation, as does a typical organic semiconductor:

$$\rho = \rho_0 \exp(\Delta\varepsilon/2\boldsymbol{k}T)$$

The Decomposition of Hydrogen Peroxide.—The rate of the decomposition of 7.3% hydrogen peroxide was determined by measuring the amounts of oxygen generated. A weighed amount of a catalyst was dispersed in 5 ml. of distilled water in a reaction vessel placed in a thermostat. After the thermal equilibrium had been reached, 5 ml. of 7.3% hydrogen peroxide was added to the dispersed solution. The amounts of oxygen generated were measured at appropriate time intervals by a gas burette connected with the reaction vessel. In order to stop the reaction after a certain time, 2 N sulfuric acid was added to the above dispersed solution. The rest of the hydrogen peroxide was titrated with potassium permanganate. The amount of oxygen generated coincided with that of hydrogen peroxide calculated by the following equation:

$$2\,H_2O_2 = 2H_2O + O_2$$

Results and Discussion

The Properties of the Semiconductive Polymers.—PA was a black-brown powder and was partially soluble in dimethylformamide. However, when the powders were placed in a solution of concentrated sulfuric acid, the solution showed a red-brown color. The infrared spectra of PA showed the absorptions of the –NH– band at 3200—3300 cm^{-1} and the out-of-plane deformation band of two adjacent free hydrogen atoms at 825—840 cm^{-1}. The ESR spectrum of PA showed the existence of unpaired electrons, and the spin concentration was about 2.2×10^{18} spins/g. PA-Cl was infusible black powders and was insoluble in any organic solvent; it showed a blue-green color in concentrated sulfuric acid. The PAS obtained by the cross-linking of PA or PA-Cl with various amounts of sulfur was an infusible black powder, most of which was insoluble even in concentrated sulfuric acid. The molar ratio of sulfur to aniline unit in PAS (r_s) was calculated by the following equation:

$$\text{Molar ratio } (r_s) = \frac{S\% \times 14}{N\% \times 32}$$

As is shown in Table I, several polymers with different sulfur contents were obtained.

The infrared spectrum of PAS was similar to that of PA. The absorption bands of PAS at 825—840 cm^{-1} and 1450—1500 cm^{-1} were shifted toward a lower-wave-number side by 10—15 cm^{-1} as compared with those of PA.

The spin concentration of PAS calculated from the ESR spectra was about $1.5—2.5\times10^{19}$ spins/g., about ten times as much as that of PA. No remarkable difference in the spin concentration was, however, observed among the different sorts of PAS polymers. The g-value for PAS was close to that of a free electron, i. e., $g\simeq2.0023$. The half width of both PA and PAS was about 13.2—19.2 gauss, as narrow as that of the lattice polymer reported in preceding papers.[4]

Electrical Conductivities.—As can be seen in Table II, the ρ_{20} value of PA-Cl was low in comparison with that of PA ($>10^{13}$ ohm-cm.). The ρ_{20} value of PAS or PAS-Cl decreased with the increase in the sulfur contents; that is, the electrical conductivity increased with the increase in the degree of the vulcanization. This would imply that the degree of the conjugation of π

electrons in PAS increases.

The Effects of the Semiconductive Polymers on the Decomposition of Hydrogen Peroxide. —As can be seen in Fig. 2, phenothiazine showed no catalytic action on the decomposition of hydrogen peroxide, but PA, PA-Cl or PAS-Cl showed a slight catalytic action. On the other hand, PAS accelerated the decomposition of hydrogen peroxide to oxygen and water, and the catalytic activity of PAS depended on the sort of PAS. The logarithmic value of the concentration of hydrogen peroxide, log $(a-x)$. decreased linearly with the reaction time after a certain induction period. The first order rate constant, k, was calculated from the straight line in Fig. 2 by the following equation:

$$k = \frac{1}{t} \log \frac{a}{a - x}$$

where a and x are the initial and the decomposed concentrations of hydrogen peroxide respectively, and where t is the reaction time. The results calculated are shown in Table II. The relationships between the spin concentration, $\Delta\varepsilon$, log σ_0, or log k and r_s are shown in Fig. 3. No parallel relationship between the catalytic activity of PAS and the spin concentration or $\Delta\varepsilon$ was observed.

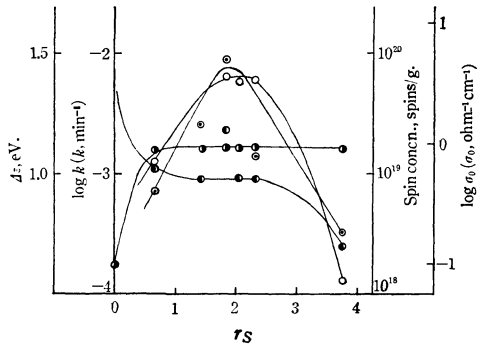

Fig. 3. Relationships between the spin concentration, $\Delta\varepsilon$, log σ_0, or log k and r_s.
◑ Spin concn., ◐ $\Delta\varepsilon$, ⊙ log σ_0, ○ log k

However, it is interesting to note that the spin concentration of PAS, which showed a catalytic activity was ten times larger than that of PA, which showed only a slight catalytic activity. The $\Delta\varepsilon$ value of PAS which shows the best catalytic activity was about 1 eV. Surprisingly, a parallel relationship was found between the variations in log σ_0 and log k for r_s. This seems to show that the catalytic activity is affected by the arrangement of the molecule, because log σ_0 is related more or less to the molecular arrangement.

The Effect of pH on the Catalytic Action.— Dokukina et al.[5] have reported that the nitrogen atoms contained in a catalyst acted as the active center on the decomposition of formic acid. In this connection, the fact that the catalytic activity of PAS decreases when $\Delta\varepsilon$ becomes smaller than 1 eV. may be caused by the decrease in the relative density of nitrogen atoms on the surface of a PAS solid. Therefore, we investigated the problem of whether the catalytic activity of PAS is affected by the variation of the pH in the solution of hydrogen peroxide. Here, the PAS with a r_s value of 1.8 was used as the catalyst, and the reaction was carried out at pH 3, 4, 5.2, 7.5, 9.8 and 11.2 respectively, in which Sörensen's buffer solutions for the 3—8 pH range, and Britton-Robinson's buffer solutions for the range of more than pH 9, were used. To 0.05 g. of PAS dispersed in 5 ml. of the buffer solution there was added 5 ml. of 7.3% hydrogen peroxide; then the amount of oxygen generated was measured at appropriate time intervals. In the solution of more than pH 9, oxygen was generated even with no addition of PAS, and so this amount was subtracted from the total amount of oxygen generated. As can be seen in Fig. 4, the catalytic effect in the acidic solution with pH values less than 4 was extremely slight. However, the PAS in neutral or alkaline solutions showed catalytic activity. This seems to show that the basicity of PAS plays an important role in the catalytic ability.

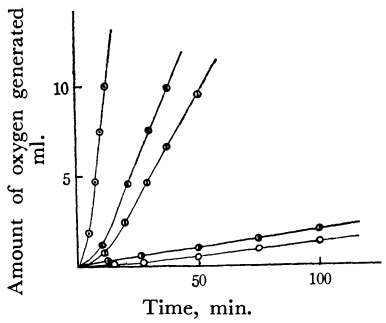

Fig. 4. Effect of pH on the catalytic action: PAS; r_s, 1.84.
○ pH 3, ◑ pH 4, ① pH 5.2, ◐ pH 9.8, ⊙ pH 11.2

The Effect of the Acceptor on the Catalytic Action.—The catalytic ability of PAS is considered also to be related to its nature as an electron donor. If so, the catalytic activity of PAS treated with an electron acceptor, for instance, iodine, 1, 3, 5 - trinitrobenzene or 7, 7, 8, 8 - tetracyanoquinodimethane, must decrease as compared with that of the untreated PAS. The treatment of PAS with the electron acceptor was carried out by dispersing PAS for 12 hr. in a solution of the electron acceptor in benzene or ethanol. As is shown in Fig. 5, the catalytic activity of the treated PAS was lower than that of the untreated PAS. Therefore, the nature of PAS as an electron donor

5) E. S. Dokukina, S. Z. Roginskii, M. M. Sakkarov, A. V. Topchiev, M. A. Geiderikh, B. E. Davydov and B. A. Krentsel, *Doklady Akad. Nauk. S. S. S. R.*, **137**, 893 (1961).

◑ Iodine, ⓘ 1, 3, 5-trinitrobenzene, ◐ sulfuric acid, ⊙ 7, 7, 8, 8-tetracyanoquinodimethane, ○ untreated PAS

seems to be important in the catalytic ability.

An Assumed Mechanism for the Catalytic Action of PAS.—As has been described above, it was assumed that the catalytic effect of the semiconductive polymers on the decomposition of hydrogen peroxide depends not only on the $\Delta\varepsilon$ value and their natures as electron donors, but also on the arrangement of the molecules and on the relative density of the nitrogen atom on the surface of the polymer solid. Though the details of the mechanism of the decomposition of hydrogen peroxide are not clear, it seems that hydrogen peroxide trapped on the nitrogen atoms on the catalyst is reduced by the conductive electron, decomposing to H_2O and O^-, and that O^- gives an electron to the hole on the catalyst, thus converting it to O_2, for example, by the following processes:

$$PAS + H_2O_2 \rightarrow PAS\cdots H_2O_2$$
$$\rightarrow PAS^+ + H_2O + O^-$$
$$PAS^+ + O^- \rightarrow PAS + O\cdot \rightarrow O_2 + PAS$$

Here, the catalytic ability must depend on the density and the arrangement of the active center such as the nitrogen atoms.

Phenazine Complexes. Their Preparation and Their Electrical Conductivity*

By Hiroo INOUE, Kentaro TAMAKI, Yoshihiro KIDA and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, The University of Osaka Prefecture, Sakai, Osaka

(Received July 5, 1965)

The photo-reduction of phenazine was carried out in isopropyl alcohol in the presence of ferric chloride or stannic chloride. In the course of the photo-reduction, a metal chelate precipitated. The metal chelate was composed of unstable black needle crystals; it was presumed, from the results of the elementary analysis, the visible and the infrared absorption spectra and the ESR spectra, to be Fe^{2+}- or Sn^{2+}-chelate of *N*-monohydrophenazyl. On the other hand, the reduction of phenazine with stannous chloride and hydrochloric acid gave a phenazhydrin - stannic chloride-complex, which was more stable than the photo-reduction products. Their resistivities at 20°C had low values of from 10^5 to 10^8 ohm-cm.

The reduction of phenazine with stannous chloride and hydrochloric acid produces a complex containing stannic chloride; the structure of this complex is not yet known, however. When this complex is treated with an aqueous solution of sodium hydroxide, it loses stannic chloride and produces free phenazhydrin.[1] The irradiation of phenazine in isopropyl alcohol by ultraviolet light also produces phenazhydrin, together with acetone.[2] The intermediates of the photo-reduction to phenazhydrin from phenazine are not certain, but one of them is supposed to be the *N*-monohydrophenazyl radical. If the *N*-monohydrophenazyl radical is produced in this process and if an electron acceptor is also present in the system, the *N*-monohydrophenazyl radical may react with the electron acceptor to produce a complex. In order to verify this assumption, the photo-reduction of phenazine was carried out in isopropyl alcohol in the presence of ferric chloride or stannic chloride. As was expected, the complex of *N*-monohydrophenazyl with ferric chloride or stannic chloride was obtained as crystals of a plate form. These complexes have an electrical conductivity as organic semiconductors. In the

present paper we will report on the syntheses of these complexes and on their properties as organic semiconductors. In addition, the properties of the phenazhydrin - stannic chloride-complex will be investigated.

Experimental

Materials.—Phenazine was prepared according to the methods described in the literature[3]; it was purified by repeated recrystallizations from ethanol.

The Preparation of Metal Chelates.—*Reduction with Stannous Chloride and Hydrochloric Acid.*—To a solution of 0.54 g. of phenazine in 20 ml. of ethanol there was added at room temperature a solution of 0.56 g. of anhydrous stannous chloride in 10 ml. of ethanol. No crystals precipitated from the greenish reaction mixture. However, the acidification of the reaction mixture with 1—2 ml. of concentrated hydrochloric acid immediately gave black-green needle crystals. After the above acidified mixture had been further refluxed for five minutes, the hot mixture was filtered and left to cool. After the cooled filtrate had then been filtered out, 0.56 g. of the metal chelate was obtained as black-green needle crystals; this was then recrystallized from ethanol.

3) A. Wohl and W. Aue, *Ber.*, **34**, 2442 (1901).

Found: N, 11.40; Cl, 14.33. Calcd. for $C_{48}H_{36}N_8$-$SnCl_4$: N, 11.42; Cl, 14.46%.

The metal chelate decomposed to phenazine and stannic chloride when dissolved in ethanol. Therefore, the phenazine content in the metal chelate could be estimated from the optical densities of the ultraviolet and visible absorption spectra of phenazine at 250 mμ and 370 mμ in ethanol. The results showed the molar ratio of phenazine to stannic chloride to be 4 : 1.

The Photo-reduction of Phenazine with Isopropyl Alcohol.—*In the Presence of Stannic Chloride.*—A solution of 0.41 g. of phenazine and 0.69 g. of stannic chloride in 40 ml. of isopropyl alcohol was placed in a test tube of a vycol (30 mm. in inner diameter, 0.5 mm. in wall thickness) and irradiated under an atmosphere of nitrogen at room temperature for 30 hr. with a 100W. mercury lamp placed 5 cm. from the vessel. About 0.32 g. of black prism crystals were precipitated. The crystals collected by filtration were dried over phosphorus pentoxide under the reduced pressure of 2—5 mmHg.

Found: N, 7.43; Cl, 19.40. Calcd. for $C_{12}H_9N_2$-$SnCl_2$: N, 7.57; Cl, 19.20%.

From the results of the visible absorption spectra, the molar ratio of phenazine to stannous chloride in the product was estimated to be 1 : 1.

In the Presence of Anhydrous Ferric Chloride.—A solution of 0.12 g. of phenazine and 0.17 g. of anhydrous ferric chloride in 25 ml. of isopropyl alcohol was irradiated for 7 hr. in a manner similar to that described above. About 0.1 g. of black needle crystals were thus precipitated. The crystals were dried over phosphorus pentoxide under the reduced pressure of 2—5 mmHg in an atmosphere of nitrogen.

Found: N, 9.22; Cl, 23.38. Calcd. for $C_{12}H_9N_2$-$FeCl_2$: N, 9.20; Cl, 23.13%.

The molar ratio of phenazine to ferrous chloride in the product was estimated from its visible absorption spectra to be 1 : 1.

Results and Discussion

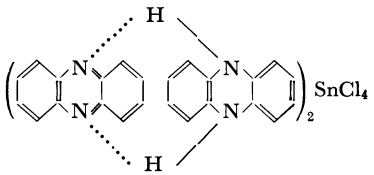
The Properites of Metal Chelates.—*The Reduction Product with Stannous Chloride and Hydrochloric Acid* (abbreviated as (ph-phH_2)$_2SnCl_4$).—The reduction product, infusible black-green needle crystals, was completely decomposed to phenazine and stannic chloride when it was dissolved in ethanol, although it was very stable in the crystalline form. The molar ratio of phenazine to stannic chloride in the product was 4 : 1.

The visible absorption spectra of a solution of phenazine, stannous chloride and hydrochloric acid dissolved in ethanol were measured at various

concentrations of the three components, phenazine, stannous chloride and hydrochloric acid. The results are shown in Fig. 1. As can be seen there, a new band appeared at 470 mμ, and the optical density of the new band increased with the increase in the molar ratio of phenazine to stannous chloride. This band seemed to be an absorption of the Sn^{2+}- or Sn^{4+}-chelate. When the concentration of each component in three components was increased, a new band appeared at about 650 mμ. This band must be a charge transfer absorption for phenazhydrin, ph-phH$_2$. On the other hand, the visible absorption spectrum as measured by the KBr disk showed two bands, at about 378 mμ and 470 mμ, while no band was observed at about 650 mμ.

The infrared absorption spectrum of the reduction product was similar to that of phenazhydrin, ph-phH$_2$, and showed the absorptions of the –N–H band at 3360 cm^{-1}, the –$\overset{+}{N}$= band at 2770 cm^{-1} and the out-of-plane deformation band at 735 cm^{-1}.

From the results described above, the following structural formula may be assigned to the structure of the metal chelate:



The spin concentration, the *g*-value and the half-width of the reduction product as calculated from the ESR spectra are shown in Table I. The ESR spectra consisted of a single narrow band; no fine structures were observed.

The Photo-reduction Product with Isopropyl Alcohol.— The photo-reduction of phenazine with isopropyl alcohol in the presence of ferric chloride gave the Fe^{2+}-chelate as black needle crystals (abbreviated as phH·FeCl$_2$). When the crystals were allowed to stand at room temperature in an atmosphere of air for a long time, their color gradually changed from black to yellow. Thus, the photo-reduction product seems to be unstable to oxygen.

The ultraviolet absorption spectrum of an ethanolic solution of the photo-reduction product, phH·FeCl$_2$, was found to be identical with that of phenazine because it was oxidized to decompose to phenazine and ferric chloride in the aerated ethanol. Therefore, the photo-reduction was carried out in a closed cell, and the variation in the visible absorption spectra during the course of the photo-reduction was measured. That is, a solution of phenazine and ferric chloride dissolved in isopropyl alcohol was sealed in the closed cell in an atmosphere of nitrogen and irradiated at room temperature for 95 hr. with a 100 W. mercury lamp; then the variation in its visible absorption spectrum with the reduction time was traced. As can be seen in Fig. 2, the absorption of phenazine at about 370 mμ decreased, while a new absorption appeared at about 500 mμ. The new band seems to be that of *N*-monohydrophenazyl, phH·

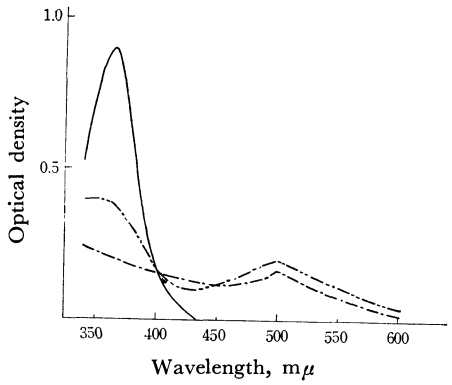


Fig. 2. The visible absorption spectra of the irradiated solution of phenazine in the presence of $FeCl_3$ or $SnCl_4$: Irradiated time; 95 hr. for $FeCl_3$ and 71 hr. for $SnCl_4$, Concentration; $FeCl_3$, 5.3×10^{-5} mol./l., $SnCl_4$, 6.09×10^{-5} mol./l. and phenazine, 6×10^{-5} mol./l.
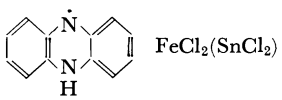
—— Before irradiation, ---- $FeCl_3$,
-·-· $SnCl_4$

Its infrared absorption spectrum was similar to that of (ph-phH$_2$)$_2$SnCl$_4$. However, the out-of-plane deformation band showed the doublet at 740 cm^{-1} and 750 cm^{-1}, such as that of phenazine or dihydrophenazine.

The ESR spectrum was broad, although the features of the spectrum were similar to those of (ph-phH$_2$)$_2$SnCl$_4$. The *g*-value was large in comparison with that of the free electron, as is shown in Table I.

On the other hand, the ultraviolet and infrared spectral properties of the photo-reduction product obtained in the presence of stannic chloride (abbreviated as phH·SnCl$_2$) were similar to those of phH·FeCl$_2$, but the ESR spectrum was different, as is shown in Table I and Fig. 2.

As has been described above, the Fe^{2+}- and Sn^{2+}-chelates obtained by the photo-reduction both have free spins, and its visible spectrum shows an absorption at about 500 mμ. Also, the infrared spectrum shows an absorption of the –$\overset{+}{N}$= band; the molar ratio of the phenazine ring to ferrous chloride or stannous chloride is 1 : 1. Hence, the structural formula of the metal chelate might be formulated as follows:



Namely, the intermediate photo-reduction product of phenazine would form the metal chelate with the Fe^{2+} or Sn^{2+} ion obtained by the photo-reduction of the Fe^{3+} or Sn^{4+} ion.

Electrical Conductivities.—The d. c. resistivity was measured under the pressure of 10^3 kg./cm^2 in vacuo according to the methods described in a previous paper.[4] In the case of phH·$FeCl_2$ or $SnCl_2$, the d. c. measurement was carried out with especial caution because it is unstable to oxygen. The dark-currents of all the metal chelates were ohmic up to 10^3 V./cm. The relationships between the d. c. resistivity and the temperature are shown in Fig. 3. The resistivity at an ascending temperature coincided with that at a descending temperature, and a linear relationship between $\log \rho$ and $1/T$ was observed. The value of $\Delta\varepsilon$ was calculated by the following equation:

$$\rho = \rho_0 \exp(\Delta\varepsilon/2\boldsymbol{k}T)$$

where $\Delta\varepsilon$ is the apparent energy gap; $\boldsymbol{k}$ is the Boltzman constant, and ρ is a specific electrical resistivity. The values of ρ_{20} and $\Delta\varepsilon$ are shown in Table I, which the values of ph-phH_2 are those reported in our previous paper.[4] The ρ_{20} values of all metal chelates were lower by about 10^2—10^5 than that of ph-phH_2. The ρ_{20} of (ph-phH_2)$_2$$SnCl_4$ was the lowest among those of all the metal chelates. The reason for this may be that the molecular arrangement of ph-phH_2 is more regular than that of the other chelates.

The Absorption Spectra of Dyes. XI.[1] A Note on the Color Change in Some Azobenzene Dyes with Variation in the Acidity*

By Yoshié TANIZAKI, Tadashi KOBAYASHI and Toshihiko HOSHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received July 8, 1965)

The absorption spectra of azobenzene and its para hydroxy, amino or dimethylamino derivative, and their sodium salts have been determined above 220 mμ in mixed solutions of water and ethanol (7 : 3 in volume) at various acidities. All the samples show characteristic changes in spectra with increase in the acidity, and the respective spectral changes keep well-defined isosbestic points, indicating a binary system spectrally. The wavelengths of the color band peaks and the corresponding spectral species have been determined. Consequently, the following order of the substitution effect has been obtained;

$$\left.\begin{matrix}-NH_3^+\\ -NHMe_2^+\end{matrix}\right)<-H<-OH<-NH_2<-O^-<-NMe_2$$

The color change in azobenzene derivatives with a variation in the pH value has been very often studied.[2] The conclusions on the proton addition, however, have not always coincided with one another. Klotz et al.,[3] for instance, have concluded that a first proton goes to the amino group and that a second proton goes to the azo group with an increase in the hydrogen ion concentration:

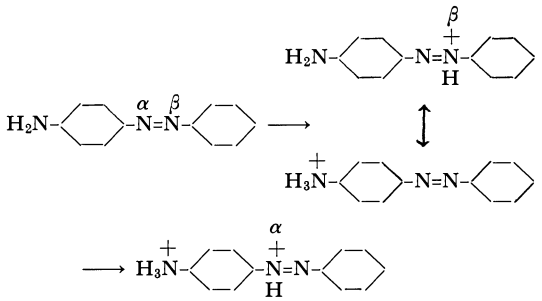
If this is true, the first proton addition must shift the color band to a shorter wavelength, because the electronic theory insists that the protonated amino group cannot conjugate with the ring system because of the loss of the π-type electrons. Therefore, this scheme cannot correspond to the red shift of the color band resulting from the first proton addition. On the other hand, Sawicki[4] has considered the tautomer concept of the proton addition, which is as follows;



According to his scheme, either the first or the second protonation process could involve three spectral species. However, as will be shown later, a careful re-examination will make it evident that, in the course of an increase in the acidity, three kinds of spectral changes appear in turn, when a dicationic species is produced, and that each spectral change has well-defined isosbestic points, thus indicating a binary system spectrally.

In the present paper, a systematic interpretation will be given of the color band peaks with relation to the proton addition to some azobenzene derivatives. At the same time, the order of the substitution effect on neutral azobenzene and azobenzenium ions will be determined.

Experimental

The azo compounds used here were azobenzene (abbreviated to AB), *p*-hydroxyazobenzene (HAB), *p*-aminoazobenzene (AAB) and *N*, *N*-dimethylaminoazobenzene (DAB) prepared from the special-grade commercial materials by recrystallizations, repeated more than ten times, from the ethanol solution. The melting points of all the applied compounds were in agreement within ± 1 °C with those in the literature. The other compounds used here were the sodium salts of DAB - *m'*-sulfonic acid, HAB - *m'*-sulfonic acid and HAB - *p'*-sulfonic acid; they were synthesized in accordance with the usual steps and were purified by repeated recrystallizations in the same way as above.

The measurement of the absorption spectra was carried out over the 220—550 mμ region using a Shimadzu QR-50 manual spectrophotometer and a Hitachi EPS-2U recording spectrophotometer.

A mixed solution of water and ethanol (7 : 3 in volume) was used as the solvent.

The samples were carefully dealt with in order to avoid converting them to the cis isomer by light.

Results

The spectral change in various acid concentrations of AB, which is the prototype of the derivatives used here, is illustrated in Fig. 1. The first absorption peak moves from 320 mμ to the long wavelength at 425 mμ with an increase in the acid concentration.

The absorption spectra of HAB are shown in Fig. 2. The spectrum with a peak at 430 mμ in a neutral solution (curve 1) changes into another one with a 350 mμ band in an acid solution (curve 3) through the isosbestic points kept by the spectra in the intermediate solutions. With a further increase in the acid concentration, HAB reveals a new band at 460 mμ and a diminution of the 350 mμ band (Fig. 3).

The spectral changes of AAB are illustrated in Figs. 4, 5 and 6. Figure 4 shows that the intense band at 380 mμ in alkaline or neutral solutions (curve 1) is made to disappear by the addition of dilute sulfuric acid, while instead two new bands appear at 317 mμ and 500 mμ (curve 3). With a further increase in the acidity, absorption curve 3 (Fig. 4) varies as follows, keeping the isosbestic points (Fig. 5): the 317 mμ band decreases, and at the same time the 500 mμ band increases in intensity without a shifting of the peaks. After the almost total disappearance of the 317 mμ band (curve 7 in Fig. 6), the intensified 500 mμ band is moved to the shorter side at 415 mμ by a further-concentrated sulfuric acid, as is shown in Fig. 6.

4) E. Sawicki, *J. Org. Chem.*, **22**, 365 (1957).

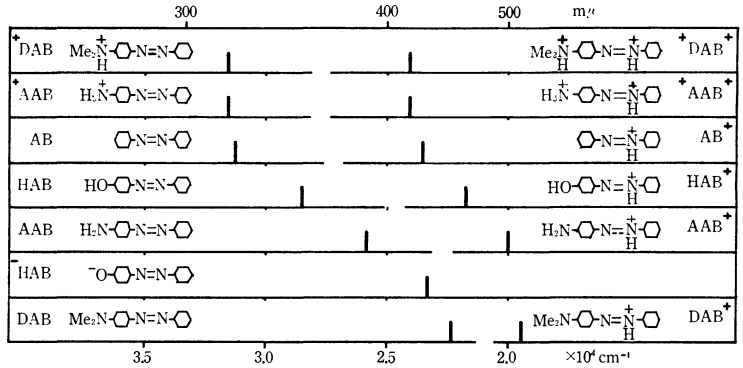

Fig. 8. Absorption maximum of the first band of azobenzene and its derivatives.

DAB behaved like AAB, though the spectral change corresponding to Fig. 5 was not so remarkable as in AAB.

The sulfonic sodium salts of HAB and AAB showed spectral changes quite similar to those of HAB and AAB, indicating essentially no effect of the sulfonic group. The spectral change of HAB - *m'*-sulfonic acid sodium salt is shown as an example in Fig. 7; it can be compared with HAB, which is shown in Fig. 2.

Discussion

The spectral change for the solvent variation in the sodium sulfonate of the azo compound is essentially identical with that of the parent azo compound. Accordingly, the discussion of the mechanism of the color change can be limited to the azo compounds, excluding the sulfonic groups, and the conclusion thus derived is also applicable to the corresponding compounds, including the sulfonic groups.

The proton addition to AB makes the 320 mμ band change to the 415 mμ band by attaching a proton to the electron pairs of one of the azo nitrogen atoms.[5] Let us describe this formally by:

$$AB(320\ m\mu) \rightarrow AB^{+}(425\ m\mu) \qquad (1)$$

As it is well known that the phenolic hydroxyl group can easily be dissociated, HAB in alkaline or neutral solutions has to be ionized; the 430 mμ band must be due to the $^{-}$HAB species. A first proton will go to the oxy-anion part of the $^{-}$HAB species, and a second one, this time preferentially, to the nonbonding σ electrons of β azo-nitrogen.[4,6] The spectral change of HAB may, therefore, be described as follows:

$$^{-}HAB(430\ m\mu) \rightarrow HAB(350\ m\mu) \rightarrow HAB^{+}(460\ m\mu) \qquad (2)$$

Now let us consider the case of AAB. According to Fig. 5, the 317 mμ and the 500 mμ band should be due to spectrally different species, while Fig. 4 indicates that the two bands behave as if they are only one species. This implies that, under such experimental conditions as are indicated in Fig. 4, there is no appreciable change in the amount-ratio of the two species. Since a first proton can be attached to either the amino-group or the β azo-nitrogen atom, representing the respective protonated species as $^{+}$AAB or AAB^{+}, the 317 mμ and the 500 mμ band may be assigned to the $^{+}$AAB and the AAB^{+} species respectively. Therefore, the spectral changes shown in Figs. 4, 5 and 6 can reasonably be explained by the following mechanism. At first, while the AAB species is usable, the amount-ratio of $^{+}$AAB and AAB^{+} is unchanged (Fig. 4); in the second step, the spectral change after using up the AAB species continues as a result of the increasing acidity until $^{+}$AAB is completely converted into AAB^{+} (Fig. 5); finally, AAB^{+} is protonated again by the further increase in acidity, thus producing the dicationic $^{+}$AAB^{+} species (Fig. 6). Thus, the following scheme is obtained for the protonation processes and the absorption peaks:

$$AAB(380\ m\mu) \rightarrow \begin{matrix} {}^{+}AAB(317\ m\mu) \\ AAB^{+}(500\ m\mu) \end{matrix} \rightarrow AAB^{+}(500\ m\mu) \rightarrow {}^{+}AAB^{+}(415\ m\mu) \qquad (3)$$

Similarly, scheme 4 may be considered to hold for the case of DAB:

$$DAB(460\ m\mu) \rightarrow \begin{matrix} {}^{+}DAB(317\ m\mu) \\ DAB^{+}(516\ m\mu) \end{matrix} \rightarrow DAB^{+}(516\ m\mu) \rightarrow {}^{+}DAB^{+}(420\ m\mu) \qquad (4)$$

where the [$^{+}$DAB]/[DAB^{+}] amount-ratio seems to be smaller than [$^{+}$AAB]/[AAB^{+}].

Correlations among the first band positions of the spectral species appearing in schemes 1—4 are summarized as a pattern in Fig. 8, which reveals quite clearly the order of the substitution effect.

5) H. H. Jaffé, *J. Chem. Phys.*, **21**, 415 (1953).
6) Cf. M. B. Robin and W. T. Simpson, ibid., **36**, 580 (1962).

The band positions of the left-side and the right-side series in Fig. 8 can be considered in relation to the substitution effect of the *p*-group to azobenzene and azobenzenium ions respectively, and they are understandable in terms of the electronic theory.

Thus we may conclude that the order of the substitution effect at the para position of both neutral and cationic azobenzene is:

$$\left.\begin{matrix}-NH_3^+ \\ -NHMe_2^+\end{matrix}\right) < -H < -OH < -NH_2 < -O^- < -NMe_2.$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 562—565 (1966)

The Ring-opening Polymerization of Ethylene-methylphosphite

By Takeo SHIMIDZU, Tomio HAKOZAKI, Tsutomu KAGIYA and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

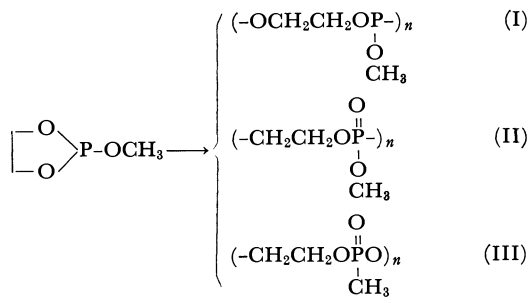
(Received July 8, 1965)

Several Lewis acids have been found to be effective catalysts for the polymerization of ethylene-methylphosphite, giving a solid polymer with a poly(ethylene-methylphosphonate) structure. The use of $Al(C_2H_5)_3$ gave a wax-like polymer with the structure of poly(ethylene-methoxy-phosphinate), while Na and Li in liquid NH_3 at $-78°C$ produced a jelly-like polymer partly composed of poly(ethylene-methylphosphite).

Recently, there have been several studies of the ring-opening polymerization of species of phosphorus containing cyclic molecules, e. g., cyclic phosphonites,[1] cyclic phosphites,[2,3] cyclic phosphonates,[4] and cyclic phosphates.[5]

It can be seen in the patent descriptions that the ring-opening polymerization of cyclic phosphites has been investigated with several kinds of catalyst systems,[2] but no information on the structure of polymers has been given. The present authors have reported that the ring-opening polymerization of ethylene-alkylphosphites at higher temperatures gave a polymer with the structure of poly(ethylene-alkylphosphonate).[3] It is known that a tautomeric pair of trivalent and pentavalent structures exists in phosphorus compounds like enol- and keto-forms of carbonyl compounds, and that the former is less stable than the latter. In addition, Mukaiyama et al. reported that the polymerization products of cyclic phosphonites have the structure of poly-(ethylene-alkylphosphinate), and suggested an intermediate of an open-chain carbonium-cation type with a phosphoryl group.[4]

The present paper concerns a study of the catalyst and the polymerization products. It was found that the polymerization products were composed of the three types of polymers represented by the following formulae:



These structures were confirmed by means of infrared absorption spectra and their hydrolyzed products.

Experimental

Ethylene Methylphosphite.—This compound was prepared from ethylene phosphochloridite, methanol and dimethylaniline according to the method of Arbuzov and Zoroastrova[6]; b. p. 40—41°C/12 mmHg, n_D^{20} 1.4484. The infrared spectrum of this compound is shown in Fig. 1. The ethylene phosphochloridite employed was prepared by the following method: Into 1 mol. of ethylene glycol there was stirred drop by drop, 1.5 mol. of phosphorus trichloride at room temperature. Then the reaction mixture was refluxed

for 5 hr. Ethylene phosphochloridite was distilled under reduced pressure: b. p. 64—69°C/45—50 mmHg, n_D^{20} 1.4953.

Catalyst.—Materials of a commercial grade were employed.

Polymerization was carried out in a sealed glass tube under a nitrogen atmosphere. The resultant polymer was washed by dry methanol, and the remaining monomer, as well as a volatile material, were removed under reduced pressure at a temperature below 50°C. The intrinsic viscosity was measured in a solution of dimethylformamide at 9°C.

The infrared absorption spectra were obtained from a KBr disk of the polymer.

The hydrolytic degradation of the polymer was carried out by refluxing it for three hours in 5 ml. of an aqueous 0.10 N sodium hydroxide solution with 30 ml. of dioxane under a nitrogen stream. After the contents had been kept standing overnight at room temperature, the precipitate was crystallized from ethanol. The identification of the polymer structure was aided by a study of its infrared spectrum and by its elementary analysis.

Results and Discussion

The results of the polymerization of ethylene-methylphosphite with various catalysts are summarized in Table I.

Ethylene-methylphosphite can be polymerized without a catalyst at high temperatures. Still, aluminum chloride and boron fluoride etherates are effective catalysts for the polymerization. They give solid polymer with the structure of poly(ethylene-methylphosphonate), $(-CH_2CH_2-\underset{\underset{CH_3}{|}}{\overset{\overset{O}{\|}}{O}}P-O-)_n$, as was reported in a preceding paper.[3] Sodium methylate also gives a jelly-like polymer at relatively low temperatures. Triethylaluminum is an effective catalyst, giving a brittle wax-like polymer the infrared spectrum of which differs a little from that of the above-mentioned polymers. This polymer has the structure of poly(ethylene-methoxyphosphinate), $(-CH_2CH_2\underset{\underset{OCH_3}{|}}{\overset{\overset{O}{\|}}{O}}P-)_n$, as is confirmed by the infrared spectrum indicated in Fig. 1 (curve B) and also by the hydrolyzed product, sodium β-hydroxyethylphosphonate.

Lithium and sodium in liquid ammonia can hardly be effective catalysts for the polymerization, but they give polymers with infrared spectra different from those of the polymers which are obtained by means of the other catalysts. Radical initiators such as 2, 2'-azobisisobutyronitrile do not polymerize ethylene-methylphosphite.

Figure 1 shows typical infrared spectra of the polymers. Curve A is that of run 1, while curve B is that of run 2-1. On the basis of these data, the absorptions at 1300 cm^{-1} (P-CH_3), 1255 and 1225 cm^{-1} (P=O) and 1175 cm^{-1} (P-OCH_3) were adopted as the key bands. These absorptions in each polymer are tabulated in Table I. Table II shows the results of the hydrolysis of the polymers.

The polymers which were obtained at the higher temperatures have absorptions at about 1300, 1255, and 1255 cm^{-1}, and their hydrolyzed products are mainly sodium salts of methyl-phosphonic acid. Conversely, the polymers which are obtained by triethylaluminum and at relatively lower temperatures (run 15 and run 2-1) have an absorption at 1175 cm^{-1} and their hydrolyzed products are mainly sodium β-hydroxyethylphosphonate. Besides, the polymers obtained by lithium and sodium in liquid ammonia at lower temperatures have a broad absorption spectrum in the range from 1170 to 1240 cm^{-1}. This suggests that the polymers have P=O and P-OCH_3 groups. To obtain those absorptions more evidently the polymer (run 13) was extracted in chloroform under nitrogen at room temperature. The results are shown in Tables II and III.

TABLE III. THE SEPARATION OF THE POLYMERS OF RUN 13 AND THEIR INFRARED ABSORPTIONS

	Absorptions at 1175	1225	1255	1300 cm^{-1}
Chloroform extr.	+	—	—	—
Residue	+	+	±	±

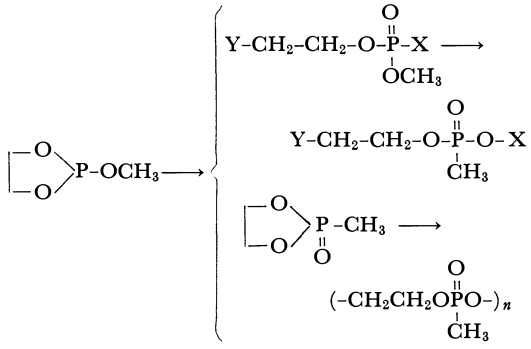
Extracted for 5 hr. under a nitrogen stream at 60°C.

The chloroform-extract of the polymer was readily oxidized when it was kept standing in the air; its infrared spectrum is shown in Fig. 1 (curve D). It has absorptions at about 1175, 1225, and 1255 cm^{-1}, but it has no characteristic absorption of the P-N bond and $-NH_2$ groups. On the basis of those data, we confirmed the

structure of the chloroform-extract to be poly(ethylene-methylphosphite), $(-CH_2CH_2OPO-)_n$ with OCH_3. No other chloroform extract with an infrared absorption spectrum of the type of curve D was found.

Thus the type of polymers produced by the ring-opening polymerization of ethylene-methylphosphite can be written as in the scheme presented at the beginning of the page. In Fig. 1, curves A, B, and C are obviously those of the polymers III, II, and I respectively.

It is interesting that the polymer of the type III is given, although it is not yet clear as to whether the polymer results from the methyl migration of an open-chain intermediate or from the ethylene-methylphosphonate which was primarily produced by a rearrangement of ethylene-methylphosphite. The latter scheme seems to be more plausible in view of the stability of the phosphoryl-type structure in phosphites.



At any rate, ethylene-methylphosphite is not so stable at higher temperature or in the presence of sodium methylate. Korshak et al.[4] have reported that cyclic phosphonates can polymerize at 140°C with water or sodium. In the reaction mixtures of both runs 1 and 11, a little methyl ethylenephosphonate, which was confirmed by its boiling point and its molecular refraction, was recovered.

Recently Denny and Giacin have reported that trialkyl phosphite and *p*-toluene sulfonic acid methyl ester yield dialkyl methyl-phosphonate.[7] It should be noted that the preparation of ethylene-methylphosphite from ethylene-phosphochloridite and sodium methoxide is not easy since they are much more liable to methyl-phosphonate. The polymer of the type II may be produced through the so-called Arbuzov rearrangement. The polymer of the type I is a very particular one. The catalyst system, sodium in ammonia, gave the polymer of the type I while sodium amide did not yield this type of polymer. It goes without saying that sodium amide must exist in liquid ammonia. If it were not for an interaction of ammonia with trivalent *P* atom in ethylene-methylphosphite in the course of polymerization, it is hard to understand how such an enol-form could be stable.

Summary

The ring-opening polymerization of ethylene-methylphosphite has been carried out using several catalyst systems. By using an acidic catalyst, such as aluminum chloride, titanium(III) chloride, boron fluoride, etc., and by working at higher temperatures, we have produced a solid polymer with the structure of poly(ethylene-methylphosphonate), the intrinsic viscosity of which in DMF is ca. 1. When triethylaluminum was used, and when we worked at relatively lower temperatures, we obtained a wax-like polymer with the structure of poly(ethylene-methoxyphosphinate), the intrinsic viscosity of which in DMF is over 1. Sodium and lithium in liquid ammonia at −78°C, although they were not very effective catalysts for the polymerization, gave a jelly-like polymer with part of the structure of poly(ethylene-methylphosphite).

These structures have been confirmed by a study of their infrared spectra and their hydrolyzed products.

Phosphorylation via the Oxidation of Phosphite. II. The Preparation of the Diesters of Phosphorous Acid by the Reaction of Alcohols with Ethyl *N*-Phenylimino Phosphite and Acids*[1]

By Teruaki MUKAIYAMA and Kazutoshi OSAKA*[2]

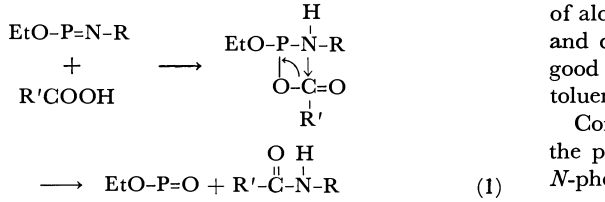
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received July 12, 1965)

The diesters of phosphorous acid were prepared in good yields by the reaction of primary or secondary alcohols, such as methanol, ethanol, and *s*-butanol, or of phenols, such as phenol, *p*-chlorophenol and *p*-cresol, with ethyl *N*-phenylimino phosphite and *p*-toluenesulfonic acid monohydrate. Similarly, when carboxylic acids, such as acetic acid, benzoic acid, *p*-chlorobenzoic acid and trichloroacetic acid, were used in place of the acid monohydrate in the above experiment, the diesters of phosphorous acid were also obtained. Ethyl *N*-*n*-propylimino or ethyl *N*-isopropylimino phosphite could be successfully used in place of ethyl *N*-phenylimino phosphite in the above experiments. Further, various derivatives of methylphosphinic acid, such as ethyl dicyanomethyl-, ethyl cyanocarboethoxymethyl- and ethyl dicarboethoxymethylphosphinate, were obtained by the reaction of ethyl *N*-phenylimino phosphite, *p*-toluenesulfonic acid monohydrate and active methylene compounds, such as malononitrile, ethyl cyanoacetate and diethyl malonate.

Recently, it has been found that diesters of phosphorous acid are successfully oxidized under mild conditions to give dialkyl hydrogen phosphates in high yields by means of monobromocyanoacetamide and benzyl alcohol. Therefore, a new useful method for the synthesis of diesters of phosphoric acid can be expected to be offered by the phosphonylation of alcohols and the subsequent oxidation of the phosphites. In this connection, the preparation of diesters of phosphorous acid by the reaction of alcohols with ethyl *N*-phenylimino phosphite and benzaldehyde was reported in the preceding paper.[1]

In the present study, the preparation of diesters of phosphorous acid from alcohols and metaphosphite, formed by the reaction of ethyl *N*-phenylimino phosphite and either carboxylic acid or *p*-toluenesulfonic acid, was attempted. The possible formation of metaphosphite from the reaction of ethyl *N*-phenylimino phosphite and carboxylic acids (Eq. 1) was suggested by the fact that the reaction of phenyl isocyanate with acetic acid resulted in the formation of acetanilide and carbon dioxide by way of a mixed anhydride of phenylcarbamic acid and acetic acid.[2]



(1)

Indeed, when acetic acid and ethyl *N*-phenylimino phosphite were refluxed in anhydrous benzene for an hour, acetanilide was obtained in a 59% yield, but the expected metaphosphite could not be detected and an orange-colored resinous product was formed.

The presence of the intermediate, i. e., metaphosphite, is demonstrated by the formation of the corresponding diesters of phosphorous acid, diethyl phosphite or ethyl butyl phosphite, along with acetanilide, when acetic acid reacts with ethyl *N*-phenylimino phosphite in the presence of such alcohols as ethyl alcohol or butyl alcohol. Similarly, dialkyl phosphites were obtained, along with the corresponding anilides, when benzoic acid, *p*-chlorobenzoic acid or trichloroacetic acid was used in place of acetic acid in the above experiment. In these cases, ethyl alkyl phosphite was contaminated with small amounts of triethyl phosphite, a compound containing a carbonyl group and aniline, the presences of which were confirmed by the infrared spectra.

On the other hand, when ethyl *N*-phenylimino phosphite was treated with a strong acid such as *p*-toluenesulfonic acid monohydrate in the presence of alcohols, an exothermic reaction soon took place and diesters of phosphorous acid were obtained in good yields, along with the anilinium salt of *p*-toluenesulfonic acid (see Table I).

Contrary to the results obtained in the case of the phosphonylation of alcohols by means of ethyl *N*-phenylimino phosphite and benzaldehyde, both

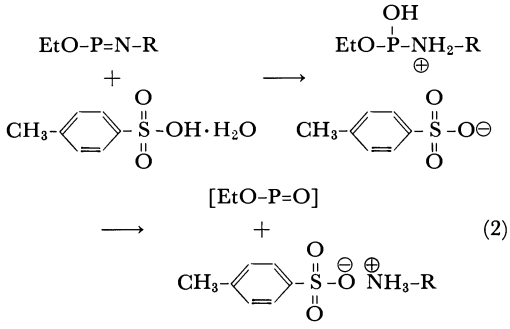
Benzyl-	Benzene	2.0	80	54	113/3	n^{20} 1.4893	90

primary and secondary alcohols were similarly phosphonylated in good yields by the present method. However, in the case of the phosphonylation of such tertiary alcohols as *t*-butyl alcohol, the yield of phosphite decreased markedly.

Further, it was established, that phenols, such as phenol, *p*-chlorophenol and *p*-cresol, reacted with ethyl *N*-phenylimino phosphite and *p*-toluenesulfonic acid to give the corresponding ethyl aryl phosphites. Unfortunately, these phosphites could not be purified by distillation; a small amount of phenols always contaminated the phosphites.

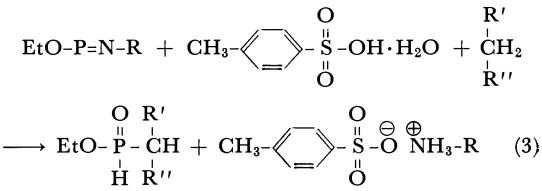
In a similar way, it was also found that ethyl *N*-isopropylimino phosphite or ethyl *N*-*n*-propylimino phosphite gave the corresponding dialkyl phosphite by reaction with ethyl alcohol and *p*-toluenesulfonic acid.

The reaction may proceed through the initial formation of an intermediate, formed by the addition of the water of crystallization of *p*-toluenesulfonic acid to ethyl *N*-phenylimino phosphite, which in trun decomposes to metaphosphite and the anilinium salt of *p*-toluenesulfonic acid, as is shown in the following scheme (Eq. 2). Alcohols then join with the metaphosphite to form diesters of phosphorous acid.



(2)

These results suggest that various derivatives of methylphosphinic acid can be prepared by the reaction of ethyl *N*-phenylimino phosphite, *p*-toluenesulfonic acid monohydrate and active methylene compounds. Indeed, when malononitrile, ethyl cyanoacetate or diethyl malonate was refluxed in benzene with ethyl *N*-phenylimino phosphite and *p*-toluenesulfonic acid monohydrate, the corresponding methylphosphinic acid derivatives, such as ethyl dicyanomethylphosphinate, were obtained (Eq. 3).



(3)

Experimental

All melting points and boiling points are uncorrected.

Solvents and Reagents.—The solvents and alcohols were dried and purified by ordinary procedures. Ethyl *N*-phenylimino phosphite was prepared from ethyl dichlorophosphite and aniline according to a method previously reported.[1]

Ethyl *N*-*n*-propylimino phosphite, b. p. 80—110°C/0.5 mmHg, 41%, and ethyl isopropylimino phosphite, b. p. 72—85°C/0.5 mmHg, 29%, were prepared by a method analogous to that used for ethyl *N*-phenylimino phosphite. These compounds were also obtained when ethyl dichlorophosphite was treated with an equimolar amount of isopropylamine or *n*-propylamine in the presence of triethylamine.

The Reaction of Ethyl *N*-Phenylimino Phosphite with Carboxylic Acids.—When a solution of acetic acid (1.20 g., 0.02 mol.) and ethyl *N*-phenylimino phosphite (1.67 g., 0.01 mol.) in 40 ml. of benzene was refluxed for an hour, acetanilide (0.80 g., 59%) was obtained, along with a colorless oily product. Similarly, benzanilide (88%) and trichloroacetanilide (96%) were obtained when benzoic acid and trichloroacetic acid respectively were used in place of acetic acid in the above experiment.

The Reaction of Ethyl Alcohol with Ethyl *N*-Phenylimino Phosphite and Acetic Acid.—Into a solution of ethyl *N*-phenylimino phosphite (1.67 g., 0.01 mol.) in 10 ml. of benzene there were stirred, at room temperature and in one portion, both a solution of acetic acid (0.60 g., 0.01 mol.) in 5 ml. of benzene and a solution of ethyl alcohol (0.46 g., 0.01 mol.) in 5 ml. of benzene. After the solvent had been removed under reduced pressure, acetanilide was separated by

TABLE II. THE REACTIONS OF ETHYL ALCOHOL WITH ETHYL *N*-PHENYLIMINO PHOSPHITE AND CARBOXYLIC ACIDS

Carboxylic acid	Reaction condition*1		Yield of anilide, %	Yield of*2 diethyl phosphite, %

Trichloroacetic	Reflux	1.0 hr.	26	33

*1 Each reaction was carried out in dry benzene on the scale of 0.01 mol.
*2 In each case, the phosphites were contaminated with small amounts of aniline, triethyl phosphite and a substance containing a carbonyl group.
*3 0.76 g. (46%) of *p*-chlorobenzoic acid was recovered.

the addition of petroleum ether to the residue. The acetanilide was then removed by filtration; 0.30 g. (22%); m. p. 113—114°C. The filtrate was fractionally distilled to give 1.00 g. (72%) of crude diethyl phosphite (b. p. 38—45°C/5 mmHg, n_D^{22} 1.4184), and the residue was solidified to give 0.50 g. (37%) of acetanilide.

Similarly, crude ethyl *n*-butyl phosphite (0.87 g., 52%; b. p. 45—77°C/4 mmHg, n_D^{19} 1.4320) was obtained by the reaction of *n*-butyl alcohol (0.74 g., 0.01 mol.) with ethyl *N*-phenylimino phosphite (1.67 g., 0.01 mol.) and acetic acid (0.60 g., 0.01 mol.). The reactions of ethyl alcohol with ethyl *N*-phenylimino phosphite and benzoic acid, *p*-chlorobenzoic acid or trichloroacetic acid gave the corresponding anilides and crude diethyl phosphite (see Table II).

The Reaction of Ethyl *N*-Phenylimino Phosphite with *p*-Toluenesulfonic Acid Monohydrate.—When ethyl *N*-phenylimino phosphite (0.42 g., 0.025 mol.) and *p*-toluenesulfonic acid monohydrate (0.43 g., 0.026 mol.) were mixed in one portion by stirring them at room temperature, white needles were soon separated. The crystalline compound, 0.50 g. (80%), m. p. 229—232°C, was filtered off and identified by a comparison of its infrared spectrum with an authentic anilinium salt of *p*-toluenesulfonic acid.

The Reaction of Ethyl Alcohol with Ethyl *N*-Phenylimino Phosphite and *p*-Toluenesulfonic Acid Monohydrate.—To a solution of ethyl *N*-phenylimino phosphite (1.67 g., 0.01 mol.) in 20 ml. of benzene there was added a mixture of *p*-toluenesulfonic acid monohydrate (1.90 g., 0.01 mol.) and ethyl alcohol (0.46 g., 0.01 mol.) in 40 ml. of benzene. After the reaction mixture had been stirred for two hours at 80°C, a separated anilinium salt of *p*-toluenesulfonic acid (2.45 g.; 93%), was filtered off; the filtrate was then concentrated under reduced pressure. The fractionation of the residual oil gave diethyl phosphite, 0.82 g. (60%); b. p. 70°C/14 mmHg, n_D^{16} 1.4081, which was identified by a comparison with both its retention time of the gas chromatography and the infrared spectrum with these of an authentic sample (see Table I).

Similarly, when 1.41 g. (0.015 mol.) of phenol was treated with 3.34 g. (0.020 mol.) of ethyl *N*-phenylimino phosphite and 3.80 g. (0.02 mol.) of *p*-toluenesulfonic acid monohydrate, crude ethyl phenyl phosphite, 1.52 g. (82%); b. p. 110—117°C/5 mmHg, was obtained. Redistillation gave 0.48 g. (26%) of pure ethyl phenyl phosphite, b. p. 105°C/5 mmHg.

Infrared spectrum: 2420 (P–H), 1270 (P=O), 1595, 1495, 760 and 690 cm^{-1} (mono-substituted benzene).

Found: C, 52.09; H, 5.86. Calcd. for $C_8H_{11}O_3P$: C, 51.69; H, 5.96%.

The Reaction of Ethyl Alcohol with Ethyl *N*-Isopropylimino Phosphite and *p*-Toluenesulfonic Acid Monohydrate.—A solution of ethyl alcohol (0.51 g., 0.011 mol.) and *p*-toluenesulfonic acid monohydrate (2.09 g., 0.011 mol.) in 5 ml. of benzene was added, drop by drop, to a solution of ethyl *N*-isopropylimino phosphite (1.44 g., 0.011 mol.) in 20 ml. of benzene. The solution was refluxed for an hour. A separated isopropylammonium salt of *p*-toluenesulfonic acid 2.47 g. (97%); m. p. 137—139°C, was filtered off. After the solvent had been removed, diethyl phosphite, 1.21 g. (80%); b. p. 45—50°C/3 mmHg, n_D^{19} 1.4070, was obtained by distillation. Similarly, ethyl *N*-*n*-propylimino phosphite gave diethyl phosphite (50%).

The Reaction of Malononitrile with Ethyl *N*-Phenylimino Phosphite and *p*-Toluenesulfonic Acid Monohydrate.—A solution of 0.66 g. (0.01 mol.) of malononitrile and 1.90 g. (0.01 mol.) of *p*-toluenesulfonic acid monohydrate in 40 ml. of benzene was added to a solution of 1.67 g. (0.01 mol.) of ethyl *N*-phenylimono phosphite in 20 ml. of benzene. After the reaction mixture had been stirred for 2.1/4 hr. under refluxing, the anilinium salt of *p*-toluenesulfonic acid, 2.40 g.; (91%), was obtained by filtration. The filtrate was fractionated to give crude ethyl dicyanomethylphosphinate, 0.92 g, (58%); b. p. 60—63°C/4 mmHg, n_D^{13} 1.4138. Redistillation gave an analytical sample, b. p. 60—64°C/4 mmHg, n_D^{15} 1.4091.

Infrared spectrum; 2440 (P–H), 2260 (CN), 1250 cm^{-1} (P=O).

Found: N, 17.93. Calcd. for $C_5H_7O_2N_2P$: N, 17.72%.

Summary

Diesters of phosphorous acid have been prepared by the reaction of alcohols or phenols with ethyl *N*-phenylimino phosphite and acids, such as acetic acid, benzoic acid and *p*-toluenesulfonic acid monohydrate. Further, methylphosphonic acid derivatives have been obtained using active methylene compounds in place of alcohols in the above reaction.

The authers wish to express their hearty thanks to Dr. Tuziaki Hata and Mr. Oyo Mitsunobu for their kind advice given during the course of this experiment. They also wish to thank Miss Toshiko Aoyagi for her microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 569—576 (1966)

Semi-empirical Treatments of the Nonlinearity of Free Energy Correlations in Aromatic Side-chain Reactions. The Multiplicity of Substituent Constants

By Takayuki FUENO, Tadashi OKUYAMA and Junji FURUKAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received July 15, 1965)

The nonlinearity of free energy correlations of the substituent effects in aromatic side-chain reactions has been treated by the simple LCAO MO method. The ionization equilibria of substituted phenylacetic acids, leading to the definition of "normal" substituent constants, σ^0, were taken as the basis for theoretical tests of the correlations. Thus, the integral parameters for various substituents were determined in such a way that the calculated π-electron charge densities for meta and para carbons in benzenes were proportional to the corresponding σ^0-constants. Several other typical side-chain reactions of substituted benzenes were simulated by the corresponding standard processes, and the effects of substituents on these reactions were examined by the perturbation calculations of the π-electron energy changes accompanying the reactions. It has been found that the substituent constants, σ, σ^+ and σ^-, are linearly related to the calculated energy changes. It is suggested that the treatment may be extended to other reactions to account for the sliding-scale variation in substituent constants from reaction to reaction.

It has been customary to utilize Hammett's $\rho\sigma$ equation[1] for correlating observations concerning the effects of ring substituents on the rate or equilibrium data for the reactions of benzene derivatives. The Hammett equation in its original form presumes that the standard free energy changes in certain types of reactions of substituted benzene derivatives are in a linear relation with those in the corresponding benzoic acid ionizations. This linear free energy relationship has been borne out well in many cases; indeed, there exists a voluminous literature that indicates the applicability of the Hammett equation.[2]

Several authors[3-9] have looked into the physical basis of the Hammett equation, particularly into the nature of the substituent constants, in terms of the simple molecular orbital method. These studies have been briefly reviewed in a recent article by Ehrenson.[9] Among others, Jaffé's attempts[3] to correlate the Hammett σ-constants with π-electron charge densities on the ring carbons bearing reaction sites seem to have illuminated, though with limited success, the role of mobile π-electrons in governing the relative magnitudes of σ-constants.

It is known, however, that the original Hammett relation suffers some limitations depending on the type of reaction and on the solvent conditions; thus, a number of modified sets of σ-values have been proposed by many authors.[2,10-13] The current belief that para substituents are more or less subject to multiplicity in σ-value is a conceptual outgrowth of these situations. This nonlinearity of free energy correlations, i. e., the "sliding-scale" character of sigma values, is believed to arise from the different extents of direct conjugation between substituents and reaction centers in different reactant structures and reaction types.[12,14] A molecular orbital consideration of such a multiplicity of substituent constants was first undertaken by Jaffé,[4] who was able to reproduce approximately the enhanced sigma values required for strongly electron-attracting para substituents in the ionizations of aniline and phenol.[1] The exalted electron-releasing character of some methylene anion-type para substituents in electrophilic substitutions was also accounted for by us from an examination of the effects of these substituents on the ring carbon localization energies.[7] Similar effects of this last group of substituents on the extracyclic reaction

sites have recently been discussed by Ehrenson.[9]

The purpose of the present paper is to analyze the relative magnitudes of various sets of substituent constants from a unified theoretical standpoint, and thereby clarify the cause of the above-mentioned nonlinearity of free energy correlations. To this end we will conduct second-order perturbation calculations of the energy changes of systems comprising substituted benzenes and reactive side-chains. In principle, this is a computational elaboration of the afore-mentioned treatment of Ehrenson.[9] As the basis for comparisons among different sets of substituent constants, the ionization equilibria of substituted phenylacetic acids, which lead to σ^0-values,[11] have been selected. This is because, in these compounds, the reaction site is insulated from the aromatic π-conjugation, which otherwise may blur the standard with which one may test the departure from the linear free energy relationships. The effects of substituents on other types of benzene side-chain reactions, leading to σ, σ^+ and σ^- constants,[1,10] will be examined by calculating the π-electronic energy changes accompanying the reactions. It will be shown that these calculated energy changes are closely related to the various substituent constants. It appears that extensions of the present treatment may provide a promising route to account for the sliding-scale variations of substituent constants from reaction to reaction.

The Method of Calculation

All the calculations were carried out by the simple LCAO MO method (overlap neglected). First, the π-electronic MO energies, $E_i=\alpha+m_i\beta$, and the corresponding MO coefficients, C_{it}, were calculated for various monosubstituted benzenes, XC_6H_5 (as the common unperturbed substrates). α and β have their usual meanings. Second, analogous calculations were made for isolated (unperturbed) extracyclic reaction centers, Y, whose energies and coefficients are $F_j=\alpha+n_j\beta$ and C_{ju} respectively. Third, the delocalization energies, DE, due to the linking of XC_6H_5 and Y to form disubstituted benzenes, XC_6H_4Y, were calculated from the following familiar expression,[15] which has been derived by the second-order perturbation method:

$$DE=2\left\{\sum_{i}^{\text{occ}}\sum_{j}^{\text{unocc}}-\sum_{j}^{\text{occ}}\sum_{i}^{\text{unocc}}\right\}\frac{(C_{ir})^2(C_{js})^2}{m_i-n_j}\left(-\frac{\gamma^2}{\beta}\right) \tag{1}$$

where the subscripts r and s denote the carbon atoms at which the components are bonded; γ is the resonance integral for such bonds. Equation 1 was used also for the system XC_6H_4Y' formed after the occurrence of the side-chain reactions. Finally, the total energy of the product, XC_6H_4Y', relative to that of the reactant, XC_6H_4Y, was obtained from

$$\Delta E_\pi=c-\Delta E \tag{2}$$

where

$$\Delta E=DE'-DE \tag{3}$$

and

$$c=2\sum_{j}^{\text{occ}}(F_j'-F_j) \tag{4}$$

The prime appearing in Eqs. 3 and 4 indicates that the quantities correspond to the product systems. Since c is independent of the substituents, X, the relative stabilities of the product systems may be expected to increase as the delocalization energy difference, ΔE, increases.

The integral parameters of heteroatoms and their bonds necessary for the calculation of the energies and coefficients of monosubstituted benzenes were determined by imposing the condition[16] that the charge densities on the para and meta ring carbons so obtained be proportional to the corresponding Taft σ^0-constants. The inductive effects of the substituents were roughly taken into account by assigning Coulomb integral increments to ring carbons.[3] Specifically, the ring carbon linked with a substituent atom, X, of the Coulomb integral parameter, k_X, was assumed to have a Coulomb integral increment, $\delta_{CX}k_X$; the inductive parameter, δ_{CX}, was taken to be 0.3 unless otherwise noted. The increments for the next-nearest ring carbons were assumed to be $\varepsilon\delta_{CX}$, with $\varepsilon=1/3$, but they were truncated for other carbon atoms.

For fixing the proportionality constant between charge densities and σ^0-values, only σ^0 meta and

a) k, Coulomb integral parameter; h, resonance integral parameter; δ, inductive parameter for the ring carbon carrying substituents.
b) Inductive effect model. Ortho carbons are assigned a Coulomb integral increment 0.3 k.
c) Used for the calculations of ionization energies of benzoic acids.

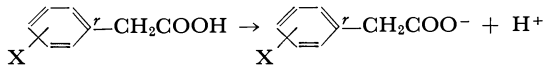
para values of the methyl group will suffice in principle, provided that the group is assumed to be a non-conjugating (inductive) substituent. In practice, however, the σ^0-values for meta and para methoxy groups were also used for the above purpose. Three unknown parameters (two Coulomb integrals, $\alpha+k\beta$, for the methoxy and methyl groups and one resonance integral, $h\beta$, for the ring carbon-methoxy bond) were so adjusted as to give the best straight-line fit of the calculated charge densities when plotted against the four σ^0-values. The slope was thus fixed. The parameters for other substituents were chosen so that the corresponding plots would fall on this straight line. The parameter values finally adopted for the various substituents investigated are listed in Table I. The proportionality of the calculated charge densities to σ^0-values is shown in Fig. 1.

Results

σ^0-Constants.—As has already been mentioned, Jaffé[3] attempted to correlate π-electron densities on meta and para carbons of substituted benzenes with the corresponding Hammett σ-constants. However, such attempts are unjustifiable, since benzoic acids, and also their conjugate bases, more or less involve resonance interactions between substituents and reaction centers.

In contrast, in the case of phenylacetic acids, the reaction site is insulated from the aromatic conjugation, so that the interactions between the ring and its substituents in these acids will remain essentially the same as in substituted benzenes. From the ionization constants of substituted phenylacetic acids, Taft[11] defined the "normal" substituent constants, σ^0. It seems, then, more reasonable to correlate the π-electron distributions in substituted benzenes with Taft's σ^0-constants than with Hammett's σ-constants.

It may be shown that the π-electron distributions in substituted benzenes are related to the dissociation energies of the corresponding phenylacetic acids. The replacement of a benzene hydrogen atom by a CH_2COOH group will introduce a perturbation to the Coulomb integral of the ring carbon, r, at which such a replacement occurs. It is to be expected that the reaction:



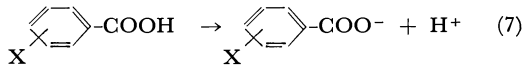
(5)

will accompany the change in this perturbation. Let us denote by $\delta\alpha_r$ and $\delta\alpha_r'$ these perturbations of the Coulomb integral before and after the reaction respectively. According to the simple LCAO MO theory, then, the total π-electronic energy change, ΔE^0, of the benzene part due to the above change in perturbation is given, to a first approximation, by

$$\Delta E^0 = q_r(\delta\alpha_r'-\delta\alpha_r) \qquad (6)$$

where q_r is the π-electron density on the ring carbon, r. Since the COO^- group is less electronegative than the COOH group, it is very likely that $\delta\alpha_r'-\delta\alpha_r>0$. Hence, the dissociation energy of phenylacetic acids will linearly increase with an increase in the q_r value.

Hammett's σ-Constants.—In the ionization of benzoic acids, the ΔE, defined by Eq. 3, is the difference in delocalization energy between benzoic acids and benzoate anions.



The integral parameters used for an isolated carboxyl group and the carboxylate anion are given in Table I. The parameter values assumed for COOH were the same as those used for COOR, except that the carbon atom in the former was assigned a smaller k value than in the latter. This assignment of a smaller k value was made in order to minimize the inductive effect of the COOH group on the ring in calculating the delocalization energies. Errors arising from such a minimization will be largely canceled by a similar disregard of the COO^- inductive effects in benzoate anions.

The values of ΔE calculated for various substituents are given in Table II. In every case the delocalization stabilization of the acid form was greater than that of the corresponding anion, i. e., $\Delta E<0$. This would mean that the smaller the ΔE in magnitude, the easier the ionization.

b) Ref. 1.

In Fig. 2 the calculated ΔE values relative to the value for unsubstituted benzoic acid are plotted against the σ-values. It may be seen there that the relative delocalization energy difference, $\delta\Delta E$, is proportional to σ, the symbol δ indicating the energy difference with respect to the substituents. It should be noted that the points for p-CH_3O and p-F groups, whose σ-values show relatively large deviations from σ^0-values, are well fitted to the straight line.

σ^+-Constants. — In electrophilic reactions, certain para-substituted compounds exhibit greater reactivities than would be expected from Hammett's σ-values of the substituents. From the data on the S_N1 solvolysis rates of substituted phenyldimethylcarbinyl chlorides (or, briefly, t-cumyl chlorides), Brown and Okamoto[10] defined the σ^+-values as a new set of electrophilic substituent constants.

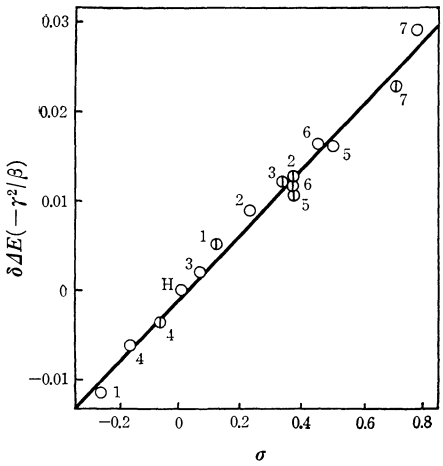

Fig. 2. The π-electronic energy changes in the ionization of substituted benzoic acids against σ-values.
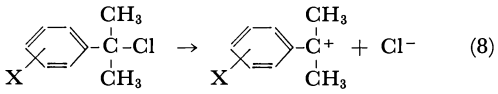
○, para; ⓘ, meta
Numbers correspond to the substituents given in Table I.

In the present calculations, we have taken the following ionic cleavage of t-cumyl chlorides as a standard reaction:



The total π-electronic energies of the chlorides may be assumed to be equal to those of the corresponding substituted benzenes. In the resulting carbonium ions, however, the side-chain, $-\overset{+}{C}(CH_3)_2$, is incorporated in the π-conjugation. Thus, the total π-electronic energies of the cations differ substantially from those of substituted benzenes. Since the carbonium ions are recognized to be very close to the transition state of the S_N1 reactions, the above energy increment, i. e., the delocalization energy which t-cumyl chlorides would acquire upon ionic cleavage, may be regarded as a measure of the relative ease of the reaction δ.[17,18]

The delocalization energies of t-cumyl chlorides may be calculated from Eq. 1, by assuming that the $-\overset{+}{C}(CH_3)_2$ group is a single heteroatom ion with a vacant π-type atomic orbital the Coulomb integral of which is $\alpha+k\beta$. These energies obtained

c) k is the Coulomb integral parameter for the side-chain carbon cation.

by the perturbation method will be denoted by ΔE_P^+. The magnitudes of ΔE_P^+ were calculated for various substituents, using varying k values ($k = 0$, 0.2 and 0.3). The results are given in Table III, together with the corresponding σ^+-constants.

An inspection of the data listed in Table III will indicate that for each k value the ΔE_P^+ values are larger for those substituents which have smaller σ^+-constants. This trend is compatible with the qualitative expectation that carbonium ions will be more stabilized as the charge-center carbons of the ions become less electron-deficient.[19] Also noticeable in Table III is the tendency that, in each substituent examined, the ΔE_P^+ value increases with an increase in the k value that is, with an increasing affinity of the exocyclic carbons toward π-electrons. However, this in itself should by no means be related to observations on the relative stabilities of benzyl-type carbonium ions bearing different alkyl groups (or hydrogen atoms) on the exocyclic carbons.[20]

A rather more important feature to be noted in the $\Delta E_P^+ - \sigma^+$ relationship is that the Coulomb parameter, k, exerts a particularly large influence on the ΔE_P^+ values of some para-substituted compounds (p-methoxy and p-fluoro derivatives). The situations are illustrated in Fig. 3, where the relative delocalization energies, $\delta\Delta E_P^+$, taking the nonsubstituted t-cumyl chloride as the standard, are plotted against the σ^+-values for each assumed value of k. In each case, a straight line is seen to fit the plots for meta substituents. In order for the para points to show the best fits to the meta line, a value of $k=0.2$ would have to be assumed for the side chain.[21] If the side-chain carbon has an electronegativity different from that specified by $k=0.2$, the effects of some para substituents on reactions of the type 8 will deviate from those to be expected from their σ^+-values. The occurrence of such deviations may be taken as an indication that the relative importance of the resonance interaction between substituents and reaction sites varies according to the structure of the reactants. This view of the sliding-scale variation of substituent constants is compatible with the physical picture underlying the Yukawa-Tsuno four-parameter equation:[12]

$$\log k/k_H = \rho\{\sigma + r(\sigma^+ - \sigma)\} \qquad (9)$$

in which r is a reaction parameter which takes account of the degree of possible resonance interactions between substituents and reaction sites in the transition states. Thus, r would increase with an increase in the k value.

19) E. Berliner and N. Shien, *J. Am. Chem. Soc.*, **79**, 3849 (1957).

20) In addition to the π-electron delocalization, several other factors, such as the inductive and hyperconjugative effects of alkyl groups and the strain relief on ionization, need to be considered with regard to the carbonium ion stability. Nevertheless we feel that the ΔE_P^+ value may be useful in comparing the relative effects of ring substituents on the stabilities of different types of carbonium ions.

21) That the positively-charged side-chain carbon is more electronegative than the ring carbons may be confirmed by a self-consistent field treatment of the ion. The simplest test of this point may be achieved by the use of the conventional ω-technique.[22] In the case of the benzyl cation the charge density calculated for the exocyclic methylene carbon by this method is roughly 0.41.[18] The Coulomb integral parameter for the exocyclic carbon orbital of the t-cumyl cation in its ultimate self-consistency will be 0.41 times $\omega(=1.4)$ plus twice the inductive parameter (-0.15) of a methyl group. Thus, $k=0.41(1.4)+2(-0.15)=0.27$, a value which is of the correct order of magnitude.

●, para; ◐, meta for $k=0$
Numbers correspond to the substituents given in Table I.

Another significant point in Fig. 3 is its indication that the k value also affects the slope of meta lines; the slope becomes steeper as the k value increases. If this is true, the reaction constant, ρ, should increase in magnitude with the increase in the resonance parameter, r, for reactions of the type 8. This expectation is borne out by the recent experimental results gained by Yukawa and Tsuno[23] who compared the substituent effects on the S_N1 solvolysis rates of *t*-cumyl and α-phenylethyl chlorides under the same conditions. They found that α-phenylethyl chlorides gave the values $r=1.16$ and $\rho=-4.95$ while *t*-cumyl derivatives had $r=1.00$ and $\rho=-4.54$. The variation in these values observed in going from *t*-cumyl to α-phenylethyl chlorides agrees at least qualitatively with our theoretical expectation.[24]

The delocalization energies were also calculated by the variation method for the case of $k=0$. The values obtained are included in Table III. The relative energies, $\delta\Delta E_V{}^+$, are found to be proportional to the corresponding $\delta\Delta E_P{}^+$ values, as is illustrated in Fig. 4. This remarkably good linear relationship confirms the validity of our present perturbation calculations.

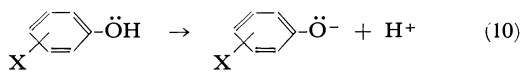
σ^--Constants.—Hammett first noted that, in the reactions of the derivatives of phenol and aniline, enhanced σ-values were required for such substituents as para-nitro and -cyano groups.[1] Just as the reactions whose transition states involve the electron-deficient side chains linked to an aromatic ring respond sensibly to electron-releasing para substituents, so the reactions which involve conjugating lone-pair electrons respond sensibly to electron-attracting para substituents. The special substituent constants for these substituents are designated by σ^-.

We calculated by the perturbation method the energy change, ΔE^-, accompanying the reaction:



(10)

Here the Coulomb integral parameters of the OH and O^- atomic orbitals are assumed to be $k=1$ and 0.8 respectively, and the energy change, ΔE^-, is the difference between the benzene delocalization energies, as defined by Eq. 3. The calculated energy changes are given in Table IV, together with the available data for σ^-.

In Fig. 5 the values of ΔE^- relative to the unsubstituted phenol, $\delta\Delta E^-$, are plotted against σ- or σ^--values, whichever are appropriate.

22) A. Streitwieser, Jr., and P. M. Nair, *Tetrahedron*, **5**, 149 (1959); A. Streitwieser, Jr., *J. Am. Chem. Soc.*, **82**, 4123 (1960).
23) Y. Yukawa and Y. Tsuno, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **86**, 873 (1965). In applying Eq. 9 to these reactions, they replaced σ by σ^0.
24) Taking one step further, one may make a more quantitative comparison between theory and experiment. From the experimental r-values, we estimated the values of k which permitted the best linear correlationships between $\Delta E_P{}^+$ and $\sigma+r(\sigma^+-\sigma)$. The k-values thus estimated were 0.20 and 0.23 for the side chains $-\overset{+}{C}(CH_3)_2$ and $-\overset{+}{C}HCH_3$ respectively. The relative slopes of the theoretical lines corresponding to these k-values were found to be 1 and 1.07. The ratio 1 : 1.07 is in reasonable agreement with the experimental ρ ratio, 1 : 1.09, found between *t*-cumyl and α-phenylethyl chlorides.

Numbers correspond to the substituents given in Table I.

Although the points are somewhat scattered in comparison with those in Figs. 1 to 3, it does appear that a single straight line fits the plots here also. Different choices of Coulomb parameters for the OH and O^- orbitals neither improve nor worsen the situation materially.

As an alternative to the above theoretical quantity, $\delta\Delta E^-$, the benzene delocalization energy itself could be used as a measure of the σ^--constants. This would be particularly valid when the ionizations of anilinium salts are to be considered. The delocalization energies calculated for the case of $k=1$ are listed in Table IV and are plotted against σ- and σ^--values in Fig. 6. It may be seen in Fig. 6 that the plots corresponding to the σ^--values fall on the meta line, in agreement with Jaffé's previous conclusion reached by the use of a different set of integral parameters.[4]

Discussion

Although it is definite that π-electrons make dominant contributions to the properties of conjugated compounds, any attempt to establish correlations between the distribution of such electrons and their role in controlling molecular reactivities must be judged with due caution. So far as the substituent effects on aromatic side-chain reactions are concerned, only those reactions which are governed by the normal substituent constants, σ^0, will respond directly to the electronic charge distributions effected by substituents. In other reactions, these two modes of substituent effects (on reactions and charge distributions) are more or less biased to the extent that they may permit discrimination. This is the basis of our present treatment of the nonlinearity of free energy correlations in aromatic side-chain reactions.

Our treatment is based on the assumption that the potential energy changes in the transition states caused by substituents would parallel the relative free energy changes for reactions. Although this assumption is a usual and irreplaceable starting point for the present sort of treatment, it is not always fulfilled in given reaction series.[13,25]

25) J. E. Leffler and E. Grunwald, "Rates and Equilibria of Organic Reactions," John Wiley & Sons, New York, N. Y. (1963), Chapter 9.

Nevertheless, we feel that imperfections arising from such difficulties will be minimized in the present treatment, inasmuch as our primary interest has been in the free energy correlations among different types of side-chain reactions. The integral parameters, which are used so as to mediate between substituent effects on different types of reactions, may partly absorb the uncertainties concerning the role of kinetic energy and entropy terms.

One major question which might be raised with regard to our treatment concerns the disregarding of the effects of factors other than π-conjugation. For instance, we have not considered explicitly the role of σ-inductive effects, which are definitely operative in reactions. Further, Dewar and Grisdale[8] have suggested that direct-field effects of substituents are even more important than σ-inductive effects and that the Hammett σ-constants may be related primarily to such effects and mesomeric effects. However, since there exists no justified way of separating σ-inductive (or, perhaps, direct-field) effects from mesomeric effects, we have avoided attempting to estimate these two contributions separately. Rather, in the interests of methodological simplicity, we have implicitly assumed that the inductive and field effects may at least be partly embodied in Hückel-type treatments by assigning relatively large inductive parameters to the ring carbons neighboring substituents.[26]

Finally, a word should be said about the inductive parameters, δ_{CX}, assumed for the C–Cl and C–F bonds. The adherence to the assignment $\delta_{CX}=0.3$ for these bonds has always resulted in anomalously large deviations of the *p*-chloro and *p*-fluoro points from the straight lines shown in Figs. 2, 3, 5 and 6. Since it turned out, from the calculations, that the choice of the values of 0.6 and 0.5 for the C–Cl and C–F bonds respectively greatly improved the corresponding plots in the ΔE-σ relationships, these values were used for testing the correlations of σ^0 with other substituent constants. It is conceivable that the parameters δ_{CX} are not constant over different bonds.

The authors wish to thank Professor Yasuhide Yukawa and Dr. Yuho Tsuno of Osaka University for their valuable suggestions and discussions.

26) It is agreed that relatively large inductive parameters are required in order to predict the reasonable magnitudes for meta electron densities.[3] Peters[6] has demonstrated that even equal π-electron densities can be predicted for para and meta carbons when the inductive parameters are assumed to propagate gradually along the bonds, diminishing by as large a constant factor as $\varepsilon=0.53$. Thus, the disregard of the π-inductive and field effects is largely counterbalanced by the choice of the parameters $\delta_{CX}=0.3$ and $\varepsilon=1/3$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 576—580 (1966)

The Determination of Micro Amounts of Polythionates. IV.* A Photometric Method for the Determination of Tetrathionate by Decomposition with Sodium Sulfite[1)]

By Iwaji IWASAKI and Shigeru SUZUKI

Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received July 16, 1965)

A new photometric method for the determination of tetrathionate by means of its decomposition with sulfite has been developed. It is based on the formation of thiosulfate equivalent to the tetrathionate, and on the photometric determination of thiosulfate by measuring its decoloration of an iodine solution. 5×10^{-6}—1×10^{-3} M (1 mg./l.—0.2 g./l.) of tetrathionate can be determined easily and rapidly within a range of error of $\pm2\times10^{-6}$—2×10^{-5} M (0.4 mg./l.—4 mg./l.) by using 20 ml. of a sample. The tetrathionate solution is decomposed with sodium sulfite in a slightly alkaline medium. After the completion of the decomposition reaction, a formaldehyde solution is added to mask the interference of the excess sulfite remaining and this solution is acidified with acetic acid. Then the standard iodine solution is added. The absorbancy of the solution is measured at the wavelength of 372 or 440 mμ 20 min. after the addition of an iodine solution. By this method tetrathionate can be determined, even when it is coexistent with thiosulfate and sulfite in up to similar amounts. Many substances, such as aluminum, calcium, cadmium, magnesium, zinc, silicate, nitrate, sulfate, phosphate, chloride and fluoride, do not interfere, but iron(II, III), manganese(II), copper(II) and sulfide do interfere.

* T. Koh and I. Iwasaki, This Bulletin, **39**, 352 (1966).

1) Presented at the Scientific Meeting on Chemistry, Tokyo, November, 1961.

There have been no suitable procedures for the determination of the polythionates in such micro amounts as are present in hot springs, although a more rapid and accurate method for determining polythionates of low concentrations is desirable for the studies of the hydrolysis and oxidation products of sulfur and sulfide.

The reactions of polythionates with sulfite, cyanide and sulfide have been reported by Kurtenacker and Goldbach.[2] Goehring, Feldmann and Helbing[3] have then applied these reactions to the determination of polythionates, depending on the iodometric titration of the thiosulfate obtained. Nietzel and DeSesa[4] determined colorimetrically the thiocyanate obtained from the reactions between tetrathionates and cyanide. In our own series of studies[5-7] of determination of micro amounts of polythionates, many fundamental processes in the reaction of polythionates with cyanide have been studied in detail.

In the present investigation, it will be confirmed that micro amounts of tetrathionate from 5×10^{-6} to 10^{-3} M can be determined photometrically by measuring the degree of the decoloration of iodine, which depends on the amounts of thiosulfate formed from the reaction of tetrathionate with sulfite. Polythionates react with sulfite in an alkaline medium to form thiosulfate as follows[2,3]:

$$S_nO_6^{2-} + (n-3)SO_3^{2-} = (n-3)S_2O_3^{2-} + S_3O_6^{2-} \quad (1)$$
$$(n=4,\ 5,\ \text{and}\ 6)$$

In this reaction 1 mol. of thiosulfate is formed from 1 mol. of tetrathionate. The thiosulfate thus formed reacts quantitatively with iodine in an acid medium. Therefore, the degree of the decoloration of iodine indicates the amount of tetrathionate in the original solution.

This paper will be concerned with the presentation of the results of this investigation and with the determination of small amounts of tetrathionate in the presence of sulfite and thiosulfate by means of its decomposition with sodium sulfite.

Experimental

Apparatus and Reagents.—A Hirama electrophotocolorimeter model II, with 10.0 mm. cells and filters of 372 and 440 mμ (maximum transmission at 372 and 440 mμ respectively), was used to measure the absorbancy.

The Standard Potassium Tetrathionate Solution.—30.25 g. of potassium tetrathionate ($K_2S_4O_6$) was dissolved in water, the mixture was then diluted to 1 l. (M/10). This stock solution was standardized by iodometric titration after decomposing it with sulfite or cyanide,[2,3] and then diluted to an adequate concentration. Potassium tetrathionate was prepared by the reaction of potassium thiosulfate with iodine; it was recrystallized with aqueous alcohol and dried in a desiccator containing sulfuric acid.[8]

The Standard Iodine Solution.—A standardized N/10 iodine solution was diluted to a desirable concentration; in all cases the concentration of potassium iodide was N/5.

The Standard Sodium Thiosulfate Solution.—24.82 g. of guaranteed reagent sodium thiosulfate pentahydrate ($Na_2S_2O_3\cdot5H_2O$) was dissolved in water and diluted to 1 l. (N/10). This solution was standardized with potassium iodate and then diluted to a concentration required.

Procedure.—20.0 ml. of a sample solution is placed in a 50 ml. volumetric flask. Then 1.0 ml. of a 0.5 M sodium sulfite solution is added and mixed in well. When this solution does not show a pink color with a phenolphthalein indicator, a 1 N sodium or potassium hydroxide solution is added drop by drop until the pink color appears. After this mixture has stood for 5 min. or longer, 1.0 ml. of a 20% formaldehyde solution[2,9] is added; this solution is then acidified with 10 ml. of a 20% acetic acid solution. 5.00 ml. of N/2000 or N/200 standard iodine solution is then added. After the flask has been filled with water to the mark, the absorbancy of the solution is measured at the wavelength of 372 or 440 mμ 20 min. after the addition of an iodine solution.

Thiosulfate and sulfite can also be determined when both are present in the sample solution. Three 20.0-ml. aliquots of the sample solution are placed in three 50-ml. volumetric flasks. The first 20.0-ml. aliquot is treated by the procedure described above. To the second, 10 ml. of a 20% acetic acid solution and 5.00 ml. of the standard iodine solution are added. To the third, after the addition of 1.0 ml. of a 20% formaldehyde solution, a 1 N alkali hydroxide solution is added drop by drop until the solution becomes alkaline to a phenolphthalein indicator. Then the solution is acidified with 10 ml. of 20% acetic acid and 5.00 ml. of the standard iodine solution is added.

The degree of the decoloration of iodine observed in the first aliquot corresponds to the sum of the amount of tetrathionate and that of thiosulfate in the solution; that observed in the second, to the sum of the amount of thiosulfate and twice the amount to sulfite in the solution, and that observed in the third, to only the amount of thiosulfate in the solution.

Results and Discussion

Working Curves.—As the final purpose of this series of investigations is to determine the polythionates to such micro amounts as are present in hot springs, the working curves were prepared with the standard sodium thiosulfate solution

—○— 20 min., —◑— 22 hr.

The Effect of the Concentration of Iodide on the Absorbancy.—The absorbancies of iodine solutions become higher with an increase in the concentration of iodide at the wavelengths of both 372 and 440 mμ. Therefore, it is necessary to keep the concentration of iodide constant in the final solutions. However, no significant difference could be found between iodide concentrations of N/5 and N/50. In this study, N/50 of iodide was used as the final iodide concentration.

Time of Reaction.—The concentration of sodium sulfite seriously affects the velocity of the

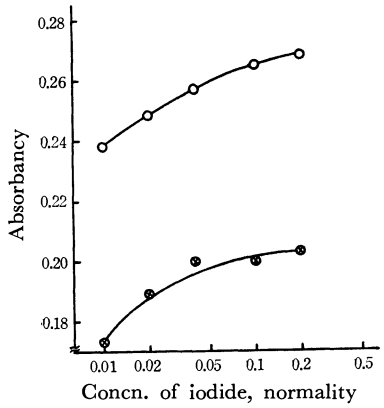

Fig. 3. Effect of the concentration of iodide on the absorbancy.

decomposition reaction of tetrathionate (Eq. 1), as is shown in Fig. 4. When 0.2 ml. of a 0.5 M sodium sulfite solution is used, it takes about 20 min. for the complete reaction, but it takes only 2 or 3 min. when 1.0 ml. of it is used. The absorbancies of the solutions obtained show the nearly constant value which is to be expected from Eq. 1. From these results it may be concluded that tetrathionate can be decomposed completely and that thiosulfate equivalent to the tetrathionate is formed quantitatively under these experimental conditions. Consequently, 1.0 ml. of a 0.5 M sodium sulfite solution was used in this study. However, when the pH value of the solution rises locally, there other

decomposition reactions[2,3] occur; this may be a cause of error.

The Effect of Formaldehyde.—Since sulfite, as well as thiosulfate, reacts with iodine in an acid medium, it must be masked with formaldehyde, as has been proposed by Kurtenacker.[9] Figure 5 shows the decoloration of iodine solutions with formaldehyde on standing after the standard iodine solution has been added to sulfite solutions when thiosulfate and tetrathionate are absent. As may be seen in Fig. 5, the differences among the effects of 0.2 ml., 1.0 ml. and 5.0 ml. of a 20% formaldehyde solution are negligible. However, both when no formaldehyde was added and when it was added in an acidified medium, the iodine was completely consumed by the reaction with the excess sulfite remaining in the solution. Therefore, formaldehyde must be added to the solution in order to mask the action of the excessive sulfite before the solution is acidified with acetic acid.

On the other hand, the decoloration of the iodine solution proceeds when it stands after the addition of iodine, especially in its lower concentrations. From the results obtained in this study, 1.0 ml. of a 20% formaldehyde solution was used, and the absorbancies of the iodine solutions obtained were measured 20 min. after the addition of an iodine solution.

⊗ 1.0 and 5.0 ml.} 5.0×10^{-4} N I_2 2.5 ml.,
◓ 0.2 ml. } at 372 mμ

The Amounts of Acetic Acid.—It is necessary to acidify the solution for the reaction of thiosulfate with iodine. Figure 6 shows the absorbancies of the solutions against the amounts of acetic acid when 2.50 ml. of a N/2000 standard sodium thiosulfate solution and 5.00 ml. of a N/2000 standard iodine solution were used.

As will be seen in Fig. 6, when more than 5 ml. of 20% acetic acid were employed the absorbancies of the solutions reached a constant value; 10 ml. of 20% acetic acid was used in this study.

The Results of the Analyses of the Synthetic Solutions.—From the experimental results, the analytical procedures described above have been established. The working curves shown in Figs. 1 and 2 were obtained by these procedures.

The results of the analyses by the present method of the samples containing tetrathionate only, tetrathionate and thiosulfate, or tetrathionate, thiosulfate and sulfite are listed in Tables I and II. Very good agreements are seen, even in the lower concentrations of these chemical species.

The Influence of Diverse Ions.—The other polythionates would interfere,[2,3] but these, as well as thiosulfate and sulfite, might be individually determined by solving the simultaneous equations derived from Eq. 1 and the following reactions[2,3]:

$$S_nO_6^{2-}+(n-1)CN^-+H_2O=S_2O_3^{2-}+SO_4^{2-}+2HCN+(n-3)SCN^- \quad (n=4,\ 5,\ \text{and}\ 6) \qquad (2)$$

$$S_nO_6^{2-}+S^{2-}=2S_2O_3^{2-}+(n-3)S \quad (n=3,\ 4,\ 5,\ \text{and}\ 6) \qquad (3)$$

$$2S_nO_6^{2-}+6OH^-=(2n-5)S_2O_3^{2-}+(10-2n)SO_3^{2-}+3H_2O \quad (n=3,\ 4,\ \text{and}\ 5) \qquad (4)$$

$$2S_6O_6^{2-}+6OH^-=5S_2O_3^{2-}+2S+3H_2O \qquad (4')$$

The influence on this method of the other ions commonly present in hot springs are given in Table III. Sulfide liberates colloidal sulfur. Iron(II) and manganese(II) are oxidized in an alkaline solution, and the iron(III) and manganese(IV) thus formed oxidize the iodide to produce iodine. The elimination of the interfering matter must be studied before we can apply this procedure to the various samples in their natural state.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 581—585 (1966)

The Coprecipitation Behavior of Strontium with Calcium Oxalate by Precipitation from a Homogeneous System

By Masakazu MATSUI

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received July 19, 1965)

The coprecipitation of strontium with calcium oxalate was studied using dimethyloxalate to precipitate calcium from a homogeneous solution. The several effects of the coprecipitation conditions on the distribution coefficients were investigated in the fractional precipitation process of calcium-strontium oxalate mixtures. Regardless of the pH value, the concentration of acetic acid and other factors, the coprecipitation curves of strontium showed similar shapes in almost all cases, although the curves well shifted up and dawn to some extent. It appears to be an anomalous system, because an increase in the fraction of the calcium precipitated tends to decrease the distribution coefficients. It is considered that two coprecipitation mechanisms are involved in the coprecipitation system; one is the surface adsorption on fine crystals, while the other is a normal systematic type. When the adsorption part was removed, it was found that the modified system obeyed the Doerner and Hoskins logarithmic distribution law and that the coefficient gave nearly a constant, 0.1.

The coprecipitation with calcium oxalate is generally used to separate strontium ions from other metals in dilute solutions.

When a strontium ion is coprecipitated with a calcium oxalate, there are two systematic ways in which strontium is distributed in crystals. One type of distribution is expressed by the homogeneous distribution law proposed by Chlopin[1] and Henderson and Kracek,[2] in which the strontium-calcium ratio in the precipitated crystals is proportional to the strontium-calcium ratio in the final solution:

$$\left(\frac{\mathrm{Sr}}{\mathrm{Ca}}\right)_{\mathrm{cryst.}} = D\left(\frac{\mathrm{Sr}}{\mathrm{Ca}}\right)_{\mathrm{soln.}} \quad (1)$$

where D is defined as the homogeneous distribution coefficient. This distribution law represents a state of true thermodynamic equilibrium, one in which the solid phase has been thoroughly digested in order to remove all the concentration gradients inside a crystal.

The other type is expressed by the logarithmic distribution law proposed by Doerner and Hoskins[3] and expressed as follows:

$$\log\frac{\text{Initial Sr}}{\text{Sr left in soln.}} = \lambda \log\frac{\text{Initial Ca}}{\text{Ca left in soln.}} \quad (2)$$

where λ is the logarithmic distribution coefficient; this law is obeyed when a replacement equilibrium is achieved on each layer of the crystal during the precipitation process. When λ is smaller than unity, the tracer component is enriched in the solution, and vice versa.

Ishibashi et al.[4] carried out an experiment in which oxalates were homogeneously precipitated, with a rise in pH value due to ammonium ions uniformly generated by the hydrolysis of urea. They found that strontium was distributed in calcium oxalate in accordance with the logarithmic distribution law, and that the extrapolation of the logarithmic distribution coefficients to 0% of calcium precipitated would give a constant value of about 0.30.

The coprecipitation behavior of scandium,[5] yttrium[6] and lanthanide[7] ions with calcium oxalate was studied by Shigematsu et al. and by the present author. Their results demonstrate that the most predominant factors affecting the coefficient are the pH value of the solution and the concentration of the organic acid used as a buffering agent, because the ionic concentrations of divalent macro and tervalent micro components vary with the coprecipitation conditions; the ionic radius also plays an important role in the coprecipitation process.

According to these papers, it may be deduced that the distribution coefficient in the case of a calcium-strontium system will not be very much affected by the precipitation condition, such as the pH value and the concentration of an organic acid, because the ratio of the complexing ability of macro and micro components with an organic acid is hardly affected at all by the above-mentioned

factors.

This paper will deal with the variable influences of the coprecipitation conditions on the distribution coefficient in the fractional precipitation process of calcium-strontium oxalate mixtures.

Experimental

Apparatus and Reagents. — The radioactivity counting was performed with a Phillips halogen-quenched G-M tube connected to a Metro dekatron scaler, Model D-5. A Hitachi-Horiba pH meter, Model M-3, was used for the pH measurements.

Strontium-89 was supplied as chloride in hydrochloric acid by the Oak Ridge National Laboratory, Oak Ridge, Tennessee, U. S. A., and was diluted to make a solution of ~1 μc./ml. Reagent-grade dimethyloxalate was purified by recrystallizing it from anhydrous methanol; it was then stored in a dry atmosphere in a desiccator. The calcium solution was prepared by dissolving dry calcium carbonate with hydrochloric acid. The strontium solution was prepared by dissolving reagent-grade strontium chloride with water, after which it was standardized with a standard EDTA solution. The EDTA solution (0.00330 M), containing a magnesium EDTA complex, was standardized by means of a calcium standard solution; it was used for the determination of the calcium ions of the sample solutions.

The other chemicals were chemically-pure or reagent-grade materials.

Procedure.—The procedure of the coprecipitation and the determination of the macro and micro components were essentially the same as those described in previous papers.[6,7] The calcium was titrated with a EDTA solution containing its magnesium chelate.

The strontium activity would be contaminated very slightly by yttrium-90 existing as a radioactive daughter of strontium-90 impurity. The yttrium activity was estimated by the coprecipitation method with ferric hydroxide, while the strontium activity in the solution phase was corrected by means of the distribution values of yttrium.[6] The homogeneous and logarithmic distribution coefficients, D and λ, will be calculated from Eqs. 1 and 2.

Results

The Effect of the pH Value.—The percentages of coprecipitated strontium in the fraction of the calcium oxalate precipitate at different pH values are plotted in Fig. 1. The experimental conditions were as follows: The concentrations of calcium, strontium and dimethyloxalate were 2.50×10^{-1} M, 10^{-6} M and 0.1 M respectively. The total volume of the reacting solution was 200 ml.; this solution was buffered with 1 M acetate or formate, and the temperature was kept at 75.0°C. As is shown in Fig. 1, the strontium ion content was enriched in the solution phase, and unlike as in the case of the calcium - rare earth system, the coprecipitation behavior was the same regardless of the pH value and the species of organic acid.

The distribution coefficients, D and λ, were calculated from these experimental data; a few examples are presented in Table I. The results show that the increase in the amounts of precipitated calcium tends to decrease the coefficients.

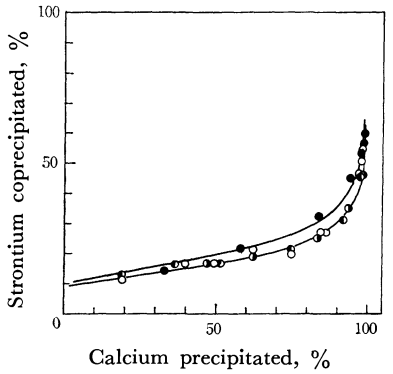

Fig. 1. The coprecipitation of strontium with calcium oxalate at different pH values.
Ca: 0.025 M, Sr: 10^{-6} M, dimethyloxalate: 0.1 M, acetate or formate: 1 M. Temp.: 75°C,
pH: ●; 2.88, ○; 3.62, ◐; 4.00, ◑; 4.79

The Effect of the Strontium Concentration.—While keeping the other variables constant, the calcium oxalate was precipitated at pH 4.00 in solutions containing 10^{-5} M, 10^{-6} M and 10^{-7} M of strontium respectively. The effect is indicated in Fig. 2; no significant change in the coprecipitation behavior was observed.

The Effect of the Acetate and Sodium Chloride Concentrations.—The effect of the acetate concentration was examined at pH 4.00 with regard to sample solutions of 0.5 M, 1.0 M and 2.0 M acetate, while the other variables were kept constant; the effect was found to be almost not noticeable in the range investigated, as is shown in Fig. 3. In order to study the effect

of the ionic concentration in a reaction solution, an effect which is concerned with the adsorption in coprecipitation, final concentrations with nil, 1.0 M and 2.0 M of sodium chloride respectively were used. Figure 4 shows that the coprecipitation of strontium behaves in a similar manner, although it is appreciably influenced at the beginning of precipitation.

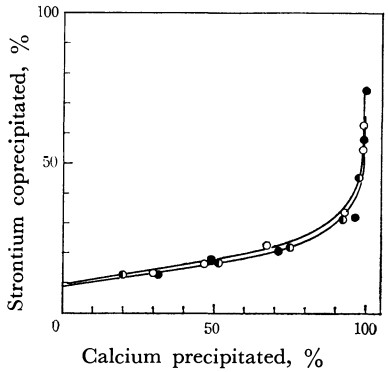

Fig. 2. The effect of the concentration of strontium.

Others are same to in Fig. 2.

The Effect of the Rate of Precipitation.— The effect of the ester was studied in order to examine the effect of the rate of precipitation. Figure 5 shows that the coprecipitation behavior almost does not change at all, except in the rapid precipitation, when the concentration of the ester changes from 0.0375 M to 0.25 M, corresponding to 1.5 and 10 times the stoichiometric quantity of calcium ions. The time required for the 90% precipitation of calcium is about 75, 580, 1350 and 2100 min. when the ratio of the ester to calcium is 10, 4, 2 and 1.5 respectively.

Discussion

As is shown in Figs. 1 to 5, the coprecipitation behavior of strontium was very similar in all cases, though the percentages of coprecipitation changed appreciably in the initial stage of the precipitation process.

The coprecipitation percentage of strontium increased very slowly to about 70 per cent, and then rapidly to the end of calcium precipitation.

An increase, in the fraction of precipitated calcium tends to decrease the distribution coefficient in all experiments, as is shown in Table I. If the decrease in λ-value is attributed to the aging of precipitate, as has been described in previous papers,[4,8] the coprecipitation behavior should be influenced by the rate of precipitation. However, the conprecipitation curves resemble each other except in the case of a very rapid precipitation.

8) M. L. Salutsky, J. G. Stites, Jr., and A. W. Martin, *Anal. Chem.*, **25**, 1677 (1953).

The coprecipitation behavior in the calcium-strontium oxalate system was postulated to be as follows: When a strontium ion is coprecipitated with calcium salt, two different mechanisms are involved. One type is the surface adsorption, with very fine crystals precipitating from a supersaturated solution. The other is a normal systematic type obeying the distribution law. When the curves are extrapolated to a zero percentage of the precipitated calcium, the adsorption part of the coprecipitation can be estimated. When the effect of the latter part is corrected, the logarithmic distribution law is followed and the coefficient can be calculated. These results are shown in Tables II to VI, in which the coefficients in the range of 40 to 95 per cent of calcium precipitated are adopted in order to make the error as small as possible, because there is a risk of producing a considerable error in the determination of the precipitated calcium or coprecipitated strontium beyond the above range.

The consistency of the λ values obtained in Table II to VI can not be explained by assuming random error. The mean values of the coefficient nearly gave a constant, about 0.1 of λ in almost all cases. Strontium, as well as other elements,

such as scandium, yttrium and lanthanide, were also coprecipitated by calcium oxalate obeying along the logarithmic distribution law proposed by Doerner and Hoskins.[3]

Tables II and III show that, in the calcium-strontium oxalate system, λ is not influenced by the pH value and the acetate concentration, unlike as in the calcium - tervalent element system.

According to Chlopin's description,[9] the homogeneous distribution coefficient, D, will practically not change if the ratio of the ionic concentration of the micro component to that of the macro component does not vary even when the composition of the solution phase varies, while the value of D will increase if the ionic concentration of the macro component decreases more rapidly than that of the micro component, and vice versa. This explanation was applied in the calcium - tervalent metal ion system, which obeyed the logarithmic distribution law.[7] This rule can be applied to the present research, because the ratio of the ionic concentration of strontium to that of calcium scarcely does change, even if the precipitation conditions vary. The coefficient, λ, is nearly 0.1, meaning that strontium is enriched in the solution phase. The homogeneous distribution coefficient, D, of course decreased as the precipitation of calcium proceeded under all coprecipitation conditions.

When a strontium ion is brought together with the calcium oxalate carrier from the sample solutions, it may, in view of the above results, be concluded that: As the concentration of calcium left in solution phase becomes lower, the percentage of the coprecipitated strontium becomes higher. It is desirable to react with high pH values (if not influenced by the carbonate ion) and with an excess of oxalic acid in order to concentrate the strontium ions in the precipitate.

The author wishes to express his thanks to Professor Tsunenobu Shigematsu and Dr. Masayuki Tabushi for their valuable advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 585—596 (1966)

The Separation of Alkali Metals as Poly-Iodides by Reversed-Phase Partition Chromatography

By Ikuko AKAZA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 22, 1965)

The liquid-liquid extraction of alkali metal ions as their poly-iodides had previously been investigated by the present author. In order to attain a good separation of each metal, this extraction system has now been extended to a reversed-phase partition chromatography in which Kel-F powder was used to support the organic phase of nitrobenzene-iodine-iodide. Column chromatographic separation was carried out in the presence of relatively large amounts of the metals by elution with water and 1 N or 6 N hydrochloric acid - eluting solutions. Chromatographic behavior of each metal ion was investigated and the elution from the column was found to be in the order of Li-Na-K-Rb-Cs. The distribution ratio of the metal ions varied with the quantity of the ions loaded on the column; the smaller the quantity of the ions used, the larger was the distribution ratio obtained. The actual separation of individual metal ions from the mixture was successfully achieved; a minute amount of cesium could be particularly isolated from large amounts of other alkali metals, even in a large volume of the sample solution. Elution curves of various amounts of metal were obtained as an aid to a discussion of the partition on the column. A comparison of the distribution ratio in the liquid-liquid extraction with that in the column chromatography showed that the extraction of the same mechanism proceeded in both cases.

Previously the author studied the liquid-liquid extraction of alkali metal ions as poly-iodides; the method presented consisted of the conversion of various kinds of alkali salts into iodides by double decomposition with ammonium iodide in an aqueous solution and the batch extraction of the iodide with nitrobenzene containing free iodine. The details of the investigation were described in a preceding paper.[1] It was found to be very difficult to separate alkali metals from one another by a batch extraction because the distribution ratios of the poly-iodides were too

1) I. Akaza, This Bulletin, **39**, 465 (1966).

close together in this extraction system. The low separation factor between each pair of metals of the alkali group led the author to seek other convenient methods which would be more efficient. Reversed-phase partition chromatography is closely related to liquid-liquid extraction, except that the water-insoluble extractant is immobilized on some stationary, inert support. In a column extraction of this type an aqueous solution containing the solute under consideration is always in contact with the fresh organic solvent on the column, and a multistage batch extraction can be carried on through the process; therefore, effective separation can be achieved even between substances with a low separation factor. Moreover, a larger quantity of material can be treated by this method.

A summary of the investigations of this method up to the end of 1964 has already been given by the present author,[2] so further description will be omitted here.

The author tested the qualifications of many substances which had been recommended for use as inert solid supporting materials to see if they were suitable for the poly-iodide extraction. Some of them could not retain nitrobenzene containing poly-iodide, while others were affected by the solvent system. However, the Kel-F (polytrifluorochloroethylene) moulding powder recommended by Hamlin et al.[3] was found to be very suitable because of its large absorptivity and capacity for the solvent and its strong resistivity against chemical agents. Therefore, this substance was finally chosen for this investigation.

Reversed-phase chromatography has never been applied in the separation of alkali metals, excepting the work of O'Laughlin and Banks[4] who separated sodium from lithium using bis(di-*n*-hexyl-phosphinyl)methane. Recently, however, Cerrai and his co-workers[5] attempted the paper chromatographic method with di-(2-ethylhexyl) orthophosphoric acid, HDEHP; the R_f value for each metal showed a good prospect of separation.

This paper will describe a column method of the reversed-phase chromatographic separation of alkali metals, using iodine - ammonium iodide - nitrobenzene as the stationary phase supported on Kel-F. The results of the investigation of the liquid-liquid extraction of poly-iodides of alkali metals described in a preceding paper[1] will be fully utilized. The elution of individual ions and their separation from their mixtures were both successfully achieved by the column method; the correlation between this chromatographic separation and the liquid-liquid extraction indicated by the detailed data obtained will be discussed.

Experimental

Apparatus. — *Column.*—A glass chromatographic column, 0.98 cm. in diameter and 23 cm. in length, and with a coase frit at the bottom, was used during this study; in order to keep the temperature constant, a water jacket was fitted so as surround the column tube, and water from the tap or a water-tank of a constant temperature was made to flow through it. A separating funnel as a reservoir of the eluting solution was fitted to the top of the column tube, a polyvinyl chloride tube 1 cm. in diameter was coiled around the funnel, and the constant-temperature water was allowed to flow through it before entering the water-jacket.

Fraction Collector.—A fraction collector (Model SF 200A of the Tōyō Roshi Co.) holding 200 tubes was employed.

Flame Photometer.—A spectrophotometer, Hitachi EPU-2, provided with a flame spectrophotometry accessory, H-2, was employed, hydrogen being used as the fuel.

Scintillation Counter.—A counting set made by the Kōbe Kōgyo Co. (Model EA-14, NaI(Tl) crystal and Model SA-250 scaler) was employed.

Pulse-height Analyzer.—A 100-channel pulse-height analyzer, model AN-100, of the Kōbe Kōgyo Co. was employed.

Reagents and Materials.—*Kel-F.*—Kel-F (polytrifluorochloroethylene), a trade name low-density 300 moulding powder, was imported from the Minnesota Mining and Manufacturing Co., U. S. A. When the material was ground with a mixing grinder and sieved through screens, particles between 42 to 80 mesh were collected for use.

Chemical Reagents.—The ammonium iodide, iodine, hydrochloric acid, nitrobenzene and alkali metal chlorides and sulfates were all of analytical reagent grade. Radio isotopes, ^{86}Rb as chloride and ^{137}Cs as nitrate, were purchased from the Radiochemical Center, Amersham, England. No diluted stock solutions were prepared; the original solutions were used as they were.

Organic Solvent as the Stationary Phase in the Column.—6.1 g. of iodine, 1 g. of ammonium iodide and 40 ml. of nitrobenzene were placed in a separatory funnel. Then there was added 40 ml. of an aqueous solution which had been selected from among distilled water, 6 N hydrochloric acid and 1 N hydrochloric acid, according to the kind of eluting solution to be used in the eluting process. After thirty minutes' shaking, the two phases were separated. The organic solvent thus treated contained iodine and iodide in the molar ratio of about 3 : 1; this ratio had been found in a preceding paper[1] to be the optimum for the extraction of alkali metal ions. The composition of the aqueous phase after the shaking should hold also in the eluting solution. Therefore, the amounts of iodine and iodide in the aqueous solution were determined and the same composition was adopted in the preparation of each eluting solution.

Eluting Solution.—*1) Aqueous Eluting Solution.*—Nitrobenzene was put in water in a separatory funnel

2) T. Kiba and I. Akaza, *Kagaku* (Chemistry), **19**, 984 (1964).
3) A. G. Hamlin, B. J. Roberts, W. Laughlin and S. G. Walker, *Anal. Chem.*, **33**, 1547 (1961).

5) E. Cerrai and G. Ghersini, *J. Chromatog.*, **13**, 211 (1964).

and shaken to produce a saturated solution, and the excess nitrobenzene was rejected through the stem of the funnel. The water thus treated was called nitrobenzene-saturated water in this investigation. On the other hand, 1.4 g. of iodine and 1.5 g. of ammonium iodide were dissolved in a small volume of the nitrobenzene-saturated water, and then the solution was diluted to 1 l. with the water.

2) 1 N Hydrochloric Acid Eluting Solution.—Nitrobenzene was dissolved to saturation in 1 N hydrochloric acid in the manner described in the case of nitrobenzene-saturated water; this solution was called nitrobenzene-saturated acid. In a small volume of the acid 0.78 g. of iodine and 0.61 g. of ammonium iodide were dissolved, and the solution was made up to 1 l. with the acid.

3) 6 N Hydrochloric Acid Eluting Solution.—Nitrobenzene-saturated 6 N hydrochloric acid was prepared in the way described above. In the 6 N acid 1.51 g. of iodine and 0.04 g. of ammonium iodide were dissolved, and the solution was made up to 1 l. with the same acid. It happened occasionally that iodine and ammonium iodide did not readily dissolve in the acid; shaking in a separatory funnel was resorted to in order to overcome this trouble. It is essential to keep the temperature constant both in the preparation of an organic solvent for the stationary phase and of eluting solutions for the mobile phase, and in carrying out the chromatographic separation.

Sample Solution.—It is often desirable, though not in all cases, that the sample solution has a composition alike to that of the eluting solution; for example, the correct amount of alkali metal salt was dissolved in a definite volume of the eluting solution mentioned above in order to make a sample solution to be tested. Three milliliters of the solution was usually employed for the chromatographic separation in the column method, but as much as 50 ml. of the solution was employed in the separation of trace amounts of ^{137}Cs from the mixture of sodium, potassium, rubidium and cesium salts.

Experimental Procedure.—*The Preparation of the Stationary Phase.*—Place in an Erlenmyer flask 6 g. of the Kel-F powder which had been dried at 80°C and stored in a calcium chloride desiccator, and then pour on it 4.5 ml. of the organic solvent solution prepared above. After stoppering the flask tigthly, shake it by hand until the content appears homogeneous and then let it stand over three hours. Add a small volume of a suitable eluting solution, stir gently to get rid of air bubbles, and pour the slurry little by little into the chromatographic column tube, taking care so as not to include any air bubbles. It is desirable to keep the temperature constant during the preparation by passing water of a constant temperature through the jacket fitted to the glass tube. Every time a portion of slurry is added, gently press the column bed with a glass rod in order to make it about 17.5 cm. in depth; meanwhile about 50 ml. of the eluting solution is passed through the column in order to remove any contaminant such as sodium that may be present in the column bed. The upper surface of the column should be below the surface of the eluting solution contained in the glass tube lest it becomes dry.

The Elution, Separation and Determination of Metals.—Pour 3 ml. of the sample solution on the upper surface of the column and allow it to percolate through the column at the rate of about 0.25 ml. per minute; then wash the inside of the glass tube above the top of the column bed twice with small portions of the eluting solution, letting them flow down at the same rate.

On the top of the glass tube, set a separatory funnel from which an eluting solution of a definite composition is supplied into the glass tube; then carry out the elution at the rate of 0.5 ml./min. During the preparation of the column and the elution of the material, the temperature should be kept constant— in this experiment 18°C was preferred. If the volume of the sample solution is large, the separatory funnel may be employed for the loading of the sample. Collect the effluent from the bottom of the column in suitable fractions with a fraction collector, and determine the content of alkali metal ions in each fraction by flame spectrophotometry. When a radioisotope was used, the activity in each fraction was counted by a scintillation counter and the nuclides separated were identified by γ-ray spectrometry.

Results and Discussion

The Characteristic Behavior of the Column.—*1) The Choice of Column Material.*—The application of the reversed-phase partition chromatography technique depends on the availability of a suitable supporting material. Several examples which had been reported were reviewed and discussed by the present author.[2] In the present work the organic phase consisted of nitrobenzene and poly-iodide; therefore, a more resistant material was sought.

The first choice was Kel-F moulding powder, previous experience having shown that the particular grade used had a large capacity for stationary phase and resistance against chemical agents.[3] A number of tests were made to find out whether other polymers or inorganic materials were equally suitable. Inorganic materials, such as alumina and silica gel, were found to be useless, as they failed to retain any nitrobenzene even after being treated with dimethyldichlorosilane. On the other hand, organic polymers such as cellulose powder, porous polyethylene chloride, and the polymer of tetrafluoroethylene (Teflon) had the disadvantages of reacting with iodine and of requiring difficult techniques in order to release the organic phase from them. The outstanding behavior of Kel-F moulding powder is presumably due to the large surface area of the aggregate and the resistance of the substance to chemical agents, but this has not been explained by organic chemists.

2) The Amounts of Nitrobenzene Adsorbed by Kel-F.—In an Erlenmyer flask fitted with a glass stopper, 45 ml. of nitrobenzene and 10 g. of Kel-F powder were left together overnight; the nitrobenzene unadsorbed was then drained through a small glass filter into a measuring cylinder placed in a slightly-evacuated vessel. The flask was washed with one milliliter of nitrobenzene, which was then poured

on the Kel-F powder, all of the excessive solvent being drained through the filter. The difference between the volume of nitrobenzene initially taken and that measured in the cylinder showed the volume of the solvent adsorbed by Kel-F; this was found to be 7.4 ml. per 10 g. of Kel-F powder.

3) The Volume of the Mobile Phase in the Column.—A column was packed with Kel-F loaded with nitrobenzene; a solution of sodium chloride saturated with nitrobenzene was poured onto the column and allowed to flow down to the bottom until the effluent became of the same concentration as the solution originally poured. After having been washed with water the inside of the glass tube below the fritted glass filter, the sodium chloride solution retained in the column was completely washed down by passing through water from the top of the column. The amount of sodium chloride contained in the washings was estimated argentimetrically. From this amount the volume of the sodium chloride solution in the column was computed as is usually done in chromatographic investigations. It was found that the volume of the mobile phase in the column was 4.68 ml. per 6 g. of Kel-F. The amount of nitrobenzene originally adsorbed on the Kel-F column was 4.5 ml., corresponding to the ratio of 7.4 ml./10 g. obtained in the experiment in 2); hence the volume ratio of the stationary phase to the mobile phase was 1 : 1 in this case. This indicates that the elution process consists of multiple extraction between equal volumes of the organic and the aqueous phases. The author's method of preparing the stationary phase and the eluting solution was built up consciously in order to maintain the above relation between the two phases during the elution.

4) Blank Test for the Column.—If alkali metal ions could be retained on the column of Kel-F without poly-iodide ions, separation by this method would not be satisfactory because of the complication caused by the adsorption on the stationary phase. To test the above phenomenon, a radioactive cesium tracer was passed through the column (cesium poly-iodide had been found by a preliminary experiment to be the most easily retained species). Six grams of Kel-F powder containing 4.5 ml. of nitrobenzene which had been pre-equilibrated with water was used for the column, while a trace of cesium-137 nitrate in 3 ml. of water pre-equilibrated with nitrobenzene was charged on the column. Elution was carried on by nitrobenzene-saturated water, and the effluent was collected in 10 ml. fractions. Strong radioactivity was found as early as in the first fraction, and the maximum appeared in the second. This showed that if poly-iodide ion was absent in the organic phase on Kel-F, no alkali metal ion will be retained on the column; there will be only a distribution caused by the poly-iodide ion in the chromatographic process.

5) Column Life and Stability.—After loading the column with 0.5 mg. of potassium, elution with an aqueous eluting solution was carried out; the usual elution curve was obtained. This experiment was repeated five times through the same column during a month's period; the band width and position of the peak were also examined. At the end of the five runs, the total volume of the eluting solution, including the preliminary washing with 1000 ml., was as large as 3070 ml. Table I shows the results. We can see that the column can stand the repeated uses, though a slight delay was observed at the front of the band and at the peak of the curve. As the nitrobenzene and poly-iodide of which the stationary phase consisted are tolerably soluble in an aqueous solution, the eluting solution and sample solution should have the same composition, as equilibrated with the organic solvent of the stationary phase, in order to prevent the degradation of the column during the continuous use.

TABLE I. VARIATION OF BAND WIDTH AND PEAK OF ELUTION CURVE DURING REPEATED USES OF THE COLUMN

Number of time	Band width shown as volume of effluent ml.	Peak of the curve shown as volume of effluent, ml.
1	243.8—413.4	300
2	249.1—408.1	300
3	265.0—402.8	307
4	254.4—413.4	315
5	242.5—388.0	291

6) The Recovery of Kel-F Powder.—The Kel-F powder could be recovered by the following method from a column degraded by long service; take out the Kel-F supporter from the column tube into a beaker, wash it with plenty of water, and filter it through a glass filter under suction. Put it back in the beaker, and pour a 30% ethanol-water mixture on it to remove roughly the nitrobenzene and poly-iodide remaining on the powder. Repeat this treatment if necessary, and finally wash it with water in order to drive off the ethanol. Stir 10 M nitric acid into the powder in order to separate the solid iodine from the poly-iodide, as in the case of the back extraction of alkali metal ions described in the preceding paper.[1] Filter the mixture of Kel-F powder and solid iodine under suction, and wash the residue with water in order to wash off the nitric acid. Transfer the residue into a beaker, and wash again with a 30% ethanol-water mixture to dissolve the iodine. Filter off the iodine solution. After preliminary washing with water, treat this Kel-F again with nitric acid and follow the serial procedure indicated, repeating the process three times. Wash the powder thus obtained by stirring it well with warm absolute alcohol in the beaker. Filter the powder under suction, and repeat the washing until the color of iodine disappears. Dry the white powder at 80°C before storing.

7) The Capacity of the Column.—The capacity of the column used was estimated by loading it with potassium salt and then examining its break through, shown in Fig. 1, in which the sharp rise of the curve indicates that the transfer rate of potassium ions is very high at the surface of and within the stationary phase. The capacity was estimated to be $17._1$ mg. of potassium when a solution containing 0.2 mg. of potassium per ml. was used as the feed solution, and $30._6$ mg. when a solution containing 5.0 mg. of potassium per ml. was used. As a matter of fact, the capacity in this case is distinctly different from that in the case of ion-exchange chromatography; the former merely depends on the partition of the substance between two phases, and its value varies remarkably with the concentration of the feed solution.

The Chromatographic Behavior of Alkali Metal Ions.—The chromatographic behavior of alkali metal ions is to be expected from the results obtained in the liquid-liquid extraction of alkali poly-iodides described in the preceding paper.[1] Their distribution ratios were found to depend on the ratio of free iodine to iodide ion in the system, on the acidity of the solution, and on the amounts of metal to be treated. Moreover, the temperature was also found to affect the distribution ratios. Because a marked effect will appear in the chromatographic process unless the temperature is kept constant, all the author's experiments were carried out at 18°C, except for the data shown in Figs. 2, 4, and 12, and in Table I. Since the distribution

the effluent, the lighter species appearing first and the heavier later.

1) The Elution Curve of Individual Ions.—In order to examine quantitatively the retention of individual ions on the column, a column prepared as described above was charged with 0.5 mg. of each ion; it was then eluted by a continuous stream of the aqueous eluting solution described above at a flow rate of 0.5 ml./min. The effluent was collected in 1.93-ml. fractions in the case of lithium and sodium, and in 9.86-ml. fractions in the case of heavier metals. The results are summarized in Fig. 2, in which it may be seen that lithium and sodium can easily be separated as a group from potassium, rubidium and cesium by this procedure. However, the later appearence of potassium and rubidium in the effluent, the plateau in their elution curves, and the failure of cesium to appear up to 3200 ml. of the effluent made it desirable to elute them faster in order to get a sharp peak on the curve. The acid eluting solution may serve for this purpose, because of the lower distribution ratio in an acid medium.

The other elution curves shown in Fig. 3 are those of potassium and rubidium eluted with a 1 N acid eluting solution; each has a relatively sharp peak. Therefore, this eluting solution is useful for the separation of potassium, rubidium and cesium from one another. On the other hand, the separation

factor between lithium and sodium is so small that the separation of the two metals was found to be extremely difficult, as may be expected from the results of their liquid-liquid extraction. An attempt to increase the separability of these two metal ions was made by the elongation of the column bed in order to increase the plate number of the extraction. However, the experiment with a long column bed failed to give a good separation, as is shown in Fig. 4, in which (1) shows the results with a long column bed, and (2) and (3), with a stationary phase containing concentrated poly-iodide.

2) The Actual Separation of Metal Ions.—a) The Separation of Li-Na.—As has been described above, the separation of lithium from sodium seemed to be difficult, but the elution was performed for mixtures of various amounts of metal chlorides, with the results shown in Fig. 5. In these experiments the same stationary phase as in Fig. 4 (3) was employed, and the peaks of elution curves were easily distinguishable from each other, even though complete separation could not be achieved.

b) The Separation of Na-K.—The column prepared as described in the general procedure was loaded with 3 ml. of an aqueous solution containing 1 ml. each of sodium and potassium as chlorides, and elution was carried out with the aqueous eluting solution. Good separation was achieved as is shown in Fig. 6. Elution for a sample solution containing 100 mg. of sodium and 0.5 mg. of potassium was attempted in the same way with the results shown in Fig. 7.

c) The Separation of K-Rb.—Three milliliters of a 1 N hydrochloric acid eluting solution containing 12 mg. of potassium and 0.5 mg. of rubidium, and another 3 ml. of the solution containing 0.5 mg. of potassium and 10 mg. of rubidium were separately fed through the column, and then eluted with a 1 N hydrochloric acid eluting solution. The results are shown in Figs. 8 and 9.

d) The Separation of Rb-Cs.—Three milliliters of a 1 N hydrochloric acid eluting solution containing 0.5 mg. of rubidium and 25 mg. of cesium was fed through the column, and eluted first with a 1 N hydrochloric acid eluting solution and then with a 6 N hydrochloric acid eluting solution. The results are shown in Fig. 10.

e) The Separation of Cesium-134 from Contaminated Rubidium-86.—Radioactive rubidium-86 chloride

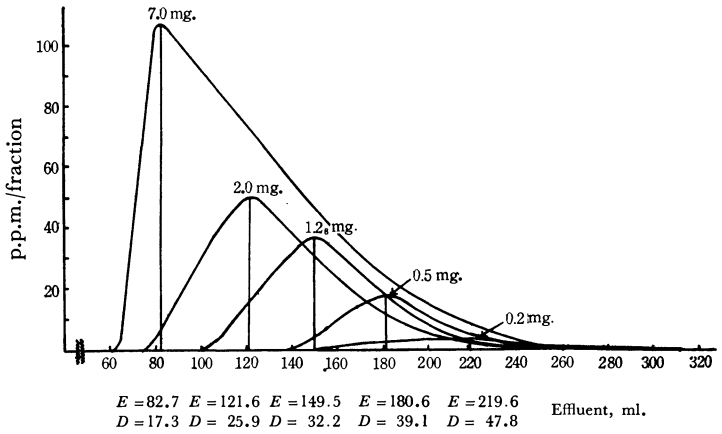

Fig. 14. Elution curve of various amounts of potassium loaded.

is sometimes contaminated with radioactive cesium derived from impurities in the target material. By eluting trace amounts of rubidium-86 chloride through the column, according to the standard procedure, with a 1 N hydrochloric acid eluting solution, the following fact was revealed. As is shown in Fig. 11, the proper elution curve was drawn up to 437 ml. of the effluent, and none of the activity seemed to remain in the column. Nevertheless, when a 6 N hydrochloric acid eluting solution was subsequently fed through the column, a minute amount of radioactivity was detected in the effluent after about 30 ml. of the new eluent had been spent. The radioactivity was shown by a γ-ray spectrometer to be the γ-activity of cesium-134. In the γ-ray spectrum no activity from rubidium was found; therefore, it was also revealed that the complete elution of rubidium had been accomplished with the 1 N hydrochloric acid eluting solution. Thus, this elution technique is useful for removing the

radioactive contaminants from rubidium-86, as well as for the determination of the amount of the contaminant.

f) The Separation of Na-K-Rb-Cs.—Three milliliters of a 1 N hydrochloric acid eluting solution containing 0.5 mg. each of the alkali metal ions together was fed to the column and eluted with a 1 N hydrochloric acid eluting solution up to 460 ml. of effluent and then further eluted with a 6 N hydrochloric acid eluting solution. The separation of the metal ions was achieved as shown in Fig. 12.

g) The Isolation of Radioactive Cesium from Large Amounts of Sodium, Potassium and Rubibium.—A mixed solution containing 100 mg. each of sodium, potassium, and rubidium, as well as a trace amount of radioactive cesium, was prepared with the 1 N hydrochloric acid eluting solution so as to bring the whole volume up to 50 ml. The entire amount was then fed to the column and eluted with the same eluting solution and then with a 6 N hydrochloric acid eluting solution. The results are shown in Fig. 13, in which it may be seen that a minute amount of cesium can be isolated from large amounts of other alkali metals, even in as large a volume of the solution as 50 ml.

h) The Separation and Recovery of Individual Ions from the Na-K-Rb-Cs Mixture.—The preceding experiments indicate that the extraction rate and the selectivity of the Kel-F/nitrobenzene-iodine-iodide column is adequate for the separation of an individual ion from other alkali metal ions. To demonstrate the practical usefulness of the method and to devise a convenient method, a typical simple separation was carried out without a fraction collector. In a few milliliters of the aqueous eluting solution, 847.28 mg. sodium chloride, 317.57 mg. potassium chloride, 9.42 mg. rubidium chloride and 9.07 mg. cesium sulfate were dissolved. Some of the nitrobenzene separated out from the solution because of the salting-out effect of the above added salts. To redissolve it, some water was added, little by little, to the above solution in a 100-ml. volumetric flask; finally, the aqueous eluting solution was added to bring it up to the mark. Three milliliters of this solution, containing 10 mg. of sodium, 5 mg. of potassium, 0.2 mg. of rubidium and 0.2 mg. of cesium, was placed in the column and eluted with the eluting solutions. Five fractions of the effluent were collected, without the help of a fraction collector, in five measuring flasks of the proper capacities. The first and second fractions, 50 ml. and 250 ml. respectively, were collected using the aqueous eluting solution; the third and fourth, 50 ml. and 250 ml. respectively, using 1 N acid eluting solution as the eluent, and the fifth, 100 ml., when the 6 N acid eluting solution was used. Each of the first three fractions was shaken well and submitted to flame photometry, at 589 mμ for sodium in the first fraction, and 768 mμ for potassium in the second. The fourth and fifth fractions were found too dilute for the determination of the amounts of rubidium and cesium, and so each fraction was evaporated to dryness under an infrared lamp and the residue was re-dissolved in 25 ml. of water. The solution thus obtained were submitted to flame photometry at 780 mμ for rubidium and at 852 mμ for cesium.

A known amount of each metal ion was dissolved in the same eluting solution as was used in the sample, and the solution was treated as above with the exception of the column process. The flame photometric value of the solution was compared with the value obtained from each fraction. Table II gives the results obtained in this separation process; each alkali metal ion was quantitatively recovered in each proper fraction without contamination.

The metal separated in each fraction could be recovered by evaporating the solution to dryness under an infrared lamp and in an electric furnace and by then treating the residue with a suitable

Table II. Recovery of alkali metal ions from their mixed solution by reversed-phase partition chromatography

Fraction of effluent No.	Eluting solution	Effluent volume ml.	Metal ion recovered mg.	Metal ion taken mg.
1	water	50	Na 10.03	Na 10.11
2	water	250	K 5.06	K 5.03
3	1 N HCl	50	—	—
4	1 N HCl	250	Rb 0.26	Rb 0.26
5	6 N HCl	100	Cs 0.20	Cs 0.20

The values in the last column were obtained from a reference solution of the identical composition.

acid to make its alkali salt, while the nitrobenzene and iodine contained in the effluent were all driven off by the heating with the strong acid.

The Relation to the Liquid-Liquid Extraction.—The reversed-phase partition chromatography is related to the liquid-liquid extraction of alkali poly-iodide into nitrobenzene described in the preceding paper.[1] The partition on the column, based on the theory of Martin and Synge,[6] seems to be equivalent to a counter current system consisting of a series of plates.

1) Distribution Ratio.—As has been described, the distribution ratio of alkali metal ions between the nitrobenzene-iodine-iodide solvent and an aqueous phase decreases with the increase in the number of metal ions; therefore, the effect of the amount of metal ions on the column upon the elution curve was also critically examined, especially in the case of potassium ions. The results shown in Fig. 14 reveal that the position of the peak of the elution curve (E in ml.) proceeds forward on the abscissa with the increase in the amount of metal ions loaded; this phenomenon seems to be caused by the decrease in the distribution ratio, which was calculated, from the data obtained by column chromatography, by the following equation[6,7];

$$D = A/RA_S - A_L/A_S = (E-F)/B \qquad (1)$$

where D is the distribution ratio; E, the volume of the effluent before the emergence of the solute in a maximal concentration; B, the volume of the stationary phase; F, the volume of the mobile phase, with empty space in the column; A, the cross-sectional area of the column; A_S, the cross-sectional area of the non-mobile phase (B/column length); A_L, the cross-sectional area of the mobile phase (F/column length), and R, the ratio of (the movement of the position of the maximum concentration of the solute) to (the simultaneous movement of the surface of the developing fluid in the empty part of the above column) (column length/E/A).

The values of D calculated from Eq. 1 by putting, for E, the volume of eluent at the peak of each elution curve are given under the respective peaks in Fig. 14. The logarithmic value of D calculated above is plotted against the logarithm of the mg. of the metal loaded on the column in Fig. 15, in which the relation is shown as a nearly straight line; if the line is elongated upward, the value of D at any point may show the value of D at any lower concentration of metal ions loaded. On the other hand, all of the tail ends of the elution curves are situated so close together on the abscissa in Fig. 14 that they seem to coincide with one another in the range of permissible error in all the procedure. Moreover, the E shifts rightward on the abscissa with the decrease in the amount of metal ions loaded on the column; the position of E when a trace amount of metal is treated may be assumed to be close to the tail end of the elution curve at last. The distribution ratio can usually be calculated from the value of E, so the position of the tail end can be used to calculate the distribution ratio at a very low concentration of the metal ions that probably may be focused on a constant value. The volume of the effluent at the tail end is 316.6 ml. in the author's experiment, while the value of D calculated from this volume is 69.3. This value of D is situated on the elongated part of the straight line in Fig. 15.

When the straight line is extended downward, it will show the relation of D to various larger amounts of potassium loaded. When potassium ions are converted into their poly-iodide, the amount of iodide present in the system may decide the maximum amount of poly-iodide to be formed; in this case, 4.5 ml. of the organic solvent held on the Kel-F supporter corresponds to 28.5 mg. of potassium ions, as calculated from the amount of iodide present in the system. On the other hand, the amount of potassium retained on the column had been estimated, from the value of one of its break-through curves in Fig. 1, as being equivalent to 30 mg. of potassium. These two values, one from the calculated and the other from the break-through, agree well with each other, though incidentally. This value seems to be the maximum amount of potassium loadable on the column; this amount is also the upper limit of the concentration of potassium on the straight line shown in Fig. 15.

As the straight solid line in Fig. 15 shows the relation of D to the amount of potassium loaded on the column, if the amount of potassium loaded on the column is known, the value of D can be estimated from the figure. Putting this value of D into Eq. 1, we get E, the location of the peak of the elution curve on the axis of the effluent volume.

Further liquid-liquid extraction experiments

were carried out between 4.5 ml. of the same solvent as the stationary phase held on Kel-F and 4.5 ml. of the eluting solution containing exactly the same amounts of potassium ion as in the column. The volume of the phase was 4.5 ml.; this amount is equal to the organic solvent held on the column. The distribution ratios obtained in these experiments are also shown in Fig. 15 as ○ marks. This relation fairly agrees well with the relation between the amounts of metal ions and D obtained in the column extraction.

Moreover, similar results were obtained in the case of rubidium, as is shown in Figs. 16 and 17. In Fig. 16, the value of E when a minute amount of the metal is treated is situated close to the tail end, as in the case of potassium, Therefore, the author calculated D at a very low concentration of the metal ions, using 233 ml. as the mean of the effluent volumes of the tail ends of many elution curves; he estimated the value to be 50.7. On the other hand, the D value calculated from the E of the elution curve of Rb-86 tracer was 45.3. The above two values seem almost to agree with each other when the difference in sensitivity between flame photometry and radioactivity measurement is taken into account. These values are also nearly equal to the value obtained by extraporating upward the straight line in Fig. 17.

The distribution was also measured by batch extraction between a Kel-F/nitrobenzene-iodine-iodide mixture and an aqueous phase of the eluting solution containing potassium ions as follows. In a glass-stoppered Erlenmyer flask 6.0 g. of Kel-F powder containing 4.5 ml. of a nitrobenzene-iodine-iodide mixture and 13.5 ml. of a water-eluting solution were placed together; the vessel was then shaken for a while. The contents of the flask were then poured onto a No. 3 glass filter, and the aqueous solution was allowed to drain into a vessel before it was submitted to flame photometry for potassium, The distribution ratio thus estimated coincided with the value obtained in the case of batch extraction with the organic solvent and the aqueous solution in the same volume ratio. From this it may be concluded that Kel-F did not participate in this reversed-phase partition chromatography at all.

2) Column Efficiency.—Column efficiency is usually presented as the number of plates of equivalent extraction carried out on the column. The author tried to calculate the number of plates, N, in this reversed-phase partition chromatography, even though the partition process was far from ideal, in which the partition coefficient remains constant. The author's tentative calculations, based on the elution curve of potassium in Fig. 14 and that of rubidium in Fig. 16, are summarized in Fig. 18, which reveals that the smaller the amount of sample loaded, the larger the plate number, N, for the distribution ratio increases with the decrease in the number of ions treated; the relation between N and D may be assumed to be roughly proportional.

Summary

Partition chromatography and liquid-liquid extraction are closely related to each other with regard to the distribution of solute between two phases. The previous investigation by the present author has clarified that an alkali metal ion can be extracted from an aqueous phase into nitrobenzene containing iodine and ammonium iodide, but the metals are so similar in distribution behavior into the organic phase that they cannot be separated from one another, even by repeated batch extraction. The author has attempted to extend this extraction method to a reversed-phase partition chromatography in which Kel-F powder was used to support the organic phase of nitrobenzene-iodine-iodide; column chromatography has been carried out by eluting with three kinds of eluting solutions. Such characteristics of the column as the volume of the stationary phase held on Kel-F, the volume of the mobile phase in the column, the column life and the capacity of the column have been investigated. The elution of alkali metals has also been carried out with each individual ion. Actual separations, between lithum and sodium, potassium and sodium, potassium and rubidium, rubidium and cesium have been successfully achieved, in addition to the separation of radioactive cesium from rubidium and from large amounts of other alkali metals and the recovery of individual metals from their mixture. The capacity of the column can be estimated as the amount of solute that the column can retain, but the amount largely depends upon the distribution of the solute in the organic phase. Elution curves of various amounts of metal have been obtained for use in discussing the partition of the metal on the column. A comparison of the distribution ratio obtained in the liquid-liquid extraction with that obtained in the column chromatography has shown that same mechanism holds in both cases. The column efficiency has also been calculated, employing the band width of the elution curves and by using the equation commonly adopted. The distribution ratio varies with the amount of solute placed in the column; the larger the distribution, the smaller the amount. In this experiment, however, the number of the plates of equivalent extraction and the distribution ratio have been found to have a linear relationship; this shows that only the partition phenomenon is predominant in this chromatographic process.

The author is deeply indebted to Professor Toshiyasu Kiba for his kind help and advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 597—602 (1966)

An Application of the Quasi Chemical Approximation to the NMR Dilution Shift in Some Binary Mixtures

By Iwao SATAKE, Masujiro ARITA, Hideo KIMIZUKA and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received July 23, 1965)

The theoretical NMR dilution curves for the ethanol - carbon tetrachloride, water-acetone and water-dioxane systems have been derived without the assumption of any particular type of H-bonded complexes in the solution. The expressions so derived contain the interchange energies as variable parameters. The use of the appropriate values of interchange energies (a few kilocalories) gives reasonable quantitative fits of the experimental dilution curves over the entire concentration range of the solutions. These values suggest that the strength of hydrogen bonding in the present systems is in the order of: water-water > water-acetone > water-dioxane > ethanol-ethanol.

A number of papers have reported on the concentration dependence of the proton resonance lines in a variety of binary mixtures, and some quantitative treatments have been made for them. Huggins et al.[1] assumed the simple monomer-dimer equilibrium in order to elucidate the dilution curves of several phenol derivatives in the extremely low concentration range and obtained the association constants by using infrared data. Mavel[2] derived the theoretical dilution curves for various kinds of complex formations over the whole concentration range and compared them with the experimental results.

In most of the papers,[3-9] including those of the above authors, the treatments are based on the assumption that there exists an association equilibrium among the particular hydrogen bonded complexes in a given concentration range of the solution. It is, however, unreasonable to assume only the particular types of H-bonded complexes, since no conclusive evidence has yet been obtained for even the existence of such complexes.

From another point of view, the so-called "hydrogen bond" should be regarded as only a kind of intermolecular interaction which has a comparatively large interaction energy—a few kilocalories. In this connection, it is important to examine whether or not the concentration dependence of the proton chemical shifts in the H-bonded systems can be interpreted in terms of the statistical mechanics without the assumption of any particular H-bonded complex in the solution.

The purpose of this paper is to apply the quasi chemical approximation, developed by Guggenheim,[10] to the ethanol - carbon tetrachloride, water-acetone and water-dioxane systems, and to evaluate the dilution curves by means of information on the number of contacts which can be enumerated by Barker's method.[11] Although several reports[4,5,8,12-14] have already been published on these systems, we have chosen them as model systems for the present discussion.

Theoretical

In general, it can be said that the molecules and their functional groups give rise to molecular contacts with appropriate orientations in conformity with their thermodynamic probability. Thus, the protons of the type i, e. g., the hydroxyl proton of water in the water - organic solvent mixture, can be present as various kinds of pairs or of contacts, such as the proton-proton acceptor group of orgainc molecule, the proton-methylene group contact, and so on. The number of these pairs may then be denoted by N_{ij} ($j=1, 2, \cdots$), where j indicates the contact points of the molecule.

In H-bonded systems a single sharp line is usually

observed for the protons under consideration because of a rapid exchange among the various types of protons present in the solution. In this case the chemical shift, δ_i, for the protons of the type i is known to be given by the weighted average of each contribution;

$$\delta_i = \sum_j N_{ij}\cdot\delta_{ij}/\sum_j N_{ij} \tag{1}$$

where δ_{ij} denotes the chemical shift for the protons of the type i in the i-j pairs. As may be seen in Eq. 1, the chemical shifts, as well as the proton fraction for each state, must be known in order to obtain the theoretical dilution curve for the H-bonded system.

Consider the mixture consisting of molecules of the types A, B,$\cdots$ arranged on a Z-coordinated lattice. For the numbers of N_{ij}^{AB} pairs, which are formed by the contacts between the i-th class of contact points of the A molecule $\binom{A}{i}$ and the j-th one of the B molecule $\binom{B}{j}$, we have:

$$2N_{ii}^{AA} + \sum_{B,j} N_{ij}^{AB} = Q_i^A\cdot N_A \tag{2}$$

and the quasi chemical equation:

$$(N_{ij}^{AB})^2 = 4\cdot N_{ii}^{AA}\cdot N_{jj}^{BB}\cdot\exp(-U_{ij}^{AB}/\boldsymbol{k}T) \tag{3}$$

where Q_i^A denotes the number of the contact points in the i-th class of the A molecule; N_A, the number of the A molecule, and U_{ij}^{AB}, the interchange energy per pair for the i-j contact.

By introducing the parameters[11]:

$$\eta_{ij}^{AB} = \exp(-U_{ij}^{AB}/\boldsymbol{k}T) = \eta_{ji}^{BA} = \eta_{ij} \tag{4}$$

and:

$$X_i^A = (N_{ii}^{AA}/N)^{1/2} \tag{5a}$$

$$X_j^B = (N_{jj}^{BB}/N)^{1/2} \tag{5b}$$

where N denotes the total number of molecules in the system, we have:

$$N_{ij}^{AB} = 2\cdot X_i^A\cdot X_j^B\eta_{ij}\cdot N \quad \text{for } \binom{A}{i} \neq \binom{B}{j} \tag{6a}$$

$$= (X_i^A)^2\cdot N \quad \text{for } \binom{A}{i} = \binom{B}{j} \tag{6b}$$

and;

$$X_i^A\sum_{B,j}\eta_{ij}X_j^B = Q_i^A x_A/2 \tag{7a}$$

$$X_j^B\sum_{A,i}\eta_{ij}X_i^A = Q_j^B x_B/2 \tag{7b}$$

where x_A and x_B denote the mole fraction of the A molecule and that of the B molecule respectively. Assuming appropriate models with reasonable values of Q_i^A's, the values of N_{ij}^{AB} can be estimated according to Eqs. 6a, 6b, 7a and 7b, provided that the values of the η_{ij}'s are known. Then the theoretical dilution curve can be obtained according to Eq. 1, provided that the δ_{ij}'s are known.

1) The Ethanol - Carbon Tetrachloride System.—We will start with the assumptions for the lattice model and molecular geometries; 1) From the approximate ratio of the molecular volume of ethanol to carbon tetrachloride, it is most reasonable to regard the ethanol molecule as a trimer and the carbon tetrachloride molecule as a pentamer. 2) We assume that each lattice point has four nearest neighbors; that is, $Z=4$. Then the number of contact points of ethanol is 8, and that of carbon tetrachloride is 12.

$$C_2H_5OH \quad r_e = 3, \quad Q_H^e = 1, \quad Q_O^e = 2, \quad Q_I^e = 5$$

$$CCl_4 \quad r_s = 5, \quad Q_s = 12$$

where the subscripts e and s refer to ethanol and carbon tetrachloride molecules respectively. Q_H^e, Q_O^e and Q_I^e denote the number of contact points of the hydroxyl hydrogen, hydroxyl oxygen and hydrocarbon parts of the ethanol molecule respectively. Further, it is necessary to assign the energy of interaction for each possible contact. The interchange energies among the equivalent contact points are zero by definition. The values of U_{OS}, U_{IS} and U_{HS} are considered to be so small, as compared with U_{HO}, that we may take them to be zero without serious error. The value of U_{HO} was determined so as to give the best fit of the NMR data.

On this simplification, Eqs. 7a and 7b may be written as:

$$\left.\begin{aligned} X_H(X_H+\eta X_O+X_I+X_S) &= x_e/2 \\ X_O(\eta X_H+X_O+X_I+X_S) &= x_e \\ X_I(X_H+X_O+X_I+X_S) &= 5x_e/2 \\ X_S(X_H+X_O+X_I+X_S) &= 6x_s = 6(1-x_e) \end{aligned}\right\} \tag{8}$$

where x_e is the mole fraction of ethanol and where $\eta = \exp(-U_{HO}/\boldsymbol{k}T)$.

The solutions of Eq. 8 can now be obtained by the convenient method described by Barker.[11] By the substitutions of the variables:

$$X_H = CY_1, \quad X_O = CY_2, \quad X_I = CY_3, \quad X_S = CY_4,$$
$$Y_1 = 1, \quad Y_2 = \alpha$$

Eq. 8 may be rewritten as:

$$\left.\begin{aligned} C^2(1+\alpha\eta+Y_3+Y_4) &= x_e/2 \\ C^2\alpha(\eta+\alpha+Y_3+Y_4) &= x_e \\ C^2Y_3(1+\alpha+Y_3+Y_4) &= 5x_e/2 \\ C^2Y_4(1+\alpha+Y_3+Y_4) &= 6x_s \end{aligned}\right\} \tag{9}$$

The solutions of Eq. 9 are given as:

$$\left.\begin{aligned} &Y_1 = 1, \quad Y_2 = \alpha, \quad Y_3 = 5(\alpha-1), \\ &Y_4 = [(2+\alpha\eta-\alpha^2)/(\alpha-2)] - Y_3 \end{aligned}\right\} \tag{10}$$

and:

$$C^2 = 6/[Y_4(1+\alpha+Y_3+Y_4) + 12(1+\alpha\eta+Y_3+Y_4)] \tag{11}$$

Any solution of Eq. 9 then serves to determine the mole fraction, x_e, as the function of α and η.

$$x_e = 12(\alpha-1)(\alpha-2)/[6\alpha^2+\alpha(\eta-21)+16] \quad (12)$$

The variable range of α is $2<\alpha<t$, where:

$$t = [(\eta+15)+\{(\eta+15)^2-192\}^{1/2}]/12 \quad (13)$$

By using Eqs. from 10 to 13, the numerical value of each number of possible contacts occurring in the ethanol - carbon tetrachloride mixture may be easily determined as a function of the concentration, provided the appropriate value of η is taken.

The hydroxyl protons participating in the rapid exchange among ethanol molecules may be classified into two groups from the electronic environmental point of view. To the first group are assigned the protons which participate in the (H-H), (H-I) and (H-S) contacts, and to the second, the H-bonded protons which participate in the (H-O) contacts. The chemical shifts of hydroxyl protons assigned to the first group are different from each other. However, we assign the same value of chemical shift, δ_F, to the protons for the (H-H), (H-I) and (H-S) contacts, since the differences among them may be considered to be fairly small.

The total number of hydroxyl protons in the mixture is $2(X_H^2+X_HX_I+\eta X_HX_O+X_HX_S)$. The number of protons assigned to the first group is $2(X_H^2+X_HX_I+X_HX_S)$, while the number assigned to the second is $2\eta X_HX_O$. If we denote the chemical shift of H-bonded protons as δ_B, the chemical shift of the –OH proton at a given concentration may be written as:

$$\begin{aligned}\delta &= [(X_H^2+X_HX_I+X_HX_S)\delta_F + \eta X_HX_O\delta_B]/\\ &\quad (X_H^2+X_HX_I+\eta X_HX_O+X_HX_S)\\ &= \delta_F + \alpha\eta(\delta_B-\delta_F)/(1+\alpha\eta+Y_3+Y_4) \quad (14)\end{aligned}$$

The substitution of Eq. 10 into Eq. 14 gives the simplified expression for δ; that is;

$$\delta = \delta_F + (\alpha-2)(\delta_B-\delta_F)\eta/(\alpha-1)(\eta-1) \quad (15)$$

Equation 15 gives the chemical shift, δ, of the –OH proton as the function of the parameter α, which is combined with the analytical mole fraction, x_e, through Eq. 12, and the unknown parameters, δ_F, δ_B and η. However, the parameters δ_F and δ_B can be eliminated from Eq. 15 by the use of boundary condition; i. e.,

$$\begin{aligned}&x_e \to 0 \qquad \alpha \to 2 \qquad \delta \to \delta_0\\ &x_e \to 1 \qquad \alpha \to t \qquad \delta \to \delta_1\end{aligned}$$

Here δ_0 is the limiting value of δ which corresponds to the chemical shift of the –OH proton extrapolated to infinite dilution, while δ_1 is the chemical shift of pure ethanol. It follows from Eq. 15 that:

$$\delta_F = \delta_0 \quad (16)$$

and that:

$$\delta_B = \delta_0 + (t-1)(\eta-1)(\delta_1-\delta_0)/\eta(t-2) \quad (17)$$

By the substitution of Eqs. 16 and 17 into Eq. 15, the final expression of the dilution curve is obtained:

$$\delta = \delta_0 + (\alpha-2)(t-1)(\delta_1-\delta_0)/(\alpha-1)(t-2) \quad (18)$$

In Eq. 18, the unknown parameter used to evaluate the value of t is η. The value of η must be determined so as to give the best fit of the observed chemical shifts.

2) The Water-Acetone System.—The elucidation of the dilution curve for water-acetone system is rather complicated, since there are two types of hydrogen bonds in solution. The molecular parameters assumed for this system are:

$$\begin{aligned}&H_2O \qquad r_w = 1 \qquad Q_H^W = 2 \qquad Q_O^W = 2\\ &(CH_3)_2CO \qquad r_a = 3 \qquad Q_H^A = 6 \qquad Q_O^A = 2\end{aligned}$$

and $Z=4$. Further, it is assumed that all of the interchange energies except U_{OH}^{WW} and U_{HO}^{WA} may be ignored. On the basis of these simplifications, two parameters,

$$\eta_1 = \exp(-U_{OH}^{WW}/\boldsymbol{k}T)$$

and

$$\eta_2 = \exp(-U_{HO}^{WA}/\boldsymbol{k}T)$$

are left to be determined. Taking the abbreviations $X_H^W=X_1$, $X_O^W=X_2$, $X_H^A=X_3$ and $X_O^A=X_4$, Eqs. 7a and 7b can be written in this form:

$$\left.\begin{aligned}&X_1(X_1+\eta_1X_2+X_3+\eta_2X_4) = x_w\\ &X_2(\eta_1X_1+X_2+X_3+X_4) = x_w\\ &X_3(X_1+X_2+X_3+X_4) = 3x_a = 3(1-x_w)\\ &X_4(\eta_2X_1+X_2+X_3+X_4) = x_a\end{aligned}\right\} \quad (19)$$

By substitutions of variables similar to those made in Sec. 1, the solutions of Eq. 19 may be easily obtained as follows:

$$\begin{aligned}&Y_1=1, \quad Y_2=\alpha, \quad Y_3=3(\alpha-1)(\eta_2+1)/(\eta_2-4\alpha+3)\\ &Y_4=2(\alpha-1)(2\alpha-1)/(\eta_2-4\alpha+3)\\ &C^2=1/[Y_4(\eta_2+\alpha+Y_3+Y_4)+(1+\alpha\eta_1+Y_3+\eta_2Y_4)]\end{aligned}$$

where the variable range of α is $1<\alpha<(\eta_2+3)/4$. The mole fraction of water, x_w, can be obtained by any one of the equations in Eq. 19.

Now, the states of the water protons in the solution may be classified into three groups. To the first are assigned the protons which come in contact with the hydroxyl proton of water or the methyl proton of acetone molecules. Their chemical shift is denoted by δ_F. To the second are assigned the protons which participate in the H-bond between the H and O atoms of water molecules. Their chemical shift is δ_W. To the third are assigned the protons which participate in the H-bond between the H atom of water and the O atom of acetone. Their chemical shift is δ_C. The chemical shift of the water proton at a given concentration is given as:

$$\delta = [(1+Y_3)\delta_F+\eta_2 Y_4\delta_C+\alpha\eta_1\delta_W]/(1+\alpha\eta_1+Y_3+\eta_2 Y_4) \quad (20)$$

By the use of boundary conditions, the unknown parameters, δ_W and δ_C, in Eq. 20 may be represented in terms of the chemical shift of pure water, δ_1, and that extrapolated to $x_w=0$, δ_0, i. e.:

$$x_w \to 1 \qquad \alpha \to 1 \qquad \delta \to \delta_1$$
$$x_w \to 0 \qquad \alpha \to (\eta_2+3)/4 \qquad \delta \to \delta_0$$

It follows, therefore, from Eq. 20 that:

$$\eta_1\delta_W = (1+\eta_1)\delta_1 - \delta_F \quad (21)$$

and that:

$$\eta_2\delta_C = (\eta_2+3)\delta_0 - 3\delta_F \quad (22)$$

The substitution of Eqs. 21 and 22 into Eq. 20 gives the final expression of δ for the water-acetone system:

$$\delta = [(1+Y_3-\alpha-3Y_4)\delta_F + \alpha(1+\eta_1)\delta_1 + Y_4(\eta_2+3)\delta_0]/(1+\alpha\eta_1+Y_3+\eta_2 Y_4) \quad (23)$$

Equation 23 contains three unknown parameters, δ_F, η_1 and η_2; the latter two must be estimated so as to give the best fit of the NMR data. If the protons in the first group can be assumed to be equivalent to the gaseous state, the chemical shift of the water vapor may be used in place of δ_F.

3) The Water-Dioxane System.—The molecular parameters assumed for the water-dioxane system are:

Water $\quad Q_H^W = 2 \quad Q_O^W = 2$

Dioxane $\quad Q_H^D = 10 \quad Q_O^D = 4$

and $Z=4$. We also assume that all of the interchange energies except U_{HO}^{WW} and U_{HO}^{WD} are negligibly The parameters to be determined are, then:

$$\eta_1 = \exp(-U_{HO}^{WW}/kT)$$

and:

$$\eta_2 = \exp(-U_{HO}^{WD}/kT)$$

By the same mathematical treatment as in Sec. 2, the theoretical dilution curve for the water-dioxane system may be derived as:

$$\delta = [(1+Y_3-\alpha-5Y_4/2)\delta_F + \alpha(1+\eta_1)\delta_1 + Y_4(\eta_2+5/2)\delta_0]/(1+\alpha\eta_1+Y_3+\eta_2 Y_4) \quad (24)$$

where:

$$Y_3 = 5(\alpha-1)(\eta_2+1)/(2\eta_2-7\alpha+5)$$
$$Y_4 = (7\alpha-3)(\alpha-1)/(2\eta_2-7\alpha+5)$$
$$1<\alpha<(2\eta_2+5)/7$$

Experimental

In the present experiment, the chemical shifts of the water proton in the water-acetone and water - 1, 4-dioxane mixtures were measured as a function of the composition (the concentration in mole fraction) of the mixture. The mixtures were prepared gravimetrically from the purified materials. Acetone was distilled twice with calcium sulfate, and 1, 4-dioxane, with metallic sodium, in order to remove traces of water. Water was distilled twice from the alkaline potassium permanganate solution.

The NMR shifts were obtained by using a Japan Electron Optics High Resolution NMR Spectrometer, JNM-3, operating at 40 Mc. The line separations were measured by the side-band technique, using cyclohexane as an external reference. The shifts were measured to an accuracy of ± 0.4 c. p. s., and each shift was corrected for the difference in the bulk diamagnetic susceptibilities of the reference and the solution.

Results and Discussion

In the present study, we applied Eq. 18 to the dilution curve of ethanol in carbon tetrachloride reported by Becker et al.[14] In Fig. 1, the chemical shift of the OH proton in the ethanol - carbon tetrachloride system determined by them is replotted against the concentration of ethanol. The

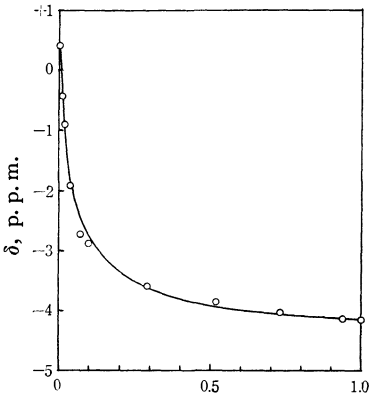

Fig. 1. The dilution curve of OH proton signal in C_2H_5OH—CCl_4 system at 27°C. The chemical shifts are referred to the central peak of the CH_3 triplet in ethanol.
○ Observed[14]
— Calculated from Eq. 18 with $\eta=180$.

most reliable value of η was found to be 180, corresponding to the interchange energy, U_{HO}, of about -3090 cal./mol. bonds at 27°C. The results calculated over the entire concentration range of ethanol is illustrated by the solid line in Fig. 1. Although slight deviations from the experimental values could not be eliminated, the agreement between the calculated and experimental curves is almost entirely satisfactory. Liddel and Becker[15] obtained 3.6 ± 0.8 kcal./mol. for the H-bond energy of this system on the basis of their infrared spectroscopic measurements.

The chemical shifts of water protons in water-acetone and water-dioxane mixtures, with reference to cyclohexane, at various concentrations x_w (mole fraction of water), are summarized in Table I.

Table I. Chemical shifts of water in the water-acetone mixture at 25°C and in the water-dioxane mixture at 35°C

Water-Acetone		Water-Dioxane	
x_w	$-\delta$, p.p.m.	x_w	$-\delta$, p.p.m.

1.000	3.391		

The concentration dependences of the water signals are also represented in Figs. 2 and 3. On applying Eqs. 23 and 24 to the water-acetone and water-dioxane systems respectively, we have used the value of +0.603 p.p.m. for δ_F, which has been determined by Schneider et al.[16] We have used the values, of −1.31 p. p. m. for δ_0 in Eq. 23 and −0.76 p. p. m. for that in Eq. 24, which have been determined by the extrapolation of the experimental dilution curves. The value of δ_0 for the water-acetone system agrees well with that (−1.308 p. p. m.) determined by Holmes et al.[5] The theoretical dilution curve calculated from Eq. 23 is given by the solid line in Fig. 2, and that calculated from Eq. 24, in Fig. 3. For the water-acetone system, the most reliable set of η_1 and η_2 vaules are found to be 1200 for η_1 and 500 for η_2; these values correspond to the interchange energies of −4200 and −3680 cal./mol. bonds respectively at 25°C. For the water-dioxane system, we find that $\eta_1=1300$ and $\eta_2=200$, corresponding to the interchange energies of −4400 and −3200 cal./mol. bonds respectively at 35°C.

Although the present treatment is an approximate one in nature, the agreement between calculated and experimental dilution curves seems almost entirely satisfactory over nearly all the concentration range. The slight deviations observed may be ascribed to the assumptions included in these treatments. The thermodynamic properties of hydrogen bonds have been determined by a number of authors, and the results have been summarized by Pimentel and McClellan.[17] However, the

interchange energies obtained above are not directly comparable with them because of the considerable scattering of ΔH values. The values of the interchange energies obtained from the present discussion are in the order of H_2O-H_2O > H_2O-$(CH_3)_2CO$ > H_2O-$C_4H_8O_2$ > C_2H_5OH-C_2H_5OH, indicating that the strength of hydrogen bonding is in this order.

Summary

The generalized quasi-chemical approximation has been applied to the ethanol - carbon tetrachloride, water-acetone and water-dioxane systems for the elucidation of NMR dilution curves. The theoretical dilution curves can be derived as the function of the interchange energies and the proton fraction by assuming appropriate molecular models. The values of the interchange energies were determined so as to give the best fit of NMR data. The most reliable set of interchange energies so determined were −3090 cal./mol. bonds at 27°C for the ethanol - carbon tetrachloride system, −4200 and −3680 cal./mol. bonds at 25°C for the water-acetone system and −4400 and −3200 cal./mol. bonds at 35°C for the water-dioxane system. The agreements between the calculated and experimental dilution curves were almost entirely satisfactory over the entire concentration range. On the basis of the values of the interchange energies obtained in the present study, the strength of hydrogen bonding was found to be in the order of water-water > water-acetone > water-dioxane > ethanol-ethanol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 602—604 (1966)

Studies of *C*-Substituted Tartaric Acid. I. The Preparation of Optically Active 2-Methyltartaric and 2, 3-Dimethyltartaric Acid

By Susumu TATSUMI, Yoshiharu IZUMI, Masami IMAIDA, Yoshio FUKUDA and Shiro AKABORI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 26, 1965)

Two racemic forms of 2-methyltartaric acid were prepared, and their optical resolutions were performed. Four optically active isomers were obtained. 2, 3-Dimethyltartaric acid was also prepared and separated into two isomeric optically inactive forms. The isomer with the higher melting point could be resolved into two optically active isomers, but the other, with the lower melting point, could not. The former was, therefore, assigned to the racemic configuration, and the latter, to the meso configuration.

Optically active 2-methyltartaric and 2, 3-dimethyltartaric acid are interesting substances to study from the stereochemical point of view in their relation to tartaric acid. Moreover, in a previous publication[1] from our laboratory, it was reported that a Raney nickel catalyst treated with aqueous solutions of these optically active hydroxy carboxylic acids has an asymmetric hydrogenation activity in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate, and that an especially high asymmetric activity is obtained with optically active 2-methyltartaric acid (B) under optimum conditions. However, preparations of optically active 2-methyltartaric and 2, 3-dimethyltartaric acid have never been described.

In the present work, optically active 2-methyltartaric and 2, 3-dimethyltartaric acid will be prepared.

The two racemic forms of 2-methyltartaric acid (I), the melting points of which are 146°C (Ia) and 161°C (Ib), were prepared from ethyl α-acetoxyacetoacetate by a modification of Schmidt's procedure,[2] and their optical resolutions were performed with brucine by the method of the differential solubility of the diastereomers in water. The optical rotation values of the four isomers were as follows:

(A) From the racemic form with the lower melting point (2-methyltartaric acid A)···(Ia):

(+) isomer $[\alpha]_D^{20}$ +8.90° (*c* 3.7, water)

(−) isomer $[\alpha]_D^{20}$ −8.94° (*c* 3.7, water)

(B) From the racemic form with the higher melting point (2-methyltartaric acid B)···(Ib):

(+) isomer $[\alpha]_D^{20}$ +5.88° (*c* 3.2, water)

(−) isomer $[\alpha]_D^{20}$ −5.60° (*c* 3.2, water)

1) Y. Izumi, S. Tatsumi, M. Imaida, Y. Fukuda and S. Akabori, This Bulletin, in press.

2) O. T. Schmidt and W. Perkow, *Chem. Ber.*, **83**, 484 (1950).

2, 3-Dimethyltartaric acid (II) has two optically inactive modifications, the meso (IIa) and the racemic forms (IIb). This acid was synthesized from diacetyl and hydrogen cyanide, and the separation into two components, the meso and racemic form, was performed by means of the differential solubility of their barium salts in water. The melting points of the free meso and racemic acid are 180 and 187°C respectively. The optical resolution of the racemic form was performed in an aqueous solution with brucine, and the optical rotation values of the two isomers were as follows:

(+) isomer $[\alpha]_D^{20}$ +13.4° (*c* 4.0, water)

(−) isomer $[\alpha]_D^{20}$ −13.4° (*c* 4.0, water)

Experimental*

The Preparation of 2-Methyltartaric Acid (I) and Separation into Two Racemic Forms (Ia and Ib).—A mixture of 28.2 g. of ethyl α-acetoxyacetoacetate in 100 ml. of ethanol and 13 g. of potassium cyanide in 50 ml. of water was cooled to 0—5°C in an ice water bath; 200 ml. of N hydrochloric acid was then vigorously stirred, drop by drop, into the mixture. The flask was tightly stoppered, and the mixture was warmed in a water bath at 50—60°C for 4 hr. and then left to stand overnight at room temperature. After the reaction mixture had been cooled in an ice water bath, it was poured into 400 ml. of concentrated hydrochloric acid; the mixture was then allowed to stand for two days. The acidic solution was refluxed for an hour and concentrated in vacuo. During the concentration inorganic salts were removed by filtration. The residue was dissolved in a small amount of water and concentrated again in vacuo.

In order to remove the free hydrochloric acid, the above operation was then repeated. The residual syrup was taken up in 150 ml. of water and decolorized with charcoal; when it was neutralized with a 3% barium hydroxide solution, a great deal of the barium salt of Ia was precipitated. After it had been stored overnight in a refrigerator, the salt was collected by filtration, washed several times with hot water, and dried in air at 80°C. Yield, 15 g. The salt was dissolved in 50 ml. of N hydrochloric acid, and the resulting solution was then evaporated to dryness in vacuo. The residue was extracted with four 20-ml. portions of acetone. The acetone extracts were combined and evaporated to a syrup. The syrupy product was cooled and crystallized by the addition of a small amount of petroleum ether. Recrystallization from dry ethyl acetate gave pure, white, crystalline Ia. Yield, 5.5 g. M. p. 146°C.

Found: C, 36.73; H, 4.89. Calcd. for $C_5H_8O_6$: C, 36.59; H, 4.91%.

The mother liquor of the barium salt of Ia was concentrated to half its volume and then left to stand for 2 hr. in an ice box. A small amount of crystalline precipitate was filtered off, and the filtrate was treated with 10 ml. of 6 N hydrochloric acid and then evaporated to dryness. The residue was extracted with acetone and then treated as above.

In this way, four grams of white crystalline Ib were obtained. M. p. 161°C.

Found: C, 36.53; H, 4.93. Calcd. for $C_5H_8O_6$: C, 36.59; H, 4.91%.

The Optical Resolution of Ia.—Forty-nine grams of Ia and 118 g. of brucine were dissolved in 1000 ml. of boiling water; the resulting solution was allowed to stand overnight in a refrigerator. The needle-like crystals of the brucine salt which precipitated were collected by filtration; six recrystallizations of this salt from ten parts of boiling water gave 61 g. of the pure brucine salt of Ia. M. p. 236—237°C, $[\alpha]_D^{20}$ −21.9° (*c* 0.4, in water). This salt was then suspended in 100 ml. of cold water and decomposed with 225 ml. of a N sodium hydroxide solution. The precipitated brucine was removed by filtration, and the alkaline filtrate was washed twice with 50 ml. of chlorofoum, neutralized with 20 ml. of concentrated hydrochloric acid, and then evaporated to a syrup. To the residual syrup a small amount of water was added, and the resulting solution was decolorized with charcoal and evaporated to dryness in order to remove the free hydrochloric acid. The residue was extracted several times with 20 ml. of acetone. These acetone extracts were then combined and evaporated to a syrup. The syrupy product was dried over sulfuric acid in a vacuum desiccator. In this way, white, hygroscopic crystals of (−)-Ia were obtained. Recrystallization from dry ethyl acetate gave 14.9 g. of optically pure (−)-Ia. M. p. 115—116°C, $[\alpha]_D^{20}$ −8.94° (*c* 3.7, water).

Found: C, 36.53; H, 5.02. Calcd. for $C_5H_8O_6$: C, 36.59; H, 4.91%.

The mother liquor of the brucine salt of (−)-Ia was concentrated to a paste. After it had been stood for a week in a refrigerator, the brucine salt of (+)-Ia was collected. Optically pure (+)-Ia was obtained from this salt by the procedure described above. Yield, 8.0 g. M. p. 115°C, $[\alpha]_D^{20}$ +8.90° (*c* 3.7, water).

Found: C, 36.57; H, 4.94. Calcd. for $C_5H_8O_6$: C, 36.59; H, 4.91%.

The Optical Resolution of Ib.—Thirty-eight grams of Ib and 91.5 g. of brucine were dissolved in 1000 ml. of boiling water, and the resulting solution was treated as in the resolution of Ia. Forty grams of the pure brucine salt of (+)-Ib were, thus obtained. M. p. 234—235°C, $[\alpha]_D^{20}$ −16.5° (*c* 0.4, water). When the brucine salt was decomposed with alkali, 8.2 g. of optically pure (+)-Ib were obtained. M. p. 130—131°C, $[\alpha]_D^{20}$ +5.88° (*c* 3.2, water).

Found: C, 36.53; H, 4.88. Calcd. for $C_5H_8O_6$: C, 36.59; H, 4.91%.

From the mother liquor of the brucine salt of (+)-Ib, 5.1 g. of optically acitive (−)-Ib were obtained by the procedures described above. M. p. 129°C, $[\alpha]_D^{20}$ −5.60° (*c* 3.2, water).

Found: C, 36.63; H, 4.79. Calcd. for $C_5H_8O_6$: C, 36.59; H, 4.91%.

The Preparation of 2, 3-Dimethyltartaric Acid (II) and Its Separation into Meso (IIa) and Racemic Forms (IIb).—Into a solution of 520 g. of sodium cyanide in 1000 ml. of water, 800 ml. of concentrated hydrochloric acid was stirred vigorously, drop by drop, below 15°C in a hood. After the addition of hydrochloric acid, 74 ml. of a 20% aqueous potassium carbonate solution was added slowly. Then 344 ml. of diacetyl was stirred in drop by drop under sufficient

* All melting points are uncorrected.

cooling, and the reaction mixture was maintained at 15—20°C for 2 hr. Then 2.4 l. of concentrated hydrochloric acid were added cautiously (the temperature of the solution rose up to 40°C with foaming). After the reaction mixture had been kept at room temperature overnight, it was refluxed for 7 hr. Inorganic salt and tar were removed by suction from the cooled hydrolyzed solution, and the filtrate was concentrated to about 800 ml. in vacuo. On the addition of 300 ml. of acetone, inorganic salt was precipitated; this was filtered off, and the solution was concentrated again. The above treatment was repeated several times in order to remove the inorganic salts, and the residual syrup was dissolved in 1.5 l. of ethanol and was esterified with blowing dry hydrogen chloride gas into the solution. The alcohol was distilled off in vacuo, and the diethyl ester of II was collected at 110—115°C (4 mmHg). Yield, 240 g.

Two hundred and forty grams of diethyl ester were refluxed with 1000 ml. of 10% hydrochloric acid for 5 hr. The hydrolyzate was decolorized with charcoal and then concentrated to a syrup. The syrupy residue was taken up in 200 ml. of water and concentrated again. The above treatment was repeated in order to remove the free hydrochloric acid, and then the residue was dissolved in 2 l. of water and neutralized slowly to pH 5.0 with a barium hydroxide solution. A great deal of the barium salt of IIa was immediately precipitated. The barium salt was collected by suction, washed with a large quantity of hot water, and dried in air at 80°C. Yield, 160 g. When the mother liquor of the barium salt of IIa was adjusted to pH 8.0, a small amount of an additional salt appeared; this was removed by filtration. The filtrate was concentrated in vacuo, and the barium salt of IIb precipitating from the solution was collected successively by suction. It was washed with a small amount of water and dried in air at 80°C. Yield, 120 g.

IIa and IIb from their barium salts were prepared essentially as described in the preceding paragraph.

From 160 g. of the barium salt of IIa, 70 g. of IIa were obtained. M. p. 180°C.

Found: C, 40.31; H, 5.64. Calcd. for $C_6H_{10}O_6$: C, 40.45; H, 5.66%.

Similarly from 120 g. of the barium salt of IIb, 53 g. of IIb were obtained. M. p. 187°C.

Found: C, 41.00; H, 5.60. Calcd. for $C_6H_{10}O_6$: C, 40.45; H, 5.66%.

The Optical Resolution of IIb.—Sixty grams of IIb and 145 g. of brucine dihydrate were dissolved in 1300 ml. of boiling water. The resulting solution was treated by the method described for the resolution of Ia; 15.5 g. of optically pure (+)-IIb were thus obtained. M. p. 158°C, $[\alpha]_D^{20}$ +13.4° (*c* 4.0, water).

Found: C, 40.72; H, 5.60. Calcd. for $C_6H_{10}O_6$: C, 40.45; H, 5.66%.

From the mother liquor of the brucine salt of (+)-IIb, 13 g. of optically pure (−)-IIb were obtained. M. p. 160°C, $[\alpha]_D^{20}$ −13.4° (*c* 4.0, water).

Found: C, 40.38: H, 5.43. Calcd. for $C_6H_{10}O_6$: C, 40.45; H, 5.66%.

Summary

1) The optical resolutions of the two racemic forms of 2-methyltartaric acid, the melting points of which are 146 and 161°C, were performed using brucine as a resolving reagent; four optically active isomers were obtained.

2) 2, 3-Dimethyltartaric acid was prepared from diacetyl and hydrogen cyanide and was separated into meso (m. p. 180°C) and racemic forms (m. p. 187°C); the racemic form was then resolved into two optically active isomers.

The authors wish to express their thanks to Miss Kikue Koike and Miss Masako Kawakita of this Institute for performing the elemental analyses. This research was made possible by support from the Kawaken Fine Chemicals Co., Ltd., Tokyo, and the Ajinomoto Co., Inc., Tokyo.

Metal Complexes of Amino Acids. II.[1] The Absorption Spectra of Geometrical Isomers of Copper(II) Complexes

By Takaji YASUI and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received July 28, 1965)

The geometrical structures of bis(α-amino-acidato)copper(II) complexes have been determined from the data of diffuse reflectance spectra (α-amino-acid = glycine, L- and DL-α-alanine, L- and DL-valine, L- and DL-threonine, L- and DL-isoleucine and α-aminoisobutyric acid). It has been shown that pairs of cis(N) and trans(N) isomers exist in glycinato and valinato complexes. It has been clarified that the other amino-acidato complexes studied exist either only in the cis(N) form or only in the trans(N) form; that is, the needle and the scaly complexes of DL-alanine, the complexes of DL- and L-threonine, and the complex of α-aminoisobutyric acid exist only in the trans(N) form, while the complexes of L- and DL-isoleucine exist only in the cis(N) form.

1) Part I of this series: T. Yasui, This Bulletin, 38, 1746 (1965).

The well-known bright-blue crystal of copper(II) glycinate has been shown through X-ray analyses[2] to consist of the bis(glycinato)copper(II) complex, which has a cis(N) configuration involving the two nitrogen atoms of the two coplanar glycinate ligands. The other bluish-violet isomer of bis-(glycinato)copper(II) had been discovered by Mauthner and Suida[3]; it has been assumed to be the trans(N) isomer from a comparison of its infrared absorption spectrum with those of the corresponding trans isomers of bis(glycinato)platinum-(II) and -palladium(II).[4]

For other amino acids, however, no pair of the cis and trans isomers of a copper(II) complex has been known. All copper(II) amino-acid complexes the structures of which were determined by X-ray analysis, had the trans configuration except for the above-mentioned cis glycinato complex. Recently Hooper et al.[5] suggested, from their infrared study, that bis(DL-isoleucinato)copper(II) monohydrate has the cis structure. One of the purposes of the present investigation is to explore other pairs of the cis-trans isomers of copper(II) complexes.

We have shown already by a circular dichroism study[1,6] that a broad visible d→d absorption band of the bis(amino-acidato)copper(II) complex consists of four split components. The difference in symmetry between the cis and the trans isomers will be reflected in the behavior of the d→d absorption bands. In the present paper, the diffuse reflectance spectra of the powdered copper(II) complexes in the region from the near infrared to visible will be reported on, and the geometrical configurations of the complexes will be discussed.

Experimental

Measurement.—The measurements of diffuse reflectance spectra were made by a Hitachi EPU-2A spectrophotometer with a diffuse reflectance attachment. The samples were prepared by grinding the complexes as finely as possible in a porcelain mortar and then in an agatic one until no change appeared in the intensity of the spectra. Magnesium oxide was employed as the reference.

Materials.—The copper(II) complexes with amino acids and with amino acid derivatives were prepared from copper(II) hydroxide by a method similar to that of Abderhalden and Schnitzler.[7]

The *cis*-bis(glycinato)copper(II) complex and the bis(amino-acidato)copper(II) complexes of DL- and L-alanine, DL- and L-valine, DL- and L-threonine, DL-α-amino-*n*-butyric acid, and α-aminoisobutyric acid were recrystallized from aqueous alcohol. The bluish-violet glycine complex was obtained by the method of Mauthner and Suida,[3] and the scaly crystals of the DL-alanine complex by following the directions of Gol'braikh.[8]

Table I. Chemical analyses of the complexes

The copper(II) complexes of DL- and L-isoleucine, ethylene-bis(α-iminophenylacetic acid)[9a] and ethylene-bis(α-iminophenylpropionic acid)[9a] were recrystallized from hot water, and that of ethylene-bis(α-iminoisobutyric acid),[9b] from aqueous acetone. An ethylenediamine compound, $Cu(en)SO_4 \cdot 2H_2O$, was obtained by the method of Pfeiffer and Glaser[10] and recrystallized from aqueous alcohol.

The results of the chemical analyses are listed in Table I for all of the complexes obtained.

The preparations of the remaining complexes have already been reported in a previous report of this series.[1]

Results and Discussion

The spectral curves obtained by the diffuse reflectance measurements are shown in Figs. 1—5. The absorption spectrum of the glycine complex in an aqueous solution shows only one broad band and gives little information about the geometrical structures. Moreover, the cis and the trans isomers give identical spectra in an aqueous solution, probably reaching a cis-trans equilibrium mixture by the rapid rearrangement of the ligands.

The spectral difference between the bright blue *cis*-[Cu gly_2]$\cdot H_2O$ and the bluish-violet [Cu gly_2]$\cdot H_2O$, which can not be observed in an aqueous solution, definitely appears in the solid states, as may be seen in Fig. 1. The spectrum of the bluish violet [Cu gly_2]$\cdot H_2O$ is similar to that in an aqueous solution, but the *cis*-[Cu gly_2]$\cdot H_2O$ in the solid state has the peak at a longer wavelength than that of the bluish-violet form and an accompanying shoulder on the longer wavelength side. This fact indicates that the structure of *cis*-[Cu gly_2]$\cdot H_2O$ in the crystal is considerably different from that in an aqueous solution, and that the symmetry of the complex molecule is rather lowered. This agrees very well with the results of the X-ray study of the *cis*-[Cu gly_2]$\cdot H_2O$.[2] The spectra of the ethylene-bridged copper(II) complexes with cis structures are similar to that of the *cis*-[Cu gly_2]$\cdot H_2O$ (Fig. 2). The spectrum of the bluish-violet [Cu gly_2]$\cdot H_2O$ coincides exactly with that of *trans*-[Cu(DL-Etgly)$_2$], the structure of which has been determined by X-ray analysis.[11] It may be concluded, therefore, that the bluish-violet [Cu gly_2]$\cdot H_2O$ is the trans form. This conclusion is also consistent with the studies of infrared spectra.[4,12]

Another difference between the spectrum of *cis*-[Cu gly_2]$\cdot H_2O$ and that of bluish-violet [Cu gly_2]$\cdot H_2O$ lies in their intensities. The maximum absorption of the former is more intense than that of the latter, although not quite definitely so, since the intensities of diffuse reflectance spectra

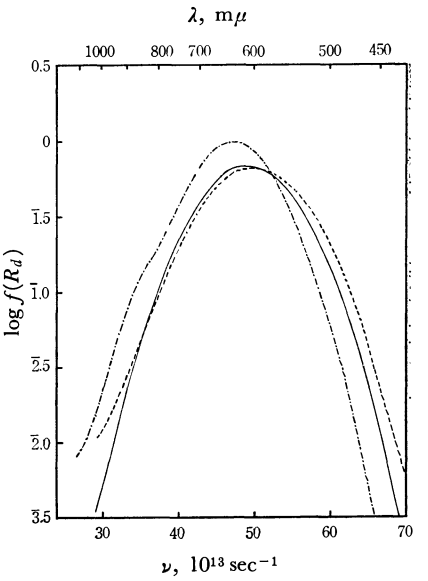

Fig. 1. The diffuse reflectance curves of *cis*-[Cu gly_2]$\cdot H_2O$ (-·-·-), bluish violet [Cu gly_2]$\cdot H_2O$ (——) and *trans*-[Cu(DL-Etgly)$_2$] (- - -).

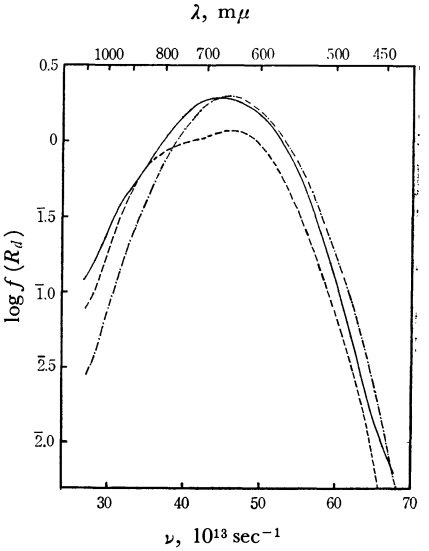

Fig. 2. The diffuse reflectance curves of [Cu(ph_2edda)]$\cdot H_2O$ (——), [Cu(ph_2edpa)]$\cdot H_2O$ (-·-·-), and $Cu(en)SO_4 \cdot 2H_2O$ (- - -).

depend on the particle size of the samples. According to Belford and Yeranos,[13] the intensities of the d→d absorption of copper(II) complexes are enhanced by the cis-structure or the strong interaction of the solvent to the fifth and/or sixth coordination positions.

In Fig. 3 the curves of [Cu(DL-ala)$_2$]$\cdot H_2O$ (needle) and of [Cu(DL-ala)$_2$] (scaly) almost coincide with that of the *trans*-[Cu(L-ala)$_2$], in which the

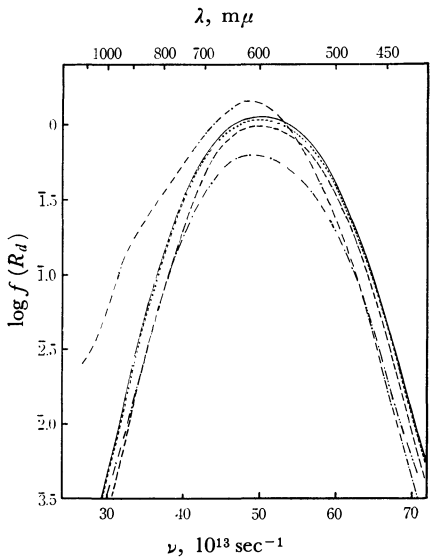

Fig. 3. The diffuse reflectance curves of [Cu(DL-ala)$_2$]·H_2O (——), [Cu(DL-ala)$_2$] (·····), [Cu(L-ala)$_2$] (- - -), [Cu(L-val)$_2$]·H_2O (-·-·) and [Cu-(DL-val)$_2$] (-·-·-·).

ligand L-alanine is coordinated to copper(II) in a trans planar configuration.[14] Therefore, it may be suggested that both the DL-alanine complexes take the trans structure, although their crystal forms and colors are different. In the valine complexes an interesting fact has been found; the spectrum of [Cu(L-val)$_2$]·H_2O corresponds to that of *cis*-[Cu gly$_2$]·H_2O, and the spectrum of [Cu-(DL-val)$_2$], to that of bluish-violet [Cu gly$_2$]·H_2O or *trans*-[Cu(DL-Etgly)$_2$] (Fig. 3). Moreover the band of [Cu(L-val)$_2$]·H_2O is more intense than that of [Cu(DL-val)$_2$]. From these facts, it may be concluded that the complex with L-valine is the cis form, and that with DL-valine is the trans form. Because of their different geometrical structures, it is possible that the interaction between the terminal isopropyl groups of the coordinated valines is smaller in the trans than in the cis complex of DL-valine, but it is smaller in the cis than in the trans complex of L-valine.

Similarly, it may be concluded from Fig. 4 that the complexes of isoleucine have the cis configuration, and that those of threonine have the trans configuration. The band of [Cu(DL-isoleu)$_2$]·H_2O has a higher intensity than that of [Cu(L-isoleu)$_2$]·H_2O; this may be interpreted as partly due to the aquo-ligand coordinated strongly to the copper atom and partly due to the cis structure.[13] The conclusion that [Cu(DL-isoleu)$_2$]·H_2O is the cis form also agrees with the conclusion which has been suggested from the infrared spectra.[5] The spectral behaviors of [Cu(DL-thr)$_2$] and [Cu(L-thr)$_2$]·

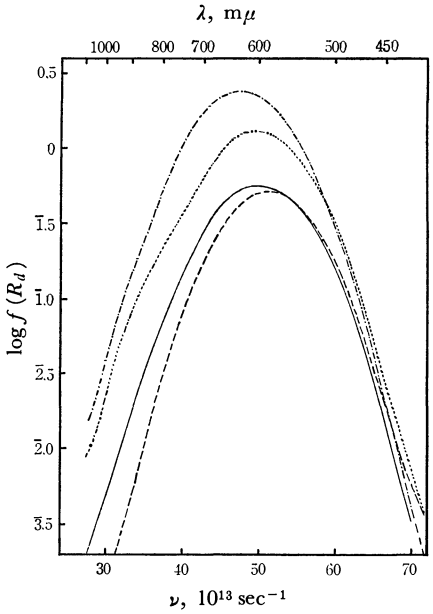

Fig. 4. The diffuse reflectance curves of [Cu(DL-(thr)$_2$] (——), [Cu(L-thr)$_2$]·H_2O (- - -), [Cu-(DL-isoleu)$_2$]·H_2O (-·-·) and [Cu(L-isoleu)$_2$]·H_2O (·····).

H_2O are almost identical with those of *trans*-[Cu(DL-Etgly)$_2$] and [Cu(DL-val)$_2$]; they show that they have the trans configuration.

The spectra of [Cu(Me$_2$gly)$_2$] and of the complex of isobutyric derivative, [Cu(ediba)]·3H_2O, show a different trend from those of the complexes with familiar amino acids mentioned above; that is, they show a shoulder on the shorter wavelength

side (Fig. 5). Graddon and Munday[15] suggested, from the shoulder of $[Cu(Me_2gly)_2]$ on the shorter wavelength side, that the complex molecule has a purely tetragonal planar structure. The lower intensity of the band of this complex may be due to its trans-structure.

The geometrical structures of the bis(amino-acidato)copper(II) complexes which have been determined from the data of diffuse reflectance spectra are summarized in Table II.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 608—610 (1966)

The Dipole Moments of the Oligether of Ethylene Glycol

By Ko KIMURA and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 31, 1965)

The dipole moments of ethylene glycol dimethyl ether ($N=1$), diethylene glycol dimethyl ether ($N=2$), triethylene glycol dimethyl ether ($N=3$), and tetraethylene glycol dimethyl ether ($N=4$), were measured in *n*-hexane or benzene at 25°C and 45°C. The observed dipole moments of $N=1$, $N=2$, $N=3$, and $N=4$ are 1.59 D, 1.92 D, 2.16 D, and 2.44 D, respectively, in *n*-hexane at 25°C, 1.71 D, 1.97 D, 2.22 D, and 2.45 D, respectively, in benzene at 25°C, and 1.72 D, 1.98 D, 2.27 D, and 2.50 D, respectively, in benzene at 45°C. The dipole moments were theoretically calculated on the assumptions that: (i) the dipole moments of these chain molecules are given by the vector sum of the polar groups of ether whose group moment is 1.20 D, and (ii) all the internal rotations of a chain molecule are free. The calculated values of $N=1$, $N=2$, $N=3$, and $N=4$ are 1.67 D, 2.03 D, 2.33 D, and 2.60 D, respectively. The agreement between the observed and the calculated values is satisfactory. The solvent effect and the temperature dependence of the observed dipole moments have also been discussed in terms of chain flexibility.

The study of the electric dipole moments of the oligomer of ethylene glycol in solutions from the point of view of thermodynamic behavior is important as well as from that of the molecular structure. The molecular structure of the oligomer of ethylene glycol in dioxane had been discussed,[1] but there is some difficulty in analyzing the experimental results because of the intra- and intermolecular hydrogen-bonding between hydroxyl groups of the solutes and the solvent. The hydrogen-bonding of the end groups may determine the configuration of chain molecules when their chain lengths are as short as those in oligomers. This paper, therefore, will present a study of the dipole moments of the dimethyl ether of monomer (ethylene glycol), dimer, trimer, or tetramer in solvents such as benzene and *n*-hexane, and will describe their correlation with their molecular configurations.

Experimental

Dimethyl ethers of the oligomer (products of the Tokyo Kasei Chemicals Co., Ltd.) were dried over calcium chloride and distilled under nitrogen several times. Benzene was purified by shaking it with concentrated

sulfuric acid and by fractional distillation through a 100 cm. column packed with stainless-steel helices. Hexane was purified by letting it stand with fuming sulfuric acid for a few months and by fractional distillation.

The measurements of the dielectric constants, ε, and the specific volumes, v, were carried out with an apparatus devised by Le Fevre and his collaborators.[2]

Results

The observed values of ε and v are expressed by linear equations of the solute concentrations, w (the weight fraction of solutes); they are summarized in Table I. Measurements were carried out at 25°C and 45°C. The calculation of the molecular polarizations, P, from these experimental data was performed according to the standard method.[3] Molecular refractions, R_D, for the sodium D line were calculated on the assumption of the additivity of bond refractions, and the distortion polarizations were assumed to be equal to $1.1\times R_D$.[1] The observed dipole moments, μ, are tabulated in Table II, together with the polarization values.

Table II. Observed dipole moments

Discussion

The dipole moment of a chain molecule consisting of n polar units is equal to:

$$\vec{\mu} = \sum_{i=1}^{n} \vec{\mu}_i \qquad (1)$$

where $\vec{\mu}_i$ is the dipole moment of each unit. In the present case, it is a group moment of ether, which is directed along the bisectrix of the C–O–C valence angle with the positive center at the side of carbon atoms. Its value, μ_0, is assumed to be 1.20 D. As a monomer consists of two units, n is equal to $N+1$. The scalar product of $\vec{\mu}$ gives:

$$\overline{\mu^2} = \sum_{i=1}^{n} \mu_i^2 + 2\sum_{i=1,\ i<j}^{n} \overline{(\vec{\mu}_i \cdot \vec{\mu}_j)} \qquad (2)$$

where $\overline{\mu^2}$ is the average μ^2 value over the angles of all internal rotations. The second term on the right hand side of (2) can be easily calculated if all the internal rotations are free.[4] The calculated results of (2) are as follows:

$$\overline{\mu^2} = (2-2\lambda^2\eta^2)\mu_0^2 \qquad \text{for } N=1$$

$$\overline{\mu^2}/2 = (3/2-2\lambda^2\eta^2-\lambda^5\eta^2)\mu_0^2 \qquad \text{for } N=2$$

(1.32Å)	(3.06)	(3.36)	(3.06)	4.67	3.97	(1.83)	3.97	(3.20)

$$\overline{\mu^2}/3 = (4/3-2\lambda^2\eta^2-4/3\cdot\lambda^5\eta^2-2/3\cdot\lambda^8\eta^2)\mu_0^2 \quad \text{for } N=3$$

$$\overline{\mu^2}/4 = (5/4-2\lambda^2\eta^2-3/2\cdot\lambda^5\eta^2-\lambda^8\eta^2 -1/2\cdot\lambda^{11}\eta^2)\mu_0^2 \quad \text{for } N=4$$

$$\overline{\mu^2}/N = [1+1/N-2\lambda^2\eta^2\{1/(1-\lambda^3) -\lambda^3(1-\lambda^{3N})/N(1-\lambda^3)^2\}]\mu_0^2 \quad \text{for } N$$

$$= \{(1-2\lambda^2\eta^2/(1-\lambda^3))\}\mu_0^2 = 12/13\cdot\mu_0^2 \quad \text{for } N\to\infty$$

where λ and η are $\cos\omega$ and $\sin\omega/2$, respectively. For the sake of simplicity, the valence angle $(\pi\text{-}\omega)$ is assumed to be tetrahedral about the oxygen atoms as well as about the carbon atoms of ether. The calculated dipole moments are tabulated in Table III, together with the observed moments. From a comparison of the calculated dipole moments with the observed ones, we can see that the former agrees satisfactorily with the latter. It may, therefore, be suggested that the oligether of ethylene glycol in non-polar solvents is in a random coil state. For $N=1$, the solvent effect makes a considerable contribution to the dipole moment compared with the temperature effect, but for $N=4$, two effects are reversed, as is shown in Table III. This result may be expected if the steric effect of the rotational isomers is taken into consideration. The distances between two methyl groups for $N=1$ are estimated for nine configurations in Table IV, when the *gauche* configuration is kept about the central bond. Only three rotational isomers among the nine are possible as a result of the overlapping of two methyl groups. This means that chain flexibility is not expected for $N=1$. Therefore, no temperature dependence of its dipole moments was observed. On the contrary, the observed dipole moments at 25°C are constant for $N=4$ within the range of experimental errors, irrespective of the solvents used, but their temperature dependence was observed. The observed moments at 45°C approach the calculated moments more closely than those at 25°C. It may, therefore, be expected that the temperature effect rather than the solvent effect will become important as a result of the increase in chain flexibility when the chain length is lengthened.

Raman spectra at low frequencies (250 cm^{-1} to 600 cm^{-1}) corresponding to the skeletal deformation show the feature already described, although measurements of Raman spectra[5] were carried out for pure liquids. Only four sharp lines are observed for $N=1$. However, as N increases, broader bands are observed at these frequencies.

Summary

The dipole moments of the oligether of ethylene glycol have been measured in *n*-hexane and benzene at 25°C and 45°C. The observed values have been compared with the calculated values derived on the assumption that all internal rotations are free. The agreement between them is satisfactory. The solvent effect and the temperature dependence of the observed dipole moments have also been discussed.

The Formation of Phenolic Ethers by the Acid-catalyzed Condensation of Phenols and Alcohols[1,2]

By Shigeru Oae

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

and Reiko Kiritani

Department of Chemistry, Radiation Center of Osaka Prefecture, Sakai, Osaka

(Received August 2, 1965)

The reaction of phenol with ethyl alcohol in strong acidic media at a somewhat high temperature gave phenyl ethyl ether in a 61% yield. The product isolated from a similar reaction between phenol and *n*-propyl alcohol was practically pure phenyl *n*-propyl ether, and no isopropyl isomer was detected. When ^{18}O-labeled phenol was treated with unlabeled ethyl alcohol, the phenetole isolated was found not to contain any excess ^{18}O. The reaction of phenol with ethyl alcohol in the presence of hydrogen chloride gave no isolable amount of phenetole. The mechanism for these reactions was then discussed.

Previously, we have reported that phenols undergo a facile oxygen-isotopic exchange with solvent water in strong acidic media at a high temperature.[3] It was suggested that, in a strong acidic media, phenol readily accepts a proton at either the ortho- or para-position to form a quasi-stable quinoid-type intermediate, whereby a nucleophilic attack of water at carbon-1 leads to the exchange of the oxygen, as is shown below.[3,4]

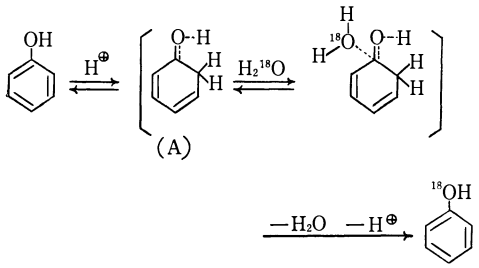

Fig. 1.

As an extension of this remarkable ^{18}O exchange reaction, it was expected that the phenolic hydroxy group would be replaced by more nucleophilic reagents, such as alcohols and mercaptans. Indeed, such reactions have been found to take place, and the details of the acid-catalyzed condensation of phenols with mercaptans have been reported in a previous paper of this series[5]. This paper will describe a more detailed investigation into the nature of the acid-catalyzed condensation of phenols and alcohols.

Results and Discussion

The acid-catalyzed formation of aryl ethers from aromatic phenols and alcohols[6] is not an entirely new reaction. Wiberg and Saegebarth[7] have reported recently that β-naphthyl methyl ether was obtained in a 70% yield when β-naphthol was heated at 100°C with methanol for 40 hr. in the presence of anhydrous *p*-toluenesulfonic acid in a sealed tube. It was suggested, on the basis of the ^{18}O tracer experiments using ^{18}O-labeled methanol, that this reaction proceeds in the following manner, similar to what was suggested by us for the oxygen-exchange reaction of phenols:

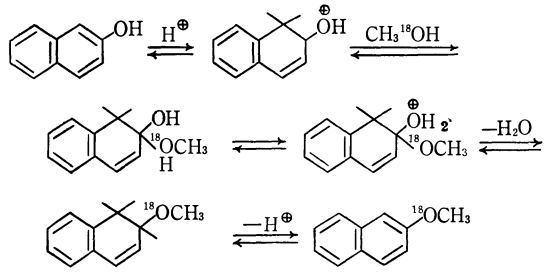

Fig. 2.

Resorcinol, which is known to have a carbonyl character, was also found to undergo a condensation reaction with methanol. However, phenol, catechol and hydroquinone were found not to undergo any condensation under the same reaction conditions.

Under the somewhat more drastic conditions under

which the ^{18}O exchange takes place, phenol undergoes a condensation with alcohol, as is shown in Table I.

a) no H_2O; *p*-toluenesulfonic acid catalyst
b) no H_2O; no catalyst
c) no H_2O; hydrogen chloride catalyst

Although the reaction is considered to proceed through the following pathway, similar to that proposed by Wiberg for the formation of β-naphthyl methyl ether:

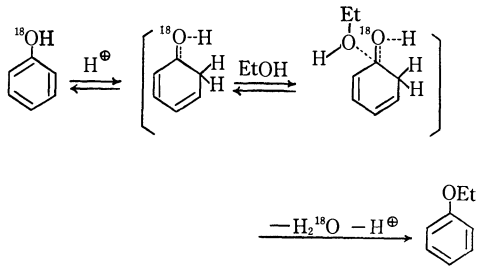

Fig. 3.

other possibilities have also to be scrutinized, because, after all, the conditions used here are so drastic that the formation of alkyl chloride or of the alkyl carbonium ion intermediate is quite conceivable during this reaction.

However, the mechanism involving the incipient formation of the alkyl carbonium ion or of alkyl chloride was excluded on the basis of the following observations:

a) When ^{18}O-labeled phenol (1.3 atom.% ^{18}O) was treated with unlabeled ethyl alcohol in an ^{18}O-enriched water (1.3 atom.% ^{18}O) solution of 12 N hydrochloric acid, the phenetole obtained was found to possess a natural abundance of oxygen (0.20 atom.% ^{18}O).

b) The product isolated in a 55.1% yield from the similar reaction between phenol and *n*-propyl alcohol was practically pure phenyl *n*-propyl ether; no isopropyl isomer was detected in the product within the range of experimental error. The carbonium ion formed from *n*-propyl alcohol must be the isopropyl cation. Hence, the reaction involving the alkyl carbonium ion should definitely give phenyl isopropyl ether as the product.

c) The reaction was found to proceed quite well with a small amount of anhydrous toluenesulfonic acid as the acid catalyst under anhydrous conditions. However, when water was excluded in the hydrochloric acid-catalyzed reaction between phenol and ethanol, no isolable amount of phenetole was obtained. The evolution of gas, presumably ethyl chloride, was noticed when the sealed tubes were opened. Probably, under anhydrous conditions, hydrochloric acid was consumed in the formation of ethyl chloride in the following equilibrium:

$$EtOH + HCl \rightleftharpoons EtCl + H_2O$$

On the other hand, the equilibrium of the reaction between ethanol and toluenesulfonic acid is undoubtedly shifted toward the left-hand side.

$$EtOH + TsOH \rightleftharpoons EtOTs + H_2O$$

It is also difficult to accept the direct aromatic nucleophilic substitution, shown below, in view of the results of previous work on the oxygen exchange reaction[8)] as well as in view of the sulfide-

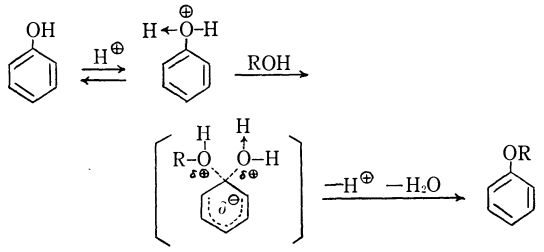

Fig. 4.

forming reaction.[5)] According to this reaction scheme, the substitution of an electron-withdrawing group at the *o*- or *p*-position will accelerate the reaction; however, the nitro group at the para position was found to retard the reaction substantially.

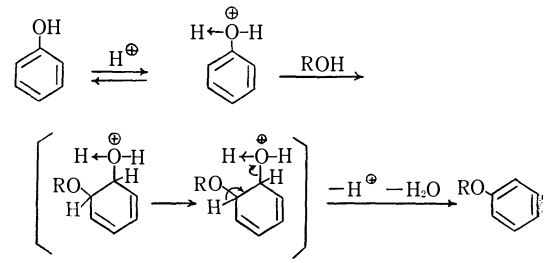

Fig. 5.

8) S. Oae and R. Kiritani, This Bulletin, to be submitted.

The other possible pathway (shown below), involving the nucleophilic attack of alcohol at the ortho or para-position of phenol and the subsequent elimination of water, can also be excluded.

There was no formation of any detectable amount of the rearranged ether from the reaction with *p*-cresol and β-naphthol.

Therefore, the only plausible pathway that can explain all these observations is the one involving the nucleophilic attack of alcohol on the incipient carbonium ion (A) formed during the reaction.

Recently, Gold and Satchell[9] have also postulated a similar ortho- or para-protonated σ-complex formation in a strong acid solution of phenolic compounds, while Kresge et al.[10] have obtained rather conclusive evidence for the protonated σ-complex through proton NMR spectroscopic measurements and through a study of the ultraviolet spectra in the case of phloroglucinol.

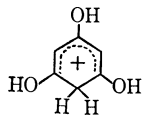

Fig. 6.

On the other hand, the formation of the σ-complex intermediate has never been successfully observed in the case of monohydroxylic phenol. However, in view of the very facile hydrogen isotopic exchange in strong acid solutions of phenol, the steady concentration of the incipient carbonium ion (A) or of the σ-complex will probably increase substantially, or the nucleophilic attack of alcohol on the carbonium ion (A) will take place more readily, or more probably the combination of the two reactions will become more facile, when the reaction temperature is elevated.

In order to shed further light on the nature of this and related reactions, condensation reactions with other nucleophilic reagents are now underway in these laboratories.

Experimental

β-Naphthyl Ethyl Ether.—β-Naphthol (1 g.) was added to 5 ml. of 10 N hydrochloric acid containing ^{18}O-enriched water (0.74 atom.% ^{18}O). The mixture was then heated in a sealed tube at 180°C for 24 hr. The recovered β-naphthol was subjected to ^{18}O analysis (0.53 atom.% ^{18}O). A mixture of 4.8 g. (0.033 mol.) of the labeled β-naphthol and 1 ml. of 12 N hydrochloric acid in 1.6 g. (0.033 mol.) of ethyl alcohol was sealed in a tube and heated at 180°C for 48 hr. Then the sealed tube was broken and, after the excess alcohol had been removed in vacuo, the whole content was extracted with ether. The ether layer was sufficiently washed with aqueous sodium carbonate and water to remove unreacted β-naphthol, and then dried over calcium chloride. When the ether extract was distilled under reduced pressure, 3 g. of a fragrant white precipitate was obtained (yield 52.3%). The product, β-naphthyl ethyl ether, was identified by means of its infrared spectrum and subjected to ^{18}O analysis (0.20 atom.% ^{18}O). M. p. 37—38°C; b. p. 124°C/5 mmHg; n_D^{20} 1.5932. Found: C, 83.78; H, 7.11%.

Phenetole.—A mixture of 2 g. (0.021 mol.) of phenol and 1 ml. of 12 N hydrochloric acid in 5 g. (0.109 mol.) of ethyl alcohol was sealed in a tube and kept at 180°C for 48 hr. After it had cooled the sealed tube was treated as has been described above. The distillate gave 1.5 g. of phenetole (yield 58.4%). The infrared spectrum was identical with that of an authentic sample. In a separate experiment, a mixture of 2 g. (0.021 mol.) of phenol and 0.2 g. (0.0012 mol.) of *p*-toluenesulfonic acid in 5 g. (0.109 mol.) of absolute ethyl alcohol was sealed in a tube and heated at 180°C for 48 hr. The sealed tube was then treated as has been described above. The ether layer was washed with aqueous sodium carbonate to remove unreacted phenol and *p*-toluenesulfonic acid, and then distilled under reduced pressure; thereby 1.6 g. of phenetole was obtained (yield 61%). B. p. 171—173°C; n_D^{20} 1.5129. Found: C, 78.68; H, 8.20%.

When the other sealed tube, which contained the same reactants, was kept at 110°C for 48 hr., no detectable amount of the product was obtained, while all of the reactants were recovered.

A solution of phenol 2 g. (0.021 mol.) in 5 g. (0.109 mol.) of ethyl alcohol in the absence of an acid catalyst was sealed in a tube. An alcohol solution of 1.3 N acid was then prepared by absorbing hydrogen chloride dried over sulfuric acid into absolute ethyl alcohol. A solution of phenol 2 g. (0.021 mol.) in 6 g. of the acidic ethyl alcohol was sealed in another tube. Both sealed tubes were heated at 180°C for 48 hr. and treated as described above; however, no phenetole was obtained.

^{18}O labeled phenol was prepared by the acid-catalyzed oxygen exchange reaction.[6] Using the ^{18}O enriched phenol (1.3 atom.% ^{18}O) thus prepared and unlabeled ethyl alcohol, the condensation reactions were carried out in the presence of an unlabeled or ^{18}O enriched (1.3 atom.% ^{18}O) water solution of hydrochloric acid in sealed tubes at 180°C for 48 hr. The products obtained in both reactions were unlabeled phenetole.

***n*-Propyl Phenyl Ether.**—A mixture of 2 g. (0.021 mol.) of phenol and 1 ml. of 12 N hydrochloric acid in 6 g. (0.1 mol.) of *n*-propyl alcohol was sealed in a tube. After the solution had been heated at 180°C for 48 hr., the sealed tube was broken and treated as has been described above. *n*-Propyl phenyl ether (0.75 g.) was obtained (yield 55.1%). The infrared spectrum was found to be identical within the range of experimental error with that of the authentic sample. B. p. 188—189°C, n_D^{20} 1.5056. Found: C, 79.41; H, 8.89%. Meanwhile, the authentic sample of *n*-propyl phenyl ether was prepared by reacting sodium phenolate with *n*-propyl bromide in a 95.6% yield.

***p*-Tolyl Ethyl Ether.**—A mixture of 2.2 g. (0.02 mol.) of *p*-cresol and 1 ml. of 12 N hydrochloric acid in 5 g. (0.109 mol.) of ethyl alcohol was sealed in a tube.

10) A. J. Kresge, G. W. Barry, K. R. Charles and Y. Chiarry, *J. Am. Chem. Soc.*, **80**, 4343 (1962).

After the mixture had been heated at 180°C for 52 hr. the sealed tube was broken and treated as has been described above. *p*-Tolyl ethyl ether (0.9 g.) was obtained (yield 33.3%). The infrared spectrum was identical with that of an authentic sample. B. p. 188—189°C, n_D^{20} 1.5038. Found: C, 79.39; H, 8.86%. Meanwhile, an authentic sample of *p*-tolyl ethyl ether was prepared in a 100% yield by reacting sodium *p*-methyl phenolate with ethyl bromide.

***p*-Nitrophenyl Ethyl Ether.**—A mixture of 1.4 g. (0.01 mol.) of *p*-nitrophenol and 1 ml. of 12 N hydrochloric acid in 2.3 g. (0.05 mol.) of ethyl alcohol was sealed in a tube. After the tube had been heated at 180°C for 48 hr., it was broken and treated as above. Only a small amount of yellow crystals of *p*-nitrophenyl ehtyl ether was obtained; this was recrystalized from ethanol. M. p. 60°C. Found: C, 57.48; H, 5.41%. Most of the reactants were decomposed. Meanwhile, an authentic sample of *p*-nitrophenyl ethyl ether was prepared in a 24% yield by reacting sodium *p*-nitro phenolate with ethyl bromide. M. p. 59—60°C.

Analysis for Oxygen-18.—The experimental procedure and method of calculation were similar to those described in the previous paper.[11]

The Reaction of Diphenyl Sulfoxide with Bromine in Aqueous Acetic Acid[1],*

By Waichiro TAGAKI,† Kunihiko KIKUKAWA,†† Norio KUNIEDA† and Shigeru OAE†

† *Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka*

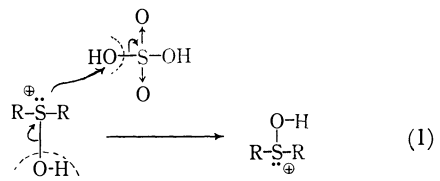
†† *Department of Applied Chemistry, Osaka Institute of Technology, Asahi-ku, Osaka*

(Received August 5, 1965)

When diphenyl sulfoxide was allowed to react with bromine in a mixture of acetic acid and ^{18}O-enriched water, the sulfoxide was recovered, together with a small amount of diphenyl sulfone. The sulfoxide recovered incorporated a very small amount of ^{18}O from the water. Meanwhile, diphenyl sulfoxide was found to undergo a facile oxygen exchange reaction with water in the presence of hydrobromic acid. Possible mechanisms for these reactions have been discussed.

Previously, we found that oxygen exchange takes place when sulfoxide is dissolved in ^{18}O-enriched concentrated sulfuric acid.[2] The mechanism suggested, on the basis of the several observations, was the nucleophilic attack of the sulfur atom of sulfoxide on sulfuric acid (Eq. 1). A similar oxygen exchange reaction is conceivable between sulfoxides and other acids, such as hypobromous acid. Hypobromous acid is known to be an equilibrium species in a bromine-water solution. Therefore, it seems that it would be interesting to examine the possibility of the oxygen exchange reaction of sulfoxide in a bromine-water mixture, although the reaction in this mixture may be expected to be somewhat complex, as will be explained later.

This paper will describe a preliminary investigation of the reactions of diphenyl sulfoxide in a bromine - water - acetic acid solution; the products were analyzed, and the oxygen exchange reaction was studied.



(1)

Reaction Products.—Diphenyl sulfoxide was found to be recovered almost quantitatively when the reaction mixture was quenched with water after the solution of diphenyl sulfoxide had been kept for 24 hr. in bromine - water - acetic acid at around room temperature (Table I). It is interesting to note, however, that a small amount of diphenyl sulfone (1—0.5%) was always isolated. Since the starting sulfoxide was prepared by the oxidation of diphenyl sulfide with hydrogen peroxide, the inclusion of a trace of sulfone in the starting sulfoxide is conceivable; in fact, the presence of a trace of sulfone was always shown by the characteristic infrared spectra near 1150 cm^{-1}, even in a pure diphenyl sulfoxide which had been obtained after repeated recrystallizations and which had the constant m. p. of 70°C. However, such a trace of the sulfone could be completely removed by purification through alumina-column

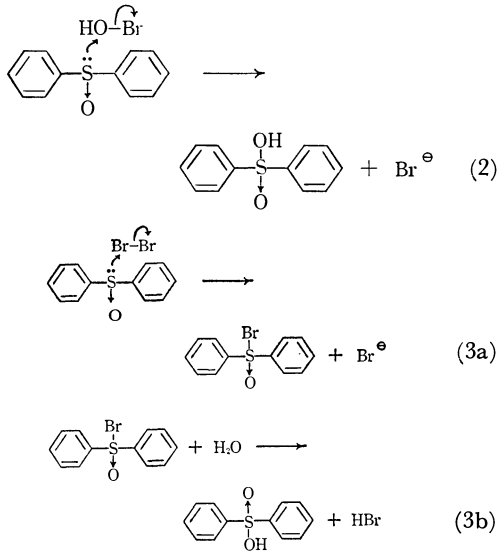
60	98—99	1—0.5	trace	—
100	—	—	—	90

chromatography using a mixture of *n*-hexane and benzene as the solvent. When the sulfoxide thus purified was used, a small amount of the sulfone was found in the quenched product described above. Therefore, the oxidation of the sulfoxide to the sulfone undoubtedly took place in this bromine - water - acetic acid solution. The yield of diphenyl sulfone increased up to 5% when the reaction mixture was quenched with aqueous sodium carbonate.

Two pathways are conceivable for the oxidation of the sulfoxide to the sulfone. One is the direct oxidation of sulfoxide by hypobromous acid (Eq. 2); the other involves the incipient formation of the bromosulfonium intermediate, which is subsequently hydrolyzed by water to give the sulfone (Eqs. 3a and 3b).



At a higher temperature, the bromination of the benzene ring and the reduction of S–O bond were observed (Table I). Thus practically all the diphenyl sulfoxide was quantitatively converted to bis-(*p*-bromophenyl) sulfide (IV) by the action of a one-mole equivalent of bromine at around 100°C.

The Oxygen Exchange Reaction of Diphenyl Sulfoxide.—The oxygen exchange reactions were carried out at 25°C for two different systems. In one system diphenyl sulfoxide with a natural oxygen- and ^{18}O-enriched water were used, while in the other the ^{18}O-labeled sulfoxide and the natural water were applied. The solvent was the same as that shown in Table I. The ^{18}O-enriched sulfoxide was prepared by the oxidation of diphenyl sulfide with *N*-bromosuccinimide in ^{18}O-enriched water,[3] since the sulfoxide thus prepared is known to be completely free from the sulfone. The results of oxygen exchange are shown in Table II.

It is interesting to note that there was a definite incorporation of ^{18}O in the recovered sulfoxide, though the amount of incorporation was very small, as can be seen from the runs 1—5 in Table II. The small decrease in ^{18}O content (except in the run 4) observed when the "crude sulfoxide" was purified to "pure sulfoxide" by alumina column chromatography, is due to the removal of the sulfone. Since at least one of the two oxygen atoms of the sulfone originates in the ^{18}O-enriched water, the ^{18}O content of the sulfone should be higher than that of the sulfoxide when the extent of the exchange reaction is low. The same conclusion can be derived more definitely by the use of the ^{18}O-labeled sulfoxide (run 6). Here, contrary to the cases in the runs 1—5, the removal of the sulfone increased the ^{18}O content of the pure sulfoxide.

The mechanism of the oxygen exchange reaction by bromine water is not clear. Although the oxygen exchange could take place between the sulfoxide and hypobromous acid much as with sulfuric acid (cf. Eq. 1), there is no definite evidence to substantiate the mechanism, nor is there any concrete evidence to exclude other possibilities. However, if one assumes that hypobromous acid causes the oxygen exchange, the accompanying oxidation of the sulfoxide to the sulfone can be nicely fit in the same reaction scheme. Another likely possibility is that the exchange reaction is due to hydrobromic acid, since hydrobromic acid is formed during the formation of diphenyl sulfone, as is illustrated in Eqs. 2 and 3. Although hydrogen chloride was recently found to be an effective catalysis for the concurrent oxygen exchange and racemization reaction of sulfoxides,

b) The recovered sulfoxide containing a trace of sulfone.
c) The sulfoxide completely free from the sulfone.

hydrobromic acid was found to cause the decomposition of sulfoxide.[4] However, we have found that, in a low concentration in aqueous acetic acid, hydrobromic acid can cause the oxygen exchange of diphenyl sulfoxide with a quantitative recovering of the sulfoxide, as is shown in Table III. In this alternative mechanism, the sulfone formation is an independent process, probably caused by the oxidation with hypobromous acid.

TABLE III. OXYGEN EXCHANGE REACTIONS OF DIPHENYL SULFOXIDE IN AN AQUEOUS HYDROBROMIC ACID - ACETIC ACID MIXTURE

Experimental

Diphenyl Sulfoxide. — This was prepared by the oxidation of diphenyl sulfide with hydrogen peroxide in acetic acid.[5] The product was recrystallized from *n*-hexane - benzene to give the sulfoxide with a constant m. p. of 70—71°C. This sulfoxide, however, was shown by the infrared spectral band near 1150 cm^{-1} to include a trace of the sulfone. Therefore, this apparently pure sulfoxide was further purified by alumina column chromatography using *n*-hexane - benzene (1 : 9 v/v) as the developing solvent. Diphenyl sulfone was eluted first; then, after the elution of a few fractions of the mixture of the sulfone and the sulfoxide, the fractions of pure sulfoxide were eluted. Usually one or two chromatographic purifications were enough to obtain the spectroscopically-pure sulfoxide.

The Reaction of Diphenyl Sulfoxide with Bromine Aqueous Acetic Acid.—Diphenyl sulfoxide (1.4 g.) (0.0069 mol.) was dissolved in 15 ml. of glacial acetic acid; to this there were added 1.0 ml. of water and an equimolar amount of bromine (1.1 g.). The reaction mixture was then left at 25°C for 24 hr. in a constant temperature bath. The initial orange color of the reaction mixture did not disappear within 24 hr. The reaction mixture was then dissolved in benzene (15—20 ml.), washed with water containing sulfur dioxide to remove free bromine, washed with a dilute sodium carbonate solution, and dried. The benzene was removed to give a colorless product (1.27 g.). The product was analyzed by the alumina column chromatography described above. In the case of the reaction at 100°C, over 90% of the product was bis-(*p*-bromophenyl) sulfide, m. p. 111—112°C (lit., 109—111°C)[6]; it was difficult to detect other products. At 60°C, a minute but definite formation of bis-(*p*-bromophenyl) sulfoxide was observed in the last fractions of the elution chromatography; this showed the melting point of 150—151°C (lit., 151°C)[7] here, and the same melting point when mixed with an authentic sample. All these results are sohown in Table I.

The Preparation of ^{18}O-Labeled Diphenyl Sulfoxide.—The method of labeling was based on our previous communication,[3] where the experimental details were not, however, described.

Diphenyl sulfoxide (5 g.) (0.027 mol.) was suspended in a solution of 5 ml. of methanol and 1 g. of ^{18}O-enriched water. Into this there was vigorously stirred, portion by portion, 5 g. (0.028 mol.) of *N*-bromosuccinimide over a 10 min. period. The reaction was very rapid and over within 10 min. When *N*-bromosuccinimide was added, a red color appeared and then faded very rapidly. The reaction mixture was stirred for an additional 20 min. and then taken up in ether. The ether solution was washed with water, dilute aqueous sodium carbonate, and water, and then dried. The ether was removed, and the residue was recrystallized from *n*-hexane - benzene to give ^{18}O-labeled diphenyl sulfoxide, 3 g.; m. p. 70—71°C; atom% of ^{18}O: 0.85 (Table II), and 0.98 (Table III). Further purification by alumina column chromatography was found to be unnecessary.

The Oxygen Exchange Reaction of Diphenyl Sulfoxide.—*With Bromine in Aqueous Acetic Acid.*—The reaction conditions and the procedures for the isolation of the products were the same as have been described for the reactions in Table I. The crude sulfoxide

4) K. Mislow, T. Simmons, J. T. Melillo and L. Ternay, Jr., *J. Am. Chem. Soc.*, **86**, 1452 (1964).
5) S. Oae and S. Kawamura, This Bulletin, **36**, 163 (1963).
6) F. Kraft, *Ber.*, **7**, 1164 (1874).
7) G. Leandri, A. Mangini and R. Passerini, *J. Chem. Soc.*, **1957**, 1386.

was obtained by the recrystallization of the crude product from *n*-hexane - benzene. The pure sulfoxide was obtained by the purification of the crude sulfoxide by alumina column chromatography, as has been described above. In a separate experiment, it was confirmed that the chromatography did not change the ^{18}O content of the sulfoxide. Analyses of ^{18}O content were made by the same procedure as has been reported elsewhere. The results are shown in Table II.

With Hydrobromic Acid in Aqueous Acetic Acid.— Volumes of commercial hydrobromic acid (48%) were diluted with 3, 7 and 15 volumes of water respectively. Each 5 ml. of these hydrobromic acid solutions was dissolved in 10 ml. of glacial acetic acid, and to this diphenyl sulfoxide (0.001 mol.) was added. The reaction mixtures were then left at room temperature (22°C) for 24 hr., poured into benzene, and washed with water, dilute aqueous sodium carbonate and water; the benzene layer was then dried over anhydrous sodium sulfate. The benzene was then removed to give the recovered sulfoxide. The yield of the sulfoxide was over 95% in each case, and the purity of the sulfoxide after one recrystallization from *n*-hexane - benzene was enough for the ^{18}O-analyses. The results are shown in Table III.

Summary

The reactions of diphenyl sulfoxide in dilute solutions of bromine in acetic acid - water mixtures have been investigated. The formation of diphenyl sulfone, bis-(*p*-bromophenyl) sulfoxide or bis-(*p*-bromophenyl) sulfide has been observed, depending on the reaction temperatures. Minutely but definitely, the oxygen exchange has been observed for the recovered diphenyl sulfoxide from this bromine solution. The oxygen exchange of diphenyl sulfoxide has also been found to take place in a dilute solution of hydrobromic acid in an acetic acid - water mixture. The mechanisms of these oxygen exchange reactions have been discussed.

NOTES

The Asymmetric Synthesis of (−)-Menthol and (−)-Isomenthol by the Hydroboration of (±)-3-*p*-Menthene

By Jun KATSUHARA, Hajime WATANABE, Komei HASHIMOTO and Masahisa KOBAYASHI

Research Laboratory, Sun Star Dentifrice Co., Takatsuki, Osaka

(Received February 24, 1965)

Brown and Zweifel[1] recently reported that the hydroboration of olefins with diisopinocampheylborane resulted in a nearly complete asymmetric synthesis of the corresponding alcohols. On the basis of the steric course proposed,[2] it should be possible to perform an asymmetric synthesis of (−)-menthol and (−)-isomenthol by means of the hydroboration of (±)-3-*p*-menthene with (+)-monoisopinocampheylborane derived from (−)-(1S : 5S)-α-pinene.

We wish here to report such a synthesis.

Because of the feeble reactivity of the trisubstituted ethylene bond in 3-*p*-menthene toward dialkylborane, the monoisopinocampheylborane was preferred here as the asymmetric hydroboration reagent to the usual diisopinocampheylborane. 2.1 g. of (−)-α-pinene ($[\alpha]_D^{20}$ −34.7°; 68% optical purity), (0.015 mol.)), and 0.8 g. of sodium borohydride were dissolved in 15 ml. of dry diglyme at room temperature; to this solution there was then stirred, drop by drop, 3.0 g. of boron trifluoride etherate (47% BF_3 content) under a nitrogen stream over a 30-min. period. The disappearance of pinene was checked from time to time by g. l. c. (±)-3-Menthene (2.1 g.) (0.015 mol.) was added to the isopinocampheylborane, and, after the completion of the reaction (2 hr.), the reaction mixture was treated with 3 N sodium hydroxide and a 30% hydrogen peroxide solution. After 16 hr., this was worked up as usual. The separation of the product by g. l. c. yielded (−)-menthol, $[\alpha]_D^{20}$ −6.9° (chloroform), optical purity 14%, 0.57 g. (24.4% based on 3-menthene), (−)-isomenthol, $[\alpha]_D^{20}$ −13.4° (chloroform), optical purity 56%, 1.03 g. (44.0%) and (+)-isopinocampheol, $[\alpha]_D^{20}$ +22.1° (chloroform), 1.82 g. Both (−)-menthol and (−)-isomenthol were identified by a comparison of their n_D, IR,

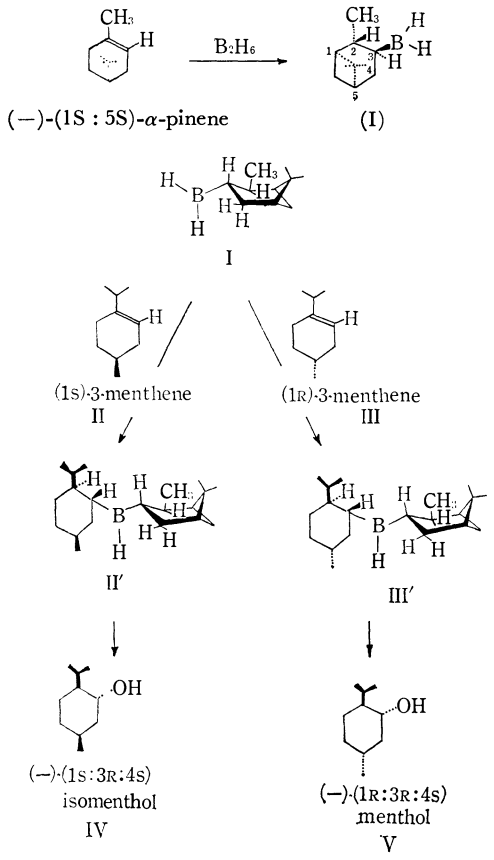
2) H. C. Brown, N. R. Ayyanger and G. Zweifel, ibid., **86**, 397 (1964).

and R^t values with those of authentic specimens.

Of the various conceivable anti-Markownikoff-*cis*-additions of the boron-hydrogen bond of (+)-monoisopinocampheylborane (I) to the double bond in both (1S)-3-menthene (II) and (1R)-3-menthene (III), the attack of I, with the less bulky C_4-methylene grouping of the isopinocampheyl moiety oriented in the front, as is illustrated, to the rear sides of both II and III should be sterically more favored than those occurring in the opposite direction. This accounts for the experimental results which show that (−)-(1S : 3R : 4S)-isomenthol and (−)-(1R : 3R : 4S)-menthol were obtained preponderantly over their respective dextrorotatory enantiomers, which would be expected from the attack of I on the front side of III and II. Moreover, an inspection of the Stuart model of III reveals considerable steric interference between the (1R)-methyl group of III and the C_4-methylene grouping of the (+)-isopinocampheyl moiety, while this is not the case with II', where the (1S)-methyl group is kept away from the C_4-methylene of I. The situation is just reversed in the less favored attack occurring on the rear side of I. This accounts for the higher optical yield of (−)-isomenthol (IV) and the lower optical purity of (−)-menthol (V).



In carrying out the conversion of (±)-3-*p*-menthene to racemic menthol by hydroboration with diborane, Ascoli[3] observed that the total yield of hydroxylic compounds was lower, the larger the ratio of menthol to isomenthol. This was ascribed to the higer oxidation-hydrolysis rate of menthylborane as compared with that of isomenthylborane. However, the (−)-menthol/(−)-isomenthol ratio (1 : 1.8) observed in our asymmetric synthesis, in which oxidation-hydrolysis was completely effected, may also be interpreted in terms of the rate of the formation of the intermediates, II' and III', from II and III respectively.

Studies of the asymmetric hydroboration of other monoterpeneolefins are currently in progress in our laboratories; they will be described elsewhere in detail.

We wish to thank Dr. Yuzo Inoue for his many helpful discussions and suggestions.

The Preparation of Several Triphenylsiloxysilanes

By Toshio TAKIGUCHI, Minoru ABE, Katsutoshi TAKAHASHI[1] and Kōji URANO

Department of Synthetic Chemistry, Kiryu College of Technology, Gunma University, Tenjin-cho, Kiryu

(Received April 30, 1965)

The reaction of an excess of sodium triphenylsilanolate with triorganochlorosilanes (trimethyl- and triphenylchlorosilane), diorganodichlorosilanes (dimethyl-, diphenyl-, methylphenyl- and vinylphenyldichlorosilane), organotrichlorosilanes (methyl-, phenyl- and vinyltrichlorosilane) and silicon tetrachloride gave the corresponding triphenylsiloxysilanes (hexaorganodisiloxanes, octaorganotrisiloxanes, organo-tris-triphenylsiloxysilanes and tetrakistriphenylsiloxysilane respectively).

The products obtained, including octaphenyltrisiloxane, 3 - vinylheptaphenyl - trisiloxane, 3-methylheptaphenyltrisiloxane, vinyl-tris-triphenylsiloxysilane and phenyl-tris-triphenylsiloxysilane, the new compounds were all crystalline substances of a high chemical stability; they were obtained in consistent yields of 63—67%. The siloxanes were all well defined and were characterized by means of their infrared absorption spectra.

Experimental

Sodium Triphenylsilanolate.—Sodium triphenylsilanolate neut. equiv. 294—297 was prepared according to the method of Hyde et al.[2]

Organolchlorosilanes.—Trimethylchlorosilane, b.p 58°C, dimethyldichlorosilane, b. p. 70—71°C, methyltrichlorosilane, b. p. 66—67°C phenyltrichlorosilane, b. p. 202—203°C, diphenyldichlorosilane, b. p. 130—133°C/2 mmHg and vinyltrichlorosilane, b. p. 90—92°C were obtained from the Shin-etsu Chemical Industrial Co. in commercial grades. All were further purified by distillation immediately before use. Triphenylchlorosilane, m. p. 97—98°C was isolated from a high boiling residue[3] of the direct synthesis of phenylchlorosilane. Vinylphenyldichlorosilane, b. p. 87—88°C/10 mmHg and methylphenyldichlorosilane, b. p. 197—199°C were synthesized by the Grignard process.[4] Reagent-grade silicon tetrachloride, b. p. 56—57°C was used after a single distillation.

Phenyl-tris-triphenylsiloxysilane.—A mixture of phenyltrichlorosilane (4 g., 0.0 2mol.), sodium triphenylsilanolate (30 g. 0.1 mol.) and a small portion of sodium ethylate in 300 ml. of toluene was heated to reflux. After this mixture had been refluxed for 15 hr., the jelly-like precipitate formed was centrifuged and the clear liquid was concentrated to about 50 ml., which in turn gave a white precipitate when added to a large excess of methanol. The precipitate was then recrystallized from 1, 4-dioxane to give 12 g. (67%) of elongated platelets, phenyl-tris-triphenylsiloxysilane, melting at 339—340°C (measured in molten *p*-diphenylbenzene as a medium), together with a small amount of hexaphenyldisiloxane.

Found: C, 76.7; H, 5.1; Si, 12.2; mol. wt., 895, 926 (in benzene). Calcd. for $C_{60}H_{50}O_3Si_4$: C, 77.4; H, 5.4; Si, 12.1%; mol. wt., 931.

Other Siloxanes.—The following siloxanes were obtained by substantially the same procedure: *Octaphenyltrisiloxane*, m. p. 153°C. Found: C, 77.7; H, 5.1; Si, 11.1; mol. wt., 720, 727. Calcd. for $C_{48}H_{40}O_2Si_3$: C, 78.8; H, 5.5; Si, 11.5%; mol. wt., 732.

3-Vinylheptaphenyltrisiloxane, m. p. 122—123°C.

Found: C, 77.0; H, 5.2; Si, 12.2; mol. wt., 659, 677. Calcd. for $C_{44}H_{38}O_2Si_3$: C, 77.4; H, 5.6; Si, 12.3%; mol. wt., 682.

3-Methylheptaphenyltrisiloxane, m. p. 119—120°C.

Found: C, 76.1; H, 5.4; Si, 12.5; mol. wt., 666, 663. Calcd. for $C_{43}H_{38}O_2Si_3$: C, 77.0; H, 5.7; Si, 12.5%; mol. wt., 670.

Vinyl-tris-triphenylsiloxysilane, m. p. 211—212°C.

Found: C, 75.8; H, 5.2; Si, 12.4; mol. wt., 894, 890. Calcd. for $C_{56}H_{48}O_3Si_4$: C, 76.4; H, 5.5; Si, 12.8%; mol. wt., 880.

Methyl-tris-triphenylsiloxysilane, m. p. 224°C (lit.[5] m. p. 224—225°C).

Found: Si, 13.2; mol. wt., 844—853. Calcd. for $C_{55}H_{48}O_3Si_4$: Si, 13.0%; mol. wt., 868.

3, 3-Dimethylhexaphenyltrisiloxane, m. p. 147—149°C (lit.[5] m. p. 155—156°C).

Found: Si, 13.6; mol. wt., 610—617. Calcd. for $C_{38}H_{36}O_2Si_3$: Si, 13.9%; mol. wt., 608.

Tetrakis-triphenylsiloxysilane, m. p. 231—232°C (lit.[6] m. p. 235°C).

Found: Si, 12.2; mol. wt., 1117, 1127. Calcd. for $C_{72}H_{60}O_4Si_5$; Si, 12.4%; mol. wt., 1130.

1, 1, 1-Trimethyltriphenyldisiloxane, m. p. 49°C (lit. m. p. 48°C[2], 51°C[7]).

Found: Si, 15.6; mol. wt., 339. Calcd. for $C_{21}H_{24}OSi_2$: Si, 16.1%; mol. wt., 348.

Hexaphenyldisiloxane, m. p. 230—231°C (lit.[7] m. p. 226°C).

Found: Si, 9.7; mol. wt., 522—528. Calcd. for $C_{36}H_{30}OSi_2$: Si, 10.5%; mol. wt., 535.

X-ray powder patterns recorded by using Cu$K\alpha$ radiation filtered by Ni are given for purposes of their rapid identification.

The authors are grateful to the Shin-etsu Chemical Industrial Co. for the supply of organochlorosilanes used in the present work.

Some Azo-compounds which form Spherical Micro-particles

By Hiroshi MIDORIKAWA, Heinosuke YASUDA, Hiroe ASABA and Tatsuo TAKESHIMA

The Institute of Physical and Chemical Research, Bunkyo-ku, Tokyo;
Department of Chemistry, Faculty of Science, Shizuoka University, Shizuoka

(Received May, 10 1965)

The present investigation will be concerned with 5-phenylazoresorcylaldehyde (I) and related compounds. I has been synthesized by Borsche.[1] He reported that the substance is prone to resinify when recrystallized, thereby preventing isolation. When he conducted the recrystallization from ethanol under a microscope, he first observed the separation of yellow needles, but they were soon covered with red-yellow resinous droplets. I was thus isolated only in the form of its phenylhydrazone.

We observed a peculiar property of the cyanoacetic ester derivative of I; it was obtained in the form of dark red spherical micro-particles and reflected the incident light fairly accurately in the opposite direction.

The present work was undertaken in order to explore the related behavior of the hydroxy derivatives of azobenzene.

I was prepared from resorcylaldehyde and, after being separated from the accompanying 3, 5 - bisphenylazoresorcylaldehyde (II), was recrystallized to yield long orange plates, m. p. 149.5—50°C. The compound, however, was apt to form spherical micro-particles in the case of recrystallization. The particles, once formed, exhibited a nature different from that of the original substance. It has no melting point and begins to carbonize, for example, above ca. 160°C and, unlike I, is hardly soluble in ethanol.

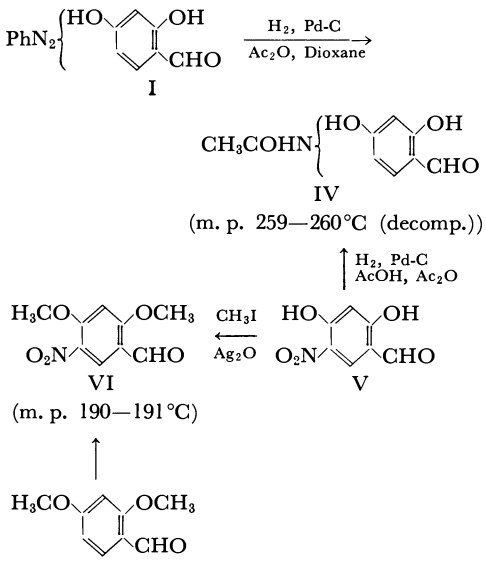
In the coupling reaction to prepare I, the 3- or 5-position of resorcylaldehyde is available for the entering phenylazo group. The assignment of the I structure is based on the following facts. I was submitted to hydrogenolysis in dioxane containing acetic anhydride. The resulting acetamidoresorcylaldehyde was identical with the acetamidoresorcylaldehyde (IV) obtained from 5-nitroresorcylaldehyde (V). However, since no rigorous determination[2] of the structure of V prepared by the nitration of resorcylaldehyde has been carried out, we methylated the nitro compound and then compared the resulting dimethoxynitrobenzaldehyde with that prepared by the nitration of 2, 4-dimethoxybenzaldehyde, which was considered to afford the 5-nitro derivative (VI) because of steric hindrance. These two specimens, prepared via alternate routes, were identical.

I, on treatment with ethyl cyanoacetate, also gave the characteristic dark red micro-particles, the composition of which varied to a certain extent;

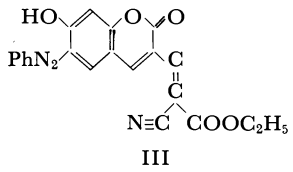
1) W. Borsche and L. E. Bolser, *Ber.*, **34**, 2098 (1901).

2) L. Gattermann, *Ann.*, **357**, 337 (1907)

for example, the substance was composed of a ratio of one mole of I to two moles of the ester.



The particles in this case seemed more stable than the preceding ones and began to carbonize above ca. 200°C without melting. When I was treated with the cyanoacetate a crystalline substance, brown needles, was obtained in addition to the particles. It seems from the analysis, the mode of reaction, and an analogy reported by Matsumura that this crystalline substance is of the III enamine structure.



3, 5-Bisphenylazoresorcylaldehyde (II), which is produced along with I in the coupling reaction, showed no tendency to form particles.

Experimental*

5-Phenylazoresorcylaldehyde (I).—Into a solution of 5 g. (0.036 mol.) of resorcylaldehyde, 3.1 g. (0.033 mol.) of aniline, and 30 ml. of concentrated hydrochloric acid in 1500 ml. of water was added portionwise 4 g. of sodium nitrite over period of ca. 10 min. at ca. 7°C with stirring. After the mixtrue had stirred for an additional 20 min., 30 g. of sodium acetate was added, and then a solution of 20 g. of potassium carbonate (anhydrous) in 100 ml. of water was added over a period of 30 min. at the same temperature. Stirring was continued for further 3 hr. and then kept overnight in an ice-box. The precipitates were collected, washed with water, and dried in a desiccator. The product, which weighed ca. 7 g., consisted of a mixture of I and 3, 5-bisphenylazoresorcylaldehyde (II). The crude product was then treated with ca. 250 ml. of hot ethanol or, bester, with the same volume of cold acetone, and filtered. From the filtrate, upon the addition of water, this was obtained ca. 3.8 g. of I, which, on repeated recrystallization from acetone containing water, formed orange long plates, m. p. 149.5—150°C (slow heating) and 156°C (rapid heating).

Found: C, 64.48; H, 4.08; N, 11.60. Calcd. for $C_{13}H_{10}O_3N_2$: C, 64.46; H, 4.16; N, 11.57%.

The 2, 4-Dinitrophenylhydrazone: brownish red plates, m. p. 275°C (decomp.).

Found: C, 57.51; H, 3.76; N, 19.58. Calcd. for $C_{24}H_{19}O_6N_7$: C, 57.48; H, 3.82; N, 19.55%.

The Semicarbazone: brown needles or long plates; m. p. above 300°C.

Found: N, 21.48. Calcd. for $C_{14}H_{13}O_2N_5+C_2H_5OH$: N, 21.27%.

3, 5-Bisphenylazoresorcylaldehyde (II). — From the acetone-insoluble fraction, red needles or long plates, m. p. 253°C (decomp.), were obtained.

Found: C, 65.81; H, 4.10; N, 16.28. Calcd. for $C_{19}H_{14}O_3N_4$: C, 65.89; H, 4.07; N, 16.18%.

The 2, 4 - Dinitrophenylhydrazone: lustrous black-purple crystals, m. p. ca. 277°C (decomp.).

Found: C, 57.36; H, 3.67; N, 21.28. Calcd. for $C_{25}H_{18}O_6N_8$: C, 57.03; H, 3.45; N, 21.29%.

The Treatment of I with Ethyl Cyanoacetate.—To a solution of 0.1 g. (0.00041 mol.) of I in 5 ml. of ethanol were added 0.1 g. (0.00089 mol.) of ethyl cyanoacetate and one drop of piperidine; the resulting solution was then warmed on a water bath for a while. The red or dark-red micro-particles (apparently a powder) produced were more stable than those obtained in the aforesaid treatment, carbonizing at a higher temperature, e. g., above 200°C. The other properties, on the whole, were similar to those of the particles described immediately above.

The Hydrogenolysis of I to 5-Acetamidoresorcylaldehyde (IV).—Into a mixture of 2 ml. of acetic anhydride and 15 ml. of dioxane, 0.16 g. of I was dissolved. The resulting solution was shaken with hydrgen in the presence of palladium-on-charcoal. The yellowish solid obtained was recrystallized from acetic acid to give yellowish crystals which melted at 259—260°C (decomp.).

Found: N, 7.23. Calcd. for $C_9H_9O_4N$: N, 7.18%.

The Reduction of 5-Nitroresorcylaldehyde (V) to IV.—A solution of 3.5 g. of V in a mixture of 100 ml. of acetic acid and 10 ml. of acetic anhydride was shaken with hydrogen in the presence of palladium-on-charcoal. Three grams of yellowish crystals, m. p. 259—260°C (decomp.), was obtained. The melting point was undepressed on admixture with the specimen obtained by the hydrogenolysis of I.

Found: C, 55.38; H, 4.63; N, 7.18. Calcd. for $C_9H_9O_4N$: C, 55.38; H, 4.65; N. 7.18%.

The 2, 4-Dinitrophenylhydrazone of IV.—This melted above 300°C.

Found: C, 48.04; H, 3.19; N, 18.40. Calcd. for $C_{15}H_{13}O_7N_5$: C, 48.00; H, 3.49; N, 18.66%.

The Preparation of 2, 4-Dimethoxy-5-nitrobenzaldehyde (VI) from V.—Into a mixture of 1.2 g. of V, 15 ml. of dioxane and 2 g. of silver oxide was added

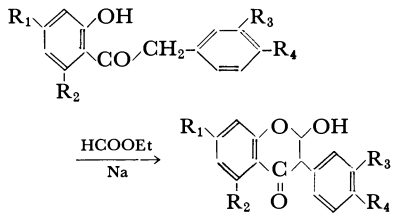
The Stereochemistry of 2-Hydroxyisoflavanones

By Shozo YAMAGUCHI, Shoei ITO, Asao NAKAMURA and Naoto INOUE

College of General Education, Tohoku University, Kawauchi, Sendai

(Received July 5, 1965)

2-Hydroxyisoflavanones are often isolated as unstable intermediates in the course of the syntheses of isoflavones by means of the reactions of 2-hydroxyphenyl benzyl ketones with ethyl formate in the presence of sodium.[1,2,4]



(I): $R_1=R_2=R_3=R_4=H$
(II): $R_1=OMe$; $R_2=R_3=R_4=H$
(III): $R_1=R_2=OMe$; $R_3, R_4 = O{>}CH_2$

The stereochemistry of 2-hydroxyisoflavanones has been discussed previously by Whalley,[3] who reported that 2-hydroxyisoflavanones have a trans configuration with equatorial C_2 hydroxyl and equatorial C_3 phenyl groups.

In order to confirm his assignment, the NMR spectra of 2-hydroxyisoflavanones were investigated; the results will be reported in this paper.

2-Hydroxyisoflavanone (I) and 2-hydroxy-7-methoxyisoflavanone (II) were synthesized, and the NMR spectra of I, II and 2-hydroxy-5, 7-dimethoxy - 3', 4' - methylenedioxy - isoflavanone (III)[4] were measured in $CDCl_3$, $CHCl_3$ (containing a trace of water or hydrochloric acid) or pyridine, depending on their solubilities. The spectra were determined with a Varian A-60 spectrometer at 60 mc., using tetramethylsilane as an internal reference, the results obtained are summerized in Table I.

In the NMR spectra of I in $CDCl_3$, the broadenings of the doublet with its center at 248.4 c. p. s. and of the triplet with its center at 348.3 c. p. s. seem to be due to the slow exchange of the C_2-hydroxyl proton. In order to confirm this consideration, the NMR spectrum of I was measured in $CHCl_3$ containing a trace of water. The broad doublet at 248.4 c. p. s. became extremely broad and almost unrecognizable; however, the integration curve showed the presence of one proton between 248 and 287 c. p. s. The triplet at 348.3 c. p. s. became a sharp doublet with its center at the same position. Furthermore, in the NMR spectrum of I in $CHCl_3$ containing a trace of hydrochloric acid, the triplet at 348.3 c. p. s. observed in $CDCl_3$ became a sharper doublet than that in the spectra measured in $CHCl_3$ containing a trace of water.

From these observations, it may be concluded that the signals of I at 233.1, 248.4 and 348.3 c. p. s. are to be attributed to the C_3-proton, hydroxyl proton and C_2-proton respectively; the coupling constant between the C_2-proton and the C_3-proton has been determined to be 4.2 c. p. s.

The NMR spectrum of III was measured in a pyridine solution because of its low solubility in $CDCl_3$. As a result of the solvent effect caused by pyridine, the signals of III were shifted to a considerably low field as compared with the corresponding signals of I in $CDCl_3$; however, the complete assignments for the signals of III could be made with reference only to those of I measured in pyridine.

---

** $CHCl_3$ + trace H_2O or trace HCl was used as solvent.
*** Pyridine was used as solvent.

Since 2-hydroxyisoflavanones have the hemiacetal structure, the coupling constant of glucopyranose can be used for determining the configurations of the compounds I, II and III.

Considering Karplus' calculated results,[5] the coupling constant of glucopyranose[6] and the observed $J_{2,3}$, of I, II and III (4.2 c.p.s., 4.0 c.p.s. and 3.5 c. p. s., respectively), it may be concluded that the 2-hydroxyisoflavanones obtained as the intermediates in the syntheses of isoflavones have cis configurations.

2-Hydroxyisoflavanones are generally converted to the corresponding isoflavones through dehydration by heating or treatment with acid.[3] However, I and II were found to give the corresponding isoflavones in a quantitative yield even when treated with ethanol or benzene under the mild conditions described in Table II.

Table II. Transformations of 2-hydroxyisoflavanones to isoflavones

(a)*—Ethanol (10 ml.), reflux 30 min.
(b)*—Pyridine (0.5 ml.) in benzene (5 ml.), 50°C, 20 min.
(c)*—Ethanolic potassium hydroxide (5% 10 ml.), room temperature, 20 hr.

* In each case 50 mg. of the sample (I or II) was employed.

Experimental

2-Hydroxyisoflavanone (I).—Into 3 g. of sodium dust there was stirred, drop by drop, over a period of 40 min. under cooling with ice, a mixture of 60 ml. of ethyl formate and 6 g. of 2-hydroxyphenyl benzyl ketone. After had been stirred the mixture three more hours, it was allowed to stand overnight under cooling with ice. To the reaction mixture there was then added ice water. The separated crystals were filtered, dried, and washed with hot petroleum ether and then with a small amount of ethanol. Recrystallization from benzene - petroleum ether (1: 1) gave 2-hydroxyisoflavanone (ν_{OH} 3600 cm^{-1}, 3400 cm^{-1}; $\nu_{C=O}$ 1695 cm^{-1}; $CHCl_3$ solution), m. p. 110—111°C (decomp.), 2.2 g. (32%).

Found: C, 74.95; H, 5.26. Calcd. for $C_{15}H_{12}O_3$: C, 74.99; H, 5.03%.

One gram of isoflavone, m. p. 132—133°C, was obtained from the mother liquor of I.

2-Hydroxy-7-methoxyisoflavanone (II).—2-Hydroxy-4-methoxyphenyl benzyl ketone was treated with ethyl formate and sodium in a manner similar to that used for the formation of I. The crude crystals were recrystallized from benzene yielding II (ν_{OH} 3350 cm^{-1}, 3460 cm^{-1}; $\nu_{C=O}$ 1688 cm^{-1}; $CHCl_3$ solution) m. p. 145—146°C (decomp.)[2] in a 43% yield. By refluxing II in acetic acid for 20 min., it was quantitatively converted to 7-methoxyisoflavone, m. p. 154—155°C.

Separation of ^{90}Sr and ^{90}Y by Paper Electrophoresis with Very Dilute Hydrochloric Acid Background Electrolyte

By Shoichi KAWAMURA and Masami IZAWA

Chemistry Division, National Institute of Radiological Sciences, Anagawa-cho, Chiba

(Received July 12, 1965)

Many methods have been employed for the separation of ^{90}Sr and ^{90}Y. One of them is paper electrophoresis, by which ^{90}Sr-^{90}Y have been separated by using lactic acid, ammonia,[1] ammonium acetate or ammonium citrate[2] as background electrolytes. The present paper will report on the successful use of 10^{-3} N hydrochloric acid as the background electrolyte for the separation of ^{90}Sr and ^{90}Y. The use of hydrochloric acid eliminates the trouble of removing the organic ingredient after the extraction of the ^{90}Sr or ^{90}Y fraction from the filter paper.

Experimental

The sample without a carrier was prepared by diluting ^{90}Sr-^{90}Y, obtained from the Oak Ridge National Laboratory, with redistilled water, while the one with a carrier was prepared by adding ^{90}Sr-^{90}Y to Sr or Y ($SrCl_2$ or YCl_3) to make 0.05 M solution. The filter paper used was Tokyo filter paper No. 3 (2×40 cm.) supplied by the Tokyo Roshi Kaisha, Ltd. The sample to be separated was applied at 10 cm. from an end of the paper. After the paper was sandwiched between plastic plates,[3] a d. c. potential of 20 V./cm. was applied to it for 30 min. After drying, the paper was cut into strips 1 cm. in length, and the activity of each strip was determined by a G. M. counter.

The relative distance, R_D, was also determined according to a slight modification of Bermes method.[4] The filter paper was sandwiched between plastic plates and arranged as is shown in Fig. 1. The background electrolyte was allowed to soak through the paper until it reached point B. When the background electrolyte reached this point, the sample to be determined was applied to point A through a hole above A. The background electrolyte was then permitted to continue its flow without the application of a d. c. current until it almot reached the other end of the paper strip, B'. Meanwhile, the sample moved to point A'. R_D was calculated from the following equation.

$$\text{Relative distance, } R_D = \frac{\text{Migrant movement}}{\text{Solvent movement}}$$

The electrosmotic flow was determined by using glucose as an indicator under the same conditions as were employed for the separation of ^{90}Sr and ^{90}Y.

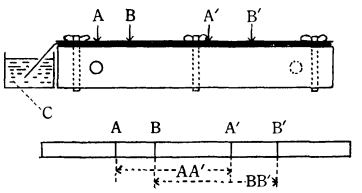

Fig. 1. Arrangement for measuring relative distance, R_D of ^{90}Sr.

$$\text{Relative distance, } R_D = \frac{AA'}{BB'} = \frac{^{90}Sr \text{ movement}}{10^{-3}\text{ N HCl movement}}$$

where A : initial ^{90}Sr position, A' : final ^{90}Sr position, B : initial 10^{-3} N HCl front, B' : final 10^{-3} N HCl front, C : 10^{-3} N HCl

Results and Discussion

As is shown in Fig. 2A, the separation of ^{90}Sr and ^{90}Y was accomplished by using 10^{-3} N hydrochloric acid as the background electroyte.

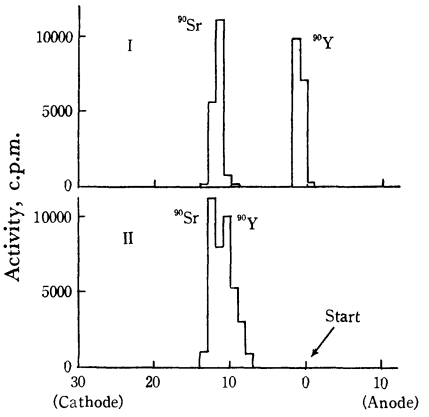

Fig. 2. Electrophoregram (20 V./cm., 30 min.) of ^{90}Sr and ^{90}Y.
I 10^{-3} N HCl II 10^{-2} N HCl

It was difficult to separate ^{90}Sr and ^{90}Y in 10^{-2} N hydrochloric acid, in which Sr and Y migrate at almost the same speed (Fig. 2B). The use of 10^{-1} N hydrochloric acid as the background electrolyte made it impossible to carry out the experiment because of the over-heating of the filter paper. When the hydrochloric acid concentration is

1) T. R. Sato, W. P. Norris and H. H. Strain, *Anal. Chem.*, **26**, 267 (1954).
2) S. Kawamura, *Japan Analyst (Bunseki Kagaku)*, **10**, 975 (1961).
3) S. Kawamura, ibid., **11**, 814 (1962).
4) E. W. Bermes, Jr., and H. J. McDonald, *J. Chromatog.*, **4**, 34 (1960).

reduced to 10^{-4} N, the current through the paper strip becomes negligible; therefore, the use of 10^{-4} N hydrochloric acid made it impossible to carry out the experiment.

In these experiments, the behavior of ^{90}Sr and ^{90}Y without a carrier was almost identical with those of the substances with a carrier. Sr and Y immersed in a filter paper strip migrate toward the cathode against the barrier effect due to the filter paper. In order to determine this effect, the relative distances suggested by Bermes were determined; the results are shown in Fig. 3.

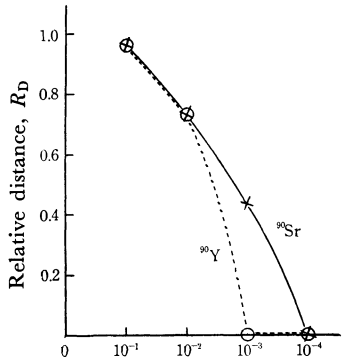

Fig. 3. Relation between relative distance and concentration of hydrochloric acid.

The results shown in Fig. 2A may be explained by the fact that the R_D value of ^{90}Y in 10^{-3} N hydrochloric acid is 0; therefore, the ^{90}Y in the solution remains at the starting point, being absorbed by the filter paper, while ^{90}Sr, on the other hand, migrates to the cathode. The migration distance of ^{90}Sr in a free solution of 10^{-3} N hydrochloric acid at 20 V./cm. was calculated from the above data as follows:

$$A = \frac{B - C}{R_D} = \frac{11 - 2.5}{0.45} = 19 \text{ (cm.)} \quad (1)$$

where

A: the migration distance of ^{90}Sr in a free solution of 10^{-3} N hydrochloric acid

B: the migration distance of ^{90}Sr in 10^{-3} N hydrochloric acid by paper electrophoresis 11 cm.

C: the migration distance due to electrosmosis 2.5 cm.

The migration distance of ^{90}Sr in a free solution is calculated as follows:

$$D = \frac{l_{Sr} \times V \times t}{F} = 22 \text{ (cm.)} \quad (2)$$

where

l_{Sr}: the ionic conductance of Sr, 59.5 coulomb, cm./V.sec.

V: the applied voltage, 20 V./cm.

t: the migration time, 30 min.

F: the Faraday constant

The migration distance in a free solution as calculated from Eq. 1 agreed fairly well with the one obtained from Eq. 2. This means that Sr migrates in the form of a divalent cation in a 10^{-3} N hydrochloric acid-background electrolyte, and that the value of R_D determined is reasonable.

The Infrared Spectra of Sublimed Methylsuccinic Acid

By Yoshiko TAKEOKA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Tokyo

(Received August 4, 1965)

It was noted by Duncanson[1] that the infrared spectrum of sublimed methylsuccinic acid was different from that of the one recrystallized from water and that this change produced by sublimation was consistent with the occurence of rotational isomers involving the central carbon-carbon bond. He proposed that, if recrystallized methylsuccinic acid from water had a form similar to that of succinic acid,[2] namely, a trans form with respect to two carboxyl groups (Fig. 1 (a)), as is suggested by its dipole measurements and its infrared spectrum, the sublimed one would probably possess a gauche form, as is shown in Fig. 1 (b). Since the infrared spectrum of *os*-dimethylsuccinic acid did not change upon sublimation, such a molecule seemed to display a fairly strong resistance of the carbonyl group to the rotation passing near a β-methyl group.

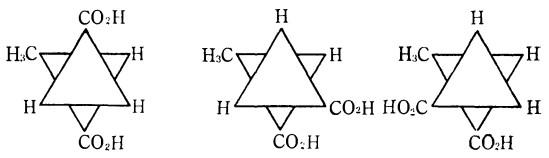

Fig. 1. Rotational isomers of methylsuccinic acid.

1) L. A. Duncanson, *J. Chem. Soc.*, **1952**, 1753.
2) J. D. Morrison and J. M. Robertson, ibid., **1949**, 980.

We have found that, when the infrared spectra of methylsuccinic acid sublimed at 70—80°C/ 1×10^{-1} mmHg and condensed on the surface of copper held at 30°C, 0°C and −145°C, were measured immediately after sublimation, some new bands appeared which did not exist in Duncanson's spectrum (Fig. 2). From these measurements, it has been shown that, with a decrease in the temperature at the copper surface, the new bands increased in intensity. Three hours after sublimation, the intensity of these bands decreased while that of some neighbouring bands increased. The spectra became very similar to those given by Duncanson in the course of two days, but after that it remained almost unchanged, even for as long as half a year. When the sublimed sample was recrystallized from water, it gave the same spectrum as that observed before sublimation. The bands of the O–H and C–O stretching vibrations almost did not change at all, and no band characteristic to anhydride appeared near 1800 cm^{-1} after sublimation. These facts suggest that succinic anhydride was not produced. In the region below 1350 cm^{-1}, most bands are modified by sublimation, as is shown in Fig. 2; some strong bands disappeared and some others appeared. Such large variations in spectra may be well explained by assuming the existence of rotational isomers, as has been pointed out by Duncanson.

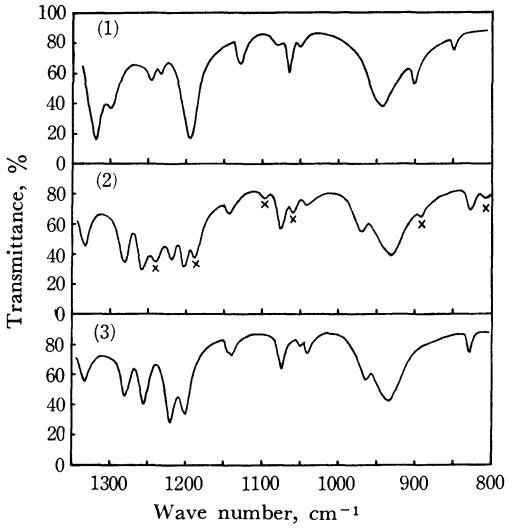

Fig. 2. Infrared spectra of methylsuccinic acid. (solid; Nujol mull)
(1) before sublimation (recrystallized from water)
(2) immediately after sublimation, condensed on Cu surface held at −145°C (×; disappeared during two days)
(3) two days after sublimation

It has been well-known that the rotational isomers of ethane derivatives possess mutually different infrared spectra. In many cases, two or more isomers coexist in the liquid or gas state, but only one isomer exists in the solid state. In the present case, the sublimed sample, condensed on the copper surface at −145°C, showed the largest spectral change, after sublimation, and many bands, even the strong band found at 1320 cm^{-1} before sublimation, did not appear in the spectrum of the sublimed sample. These facts suggest that rotational isomers, produced by sublimation in the state and possessing different configurations, might have produced unstable crystals when rapidly cooled.

As has been mentioned above, the spectra of the sublimed product changed gradually. The intensity of some bands increased and that of some others decreased; the former bands disappeared completely in two days, after which none of the spectra showed any more variation. From such behavior it may be supposed that the sublimed sample probably has at least two rotational isomers. Since the energy difference is small, the unstable form is transformed into the stable one in two days. The spectral change occured in the solid state, so it seems that the potential barrier between one isomer and another is not so high.

These observations can be well explained by the following considerations. If we assume, as did Duncanson, that the molecule of methylsuccinic acid before sublimation has a form similar to that of succinic acid, such as a trans form, the configurations of its probable rotational isomers can be represented as in Fig. 1 (b) and (c). It is known that, at low pressures and at high temperatures, the vapor of carboxylic acids consists to a large extent of the monomeric form. Therefore, in the present case, many molecules in the gas state exist, perhaps as monomers after sublimation. They probably prefer to be in a gauche form, for they could be stabilized in this form only as a result of forming an intramolecular hydrogen bond. The b form seems to be more stable than c, because in the former the methyl group is not situated near carboxyl groups. The transformation from the a form into the b can be realized by the rotation in which methyl and carboxyl groups pass only near the hydrogen atom. In the changes from the a or b form to the c, the carboxyl groups may find it difficult to pass near the β-methyl group, as has been indicated by Duncanson; however, we consider the transformation from the b form to the c to be possible by means of the following assumptions. In the b form, this molecule is probably stabilized in the gas state by the formation of an intramolecular hydrogen bond consisting of a seven-membered ring. By the inversion of this seven-membered ring, as in the case of cyclohexane ring, the b form may then be transformed into the c rather easily, leaving the intramolecular hydrogen bond unchanged. Therefore, it may be supposed that the

sublimed molecules immediately after sublimation have the b and c forms as a result of the rapid cooling and that the spectral change in the sublimed solid is due to the transformation from the c form to the b. However, in the solid state the intermolecular hydrogen bond can be formed in either the b or the c form, so the situation is more complicated than in the gas state.

The band at 945 cm^{-1} in the solid spectrum before sublimation becomes extremely broad in the liquid; it can be assigned to the O–H out-of-plane deformation vibration, much as in the case of succinic acid.[3] The frequency of this band is greatly lowered (934 cm^{-1}) by sublimation, showing a weaker hydrogen bond. However, in the sublimed solid spectrum, this band shows only a small shift (936 cm^{-1}) in two days. This fact suggests that the isomers coexisting in the sublimed solid are similar to each other in the strength of their hydrogen bonds. The band of the O–H stretching vibration shifts to a higher frequency upon sublimation; this fact shows as in the case of the O–H out-of-plane deformation vibration mentioned above, that the molecule before sublimation has a stronger hydrogen bond than the sublimed molecule.

For many ethane derivatives, such as 1, 2-dichloroethane or 1, 2-dibromoethane, a trans form is generally more stable than a gauche form in the gas state. However, the more stable form of ethylene chlorohydrin in the gas state is a gauche form, for stabilization by the formation of the intramolecular hydrogen bond is possible only in the gauche form.[4] Similarly, it may well be assumed that methylsuccinic acid also possesses a gauche form in the gas state, as it is more stable configuration.

The author wishes to express her thanks to Professor Shiro Maeda for his valuable discussions.

The Absorption Spectra of 2, 4, 6-Trinitroanisole in Methanolic Sodium Methoxide

By Takehiro ABE

The College of General Education, Tohoku University, Kawauchi, Sendai

(Received August 4, 1965)

It has been reported that the absorption spectrum of a colored methanolic solution of 2, 4, 6-trinitroanisole in the presence of sodium methoxide is due to the Meisenheimer complex I.[1-4] In the present work, an attempt has been made to investigate the further interaction of 2, 4, 6-trinitroanisole with the methoxide ion at very high methoxide concentrations. For this purpose, the author measured the spectra of the colored solutions at various methoxide concentrations, using a Hitachi EPU-2A spectrophotometer at room temperature. The solutions were left to stand for half an hour before

the measurements, because it took at least several minutes for the equilibrium needed for the formation of the first complex to be attained.[2,4] In the present wavelength region, 2, 4, 6-trinitroanisole at a low concentration and the methoxide ion did not absorb. The results are shown in Fig. 1.

Absorption curve 1, with two maxima at ca. 485 and 410 mμ for the solution at the methoxide concentration of 1.01×10^{-2} M in Fig. 1, may be ascribed to the complex I.[1-4] The sbsorption intensity of the band at 410 mμ is stronger than that at 485 mμ. When the concentration of the methoxide is increased, the absorption intensity of the band at ca. 480 mμ is stronger than that at ca. 410 mμ at the methoxide concentration of 3.94 M. From those results, the absorption maximum at 480 mμ in the curve 4 can be attributed to a second complex, one formed by a further reaction between the first complex I and the methoxide, as was suggested by Gold and Rochester.[2] They suggested that the second complex is likely to involve two methoxide ions per methyl picrate molecule. At the very much higher methoxide concentration of 4.92 M, the absorption intensity at ca. 480 mμ decreases and the absorption maximum at ca. 410 mμ disappears. This can be interpreted in terms of the formation of a third complex between the second complex and the methoxide, a complex with no absorption in the visible region. The above results lead to the conclusions that the Meisenheimer complex I has two bands, at ca. 485 and 410 mμ; that the second complex has a band at ca. 480 mμ, and that the third complex has no bands in the visible region.

Assuming that the second and the third complex are II and III respectively, the present author calculated the energy levels of the molecular orbitals of π-electrons in the three complexes I, II and III, using the same parameters as in the previous paper[3] by means of the simple LCAO MO method. The results are shown in Fig. 2. The predictions for the transitions in the complexes, indicated in Fig. 2, agree qualitatively with the experimental results in Fig. 1. Accordingly, it is likely that the second complex II with the absorption maximum at ca. 480 mμ and the third complex III with no absorption in the visible region are formed as the concentration of sodium methoxide increases.

The Fundamental Fragmentation of Several Fulvenes upon Electron Impact

By Yoshio KITAHARA, Ichiro MURATA and Kunikatsu SHIRAHATA*

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 16, 1965)

A few papers have appeared concerning the mass spectral fragmentation patterns of non-benzenoid aromatic compounds.[1,2] Here we will report, in a preliminary form, as the behavior of several simple fulvene derivatives upon electron impact.

The fragmentation of 6-methylfulvene by electron impact was first observed by Hanus and Dolejsek[3] in relation to their study of the series of hydrocarbons which have the molecular formula of C_7H_8, e. g., toluene, cycloheptatriene, spiro-[2, 4] - heptadiene - 2, 4, ethinylcyclopentene - 1, ethinylcyclopentene-2, etc. The most important step of the fragemtation is the formation of the tropylium ion by the expulsion of hydrogen from the molecular ion. The feature is common to all of the C_7H_8 isomers.

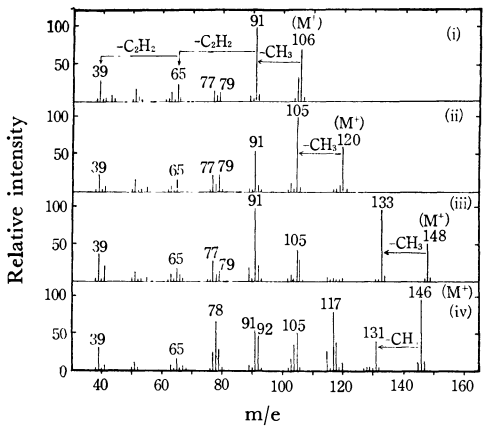

Fig. 1. Mass spectra of 6,6-dialkylfulvenes.
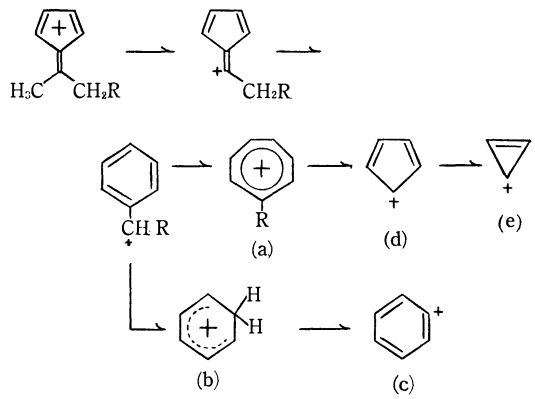
(i) 6,6-Dimethylfulvene
(ii) 6-Methyl-6-ethylfulvene
(iii) 6-Methyl-6-isobutylfulvene
(iv) 6,6-Pentamethylenefulvene

In the mass spectra of the 6, 6-dialkyl derivatives, such as dimethyl- (1), methyl-ethyl- (2) and methyl-isobutylfulvene (3) [see Fig. 1], the base peaks [*m/e* 91, 105, and 133] produced by the elimination of a fragment of 15 mass units from the corresponding parent ions may safely be assumed to be the tropylium, methytropylium, and isopropyltropylium ions (a: R=H, CH_3, *i*-C_3H_7) respectively. The formation of these ions is probably associated with the loss of the methyl radicals from the 6-position of the fulvenes. In the low mass region of the spectra of these fulvenes, a group of peaks, *m/e* 79, 77, 65 and 39, is characteristic of all isomers of the hydrocarbons of C_7H_8; the peaks may reasonably be interpreted as indicating the ions of benzonium (b), phenyl (c), cyclopentadienyl (d), and cyclopropenylium (e) respectively.



(1′) : R=H
(2′) : R=CH_3
(3′) : R=$CH(CH_3)_2$

6, 6-Pentamethylenefulvene (4), however, showed a peculiar fragmentation pattern. In spite of the fact that compound 4 has no methyl substituent on the 6-position, the first step of the fragmentation is the loss of a methyl radical [*m/e* 131, M^+-15]. The process is confirmed by the existence of an appropriate metastable ion peak at *m/e* 117.5. This suggests that the first step of the fragmentation is the well-known β-fission of the aliphatic moiety, with a simultaneous expulsion of the methyl radical, thus leading to the ion of *m/e* 131 (f). The mechanism of the appearance of peaks at *m/e* 92 and 78 [Fig. 1, (iv)] with a considerable intensity still remains in question.

(4′) (f)

The base peaks from 6-phenyl- (5) and 6-methyl-6-phenylfulvene (6) [see Fig. 2] are ions of *m/e* 153 (g); they correspond to the loss of the hydrogen and the methyl radicals [M^+-1 and M^+-15] respectively.

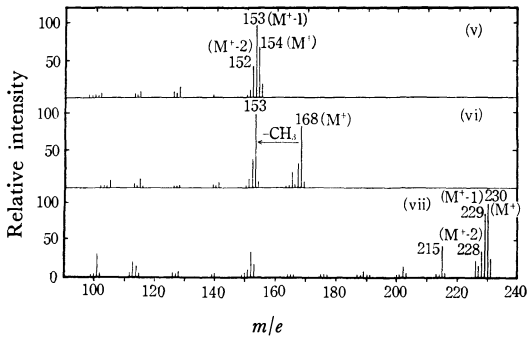

Fig. 2. Mass spectra of 6-arylfulvenes.
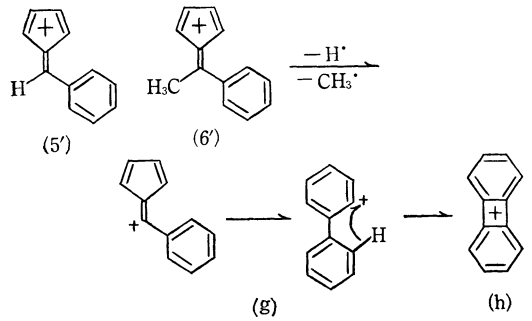
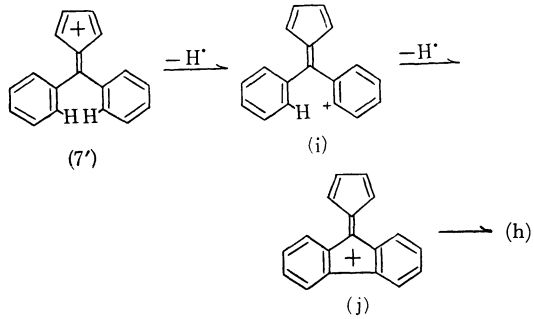
(v) 6-Phenylfulvene
(vi) 6-Methyl-6-phenylfulvene
(vii) 6,6-Diphenylfulvene

The moderately intense peak at *m/e* 152 in both compounds is presumably a biphenylene ion (h) produced by the further loss of hydrogen. This is supported by the fact that the spectra in the low mass region [less than *m/e* 153] of the compounds 5 and 6 were similar to that of biphenyl.



(5′) (6′) (g) (h)

6,6-Diphenylfulvene (7) does not show any tendency to eliminate the phenyl radical from the 6-position, but it does show very intense peaks at *m/e* 229 [M^+-1] (i) and at *m/e* 228 [M^+-2] (j). In this case, the interaction of two sterically crowded phenyl groups probably plays an improtant role in the fragmentation process of this compound. Thus, the formation of a [M^+-2] ion through an intramolecular abstraction of a hydrogen atom from the ortho position of the phenyl group is conceivable. This [M^+-2] ion may naturally by represented as a dibenzofulvalene ion (j). Furthermore, the prominent metastable ion peak at *m/e* 101.5 suggests that the next fragmentation step is the formation of the biphenylene ion.



(7′) (i) (j)

Finally, it should be pointed out that the most fundamental fragmentation of 6-substituted fulvenes is initialed by the fission of hydrogen or substituents at the 6-position, thus forming stable aromatic ions except in the case of 6,6-diphenylfulvene (7).

The mass spectra were taken with a Hitachi Mass Spectrometer, Model RMU-5B, using an all-glass inlet system. The ionizing potential was kept at 75 eV., and the ionizing current, at 80 μamp.

The authors are grateful to Messers. Tamotsu Noda, Yasuo Nakajima and Hiroshi Sato of the Naka Works, Hitachi Co. Ltd., Katsuta, Ibarki, for their kind measurement of the mass spectra.

SHORT COMMUNICATIONS

A Novel Deacylation of the γ-Oxoacyl Amino Acid and Peptide

By Fumio SAKIYAMA, Michiyo MORISHITA, Tsuneo SOWA and Kozo NARITA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received September 7, 1965)

Several attempts to effect the cleavage of a specified peptide bond by a chemical reagent have been reported, and some of them are widely utilized for the sequential analysis of protein.[1] For the tyrosyl and tryptophyl bond cleavage, the NBS[2] method has successfully been used. Recently Shaltiel and Patchornik[3] effected an histidyl bond cleavage by using the same principle.

The present aughors have exploited another principle to cleave the histidyl and the tryptophyl bonds. This principle is based, first, on the formation of the γ-oxo group which can be derived from the above residues by the proper reactions: namely, Bamberger's degradation[4] and the subsequent mild hydrolysis of the γ-benzamino group for the histidine residue and peroxide or ozone oxidation[5] for the tryptophan residue. Secondly, the elimination of the γ-oxoacyl group by tetrahydropyridazone formation with hydrazine leads to an exposure of the amino group, which is bonded with the carboxyl side of the amino acid residue in question.

N-Laevuloyl-, *N*-(3-benzoyl-propionyl)- and *N*, *N'*-dibenzoyl-γ-oxoornithyl-L-phenylalanine and *N*-(3-benzoylpropionyl)-L-leucylglycine have been prepared as model compounds for the reaction of the second step.[6] The deacylation of *N*-laevuloyl-L-phenylalanine was performed by the following procedure. *N*-Laevuloyl-L-phenylalanine dicyclohexylamine salt (m. p., 155—156°, 20 μmol.) was heated to a boil in 2 ml. of a 2.0 M acetate buffer (pH 3.6) containing hydrazine (100 μmol.). An aliquot was examined by paper chromatography,[7] and the amino acid released was determined by densitometry after Cd-ninhydrin colorization[8] (Fig. 1). The phenylalanine, quantitatively released after half an hour, was identified as both free amino acid and the DNP[9] derivative by paper and thin-layer chromatography.[10] The cyclization product obtained from the laevuloyl group and hydrazine was shown to be identical with 6-methyl-2, 3, 4, 5-tetrahydropyridaz-3-one[11] by paper and thin layer chromatography[12] and by infrared spectroscopy.

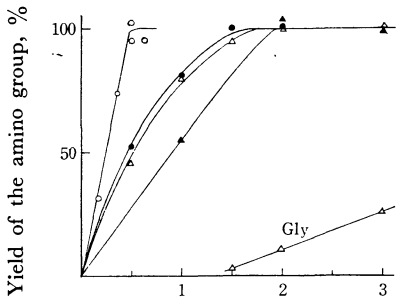


Fig. 1. The release of the amino group from the γ-oxoacyl amino acid and peptide.
○: *N*-laevuloyl-L-phenylalanine
●: *N*-(3-benzoylpropionyl)-L-phenylalanine
△: *N*-(3-benzoylpropionyl)-L-leucylglycine
▲: *N*-(*N*, *N'*-dibenzoyl-γ-oxoornithyl)-L-phenylalanine
Determination of the amino group was performed after paper chromatographic separation of the reaction mixture.

The rate of the release of the amino group depends mainly on the nature of the γ-oxoacyl group, as is shown in Fig. 1. The *N*, *N'*-dibenzoyl-γ-oxoorinthyl group, a descendant of the histidyl residue, was most resistant to cyclization under the present conditions. Prolonged heating caused an appreciable hydrolysis of the peptide bond.

Deacylation from the acetoacetyl derivative of amino acid and peptide can be accomplished by the reaction with phenylhydrazine.[13] A detailed description of this study will be presented elsewhere.

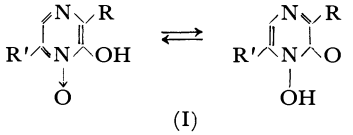
Totalsynthese der Racemischen Aspergillsäure

Von Yasuhiro CHIGIRA, Mitsuo MASAKI und Masaki OHTA

Laboratorium für Organische Chemie, Tokyo Institut für Technologie, Ookayama, Tokyo

(Eingegangen am 20. November, 1965)

Über die Aspergillsäure, die 1943 von White und Hill[1] aus dem Kulturfiltrat von Aspergillus flavus isoliert wurde, wurde geschlossen, dass die Substanz 3-Isobutyl-6-*sek*-butyl-2-hydroxypyrazin-1-oxyd oder dessen tautomere Hydroxamsäure (I-a)[2] darstellt. Vier weitere eng verwandte Antibiotika—Hydroxyaspergillsäure (I-b),[3] Mutaaspergillsäure (I-c),[4] Neoaspergillsäure (I-d)[5] und Neohydroxyaspergillsäure (I-e)[7]—sind auch wahrscheinlich 3, 6-Disubstituierte-2-hydroxypyrazin-1-oxyd, obwohl Synthese dieser Antibiotika bisher noch nicht berichtet worden sind.



(I)

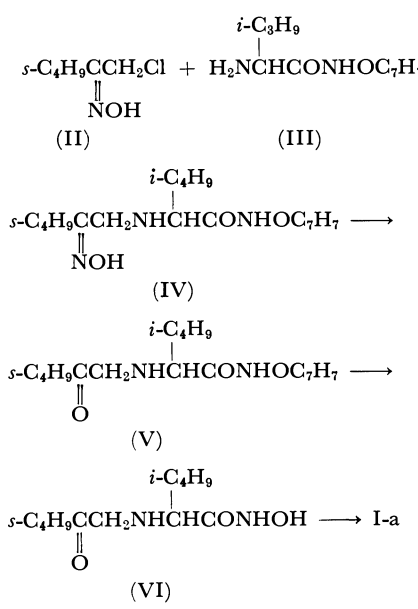
R = $C_3H_7{}^iCH_2$–

R' = a, $C_2H_5(CH_3)CH$–
b, $C_2H_5(CH_3)(OH)C$–
c, $(CH_3)_2(OH)C$–
d, $C_3H_7{}^iCH_2$–
e, $C_3H_7{}^i(OH)CH$–

Kürzlich gelang uns die Synthese von Neoaspergillsäure,[7] indem man das Verfahren, das zur Herstellung von Pyrazin Hydroxamsäure in unserem Laboratorium ergeben worden ist,[8] anwendet.

In analoger Weise konnten wir nun ja weiter die racemische Aspergillsäure totalsynthetisch herstellen (Formelschema 1).

Umsetzung von 1-Chlor-3-methyl-2-oximinopentan (II)[9] mit *N*-Leucyl-*O*-benzylhydroxylamin (III)[8] in Tetrahydrofuran beim Zimmertemperatur führte zu *N*-[4-Methyl-2-(3-methyl-2-oximinopentylamino)valeryl]-*O*-benzylhydroxylamin (IV), welches mit Salzsäure in Methanol bei 42—45°C zu 2-Ketopentylamino-körper (V) verseift wurde. Beim Reduktiv-Debenzylierung ergab V 4-Methyl-2-(3-methyl-2-oxopentylamino)valerohydroxamsäure (VI) vom Schmp. 134°C (Zers.) (Gef.: C, 59.25; H, 10.15; N, 11.65. Ber. für $C_{12}H_{24}N_2O_3$: C, 58.99; H, 9.90; N, 11.47%.).



Formelschema 1

Durch die direkte Cyclisierungsreaktion konnten wir VI zu 3-Isobutyl-6-*sek*-butyl-2-hydroxypyrazin-1-oxyd (I-a) (60 mg) überführen, indem man VI (0.7 g) ammoniakalischem Methanol (20 ml) bei Zimmertemperatur behandelt. Die letzte Stufe der Synthese ist die Luft-Oxydation, die in den meisten Pyrazinsynthesen allgemein ist.[10] Die racemische Aspergillsäure (gelbliche Nadeln vom Schmp. 97.5—98.0°C aus 60 proz. Methanol) ergab mit Ferrichlorid in Methanol eine rote Färbung und liess sich durch Elementaranalyse (Gef.: C, 64.21; H, 9.17; N, 12.56. Ber. für $C_{12}H_{20}N_2O_2$: C, 64.25; H, 8.99; N, 12.49%.) und durch Ultraviolet-Spektrum [λ_{max}^{EtOH} 233 mμ (ε=7600) und 328 mμ (ε=8700)] sowie durch Infrarot-Spektrum [scharfe Banden bei 2050, 2870, 2950 und 3130 cm^{-1} und breite Banden bei 2300—2800 und 3300—3600 cm^{-1}] charakterisieren. [Lit. der Aspergillsäure[11] Schmp. 97—99°C, UV-Spektrum λ_{max}^{EtOH} 234 mμ (ε=6500) und 328 mμ (ε=8300)].

Studies of Purine *N*-Oxides. I. The Synthesis of Hypoxanthine 1-*N*-Oxide

By Hideaki KAWASHIMA, Takashi MEGURO and Izumi KUMASHIRO

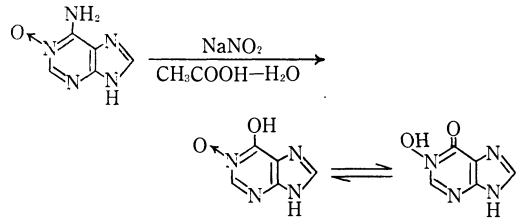
Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received December 16, 1965)

Hypoxanthine 1-*N*-oxide has been synthesized by the orthoformate ring closure of 4-amino-imidazole-5-hydroxamic acid.[1] However, this method is not applicable to a large scale synthesis, because 4-aminoimidazole-5-hydroxamic acid cannot be obtained easily.

Hypoxanthine is not convertible to hypoxanthine 1-*N*-oxide by direct oxidation. However, adenine has been readily oxidized with hydrogen peroxide in aqueous acetic acid to give adenine 1-*N*-oxide.[2,3]

The present paper will deal with the deamination of adenine 1-*N*-oxide with nitrous acid to give hypoxanthine 1-*N*-oxide. Five grams of adenine 1-*N*-oxide were treated with 23 g. of sodium nitrite in 350 ml. of 29% acetic acid solution at room temperature. After it had stood for four days, the precipitate was collected and washed with water. Light yellow crystals of hypoxanthine 1-*N*-oxide were obtained in a 90% yield (4.5 g.). The crystals showed a single spot on chromatography.[1] After being recrystallized several times, colorless crystals were obtained (Found: C, 39.92; H, 3.07; N, 37.14. Calcd. for $C_5H_4O_2N_4$: C, 39.48; H, 2.65; N, 36.84%).



The crystals were identified by means of a study of their paper chromatographic behavior and by a comparison of their ultraviolet and infrared absorption spectra with those of an authentic sample.[1] The catalytic reduction of this product with hydrogen (10 kg./cm^2) afforded hypoxanthine in the presence of Adams' catalyst at 60°C for 24 hr.

After the present work, had been finished, adenosine 1-*N*-oxide and AMP-5' 1-*N*-oxide were found to be deaminated with nitrosyl chloride, yielding inosine 1-*N*-oxide and IMP-5' 1-*N*-oxide respectively.[4]

π-Allyl-cycloocta-1, 5-diene-rhodium (I)

By Akira KASAHARA and Keiko TANAKA

Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Yamagata

(Received December 16, 1965)

Recently a number of organometallic π-complexes of π-allyl systems have been reported,[1] and the first π-allylic complex of rhodium(III), π-cyclododeca-1, 5, 9-trienyl-rhodium(III)-dichloride, has been isolated.[2] However, no report on an example of the π-allyl complexes of rhodium(I) has yet been published. In this paper we wish to describe the preparation of π-allyl-cycloocta-1, 5-diene-rhodium(I).

The treatment of a solution of bis-(cyclooct-1, 5-diene)-μ, μ'-diiodo - dirhodium[3] in anhydrous tetrahydrofuran with a four-equivalent amount of allyl magnesium bromide in ether at 0°C under nitrogen, followed by hydrolysis with aqueous ammonium chloride and chromatography on alumina, resulted in the formation of pale yellow crystals of π-allyl-cycloocta-1, 5-diene-rhodium(I), (yield, 30%; m. p. 108—112°C (decomp.). Found: C, 51.93; H, 6.97; mol. wt. (in benzene), 248. Calcd. for $C_{11}H_{17}Rh$: C, 52.39; H, 6.79%; mol. wt., 252).

The π-allylic sandwich structure for this compound is supported by its proton magnetic resonance in deuteriochloroform. The spectrum has a peak at 6.04τ of a relative intensity of 4 for the olefin hydrogens of the cyclooctadiene ring; a peak at 6.95τ of a relative intensity of 8 for the methylene hydrogens of the cyclooctadiene ring, and a multiline pattern at 4.83τ of a relative intensity of 1 for the central hydrogen atom of the π-allyl group. The characteristic doublets for the π-allyl group are present at 7.35τ and 8.38τ with J=6 c. p. s. and J=10 c. p. s. respectively, and with relative intensities of 2 : 2.

π-Allyl-cycloocta-1, 5 - diene - rhodium(I), was found to be diamagnetic, stable enough to be handled in air and soluble in most organic solvents, although it was poorly soluble in cyclohexane and decomposed slowly in hot cyclohexane. The treatment of π-allyl-cycloocta-1, 5-diene-rhodium with hydrochloric acid (in dichloromethane at room temperature) caused a cleavage of the compound at the π-allyl group; bis-(cycloocta-1, 5-diene)-μ, μ'-dichloro-dirhodium[3] was thus isolated. A similar result was obtained when the π-allyl rhodium complex was reacted with anhydrous aluminum chloride in dichloromethane at 0°C.

The Reaction of Benzenesulfonyl Azide with Phenylmagnesium Bromide

By Suketaka Ito

Department of Industrial Chemistry, Faculty of Engineering, Shinshu University, Nagano

(Received December 27, 1965)

Diazocyclopentadiene has been prepared by the reaction of cyclopentadienyllithium with *p*-toluenesulfonyl azide,[1] and some active methylene compounds have been diazotized by *p*-toluenesulfonyl azide in the presence of a base.[2]

This communication will report that benzenesulfonyl azide reacts with phenylmagnesium bromide to yield the salt of 3-benzenesulfonyl-1-phenyltriazene, which then decomposes to give phenyl azide and the salt of benzenesulfinic acid.

$$C_6H_5MgBr + C_6H_5SO_2N_3 \longrightarrow C_6H_5\text{-}N{=}N\text{-}N(MgBr)\text{-}SO_2C_6H_5$$

$$\longrightarrow C_6H_5N_3 + C_6H_5SO_2MgBr$$

Benzenesulfonyl azide was prepared by a modification of the procedure of Curtius,[3] by means of the action of sodium nitrite on benzenesulfonhydrazide in dilute hydrochloric acid. The almost colorless oily sulfonyl azide (n_D^{25}: 1.5488) was stored over anhydrous sodium carbonate in a dark place.

Into a stirred solution of 9.2 g. (0.05 mol.) of benzenesulfonyl azide in 60 ml. of dry ether, there was added over a period of 30 min., a solution of phenylmagnesium bromide (prepared from 1.5 g. (0.064 mol.) of magnesium and 9.4 g. (0.06 mol.) of bromobenzene in the usual way) in 60 ml. of ether at −18—−15°C; hereupon white precipitates separated simultaneously and the reaction mixture turned slightly yellow. The mixture was then separated by filtration into a yellow ether solution and a slight yellow solid, which was then washed with ether and dried in a vacuum desiccator. The yield was 21.4 g.

From the filtrate, 0.9 g. of unreacted sulfonyl azide was recovered.

In a 300 ml. round-bottomed flask 21.0 g. of the powdered solid was placed; the flask was then connected to a series of traps and a vacuum system. The flask was heated to 50°C (0.1 mmHg) to effect a final drying and then to 120—130°C (0.1—3.0 mmHg) in an oil bath for an hour.

Yellow crude phenyl azide was condensed at −70°C (4.9 g.; 82% of the theoretical amount); distillation in vacuo (4 mmHg) gave purified pale yellow azide (n_D^{25}: 1.5593), the infrared spectrum of which was spectroscopically identical with that of an authentic sample.

The reduction of the product with sodium and ethanol gave aniline, which was then acetylated with ketene to yield acetanilide, m. p. 114.0—114.5°C.

The residual powder obtained after the pyrolysis was dissolved in alkaline water and filtered; the filtrate was then acidified with hydrochloric acid. The resulting precipitate was filtered and dried to give 4.0 g. of benzenesulfinic acid, the infrared spectrum of which was spectroscopically identical with that of an authentic sample.

By the treatment of the sodium salt of the sulfinic acid with benzyl chloride in ethanol, phenyl benzyl sulfone was obtained, m. p. 147.0—148.0°C, its infrared spectrum was spectroscopically identical with that of an authentic sample.

The Anodic Oxidation of Ethylenediaminetetraacetic Acid and Its Divalent Metal Chelates at the Carbon Paste Electrode

By Toyokichi KITAGAWA and Syōichirō TSUSHIMA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 14, 1966)

Recent works in voltammetry[1,2] have shown the existence of oxide films on platinum electrodes after they had been anodized at highly positive potentials. Therefore, it is not suitable to use a platinum electrode as an indicator electrode at a positive potential region. A carbon paste electrode (graphite intimately mixed with Nujol) has been reported to possess unique advantages and to be very precise in anodic voltammetry.[3]

A single anodic wave of EDTA is observed in the pH range from 1.8 to 2.5, with $E_{P/2}$ of +0.93 V. (vs. SCE) varying slightly with the pH. A second wave appears in the pH range from 4 to 6. The second wave shifts to less positive potentials with an increase in the pH and merges into the first wave.

The peak current - concentration relationship is linear for the first wave in the range from 10^{-2} mM to 1 mM at any pH less than 5 and is reproducible within ±2 to 3%.

The anodic oxidation of metal-EDTA complexes containing a slight excess of metal ions in a 0.1 M HOAc - 0.1 M NaOAc buffer solution with 0.005% polyacrylamide was also investigated at the carbon paste electrode. According to the anodic oxidation potential of metal-EDTA complexes, the following four situations arise, as is shown in Fig. 1: (a) Co(II)EDTA is oxidized more easily than EDTA. The anodic oxidation of Co(II)EDTA to Co(III)EDTA was confirmed by chronopotentiometry. (b) Ni(III)EDTA shows an anodic wave at almost the same potential as that of EDTA. The peak current is, however, about one-half that of EDTA. (c) The anodic wave of Cu(II)EDTA appears at a potential less negative than that of EDTA. This peak current is also about one-half that of EDTA at the same concentration. (d) Cd(II)EDTA does not show any anodic wave until the final increase in the background current appears. Pb(II)EDTA and Zn(II)EDTA behave the same way.

The details of the mechanisms of these electrode reactions will be reported later.

The Proton Magnetic Resonance Spectra of Hydrogen Selenide and HDSe

By Kensuke TAKAHASHI and Genjiro HAZATO

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received January 17, 1966)

The proton magnetic resonance spectrum of HDSe has not yet been observed. Our interest has been drawn to comparing the proton-deuteron coupling constant of HDSe with such other hydrides as HDS[1]. After we had reported the multiplet structure of HDS in gas in a previous paper,[1] we observed the multiplet structures of both HDS and HDSe in liquid. Aluminum selenide[2] was placed in a bottle connected with a vacuum line and was treated with D_2O in a vacuum. In this case the impurity, H_2O, in D_2O was used as a source of the proton for HDSe. The D_2Se evolved, containing HDSe to a minor extent, was then introduced into a 5-mm. glass tube in a vacuum, with a small amount of TMS added as an internal reference. This liquid mixture of HDSe and D_2Se gave only a triplet signal of HDSe 0.85_5 p. p. m. upfield from that of TMS, as is shown in Fig. 1. The observed proton-deuteron coupling constant is 2.04 ± 0.05 c. p. s. The proton-proton coupling constant for hydrogen selenide thus obtained is 13.28 ± 0.33 c.p.s.; this magnitude is almost the same as that of HDS.[1]

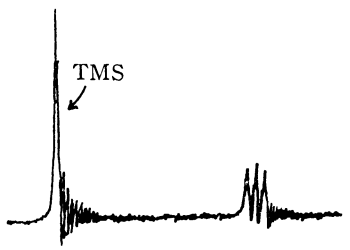

Fig. 1. The proton magnetic resonance spectrum of a liquid mixture of D_2Se and HDSe at 24°C in a sealed glass tube. The applied magnetic field increases from left to right.

Many factors may be considered to contribute to the coupling constants between two protons. In a way, it can be expressed as follows:

$$J_{ij}=A(r,\ \theta)\ \rho(i)\ \rho(j)$$

where $A(r, \theta)$ will be a function defined by the bond length, r, and the bond angle, θ, in a molecule, and where $\rho(i)$ and $\rho(j)$ express the electron densities around the protons in question, i and j respectively. In the case of the simple hydrides, H_nX, $\rho(H)$ will decrease with an increase in the electronegativity of X. Now we can compare the coupling constants of some simple hydrides, H_2O,[3] NH_3,[4] CH_4,[5] H_2S[1] and H_2Se. The order of the magnitudes of their coupling constants is approximately parallel to that of the decreasing electronegativities of the center atoms.

The isotope shift of HDSe with reference to H_2Se was also observed in the spectrum of the sample prepared by using a mixture of H_2O and D_2O as a reactant for aluminum selenide. The triplet of HDSe was centered 0.036 ± 0.003 p. p. m. upfield from the hydrogen selenide resonance, which overlapped with one of the triplet lines of HDSe. Two satellites were observed on both sides of the center band; they may be due to the isotope of selenium-77, the natural abundance of which is 7.5%. The observed proton - selenium-77 coupling constant for hydrogen selenide is 60.5 ± 0.5 c. p. s. As far as we know, this is the first case of a coupling constant observed in the direct H-Se^{77} bond. The signal of hydrogen selenide was also observed in the gaseous phase 1.78 p. p. m. upfield from TMS in contact with the liquid phase at 24°C,

The equilibrium constant of the following exchange reaction:

$$H_2Se + D_2Se \rightleftarrows 2HDSe$$

was estimated to be approximately 0.8 in liquid at 24°C by the use of the intensity measurement of the absorption signal of H_2Se and HDSe, and by the use of some approximations concerned with the initial concentration of hydrogen and deuterium. The rate of the above exchange reaction in liquid can be estimated to be slower than $0.5\ sec^{-1}$ at 24°C. Details will be given later elsewhere.

The Spectrophotometric Determination of Fluorine with a PAC-Th Complex

By Kyoji Tōei, Tadashi Hayami,* Haruo Miyata and Yasuaki Shimoishi

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama

(Received January 24, 1966)

In the course of our studies of the thorium complex formed with ortho-substituted phenylazochromotropic acid, it was found that the thorium complex of PAC, [2-(1, 8-dihydroxy-3, 6-disulfo-2-naphthylazo)-phenoxy acetic acid],[1] can be used in the spectrophotometric determination of microgram quantities of fluoride ions, and that the sensitivity of the thorium complex towards fluoride ions was almost twice that of the thorium Neo-thorin complex.[2]

The principle of the determination of fluoride ions with the thorium complex was the same as the case of the thorium Neo-thorin complex; it was based on the bleaching effect of the fluoride ions on the thorium complex.

Figure 1 shows the absorption spectra of the reagent and its thorium complex. The color of the reagent is pink, while the thorium complex is a bluish violet.

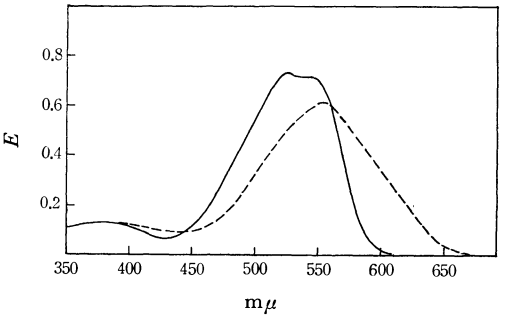

Fig. 1. Absorption spectra of the reagent and its thorium complex (broken line) at pH 2.7.
—— 2.0×10^{-5} M
---- Thorium concn. to the reagent concn. =0.68 : 1

Figure 2 shows the effect of pH on the absorbances of the thorum complex and the reagnet at 610 mμ. The absorbance of the thorium complex remains constant between the pH values of 2.5 and 4.0.

According to the mole ratio method, the thorium complex in the pH range was a 1 : 1 complex[1] formed completely by adding less than 0.75 mol. thorium to one mole of the reagent in the molar ratio cited. Therefore, the reagent used in the present experiment was composed of a 0.68 : 1 mixture of thorium and PAC (on the molar basis).

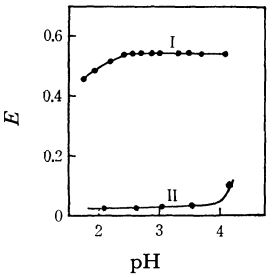

Fig. 2. Effect of pH on the absorbance of the thorium complex at 610 mμ.
I The thorium complex (the reagent concn.$=4.0\times10^{-5}$ M)
II The reagent

Figure 3 shows the calibration curve of fluoride ions: Five milliliters of the reagent (2×10^{-4} M), 0.3 ml. of the thorium nitrate solution (2.27×10^{-3} M), varying amounts (0—1.2 ml.) of the standard sodium fluoride solution (1.91×10^{-3} M) and 0.2 ml. of a 0.2 N perchloric acid solution were mixed in order to adjust the pH and then diluted to 25 ml. with distilled water. The absorbance was measured at 610 mμ in a 1 cm. cell against a water blank.

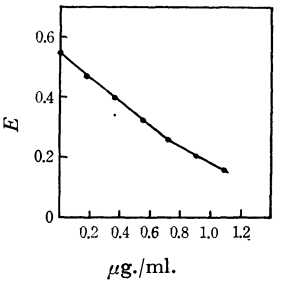

Fig. 3. Calibration curve of fluoride ion.

Beer's law is obeyed over the range from 0 to 0.6 μg. per ml. of fluoride ions.

Further, detailed studies are now in progress.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 639—642 (1966)

Effects of Pressure on the Chemical Properties of the Solid Surface. II. The Surface Acidity and the Catalytic Activity of Compressed Potassium Bisulfate

By Yoshisada OGINO, Takeshi KAWAKAMI and Kazuyuki TSURUMI

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Sakura-koji, Sendai

(Received April 13, 1965)

Experimental studies of the chemical properties of the surface of potassium bisulfate samples which had been subjected to compressions of 0—3750 kg./cm^2 at room temperature were carried out. Namely, on the compressed sample, the surface acidity at room temperature was measured by the indicator method, while the catalytic activity for the conversion of acetaldehyde to metaldehyde was measured at the temperature of a dry ice - methanol mixture by the bulk polymerization technique. Experimental results showed that the compression of the bisulfate resulted in an increase in the surface acidity at $H_0=1.5$ and in a reduction of the acidity at $H_0=4.0$. Further, it was found that the increase in the compressing pressure resulted in an increase in the catalytic activity of the sample. Thus, the existence of a close relation between the catalytic activity and the surface acidity at $H_0=1.5$, and the effectiveness of the pressure in the improvement of the catalytic activity through changing the acid strength distribution on the sample surface were experimentally demonstrated.

Little attention has been directed to the effect of compacting pressure on the chemical properties of solid surfaces. In view of this, the present authors started to study the surface properties of compressed solids; they have found[1] that the surface acidity of various metal sulfates can be varied by varying the compression. The present research is an extension of the finding to the field of surface catalysis.

According to the current theory[2] of catalysis, the surface acidity of a solid has a close relation to the catalytic properties of the solid; thus, an increase in the surface acidity is a useful way to improve the catalytic activity. A common way to increase the surface acidity is to heat the solid at a suitable temperature.[3] The compression of the solid has not yet been attempted.

In the present research, potassium bisulfate was chosen as the sample material, and the effects of compacting pressure on the surface acidity and the catalytic activity of the bisulfate in the conversion of acetaldehyde to metaldehyde were studied. The experimental results showed that the compression was effective in improving the catalytic activity. Further, the acid strength distribution, which is related to the catalytic activity, was found to vary upon compression.

Experimental

Sample.—About 0.5 g. of potassium bisulfate was compressed by essentially the same apparatus as that described in a previous paper.[1] Samples compressed at 0, 1250, 2500 and 3750 kg./cm^2 were prepared. The pelleted material was ground and pulverized in an agate mortar and stored for 6 hr. in a desiccator containing granules of freshly-dried silica gel. Immediately after the drying, the acidity measurement or the activity test was carried out.

Surface Acidity.—The acidity was determined by Benesi's method[4] with the following four indicators; phenylazonaphthylamine ($pK_a = 4.0$), *p*-dimethylaminoazobenzene ($pK_a = 3.3$), benzeneazodiphenylamine ($pK_a=1.5$), and dicinnamalacetone ($pK_a=-3.0$).

Catalytic Activity.—As a measure of the catalytic activity of the sample material, the conversion of acetaldehyde to metaldehyde was measured with the apparatus indicated in Fig. 1.

After the purified acetaldehyde (containing only traces of water) had been distilled in vacuo from Tube

D into Tube A, which was kept at −76°C, Tube A was weighed and the temperature was brought to 0°C. Then the aldehyde was distilled again in vacuo, at the rate of 10 g./hr., into the reaction tube, B, which was kept at −76°C and which contained 0.2 g. of catalyst powder. Finally, Tube A, containing residual aldehyde, was reweighed. This enabled us to evaluate the quantity of aldehyde monomers charged in the reaction tube. Usually the ratio of the monomer to the catalyst (by weight) was adjusted to 80.

The reaction was started by shaking the reaction tube; it was interrupted after 30 hr. by adding 20 ml. of a 1% solution of β-naphthylamine in acetone into the reaction tube. After the interruption of the reaction, the mixture in the reaction tube was filtered by suction. The solid product obtained on the filter paper was thoroughly washed with distilled water and, after it had been dried in vacuo, weighed. The conversion was estimated from the ratio of the weight of the product to that of the initial charge of the acetaldehyde monomer.

The solid product was identified by means of an infrared spectrometer and an X-ray diffractometer.

Results

Surface Acidity.—The relation between the surface acidity of potassium bisulfate and the compacting pressure is given in Fig. 2. As may be seen in this figure, the acidity at H_0*1=4.0 diminishes on compression, while the acidity at H_0=1.5 increases on compression. On the other hand, the acidity at H_0=3.3 varied in an irregular manner, and the acidity at H_0=−3.0 was essentially zero.

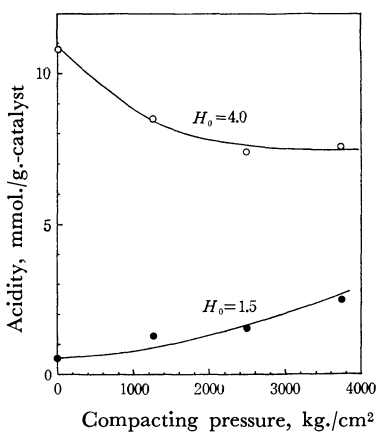

Fig. 2. Relations between the compacting pressure and the surface acidity.

Catalytic Activity.—The conversion of acetaldehyde to the solid product is given in Fig. 3 as a function of the compacting pressure. The figure shows that the catalytic activity of potassium bisulfate increases almost linearly with the compacting pressure.

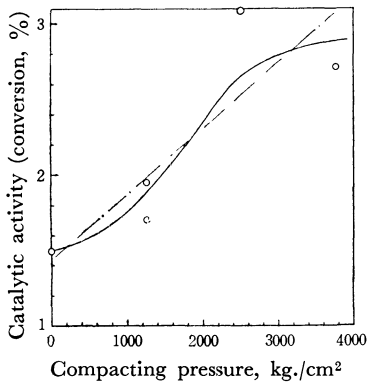

Fig. 3. The relation between the compacting pressure and the catalytic activity.

The reaction product was a white, non-tacky solid. This solid was found to decompose at 110—120°C, and it was insoluble in ordinary organic solvents. From the infrared absorption spectra given in Fig. 4 and the powder X-ray diffraction patterns given in Fig. 5, the reaction product was identified as metaldehyde. The other products, such as paraldehyde or high polymers, were found to be negligible.*2

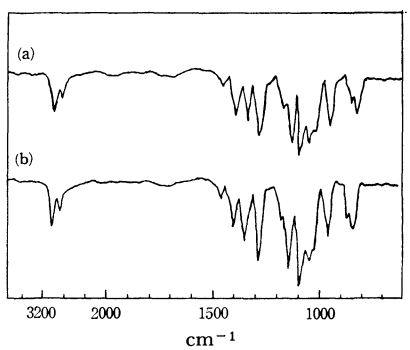

Fig. 4. Infrared absorption spectra of the solid product (a) and metaldehyde (b).

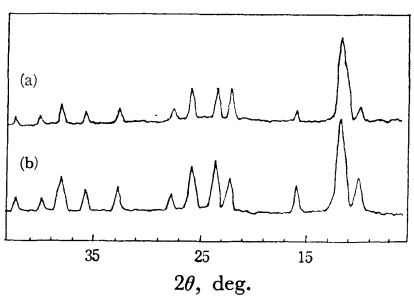

Fig. 5. X-Ray diffraction patterns of the solid product (a) and pure metaldehyde (b).

*1 H_0 means Hammett's acidity function (*J. Am. Chem. Soc.*, **54**, 2721 (1932)).

*2 By adopting some different methods of reaction, an amorphous high polymer of acetaldehyde could be formed using potassium bisulfate as a catalyst.

Discussion

One of the most important facts which were established in the present research is that the distribution of acid strength on the surface of potassium bisulfate varied upon compression. Calculations based on the experimental results indicated in Fig. 2 show that the total acidity, as defined by the acidity at $H_0=4.0$, was diminished to about 70% of the original value by the compression at 3750 kg./cm^2. On the other hand, the percentage of the acidity at $H_0=1.5$ against the total acidity was increased from 5% (original value) to 32% by the compression at 3750 kg./cm^2. These results show that the quantity of weak acid on the surface was reduced by the compression, while the quantity of the strong acid, which has a H_0 value between 1.5 and -3.0, was increased by the compression.

Although the detailed mechanisms of the change in the acid strength distribution have not yet been clarified, some important roles played by the crystal imperfections formed through the dehydration[1] of potassium bisulfate to potassium pyrosulfate may be supposed. According to high-pressure chemistry,[5] dehydration due to compression can occur. However, the same sort of dehydration may also occur when the sample is heated. In fact, Tanabe and his cowerkers[6] considered that the surface acidity of nickel sulfate is due to the crystal imperfection contained in an unstable phase produced by heating the sulfate. Thus, it must be suspected that the compression of the sample might cause a rise in the temperature of the sample.

According to a preliminary experiment*3 in the present work, the temperature of the sample was raised only 3°C by the compression at about 3000 kg./cm^2. Therefore, increases in the temperature on compression might not be the cause of the acidity change; the main cause of the change might be the formation of the crystal imperfection due to the compression.

As may be seen in Fig. 3, the catalytic activity of potassium bisulfate was increased by the compression. This experimental fact may be explained in terms of the acidity change on compression. The relations between the catalytic activity and the surface acidity at $H_0=4.0$ and at $H_0=1.5$ are given in Fig. 6. The figure reveals that the increase in the surface acidity at $H_0=4.0$ results in the reduction of the catalytic activity, whereas the increase in the surface acidity at $H_0=1.5$ makes the surface more active for the reaction. In the previous paragraph it was shown that the compression of potassium bisulfate was effective in increasing the surface acidity at $H_0=1.5$. Accordingly, it can be understood that the compression makes the surface richer in strong acids, whereby the surface of the bisulfate is brought to a more active state.

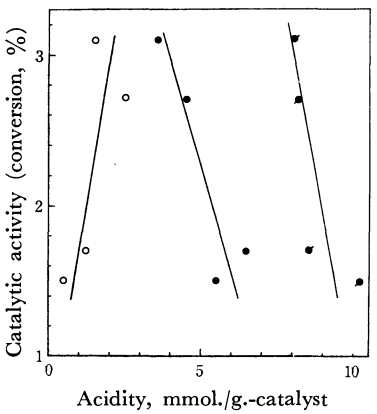

Fig. 6. Relations between the catalytic activity and the surface acidities at $H_0=4.0$ (◉), $H_0=3.3$ (●), and $H_0=1.5$ (○).

It is an important fact that the compression is effective in improving the catalytic activity through changing the acid strength distribution. Although the possibility of cases where the catalytic activity is independent of the total acidity can not be completely denied, many experimental results which support an intimate relation between the catalytic activity and the surface acidity at a given H_0 value can be seen in the literature. For instance, Takida and Noro[7] described how the catalytic activity of metal sulfates in the polymerization of acetaldehyde to an amorphous high polymer was dependent on the surface acidity at $H_0=3.3$. Thus, in order to improve the catalytic activity of acidic solids, some suitable procedures which can adjust the acid strength distribution on the solid surface are required. The experiments in the present research were confined to the case of potassium bisulfate, but it seems that the knowledge obtained here can make some contribution toward this requirement.

Summary

The acidic nature of the potassium bisulfate surface varied with the compression. Namely,

6) T. Takeshita, R. Ohnishi, T. Matsui and K. Tanabe, *J. Catalysts Soc. Japan* (*Shokubai*), **6**, 270 (1964).

*3 The temperature of the compressed sample was measured in the following way. The same apparatus as that described in the previous paper was used. A small hole, 3 mm. in diameter, was drilled at the center of the bottom cover of the apparatus. The inside opening of the hole was covered with a copper disk which was sufficiently thick to create an internal pressure of below 3000 kg./cm^2. Then the sample material was packed into the sample room of the apparatus, and it was compressed to about 3000 kg./cm^2. Thus, the disk was broken. At the instant of the breaking, the temperature of the sample which was flowing out from a hole opened in the disk was measured with a thermocouple.

7) H. Takida and K. Noro, *Chemistry of High Polymers* (*Kobunshi Kagaku*), **21**, 23 (1964).

the total acidity, as defined by the acidity at $H_0=4.0$, is reduced, while the acidity at $H_0=1.5$ is increased by the compression. These facts have been considered to show that the acid strength distribution on the surface of potassium bisulfate can be adjusted by the compression.

The catalytic activity of the bisulfate in the reaction of acetaldehyde to metaldehyde is increased by compressing the material. This increase in the catalytic activity can be related to the increase of acidity at $H_0=1.5$. On the basis of the experimental results, it has been suggested that the compression might be effective in improving the catalytic activity of acidic solids.

The Spectrophotometric Determination of Thiophene in Petroleum Naphtha with α-Nitroso-β-naphthol

By Masayuki KASHIKI and Kazuyoshi ISHIDA

Research Center, Maruzen Oil Co., Ltd., Shimotsu-Cho, Kaiso-Gun, Wakayama

(Received April 14, 1965)

A colorimetric method for the direct estimation of thiophene in petroleum naphtha without interference from the other sulfur compounds present has been worked out. The test is based on the blue-green color produced by the reaction between thiophene and α-nitroso-β-naphthol in the presence of sulfuric acid. The procedure accounted for from 10.0 mg./ml. of thiophene sulfur down to a mere trace of thiophene, of the order of 0.01 mg./ml. thiophene sulfur.

In the preceding paper[1] we have reported a s. w. polarographic determination of mercaptan compounds and free sulfur in petroleum naphtha. This paper will describe an investigation of α-nitroso-β-naphthol as a colorimetric reagent in concentrated sulfuric acid for the determination of thiophene. A survey of the literature revealed that α-nitroso-β-naphthol has not been reported on previously for the colorimetric determination of thiophene. The absorption curves of the reaction products are given in the visible region. Isosbestic absorption occurs at 640 mμ, where Beer's law is obeyed, and the color is stable for at least 4 hr. Thiophene can be determined in petroleum naphtha at concentrations as low as 0.01 mg. per ml., with a percentage error of 16.0%.

The effects on the absorbance of a reagent solution by many of the more common sulfur compounds were studied; the following compounds did not interefere at the concentrations tested: elemental sulfur (1.0 mg./ml.), di-*n*-butyldisulfide (1.0 mg./ml.), di-*n*-butylmercaptan (1.0 mg./ml.), and di-*n* butyltrisulfide (1.0 mg./ml.).

The reagent, which consists of α-nitroso-β-naphthol dissolved in concentrated sulfuric acid, reacts quantitatively with thiophene compounds, producing a stable blue-green color. The color formation, like that of the Indofenin reaction,[2-4] is believed to be due to the formation of dehydrocondensation compounds by the concentrated sulfuric acid in the reaction mixture.

Experimental

Reagents.—A thiophene (Tokyo Kasei Organic Chemicals) stock solution was prepared by dissolving thiophene of an analytical grade in petroleum naphtha free from sulfur compounds. It was then diluted with that same petroleum naphtha to a desired concentration. An α-nitroso-β-naphthol (Wako Chemicals) was dissolved in concentrated sulfuric acid (Ishizu Chemicals) to give a concentration of 5×10^{-5} mol./l.

Apparatus. — Spectrophotometric measurements were made with a Shimazu, model SV-50A, spectrophotometer, using 5 cm. transmission cells. All experiments were carried out at 25±0.5°C.

Procedure.—Pipet 2.5 ml. of 1×10^{-3}M α-nitroso-β-naphtohol solution and 10 ml. of the sample solution into a 100 ml. separatory funnel. Stopper the funnel and shake vigorously for at least 60 sec. Allow the two phases to separate, and draw off the lower sulfuric acid layer into a clean, dry, 50 ml. volumetric flask. Add 10 ml. of sulfuric acid, stopper the funnel, and shake for 30±5 sec. Again allow the layers to separate. Draw off the lower layer and combine it with the first extract in the 50 ml. volumetric flask. Dilute to volume with sulfuric acid and mix well.

Read the absorbance at 640 mμ, using a 5-cm. cell and using the reagent blank as the reference material.

Results and Discussion

The intensity and stability of the colored complex formed are not influenced by the temperature

of the solvents, the photochemical reaction, or the presence of impurities in the reaction mixture at 640 mμ. To illustrate the influence of each variable and to find the best conditions for obtaining reproducible results, each variable was considered separately.

Absorption Spectra.—The absorption spectrum of the reagent was studied from 380 to 720 mμ. The absorbance was negligible above 380 mμ, but it showed a steady increase at lower wavelengths without reaching a maximum. The absorption spectrum of the complex was studied from 380 to 720 mμ. No study was made below 380 mμ because of the high absorbance of the reagent in this range. Two absorption maxima occur in the spectrum of the complex between 380 and 720 mμ. The working portion of the curve is shown in Fig. 1. All the absorbance measurements for this investigation were made at 640 mμ in order to minimize the interfering absorbance of the α-nitroso-β-naphthol - thiophene complex, which is lower at this wavelength than at 430 mμ.

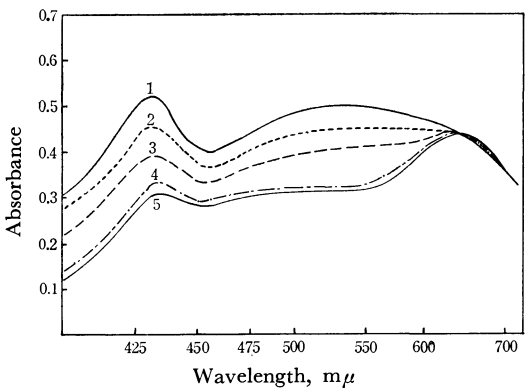

Fig. 1. Absorption spectrum of the reaction product of thiophene and α-nitroso-β-naphthol, and the effect of time.
1: 25 min. 2: 45 min. 3: 90 min. 4: 150 min.
5: 180 min. Thiophen: 0.85 mg./ml.

The Effect of Reagent Concentration.—In order to study the effect of the concentration of α-nitroso-β-naphthol, a series of absorbances was measured at various concentrations of α-nitroso-β-naphthol, using standard petroleum naphtha and reagent blanks of the same concentration as points of reference. Figure 2 gives the effect of the concentration of α-nitroso-β-naphthol in the reaction mixture on the absorbance of solution. It is apparent that a concentration of 5×10^{-5} mol./l. α-nitroso-β-naphthol is necessary in order to obtain a maximum color with this reaction. The absorbance at the isosbestic point of 640 mμ is affected by the amount of α-nitroso-β-naphthol below 5×10^{-5} mol./l. In the thiophene determination, therefore, a 5×10^{-5} mol./l. reagent solution was used, and the absorbance

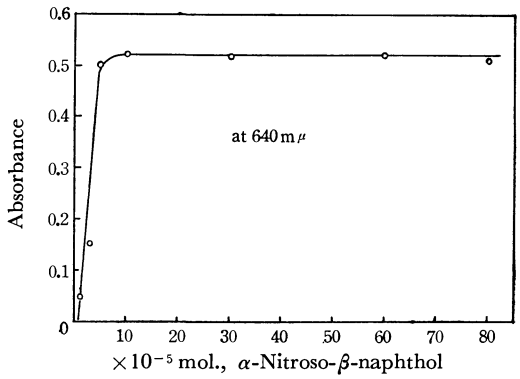

Fig. 2. The effect of addition of α-nitroso-β-naphthol. Thiophene: 1.0 mg./ml.

measurements were made at 640 mμ.

Shaking.—The maximum absorptivity was obtained when the α-nitroso-β-naphthol - concentrated sulfuric acid and petroleum naphtha (sample) were shaken vigorously for at least 60 sec. Procedure is recommended in order to minimize any variations resulting from differences in the rate of shaking.

The Effect of the Temperature on Color Formation.—The absorbance of the solution of the α-nitroso-β-naphthol - thiophene complex at 430 mμ gradually decreased with the time of standing at 10 to 35°C. About 15% of its intensity diminished within the first 2 hr., then it

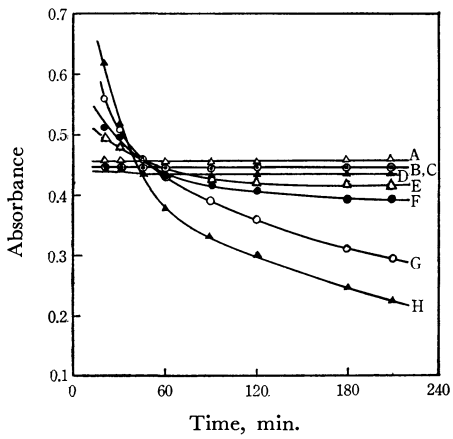

Fig. 3. Effect of temperature and time on color development.

Thiophene: 0.85 mg./ml.

remained constant for an additional 2 hr. However, the absorbance at the isosbestic point (see Fig. 1) of 640 mμ remained constant for several hours (see Fig. 3).

The Effect of the Photochemical Reaction.—The authors have found that ordinary room

light (from 100 W. tungsten bulbs) catalyzes the undesired reaction. Fig. 4 shows that the spectrum of the α-nitroso-β-naphthol - thiophene complex is stable if the solutions are kept in the dark or are exposed to light at 640 mμ, but that a change occurs at 430 mμ. The authors find that the absorbance at 430 mμ decreased appreciably in a few minutes if exposed to light, but it decreased much more slowly if kept in the dark.

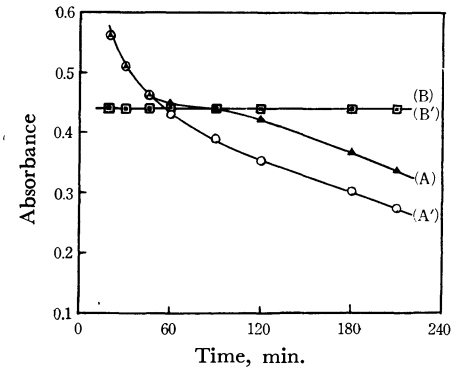

Fig. 4. Effect of light on spectra of α-nitroso-β-naphthol - thiophene complex.
Thiophen: 0.85 mg./ml.
(A): in Dark, (A'): in Light } 430 mμ, (B): in Dark, (B'): in Light } 640 mμ

Conformity to Beer's Law.—Measurements of the absorbance were made with a number of colored solutions containing varying amounts of thiophene. The straight-line calibration curve (see Fig. 5) showed a conformity to Beer's law for the concentration range studied. The useful range for a 5 cm. cell is 0.01 to 0.12 mg. per ml.

The Determination of the Formula of the Complex.—The methods of continuous variation[5] were employed in order to determine spectrophotometrically the reagent-to-thiophene ratio of the complex. The continuous-variations method was performed by mixing $4-X$ ml. of a 0.01 M solution of α-nitroso-β-naphthol and X ml. of a thiophene solution of the same concentration. Absorbance measurements were made at 640 mμ for the eight solutions. The continuous-variation plot using corrected absorbance values is shown in Fig. 6. The maximum absorbance occured at about a 0.5 mol. fraction of thiophene, indicating that one mole of α-nitroso-β-naphthol coordinated with one mole of thiophene.

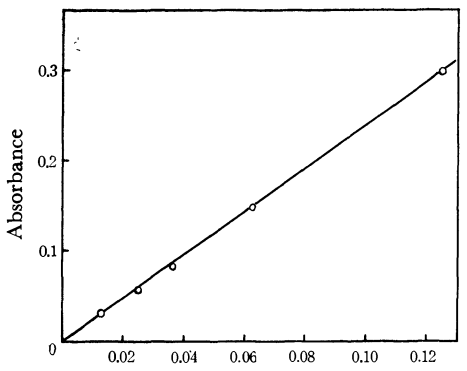

Fig. 5. Calibration curve.

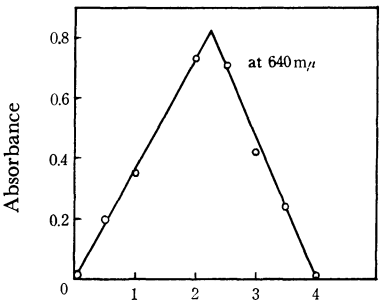

Fig. 6. Continuous variation method.
Continuous variation method applied to α-nitroso-β-naphthol - thiophene complex, X ml. of reagent added to $4-X$ ml. of thiophen solution.

Relative Error in the Determination of Thiophene.—The method seems to be the most favorable one for thiophene determination. The results obtained by the proposed procedure are shown in Table I.

TABLE I. RELATIVE ERROR IN THE DETERMINATION OF THIOPHENE

Concn. mg./ml.	Percentage error %
0.01	16.0
0.02	10.5
0.03_8	5.0

Calculation of the Three π—π^* Absorptions of Conjugated Systems by Hückel MO Method

By Kichisuke NISHIMOTO†

Mellon Institute, Pittsburgh, Pennsylvania, U. S. A.

(Received April 22, 1965)

Correlation relations between the Hückel molecular orbital energies and the absorption wavelengths of the ^1L_a, ^1L_b, and ^1B_b species of an alternant hydrocarbon are presented. After a small modification, the present relations are applied fairly well to the calculations of the electronic spectra of α-substituted hydrocarbon and *N*-heterobenzenes. This shows us that the nature of the electronic spectra of these compounds are very similar with those of parent hydrocarbon. On the other band, the calculation for β-substituted derivatives does not give good results, although the agreement between the calculated and observed values is semi-quantitatively satisfactory. This should be attributed to the complicated configuration interaction scheme between the lower excited configurations of the molecule.

It is widely recognized that the Hückel molecular orbital theory[1] (HMO theory) provides very useful theoretical information for the prediction of the various ground state properties of the conjugated molecules, such as bond distances, reactivity, resonance energy, and dipole moment, in spite of its appalling simplicity. However, only a few attempts[2] made to positively treat the electronic spectra of the aromatic compounds by HMO theory, because this theory does not explicitly, but only implicitly, take the electron repulsions into account. It would be, however, very convenient when we can calculate the electronic spectra of these compounds in the framework of HMO theory.

The present paper shows that there is a possibility for the prediction of the main three absorptions of a given aromatic compound in the near ultraviolet or visible region by HMO theory, when we set up an appropriate HMO transition energy - absorption wavelength relationship, just as in the case of the bond length calculation for which we usually use Coulson's bond order - bond length relation.[3] In this paper, first of all, we will provide some relationships between HMO transition energies and the absorption wavelengths of ^1L_a, ^1L_b, and ^1B_b species for the alternant hydrocarbon. Secondly, we will apply these relations to some *N*-heterocycles and aromatic derivatives. All of the HMO calculations are carried out by the IBM 7090 computer of the University of Pittsburgh.

HMO Energy - Absorption Wavelength Relations

Alternant Hydrocarbons.—The spectra of an aromatic hydrocarbon in the longer wavelength region has usually three absorption maxima: weak, medium, and intense bands, which on an empirical basis Clar[4] classified as α-, *p*-, and β-bands, respectively. However, on a theoretical point of view, a spectroscopic symbolism developed by Platt[5] on the basis of free electron model is more convenient for the classification of the absorption bands. According to this nomenclature, the ^1L_a band (Clar's *p*-band) is associated with a transition from the highest occupied MO, ψ_1, to the lowest vacant MO, $\psi_{1'}$. A convention given in the previous paper[6] is used for numbering of MO. In HMO theory, the MO energy associated with *i*th MO, ψ_i, is expressed by

$$\psi_i; \quad \varepsilon_i = \alpha + m_i\beta \tag{1}$$

where α and β are conventional Coulomb and resonance integrals, respectively. The eigenvalue m_i is a root of the secular determinant. The HMO transition energy associated with ^1L_a absorption is, therefore, given by

$$E(^1L_a) = (m_1 - m_{1'})\beta$$

or

$$\Delta m = E(^1L_a)/\beta = m_1 - m_{1'} \tag{2}$$

For the convenience, an excited configuration associated with one electron transition from an

occupied orbital, ϕ_i, to a vacant orbital, ϕ_j, is represented by χ_{i-j} in this paper. In an alternant hydrocarbon, the two excited configurations, $\chi_{1-2'}$ and $\chi_{2-1'}$ are degenerate, namely

$$\Delta m = m_1 - m_{2'} = m_2 - m_{1'} \qquad (3)$$

and interact each other by the first order configuration interaction, as shown in Fig. 1. This configuration interaction gives rise to a highly allowed intense ^1B_b band (Clar's β band) and a very weak ^1L_b band (Clar's α-band). According to the Pariser-Parr-Pople theory,[7] in which the electron repulsions are explicitly taken into account, the energy associated with a singlet electronic transition $^1\chi_{i-j}$ is given by:

$$\Delta E_{i-j} = \varepsilon_j^F - \varepsilon_j^F - [ii|jj] + 2[ij|ij] \qquad (4)$$

where ε_i^F and $[ij|kl]$ are the Hartree-Fock orbital energy associated with ϕ_i and the electron repulsion integral over MO's, respectively. The peculiar degeneracy in an alternant hydrocarbon,

$$\Delta E_{1-2'} = \Delta E_{2-1'}$$

is still valid in Pariser-Parr-Pople treatment. However, the comparison of Eq. 2 with Eq. 4 makes clear that in the discussion of electronic spectra, the conventional resonance integral β does not have its original meaning, which is a characteristic integral for a given carbon-carbon bond, but it is a complicated function of electron repulsion integrals and core integrals over atomic orbitals. The value should, therefore, depend on the molecular shape and varies from molecule to molecule. However, as shown in the previous paper,[6] in linear polyacene series the value of ε_i and $[ij|kl]$ monotonously decreases with increase in the molecular size.

7) K. B. Wiberg, "Physical Organic Chemistry," John Wiley & Sons, Inc., New York (1963), p. 116.

This suggests that in a linear polyacene series there are some relationships between the wavelengths of three main absorptions, $\lambda(^1L_a)$, $\lambda(^1L_b)$, and $\lambda(^1B_b)$, and the corresponding Δm values of Eqs. 2 and 3. The plot of the absorption wavelength against the $1/\Delta m$ in Fig. 2 shows excellent correlations. The correlations are satisfactorily represented by:

$$\lambda(^1L_a) = 474(\Delta m)^{-1/2} - 145 \text{ m}\mu \qquad (5)$$

$$\lambda(^1L_b) = 428(\Delta m)^{-1} + 50 \text{ m}\mu \qquad (6)$$

$$\lambda(^1B_b) = 358(\Delta m)\text{m}\mu \qquad (7)$$

respectively. Rather similar relations have been found by Streitwieser,[1] except for ^1L_a species. The calculated wavelengths for various hydrocarbons are compared with the experimental data in Table I. The agreement between the calculated and observed values is satisfactory in the whole. From Eq. 5, the conventional resonance integrals for ethylene and acetylene are estimated as $\beta_{C=C}=1.1\beta$ and $\beta_{C\equiv C}=1.2\ \beta$, respectively. In benzene and acetylene, the configurations $\chi_{1-1'}$ and $\chi_{2-2'}$ are degenerate and interact each other. This gives rise to a weak ^1L_a and strong ^1B_a absorptions. Therefore, the calculated $\lambda(^1L_a)$ should be compared with the harmonic mean of the observed $\lambda(^1L_a)$ and $\lambda(^1B_a)$.

The correlation equations, 5 and 7, have the following noteworthy features; that is, the transition energy associated with the ^1B_b species is proportional to the corresponding HMO energy ($\beta=-3.46$ eV.), whereas $\lambda(^1L_a)$ varies linearly with the inverse square root of Δm. This seems to suggest us that when we use the valence bond language the excitation from the ground state to the ^1L_a state may be described by the change in the covalent structure and that to ^1B_b state may be represented by the change from covalent to

charge resonance structure. Indeed, every ^1L_a absorption of a hydrocarbon is accompanied with the vibrational fine structure which is resulted from a vibronic coupling. Whereas, the ^1B_b absorption is usually consisted of only one sharp and high peak, as the absorption band in a charge resonance system, e. g. cyanine analogs[8] and some organic ions.[9] In polyacene series, the ^1L_a absorption is polarized to the direction of the molecular short axis.[10] On the other hand, the ^1L_b and ^1B_b absorptions are polarized in the direction of the molecular long axis. Consequently, the electron displacement in the ^1L_a species is limited at the largest in 2.78 A, however in the latter species the largest electron displacement will be proportional to the number of benzene rings. This situation may partly be responsible to such characteristic shifts as represented by the correlation equations.

α-Substituted Hydrocarbons.—In an aromatic derivative, the peculiar degeneracy of the two excited configurations, $\chi_{1-2'}$, and $\chi_{2-1'}$, of the parent hydrocarbon is removed by the perturbation of the substituent. Furthermore, this perturbation leads to an interaction between all configurations. However, as pointed out in the previous paper,[6] in α-substituted hydrocarbon which has an auxochromic substituent in the α-position, such as α-naphthol, $\chi_{1-2'}$ strongly interacts with $\chi_{2-1'}$, but only slightly with $\chi_{1-1'}$, so that the nature of the π—π^* absorption is practically the same as that of the parent hydrocarbon. We will, therefore, be able to calculate the $\lambda(^1L_a)$ of an α-derivative from Eq. 5. On the other hand, the calculations of the $\lambda(^1L_b)$ and $\lambda(^1B_b)$ are very difficult, because there is no means of estimating the interaction energy between the configurations χ_{1-2} and χ_{2-1}. The configurational energy associated with χ_{1-2} is approximately given by a harmonic mean of the hypothetical $\lambda(^1B_b)$ and $\lambda(^1L_b)$, which are calculated from Eqs. 6 and 7, using $\Delta m = m_1 - m_{2'}$. Similarly, the energy of $\chi_{2-1'}$ is estimated. One approximation is that a geometric mean of Δm_{1-2} and Δm_{2-1} is assigned to Δm. However, this approximation has not any theoretical background, but only an intuitive analogy with a well-known approximation for the interaction energy between two different molecules.[11] In summarizing, the three absorption wavelengths of an α-substituted hydrocarbon are calculated from the following equations;

$$\lambda(^1L_a) = 474(\Delta m_1)^{-1/2} - 145\ \mathrm{m}\mu \quad (8)$$

$$\lambda(^1L_b) = 428(\Delta m_2)^{-1} + 50\ \mathrm{m}\mu \quad (9)$$

$$\lambda(^1B_b) = 358(\Delta m_2)^{-1}\mathrm{m}\mu \quad (10)$$

where

$$\Delta m_1 = m_1 - m_{1'}$$

$$\Delta m_2 = \sqrt{(m_1 - m_{2'})(m_2 - m_{1'})}$$

Table II. Parameterr for HMO calculation

		C-F	0.6

a) = means an aromatic bond.

The HMO calculations are carried out using the parameters given in Table II. In Table II, the conventional Coulomb and resonance integrals are expressed as follows;

$$\alpha_X = \alpha + \delta_X\beta$$

$$\beta_{XY} = k_{XY}\beta$$

where δ_X and k_{XY} are the characteristic constants for atom core X and bond X-Y, respectively. It would be reasonable to compare α_X with the diagonal element of the Hartree-Fock operator, F_{XX}, over the π-AO of atom X. F_{XX} should be considered as the effective electronegativity of atom X in the molecule.[12] To a first approximation, α_X is, therefore, given by the valence state electronegativity, which was circumstantially investigated by Prichard and Skinner[13] and Hinze and Jaffé[14]. According to their study, the electronegativity in a given valence state increases almost linearly with the atomic number in the same period. The δ_X values given in Table II are in accord with their results. The calculated absorption wavelengths for some α-derivatives are compared with the experimental values in Table III. Table III shows that the simple correlations are still applicable to the prediction of the three main absorptions of these compounds.

Benzene Derivatives and *N*-Heterobenzenes.—In the calculation of benzene's $\lambda(^1L_a)$, we have used the harmonic mean of observed $\lambda(^1L_a)$ and $\lambda(^1B_b)$ as the reference, because they come from two degenerated configurations $\chi_{1-1'}$ and $\chi_{2-2'}$. In benzene derivatives and *N*-heterobenzenes, we can not neglect the configuration interaction between $\chi_{1-1'}$ and $\chi_{2-2'}$. Fortunately, this configuration interaction energy has, however, practically the same value with that of benzene.[6,12,15] So that, in good approximation, the $\lambda(^1L_a)$ of a benzene derivative or a *N*-heterobenzene is given by

In Table IV, the calculated absorption wavelengths of a number of benzene compounds are shown and compared with the experimental data. Generally speaking, the agreement between them is satisfactory, except for the $\lambda(^1L_b)$'s of *s*-triazine and 4-OH pyridine.

Micellaneous Compounds.—As pointed out in the previous paper,[6] in β-substituted derivatives, such as β-naphthol, all of the lower excited configurations interact strongly each other, so that the transition characteristics of the parent hydrocarbon are completely lost. Namely, we can not represent the ^1L_a species by $\chi_{1-1'}$ and so on. In attempts to explain the electronic spectra of a β-derivative, we have therefore to consider the interaction among all configurations. It would be, however, desirable to examine to what extent we can expect the electronic spectra of a β-derivative, making the same assumption with an α-derivative. In Table V, the calculated absorption wavelengths for quinoline, isoquinoline, phenanthrene, and their hydroxy derivatives, using Eqs. 8—10 are given and compared with the experimental values. Generally speaking, although the agreement between calculated and observed values is semiquantitatively satisfactory, it is not quite so good as that of α-derivative.

In order to explain the electronic spectra of a β-derivative by HMO theory, we have to set up other correlation equations considering the complicated configuration interactions. The present correlation equations predict fairly well the $\lambda(^1L_a)$ and $\lambda(^1B_b)$ of azulene as shown in Table V. The scheme of configuration interaction in a derivative having a chromophor, such as $-NO_2$, $-NO$, $-COR$, etc., is an intricate problem. However, the preliminary calculation shows that the ^1L_a absorptions of such derivatives are satisfactorily calculated by Eq. 8.

Conclusion

The results of this study indicate that the HMO method is applicable to the prediction of the three π-π^* absorptions of conjugated systems, when we set up the appropriate relationships. Simple correlation equations provided in the present study are particularly useful for the alternant hydrocarbons and their α-derivatives having an auxochromic group and also for some *N*-heterocycles. In order

to predict the electronic spectra of β-derivatives and the derivatives having a chromophor, we have to set up other relationships considering the complicated configuration interaction scheme.

Polyesters Containing Carbazole Rings in the Main Chain. III. Syntheses of New Polyesters from Carbazole-dibasic Acids

By Yoshio NAGAI and Chin-Chuan HUANG

Institute of Industrial Science, The University of Tokyo, Azabu, Tokyo

(Received May 18, 1965)

Several new polyesters were synthesized by the reaction of ethylene glycol with such carbazoledicarboxylic acids as carbazole-3, 6-dicarboxylic, 9-ethylcarbazole-3, 6-dicarboxylic, carbazole-3, 6-dibutanoic and 9-methylcarbazole-3, 6-dibutanoic acid in the presence of various catalysts.

Several new polyesters were prepared from ethylene glycol and acids of the general formula HO_2C-$(CH_2)_n$  $(CH_2)_nCO_2H$,[1,2] in which n is 0 or 3, and R indicates –H or alkyl groups (–CH_3 or –C_2H_5). With respect to the polymer-melt temperature, intrinsic viscosity, color, and resistance to organic solvents, the new polyesters have, in general, better properties than those derived from ethylene glycol and carbazole keto acids HO_2C-$(CH_2)_2OC$  $(CH_2)_2CO_2H$, in which R indicates –H or –CH_3 group.

Experimental

Preparation of Monomers.—The syntheses of carbazole - 3, 6 - dicarboxylic acid (CDA), diethyl carbazole - 3, 6 - dicarboxylate (diEtCD), 9 - ethylcarbazole-3, 6-dicarboxylic acid (9-EtCDA), diethyl 9-ethylcarbazole - 3, 6 - dicarboxylate (diEt 9 - EtCD), carbazole-3, 6-dibutanoic acid (CDBA), and 9-methylcarbazole-3, 6-dibutanoic acid (9-MeCDBA) were described in previous papers.[1,2] Ethylene glycol was purified according to the previous method.[2]

Polycondensation. — *Preparation of Poly(ethylene carbazole-3, 6-dibutanoate) (PECB) and Poly(ethylene 8 - Methylcarbazole - 3, 6 - dibutanoate) (9-MePECB).* — A highly polymeric PECB or 9-MePECB can be made by heating ethylene glycol with CDBA or 9-MeCDBA, in which the molar ratio of ethylene glycol and CDBA or 9-MeCDBA is 2 : 1. Preferably the higher molar ratios of ethylene glycol for the simple ester of the acid or the acid are used. During the ester interchange period the temperature advantageously approaches the boiling point of the glycol. In the first stage, in the preparation of β-hydroxyethyl carbazole-3, 6-dibutanoate or β-hydroxyethyl 9-methylcarbazole-3, 6-dibutanoate, there is no particular need to add the catalysts. Once all of the acid has reacted with glycol, the temperature is raised and the excess glycol is removed from the reaction mixture in the presence of various catalysts by distillation under reduced pressure. During this process of heating the viscosity of reaction mixture gradually increases. The heating may be effected in an inert atmosphere, for instance, in a stream of nitrogen gas.

Preparation of Poly(ethylene Carqazole-3, 6-dicarboxylate) (PECC) and Poly(ethylene 8-Ethylcarbazole-3, 6-dicarboxylate) (9-EtPECC).—Since CDA and 9-EtCDA sparingly dissolve in most organic solvents, diEtCD and diEt 9-EtCD are used in the polycondensation. The reaction is carried out under conditions in which the displaced ethanol can be removed by distillation. At least two moles of ethylene glycol per mole of diEtCD or diEt 9-alkylCD should be used. Preferably the heating is effected in an inert atmospher, and is continued until the distillation of the displaced ethanol ceases.

The low polymeric product can be converted into the highly polymeric polyester by heating it above 280°C for several hours under reduced pressure.

Examples of Polycondensation.—*PX-11*—One gram of ethylene glycol and 2.5 g. of CDBA were heated in the presence of 0.0026 g. of germanium dioxide in a stream of oxygen-free nitrogen for about 2 hr. at 194°C. The resulting β-hydroxyethyl carbazole-3, 6-dibutanoate was further heated in a stream of nitrogen for three hours at 237°C, and finally at 285°C for 30 min. The low polymeric product was then heated at 285°C for an additional 30 min. under reduced pressure (0.2 mmHg). The polycondensation product showed an intrinsic viscosity of 0.54 in *m*-cresol at

30°C; the color of the polymer was light yellow and transparent.

Found: C, 71.97; H, 6.39; O, 17.75. Calcd. for $-(C_{22}H_{23}O_4N)-$ or $-OC(CH_2)_3-C_{12}H_7N-(CH_2)_3CO_2-(CH_2)_2O-$, where $C_{12}H_9N$ is the carbazole ring: C, 72,23; H, 6.3; O, 17.53%.

9-MePECB.—A mixture consisting of 2.0 g. of 9-MeCDBA, 1.0 g. of ethylene glycol, and 0.003 g. of germanium dioxide was heated in a hard glass flask under the same conditions as in the previous example, thus giving a polyester which is light amber color and shows an intrinsic viscosity of 0.41 in *m*-cresol at 30°C.

Found: C, 72.01; H, 6.73; O, 17.20. Calcd. for $-(C_{23}H_{25}O_4N)-$ or $-OC(CH_2)_3-C_{13}H_9N-(CH_2)_3CO_2-(CH_2)_2O-$, where $C_{13}H_9N$ is the 9-methylcarbazole ring: C, 72.83; H, 6.59; O, 16.89%.

PX-5.—Two grams of diEtCD, 1.0 g. of ethylene glycol, and a blended catalyst of 0.005 g. of cobaltous acetate and 0.003 g. of calcium hydride were heated in a hard glass flask at 194°C for 1 hr. in a stream of oxygen-free nitrogen. The resulting β-hydroxyethyl carbazole-3, 6-dicarboxylate was heated at 235°C for 2 hr. in the same inert atmosphere and finally at 285°C for 30 min., while the pressure of the system was gradually reduced to 0.2 mmHg. Heating at 285°C was then continued for an additional hour under the same pressure. The product was a light yellowish-white opaque solid showing an intrinsic viscosity of 0.51 in *m*-cresol at 30°C; the polymer-melt point was above 210°C.

Found: C, 63.52; H, 4.08; O, 23.21. Calcd. for $-CO-C_{12}H_7N-CO_2(CO)_2O-$: C, 64.77; H, 3.91; O, 22.81%.

9-EtPECC.—A mixture consisting of 2.0 g. of diEt 9-EtCD, 1.0 g. of ethylene glycol, 0.005 g. of cobaltous acetate, and 0.002 g. of calcium hydride was allowed to react under the same conditions and over the same period as in the synthesis of PECC. The polycondensation product showed an intrinsic viscosity of 0.34 in *m*-cresol at 30°C.

Found: C, 69.57; H, 4.95; O, 21.48. Calcd. for $-(C_{18}H_{15}O_4N)-$ or $-OC-C_{14}H_{11}N-CO_2(CH_2)_2O-$, in which $C_{14}H_{11}N$ is the 9-ethylcarbazole ring: C, 69.90; H, 4.85; O, 20.71%.

Results and Discussion

As has been described previously[2] polyesters obtained from ethylene glycol and diethyl carbazole-3, 6-γ, γ'-diketobutanoate, diEtCDKB, or diethyl 9-methylcarbazole-3, 6-γ, γ'-diketobutanoate, diEt 9-MeCDKB, suffer from the defects of dark color

and brittleness, though they have rather good resistance to many organic solvents. It seems that the dark color of poly(ethylene CDKB) or poly(ethylene 9-MeCDKB) can be partly ascribed to carbonyl groups which attach directly to two benzene rings of the carbazole molecule and which may serve as possible chromophores, because PECB or 9-MePECB, which has no such groups, is in general a lighter color. Such catalysts as lead and cobaltous acetate or alkali metals can also exert a marked effect on the color of PECKB and PECB when added in large amounts. Blended catalysts

are prone to give a darker polycondensation products, as is shown in Table II.

Numerous PECB by adding different amount of germanium dioxide, ranging from 0.03 to 0.32% by weight of CDBA, exhibited a light yellow color, and the crude product was transparent. Figure 2 shows that the viscosity of the resulting PECB tended to decrease when more than 0.13% of germanium dioxide (based on the weight of CDBA) was added in a polycondensation. As is shown in Fig. 1, calcium acetate, used singly, was equally as effective as the combined catalyst ($Ca(CH_3CO_2)_2 \cdot H_2O/Sb_2O_3=4/1$). The antimony trioxide in combination with calcium hydride exerted a good effect, whereas it did not enhance the marked catalyst effect when used together with calcium acetate, as is shown in Table I.

Table V. Dependence of polymer-melt temperature on structure of acid component (acid or simple ester of general formula

		R_2	PMT (°C)

* Polymer softening temperature

The catalysts effective in the syntheses of PECKB and PECB were mostly ineffective in the preparation of PECC (for instance, calcium acetate or germanium dioxide). In the absence of calcium halide, the reaction of diEtCD and ethylene glycol at the early stage did not proceed smoothly, so that β-hydroxyethyl carbazole-3, 6-dicarboxylate was obtained in only a low yield. On the other hand the reaction proceeded readily in the presence of calcium hydride.

In the synthesis of PECC, calcium acetate as a single catalyst proved to be ineffective, whereas lead acetate was suitable. Under the influence of blended catalysts, such as lead acetate and antimony trioxide, an infusible and insoluble PECC was obtained. However, a mixture of lead acetate and calcium hydride or cobaltous acetate and calcium hydride was revealed to be a good catalyst blend in preparing PECC.

The polymer melt temperature or the polymer softening temperature depends greatly on the structure of the acid component, as is shown in Table V. In contrast to PECB, which was more susceptible to deformation by heat, PECC showed a fairly high polymer melt temperature.

The infrared spectra of the starting monomers and the polyesters (PECC, 9-EtPECC, PECB, and 9-MePECB) were compared in order to establish the structures of polycondensation products. Figures. 3, 4 and 5 show the characteristic N–H stretching absorptions. As is illustrated in the figures, these absorptions are apparently absent in the spectra of 9-MeCDBA, 9-MePECB, 9-EtCDA, and 9-EtPECC. The presence of an aromatic-type structure is also evidenced by the absorption near 3030 cm^{-1}, as shown in Figs. 3, 4, and 5. These characteristic absorptions, as

well as other absorptions in the lower regions of the charts (arising from the C=O and C=C groups), together with the data of the elementary analyses of the polyesters, indicated that PECB and PECC are linear polyesters with the following recurring units:

PECB, $-(OCOC_3H_6-C_{12}H_7N-C_3H_6CO_2C_2H_4O)-$, in which $-C_{12}H_7N-$ is the carbazole ring; PECC, $-(OC-C_{12}H_7N-CO_2C_2H_4O)-$. in which $-C_{12}H_7N-$ is the carbazole ring.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 654—664 (1966)

Single Stage Oxidation of *p*-Xylene with Ozonized Air

By Tsuguo TAKAYA, Tadashi KOGA and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received May 22, 1965)

A new method has been found by which terephthalic acid can easily be obtained by a single-stage oxidation of *p*-xylene in glacial acetic acid. *p*-Xylene was oxidized with ozonized oxygen or air at 90°C in the presence of cobaltous acetate, ammonium bromide and an unsaturated aliphatic compound such as tetrachloroethylene. The effects of various factors on the oxidation rate were examined by measuring the absorption rates of oxygen. The reaction rates were measured for two steps, i. e., *p*-xylene to *p*-toluic acid and *p*-toluic acid to terephthalic acid, in the presence and absence of ozone respectively. The reaction mechanisms for each step have been discussed. It seems that the role of ozone and tetrachloroethylene in the present oxidation reaction can be attributed to the formation of ozonide which is transformed to hydroperoxide and which then participates in the chain reaction.

Many attempts have been made to obtain terephthalic acid by the oxidation of *p*-xylene with nitric acid,[1] air,[2] or oxygen gas,[3] sulfur in ammonium hydroxide[4] or ammonium sulfide,[5] and their combinations,[6] etc. Most of these attempts have been carried out under drastic reaction temperature and pressure conditions. The method developed by Brill[3] gives terephthalic acid in a good yield by the single-stage oxidation of *p*-xylene under the following conditions: oxidizing agent: oxygen gas; pressure: 1 atm.; solvent: glacial acetic acid; temperature: 90°C; catalysts: cobaltous acetate tetrahydrate; activator: a ketone containing an α-methylene group; and reaction time: 24 hr. However, the reaction does not proceed with air instead of oxygen. The present experiment was, therefore, carried out with the objectives of finding a catalyst with which the oxidation reaction of *p*-xylene is allowed to proceed under conditions milder than those in the conventional method, and of clarifying the reaction mechanism.

As a result of experiments, a new method was developed, and crude terephthalic acid was obtained in an about 95% yield under the following conditions: temperature: 90°C; pressure: 1 atm.; reaction time: 6 hr.; catalysts: cobaltous acetate, ammonium bromide, and a small amount of unsaturated aliphatic compound; oxidant: ozonized oxygen or air; and solvent: glacial acetic acid.

Though the ozone[8] has been reported to be effective as an initiator for the liquid-phase oxidation of *p*-xylene, no method has been reported in detail. According to the present procedure, the methyl groups bonded directly to the benzene ring are easily oxidized to the carboxyl groups, and crude terephthalic acid is obtained in a 83—85% yield by the single-stage oxidation of *p*-xylene using air which contains about 0.5% ozone. Unsaturated aliphatic compounds are effective as the promotor; upon their use the yield of terephthalic acid increases more than 10%.

Though the rate equation in the oxidation stage from *p*-toluic acid to terephthalic acid has been given by Ravens,[7] no rate equation has been reported with the *p*-xylene → *p*-toluic acid, and *p*-xylene → *p*-toluic acid and *p*-toluic acid → tetrephhalic acid oxidations using ozonized oxygen. Therefore, the rate equation was studied by measuring the absorption rate of oxygen gas, and the reaction mechanism was considered.

Experimental

Reagents.—*p*-Xylene (98.5% purity) presented by the Maruzen-Sekiyu Co., Ltd., was treated with sulfuric acid, sodium hydroxide, and water in that order,

1) U. S. Pat. 2636899 (1953).
2) U. S. Pat. 2833816 (1958).
3) W. F. Brill, *Ind. Eng. Chem.*, **52**, 837 (1960).
4) U. S. Pat. 2762839 (1956).
5) W. A. Pryor, *J. Am. Chem. Soc.*, **80**, 6481 (1958).
6) For example, U. S. Pat. 2653165 (1954).
7) D. A. S. Ravens, *Trans. Faraday Soc.*, **55**, 1768 (1959).

dehydrated, and distilled; the distillate was then purified by fractional crystallization. Acetic acid containing 0.38 wt.% water was used. The cobaltous acetate and ammonium bromide were of the reagent grade. The tetrachloroethylene was treated with sulfuric acid, sodium hydroxide, and water in that order, and distilled. The other reagents were used after purification.

Apparatus.—A Siemens-type ozonizer was built up with Pyrex glass, and about 10 kV. of voltage was applied to it through a transformer. The ozonized air was washed with a 10% sodium hydroxide solution in order to remove the oxides of nitrogen, dehydrated with concentrated sulfuric acid and calcium chloride (anhydride), and introduced into a reaction vessel. A 500 ml. reaction vessel attached with four holes to a thermometer, a stirrer, a condenser, and a gas-inlet was used. The reaction vessel was heated by a mantled heater. The oxidants were introduced into the reaction vessel through the ozonizer from an oxygen bomb or after the compressed air had been dehydrated with concentrated sulfuric acid and silica gel. The reaction rate was measured by the apparatus shown in Fig. 1. F is thermostatted at 90°C in an oil-bath, and A, B, and C at 25°C. *p*-Xylene is made to react with oxygen in the cell, F, and the solution is stirred by a magnetic stirrer. The manostat, B, operates by the absorption of oxygen gas, and then the electrolyzer, D, operates until the oxygen pressure in the system becomes equal to the original. The gas evolved by D is sent to the left-hand side of the gas-burette, A, and the meniscus of the right-hand side is raised. The amount of oxygen gas absorbed is read on the right-hand side of A. To operate this apparatus, all the cocks except the cocks 3, 7, 8, and 12 are opened, and the system is evacuated. Then the cocks 1 and 4 are closed in that order, and more than 1 atm. of oxygen gas is introduced into the balloon through the cock 3. The cock 4 is opened, and the system is filled with oxygen gas. The cocks 4 and 2 are closed in that order, and the cock 1 is opened. The cock 7 is gradually opened. For a measurement, the cock 8 is opened, and the cocks 5, 6, 7, 9, 10, and 11 are closed, followed by the opening of the cock 12. When the meniscus of A on the right-hand side has risen up to the top, the cocks 6, 9, and 11 are opened after the closure of the cock 12 and the opening of the cocks 10 and 7, and the measurement is continued as before. F is dipped into the oil-bath when the cock 15 is opened, and the cock is closed just before the measurement. Since the vapor pressure of acetic acid at 90°C is 300 mmHg, the vapor pressure of air at the same temperature is given by 760−300=460 mmHg. By assuming the composition of the air to be $O_2 : N_2 = 1 : 4$, the partial pressure of oxygen gas at 90°C is found to be approximately 92 mmHg through all the experiments.

The Analysis of the Oxidation Products.—After the reaction had finished, the products were filtered, washed with glacial acetic acid and water, dried, and weighed, and the yields of crude terephthalic acid were calculated. When an aliquot amount of crude terephthalic acid was esterified with methanol and sulfuric acid, the ester showed a m. p. of 140.2—140.9°C. The aldehyde content was determined by dissolving a sample in an excess silver nitrate/ammonium hydroxide solution, by filtering the deposits off, and by estimating the remaining silver by the Volhard method. The carboxyl group content was also determined conductometrically by dissolving an aliquot amount of the sample in ammonium hydroxide and by titrating it with a standard lithium hydroxide solution. According to this procedure, each acid is determined graphically, since the mixture consisting of mono- and di-basic acids gives two inflection points on the titration curve.

The Determination of the Ozone.—The apparatus shown in Fig. 2 was devised. In Fig. 2, I is the inlet for the sample gas, and II, the outlet. In order to determine the ozone content, the gas sample is passed through the flask, III, and then the cock, IV, and the flask are turned to take a definite volume of the sample. The vessel, V, is filled with an excess potassium iodide solution, and most of the solution is dropped into III by compressed air, after which IV is closed. Then the apparatus is shaken for a minute, and the flask is taken off. The inside of the upper part is washed down with water, and the combined solution is titrated with a standard sodium thiosulfate solution. The results obtained by this procedure agreed with those obtained by the conventional method; the ozone contents in the ozonized oxygen gas and air used in this experiments were approximately 1.0 and 0.5 vol.% respectively.

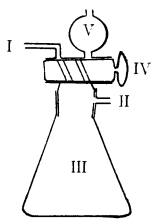

Fig. 2. An apparatus for determination of ozone in ozonized gases.
I: Gas inlet IV: Cock
II: Gas outlet V: KI tank
III: Flask

The Measurement of the Reaction Rate and Order.—The sample is put in the reaction cell, and the

cell is heated at 90°C for 5 min. After exactly 5 min., or after 10 minutes' passage of the ozonized oxygen containing approximately 0.8 vol.% ozone, the measurement is started, and the oxygen amount absorbed is read at definte intervals. The reaction rate was expressed as the mean value obtained by dividing the total oxygen amount absorbed by the reaction time.

In order to determine the reaction order of a certain component, the oxygen amount absorbed was measured under conditions in which the concentration of the component was varied, and the reaction rate was plotted against the concentration of the component. The reaction order of the component was found from the slope of a straight line on the graph.

Results and Discussion

The Oxidation of *p*-Xylene with Ozonized Oxygen.—In order to examine the effect of ozone on the oxidation of *p*-xylene, the reaction was carried out under the following conditions: acetic acid: 200 ml.; *p*-xylene: 25.0 ml.; cobaltous acetate tetrahydrate: 4.982 g.; ammonium bromide: 0.1 g.; tetrachloroethylene: 1.0 ml.; reaction temp.: 90°C; ozone content: 1.0 vol.%; gas flow rate: 140 l./hr.; and reaction time: 6 hr. The results obtained are shown in Table I.

TABLE I. THE EFFECT OF OZONE ON THE YIELDS OF TEREPHTHALIC ACID

No.	Yield %	No.	Yield %
1	77.1	4	82.4
2	68.7	5	93.5
3	72.1	6	95.6

No. 1: Ozonized oxygen until the deposit of terephthalic acid, and then oxygen alone
No. 2: Oxygen alone until the deposit of terephthalic acid, and then ozonized oxygen
No. 3: Oxygen alone
No. 4: Ozonized oxygen for 2 hr., and then oxygen for 4 hr.
No. 5: Ozonized oxygen for 3 hr., and then oxygen for 3 hr.
No. 6: Ozonized oxygen for 6 hr.

It has been reported that ozone is effective as an initiator,[8] but it is not always necessary after the solution has become dark green. However, it may be seen from Table I that ozone is effective not only as an initiator but also as an activator during the reaction. In order to examine the effect of aliphatic unsaturated compounds on the yields of terephthalic acid, the oxidation was carried out under the same conditions as before except in the presence of various unsaturated compounds. The results obtained are shown in Table II. As can be seen from Table II, the yields increase in the presence of aliphatic unsaturated compounds. This seems to be because of the interaction between the ozone and the double bond.

It has been also reported[9] that *p*-xylene could be oxidized into terephthalic acid under these conditions: catalysts: Co^{2+}, Mn^{2+}, Cl^-, and Br^-; solvent: propionic acid; reaction temp.: 137°C; and reaction time: 5.1 hr. It may, however, be supposed from Table II and the data that the double bond may affect the yields of terephthalic acid more than chloride ions. The product is white in the presence of chloride ions, while yellow in their absence. Therefore, tetrachloroethylene was used as the aliphatic unsaturated compound in the experiments below. The experiments were also designed to examine the effects of cobaltous acetate, bromide, and tetrachloroethylene on the yields of terephthalic acid; the results obtained are shown in Tables III and IV.

Judging from the results shown in Tables III and IV, the following conditions are recommended for the oxidation of *p*-xylene: acetic acid: 200 ml.; *p*-xylene: 25.0 ml.; cobaltous acetate tetrahydrate: 4.982 g.; ammonium bromide: 0.1 g.; tetrachloroethylene: 1.0 ml.

Cobaltous acetate and ammonium bromide had the main effects on the yields. In the case of the oxidation with ozonized oxygen, no interaction was found among cobaltous acetate, ammonium bromide, and tetrachloroethylene, while the reverse was true in the case of the oxidation with oxygen alone. It may, therefore, be supposed that cobalt, bromide, and tetrachloroethylene may be separately activated with ozone to take part in the oxidation reaction. The relationships between the reaction time, or the reaction temperature, or the water content, and the yields were also examined by carrying out the oxidation under the optimum conditions mentioned above; the yields were 35.2, 64.9, 89.6, 94.7 95.6, 96.8, and 97.3% for 2, 3, 4, 5, 6, 8, and 10 hours' reactions respectively; 0, 56.3, 63.3, 69.2, 96.1, and 83.5% at 50, 60, 70, 80, 90, and 100°C respectively; and 92.4, 89.8, 90.1, 90.6, 87.0, 81.2, 78.2, and 22.9% in 0, 1.0, 2.0, 3.0, 4.0, 10.0, 15.0, and 20.0 ml. of waters respectively.

The oxidation products were analyzed by the above mentioned procedures; the results are

2	88.6	2.9	8.6
3	87.2	5.8	6.8

shown in Table V. *p*-Toluic acid and *p*-formylbenzoic acid were found as the impurities. *p*-Formylbenzoic acid was easily oxidized into terephthalic acid with Tollen's reagent, and terephthalic acid was recovered with a purity of ca. 99%. Since the contamination with *p*-formylbenzoic acid as an impurity is a serious obstacle to obtaining highly-pure terephthalic acid, an effort is being made to prepare the terephthalic acid free from *p*-formylbenzoic acid.

The present method was further applied to the oxidation of alkylbenzenes; the yields of benzoic acid from toluene, isophthalic acid from *m*-xylene, and phthalic acid from *o*-xylene in 6 hours' reaction were 97.4, 93.3, and 48.8% respectively. However, the yield of phthalic acid increased to 95.2% in 10 hours' oxidation.

The oxidation rate of *o*-xylene is smaller than those of *m*- and *p*-xylene; this shows a close relation with the average reaction rate,[10] $o < m \fallingdotseq p$,

in the xylene isomers. It has been reported that the smaller reaction rate of *o*-xylene seems to be based on the chelation between cobaltous ions and phthalic acid, and on the fact that the acidity[10] of phthalic acid is stronger than that of the others.

The Oxidation of *p*-Xylene with Ozonized Air.—The oxidation procedure with ozonized air differs from that with ozonized oxygen in the following points; 1) Ozonized air is blown into the solution; 2) The ozone content is

K: Cobaltous acetate, L: Ammonium bromide, M: Tetrachloroethylene

about 0.5%; 3) The flow rate is about 300 l. per hour; 4) Two portions of ammonium bromides are added, one at the beginning of the reaction and the other at just one-half the time from the deposit of terephthalic acid to the end, and 5) Chloroacetic acid is added as a co-catalyst.

The effects of ammonium bromide on the yields are shown in Table VI.

It was found that the yields in the presence of tetrachloroethylene increase by 10—13%. The yields were 70.9, 74.5, 75.6, 81.3, 81.1, 79.0, and 57.1%, respectively in the presence of each 0.1, 0.2, 0.3, 0.5, 0.8, 0.9, and 0 g. of chloroacetic acids. Since terephthalic acid was obtained in a high yield in the case of ozonized oxygen, the effects of chloroacetic acid could not be discriminated from its yield. Chloroacetic acid has been reported[11] to be effective for the oxidation of *p*-xylene; this coincides well with the present results. In the coming experiments, chloroacetic acid is always added in 0.5 g. portions until otherwise stated.

The yields were 58.9, 69.3, 81.3, 70.0, 67.9, and 63.6%, respectively, with each 2.491, 4.982, 7.473, 9.964, 12.455, and 14.946 g. of cobaltous acetate tetrahydrate. As may be seen from these results, up to a definite concentration Co^{2+} behaves positively, while it behaves negatively with a greater concentration. Since it has been established that the metal ions showing reversibly changeable valencies often behave as inhibitors in the radical chain reaction,[12,13] the negative behavior of cobaltous ions seems to be based on a similar mechanism.

The yields were 84.3, 87.6, 87.8, and 90.3%, respectively, in 6, 7, 8, and 10 hours' reactions. Since some *p*-xylene was lost, together with some air, it was difficult to raise the yields higher, even by making the reactions last more than 10 hr. When the oxidation products were analyzed, they were found to be composed of 76.9—79.6% terephthalic acid, 10.5—11.97% *p*-toluic acid, and 10—14.8% *p*-formylbenzoic acid. It was also noted that the contents of *p*-toluic acid and *p*-formylbenzoic acid are larger than those in the ozonized oxygen.

The Reaction Rate from *p*-Xylene to *p*-Toluic Acid.—At first, the reaction rate was measured under an oxygen pressure of 92 mmHg without allowing the solution to come in contact

with the ozone. The amounts of the oxygen absorbed were measured on the basis of the design of the experiments in which cobaltous acetate, ammonium bromide, and tetrachloroethylene are looked upon as factors; duplicate experiments are planned at the level of $2\times2\times3$. Tables VII and VIII show the original data and the analysis of the variance respectively.

When the significant level is adopted as 10% by taking the reproducibility and the error in measurement into account, the effects are found in all the factors. However, the main effect of cobalt, and the interaction between cobaltous ions and bromide, are predominant among them. The reaction shows an independence of the concentration of *p*-xylene. The reaction also shows a first-order dependence on the concentration of cobaltous acetate at $[Co^{2+}]\leqq0.024$ mol./l.; thereafter the rate decreases with an increase in $[Co^{2+}]$. The reaction shows a one-fourth-order dependence on the concentration of ammonium bromide at $NH_4Br\leqq10.0$ mg., and a negative one-half-order dependence on the concentration of tetrachloroethylene. The negative effect of tetrachloroethylene in the absence of ozone seems to be based on the facts that tetrachloroethylene can be only activated with difficulty and that it consumes the radical in the radical chain reaction. Because 1) the reaction mixture does not become dark green at all, just as in the presence of a considerable amount of bromide, and 2) the interactions among cobalt, bromide, and tetrachloroethylene are found in the design of experiments, it may be supposed that tetrachloroethylene not only consumes the radical but also accelerates the reaction from cobaltic to cobaltous ions in accordance with the following mechanism:

$$Co^{3+} + HBr \rightleftharpoons Co^{2+} + Br\cdot + H^+$$

$$Cl_2C{=}CCl_2 + Br\cdot \cdots\longrightarrow \text{inactives}$$

The reaction shows a first-order dependence on the concentration of chloroacetic acid at $[ClCH_2COOH]\leqq0.13$ mol./l.

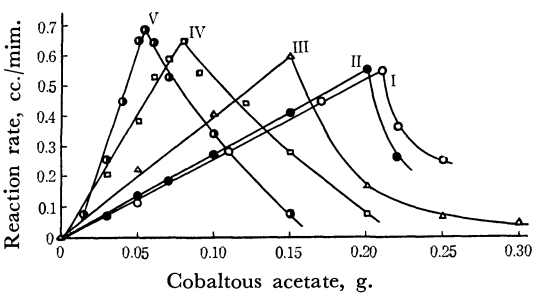

Fig. 3. Relationship among the amounts of cobaltous acetate and ammonium bromide, and the reaction rate.
I: NH_4Br 0.005 g. IV: NH_4Br 0.030 g.
II: NH_4Br 0.010 g. V: NH_4Br 0.040 g.
III: NH_4Br 0.020 g.

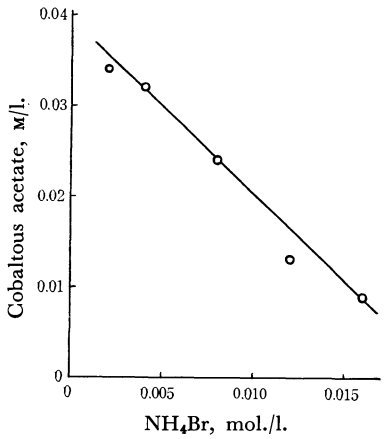

Fig. 4. Relationship between the amounts of cobaltous acetate and ammonium bromide at the maximum reaction rates.

The relationship among the reaction rate and the concentrations of cobaltous acetate and ammonium bromide is given in Fig. 3. The relationship between the concentrations of cobaltous acetate and ammonium bromide at the maximum absorption rate is further shown in Fig. 4, where it is given by a straight line. On the basis of Fig. 4, the relationship is expressed as follows:

$$[Co^{2+}] + 2[NH_4Br] \leqq 0.04 \text{ mol./l.}$$

By combining the above results, the reaction rate at $[Co^{2+}] + 2[NH_4Br] \leqq 0.04$ mol./l. and $[ClCH_2COOH]\leqq0.13$ mol./l. is expressed by the following equation:

$$R_1 = k_1[Co^{2+}][NH_4Br]^{1/4}\cdot [ClCH_2COOH][Cl_2C{=}CCl_2]^{-1/2}$$

With the objective of examining the effect of ozone on the initial reaction, the absorption rate of oxygen after 10 minutes' passage of ozonized oxygen was measured. Though the reaction rates in the above experiments were measured under an oxygen pressure of 92 mmHg, those after the passage of the ozonized oxygen were measured under an oxygen pressure of 460 mmHg. The reaction shows one-half-order, three-second-order, one-half-order at $[NH_4Br]/[Co^{2+}]\leqq5/4$ or first-order at $[NH_4Br]/[Co^{2+}] > 5/4$, zero-order, and zero-order dependences on the concentrations of *p*-xylene, cobaltous acetate, ammonium bromide, tetrachloroethylene, and chloroacetic acid, respectively.

It may be noted that tetrachloroethylene has a negative effect on the progress of the reaction in the absence of ozonized oxygen, while the reaction rate after 10 minutes' passage of ozonized oxygen is independent of the concentration of tetrachloroethylene. Therefore, ozone may be expected to exert a positive effect on the reaction when it is passed through during the experiment.

This is consistent with an increase of the yield of terephthalic acid in the presence of ozone.

To summarize the above results, the initial rates after 10 minutes' passage of ozonized oxygen are as follows:

$$R_2 = k_{II}[p\text{-xylene}]^{1/2}[Co^{2+}]^{3/2}[NH_4Br]^{1/2} \quad \text{at } [NH_4Br]/[Co^{2+}] \leqq 5/4$$

$$R_3 = k_{III}[p\text{-xylene}]^{1/2}[Co^{2+}]^{3/2}[NH_4Br] \quad \text{at } [NH_4Br]/[Co^{2+}] > 5/4$$

The Reaction Rate from *p*-Toluic Acid to Terephthalic Acid.—At first, the absorption rate of oxygen in the absence of ozone was measured much as in the above experiment. The reaction shows an independence of the concentration of *p*-toluic acid, and a first-order dependence on that of cobaltous acetate. The reaction shows a one-half-order dependence on the concentration of ammonium bromide at $[NH_4Br] \leqq 0.04$ mol./l. and $[NH_4Br]/[Co^{2+}] \leqq 5/4$. The reaction rate increases ca. 12.5% upon the addition of any tetrachloroethylene, while it shows independences of the concentrations of chloroacetic acid and tetrachloroethylene. To summarize the above results, the reaction rate may be given as follows:

$$R_4 = 1.125k_{IV}[Co^{2+}][NH_4Br]^{1/2}$$
at $[NH_4Br] \leqq 0.04$ mol./l.
and $[NH_4Br]/[Co^{2+}] \leqq 5/4$

Then the absorption rate of oxygen after 10 minutes' passage of ozonized oxygen was measured much as before. The reaction shows an independence of the concentration of *p*-xylene, and three-second-order and one-fourth-order dependences on the concentrations of cobaltous acetate at $[Co^{2+}] \leqq 0.024$ mol./l. and $([Co^{2+}]+[NH_4Br]) \leqq 0.028$ mol./l., and at $[Co^{2+}] > 0.024$ mol./l. and $([Co^{2+}]+[NH_4Br]) > 0.028$ mol./l., respectively. The reaction also shows a one-half-order or second-order dependence on the concentrations of ammonium bromide at $[NH_4Br] \leqq 0.012$ mol./l. and $([Co^{2+}]+[NH_4Br]) \leqq 0.028$ mol./l., and at $[NH_4Br] > 0.012$ mol./l. and $([Co^{2+}]+[NH_4Br]) > 0.028$ mol./l. Further, the reaction shows an independence of the concentration of tetrachloroethylene. To summarize the above results, the reaction rate may be given as follows;

$$R_5 = k_V[Co^{2+}]^{3/2}[NH_4Br]^{1/2}$$

at $[NH_4Br] \leqq 0.012$ mol./l. and $([Co^{2+}]+[NH_4Br]) \leqq 0.028$ mol./l.

$$R_6 = k_{VI}[Co^{2+}]^{1/4}[NH_4Br]^{2.0}$$

at $[NH_4Br] > 0.012$ mol./l. and $([Co^{2+}]+[NH_4Br]) > 0.028$ mol./l.

Reaction Mechanism.—Since no reaction mechanism has been reported with regard to the oxidation of *p*-xylene to *p*-toluic acid, it has been considered first. It is supposed in glacial acetic acid that the following reaction occurs easily, and that [HBr] is directly proportional to $[NH_4Br]$, since hydrogen bromide does not dissociate so much.[14]

$$NH_4Br + CH_3COOH \rightleftharpoons HBr + CH_3COONH_4$$

Thus the reaction rate obtained experimentally may be expressed as a dependence on $[HBr]^{1/4}$. Hydrogen bromide is thus made to react with oxygen to produce the radical in accordance with the reaction 1:

$$HBr + O_2 \xrightarrow{k_1} Br\cdot + HO_2\cdot \qquad v_1 \quad (1)$$

By expressing $-\langle\bigcirc\rangle-CH_3$ with ϕ, reactions 2 and 3 are given as:

$$\phi CH_3 + Br\cdot \xrightarrow{k_2} \phi CH_2\cdot + HBr \qquad v_2 \quad (2)$$

$$\phi CH_2\cdot + O_2 \xrightarrow{k_3} \phi CH_2O_2\cdot \qquad v_3 \quad (3)$$

The absence of *p*-xylene from the rate equation establishes that it does not enter into the propagation steps; the reaction 3a, which would involve a first-order dependence on [*p*-xylene], is therefore excluded:

$$\phi CH_3 + \phi CH_2O_2\cdot \rightarrow \phi CH_2OOH + \phi CH_2\cdot \quad (3a)$$

The replacement of 3a by an electron-transfer reaction between a cobaltous ion and a hydroperoxy-radical may be suggested; 4 represents the sum of two possible courses, 4a—4b and 4c—4d:

$$\phi CH_2O_2\cdot + Co^{2+} \xrightarrow{k_4} \phi CHO + OH^- + Co^{3+} \qquad v_4 \quad (4)$$

(i) $\phi CH_2O_2\cdot \rightarrow \phi CHO + OH\cdot$ (thermal) (4a)

$$OH\cdot + Co^{2+} \rightarrow Co^{3+} + OH^- \quad (4b)$$

(ii) $\phi CH_2O_2\cdot + Co^{2+} \rightarrow \phi CH_2O_2^- + Co^{3+}$ (4c)

$\phi CH_2O_2^- \rightarrow \phi CHO + OH^-$ (very fast) (4d)

Of these mechanisms, it is the more probable, since it is unlikely that the thermal decomposition of a hydroperoxyradical would produce an aldehyde exclusively. The regeneration of the cobaltous ion by the reaction 5 is suggested:

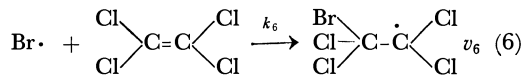
$$Co^{3+} + HBr \underset{k_{-5}}{\overset{k_{+5}}{\rightleftharpoons}} Co^{2+} + Br\cdot + H^+ \qquad \begin{matrix} v_{+5} \\ v_{-5} \end{matrix} \quad (5)$$

The concentration of Co^{3+} appears to be much smaller than that of Co^{2+}, since the color of the solution during an oxidation shows none of the deep green usually associated with the cobaltic state. The reaction 5 is considered to be reversible and in an equilibrium under a steady state. Since $[Co^{3+}]$ is much smaller than $[Co^{2+}]$, v_{+5} is

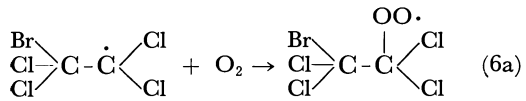
14) I. M. Kolthoff and A. Willman, *J. Am. Chem. Soc.*, **56**, 1007 (1934).

thought to be very large compared to v_{-5}; therefore, the apparent rate of the reaction 5 may be approximately given by v_{+5}.

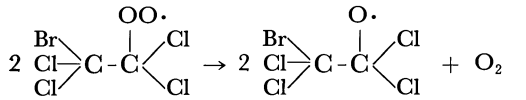
The reaction accompanying tetrachloroethylene is thought to proceed in accordance with the reaction 6, 6a, 6b, and 6c on the basis of the mechanism proposed by Schumacher et al.[15] with regard to the reaction-between Cl· and tetrachloroethylene:



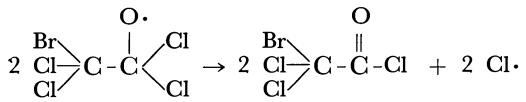
(6)



(6a)



(6b)



(6c)

On the basis of the data* obtained by the present authors, the Br· in 6 might be replaced by an increasing amount of Cl· in 6c, and there might be a chain reaction consisting of 6—6c. Though a small amount of oxygen is consumed through the reactions 6—6c, the consumption of Br· in 6 would involve a retardation of 2 in the principal chain reaction and would, therefore, allow tetrachloroethylene to behave negatively. By considering further that the velocity of the propagation reaction in the *p*-xylene → *p*-toluic acid reaction is larger than that in the *p*-toluic acid → terephthalic acid reaction, it may be understood that the rate in the former is independent of the concentration of tetrachloroethylene, but that it increases by ca. 12.5%. It is further assumed that the reaction 6 is a rate-determining step in 6—6c, and that, therefore, v_6 is approximately equal to the apparent rate.

By assuming that $v_3 \gg v_4$** even under an oxygen pressure of 92 mmHg, the chain-termination is expressed by the reaction 7:

$$2\ \phi CH_2O_2\cdot \xrightarrow{k_7} \text{inactives} \qquad v_7 \quad (7)$$

When the reaction has reached a steady state, the rate of initiation is equal to the sum of v_6 and v_7.

$$k_1[HBr][O_2] = k_7[\phi CH_2O_2\cdot]^2 + k_6[Cl_2C{=}CCl_2][Br\cdot] \qquad (a)$$

By assuming $v_7 \gg v_6$, since a considerable amount of tetrachloroethylene was recovered after the oxidation of *p*-xylene, Eq. a is given by b and c:

$$k_1[HBr][O_2] = k_7[\phi CH_2O_2\cdot]^2 \qquad (b)$$

$$\text{hence:}\quad [\phi CH_2O_2\cdot] = \{(k_1/k_7)[HBr][O_2]\}^{1/2} \qquad (c)$$

By supposing that v_6 is constant, since [Br·] ≪ [tetrachloroethylene] and both are approximately constant at a steady state, Eqs. d and e are obtained:

$$v_6 = k_6[Cl_2C{=}CCl_2][Br\cdot] = K_I \qquad (d)$$

$$\text{therefore:}\quad [Br\cdot] = (K_I/k_6)[Cl_2C{=}CCl_2]^{-1} \qquad (e)$$

Under a steady state, the radical and Co concentrations may be considered stationary; i. e., $d[Co^{3+}]/dt = d[\phi CH_2\cdot]/dt = d[\phi CH_2O_2\cdot]/dt = 0$. The following relations are then obtained:

$$v_3 = v_2 = v_4 + v_7, \qquad v_4 = v_{+5},$$

$$v_1 = v_5 + v_6 \fallingdotseq v_7$$

and
$$-d[O_2]/dt = v_1 + v_3 = 2\ v_1 + v_4$$
$$= 2k_1[HBr][O_2] + k_4[\phi CH_2O_2\cdot][Co^{2+}]$$

If it is further assumed that the propagation chains are long compared to the initiation reaction, the oxygen absorption by the initiation reaction may be neglected, and Eq. f is obtained:

$$-d[O_2]/dt = k_4[\phi CH_2O_2\cdot][Co^{2+}] \qquad (f)$$

From $v_4 = v_{+5}$, Eq. g is obtained:

$$[\phi CH_2O_2\cdot] = (k_{+5}/k_4)\{[Co^{3+}][HBr]/[Co^{2+}]\} \qquad (g)$$

By introducing v_{+5}/v_{-5} = constant, h is derived:

$$[Co^{3+}] = (k_{-5}K_{II}/k_{+5})\{[Co^{2+}][Br\cdot][H^+]/[HBr]\} \qquad (h)$$

By combining g and h:

$$[\phi CH_2O_2\cdot] = (k_{-5}K_{II}/k_4)[Br\cdot][H^+] \qquad (i)$$

By multiplying c by i, and by taking its square root, j is derived:

$$[\phi CH_2O_2\cdot] = (k_1/k_7)^{1/4}(k_{-5}K_{II}/k_4)^{1/2}\cdot [HBr]^{1/4}[O_2]^{1/4}[Br\cdot]^{1/2}[H^+]^{1/2} \qquad (j)$$

By substituting e for [Br·]:

$$[\phi CH_2O_2\cdot] = (k_1/k_7)^{1/4}(k_{-5}K_{II}/k_4)^{1/2}(K_I/k_6)^{1/2}\cdot [HBr]^{1/4}[O_2]^{1/4}[Cl_2C{=}CCl_2]^{-1/2}[H^+]^{1/2} \qquad (k)$$

By combining f and k, Eqs. l and m are derived:

$$-d[O_2]/dt = (k_4k_{-5}K_IK_{II}/k_6)^{1/2}(k_1/k_7)^{1/4}\cdot [Co^{2+}][HBr]^{1/4}[O_2]^{1/4}\cdot [Cl_2C{=}CCl_2]^{-1/2}[H^+]^{1/2} \qquad (l)$$

15) H. J. Schumacher and W. Thurauf, *Z. Physik. Chem.*, **A189**, 183 (1941).

* Y. Sakuyama and T. Hara, unpublished. The amount of bromide and chloride in the reaction mixtures during the oxidation were investigated potentiometrically by using a glass electrode-silver (silver chloride) electrode combination, and by titrating this with a silver acetate solution in glacial acetic acid. The amount of bromide decreased at the beginning of the reaction, while the amount of chloride increased gradually. There was a considerable amount of chloride at the end of oxidation. These results give an indirect certification for the reactions 6-6c.

** Though this relation generally holds when the oxygen pressure is above ca. 100 mmHg, it is also assumed in the present case, since a similar rate equation, as will be shown later, was obtained at oxygen pressures 92 mmHg or higher pertaining to the oxidation of *p*-toluic acid. Cf. L. Bateman, G. Gee, A. L. Morris and W. F. Watson, *Discussions Faraday Soc.*, **10**, 250 (1951); F. Mashio, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **63**, 699 (1960).

$$-d[O_2]/dt = k_p[Co^{2+}][HBr]^{1/4}[Cl_2C{=}CCl_2]^{-1/2} \quad (m)$$

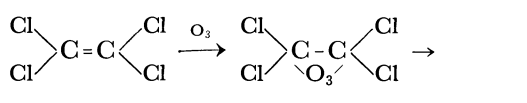
where

$$k_p = (k_4 k_{-5} K_I K_{II}/k_6)^{1/2}(k_1/k_7)^{1/4}[O_2]^{1/4}[H^+]^{1/2}$$

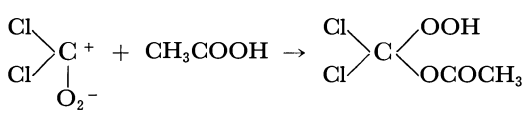
Since the present experiment was carried out under a definite oxygen pressure and since the reaction orders of all the factors except chloroacetic acid were examined in the absence of chloroacetic acid, $[H^+]$ may be considered constant and the term of chloroacetic acid in the experimental rate may be independent. Thus Eq. m agrees in form with the rate equation found by the experiment.

Though chloroacetic acid has been reported to act in three ways:[11] 1) enhancing the reactivity of alkylbenzenes, 2) increasing the activity of catalyst, and 3) offering a radical in itself, its behavior in the present reaction still remains unknown.

Since it seemed to be very difficult technically to oxidize *p*-xylene with oxygen of air containing a definite amount of ozone and to analyze the reaction mechanism, the effect of ozone on the reaction rate was examined by comparing it with one in oxygen alone. The reaction showed a negative one-half-order dependence on the concentration of tetrachloroethylene in the absence of ozone, but a zero-order dependence after 10 minutes' passage of ozone. It is, therefore, supposed in the latter case that the reaction 6 does not occure, but the reactions 8 and 9, which were proposed by Rieche[16] and Criegee,[17] do.



(8)



(9)

Judging from the experimental results, it may further be supposed that the formation of ozonide is not so slow as to consume Br· markedly, and that the hydroperoxide produced in 9 takes part in the propagation reaction, which results in an increase of the yield. By accepting these assumption, it is understandable that the reaction shows an independence of the concentration of tetrachloroethylene. By passing ozonized oxygen into the reaction mixture for 10 min. at 90°C, the cobalt-peroxy-radical shown in the reaction 10 can be produced, as has been proposed by several persons.[18]

$$Co^{2+} + O_2 \underset{k_{-10}}{\overset{k_{+10}}{\rightleftharpoons}} Co^{2+}\cdot O_2\cdot \qquad \begin{matrix} v_{+10} \\ v_{-10} \end{matrix} \quad (10)$$

The reaction 10 is assumed to be reversible and in an equilibrium. Therefore, Eq. 10-1 and 10-2 are derived:

$$K_{III} = \frac{k_{+10}[Co^{2+}][O_2]}{k_{-10}[Co^{2+}\cdot O_2\cdot]} \quad (10\text{-}1)$$

$$[Co^{2+}\cdot O_2\cdot] = (k_{+10}/K_{III}\cdot k_{-10})[Co^{2+}][O_2] \quad (10\text{-}2)$$

The chain reaction is supposed to be initiated by the reactions 11 and 12, followed by the propagation reactions, 13, 14, 15, 16, and the termination reaction, 17.

$$Co^{2+}\cdot O_2\cdot + HBr \xrightarrow{k_{11}} Co^{3+} + HO_2\cdot + Br\cdot \qquad v_{11} \quad (11)$$

$$Co^{2+}\cdot O_2\cdot + \phi CH_3 \xrightarrow{k_{12}} Co^{2+} + HO_2\cdot + \phi CH_2\cdot \qquad v_{12} \quad (12)$$

$$\phi CH_3 + Br\cdot \xrightarrow{k_{13}} \phi CH_2\cdot + HBr \qquad v_{13} \quad (13)$$

$$\phi CH_2\cdot + O_2 \xrightarrow{k_{14}} \phi CH_2O_2\cdot \qquad v_{14} \quad (14)$$

$$\phi CH_2O_2\cdot + Co^{2+} \xrightarrow{k_{15}} \phi CHO + OH^- + Co^{3+} \qquad v_{15} \quad (15)$$

$$Co^{3+} + HBr \xrightarrow{k_{16}} Co^{2+} + H^+ + Br\cdot \qquad v_{16} \quad (16)$$

$$2\ \phi CH_2O_2\cdot \xrightarrow{k_{17}} \text{inactives} \qquad v_{17} \quad (17)$$

By introducing a steady state, $v_{17} = v_{11} + v_{12}$, and Eq. n is derived:

$$k_{17}[\phi CH_2O_2\cdot]^2 = (k_{+10}k_{11}/K_{III}k_{-10})[Co^{2+}][O_2][HBr] + (k_{+10}k_{12}/K_{III}k_{-10})[Co^{2+}][O_2][\phi CH_3] \quad (n)$$

By assuming $v_{11}/v_{12} = K_{IV}$,

$$k_{11}[Co^{2+}\cdot O_2\cdot][HBr]/k_{12}[Co^{2+}\cdot O_2\cdot][\phi CH_3] = K_{IV}$$

Hence, $k_{11}[HBr] = K_{IV}k_{12}[\phi CH_3]$, and

$$k_{12}[\phi CH_3] = (k_{11}/K_{IV})[HBr]$$

By substituting these values into Eq. n, Eqs. o and o' are obtained:

$$[\phi CH_2O_2\cdot] = (k_{10}k_{12}/K_{III}k_{-10}k_{17})^{1/2}\cdot (K_{IV}+1)^{1/2}[Co^{2+}]^{1/2}[O_2]^{1/2}[\phi CH_3]^{1/2} \quad (o)$$

or:

$$[\phi CH_2O_2\cdot] = (k_{10}k_{11}/K_{III}k_{-10}k_{17})^{1/2}\cdot (1+1/K_{IV})^{1/2}[Co^{2+}]^{1/2}[O_2]^{1/2}[HBr]^{1/2} \quad (o')$$

Consequently, Eqs. p and p' are derived:

$$-d[O_2]/dt = v_{14} + v_{10} = v_{15} + v_{17} + v_{10} \fallingdotseq v_{15} = k_{15}[\phi CH_2O_2\cdot][Co^{2+}]$$

16) A. Rieche, *Angew. Chem.*, **70**, 251 (1958).
17) R. Criegee and M. Lederer, *Ann.*, **583**, 29 (1953).
18) P. George and A. Robertson, *Trans. Faraday Soc.*, **42**, 217 (1946); G. Wittig, *Angew. Chem.*, **60**, 169 (1948); N. Uri, *Nature*, **177**, 1177 (1956); H. Kropf, *Ann.*, **637**, 73 (1960).

$$= k_{15}(k_{10}k_{12}/K_{III}k_{-10}k_{17})^{1/2}(K_{IV}+1)^{1/2}\cdot [Co^{2+}]^{3/2}[O_2]^{1/2}[\phi CH_3]^{1/2} \quad (p)$$

or:

$$-d[O_2]/dt = k_{15}(k_{10}k_{11}/K_{III}k_{-10}k_{17})^{1/2}\cdot (1+1/K_{IV})^{1/2}[Co^{2+}]^{3/2}[O_2]^{1/2}[HBr]^{1/2} \quad (p')$$

Under a definite oxygen pressure, the initial rate is expressed as Eq. q:

$$-d[O_2]/dt = k_q[Co^{2+}]^{3/2}[HBr]^{1/2}[\phi CH_3]^{1/2} \quad (q)$$

Equation q agrees in form with the rate obtained experimentally. Though the reaction showed a first-order dependence on the concentration of hydrogen bromide at $[HBr]/[Co^{2+}]>5/4$, this is considered to be due to the increase in v_{11} and to the velocities in the coming reactions.

Though the reaction conditions from *p*-toluic acid to terephthalic acid in the present experiment are different in temperature and oxygen pressure from those used by Ravens, the reaction rate has been obtained in a form similar to that obtained by Ravens. The reaction rate by Ravens is shown by:

$$-d[O_2]/dt = k_r[Co^{2+}][NaBr]^{1/2}[O_2]^{1/2} \quad (r)$$

while that of the present authors is given by:

$$-d[O_2]/dt = 1.125k_s[Co^{2+}][NH_4Br]^{1/2} \quad (s)$$

In the latter, the reaction shows independences of the concentrations of both chloroacetic acid and tetrachloroethylene. Therefore, the reaction is considered to proceed by the following mechanism, which is similar to that proposed by Ravens:

$$NH_4Br + CH_3COOH \rightleftharpoons HBr + CH_3COONH_4 \quad (18)$$

$$HBr + O_2 \rightarrow Br\cdot + HO_2\cdot \quad (19)$$

$$\phi'CH_3 + Br\cdot \rightarrow \phi'CH_2\cdot + HBr \quad (20)$$

$$\phi'CH_2\cdot + O_2 \rightarrow \phi'CH_2O_2\cdot \quad (21)$$

$$\phi'CH_2O_2\cdot + Co^{2+} \rightarrow \phi'CHO + OH^- + Co^{3+} \quad (22)$$

$$Co^{3+} + HBr \rightarrow Co^{2+} + Br\cdot + H^+ \quad (23)$$

$$2\,\phi'CH_2O_2\cdot \rightarrow \text{inactives} \quad (24)$$

where ϕ' means -COOH.

Though the reaction showed an independence of the concentration of tetrachloroethylene, the rate always increased by 12.5% in the presence of any amount of it. This phenomenon has already been explained. Chloroacetic acid was effective in the $\phi CH_3 \rightarrow \phi'CH_3$ reaction, but not in the $\phi'CH_3 \rightarrow \phi'COOH$ reaction. The reason for this remains unknown.

By assuming that the reaction mechanism in the oxidation of *p*-toluic acid to terephthalic acid after the passage of ozonized oxygen is similar to that of *p*-xylene to *p*-toluic acid, a rate which is the same as that obtained experimentally is derived; it is shown by Eq. t:

$$-d[O_2]/dt = k_t[Co^{2+}]^{3/2}[NH_4Br]^{1/2} \quad (t)$$

The facts that the reaction shows one-fourth- and second-order dependences on the concentrations of cobaltous ion and ammonium bromide respectively at $([Co^{2+}]+[NH_4Br])>0.028$ mol./l. may be attributed to a decrease in the velocity in the reaction corresponding to 12 and to an increase in the concentration of bromide radicals by another reaction, e. g., the direct reaction between oxygen and hydrogen bromide.

Summary

It has been found that terephthalic acid can be obtained by single-stage oxidation in the liquid phase under certain conditions such as the following: *p*-xylene: 25.0 ml.; $Co(OAc)_2\cdot 4H_2O$: 4.982 g.; NH_4Br: 0.1 g.; tetrachloroethylene: 1.0 ml.; solvent: 200 ml. HOAc; reaction temp.; 90°C; oxidant: ozonized oxygen or air; chloroacetic acid: 0.5 g. (used only in the case of ozonized air); and reaction time: 6 hr.

The yields as crude terephthalic acid were 95% with oxygen and 84% with air. The individuality of the present method consists in the use of the ozonized oxygen or air, together with an aliphatic unsaturated compound.

The reaction rates have been examined by measuring the absorption rate of oxygen; they may be expressed as follows:

1) From *p*-xylene to *p*-toluic acid:

a) Ozone-free (under an oxygen pressure of 92 mmHg)

$$R_1 = k_1[Co^{2+}][NH_4Br]^{1/4}\cdot [ClCH_2COOH][Cl_2C=CCl_2]^{-1/2}$$

where $[Co^{2+}]+2[NH_4Br] \leqq 0.04$ mol./l. and $[ClCH_2COOH] \leqq 0.13$ mol./l.

b) Ozone present (under an oxygen pressure of 460 mmHg)

$$R_2 = k_{II}[p\text{-xylene}]^{1/2}[Co^{2+}]^{3/2}[NH_4Br]^{1/2}$$ at $[NH_4Br]/[Co^{2+}] \leqq 5/4$

$$R_3 = k_{III}[p\text{-xylene}]^{1/2}[Co^{2+}]^{3/2}[NH_4Br]$$ at $[NH_4Br]/[Co^{2+}]>5/4$

2) From *p*-toluic acid to terephthalic acid:

a) Ozone-free (under an oxygen pressure of 92 mmHg)

$$R_4 = 1.125k_{IV}[Co^{2+}][NH_4Br]^{1/2}$$ at $[NH_4Br] \leqq 0.04$ mol./l. and $[NH_4Br]/[Co^{2+}] \leqq 5/4$

b) Ozone present (under an oxygen pressure of 460 mmHg)

$$R_5 = k_V[Co^{2+}]^{3/2}[NH_4Br]^{1/2}$$

at $[NH_4Br] \leqq 0.012$ mol./l.

and $([Co^{2+}]+[NH_4Br]) \leqq 0.028$ mol./l., and

$R_6 = k_{VI}[Co^{2+}]^{1/4}[NH_4Br]^{2.0}$

at $[NH_4Br] > 0.012$ mol./l.

and $([Co^{2+}]+[NH_4Br]) > 0.028$ mol./l.

The reaction mechanism has been further discussed, and the rate equations have been derived by assuming the steady state.

The authors wish to express their hearty thanks to Mr. Sadao Hoshizake, Mr. Yasuo Hayano, Mr. Hiroshi Yamamoto, Mr. Kazuhiro Kashima, Mr. Yasuo Matsumura, Mr. Hitoshi Matsubayashi, and Mr. Ryohei Matsumoto for their help in the experiment. Their thanks are also due to the Maruzen Sekiyu Co., Ltd., which provided the *p*-xylene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 664—672 (1966)

The Oxidation of Acetylacetone in the Presence of Cobaltous Ions

By Tadashi KOGA and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kamikyo-ku, Kyoto

(Received May 22, 1965)

Concerning the oxidation of toluene and *p*-xylene with atmospheric oxygen at 90°C in glacial acetic acid in the presence of cobaltous acetate and acetylacetone (HAAH), it was found that the reaction proceeds smoothly only at the mole ratio of $[HAAH]/[Co^{2+}]=2$. When the absorption rate of oxygen was then measured for acetic acid solutions containing cobaltous ions and HAAH, the following results were obtained:

at $[HAAH]/[Co^{2+}] \leqq 3$, $-d[O_2]/dt = K_a[HAAH]^{1/2}[Co^{2+}]^{-1/3}$

at $[HAAH]/[Co^{2+}] \geqq 4$, $-d[O_2]/dt = K_b[HAAH][Co^{2+}]^{1/4}$

These rates agree well with those derived by means of elementary equations in the radical chain reactions. It was further supposed, on the basis of the elementary equations, that active intermediates, such as Co^{3+}, $[Co^{3+}(AAH^-)_2]^+$, and some radicals, were produced smoothly at the mole ratio of $[HAAH]/[Co^{2+}]=2$. However, ketones, such as acetonylacetone and ethyl acetoacetate, were still active even at the mole ratio of $[ketone]/[Co^{2+}]=3$. This seems to stem from the differences in complex stabilities between cobalt and HAAH or other ketones.

It was reported by Brill[1] in 1960 that alkylbenzenes are effectively oxidized when an alkylbenzene in glacial acetic acid in the presence of cobaltous acetate tetrahydrate and ethyl methyl ketone (a ketone containing an α-methylene group) is allowed to contact with oxygen while being sufficiently stirred at 90°C under an atmospheric pressure. This report attracted the present authors, since it enabled us to anticipate some effects based on the chelate formation between cobalt and such a ketone as acetylacetone, and provided a clue as to the nature of the oxidation mechanism.

p-Xylene was then oxidized under the same conditions as were used in Brill's method, except for the utilization of acetylacetone in its various mole ratios to cobalt; it was thus found that terephthalic acid could be obtained only at the cobalt: acetylacetone mole ratio of 1 : 2. Since this fact was very interesting to the present authors, a study was primarily made of the oxidation of acetylacetone in the presence of cobaltous ions by measuring the absorption rate of oxygen.

With a view to identifying the final products in the oxidation of acetylacetone, acetylacetone was oxidized in propionic acid much as in glacial acetic acid, and the oxidation products were examined by gas chromatography.

Experimental

Reagents.—The *p*-xylene obtained from the Maruzen Sekiyu Co., Ltd., was treated with sulfuric acid, sodium hydroxide and water, and recrystallized twice; the distillate with a b. p. of 138.5°C was used. Toluene was treated much as was *p*-xylene, but the distillate with a b. p. of 110.5°C was used. The cobaltous acetate tetrahydrate and the glacial acetic acid were both of an analytical reagent grade. Acetylacetone was distilled, and the distillate with a b. p. of 137°C was used. Cobaltous propionate was synthesized from propionic acid and cobaltous carbonate, and recrystallized from ethanol and diethyl ether. The cobalt was determined chelatometrically by using ethylenediaminetetraacetic acid and murexide. The distillate with a b. p. of 141°C was used for propionic acid.

1) W. F. Brill, *Ind. Eng. Chem.*, **52**, 837 (1960).

Table I. Relationship between the mole ratios of charged ketones to cobalt and the oxidation products

No.	Ketones containning α-methylene group	mol./l.	*p*-Xylene mol./l.	$Co(OAc)_2 \cdot 4H_2O$ mol./l.	Terephthalic acid
1	Ethyl methyl ketone* ($CH_3CH_2COCH_3$)	0.2	1	0.1	(yield** about 65%)
2	Acetylacetone ($CH_3COCH_2COCH_3$)	0.1	1	0.1	impossible
		0.2	1	0.1	(yield about 75%)
		0.3	1	0.1	impossible
		0.4	1	0.1	impossible
		0.5	1	0.1	impossible
3	Acetonylacetone ($CH_3COCH_2CH_2COCH_3$)	0.2	1	0.1	yield 40% (toluic acid about 40%)
		0.3	1	0.1	yield 40% (toluic acid about 40%)
4	Ethyl acetoacetate ($CH_3COCH_2COOC_2H_5$)	0.2	1	0.1	yield 40% (toluic acid about 20%)
		0.3	1	0.1	yield 40% (toluic acid about 20%)
			Toluene mol./l.		Benzoic acid
5	Acetylacetone	0.2	1	0.1	possible
		0.3	1	0.1	impossible

* The same conditions as in Brill's experiment.
** The yields are given by the mole per cent of the oxidation products to charged *p*-xylene.

The Oxidation of *p*-Xylene and Toluene.—To 200 ml. of glacial acetic acid, 0.02 mol. of cobaltous acetate tetrahydrate, 0.2 mol. of *p*-xylene or toluene, and 0.02—0.1 mol. of a ketone such as acetylacetone, acetonylacetone, ethyl acetoacetate and ethyl methyl ketone are added. The solution is then placed in contact with oxygen for 24 hr. at 90°C, 1 atm., and 800—1000 r. p. m.

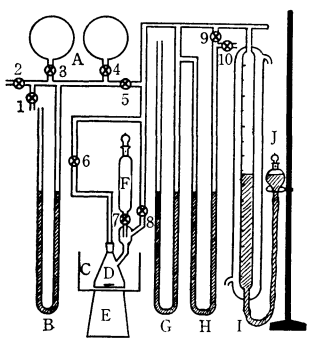


Fig. 1. An apparatus for the measurement of oxygen absorption rate.
A: gas storage B: manometer (charged with mercury) C: thermostat D: reaction vessel E: magnetic stirrer F: funnel for supplying sample G: manometer (charged with mercury) H: manometer (charged with dibuthylphthalate) I: gas burette J: mercury pool

The Absoption Rate of Oxygen.—The absorption rate of oxygen was measured by the apparatus shown in Fig. 1. The apparatus was operated as follows: all the cocks except the cocks 2, 7 and 10 are opened after J has been lowered, and the system is made completely vacuous through the cock 1. The cocks 1 and 5 are then closed, and A is filled with more than 1 atm. of oxygen through the cock 2. Then the cock 2 is closed, and the oxygen gas pressure is adjusted to the atmospheric pressure by opening the cock 5 and reading the manometer, G, charged with mercury. The cock 9 is closed, and the cock 10 is opened. To the reaction vessel, D, 50 ml. of glacial acetic acid and cobaltous acetate are added, and the solution is heated at 60±0.2°C, The liquid surfaces of the manometer, H, charged with dibutyl phthalate are adjusted to the same level by moving J vertically. Acetylacetone is added through the cock 7, and the reaction is started.

During the reaction, the liquid surfaces of the manometer, H, are held on the same level by moving J; thereby the oxygen gas pressure is always maintained at 1 atm. The absorption rate of oxygen is measured by reading the gas burette, I, at definite intervals. Oxygen is supplied to the system by closing the cocks 6 and 8, lowering J, and introducing oxygen through the cock 5 until the liquid surfaces of H reach just the same level. I is read at once, and measurement is continued after the opening of the cocks 6 and 8.

The Identification of the Oxidation Products of Acetylacetone.—Since the absorption rate of oxygen in propionic acid was confirmed to be quite similar to

that in glacial acetic acid, except for a slight elongation of the induction period, the oxidation products of acetylacetone were identified as follows: Acetylacetone in 1.5×10^{-2} mol. and cobaltous propionate in 5×10^{-3} mol. are dissolved in 50 ml. propionic acid, and the solution is placed in contact with oxygen for 3 hr. at 60°C, 1 atm. Then the solution is distilled by introducing the vapor of methanol or ethanol, and the acids in the distillate are directly converted into their esters. After esterification, the esters are distilled, and the residues are diluted with water and then extracted with ether. Both the extract and the distillate are examined by gas chromatography.

Results

The Oxidation of *p*-Xylene and Toluene.— For the oxidation of *p*-xylene in the presence of 0.02 mol. of cobaltous acetate and 0.04 mol. of acetylacetone, the solution gradually changed its color from violet to brown, and finally to dark green after about 6 hours' reaction, whereupon a small amount of terephthalic acid began to deposit.

In any mole ratios other than acetylacetone: cobalt=2 : 1, terephthalic acid was not identified in 24 hours' reaction, and the unreacted *p*-xylene was found in the oily phase after the reaction mixture had been diluted with water.

When the mole ratios of acetonylacetone or ethyl acetoacetate to cobaltous acetate were 2 : 1 and 3 : 1 respectively, however, terephthalic acid was identified after 7 hours' reaction.

For the oxidation of toluene, benzoic acid was obtained in a good yield at only the mole ratio of acetylacetone : cobalt=2 : 1.

The Oxidation of Acetylacetone.—The absorption rate of oxygen was measured for the oxidation of acetylacetone in the absence of alkylbenzene; the results obtained are shown in Table II. As can be seen from Experiments Nos. 1—8 in Table II, the amount of oxygen gas absorbed increases with the concentration of HAAH at 0.1 mol./l. cobaltous acetate; the relationship between the amount of oxygen gas absorbed and the concentration of HAAH is shown in Fig. 4. Here,

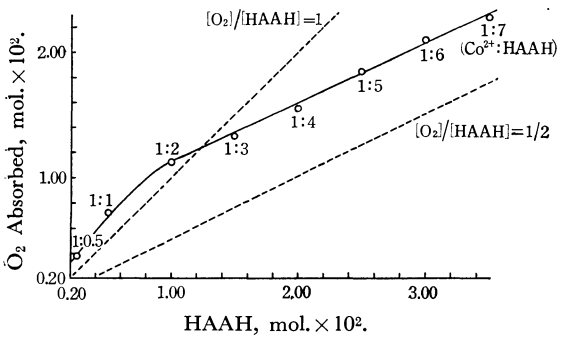

Fig. 4. Relationships between the mole ratio of [HAAH]/[Co^{2+}] and the amount of O_2 absorbed; [Co^{2+}]: 0.1 mol./l.

HAAH, HAA· and AAH^- are given by the following:

HAAH: $CH_3-\overset{\overset{O}{\|}}{C}-CH_2-\overset{\overset{O}{\|}}{C}-CH_3$, HAA·: $CH_3-\overset{\overset{O}{\|}}{C}-\dot{C}H-\overset{\overset{O}{\|}}{C}-CH_3$, and AAH^-: $CH_3-\overset{\overset{O^-}{|}}{C}=CH-\overset{\overset{O}{\|}}{C}-CH_3$

Figure 4 shows that the mole ratios of the [HAAH] to the [O_2] absorbed are equal to 1 and 2 at [HAAH]/[Co^{2+}]<2 and [HAAH]/[Co^{2+}]>3 respectively.

In Experiments Nos. 9—15, the concentration of cobaltous ions was varied against 0.2 mol./l. HAAH, but the amounts of oxygen gas absorbed were almost constant. These results are shown in Fig. 5. The straight line in Fig. 5 is represented by $t=k([HAAH]^2/[Co^{2+}])K^{1/4}$, where t is referred to the induction period and K, to the [HAAH]/[Co^{2+}]. It may be seen from the above equation that t does not only depend on the mole ratio of HAAH to Co^{2+}, but also on their concentrations.

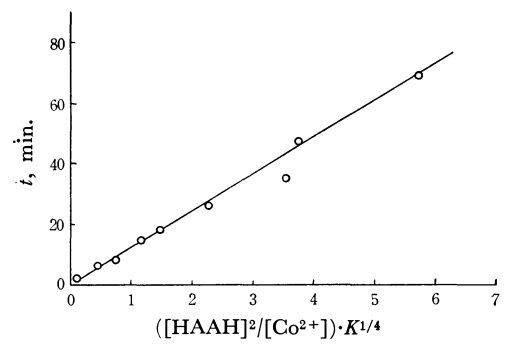

Fig. 5. Relationships between the introduction period, t, and $([HAAH]^2/[Co^{2+}])\cdot K^{1/4}$.

After the induction period, the temperature of the reaction mixture increased in accordance with the changes in color from pink to dark green. This color change is considered to be due to the formation of cobaltic ions. After the absorption of oxygen had finished, the solution was red at the mole ratio of [HAAH]/[Co^{2+}]<3, but dark green at [HAAH]/[Co^{2+}]>4. When the dark-green substance was extracted into the benzene layer, the aqueous layer remained wine-red. The spectrophotometric absorption curves of the benzene and aqueous layers showed their maximum absorptions at 600 and 510 mμ respectively; they were compared with those of $Co^{2+}(OAc^-)_2$, $Co^{2+}(AAH^-)_2$, and $Co^{3+}(AAH^-)_3$.

The Oxidation Rate of Acetylacetone.—The relationship between the absorption rate of oxygen and the concentrations of HAAH or Co^{2+} are shown in Tables III and IV. Since there are linear relations between $\log(d[O_2]/dt)$ and log-[HAAH], and $\log(d[O_2]/dt)$ and $\log[Co^{2+}]$ respectively, the absorption rates of oxygen are given

Table III. The concentration of acetylacetone and the oxygen absorption rate

Reaction temp.: 60±0.2°C

4	19.56	1.2914	0.3	−0.5229	16.6
5	15.33	1.1852	0.4	−0.3979	68.0
6	19.73	1.2952	0.5	−0.3010	70.0
7	23.52	1.3715	0.6	−0.2218	69.5
8	24.36	1.3867	0.7	−0.1549	61.6

Table IV. The concentration of cobalt and the oxygen absorption rate

Reaction temp.: 60±0.2°C

Oxygen pressure: 1 atm., [HAAH]: 0.1 mol./l.

No.	$d[O_2]/dt$* ml. sec^{-1}	log-$(d[O_2]/dt)$	[Co^{2+}] mol. l^{-1}	log-[Co^{2+}]	Apparent rate constant
9	13.45	1.1287	0.01	−2.0000	212
10	15.67	1.1951	0.02	−1.6990	208
11	18.31	1.2627	0.04	−1.3979	205
12	20.92	1.3220	0.05	−1.3010	221
13	19.71	1.2947	0.07	−1.1549	18.1
14	16.13	1.2076	0.10	−1.0000	16.8
15	14.25	1.1538	0.20	−0.6990	18.6

* These values were obtained by differentiating the oxygen absorption curves at 25°C.

as follows:

at $[HAAH]/[Co^{2+}] \leq 3$,

$$-d[O_2]/dt = k_a[HAAH]^{1/2}[Co^{2+}]^{-1/3}$$

at $[HAAH]/[Co^{2+}] \geq 4$,

$$-d[O_2]/dt = k_b[HAAH][Co^{2+}]^{1/4}$$

Since the concentration of HAAH is enough in Experiments Nos. 5—8, the dissolution velocity of oxygen into the solution is considered to be rate-determining; therefore, their apparent rate constants are supposed to be smaller than those in Nos. 9—12. That the apparent rate constants in Nos. 5—8 are much smaller than those in Nos. 9—12 is due to the facts that the dissolution velocity of oxygen into the solution is rate-determining and that it is smaller than the consumption velocity of oxygen in the oxidation reaction. It may, therefore, be supposed that the apparent rate constants in the case of $[HAAH]/[Co^{2+}] \geq 4$ are equal to those in Nos. 9—12.

The Identification of the Oxidation Products of HAAH.—The sample distilled with the vapor of methanol was analyzed by gas chromatography under the following conditions: carrier gas: hydrogen; flow rate: 30 ml./min.; column: dioctyl phthalate, and column temperature: 50°C. It was confirmed from the gas chromatogram that there were aldehydes, methyl formate, methanol (solvent), methyl acetate or acetone, and methyl propionate. The distillate with the vapor of ethanol and the extracts with ether from the residues after esterification were also analyzed, under the same conditions as above except for the column temperature, which was here 60°C or 100°C respectively. The following substances were confirmed: ethyl formate, ethanol (solvent), ethyl acetate, and ethyl propionate for the former, in which acetone was negative; and ether (solvent), ethyl propionate, and ethyl pyruvate for the latter. On the basis of the gas chromatographic data and the detection of aldehyde with an ammoniacal silver nitrate solution, it was concluded that the oxidation products of HAAH were composed of acetic acid and formic acid as the major constituents, and of formaldehyde, acetaldehyde and pyruvic acid as the minor constituents.

Discussion

The oxidation mechanism of HAAH in glacial acetic acid in the presence of cobaltous ions is considered to be as follows:

In the Case of $[HAAH]/[Co^{2+}] \leq 3$:

It is assumed that the reaction proceeds in accordance with the following radical chain reaction, in which the rate constants are given by the k_1—k_{10} value:

Initiation

$$\begin{cases} Co^{2+} + AAH^- \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} Co^{2+}(AAH^-) & V_1,\ V_{-1}\ (1) \\ Co^{2+}(AAH^-) + O_2 \xrightarrow{k_2} Co^{2+} + HAA\cdot + \cdot O_2^- & V_2\ (2) \end{cases}$$

Propagation

$$\begin{cases} HAA\cdot + O_2 \xrightarrow{k_3} HAAO_2\cdot & V_3\ (3) \\ HAAO_2\cdot + HAAH \xrightarrow{k_4} HAAO_2H + HAA\cdot & V_4\ (4) \\ \begin{cases} HAAO_2\cdot + \{Co^{2+}(AAH^-)_2\}\cdots O_2 \xrightarrow{k_5} \text{complex} & V_5\ (5) \\ \text{Complex} \xrightarrow{k_6} 2Co^{2+}(AAH^-)_2O_2 + HAA\cdot & V_6\ (6) \end{cases} \end{cases}$$

Branched propagation

$$\begin{cases} Co^{2+} + HAAO_2H \xrightarrow{k_7} Co^{3+} + HAAO\cdot + OH^- & V_7\ (7) \\ Co^{3+} + HAAH \xrightarrow{k_8} Co^{2+} + HAA\cdot + H^+ & V_8\ (8) \\ HAAO\cdot + HAAH \xrightarrow{k_9} HAAOH + HAA\cdot & V_9\ (9) \end{cases}$$

Termination

$$\{2HAAO_2\cdot \xrightarrow{k_{10}} \text{Inactive products} \qquad V_{10}\ (10)$$

In the initiation reaction, the 1 : 1 cobaltous chelate is made to react with oxygen to produce HAA·, while the HAA· induced the propagation reactions, which consist of two courses: 3—4, and 3—5—6. The hydroperoxide produced in the reaction 4 induces the reaction 7—9. It seems to be reasonable to suppose the branched reaction, since the solution during the oxidation shows the dark green usually associated with the cobaltic state. It is considered that in the reaction 5 the bridged compound, $\{(AAH^-)_2Co^{2+}\cdots O_2\cdots Co^{2+}(AAH^-)_2\}$,[2] in which each cobalt has a vacant position on the coordination sphere, is coordinated of with $HAAO_2\cdot$ to produce a complex compound.[3]

The absorption rate of oxygen is given by Eq. a·1:

$$-d[O_2]/dt = V_3 = k_3[HAA\cdot][O_2] \qquad (a\cdot1)$$

Under a steady state, the following i—iii are assumed:

i) By assuming $d[HAAO_2\cdot]/dt = 0$, $V_3 = V_4 + V_5 + V_{10}$:

Here, V_{10} is neglected, since the chain is long enough and since $V_{prop.} \gg V_{term.}$.

By assuming that the ratio, C, of V_5 to V_4 is constant and that the reaction 5 is the rate-determining step in the course 5—6, Eq. a·1 is rewritten by Eq. a·2:

2) A. Werner and A. Mylius, *Z. Anog. Chem.*, **16**, 1245 (1898).

3) For example, P. George and A. Robertson, *Trans. Faraday Soc.*, **42**, 217 (1946).

$$-d[O_2]/dt = (1+C)V_4$$
$$= (1+C)k_4[HAAO_2\cdot][HAAH] \quad (a\cdot2)$$

ii) By assuming $V_{\text{Inlt.}} = V_{\text{term.}}$, Eq. b·1 is obtained:

$$k_2[Co^{2+}(AAH^-)][O_2] = k_{10}[HAAO_2\cdot]^2 \quad (b\cdot1)$$

By supposing $k_1/k_{-1} = K_m$ in the reaction 1:

$$[Co^{2+}(AAH^-)] = K_m[Co^{2+}][AAH^-]$$

By introducing $HAAH \overset{Ka}{\rightleftarrows} AAH^- + H^+$, in which K_a is referred to the dissociation constant, $K_a = [AAH^-][H^+]/[HAAH]$; therefore, $[AAH^-] = K_a^{1/2}[HAAH]^{1/2}$.

Hence, Eq. b·1 is expressed by b·2:

$$[HAAO_2\cdot]^2 = (k_2\cdot K_m\cdot K_a^{1/2}/k_{10})\cdot [Co^{2+}][O_2][HAAH]^{1/2} \quad (b\cdot2)$$

iii) By assuming $d[HAAO_2\cdot]/dt = 0$ and $d[\{Co^{2+}(AAH^-)_2\}\cdots O_2]/dt = 0$* in the reaction 5, Eq. c·1 is obtained:

$$k_5[\{Co^{2+}(AAH^-)_2\}\cdots O_2][HAAO_2\cdot] = K_c \quad (c\cdot1)$$

By introducing $[\{Co^{2+}(AAH^-)_2\}\cdots O_2] = K_1^2\cdot K_m^2\cdot K_a^2\cdot[Co^{2+}]^2[HAAH]^2[O_2]$ into Eq. c·1, Eqs. c·2 and c·3 are obtained:

$$k_5\cdot K_1^2\cdot K_m^2\cdot K_a^2[Co^{2+}]^2[HAAH]^2\cdot [O_2][HAAO_2\cdot] = K_c \quad (c\cdot2)$$

Hence,

$$[HAAO_2\cdot] = K_c(k_5\cdot K_1^2\cdot K_m^2\cdot K_a^2)^{-1}\cdot [Co^{2+}]^{-2}[HAAH]^{-2}[O_2]^{-1} \quad (c\cdot3)$$

By mutiplying c·3 by b·2, Eq. d is derived:

$$[HAAO_2\cdot]^3 = \{(k_2\cdot K_c)/(k_5\cdot k_{10}\cdot K_1^2\cdot K_m\cdot K_a^{3/2})\}\cdot [Co^{2+}]^{-1}[HAAH]^{-3/2}$$

hence:

$$[HAAO_2\cdot] = \{(k_2\cdot K_c)/(k_5\cdot k_{10}\cdot K_1^2\cdot K_m\cdot K_a^{3/2})\}^{1/3}[Co^{2+}]^{-1/3}[HAAH]^{1/2} \quad (d)$$

By substituting d into a·2, Eq. e is obtained and rewritten as Eq. f:

$$-d[O_2]/dt = k_4\{(k_2\cdot K_c)/(k_5\cdot k_{10}\cdot K_1^2\cdot K_m\cdot K_a^{3/2})\}^{1/3}\cdot [Co^{2+}]^{-1/3}[HAAH]^{1/2} \quad (e)$$

or: $$-d[O_2]/dt = k_a[Co^{2+}]^{-1/3}[HAAH]^{1/2} \quad (f)$$

where $k_a = k_4\{(k_2\cdot K_c)/(k_5\cdot k_{10}\cdot K_1^2\cdot K_m\cdot K_a^{3/2})\}^{1/3}$.

In the Case of [HAAH]/[Co²⁺]≧4:

It is assumed that the chain reaction proceeds by way of Eqs. 11—19:

Initiation

$$\begin{cases} Co^{2+} + O_2 \overset{k_{11}}{\underset{k_{-11}}{\rightleftarrows}} Co^{2+}\cdots O_2{}^{6)} \text{ (or } Co^{3+}\cdots O_2{}^-)^{6)} & V_{11},\ V_{-11} \quad (11) \\ Co^{2+}\cdots O_2 + HAAH \overset{k_{12}}{\rightarrow} Co^{2+} + HAA\cdot + HO_2\cdot & V_{12} \quad (12) \end{cases}$$

Propagation

$$\begin{cases} HAA\cdot + O_2 \overset{k_{13}}{\rightarrow} HAAO_2\cdot & V_{13} \quad (13) \\ HAAO_2\cdot + HAAH \overset{k_{14}}{\rightarrow} HAAO_2H + HAA\cdot & V_{14} \quad (14) \end{cases}$$

Branched propagation

$$\begin{cases} Co^{2+}(AAH^-)_2 + HAAO_2H \overset{k_{15}}{\rightarrow} \{Co^{3+}(AAH^-)_2\}^+ + HAAO\cdot + OH^- & V_{15} \quad (15) \\ \{Co^{3+}(AAH^-)_2\}^+ + HAAH \overset{k_{16}}{\rightarrow} Co^{2+}(AAH^-)_2 + HAA\cdot + H^+ & V_{16} \quad (16) \\ HAAO\cdot + HAAH \overset{k_{17}}{\rightarrow} HAAOH + HAA\cdot & V_{17} \quad (17) \end{cases}$$

Termination

$$\begin{cases} 2HAAO_2\cdot \overset{k_{18}}{\rightarrow} \text{Inactive products} & V_{18} \quad (18) \\ Co^{3+}(AAH^-)_2O_2{}^- + HAA\cdot \overset{k_{19}}{\underset{k_{19}}{\rightleftarrows}} Co^{3+}(AAH^-)_3 + O_2 & V_{19},\ V_{-19} \quad (19) \end{cases}$$

In this case, the reaction is initiated by the action of cobaltous peroxide on HAAH, since the concentration of HAAH is higher than that in the preceding case, and the HAA· produced induces the propagation reaction. The hydroperoxide produced in the reaction 14 induces the branched propagation reaction. The reactions 18 and 19, in which the former belongs to the conventional self-termination while the latter belongs to the exchange reaction between the ligands, is supposed to be the termination stage. By assuming $V_{18} \gg V_{19}$ on the basis of the experimental conditions, the reaction 18 may be expected to be predominant in the termination stage. The reaction 19 is supposed to be reversible, since the solution was dark

* The bridged compound, $(AAH^-)_2Co^{2+}\cdots O_2\cdots Co^{2+}(AAH^-)_2$, is formed as follows:[4]

$$Co^{2+}(AAH^-) + HAA\cdot \text{ (or } HAAO\cdot, HAAO_2\cdot) \overset{K_d}{\rightleftarrows} Co^{3+}(AAH^-)_2$$
$$Co^{3+}(AAH^-)_2 + O_2 \overset{K_e}{\rightleftarrows} Co^{3+}(AAH^-)_2O_2 \overset{K_f}{\rightleftarrows} Co^{2+}(AAH^-)_2O_2\cdot$$
$$2Co^{2+}(AAH^-)_2O_2\cdot \overset{K_g}{\rightleftarrows} \{Co^{2+}(AAH^-)_2\}_2\cdots O_2 + O_2$$

Hence:

$$K_d\cdot K_e\cdot K_f\cdot K_g = K = [\{Co^{2+}(AAH^-)_2\}_2\cdots O_2]/[Co^{2+}(AAH^-)]^2[HAA\cdot]^2[O_2]$$

Since HAA· (or HAAO·, $HAAO_2\cdot$) is constant at a steady state and since $Co^{2+}(AAH^-)$ is approximately constant at $[HAAH]/[Co^{2+}] \leq 3$ on the basis of the Bjerrum's assumption,[5] the $\{Co^{2+}(AAH^-)_2\}_2\cdots O_2$ value is almost constant also. Since HAA· is formed through the reaction accompanying HAAH or AAH^-, at a steady state it may be proportional to $[AAH^-]$.

Therefore, $[HAA\cdot] = K_1\cdot[AAH]$, and:

$$K = [\{Co^{2+}(AAH^-)_2\}_2\cdots O_2]/K_1^2\cdot K_m^2\cdot[Co^{2+}]^2[AAH^-]^4[O_2]^{-1} = [\{Co^{2+}(AAH^-)_2\}_2\cdots O_2]/K_1^2\cdot K_m^2\cdot K_a^2\ [Co^{2+}]^2[HAAH]^2[O_2]^{-1}$$

4) Cf. E. M. Arnett and M. A. Mendelsohn, *J. Am. Chem. Soc.*, **84**, 3828 (1962).

5) J. Bjerrum, "Metal Ammine Formation in Aqueous Solution," P. Hasse Son, and Copenhagen (1941).

green even after the completion of the oxidation reaction, and green cobaltic chelates, $Co^{3+}(AAH^-)_3$, were extracted into the benzene layer. The absorption rate of oxygen is shown by Eq. A·1.

$$-d[O_2]/dt = V_{13} = k_{13}[HAA\cdot][O_2] \quad (A\cdot1)$$

i—iii below are assumed under a steady state.

i) By assuming $d[HAAO_2\cdot]/dt=0$, $V_{13}=V_{14}+V_{18}$. Since the chain is long enough and since $V_{prop.} \gg V_{term.}$, V_{13} is approximately equal to V_{14} and Eq. B is obtained:

$$k_{13}[HAA\cdot][O_2] = k_{14}[HAAO_2\cdot][HAAH] \quad (B)$$

Therefore, A·1 is expressed by A·2:

$$-d[O_2]/dt \fallingdotseq V_{14}=k_{14}[HAAO_2\cdot][HAAH] \quad (A\cdot2)$$

ii) The rate of the initiation reaction, $V_{init.}$, should be equal to the rate of the termination reaction, $V_{term.}$, in order that the propagation reaction may proceed under a steady state. Therefore, $k_{12}[Co^{2+}\cdots O_2][HAAH]=k_{18}[HAAO_2\cdot]^2$.

By introducing $k_{11}/k_{-11}=K_n$ and $[Co^{2+}\cdots O_2]=K_n[Co^{2+}][O_2]$, Eq. C·1 is obtained:

$$k_{12}\cdot K_n[Co^{2+}][O_2][HAAH] = k_{18}[HAAO_2\cdot]^2 \quad (C\cdot1)$$

By substituting $[AAH^-]=K_a^{1/2}[HAAH]^{1/2}$ into C·1, Eq. C·2 is obtained:

$$[HAAO_2\cdot]=(k_{12}\cdot K_n\cdot K_a/k_{18})^{1/2}\cdot [Co^{2+}]^{1/2}[O_2]^{1/2}[AAH^-] \quad (C\cdot2)$$

iii) By assuming $V_{19}/V_{-19}=K_h$, in which K_h is constant, Eq. D·1 is obtained:

$$K_h = (k_{19}[Co^{3+}(AAH^-)_2O_2^-][HAA\cdot])/(k_{-19}[Co^{3+}(AAH^-)_3][O_2]) \quad (D\cdot1)$$

The cobaltic chelates are formed in accordance with the following reactions:

$$\{Co^{3+}(AAH^-)_2\}^+ + AAH^- \overset{Ki}{\rightleftarrows} Co^{3+}(AAH^-)_3$$

$$\{Co^{3+}(AAH^-)_2\}^+ + O_2^- \overset{Kj}{\rightleftarrows} Co^{3+}(AAH^-)_2\cdot O_2^-$$

By using these relations, Eq. D·1 may be rewritten as Eq. D·2:

$$[HAA\cdot] = (k_{-19}\cdot K_h\cdot K_i/k_{19}\cdot K_j)\cdot [AAH^-][O_2][O_2^-]^{-1} \quad (D\cdot2)$$

By combining B and D·2, Eq. E is obtained:

$$[HAAO_2\cdot]=(k_{13}\cdot k_{-19}\cdot K_h\cdot K_i/k_{14}\cdot k_{19}\cdot K_j\cdot K_a^{1/2})\cdot [AAH^-]^{-1}[O_2]^2[O_2^-]^{-1} \quad (E)$$

By multiplying C·2 by E, Eq. F is obtained:

$$[HAAO_2\cdot]^2= (k_{12}\cdot K_n/k_{18})^{1/2}(k_{13}\cdot k_{-19}\cdot K_h\cdot K_i/k_{14}\cdot k_{19}\cdot K_j)\cdot [Co^{2+}]^{1/2}[O_2]^{5/2}[O_2^-]^{-1}$$

Hence:

$$[HAAO_2\cdot]= (k_{12}\cdot K_n/k_{18})^{1/4}(k_{13}\cdot k_{-19}\cdot K_h\cdot K_i/k_{14}\cdot k_{19}\cdot K_j)^{1/2}\cdot [Co^{2+}]^{1/4}[O_2]^{5/4}[O_2^-]^{-1/2} \quad (F)$$

By substituting F into A·2, Eq. G is obtained:

$$-d[O_2]/dt= k_{14}(k_{12}\cdot K_n/k_{18})^{1/4}(k_{13}\cdot k_{-19}\cdot K_h\cdot K_i/k_{14}\cdot k_{19}\cdot K_j)^{1/2}\cdot [Co^{2+}]^{1/4}[HAAH][O_2]^{5/4}[O_2^-]^{-1/2} \quad (G)$$

Since the oxygen pressure is definite and since the $[O_2^-]$ value is approximately constant under a steady state, G is expressed briefly by Eq. H:

$$-d[O_2]/dt = k_b[Co^{2+}]^{1/4}[HAAH] \quad (H)$$

By taking the following equilibrium into consideration, Eq. 1 is obtained:

$$Co^{2+}(AAH^-)_2 + O_2 \overset{K_p}{\rightleftarrows} Co^{2+}(AAH^-)_2\cdots O_2 \overset{K_q}{\rightleftarrows} Co^{3+}(AAH^-)_2\cdots O_2^- \overset{K_j^{-1}}{\rightleftarrows} \{Co^{3+}(AAH^-)_2\}^+ + O_2^- \quad (20)$$

$$Co^{2+} + 2AAH^- \overset{K_s}{\rightleftarrows} Co^{2+}(AAH^-)_2, \text{ and}$$

$$Co^{3+} + 2AAH^- \overset{K_t}{\rightleftarrows} \{Co^{3+}(AAH^-)_2\}^+$$

$$[O_2^-]=\{(K_p\cdot K_q\cdot K_j^{-1}\cdot K_s)/K_t\}\cdot [O_2][Co^{2+}]/[Co^{3+}] \quad (I)$$

Since the $[Co^{2+}]/[Co^{3+}]$ is considered to be approximately constant under a steady state, the $[O_2^-]$ may also be expected to be almost constant.

The Relationship among the Induction Period, [HAAH] and the Total Amount of Oxygen Absorbed.—The induction period is supposed to depend on the time interval in which the amount of HAA· necessary for the progress of the reaction 3 or 13 could be accumulated in the solution. In the reaction using a definite amount of Co^{2+}, the concentration of Co^{2+} decreases with an increase in the mole ratio of [HAAH]/$[Co^{2+}]$, since Co^{2+} is more or less consumed in the formation of the chelate. The induction period is, therefore, considered to become longer with an increase in the mole ratio of [HAAH]/$[Co^{2+}]$.

It may also be supposed, on the basis of the experimental results, that the liberated HAAH can be oxidized more easily than the chelated HAAH. When the amount of HAAH increases in proportion to a definite amount of cobalt, the increases in the liberated HAAH is not so large as the increase in the HAAH added, since some parts of HAAH are consumed in the formation of the chelate.

Therefore, the total amount of the oxygen absorbed is not considered to increase markedly in comparison with the increase in the [HAAH] added. In the case of $[HAAH]/[Co^{2+}]>3$, about one-half of the increment in the HAAH added is considered to take part in the chelate formation.

The Oxidation of *p*-Xylene and Toluene Using the Co-HAAH System.—At the beginning of the radical chain reaction, the formation of

the radicals by withdrawing the hydrogen atom from the hydrocarbons is induced with tervarent cobalt,[1,7] including the metal peroxide.[6,8] Though the formation of Co^{3+} in an aqueous solution is not easy, since $E°=-1.84$ V., the cobalt in the activated state seems to be easily formed in glacial acetic acid in the presence of such ketones as ethyl methyl ketone, HAAH, acetonylacetone and ethyl acetoacetate.

It is easily ascertained spectroscopically that Co^{2+} is converted with oxygen into the higher valency state or the activated state in the presence of HAAH.

Therefore, the formation of the radicals from *p*-xylene and toluene seems to be reduced to the action of $HAAO_2\cdot$, Co^{3+} and $\{Co^{3+}(AAH^-)_2\}^+$, etc., against them. As is shown in Fig. 2, the absorption rate of oxygen in the presence of 0.5 mol./l. *p*-xylene is slower than that in the absence of *p*-xylene.

This shows that the active species produced in the solution might be consumed by reacting with *p*-xylene. However, the formation of the radical seems to be based on the action of Co^{3+} and $\{Co^{3+}(AAH^-)_2\}^+$, since the concentration of $HAAO_2\cdot$ is not as high as is necessary for Eq. 21 to hold:

$$RH + HAAO_2\cdot \rightarrow R\cdot + HAAO_2H \qquad (21)$$

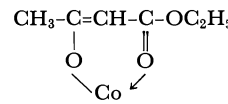
It is clear from Fig. 3 that the cobaltic acetylacetonate, $Co^{3+}(AAH^-)_3$, could be almost stable for the oxidation with oxygen. Though the co-existence of a suitable amount of HAAH is necessary for the oxidation of *p*-xylene and toluene, the formation of $Co^{3+}(AAH^-)_3$ becomes easier with an increase in the mole ratio of [HAAH]/[Co^{2+}], while the formation of the activated species of Co^{2+} becomes more difficult with a decrease in the mole ratio of [HAAH]/[Co^{2+}]. Therefore, the optimum conditions for the oxidation of *p*-xylene and toluene are when [HAAH]/[Co^{2+}]=2.

In the cobaltous acetylacetonate, $Co^{2+}(AAH^-)_2$, four co-ordination positions are already occupied with AAH^-, but there are still two vacant positions which can be easily co-ordinated with water, acetic acid, oxygen molecules, etc.

In the case of a co-ordination with O_2 as is shown in the reaction 20, it is supposed that Co^{2+} and O_2 are converted into Co^{3+} and O_2^- respectively; these activated species make the withdrawing of hydrogen atoms from hydrocarbon easier. Since the ease of the formation of the negatively charged oxygen species are generally in the order of $O_2^->O^->O^{2-}$,[9] the oxygen in the activated species is assumed to be O_2^-.

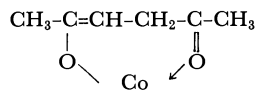
Since such ketones as ethyl acetoacetate and acetonylacetone show a smaller co-ordination ability to cobalt ions than HAAH, the cobalt chelates with these ligands are expected to be too unstable to resist oxidation.

When the authors write the structure of the chelate of the acetoacetic ester:



it may be seen that the enolate (or benzenoid) resonance involving the cobalt is greatly interferred with by the participation of one of the C=O groups in the very strong ester resonance, thus accounting for the very large decrease in the stability of the chelate.[10]

Since it is generally accepted that a six-membered chelate ring is much more stable than a seven-membered one,[11] the cobalt chelate of acetonlylacetone with a seven-membered ring is not expected to be more stable than that of HAAH with a six-membered ring.



Hence, the equilibrium concentrations of the unbound acetoacetic ester and acetonylacetone

are expected to be higher than that in HAAH.

It is, therefore, considered that the oxidation of hydrocarbons in the presence of the above ketones proceeds favorably even when the mole ratio is [ketone]/[Co^{2+}]=3.

Oxidation Products of Acetylacetone. — The oxidation products identified by gas chromatography are considered to come from $HAAO_2H$ or $HAAO_2\cdot$ by the mechanisms as show in page 671.

Summary

Acetylacetone is oxidized in a glacial acetic acid solution containing bi-valent cobalt to produce α-hydroperoxyacetylacetone, by which Co^{2+} is further oxidized to Co^{3+}.

At the end of the oxidation, acetylacetone is converted into formic acid, acetic acid, and small amounts of aldehydes.

Under a definite pressure of oxygen, the oxidation rates are as follows; at [HAAH]/[Co^{2+}]$\leq$3,

$$-d[O_2]/dt = k_a[HAAH]^{1/2}[Co^{2+}]^{-1/3}$$

and at [HAAH]/[Co^{2+}]$\geq$4,

$$-d[O_2]/dt = k_b[HAAH][Co^{2+}]^{1/4}$$

In order to oxidize toluene and *p*-xylene in the glacial acetic acid solution containing Co and HAAH catalysts, the formation of Co^{3+} and $\{Co^{3+}\text{-}(AAH^-)_2\}^+$ in the solution is indispensable. Since the [HAAH] is insufficient for the formation of Co^{3+} at the mole ratio of [HAAH]/[Co^{2+}]$<$2, and since the stable chelate, $Co^{3+}(AAH^-)_3$, is easily produced at the mole ratio of [HAAH]/[Co^{2+}]$>$3, the Co-HAAH systems are considered to be active only at the mole ratio of [HAAH]/[Co^{2+}]=2 for the oxidation of *p*-xylene and toluene. However, such ketones as acetonylacetone and ethyl acetoacetate are still active at the mole ratio of [ketone]/[Co^{2+}]=3, since these ligands form less stable complexes than the complex with HAAH.

The NMR Analysis of the Water of Crystallization in Beryl

By Yoshinori SUGITANI, Kozo NAGASHIMA and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received May 26, 1965)

The existence of two types of protons in beryl was proved by the proton magnetic resonance technique; one is as a molecular form of water in the channel of the crystal, while the other is as a hydroxyl-ion replacing O^{2-} ion of the crystal lattice. The proton-proton line of the water was found to be parallel to the c-axis of the crystal.

There are many minerals which contain an indefinite amount of the water of crystallization. Beryl, $Be_3Al_2Si_6O_{18}\cdot nH_2O$, is one of them; it usually contains about one to three weight per cent of water.

Some studies have been carried out concerning the water in beryl by thermogravimetric analysis (TGA), infrared spectroscopy, differential thermal analysis (DTA), and so on. According to Matsuda's finding,[1] two abrupt changes in the ignition loss of water were observed in TGA, and also two endothermic peaks in DTA.

Furthermore, after a detailed consideration using the ordinary methods mentioned above, Sugiura[2] proposed the presence of two types of water in cordierite and beryl - one, a molecular form in the tubular channel of the crystal, and the other, an OH^- ion form replacing the O^{2-} ion of the lattice point. In the present paper, the structure of water in beryl will be investigated by the broad-line NMR technique.

The crystal structure of beryl is shown in Fig. 1. Its crystal system is hexagonal, with a space group 6/m 2/m 2/m. A unit cell contains two molecules; the lattice parameters are $a=9.215$ Å and $c=9.17$ Å. As can be seen in the figure, there are holes about 4.5 Å in diameter, and they line up in a row along the c-axis, making tubular channels which serve to accomodate water molecules, occluded gases and alkali ions. The holes are 4.59 Å apart from each other. If a water molecule is placed in each of these holes, the n number in the chemical formula is equal to 1; if they are placed in every other hole, n is equal to 0.5.

Experimental

A single crystal of the prismatic form, which was obtained in Saga,* was cut into a size proper for being

inserted into an rf coil. The water content of this sample is determined to be 3.05% by means of the ignition-loss method. A simple calculation shows that the n number in the chemical formula of this sample is nearly equal to 1.

The spectra were measured at 30 Mc and in the $-100 \leftrightarrow +150$°C temperature range by using an NMR spectrometer, type JNM-W-30, manufactured by the Japan Electron Optics Laboratory Co., Ltd.

Results and Discussion**

First, the sample was placed in a probe with the c-axis perpendicular to the main magnetic

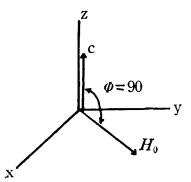

Fig. 2. The c-axis is fixed parallel to the z-axis, and the H_0 field rotates around the origin, O, with the Φ angle always kept 90°.

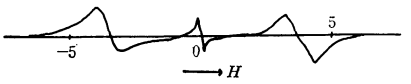

Fig. 3. One of the NMR spectra observed. The other spectra closely resemble this fugure.

field, H_0. The crystal was then rotated and measured at 15° intervals about the c-axis. The line shape of the spectrum did not change with this rotation. One of the spectra obtained is given in Fig. 3. Next, the crystal was placed with the c-axis parallel to H_0, and rotated about the g_1- or $[2\bar{1}\bar{1}0]$-axis, so as to change the angle, Φ, between the c-axis and the magnetic field H_0. The line shape varied with the angle Φ, as is shown in Fig. 5. Similar results within the range of experimental errors were obtained for rotations about five other axes, g_2, g_3, g_4, g_5, and g_6; these are shown in Fig. 6.

As may be seen in Fig. 5, each observed spectrum is composed of three parts, one very narrow, and two broad. The two broad parts are always symmetrically shifted from the center of the narrow part.

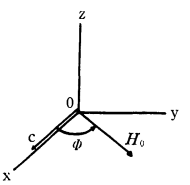

Fig. 4. The angle, Φ, between the c-axis and the H_0 field varies as H_0 rotates around the origin, O, in the xy plane.

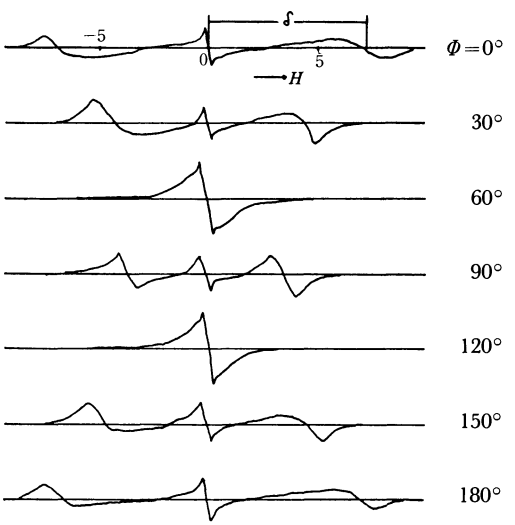

Fig. 5. NMR spectra observed at various angles. The spectra were measured at 15° intervals between 0° and 180°; however, only the spectra observed at 30° intervals are shown in this figure.

* Sugiyama in Saga prefecture. The sample is hexagonal prismatic, about 1.5 cm. long, 0.7 cm. in diameter, and pale green in color.

** After we finished our work, the following paper has come to our attention: X. Parè and P. Ducros, Bull. Soc. Franç. Minér. Crist. (1964) LXXXVII, 429—433. While their results are in accordance with ours, they do not indicate the presence of two types of protons.

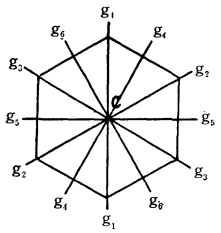

Fig. 6. The hexagon represents the (0001) plane of the single crystal of beryl, while the line perpendicular to this plane at point c is the six-fold axis of the crystal.

From the results obtained above, the protons which contribute to the observed NMR spectra may be classified into two types. The narrow component may be ascribed to either protons which are very easy to move, such as the water molecules in the liquid state, or to protons which are isolated from each other nd which so have negligible dipolar interactions.

The former possibility can be eliminated for two reasons: i) The water molecule in beryl can not be removed easily by heating it up to several hundred degrees, and therefore, it cannot be in a liquid state; ii) we could not find any fluid inclusion in our sample under a microscope.

Therefore, we may assume that the narrow part of the spectrum is due to the protons of the OH^- ions which occupy the position of the O^{2-} ions in the crystal. This conclusion coincides with the results obtained by the IR and other methods by Sugiura.

The remaining two broad parts may be interpreted in terms of the dipolar interactions between two protons belonging to the same water molecule. This means assuming a two-spins system. The magnetic field provided by one of the two water protons is given by[3]:

$$H = H_0 \pm \alpha(3\cos^2\theta - 1), \quad \alpha = \frac{3}{4}\frac{\gamma\hbar}{r^3}$$

where θ is the angle between the line connecting the two protons and the H_0 field; γ, the proton gyromagnetic ratio; $\hbar$, Planck's constant divided by 2π, and r, the distance between two interacting protons in a water molecule.

3) G. E. Pake, *J. Chem. Phys.*, **16**, 327 (1948).

In Fig. 7, the open circles are the observed shifts, δ, of the broad part from the center of the narrow part, while the solid lines represent the plots of the function, $\pm\alpha(3\cos^2\theta - 1)$, fitted to the experimental value at $\Phi = 90°$. The agreement between the two plots is fairly good.

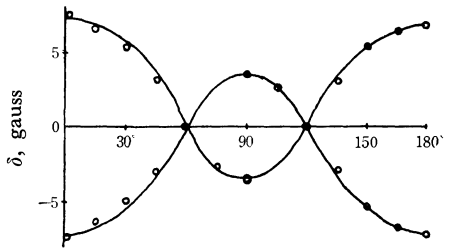

Fig. 7. The solid lines are the calculated lines of the functions, $\pm\alpha(3\cos^2\theta - 1)$, while the open circles are the observed values of δ.

From these results, it can be concluded that the angle, θ, between the proton-proton line and the H_0 field indicates the angle, Φ, between the c-axis and the H_0 field; that is, the proton-proton line of a water molecule is parallel to the c-axis of the crystal. (The position of the oxygen atom of the water molecule has not been determined by the present experiment).

Measurements of the temperature dependence of the line shapes were taken in the $-100 \leftrightarrow +150$°C range. In this experiment, the crystal was placed in the probe with the c-axis perpendicular to the H_0 field. The separation, 2δ, of the two broad parts varied slightly with the temperature, as is shown in Fig. 8. The explanation of this temperature dependence will be the subject of a future study.

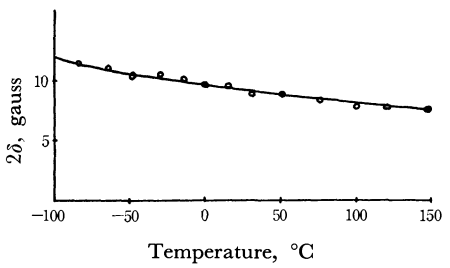

Fig. 8. Temperature dependence of the separation 2δ between the two broad parts.

A Kinetic Study of the γ-Radiation-Induced Polymerization of Ethylene at a Normal Temperature*

By Sueo MACHI, Miyuki HAGIWARA, Masao GOTODA and Tsutomu KAGIYA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma

(Received May 31, 1965)

The gamma-radiation-induced polymerization of ethylene was carried out in the intermediate pressure region from 70 to 400 kg./cm^2 with a dose-rate from 5×10^3 to 4.3×10^5 rad./hr. and at a temperature of 30°C. An overall G-value of the 10^4 order was usually obtained. No induction period for polymerization was observed. The polymerization rate and the molecular weight of the polymer formed were shown to increase almost proportionally with the reaction time and with the pressure of ethylene. The dose-rate exponents of the rate and the molecular weight were found to be 0.9 and 0 respectively. These results indicate that the stationary-state hypothesis, i. e., that the rate of initiation is equal to that of termination, is not realized in this polymerization. From the kinetic discussion of the initial stage of polymerization, where the concentration of monomer remains essentially constant, it was concluded that the rates of termination and transfer reaction are very small; the life of polymer radicals is, therefore, quite long and the growing of polymer radicals proceeds successively under irradiation.

Several studies[1-7] of the γ-radiation-induced polymerization of ethylene have been published during the past ten years. Hayward and Bretton,[1] for instance, reported that the reaction consisted of two parts; the one was strongly inhibited by a trace of oxygen, and the other was not. Laird et al.[2] reported that the rate of polymerization depended on the ethylene pressure (P) and the radiation intensity (I), as the rate$=kP^{2.6}I^{0.9}$, with the overall activation energy of 3.3 kcal./mol. at lower temperatures of 20 to 125°C and at pressures from 473 to 1185 atm., while at higher temperatures (from 100 to 200°C) the rate$=kP^{3.1}I^{0.8}$, with the activation energy of 13.6 kcal./mol. Medvedev et al.[5] observed that the rate of polymerization increased with the reaction time, and that the maximum rate was proportional to the ethylene concentration to the power of 4—5 and to the 0.3 th power of the dose rate. More recently, Steinberg et al.[7] reported the rate equation to be rate$=kP^{1.02}I^{0.42}$ and that the G-value was very high.

We are now undertaking a series of investigations of the γ-radiation-induced polymerization of ethylene in order to find its mechanism. We have already communicated briefly[8,9] that the polymerization rate and the molecular weight of the polymer increase with the reaction time, and that the life of the growing polymer radical is long at 30°C under irradiation. In the present work, the polymerization rate and the molecular weight have been measured in the pressure range from 70 to 400 kg./cm^2, at the temperature of 30°C, and at dose-rates from 5000 to 430000 rad./hr. using ethylene of a high purity. The main topic of this paper is a kinetic discussion of the polymerization at normal temperature.

Experimental

A scheme of the experimental equipment is shown in Fig. 1. The reaction vessel was an unstirred stainless-steel (SUS-27) autoclave with a capacity of 100 ml. The pressure measurements were made by a Bourdon tube gauge. A chromel-alumel thermocouple with a recorder was used for the continuous temperature measurements. The reaction temperature was regulated within 2°C by an automatic controller. The reactions were carried out by the batch stysem.

Before the vessel was filled with ethylene, the system was evacuated and swept out with ethylene three times; then ethyene was introduced from a reservoir to the vessel, which had been cooled in a methanol - dry ice

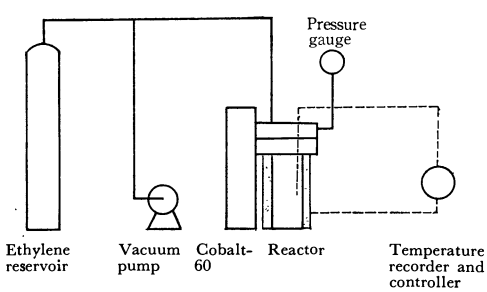

Fig. 1. Experimental equipment.

bath. The vessel was then brought to the desired reaction temperature and pressure. As a source of γ-ray, 400-curie and 12000-curie cobalt-60 were used. The radiation intensity inside the reaction vessel was measured by ferrous sulfate dosimetry. At the end of the irradiation period, the unpolymerized ethylene was purged and the vessel was opened in the air. The amount of polymer formed was determined by direct weighing.

The ethylene used was commercially available and was 99.9% pure (free of CO and H_2S), containing 48 p. p. m. acetylene and 3 p. p. m. oxygen. The density and fugacity of ethylene at a given pressure and temperature are known from Benzler's pressure-enthalpy diagram.[10]

The solution viscosity of the polyethylene formed was measured in tetralin at 130°C. The number-average molecular weight of polymer was estimated by Tung's formula[11]:

$$[\eta] = 4.60 \times 10^{-4} \overline{M}_n^{0.725}$$

Results

The results are summarized in Tables I and II.

The polymer yield is plotted against the reaction time in Fig. 2. In these experiments there is no induction period in which no polymer is formed. The yield of the polymer formed increases rapidly with the reaction time in the early stage, while in the stage of higher conversion, the increasing rate is gradually reduced because of the drop in pressure.

Reaction temperature, 30°C

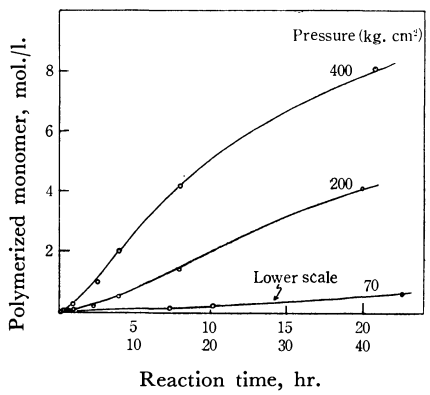

Fig. 2. The amount of ethylene polymerized vs. reaction time.
(Reaction temperature, 30°C; dose-rate, 2.5× 10^4 rad./hr.)

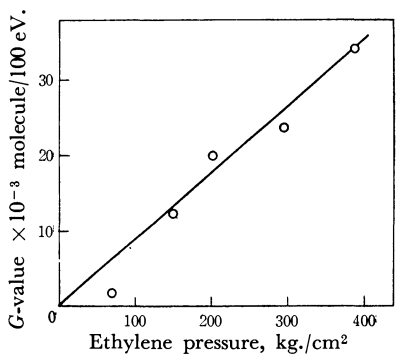

Fig. 3. G-value vs. initial ethylene pressure.
(Reaction temperature, 30°C; dose-rate, 2.5× 10^4 rad./hr.; reaction time, ca. 20 hr.)

The G-value (molecules of ethylene polymerized per 100 eV. absorbed in the mass of the monomer and the polymer) is also shown in Tables I and II. The G-value depends on the reaction time, the ethylene pressure, the dose-rate and the reaction temperature; it lies between 1.8×10^3 and 4.3×10^4. Figure 3 indicates that the overall G-value is proportional to the initial pressure of ethylene.

Polymerization under a Low Conversion.—The experiments concerned with kinetic study were carried out under conditions in which the conversion of ethylene to polymer was low and the pressure remained essentially constant during the course of the reaction.

Polymer Yield.—The polymer yield, with a dose rate of 2.5×10^4 rad./hr. under various pressures, is plotted against the time in Fig. 4. No induction period was observed in our experiments. As is shown in Table I, at a pressure of 400 kg./cm² under 30°C, 0.03 g. of polymer is formed in only 16 min. in a 100 ml. reactor. On the other hand, an induction period of more than several hours, as a result of oxygen, was reported in the case of the polymerization of ethylene containing over 60 p. p. m. oxygen by Steinberg et al.[7] and by Hayward et al.[1] The reason for the difference between these results and ours is not clear,

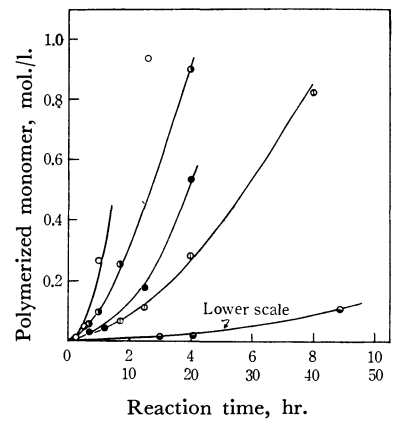

Fig. 4. The amount of polymerized monomer vs. reaction time.

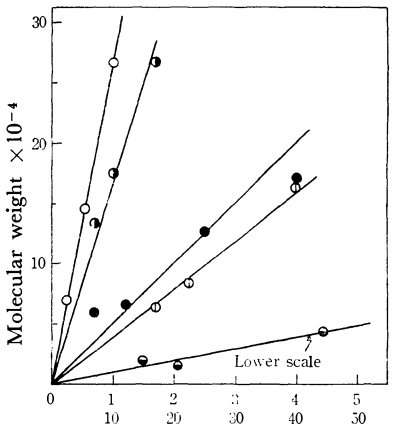

Fig. 6. Molecular weight vs. reaction time. (Reaction conditions and notes are the same as Fig. 4.)

but it may be ascribed to the difference in the amounts of oxygen; i. e., the ethylene used in our experiments contains only 3 p. p. m. oxygen, plus other impurities.

Since the polymer yield increases rapidly with the reaction time, as is shown in Fig. 4, it should be noted that a rate acceleration is observed in this polymerization.

The effect of the intensity was investigated over the dose-rate range from 0.5×10^4 to 43×10^4 rad./hr.; a hundred-fold range was thus covered. In Table II, it is shown that the amount of polymer formed increases with the dose-rate. Figure 5 indicates that the polymer yield at a constant time increases rapidly with the pressure.

Molecular Weight.—In these experiments, the molecular weight falls in the wide range from 20000 to 300000, depending on the reaction conditions.

The molecular weight of the polymer formed in the early stage of less than ca. 3% conversion is plotted against the reaction time at each respective pressure (but these pressures are almost constant during the reaction) in Fig. 6. It is a characteristic phenomenon that the molecular weight of the polymer formed increases proportionally with the reaction time. The increase in ethylene pressure obviously gives the increase in the molecular weight of the polymer.

The dependence of the molecular weight of the polymer on the radiation dose-rate is seen in Table II. It is interesting that the molecular weight at the unit reaction time is almost independent of the dose rate.

Discussion

From the characteristic features—(1) the reaction rate increases with the reaction time; (2) the molecular weight of the polymer formed increases with the reaction time, and a polymer of a very high molecular weight is easily obtained, and (3) the radiation dose-rate has little effect on the molecular weight of the polymer, it can be concluded that the stationary-state hypothesis, that the rate of initiation is equal to that of termination, is not realized in this polymerization.

In our kinetic study experimental results are, therefore, treated without using the stationary-state hypothesis.

Polymerization Rate.—The following elementary reactions are assumed for the γ-radiation-induced polymerization of ethylene in bulk; the respective rate expressions are also shown at the right.

1. Initiation $\quad M \xrightarrow{k_i} R_1\cdot \quad R_i=k_i\rho_M I \quad (1)$
2. Ethylene excitation $\quad M \rightleftarrows M^*$
$$M+M^* \rightleftarrows M_2^* \quad f_{M_2^*}=K_e f_M^2 \quad (2)$$
3. Propagation $\quad R_1\cdot+M_2^* \xrightarrow{k_p} R_3\cdot$
$$R_{n-2}\cdot+M_2^* \xrightarrow{k_p} R_n\cdot$$
$$R_p=k_p[R\cdot]f_{M_2^*} \quad (3)$$
4. Termination $\quad R_m\cdot+R_n\cdot \xrightarrow{k_{t1}} P_{m+n}$
$$R_n\cdot+Z \xrightarrow{k_{t2}} P_n$$
$$R_t=k_{t_1}[R\cdot]^2+k_{t_2}[R\cdot][Z] \quad (4)$$
5. Transfer $\quad R_n\cdot+Y \xrightarrow{k_{tr}} P_n+Y\cdot$
$$R_{tr}=k_{tr}[R\cdot][Y] \quad (5)$$

where M represents the ethylene monomer; $R_n\cdot$, an active polymer chain composed of n monomers; $[R\cdot]$, the total concentration of all the active polymer chains, irrespective of size (i. e., $\sum_{n=1}^{\infty}[R\cdot_n]$); M*, the excited ethylene monomer; M_2^*, the excited ethylene dimer; Y, the substance to which the activity of $R\cdot_n$ is transferred; Z, the substance by which $R\cdot_n$ is deactivated; P_n, a dead polymer composed of n monomers; R_i, R_p, R_{tr}, and R_t, the rates of initiation, propagation, transfer, and termination; k_i, k_p, k_{tr}, and k_t, the rate constants of these reactions; ρ_M the density of ethylene; I, the dose rate; f_M, the fugacity of ethylene; $f_{M_2^*}$ the fugacity of the excited ethylene dimer, and K_e, the equilibrium constant of the 2nd step.

Since the initiation step is brought about by the absorption of the radiation energy by the monomer, the rate of the initiation reaction may be considered to be proportional to the density of ethylene presented in the reactor and to the intensity of radiation. The rate expression 1 is, therefore, given for the initiation reaction. The 2nd step is characteristic in this scheme. The step of the formation

of the excited dimer from the monomer with radiation is introduced because of the following facts; (1) as was reported before,[9] the propagation reaction does not take place without radiation, though it takes place with a radiation of a very low dose rate, and (2) the rate of propagation is proportional to the 2nd power of ethylene fugacity, as will be described later. It is well known that the rates of excitation and energy transfer are very fast in the radiation chemistry. The 2nd step is, therefore, very fast compared with the 3rd step and is in equilibrium.

In the propagation step, the excited dimer adds to the propagating chain. Ordinary chain termination and transfer are assumed. The overall rate of polymerization is approximately equal to the rate of propagation; accordingly, it becomes:

$$R=\mathrm{d}M_p/\mathrm{d}t\simeq R_p=k_p[\mathrm{R}\cdot]f_{\mathrm{M}}^*, \qquad (6)$$

where R represents the overall polymerization rate, and M_p, the amount of monomer polymerized. Here, without the assumption of stationary-state, [R·] is given by:

$$[\mathrm{R}\cdot]=k_i\rho_{\mathrm{M}}It-\int R_t\mathrm{d}t \qquad (7)$$

From the facts that the rate of polymerization and the molecular weight of the polymer increase with the reaction time, it can be assumed that no termination reaction occurs, that, namely, R_t is zero. Equation 7 then becomes:

$$[\mathrm{R}\cdot]=k_i\rho_{\mathrm{M}}It \qquad (8)$$

From the combination of Eqs. 2, 6 and 8, the overall rate of polymerization can be expressed by the following equation:

$$R=\mathrm{d}M_p/\mathrm{d}t\simeq R_p=k_pk_iK_e\rho_{\mathrm{M}}f_{\mathrm{M}}^2It \qquad (9)$$

By integrating Eq. 9, the amount of the monomer polymerized is expressed as a function of the density and the fugacity of ethylene, the dose rate, and the reaction time; namely,

$$M_p=(1/2)\cdot k_pk_iK_e\rho_{\mathrm{M}}f_{\mathrm{M}}^2It^2 \qquad (10)$$

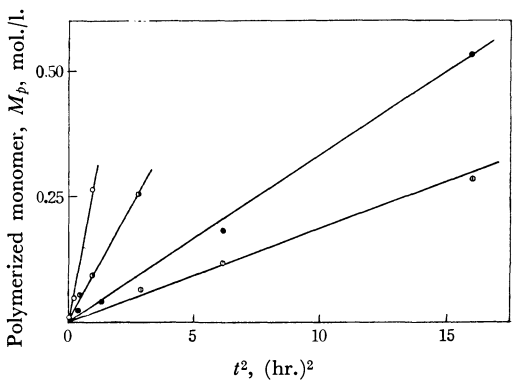

Fig. 7. The amount of polymerized monomer vs. square of reaction time.
(Reaction conditions and notes are the same as Fig. 4.)

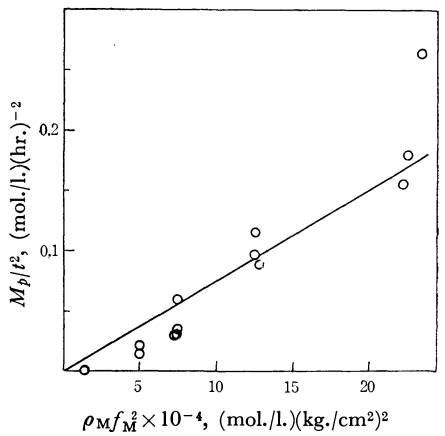

Fig. 8. M_p/t^2 vs. $\rho_{\mathrm{M}}\cdot f^2{}_{\mathrm{M}}$.
(Reaction temperature, 30°C; dose-rate, 2.5×10^4 rad./hr.; ethylene pressure, 70 to 400 kg./cm^2).

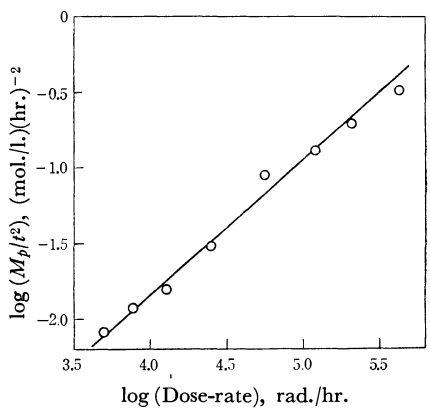

Fig. 9. Logarithmic plots of M_p/t^2 vs. dose-rate.
(Reaction temperature, 30°C; ethylene pressure, 200 kg./cm^2)

A distinct linear relation exists between the amount of monomer polymerized and the square of the reaction time at each respective pressure, as is indicated in Fig. 7. The plot of $\rho_{\mathrm{M}}f_{\mathrm{M}}^2$ versus M_p/t^2 also gives the straight line in Fig. 8. The logarithmic plot of the dose-rate against M_p/t^2 is shown in Fig. 9, from which the dose-rate exponent of M_p/t^2 may be seen to be 0.9.

The results are combined and an empirical expression of amount of monomer polymerized is obtained as:

$$M_p=k_1\rho_{\mathrm{M}}f_{\mathrm{M}}^2I^{0.9}t^2 \qquad (11)$$

The approximate agreement of the empirical expression with the theoretical one (10), derived from the elementary reactions presumed above, is thus shown.

The Degree of Polymerization.—The number-average degree of polymerization at a given reaction time is written for the polymerization with no termination by recombination as follows:

$$\overline{DP}=(\int R_p\mathrm{d}t)/(\int R_i\mathrm{d}t+\int R_{tr}\mathrm{d}t) \qquad (12)$$

where $\overline{DP}$ represents the number-average degree of polymerization, and $\int R_p\mathrm{d}t$ is as given in Eq. 10 ($\int R_i\mathrm{d}t$ is also obtained from Eq. 1); accordingly:

$$\overline{DP}=\frac{(1/2)\cdot k_p k_i K_e \rho_M f_M^2 I t^2}{k_i \rho_M I t+(k_{tr}/k_p K_e)\cdot([Y]/f_M^2)\cdot M_p} \qquad (13)$$

then;

$$1/\overline{DP}=(2/k_p K_e f_M^2 t)+(k_{tr}/k_p K_e)\cdot([Y]/f_M^2) \qquad (14)$$

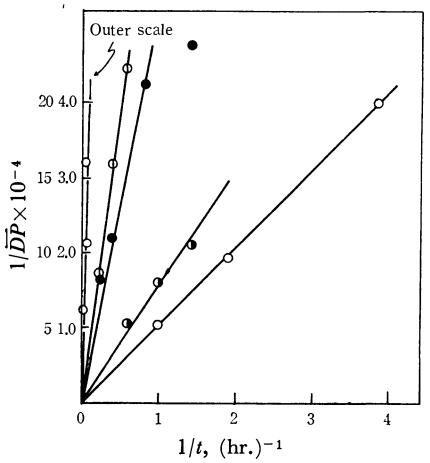

Fig. 10. Reciprocal of degree of polymerization vs. reciprocal of time.
(Reaction conditions and notes are the same as Fig. 4.)

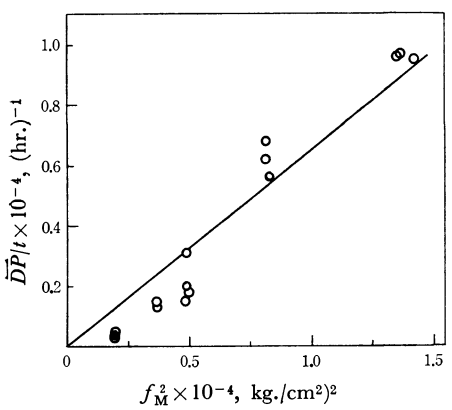

Fig. 11. $\overline{DP}/t$ vs. square of ethylene fugacity.
(Reaction temperature, 30°C; dose-rate, 2.5×10^4 rad./hr.; ethylene pressure, 70 to 400 kg./cm^2)

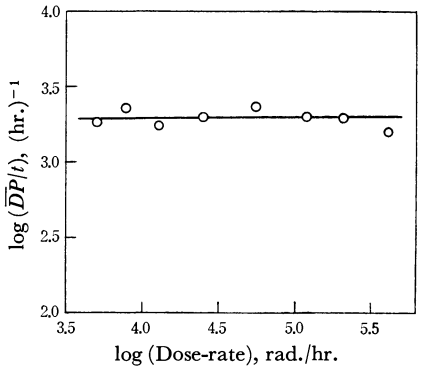

Fig. 12. Logarithmic plots of $\overline{DP}/t$ vs. dose-rate.
(Reaction temperature, 30°C; ethylene pressure, 200 kg./cm^2)

The plot of the reciprocal of $\overline{DP}$ against the reciprocal of the reaction time gives a straight line through the origin, as is shown in Fig. 10. The fact that the line goes through the origin indicates that there is no transfer reaction in the polymerization; Eq. 14 thus becomes:

$$\overline{DP}=(1/2)\cdot k_p K_e f_M^2 t \qquad (15)$$

The linear relation between $\overline{DP}$ and the time has previously been shown in Fig. 6. In Fig. 11, it is shown that the ratio of the degree of polymerization to the reaction time is approximately proportional to the square of ethylene fugacity. Figure 12 shows that the dose rate does not influence $\overline{DP}/t$. By combining these results, the following empirical expression of the degree of polymerization is obtained:

$$\overline{DP}=k_2 f_M^2 t \qquad (16)$$

The empirical expression is shown to agree with theoretically derived Eq. 15.

In the view of fact that the experimental results on both polymerization rate and the degree of polymerization coincide with the equation theoretically derived, the proposed elementary reaction and the assumption that the termination is essentially eliminated, and that the stationary state is not realized in this polymerization, may be accepted. In other words, the propagation, proceeds successively, and a long-lived active polymer chain may exist under irradiation. The long life-time of the active chain has been proved by a kind of post polymerization experiment.[9]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 681—684 (1966)

The Combustion-Gas Chromatographic Determination of Minute Quantities of Sulfur in Metals

By Jiro KASHIMA and Takuo YAMAZAKI

The Castings Research Laboratory, Waseda University, Shinjuku-ku, Tokyo

(Received June 7, 1965)

The determination of minute quantities of sulfur in metals is an important problem in refinery processing. This paper will describe a combustion-gas chromatographic method which gives precise results. This method is applicable to various metals, including iron and steels. Standard samples containing 0.011% of sulfur show a standard deviation of 0.0001%. Titanium and copper containing from 0.004 to 0.008% of sulfur show a mean deviation of 0.0003%. The limit of detection is 10 μg. (0.001%) of sulfur in a 1.0 g. sample. It takes about 10 min. to determine the sulfur content by this method.

Because of the adverse effect of sulfur on the physical properties of pure metals, steel and cast iron, a method for controlling the sulfur content during refining is desirable. The determination of sulfur in metals is generally performed by a chemical method which measures the concentration of SO_4^{2-} or SO_3^{2-} ions formed by bubbling the combustion products (carbon dioxide, sulfar dioxide, water, etc.) through an aqueous solution of hydrogen peroxide. Several other methods[1-7] have been proposed for the determination of minute quantities, i. e., several micrograms, of sulfur. Colorimetric,[1-3] conductometric[4,5] and chromatographic - gravimetric[7] methods are available for the determination of extremely small amounts of sulfur in metals. For rapid analysis, a neutron-activation analysis[6] is used. Recently, a combustion-gas chromatographic method[8] has been proposed to determine carbon and sulfur simultaneously in ferrous metals.

This paper will describe a combustion-gas chromatographic method which is capable of determining sulfur accurately in various metals. The method is a simplification in the following three ways: a gas chromatograph was used for the analysis of the combustion gases; a simple chromatographic concentration technique[9] was used for isolating sulfur dioxide and pure copper powder or foil was used as the bedding material to burn titanium, silicon, etc., in a commercially-available H-F combustion furnace. Minute amounts of sulfur can be accurately determined by this method within ten minutes.

Experimental

Apparatus.—A simple schematic diagram is shown in Fig. 1. The apparatus is simlar in principle to that described[8] elsewhere by the present authors and used for the determination of small amounts of carbon in pure iron and steel; it consists of a commercially-available combustion funace to ignite the sample and a gas chromatograph connected to the concentration column to isolate sulfur dioxide in the combustion products. Some changes have, however, been made in the apparatus and in the procedure used previously for the determination of carbon. A silica gel column

was used instead of an activated charcoal column, and accelerator was added.

Oxygen gas of a commercially-pure grade was introduced from a gas cylinder through the reducing valve. The gas was further purified by passing it through tubes of granular potassium hydroxide and of phosphorus pentoxide, thus removing the sulfur dioxide and water.

The combustion was carried out by the use a of Kokusai Denki H-F combustion furnace; the oxygen stream was regulated by means of a reducing valve attached to the gas cylinder.

The combustion products were led into concentration column, D, by stainless steel tubing (2 mm. in diameter.) through a Drierite, B, and a silica wool plug.

C_1 is a four-way cock which connects the concentration column, D, and the gas-sampling cock, C_2, of the gas chromatograph, as is shown in Fig. 1.

The Flikentite cuplets (crucibles) and the caps (made by the Nihon Kagaku Kogyo Co.) were prebaked for 3 hr. at a temperature of about 1500°C in a hydrogen stream; the cuplets were then baked for 4—5 more min. in the same manner as in the ordinary combustion procedure.

Gas Chromatography.—A Yanagimoto gas chromatograph, Model GCG 100, and a Minneapolis-Honeywell recorder, Model SY 153, with a full-scale sensitivity of 50 mV. were used. In order to measure a minute quantity of sulfur dioxide, the recorder was connected with an Ohkura DC. amplifier, Model AM 101, and employed at a full-scale sensitivity of 500 μV. The detector was a thermal conductivity cell with a pair of tungsten filaments; the current supply to the bridge circuit was adjusted to 150 mamp.

The argon gas, which was less than 0.01% impure, was used as the carrier gas at a flow rate of 50 ± 2 ml./min.

The chromatographic column was a copper tube 50 cm. long and 6 mm. in diameter. It was packed with 30—64 mesh Celite 545 containing 30% tricresyl phosphate and was kept at the temperature of 40°C in a thermostat chamber.

The concentration column was a copper tube 10 cm. long and 6 mm. in diameter.; it was packed with 30—64 mesh silica gel. This column was used for concentrating only sulfur dioxide at room temperature. The concentrated gas was injected into the chromatograph at the temperature of 120°C.

Procedure.—The concentration column, D, was heated in a salt bath, with the argon gas allowed to flow through for several minutes, until the water absorbed in the silica gel had been removed. In order to remove the water from the combustion system, it was heated in oxygen gas.

The sample (approximately 1.0 g.) was weighed into a cuplet, together with the analytical-grade accelerators, i. e., 100 mg. of tin shot and 50 min. of chromium(III) oxide powder. The sample was placed in position, and then agron gas was passed through the apparatus for 2 min. The column, D, was connected with the combustion tube by turning cocks C_1, C_2 and C_3 to the positions shown in Fig. 1; the rate of oxygen flow was adjusted to 150 ml./min., and then the combustion was started.

The products of the combustion were collected in the column at room temperature for 3—5 min. while the sample was being burned. The three-way cock, C_3, was then turned 90° to cut off the oxygen flow. The sample cuplet was removed from the combustion tube to avoid overheating the silicone gaskets. By opening the needle valve, the oxygen in the column was expelled in 20—30 sec. by the argon stream at a flow rate of 50 ml./min. C_3 was then returned to the previous position, and the column was immersed in a potassium carbonate bath at 120—130°C. By turning C_2, the gases in the column were then injected into the gas chromatograph. A typical chromatogram is shown in Fig. 3.

The blank value for this method was obtained from the data derived from the ordinary results. The blank value was about 12 μg. of sulfur; this was very low in comparison with the amounts of sulfur in 1—2 g. samples of steel. A fluctuation of the blank values was, however, found between various kinds of crucibles used. The measurement of a peak area of sulfur dioxide was carried

out by the use of a planimeter or by the conventional appoximate method, while the sulfur content in the sample was obtained by the following equation:

$$\text{Sulfur, } \% = (a_t - a_b)/w \cdot K$$

where a_t: the area of the chromatogram of sulfur dioxide in sq. mm. for the sample; a_b: the area of the chromatogram of sulfur dioxide in sq. mm. for the blank test; w: the sample weight in mg. and K: the constant = 0.15 (μg. sulfur per sq. mm.), which was determined by using standard samples of known compositions or standard gas.

* Sulfur content obtained by a combustion-conductometry.

The calibration was carried out with three samples measured manometrically using a standard gas of sulfur dioxide in the 1.0-ml. sampling cell used for quantitative gas analysis, where the system for sampling was evacuated to 10^{-3} mm. Hg by means of a rotary oil pump. The calibrated value was obtained from the relationship between the concentration and the chromatogram area. However, when the calibration was carried out by using the standard steel sample, this value was different from that obtained by using the gas.

Results

The accuracy of this method and agreement of the results with those shown in JISS were tested by determining the sulfur content of JISS No. 11 and No. 5(d) and of the electrolytic iron samples; the results are shown in Tables I and II. The data were obtained from 1—2 g. samples to which suitable accelerators had been added.

The usefulness of this method was proved by determining the sulfur contents of cast iron, titanium, silicon, copper, chromium and manganese; the results are given in Tables III and IV. In these metals only copper was effectively burnt by the H-F combustion technique; commercial copper powder or foil could be used as the bedding material in place of iron powder. The data were obtained with 0.3—1.0 g. samples, with 1—1.5 g. of copper and with 0.1 g. of chromium(III) oxide used as the accelerators.

Discussion

The use of a highly-sensitive gas chromatograph for the analyses of combustion gases enables us to determine sulfur contents as low as 10 μg. in pure metals; in this case, the blank value of this method can be kept below 3 μg. of sulfur by using the Leco. 528-31 cuplet. The determination of sulfur contents below 100 μg. is difficult in the conventional method. By using the Leco. cuplet, this method can also be applied to non-ferrous pure metals by the addition of special purified copper foil and some accelerators. It is of a great advantage to be able to use the Flikentite or the Leco. cuplet, since they require no complicated pretreatment, unlike as in the other combustion method. If the Flikentite cuplet prepared for carbon analysis was used for the determination of the sulfur content in cast iron, however, a lower value was obtained. For this reason, the study of the modification of refractory materials for the crucible is now being continued with the cooperation of other laboratories.

The sulfur contents in the silica gel column as found by the actual combustion are given in Table V. The data were obtained with an oxygen stream with a flow rate of 150 ml./min. at room temperature. From this table, it is clear that an oxygen flow of 6 min. is sufficient.

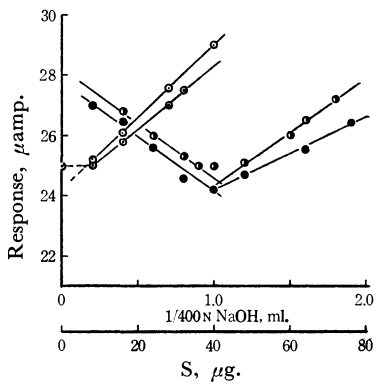

Fig. 4. A typical titration of SO_4^{2-} by H-F conductometry.
-◑- -●- plots on 1.0 ml. of 1/400 N sulfuric acid
—⊙— plots on the solution washed sulfur trioxide absorbed in the concentration column with a little neutral water

Some investigators[2,9,10] have described how materials with sulfur contents of above 90% were converted into sulfur dioxide by the complete combustion of the metal. Similar results seem to be obtained by the present experiment. If sulfur trioxide is formed in the combustion products, the results obtained are erratic, because sulfur trioxide is absorbed in the concentration column. The experiment was carried out to measure the concentration of SO_4^{2-} ions by means of highly-sensitive conductometry using a Shimadzu H-F titrator. The above-mentioned SO_4^{2-} ions were present in the 20 ml. of water used to wash the column. The titration curves of an aqueous solution containing 1.0 ml. of 1/400 N standard sulfulic acid and those of this washed solution are shown in Fig. 4. The sulfur content as SO_3 was below 8 μg.; this quantity is below the limit of detection by conductometry.

Combustion times of 5—6 min. were found to be effective in the oxidation of metals. Copper, used as the bedding material in these experiments, burned smoothly at high temperatures (above 1600°C). In the reaction it was dissolved in crucible materials; copper is one of the metals with the lowest sulfur content. When it is then used together with the Leco. crucible, which shows a small blank value, the correction becomes small.

Because a small amount of lump silicon was available for performing the complete combustion, 200—300 mg. of the samples was used with 2 g. of the foil copper; satisfactory burnings were still obtained with titanium, however, when only 1 g. samples and 1—1.5 g. of copper powder were used.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 685—694 (1966)

Colloid Chemical Studies of Phase Diagrams of Binary Polyoxyethylene Nonylphenyl Ether - Water Systems

By Kazutoshi KENJO

Takahashi Toyodo Co., Ltd., Shinogawa-machi, Shinjuku-ku, Tokyo

(Received June 26, 1965)

Colloid chemical studies of the phase diagrams of binary systems of aqueous polyoxyethylene nonylphenyl ethers with different degrees of the polymerization of ethylene oxide, n, have been undertaken. The phase diagrams obtained have been divided into the heterogeneous region I, existing in the range of temperature higher than cloud points; the homogeneous phase region II; the heterogeneous region III, existing below the II region; and the solid phase region IV. The II region contains a gel-like hardening region. The III region has been further divided into two sub-regions, on the higher and lower concentration sides; these subregions contain one hardening region each. The molecular and micellar structure models of these hardening regions have been presented. An unusual zone has been found in the phase diagram of the system for $n=7.5$; its state has also been discussed. Further, the mechanisms of the phase separation and phase inversion have been proposed, and three different types distinguished for the phase separation at the cloud point. A functional relationship has been found between the cloud point, the water content of an aqueous solution at the cloud point (the water affinity), and the n value. A linear relation has also been found between the solidification points of 100% surfactants and the ethylene oxide contents of the surfactants.

Owing to their stability against hydrolysis, heavy metal ions and pH change, and their rapid progress in chemical synthesis, the non-ionic surfactants are finding wide use in various industries. However, as for their chemical nature and fundamental properties, relatively few studies have been reported compared with the studies of the ionic surfactants.[1-4]

The present author has previously studied[5] ternary systems consisting of decaoxyethylene nonylphenyl ether, essential oils and water, and found some unusual phenomena, such as the existence of two cloud points in the same system, a discontinuity in the curve of the cloud point vs. the concentration, and a gel-like hardening.

The first phenomenon is very similar to the so-called "double cloud point" already reported,[6] which afterwards turned out to be due to the presence of impurities.[7] However, it is worth studying the phenomena in further detail since they have much to do with the practice of surfactant application. To facilitate the understanding of the phenomena shown by the ternary systems, it is pertinent first to get much information about the more simple binary systems, composed of the nonionic surfactants and water. As for such studies of binary systems, we have a few, but only a few reports, on, for instance, a possible phase diagram,[8,9] on the viscosity,[10-12] on the gel formation,[1,10,11,13] and especially on concentrated systems, for the variation of viscoelastic properties with the temperature,[14] the concentration,[15] and the frequency.[16]

Under such circumstances, the present author has taken up a binary system of aqueous nonionic surfactants of the polyoxyethylene nonylphenyl ether type, which are now widely used in practice, at temperatures ranging between -10°C and 100°C, constructed phase diagrams, and made colloid chemical studies by observing the change in the diagrams with the change in the degree of polymerization of ethylene oxide.

ethylene oxide) made by Nikko Chemicals and polyethylene glycol (abbreviation; PEG-n', n' being the mean molecular weight) made by Sanyo Kasei were used after drying to a constant weight at 105°C. Some of their properties are shown in Table I. The NP-8.5 P in Table I was a sample derived from NP-7.5 by extracting it repeatedly, first with *n*-hexane at room temperature and then with water at temperatures higher than the cloud point. Thus, from 20 g. of NP-7.5, there were obtained 14.5 g. of a non-ionic agent, 5.1 g. of a *n*-hexane-soluble matter, and 0.2 g. of a hot water-soluble matter. Here, NP-8.5P denotes that the substance is purified from NP-7.5; the degree of the polymerization of ethylene oxide was found from its hydroxyl value to be about 8.5.

TABLE I. PROPERTIES OF MATERIALS USED

Material	Hydroxyl value	Solidification point, °C
NP-5	125	
NP-7.5	103	−11.8
NP-8.5	93.0	−1.8
NP-10	87.1	7.3
NP-12.5	76.8	14.0
NP-15	70.0	19.0
NP-18	58.3	25.2
NP-20	53.4	31.6
NP-25	45.9	35.0
NP-30	34.0	37.0
NP-50	25.8	43.5
PEG-1000	110	35.0
PEG-2000	54.5	47.2
NP-8.5P	94.5	−9.0

Experimental

Turbidity and Viscoelasticity Measurement.—Aqueous solutions or heterogeneous mixtures of water and non-ionic surfactants were taken in test tubes; the contents were heated to 100°C, and then cooled gradually. The change in the turbidity and viscoelastic appearance up to the solidification of the system was observed visually for rising and falling temperatures. The cooling curve was further constructed, and from it the solidification point was obtained.

Thus, the temperatures showing abrupt changes in turbidity and viscoelastic properties were plotted against the concentration of surfactant; the phase diagrams consisting of different dispersion states were thus obtained

The Observation of the Phase Separation.—The appearance of phase separation was visually observed for NP-7.5-surfactant solutions of 6, 8, 15, 33, 42 and 57% concentrations at varying temperatures (±0.2°C), and the volume fraction of the lower phase separated was measured.

Notations of the States of the System.—The turbid states were divided into five patterns, of the following increasing order of turbidity, on the phase diagrams:

transparent, half-transparent,

slightly turbid, turbid,

strongly turbid

Here "half-tranaparent" corresponded to a TiO_2 (R-820 TiO_2, made by Ishihara Sangyo) aqueous dispersion below 0.0015%, "slightly turbid" to 0.0015—0.005%, "turbid" to 0.005—0.02%, and "strongly turbid" to above 0.02%-by-weight TiO_2.

The viscous states were divided into four gradations of "liquid" (S_1), "slightly viscous" (S_2), "viscous" (S_3) and "heavily viscous" (S_4) in the order of increasing viscosity. Here, S_1, S_2, S_3 and S_4 corresponded approximately to the viscosities below 0.5, 0.5—3, 3—12 and 12—50 poises respectively.

The hardened states were divided into four gradations of "weak paste" (P_1), "paste" (P_2), "strong paste" (P_3) and "rigid paste" (P_4) in the order of increasing consistency; they were qualitatively detected by the flow resistance of the paste. The "weak paste" was distinguished from the "heavily viscous" liquid in that the former did not deform perceptibly for at least ten seconds when the test tube used was kept horizontal. Here P_1, P_2, P_3 and P_4 corresponded approximately to 100—200, 200—600, 600—2000 and above 2000 poises respectively.

The Curves of the Diagrams.—CP-curve: cloud point curve; TP-curve; the curve of transparent points dividing the upper transparent and lower turbid regions; SP-curve: solidification point curve, and HP-curve: hardening point curve.

Results

Phase Diagrams.—The phase diagrams of NP-5 to NP-50 are shown in Figs. 1 to 11, and those of PEG·1000, PEG·2000 and NP-8.5P, in Figs. 12 to 14.

Symbols used in Figs. 1—14.

Regions

I: Region of two phase system
II: Region of homogeneous phase system
IV: Region of solid phase
R_{TP_1}, R_{TP_2}: Region of microheterogeneous system
R_{HP_1}, R_{HP_2}, R_{HP_3}: Region of hardening system
Ru: Unusual zone

Curves

SP: Solidification point curve
CP: Cloud point curve
TP_1, TP_2: Transparent point curve
HP_1, HP_2, HP_3: Hardening point curve
FP: Freezing point curve
T_I: Line of phase inversion

States of systems

Viscosity: Liquid (S_1), slightly viscous (S_2), viscous (S_3), and heavily viscous (S_4).

Consistency: Weak paste (P_1), paste (P_2), strong paste (P_3), and rigid paste (P_4)

Turbidity: Transparent

half-transparent

slightly turbid

turbid

strongly turbid

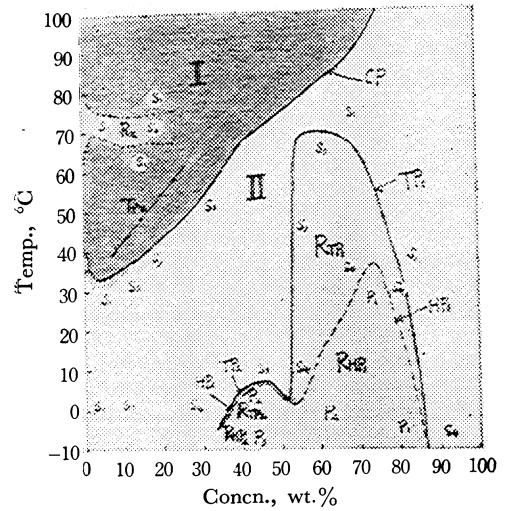

Fig. 14. Phase diagram of NP-8.5P - water system.

All the phase diagrams obtained were divided into four regions: I (a two-phase system existing above the CP-curve), II (a homogeneous phase system), III(a microheterogeneous or dispersed system below the TP-cruve) and IV (a solid phase system). For n values above 15, there was a region of clear paste, R_{TP_3}. The III region was further divided into two sub-regions, R_{TP}, and R_{TP_2}. containing R_{TP_1} and R_{TP_2} paste regions respectively, The phase diagram of PEG-2000 ($n \fallingdotseq 45$) system resembled that of the NP-50 system, but at lower temperatures the former system was much less biscous than the latter; at -20°C it remained in S_3 states, while the NP-50 system hardened at this temperature and in a concentration of about 52%.

A peculiarity was noted in the region I of the NP-7.5 system, which was divided into two parts by an "unusual zone" (Fig. 2). In this unusual zone the system did not separate into macroscopic phases, even after prolonged standing.

Phase Separation.—The results for the phase-separation experiments in the case of a 6% aqueous solution of NP-7.5, for instance, showed that, at the temperatures slightly above 76°C and 28°C, the lower phase considered as the dispersed phase sedimented in the upper phase of the dispersion medium, while slightly below these temperatures the lower phase changed into the dispersion medium and the upper phase creamed up and separated from the lower one.

Therefore, 28°C and 76°C are considered to be the temperatures of the phase inversions in this system. The volume fraction of the lower phase after the complete separation into two layers and the time required for it are plotted against the temperature in Fig. 15.

Usually, the lower phase after complete separation became turbid when the temperature was slightly raised, while it suffered no change when the temperature was lowered. However, somewhat different features were seen near 76°C; namely, the

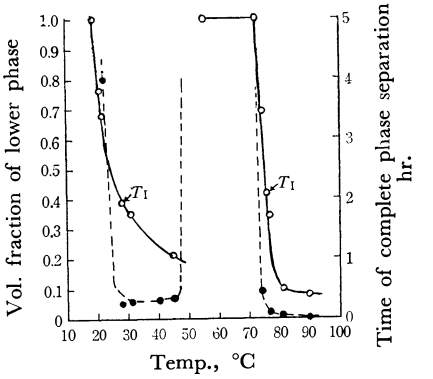

Fig. 15. Relative phase volume (solid line) and time of complete phase separation (broken line) vs. temperature for 6% aqueous solution of NP-7.5.
T_I indicates the temperature of phase inversion.

lower phase separated at 76°C, became transparent between 74.5°C and 76°C, and turbid below 74.5°C and above 76°C, while the upper phase suffered no change upon such a slight change of temperature. From these facts it follows that a narrow region, presumably belonging to the region II, may exist close to the upper limit of the unusual zone.

Calculating from the concentrations and the volume fractions of the lower phases, the concentration of NP-7.5 in the upper phase was found to be almost zero within the range of experimental errors for all cases; this can also be expected from the phase diagram (Fig. 2), and it is also in agreement with the result obtained by Nakagawa et al.[17] Figure 15 shows that there are two phase-inversion temperatures and that the volume fractions, of the lower phase at these two temperatures are nearly equal (0.42 and 0.39 respectively). This would mean that the volume ratio of the phase inversion is distinctly fixed for a given concentration of the surfactant. Results in the case of 8% and 15% solutions of NP-7.5 were similar to that of the 6% solution.

In the case of a 33% solution at 77.5°C, corresponding to the system in the narrow projected region I, the turbid liquid gradually turned into fluorescent heterogeneous state, but it did not separate into two phases, even after prolonged standing; this was presumably due to the small difference between the compositions of these two phases. In the case of a 42% solution at 79°C, the system rapidly separated into two phases, and the volume fraction of the lower phase was 0.35. From this result, the two phases separated are considered to have compositions corresponding to the U (33.3%) and L (60.5%) points in Fig. 2, the upper and the lower phases respectively. The upper phase, U, should then further separate very rapidly into two phases when the temperature is further raised slightly, since they are quite different in composition but are nearly equal in volume, while the lower phase, L, is expected to show only a slight turbidity. Such was actually proved to be the case. Thus it was confirmed that the point U in Fig. 2 is the extreme point of the narrow projection of the unusual zone, as is shown in Fig. 2. In the case of a 57% solution, the appearance of phases separated above the cloud point (78.5°C) was similar to that of the 6% solution, but below 77°C in the R_{TP_1} region the system did not separate into two phases, even after standing for 24 hr.

The temperatures of phase inversion obtained above were also plotted against the concentration in the phase diagrams, which can be expressed approximately by the following equation:

$$T_I = Ac + B \quad (1)$$

where T_I denotes the temperature of the phase inversion; and c, the concentration by weight % of the surfactants, and A and B are constants depending only on n. The values of A and B obtained are shown in Table II, while the straight lines obtained are indicated on the phase diagrams by the line T_I.

Table II. The values of A and B

Surfactant	A	B
NP-5	0.96	30.2
NP-7.5	1.48	18.4
NP-8.5	1.15	38.7
NP-10	0.69	62.3
NP-12.5	0.46	80.2
NP-8.5P	1.21	29.9

Discussion

Solidification Point.—The solidification points of 100% surfactants shown in Table I first rose markedly, and then gradually, with the increase in n. However, plotting the 100% solidification points, S, against the weight content, E, of ethylene oxide in a surfactant molecule (Fig. 16) gives:

$$S = 168E - 106 \quad (2)$$

where $E = 44n/(220+44n)$.

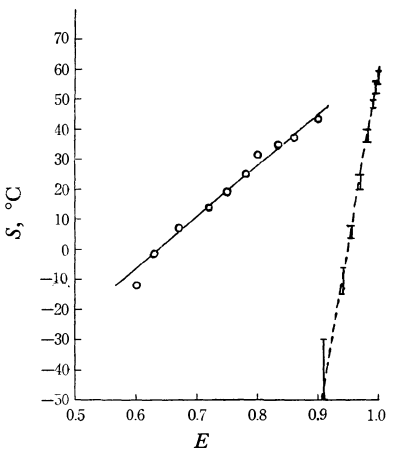

Fig. 16. Solidification point vs. weight content of ethylene oxide in NP-series (solid line) and PEG series (broken line).
S : Solidification point of 100% substances
E : Weight content of ethylene oxide in a molecule

The deviation of the solidification point of NP-7.5 from the straight line in Fig. 16 is considered to be due to its being a lower member.

A similar linear relation (Fig. 16) is obtained for polyethylene glycol homologues (F-4772 of the Union Carbide Chemical Co., U. S. A.) as follows:

$$S = 1200E - 1139.5 \quad (3)$$

17) T. Nakagawa, K. Tori, *Kolloid-Z.*, **168**, 132 (1960).

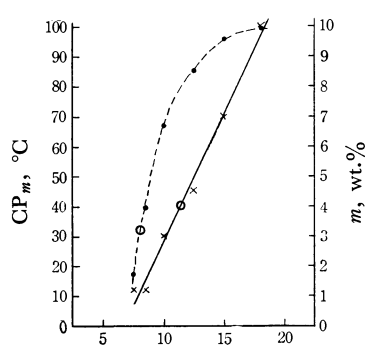
where S denotes the solidification point of 100% polyethylene glycol, and E, the weight content of ethylene oxide calculated from $44n/(18+44n)$.

Equations 2 and 3 indicate that the solidification is affected mainly by the polyoxyethylene chain and that the solidification point rises linearly with the ethylene oxide content of the molecule. The larger the weight of the part of the molecule to which ethylene oxides are attached, the smaller the slope of the straight line which may result, presumably because of their stronger resistance against the solidification.

It may be seen from the phase diagrams obtained that the smaller the n value of the surfactants, the greater the slope of the SP curves near 100% surfactants becomes, and that the slopes near 100% are smaller for PEG systems than for NP systems. This is because the weight fraction of the polyoxyethylene chain mainly responsible for solidification becomes smaller with the decrease in n for the NP series and is smaller for the surfactant than for polyethylene glycol possessing an approximately equal n value for an equal solute concentration.

Recently, Iino et al.[18] measured the solidification points of polyoxyethylene fatty acid esters, the fatty acid radical of C_6—C_8 chain length and the polyoxyethylene of n=2—30 mol. ethylene oxide. If the solidification points they obtained are plotted against the ethylene oxide content in the esters given above, linear relations are obtained for the esters of fatty acids of C_6 and C_8 possessing polyoxyethylene chains longer than the one corresponding to the minimum point, but not for those of fatty acids above C_{10}. This again confirms the above solidification effect of polyoxyethylene, while too long a fatty acid chain interferes with, and causes anomalies in, solidification.

Cloud Point.—In Fig. 17 the minima of CP-curves, CP_m, and the corresponding concentration, m, are plotted against n, the latter being linear, as is shown. The CP_m and m values NP-8.5P, which are shown by circles in the figure, correspond approximately to those of n=8 and n=11.5 respectively. Thus it is shown that the removal of lesser hydrophilic compounds such as the lower homologues results in a little increase in CP_m but a large increase in m when expressed in terms of n.



Degree of polymerization of ethylene oxide, n

Fig. 17. Change of temperature (●: CP_m) and concentration (×: m) of minimum in CP-curve with n.
Circles indicate the value for NP-8.5 P.

Such minima of CP curves in relatively dilute solutions were also found for the series of polyoxyethylene isooctylphenyl ethers.[19]

Phase Separation and Phase Inversion.—The heterogeneous system above the CP curve (Fig. 18) is composed of an upper layer of water or a dilute aqueous solution and a lower layer of a surfactant-rich solution. The line MN in the figure shows the line of the phase inversion.

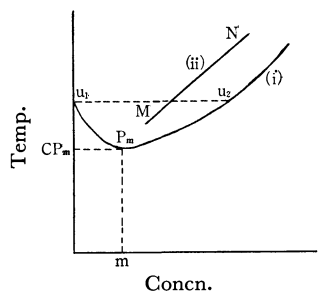


Fig. 18. CP-curve (i) and line of phase inversion (ii).

The heterogeneous region left to the line MN forms an emulsion of the surfactant-in-water type, while the heterogeneous region to the right of the line MN forms the opposite type of emulsion. The line MN passes through the minimum point P_m of the CP curve. Therefore, the heterogeneous system with a surfactant concentration larger than that of the point P_m shows the phase inversion phenomena when the system above the line MN is cooled, while the heterogeneous system with a concentration less than that of P_m shows no indication of a phase inversion under similar treatment. The clouding behavior of the heterogeneous system at the cloud point when heated also differs according as the concentration is below that of P_m, between P_m and U_2 in Fig. 18 (namely, the lowest possible concentration at which pure water separates at the cloud point), and above U_2. The results of the experiments showed that the first system separated minute droplets of a relatively-concentrated surfactant solution; the second, a dilute aqueous solution, and the third, pure water. The first case mentioned above is in agreement with the findings of Nakagawa et al.[20] that very large micelles

18) S. Iino, K. Tagawa and N. Oba, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **65**, 2047 (1962).

19) M. Aoki and Y. Iwayama, *J. Pharm. Soc. Japan*, **79**, 516 (1959).

20) T. Nakagawa, K. Kuriyama and H. Inoue, Symposium on Colloid Chem., (Chem. Soc. Japan) 12th symposium, p. 29 (1959).

suddenly appear at the cloud point.

Shinoda et al.[21] have regarded the cloud point as the temperature of the pseudo-phase inversion in veiew of the fact that the micelle formation is a phenomenon similar to a phase separation and because it is considered that, upon being heated, the systems of aqueous non-ionic detergent are altered from a detergent-in-water type to a water-in-detergent type at the cloud point. As has been mentioned above, not the region II below the CP curve but the region I above the CP curve is regarded in the present study as a dispersion or a heterogeneous system in the usual sense, one in which phase inversion occurs. Thus, the concept of the phase inversion is different in the present study from the concept of pseudo-phase inversion of Shinoda et al.

Water Affinity.—In the case of the concentration range above the minimum m of the CP curve, when a system has reached the CP curve by the repeated addition of water to the surfactant at a certain temperature, the system became turbid because of the deposit of a slight excess of water. Therefore, we call the weight ratio, x, of water to surfactant at the cloud point the "water affinity" of the surfactant at that temperature. By plotting the logarithm of the water affinity against the cloud point, as in Fig. 19, a linear relation is found between them in the surfactant-rich region of the CP curve measured; this is shown by the following general equation:

$$\log x = \log X + K(100-t) \tag{4}$$

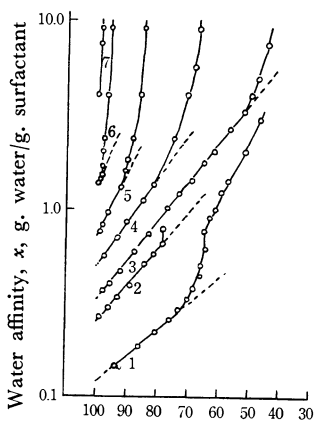

Fig. 19. Relation between the water affinity and cloud point.

1	NP-5	4	NP-10	7	NP-18
2	NP-7.5	5	NP-12.5		
3	NP-8.5	6	NP-15		

where t represents the cloud point; X, the water affinity of the surfactant at 100°C, and K, a constant.

21) K. Shinoda and H. Arai, *J. Phys. Chem.*, **68**, 3485 (1964).

In Eq. 4, the constants, X and K, are found to be expressed as a function of n, as is shown by the following equations:

$$\log X = \log 0.0320 + 0.117n \tag{5}$$

$$K = 0.00257n \quad (n<12.5) \tag{6}$$

From Eqs. 4, 5 and 6 we obtain for $n<12.5$, and $t\approx100$°C:

$$\log x = \log 0.0320 + 0.117n + 0.00257n(100-t) \tag{7}$$

The Transparent Point, the Hardening Point and Their Regions.—In the hardening region, the molar ratio of water to ethylene oxide units in a surfactant is considered to be more significant than the concentration. Thus, for instance, the relationship of such a molar ratio for three hardening regions and n at 20°C is as is shown in Fig. 20. This figure shows that every surfactant of the NP-n series possesses no, one or two hardening regions, according to the variation in n value.

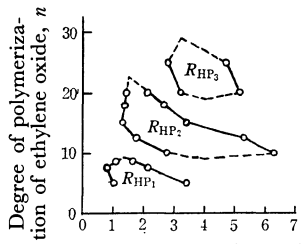

Fig. 20. Relation between n and molar ratio of water to ethylene oxide unit in surfactants in each hardening region at 20°C.
Broken lines indicate the ranges presumed from diagrams.

The relation between n and the nature of the hardening regions at various temperatures is shown in Table III.

The maxima of the viscosity of the aqueous solutions of non-ionic surfactants have been reported,[10] and the gel formation of such systems have also been found.[11-13,15] The systems showed a single concentration region in most cases, but the existence of two concentration regions of gel formation was reported in a few special cases.[1,12] Thus, for instance, Schönfeldt[1] measured the viscosity of the aqueous solutions of the NP-n series and found a single gel region for each surfactant in the range of n between 8.0 and 36.0, with two exceptions (the n values of 9.0 and 17.2 showed two gel regions each).

Comparing our hardening regions (in Table III) with those of Schönfeldt, the hardening regions of his $n=9.0$ value correspond to our R_{HP_1} and R_{HP_2} regions, while those of his $n=17.2$ value correspond to our R_{HP_2} and R_{HP_3} regions.

Several explanations have been given for the maximum of the viscosity versus the concentration

TABLE III. THE RANGES OF n FOR VARIOUS HARDENING REGIONS AND TEMPERATURE

Number of hardening regions	0	1			2	
Type of hardening regions		R_{HP_1}	R_{HP_2}	R_{HP_3}	R_{HP_1} and R_{HP_2}	R_{HP_2} and R_{HP_3}

curve and for the gel formation: (1) the interlocking of incompletely-hydrated surfactant molecules to form a network,[5] (2) a phenomenon resembling the phase inversion in the emulsion consisting of water as one phase, and hydrated surfactants assumed to be composed of one water molecule per ether linkage as another phase,[12] and (3) the immobilization of the water in the network by the entanglement of the hydrophilic groups of surfactants because of their spacious properties.[15] Kuroiwa[15] has further suggested that the decrease in viscoelasticity at the higher concentrations is produced by the formation of inverse micelles in the system.

However, these explanations can not well be applied to the system showing two or more maxima in viscoelastic properties, as was found in the present NP-8.5, 10, 15, 18, 20, and 25 systems.

The phenomena observed in the present experiments may, however, be appropriately explained as follows.

As the concentration of a surfactant is increased at a constant temperature, the micelles increase, while, at a certain concentration, depending upon the n and on the temperature, the system hardens because of the network composed of micelles and water acting as adhesives between micelles by means of hydrogen bonding with polyoxyethylene groups of the surfaces of micelles and by means of the immobilization of the aqueous solution with a monomolecular dispersion. The ability of water to act as an adhesive is considered to have an optimum range of compositon depending on the temperature, the n value, and the nature of the surfactant molecule. As is clear from such an explanation, this hardening region should be the one appearing in the region II; it is considered to correspond to R_{HP_3} or R_{HP_2}.

On a further increase in the concentration, micelles further increase in number, but the water molecules combining them become insufficient; accordingly, each individual micelle is rendered relatively free in motion. This state coincides with the part of the region II, between two hardening region in the phase diagrams.

A further increase in the concentration results in the approach of micelles more closly, and the inverse micelles appear with a saturated aqueous phase inside. The region of the concentartion where such an iversion of micelle type occurs and where both types of micelles coexist is considered to correspond to another hardening region, R_{HP_2} or R_{HP_1}. The systems of these hardening regions are more or less turbid because they are mixtures of two phases. The smaller the value of n becomes, the greater the difference between the two types of micelles may be expected to grow because of the more hydrophobic property of the surfactant. This results in the increasing turbidity and the decreasing viscosity of the system in R_{HP}. On the contrary, the system of the surfactant with a larger n value is considered to be somewhat similar in structure between the two phases. This hardening system would be something like the lamellar structure of micelles with sandwiched water;[22] therefore, it results in a much less turbid and more rigid state, as in R_{HP_2}.

Upon the further addition of the surfactant, the system eventually turns into a single-phase system composed of the inverse micelle type or the surfactant, with water dissolved in it, which is transparent and low in viscosity.

The above explanation of the two maxima of viscoelasticity in the nonionic surfactant-water system coincides approximately with those suggested by Kuroiwa[15] for the hardening region in the lower concentration and by Greenwald et al.[13] for the hardening region in the higher concentration. In the former mechanism of the hardening, of course, the polyoxyethylene group must be long enough to exhibit an effective adhesive field for hydration. The adequate chain length is considered to correspond to $n=22$ for R_{HP_3} and $n=15$ for R_{HP_2} in the NP-n series.

The appearance of the R_{TP_1} and R_{TP_2} regions is explained somewhat similarly to that of R_{HP_1} but all the regions, except for R_{HP}, were out of the range of the suitable ratio between water and surfactant for the hardening or the higher temparature range, showing no hardening due to the reduced hydration. The fact that R_{TP_1} had quite a wide range at temperatures higher than R_{HP_1} can be explained by the fact that the system of this region contains relatively little water and appears

22) S. S. Marsden and J. W. McBain, ibid., **52**, 110 (1948).

only in the case of surfactant with a low n value. Therefore, it should be cooled to a temperature sufficiently low in order for hydrogen bonding to harden the system.

Unusual Zone.—Sugano[7] found an unusual zone such as is shown in Fig. 2 above the cloud point in the aqueous solution of crude hexaoxyethylene lauryl ether. He ascribed the appearance of this phenomenon to such impurities as the higher alcohols or non-ionic surfactants of a low hydrophilic property. Since his unusual zone indicated an unusually high viscosity and a double refraction, he concluded that the zone was similar to the liquid crystalline state formed when amphiphilic compounds were added to the aqueous solution of ionic surfactants.[23] It has been further referred to the G-phase obtained by Winsor[24] and to the optical anisotropic state found in concentrated solutions of sodium laurate and hexanolamine oleate.[25]

If the unusual zone found in the present study is considered to be the liquid crystalline state, this zone can well be explained as that formed by the extension of the R_{TP_1} region in the direction of higher temperatures and lower concentrations, as may be seen from its contact with R_{TP_1}, which is considered to be optically anisotropic.[8] This also explains the discontinuity in the CP cruve.

If the unusual zone appears because of the existence of R_{TP_1}, it would not appear in any aqueous system of the surfactant with an n value above 12.5, but in fact it may appear even in such a system because of the possible transition of R_{TP_2} into R_{TP_1} by the addition of the lower homologues, as in the change of the NP-8.5P to the NP-7.5 system.

Although the NP-5 system (Fig. 1) seems not to show the unusual zone, it shows considerable anomalies below a 70% surfactant solution. The narrow transparent zone is somewhat similar to the narrow transparent part of the unusual zone of the NP-7.5 system (Fig. 2). The slopes of the CP curve below 70% of a surfactant and the slopes of the line of the phase inversion were smaller than those of NP-7.5. Further, the transparent hardening region found above the TP_1 curve is simialr to the part at the highest concentration of the unusual zone in the NP-7.5 system. In veiw of these points, the NP-5 system below 70% of the surfactant may be considered to show an unusual zone except for the region I.

The author wishes to express his deep gratitude to Professor Tsunetaka Sasaki of Tokyo Metropolitan University for his valuable advice and for his inspection of this report; to Mr. Tsunetaro Matsumoto, Manager of the Laboratory of Takahashi Toyodo Co., Ltd., for his encouragement throughout this investigation, and to the President of the Takahashi Toyodo Co., Ltd., for permission to publish this research. He is also grateful to Miss Sadako Usui for her aid in preparing this paper.

The Stereoselectivity of Catalysts in Hydrogenation. I. The Catalytic Hydrogenation of 2-Cyclopentylidene-cyclopentanol and 2-Benzylidene-1-tetralol

By Sekio MITSUI, Yasuhisa SENDA and Hideyo SAITO

Department of Applied Science, Faculty of Engineering, Tohoku University, Sendai

(Received July 9, 1965)

2-Cyclopentylidenecyclopentanol (I) was hydrogenated over Raney Ni to produce a mixture of 95% of *trans*- and 5% of *cis*-2-cyclopentylcyclopentanol (III). However, over a Pd catalyst I gave a mixture of 2-cyclopentylcyclopentanone (IV), cyclopentylcyclopentane (V) and *trans*- and *cis*-III. In the hydrogenation of I over PtO_2, *trans*-III was a predominant product (93%) in ethanol, whereas in acetic acid a mixture of 2 parts of *trans*- and 1 part of *cis*-III was obtained, and in acetic acid with one drop of hydrochloric acid, the ratio of trans and cis was one to two. A large amount of V was also obtained in cases of both acetic acid. The hydrogenation of 2-benzylidene-1-tetralol (II) resulted in 2-benzyl-1-tetralols (VI), the yields of *trans*- and *cis*-VI being as follows: over Raney Ni, 78% and 19%; over Pd, 33% and 63%; and over PtO_2 in ethanol, 58% and 34%, respectively. From these results, it was found that, in the cases of Raney Ni and PtO_2 in ethanol, the directive effect of the hydroxyl group is very efficient, but that it is small over Pd, while in acetic acid, especially with hydrochloric acid, such an effect decreases over PtO_2.

Recent communications[1,2] reporting that the catalytic hydrogenation of 2-cyclopentylidenecyclopentanol and its methyl ether over Raney nickel gave *trans*-2-cyclopentylcyclopentanol and its methyl ether respectively, have prompted us to report our observations of stereoselectivity of the catalysts in the hydrogenation of some allyl-type alcohols.

We have investigated to see whether such a directive effect of the hydroxyl group may be found in the hydrogenation of allyl-type alcohols as has been observed in the hydrogenolysis of some optically-active benzyl-type alcohols.[3-6]

2-Cyclopentylidenecyclopentanol (I) and 2-benzylidene-1-tetralol (II) have been hydrogenated over Raney nickel, palladium-charcoal and platinum oxide at room temperature and atmospheric pressure (Tables I and II). The Raney nickel hydrogenation of I had already been done by Howard,[1] who obtained mainly a single entity, *trans*-2-cyclopentylcyclopentanol (III). Similar results were obtained in the present work. III was formed in a ratio of 95% trans and 5% cis. The palladium-charcoal hydrogenation of I gave a mixture containing cis and trans isomers of III, along with 2-cyclopentylcyclopentanone (IV) and cyclopentylcyclopentane (V). The products were analyzed by vapor phase chromatography (Hitachi model F-6, P. E. G. 45 m. Golay column).

2-Benzylidene-1-tetralol (II) (m. p. 72°C) was hydrogenated to give 78% *trans*-2-benzyl-1-tetralol (VI) (m. p. 119°C) over Raney nickel, but a 63% cis isomer (m. p. 72°C) over palladium-charcoal. The products were separated by fractional recrystallization from petroleum benzine and confirmed by elementary analysis. An authentic sample of the trans isomer of VI was synthesized by the hydroboration[7] of 3-benzyl-1, 2-dihydronaphthalene, which had been prepared by the dehydration of VI with *p*-toluenesulfonic acid in benzene, followed by oxidation with alkaline hydrogen peroxide.

It may be considered from the results that, if it is accepted that hydrogen adds cis from the catalyst surface, the unsaturated alcohols are preferentially adsorbed with the hydroxyl group directed toward the surface of the Raney nickel catalyst by the interaction of the lone pair of oxygen as well as of the π-electrons of the double bond, with the catalyst, and that the addition of hydrogen to the compounds in these adsorbed states will give the trans alcohols[1] (Fig. 1). On the other hand, in the case of the palladium catalyst, the adsorbed states where the hydroxyl group is directed away from the catalyst surface are assumed to increase in the course of the reaction (Fig. 1).

The formation of IV and V on the palladium catalyst may also be explained from the adsorbed state shown in Fig. 1 (see Figs. 2 and 3). 2-Cyclopentyl-1-cyclopentene-1-ol, the enol form of IV, may be obtained by the same kind of isomerization as was observed in the isomerization reported by Henbest et al.[8] (Fig. 2). Since it was reported that the hydrogenolysis of the optically-active benzyl-type alcohols over the palladium catalyst proceeds with an inversion of the configuration,[3-6] the allylic alcohol such as I may also be hydrogenolyzed with inversion to give cyclopentylidenecyclopentane, which is then hydrogenated to V (Fig. 3). It may be argued from these considerations that the favored adsorbed state on the palladium catalyst is the one in which the hydroxyl group is directed away from the catalyst surface, especially on palladium-charcoal-A.[9]

On the hydrogenation of II over palladium-charcoal, the cis isomer of VI was obtained preferably.

Since it has been reported that the hydrogenolysis of the C–O bonds of benzyl-type alcohols and alkyl ethers takes different courses of reaction according to the kind of catalyst used,[3-6] it may be suggested that the difference in the affinity of nickel and palladium for the oxygen atom controls not only the stereochemistry of the hydrogenolysis of benzyl-type alcohols, but also that of the hydrogenation of the double bond of allyl-type alcohols. Therefore, the composition of the products is affected by the difference in this affinity with the kind of catalyst. The platinum oxide hydrogenation of I in ethanol gave the trans isomer as the predominant product (trans : cis=23 : 1). It may be presumed that this is because of the directive effect of the hydroxyl group, as was observed in the Raney nickel hydrogenation. In acetic acid, I was hydrogenated to give a mixture containing 22% *trans*- and 10% *cis*-III (trans : cis=2 : 1), 3% IV and 50% V. The hydrogenation in acetic acid containing one micro drop of concentrated hydrochloric acid gave more than 90% hydrocarbon (V), 3% *trans*- and 6% *cis*-III (trans : cis=1 : 2). These results show that the presence of acid increases the percentage of the cis product.

On the hydrogenolysis of optically-active 2-phenyl-2-butanol in ethanol over platinum oxide, which usually contains a trace of alkaline substances,

a slight excess of a configurationally inverted product (55%) was obtained, but upon the addition of two micro drops of concentrated hydrochloric acid to the solvent, the reaction proceeded predominantly with an inversion of the configuration (80%).[5] Consequently, it may be assumed that, in an acidic solvent, the hydrogenolysis of a benzyl- or allyl-type alcohol such as I takes place mainly, with an inversion of the original configuration over platinum oxide. These results are in line with the present observations that, on platinum oxide which contains a trace of basic substances, the directive effect of the hydroxyl group is observed in ethanol to be as on Raney nickel,[10] while in acetic acid this effect decreases,[11] that the attack of hydrogen on the double bond or the carbon atom to which the hydroxyl group is attached, occurs from the less hindered side, and that it seems that this trend is promoted by the presence of hydrochloric acid.

As III was not acetylated by letting it stand with acetic acid, the III-acetate obtained (in Experimental Runs 5 and 6 in Table I) seems to be the hydrogenated product of I-acetate formed by the acetylation of I during the course of the reaction.

Experimental

2 - Cyclopentylidenecyclopentanone. — 2 - Cyclopentylidenecyclopentanone was prepared by the method of Hückel et al.,[12] by the self-condensation of cyclopentanone. From 84 g. of cyclopentanone and 4 g. of sodium hydroxide in 250 ml. of 30% aqueous ethanol, there was obtained 30.4 g. (40%) of the product, b. p. 96—101°C/5.0 mmHg.

2-Cyclopentylidenecyclopentanol (I).—I was prepared by the method of Le Guillanton[13] by the reduction of 2-cyclopentylidenecyclopentanone with lithium aluminum hydride in ether at 0——10°C. The distilled substance (b. p. 91—101°C/1.0 mmHg) was partly solidified, and the oily part, which was expected to be the saturated alcohol, was removed by absorption on a porous plate. The solid was recrystallized from petroleum ether to give pure I, m. p. 57—59°C; yield 12 g. (39%).

The Catalytic Hydrogenation of I.—I (1.5 g.), a catalyst and 50 ml. of solvent were stirred with hydrogen at an ordinary temperature and at atmospheric pressure. After the hydrogenation was over, the catalyst was filtered and the products were analyzed by V. P. C. The experimental data are summarized in Table III.

2-Benzylidene-1-tetralone.—Benzaldehyde (17 g.) was added drop by drop to a mixture of 20 g. of 1-tetralone in 300 ml. of 60% aqueous ethanol and 9.5 g. of sodium hydroxide. The reaction mixture was stirred at room temperature for 4 hr., and then 250 ml. of water was added. The yellow solid which separated was filtered, washed with water, and recrystallized from ethanol, m. p. 107°C; yield 27.5 g. (85%).

Found: C, 87.04; H, 5.78. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.02%.

Table III. Experimental data of catalytic hydrogenation

1) 2-Cyclopentylidenecyclopentanol (1.5 g.)

Catalyst	Weight of catalyst, g.	Hydrogen Uptake ml. (mol.)	Solvent
Raney nickel	0.4	220 (1.0)	Ethanol
5% Palladium charcoal-A	0.1	380 (1.7)	Ethanol
5% Palladium charcoal-B	0.1	225 (1.0)	Ethanol
Platinum oxide	0.1	273 (1.2)	Ethanol
Platinum oxide	0.1	295 (1.3)	Acetic acid
Platinum oxide	0.1	477 (2.1)	Acetic acid with one micro drop of HCl

2) Benzylidene-1-tetralol (1.4 g.)

Catalyst	Weight of catalyst, g.	Hydrogen Uptake ml. (mol.)	Solvent
Raney nickel	0.5	146 (1.1)	Ethanol
5% Palladium charcoal-B	0.2	139 (1.0)	Ethanol
Platinum oxide	0.04	160 (1.2)	Ethanol

2-Benzylidene-1-tetralol (II).—Sodium borohydride (0.4 g.) was added gradually to a solution of 4.5 g. of 2-benzylidene-1-tetralone in 150 ml. of methanol at room temperature. The reaction mixture was then stirred at room temperature for 4 hr.; about 100 ml. of methanol was removed by distillation, and then an equal volume of water was added. The white solid which separated was filtered, washed with water, and recrystallized from petroleum benzine, m. p. 71—72°C; yield 3.9 g. (85%).

Found: C, 86.59; H, 6.99. Calcd. for $C_{17}H_{16}O$: C, 86.40; H, 6.83%.

3-Benzyl-1, 2 - dihydronaphthalene. — 2-Benzyl -1-tetralol (1.5 g.) was heated with 0.5 g. of *p*-toluenesulfonic acid in 200 ml. of benzene for 15 hr. Water was successively removed by azeotropic distillation; the benzene layer was washed with a sodium bicarbonate solution and water, and the benzene was distiled off under reduced pressure. 1.2 g. of 3-benzyl-1, 2-dihydronaphthalene was thus obtained. This compound was checked by a study of its infrared spectrum and V. P. C.

The Hydroboration[14] of 3-Benzyl-1, 2-dihydronaphthalene.[12]—To a solution of 0.4 g. of sodium borohydride in 10 ml. of diglyme containing 1.1 g. of 3-benzyl-1, 2-dihydronaphthalene, there was added 0.76 ml. of boron trifluoride etherate at room temperature. The mixture was stirred for 3 hr. before the excess hydride was decomposed with water. The organoborane was oxidized at room temperature by the addition of 4 ml. of a 3 N solution of sodium hydroxide, followed by the drop-by-drop addition of 4 ml. of 30% hydrogen peroxide. The reaction mixture was extracted with ether, and the extract was washed five times with equal volumes of a saturated salt solution in order to remove the diglyme. The extract was then dried over anhydrous sodium sulfate. The residue left after the solvent had been removed, was recrystallized from petroleum benzine. The yield of *trans*-2-benzyl-1-tetralol was 0.95 g. (80%), m. p. 119°C.

Found: C, 85.95; H, 7.82. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

The Catalytic Hydrogenation of II.—The following general procedure was used. 1.4 g. of II, a catalyst, and 50 ml. of ethanol were stirred with hydrogen at an ordinary temperature and at atmospheric pressure. The hydrogen uptake ceased after one mole of hydrogen had been absorbed; the catalyst was then filtered and, the ethanol distilled off.

Over Raney Nickel.—The residue was recrystallized from petroleum benzine to give the trans isomer of VI, m. p. 119°C. The yield was 1.09 g., 78%.

Found: C, 85.23; H, 7.71. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

When the mother liquor was concentrated, the cis-isomer of VI was obtained, 0.27 g.; 19%. The melting point was 72°C.

Found: C, 85.37; H, 7.78. Calcd. for $C_{17}H_{18}O$: C, 85.67; H, 7.61%.

Over Palladium Charcoal-B.—The residue was recrystallized from petroleum benzine to give *trans*-VI, m. p. 119°C. The yield was 0.47 g., 33%. When the mother liquor was concentrated, *cis*-VI was obtained, m. p. 72°C. The yield was 0.88 g., 63%.

Over Platinum Oxide.—The residue was recrystallized from petroleum benzine to give *trans*-VI, m. p. 119°C. The yield was 0.81 g., 58%. When the mother liquor was concentrated, *cis*-VI was obtained, m. p. 72°C. The yield was 0.48 g., 34%. The products of the hydrogenation over palladium charcoal-B and platinum oxide were, by means of a mixed fusion and a comparison of the infrared spectra, identified with the samples obtained by the hydrogenation of II over Raney nickel.

The experimental details are summarized in Table III.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 698—702 (1966)

Catalytic Asymmetric Benzaldehyde Cyanohydrin Synthesis with Synthetic Optically Active Polymer. III. *N*-Substituted Poly-(s)-isobutylethylenimine

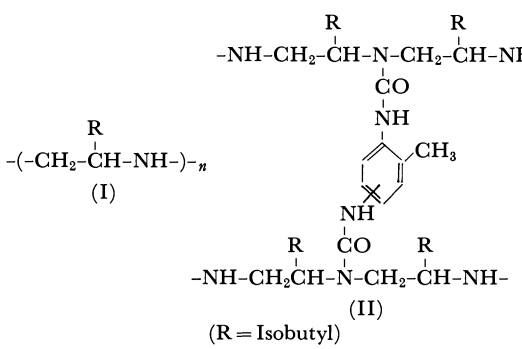
By Sei Tsuboyama

Laboratory of Polymer Chemistry, The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

(Received July 10, 1965)

Asymmetric syntheses of benzaldehyde cyanohydrin in the presence of polymers of *N*-methyl-, *N*-ethyl- and *N*-benzyl-(s)-2-isobutylethylenimine as catalysts have been studied. The selectivity of these polymers was poor (optical yield of (−)-isomer obtained; 0—1%) compared with that of a non-*N*-substituted polymer (20%). It seems that the large difference in the optical yield can be ascribed to their conformation. As to the polymer being capable of promoting the reaction asymmetrically, it is assumed that the isobutyl group and a helical form are the responsible factors. On the basis of these findings, a model for the addition step has been suggested in order to explain the observed result.

In asymmetric syntheses of benzaldehyde cyanohydrin using poly-(s)-isobutylethylenimine (I) and its cross-linked polymer (II) as catalysts, the signs of the optical rotation of cyanohydrin produced were unexpectedly opposite to each other,



(I)

(II)

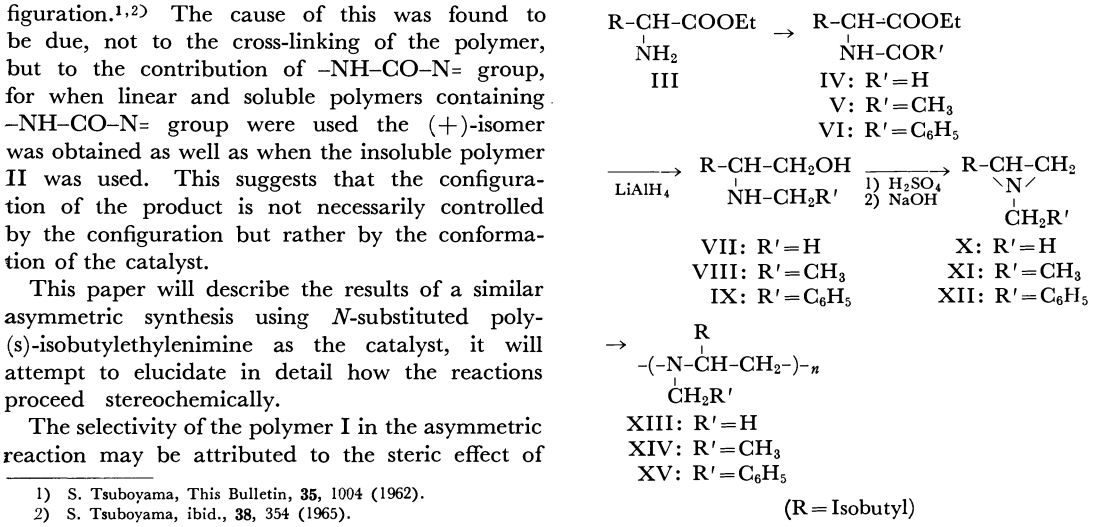
(R = Isobutyl)

though the two polymers are of the same configuration.[1,2] The cause of this was found to be due, not to the cross-linking of the polymer, but to the contribution of –NH–CO–N= group, for when linear and soluble polymers containing –NH–CO–N= group were used the (+)-isomer was obtained as well as when the insoluble polymer II was used. This suggests that the configuration of the product is not necessarily controlled by the configuration but rather by the conformation of the catalyst.

This paper will describe the results of a similar asymmetric synthesis using *N*-substituted poly-(s)-isobutylethylenimine as the catalyst, it will attempt to elucidate in detail how the reactions proceed stereochemically.

The selectivity of the polymer I in the asymmetric reaction may be attributed to the steric effect of the regularly-arranged isobutyl group adjacent to the catalytic center and to the conformation effect of the polymer. For conformation of this, we have so far no data with which to draw any conclusion, yet if we assume a helical form for it, the reaction can be explained. In the *N*-substituted polymer, we can imagine that the pitch of the presumed helix becomes elongated by the steric hindrance of *N*-substituent and by the disappearance, in consequence of tertiarization, of hydrogen atom that might otherwise form hydrogen bonding between nitrogen atoms. Therefore, the said steric effect of the isobutyl group will be reduced by the unfavorable conformation, and a low selectivity may be expected.

Synthesis of Polymer.—Polymers of *N*-methyl- (XIII), *N*-ethyl- (XIV) and *N*-benzyl-(s)-isobutylethylenimine (XV) were prepared by the following process:



(R = Isobutyl)

*1 *c* 0.5—2 in benzene. *2 *c* 1—5 in benzene.
*3 Lower molecular weight fraction. Molecular weight of polymer I: 1020, 5000.

Optically active *N*-substituted imine monomers, which were prepared from acylated amino acid esters through the corresponding amino alcohols, were polymerized by boron trifluoride-etherate under nitrogen. They became tacky low-molecular-weight polymers when heated at 100—120°C for a day or two; heating at higher temperatures causes thermal degradation.[3] Several fractionations in acetone gave *N*-ethyl and *N*-benzyl polymers of a fairly high degree of crystallinity but with the low molecular weights of 1300—1600. For reference, the polymer I was treated with formaldehyde and formic acid (XIII-1) or methyl iodide (XIII-2) in order to introduce the *N*-methyl group into it. According to the analytical data and the infrared spectra, XIII-1 seemed to be partly acylated, and the amino groups of XIII-2 were partially quarternarized. In both cases, various treatments failed to remove the groups involved. The infrared spectra and optical rotatory dispersion curves of these polymers are shown in Figs. 1 and 2.

Asymmetric Synthesis.—The asymmetric synthesis and analysis of the product were carried out in the manner described in a previous paper.[1] The results are summarized in Table I.

The selectivity of these polymers for the asymmetric reaction was quite low or non-existent and was independent of their molecular weight. As regards the *N*-methyl polymer XIII-2, NH group capable of promoting the asymmetric reaction

3) W. G. Barb, *J. Chem. Soc.*, **1955**, 2577.

seemed still to remain in it. The rates of cyanohydrin formation with the polymers XIII and XIV indicated that the reactions did not proceed asymmetrically from the beginning (Fig. 3). These findings justify the expectation mentioned above; nevertheless, some other causes might produce a similar result. For instance, if the racemization rate of cyanohydrin is faster than the rate of formation during the reaction, the selectivity of the reaction will become hardly observable. In confirmation of this, the racemization of optically active cyanohydrin in the presence of the polymer XIV was examined; we thus found that the optical rotation of cyanohydrin is not affected by the presence of the polymer.

There still remains the problem of the stereoregularity of these polymers. Though there is no suitable method for the direct determination of the regularity, it seems likely that, in acid-catalyzed polymerization, a preferential break

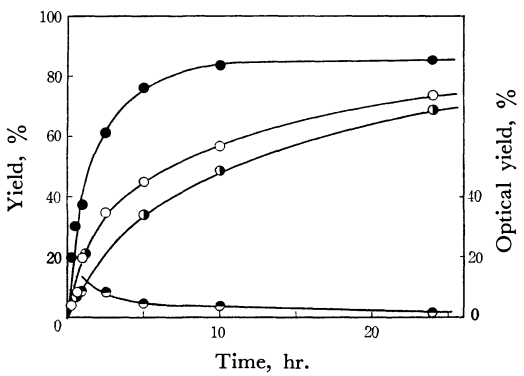

Fig. 3. Time dependence of cyanohydrin formation and its optical yield: ○, polymer XIII (*N*-methyl); ●, polymer XIV (*N*-ethyl); ◑, polymer XV (*N*-benzyl); ◓, optical yield with polymer XV.

in the cyclic imine ring at CH_2–N bond occurs independently of the asymmetric carbon, giving rise to polymers with an unaffected asymmetry.[4-6] Consequently, the configuration of the asymmetric atoms in the polymer must be identical to those of the monomer. This matter will be discussed in another paper on the ring-opening orientation of (R) (+)-ethylethylenimine. Furthermore, the optical rotatory dispersion data may account for the configurational regularity, though the following is not necessarily a proper comparison because it contains an involved group, as has been described above. As is shown in Fig. 2, the curve of the polymer I is positive, whereas when the polymer is *N*-methylated, the curve becomes negative, similar to that found in the case of the polymer XIII prepared from monomers already containing *N*-methyl groups. Therefore, the regularity of these polymers may be considered to be similar despite the large difference in selectivity. This again seems to suggest that the variances in the contributions of these polymers to asymmetric synthesis as catalysts are ascribable, not to their configurational regularity, but to their overall molecular arrangement—conformation. As regards the *N*-benzyl polymer, it may be different from *N*-alkylated polymers with a slight selectivity as a result of a favorable conformation resulting from interaction between aromatic rings in the side chain of the polymer.

Previously it was postulated that the amine catalyst in this asymmetric synthesis should have not only one steric group in a monomeric unit, but also one more obstructive factor with regard to the mobile catalytic center. However effective the steric group may be, because of the ability of trivalent nitrogen to undergo rapid inversion,[7] and since the catalytic center in a monomeric unit may also be converted into their conformers and since asymmetric reactions occur on two sides of the conformer, the products that arise there are enantiomers of equal amounts; hence, there will be no optical rotation. Therefore, only when the accessibilities of the reagent to the catalytic center are different on the two sides of the amine does an asymmetric reaction become possible. In the polymer I, the isobutyl group and the helical conformation are likely to be responsible for the asymmetric reaction. In the *N*-substituted polymer, however, the contribution of the conformation to the reaction is smaller than in the polymer I; this will cause the reagent to approach the active site equivalently, and therefore the optical yield will be lowered.

In the early stage of the reaction, the carbonyl reagent and the amine catalyst form a stereospecific transition complex, to which cyanide ion is then added.[8] Accordingly, the conformation of the transition intermediate should be the most important factor in controlling the steric course of the reaction. In the model of the polymer I shown in Fig. 4, it is assumed that the conformation is helical, even in such a solvent. The isobutyl group will be found on the outside of the helix, with its axis perpendicular to the plane of the paper. In the transition state, the carbonyl reagent will approach the least-hindered site of the conformation of the catalyst as a result of the

steric group. Hence, the product may be expected to be of the s-configuration. Cyanohydrin was found by observation to be negative in sign, which means that it has the s-configuration and that the assumption of a steric course is justified. For the cross-linked polymer II, some other model must be constructed.

Experimental

***N*-Formyl-L-leucine Ethyl Ester (IV).** — The procedure proposed by du Vegneaud and Meyer for the formylation of phenylalanine[9] was used with a slight modification. To a solution of L-leucine ethyl ester (III) (32 g., 0.2 mol.) in 88% formic acid (360 g., 7 mol.) was added dropwise acetic anhydride (122 g., 1.2 mol.) at room temperature with vigorous stirring. The reaction mixture was then kept at 70°C for 15 min. After the excess of the reagents had been removed in vacuo, the residual liquid was distilled under reduced pressure to give 36 g. (96%) of a colorless liquid, b. p. 124—125°C/3 mmHg, n_D^{27} 1.4459, $[\alpha]_D^{27}$ −31.90° (*c* 2.539, ethanol).

Found: C, 57.72; H, 8.99; N, 7.32. Calcd. for $C_9H_{17}NO_3$: C, 57.73; H, 9.15; N, 7.48%.

***N*-Acetyl-L-leucine Ethyl Ester (V).**—This was prepared according to the method of the literature.[10] The acetylated ester V was obtained in 94% yield, b. p. 138—139°C/6 mmHg, n_D^{20} 1.4470, $[\alpha]_D^{20}$ −42.07° (*c* 2.686, ethanol). (Found: C, 59.62; H, 9.19; N, 6.87%.)

***N*-Benzoyl-L-leucine Ethyl Ester (VI).**—The ester was prepared by the method given by Bergmann and Zervas.[11] Recrystallization from petroleum ether afforded 25 g. (95%) of fine needle crystals (from 16 g., 0.1 mol. of ester), m. p. 66.5—67.5°C, $[\alpha]_D^{25}$ −22.47° (*c* 1.112, ethanol). (Found: C, 68.18; H, 8.03; N, 5.24%)

***N*-Methyl-L-leucinol (VII).**—The amino alcohol was obtained from IV (18.7 g., 0.1 mol.) by refluxing with lithium aluminum hydride for 24 hr. in ether. The yield of VII was 10.6 g. (81%), and it had b. p. 84.5—85°C/8 mmHg, n_D^{27} 1.4425, $[\alpha]_D^{23}$ +47.33° (*c* 1.627, ethanol).

Found: C, 64.08; H, 13.46; N, 10.93. Calcd. for $C_7H_{17}NO$: C, 64.07; H, 13.06; N, 1.68%.

Monooxalate: crystallized from ethanol in needles, m. p. 143—143.5°C, $[\alpha]_D^{30}$ +12.45° (*c*, 0.964, ethanol).

Found: C, 48.68; H, 8.49; N, 6.22. Calcd. for $C_9H_{19}NO_5$: C, 48.85; H, 8.66; N, 6.33%.

***N*-Ethyl-L-leucinol (VIII).**—The amino alcohol was prepared in 77% yield (8.3 g.) from V (15 g., 0.075 mol.) according to the procedure described above. The product had b. p. 82—83°C/6 mmHg, m. p. 38—39°C, $[\alpha]_D^{18}$ +48.01° (*c* 2.084, ethanol).

Found: C, 66.11; H, 13.10; N, 9.50. Calcd. for $C_8H_{19}NO$: C, 66.15; H, 13.19; N, 9.64%.

***N*-Benzyl-L-leucinol (IX).**—This compound also was prepared from VI (17 g., 0.064 mol.) and lithium aluminum hydride in tetrahydrofuran. The solution of the ester was refluxed for 3 hr. A silky crystal (10.9 g., 81%) was obtained by recrystallization from petroleum ether, m. p. 73—74°C, $[\alpha]_D^{26}$ +23.44° (*c* 1.024, benzene).

Found: C, 75.46; H, 10.19; N, 6.66. Calcd. for $C_{13}H_{21}NO$: C, 75.31; H, 10.21; N, 6.76%.

***N*-Methyl-(s)-isobutylethylenimine (X).** — The procedure followed was Leighton's method.[12] Redistillation over sodium gave 4.5 g. (40%) of a volatile liquid which odored of imine from VII (13 g., 0.1 mol.), b. p. 116—117°C, $n_D^{31.5}$ 1.4063, $[\alpha]_D^{31.5}$ +30.18° (*c* 0.994, benzene). The infrared specturm showed the presence of an imine ring (3050 cm^{-1}) and of the N–CH_3 group (2785 cm^{-1}).

Found: C, 73.85; H, 13.11; N, 12.43. Calcd. for $C_7H_{15}N$: C, 74.27; H, 13.36; N, 12.37%.

The reaction product of X with hydrogen chloride in ether was recrystallized from ether-ethanol, m. p. 149—150°C, $[\alpha]_D^{21}$ +23.32° (*c* 2.745, ethanol). It is probably 1-chloro-4-methyl-2-methylaminopentane hydrochloride.

Found: C, 45.11; H, 9.08; N, 7.33; Cl, 38.65. Calcd. for $C_7H_{17}NCl_2$: C, 45.17; H, 9.21; N, 7.53; Cl, 38.10%.

***N*-Ethyl-(s)-isobutylethylenimine (XI).**—This also was prepared by Leighton's method. From VIII (18 g., 0.12 mol.), the imine was obtained as a colorless liquid (7.5 g., 48%), b. p. 135—136°C, n_D^{20} 1.4161, $[\alpha]_D^{20}$ +22.67° (*c* 1.147, benzene). The infrared spectrum showed the presence of an imine ring at 3060 cm^{-1}.

Found: C, 75.41; H, 13.23; N, 10.98. Calcd. for $C_8H_{17}N$: C, 75.52; H, 13.47; N, 11.01%.

The reaction product of XI with hydrogen chloride in ether was white flakes and had m. p. 141—142.5°C, $[\alpha]_D^{25}$ 0.00° (*c* 0.2132, ethanol), after several recrystallizations from ether-ethanol.

Found: C, 48.17; H, 9.28; N, 6.75; Cl, 35.61. Calcd. for $C_8H_{19}NCl_2$: C, 48.01; H, 9.57; N, 7.00; Cl, 35.43%.

From the mother liquor another crystal was obtained, m. p. 204—205°C, $[\alpha]_D^{28}$ +8.48° (*c* 1.061, ethanol).

Found: C, 48.20; H, 9.37; N, 7.23; Cl, 35.11. Calcd. for $C_8H_{19}NCl_2$: C, 48.01; H, 9.57; N, 7.00; Cl, 35.43%.

It is probable that the former is 2-chloro-1-ethylamino-4-methylpentane hydrochloride and that the latter is 1-chloro-2-ethylamino-4-methylpentane hydrochloride, because the latter, which has an optical activity, seems to be produced by breaking at the primary

carbon of the cyclic imine ring, regardless of the asymmetric carbon, and so the asymmetry is maintained.

***N*-Benzyl-(s)-isobutylethylenimine (XII).**—The imine was produced in 46% yield (3.1 g.) from IX (7 g., 0.034 mol.) by the procedure described above. The product had b. p. 98.5—99.5°C/6 mmHg, n_D^{23} 1.4975, $[\alpha]_D^{23}$ +9.74° (*c* 1.129, benzene). The infrared spectrum indicated an imine band at 3030 cm^{-1}.

Found: C, 82.35; H, 9.93; N, 7.97. Calcd. for $C_{13}H_{19}N$: C, 82.48; H, 10.12; N, 7.40%.

Poly-(s)-*N*-methylisobutylethylenimine (XIII).—The polymerization of the imine was carried out as described previously,[1] and the product obtained was refined by fractionation in cold acetone. The product was a light-yellow tacky solid which was soluble in common organic solvents but insoluble in water, and which exhibited no crystallinity. The infrared specturm of film evaporated from a benzene solution showed an N-CH_3 band at 2785 cm^{-1}, while the band at 3050 cm^{-1} disappeared; $[\alpha]_D^{20}$ −70.00° (*c* 1.000, benzene), molecular weight, 1330 (cryoscopic method with benzene).

Found: C, 72.44; H, 13.13; N, 12.15. Calcd. for $(C_7H_{15}N)_n$: C, 74.27; H, 13.36; N, 12.37%.

Poly-(s)-*N*-ethylisobutylethylenimine (XIV).—After fractionation using acetone, the precipitate was freeze-dried to give a white powder, m. p. 146°C, $[\alpha]_D^{15}$ −207.4° (*c* 1.176, benzene), molecular weight, 1340; it had a high crystallinity.

Found: C, 75.71; H, 13.19; N, 10.99. Calcd. for $(C_8H_{17}N)_n$: C, 75.52; H, 13.47; N, 11.01%.

Poly-(s)-*N*-benzylisobutylethylenimine (XV).—The polymer obtained had m. p. 118—121°C, $[\alpha]_D^{22}$ −219.0° (*c* 0.950, benzene), molecular weight, 1645. Although the infrared spectrum still showed the band near 3050 cm^{-1} despite treatment several times with various methods, it seems not to be the absorption band of the imine ring but that of the C-H stretching of the aromatic ring. An X-ray examination of the polymer showed a fairly high degree of orientation.

Found: C, 82.12; H, 10.16; N, 7.30. Calcd. for $(C_{13}H_{19}N)_n$: C, 82.48; H, 10.12; N, 7.40%.

***N*-Methylation of Polymer I.**—*By Eschweiler-Clarke's Method (XIII-1).*—Attempts to prepare a product which had no carbonyl group were unsuccessful. The polymer I (200 mg.) was added to a solution of 35% formaldehyde (1 g.) and 88% formic acid (0.25 g.) with a slight warming. The mixture was heated gently until the evolution of carbon dioxide ceased, and then it was refluxed on a steam bath for 5 hr. The solution obtained was cooled and saturated with solid potassium hydroxide. The organic layer was separated, diluted with benzene, and washed with water until it was neutral. After freeze-drying, the benzene solution gave 170 mg. of a pale yellow powder, m. p. 132—140°C, $[\alpha]_D^{25}$ −46.03° (*c* 1.035, benzene). In the infrared specturm, the band of the N-CH_3 group is observed instead of the disapperance of the N-H band near 3285 cm^{-1}. Besides, a strong peak near 1700 cm^{-1} appears even after various purifications. It perhaps indicates a carbonyl group coming from alkylating agents.

Found: C, 72.35; H, 12.04; N, 10.46. Calcd. for $(C_7H_{15}N)_n$: C, 74.27; H, 13.36; N, 12.37%.

By Methyl Iodide (XIII-2).—The polymer I (300 mg.) was dissolved in 10 g. of methyl iodide and then allowed to stand at 50°C for 48 hr. After the excess of the reagent had been removed, the residue was added to benzene and washed by alcoholic potash, 3 N potassium nitrate, N sodium chloride, N sodium hydroxide solution, and water successively. A yellow, powdery polymer was obtained by freeze-drying. The yield was 310 mg., $[\alpha]_D^{31}$ −6.20° (*c* 1.000, benzene). Although the reaction and treatment were repeated, the alkylation of the polymer was not sufficient and no halogene could be removed: $[\alpha]_{30}^{D}$ −10.62° (*c* 2.730, benzene).

Found: C, 68.20; H, 12.05 N, 11.78; Halogene as iodide, 6.86. Calcd. for $(C_5H_{19}NO)_n$: C, 66.15; H, 13.19; N, 11.02%.

A similar polymer was obtained by the quaternarization of polymer XIII with methyl iodide, but it was more difficult to obtain it in a pure state than in the case of XIII-2.

Asymmetric Synthesis.—A catalyst polymer (0.5 mmol.) in benzene was added to a solution of refined benzaldehyde (5 ml.) and anhydrous hydrogen cyanide (2 ml.) in benzene at 20°C; then the mixture was made up to 25 ml. with benzene. After this solution had been allowed to stand at 20°C for 20 hr., the reaction mixture was quenched by 10% sulfuric acid solution; the unchanged hydrogen cyanide was then removed in vacuo in the presence of one drop of phosphoric acid. The residue was decanted or filtered off, and the resulting solution was again made up to 25 ml. with benzene. The optical rotation of the solution was measured in a 2 dm. tube. Whenever the rotatory power was very small, distillation was carried out and the optical rotation was checked by a photoelectric instrument. The concentration of the solution was determined by titration with 0.1 N silver nitrate solution by a method described previously.[1]

Rate of Cyanohydrin Formation.—A polymer was dissolved in a mixture of benzene and 20 ml. of refined benzaldehyde. To the solution, hydrogen cyanide (8 ml.) was then added, and the mixture was made up to 100 ml. with benzene at 20°C. The solution was kept at 20°C. At intervals, 5 ml. portions were withdrawn and treated in a way similar to that described above except that the sample was made up to 10 ml.

Racemization of Cyanohydrin by Polymer XIV.—The polymer XIV (63.6 mg.) was added to (+)-cyanohydrin ($[\alpha]_D^{25}$ +1.49°, *c* 9.340) benzene solution at 20°C. The mixture was then kept at 20°C for 105 min. Distillation gave (+)-isomer with $[\alpha]_D^{25}$ +1.47° (*c* 20.400, benzene). When the distillation was carried out in the presence of the polymer XIV and one drop of phosphoric acid, no racemization of the cyanohydrin occurred. Before distillation, $[\alpha]_D^{25}$ −0.52° (*c* 21.24, benzene); after distillation, $[\alpha]_D^{25}$ −0.52° (*c* 3.09, benzene).

Optical Rotatory Dispersion.—This was measured by Rudolph spectro-polarimeter. Model 200-S-80 and Nihon Bunko, Jasco ORD/UV-5 type.

The author wishes to thank Dr. Masaya Yanagita for his stimulating discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 703—708 (1966)

The Determination of Micro Amounts of Polythionates. V.* A Photometric Method for the Determination of Polythionates When Two Species of Them, Tetra-, Penta- and Hexathionate, are Present Together[1]

By Tomozo KOH and Iwaji IWASAKI

Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received July 28, 1965)

In the previous papers of this series, the present authors have found the conditions under which all three polythionates (n=4, 5 and 6) are quantitatively converted into thiocyanate. When one mole of polythionate undergoes cyanolysis, one mole of thiosulfate and ($n-3$) moles of thiocyanate are formed. The thiosulfate formed from polythionate is then converted into thiocyanate by the addition of a cupric chloride solution. A photometric method for the determination of polythionate when two species of polythionates, tetra-, penta- and hexathionate, are present toghther has been devised; it depends upon the determination of the different amounts of thiocyanate formed from the cyanolysis of polythionates both in the presence of cupric ions and in their absence. The mean number of sulfur atoms, n, in the formula, $S_nO_6^{2-}$, for polythionate, was determined; the polythionate composition of the solution was also evaluated from the n value

In the previous papers[2-4] of this series, the present authors have established excellent methods for the determination of polythionates, tetra-, penta- and hexathionate. These methods are based on the reaction:

$$S_nO_6^{2-} + (n-1)CN^- + H_2O = S_2O_3^{2-} + SO_4^{2-} + 2HCN + (n-3)SCN^- \quad (A)$$
(n=4, 5 and 6)

followed by the photometric determination of the thiocyanate thus formed with ferric iron when tetra-, penta- or hexathionate is present by itself alone. They also have found the conditions under which all these polythionates are quantitatively converted into thiocyanate.

Iwasaki and his co-worker[5] have proposed a method for the determination of tetrathionate by means of its decomposition with sulfite.

It would be important and interesting, from the analytical and the geochemical viewpoints, to determine micro quantities of polythionates mixed with one another, but no satisfactory method has yet been devised for when they are present together. In the present paper, an attempt has been made, as the initial step, to determine polythionate when two species of polythionates, tetra-, penta- and hexathionate, are present together. It has been stated in the literature[6] that cupric ion has a catalytic effect on the conversion of thiosulfate into thiocyanate. Consequently, if the cupric chloride is added after the above Eq. A has been completed, then the thiosulfate formed from polythionate is further converted into thiocyanate. The overall reaction of polythionates, accordingly, is as follows:

$$S_nO_6^{2-} + nCN^- + H_2O = SO_3^{2-} + SO_4^{2-} + 2HCN + (n-2)SCN^- \quad (B)$$
(n=4, 5 and 6)

Urban[7] has evaluated n in the formula, $S_nO_6^{2-}$, for polythionates by means of the photometric determination of different amounts of the thiocyanate formed in accordance with Eq. A and B. However, penta- and hexathionate, as has been pointed out in the previous papers,[2,3] are not quantitatively converted into thiocyanate under the conditions of Urban's method,[7] because of the partial alkaline decomposition arising from the higher pH value caused by the addition of a sodium cyanide solution. Therefore, Urban's method is inapplicable to the evaluation of n in the formula, $S_nO_6^{2-}$, for polythionates.

The present authors will here investigate, in greater detail, a photometric method for the determination of thiosulfate which is based on the formation of thiocyanate from thiosulfate by reaction with cyanide in the presence of cupric ions; they will propose a method for the determination of micro amounts of polythionates when two species of them are present together by means of the photometric determination of different amounts

of the thiocyanate formed in accordance with Eqs. A and B. They will also determine n, the mean number of sulfur atoms in the formula, $S_nO_6^{2-}$, for polythionates above trithionate, and, at the same time, will evaluate the polythionate composition of the solution from the n values.

Experimental

Apparatus and Materials.—Unless stated otherwise, the apparatus and materials used in this investigation were the same as those described in previous papers.[2-4]

The Standard Thiosulfate Solution.—The stock solution of thiosulfate was prepared by dissolving guaranteed sodium thiosulfate pentahydrate in freshly-boiled and cooled redistilled water containing a small amount of sodium carbonate; it was then standardized with a standard potassium iodate solution. The working thiosulfate solutions were prepared by diluting the stock solution properly.

The Cupric Chloride Solution.—The working cupric chloride solutions were prepared by diluting a 1 M solution properly.

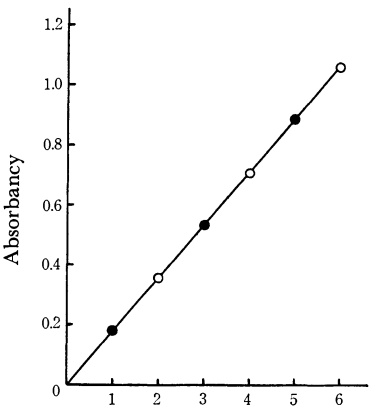
Buffer Solution.—The solutions of acetic acid - sodium acetate (0.1 M), sodium dihydrogen phosphate-sodium hydroxide (0.2 M), borax - hydrochloric acid (0.2 M—0.1 N) and disodium phosphate - sodium hydroxide (0.1 M) were mixed with each other, at various ratios, in order to obtain buffer solutions from pH 3.2 to 5.0, from pH 6.0 to 8.0, from pH 8.8 to 10.0, and from pH 11.2 to 12.0 respectively.

Procedure A.—A sample solution of 10.0 ml. is placed in a 25 ml. volumetric flask. To this solution are added, first, 4.0 ml. of a phosphate buffer solution of pH 7.0, and then 2.5 ml. of a 0.1 M sodium cyanide solution; the pH of the solution is thereby brought to 8.7. The volumetric flask is kept in the thermostat at 40°C for 30 min.; polythionates are thereby quantitatively converted into thiocyanate according to Eq. A. Then 3.0 ml. of a 1.5 M ferric nitrate - perchloric acid solution is added. After the flask has been filled with redistilled water to the mark, the contents are mixed well. The absorbancy of the solution of the ferric-thiocyanate complex thus formed is measured at the wavelength of 460 mμ, using the reagent blank as a reference.

Procedure B.—To 10.0 ml. of a sample solution in a 25-ml. volumetric flask there are added, first, 4.0 ml. of a buffer solution of pH 7.0, and then 2.5 ml. of a 0.1 M sodium cyanide solution. After the volumetric flask has been kept in the thermostat at 40°C for 30 min., 1.5 ml. of a 0.05 M cupric chloride solution is added; the pH of the solution is thereby brought to 7.1. The mixture is shaken vigorously, whereupon polythionates are converted into thiocyanate quantitatively in accordance with Eq. B. Then 3.0 ml. of a perchloric acid solution of ferric nitrate is added; after filling the flask with redistilled water to the mark, the contents are mixed well. The absorbancy of the solution of the ferric-thiocyanate formed is measured at 460 mμ against the reagent blank.

Results and Discussion

Calibration Curves.—The calibration curves shown in Fig. 1 were obtained by the procedure B, using the standard solutions of thiosulfate and thiocyanate.



Concn. of $S_2O_3^{2-}$ and SCN^-, $\times 10^{-4}$ M

Fig. 1. Calibration curves.

○ Thiosulfate, ● Thiocyanate

When one ion of thiosulfate undergoes cyanolysis, one ion of thiocyanate is formed. Therefore, if thiosulfate is converted into thiocyanate quantitatively and completely, the calibration curve of thiosulfate should be in full accord with that of thiocyanate when plotted by the mole concentrations for thiosulfate and thiocyanate. Figure 1 shows that the reaction of thiosulfate with cyanide in the presence of cupric ions is stoichiometric and goes well to completion under the conditions mentioned above.

The standard solutions containing various amounts of tetra-, penta-, hexathionate and thiocyanate were treated by the procedure B described above; the experimental results are plotted in Figs. 2 and 3.

Fig. 3. Calibration curves.

● Thiocyanate, ⊗ Tetrathionate
⊙ Pentathionate, ○ Hexathionate

According to Eq. B, when one ion of polythionate, $S_nO_6^{2-}$ (n=4, 5 and 6), undergoes cyanolysis, ($n-2$) ions of thiocyanate are formed. As a matter of fact, Fig. 2 shows that the calibration curves of tetra-, penta- and hexathionate are, respectively, twice, three times and four times as sensitive as that of thiocyanate when plotted by the molar concentration.

As can also be seen in Fig. 3, their calibration curves are in exact accordance with that of thiocyanate when the scales of the concentrations of thiocyanate, tetrathionate and pentathionate are made to one-fourth, two-fourths and three-fourths of the hexathionate concentration, demonstrating that all three of these polythionates are quantitatively converted into thiocyanate according to Eq. B.

The Effect of the pH.—In order to study the effect of the pH on the cyanolysis, the reaction of thiosulfate with cyanide in the presence of cupric ions was carried out at various pH values. Figure 4 shows that the optimum pH value for the complete and stoichiometric reaction is within a range from 5.0 to 9.0 under the conditions of the procedure B described above.

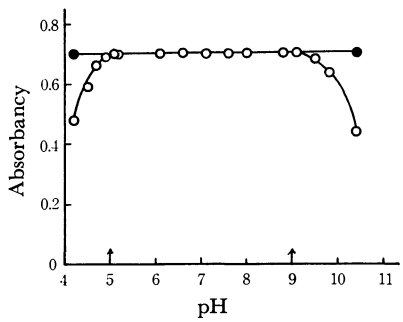

Fig. 4. The effect of the pH.

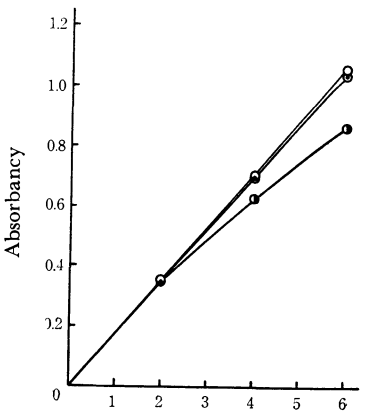
● 4.0×10^{-4} M SCN^-, ○ 4.0×10^{-4} M $S_2O_3^{2-}$

The pH of the solution, after the cyanolysis of polythionates in accordance with Eq. A, was brought from 8.7 to 7.1 by the addition of a 0.05 M cupric chloride solution in the procedure B.

The decreases in absorbancy below the pH value of 4.9 and above pH 9.1 may be attributed to the decrease in the concentration of cyanide ions with the lowering of the pH, and to the decrease of the concentration of cupric ions due in all probability to the formation of the cuprous-cyanide complex[8] which might result from the increase in the concentration of cyanide ions with the elevation of the pH.



Concn. of thiosulfate, $\times 10^{-4}$ M

Fig. 5. The effect of the amount of sodium cyanide. The pH was adjusted to the range from 5.0 to 9.0 in all cases.

○ 0.1 M NaCN 1.2, 1.5, and 2.5 ml. (III)
◑ 0.1 M NaCN 0.5 ml. (I)
⊙ 0.1 M NaCN 1.0 ml. (II)

The Effect of the Amount of Sodium Cyanide.—In measuring the effect of the amount of sodium cyanide on the conversion of thiosulfate into thiocyanate, a volume of from 0.5 to 2.5 ml. of 0.1 M sodium cyanide was employed; in all cases the solution was buffered to the optimum pH range. The resulting effect is shown in Fig. 5.

The calibration curves with 0.5 and 1.0 ml. do not form straight lines (see I and II), indicating that the conversion of thiosulfate is not quantitative because of insufficient amounts of cyanide. Figure 5 shows that 1.2 ml. of a 0.1 M sodium cyanide solution is sufficient for the quantitative conversion and that the amount of sodium cyanide does not have any effect on the method as long as

it is sufficient and the pH is adjusted to an optimum value. From a consideration of the cyanolysis of polythionate prior to the cyanolysis of the thiosulfate formed from the reaction of polythionate with cyanide, 2.5 ml. of a 0.1 M sodium cyanide solution was added in the present work.

The Effect of the Amount of Cupric Chloride.—In order to investigate the effect of the quantity of cupric ions, a solution of from 0.5 to 2.0 ml. of 0.05 M cupric chloride was employed; in all cases the solution was buffered to a pH value from 5.0 to 9.0. The results listed in Table I show that 1.5 ml. of a 0.05 M cupric chloride solution is sufficient for quantitative cyanolysis and that thiosulfate is instantly converted into thiocyanate in the pre- sence of cupric ions.

The Effect of Shaking on the Cyanolysis of Thiosulfate.—Table II shows that the shaking has to be made after the addition of a cupric chloride solution in order that the cyanolysis of thiosulfate may be stoichiometric and may go well to completion; otherwise the quantitative reaction does not occur.

Table II. Effect of shaking on cyanolysis of thiosulfate

Sample	Concn., $\times10^{-4}$ M	Absorbancy: No shaking	No shaking	Shaking	Shaking
SCN^-	4.0	0.704	0.706	0.705	0.705
$S_2O_3^{2-}$	4.0	0.592	0.538	0.705	0.705

The Evaluation of n in $S_nO_6^{2-}$ for Polythionates.—Suppose A and B are the absorbancies obtained by the two procedures, A and B, described above, then:

$$A/B = (n-3)/(n-2)$$

When rearranged:

$$n = A/(B-A)+3 \quad \text{or} \quad n = (3B-2A)/(B-A)$$

The former, being the simpler for determining the n value, was used in this work. The results obtained when applied to solutions of tetra-, penta- and hexathionate are listed in Table III.

Table III. The evaluation of n in $S_nO_6^{2-}$ for polythionates

Sample	Concn. $\times10^{-4}$ M	Absorbancy: A	B	n
$S_4O_6^{2-}$	1.5	0.268	0.525	4.04
$S_5O_6^{2-}$	1.5	0.522	0.801	4.87
$S_6O_6^{2-}$	1.5	0.801	1.063	6.06

Urban[7] has pointed out that polythionates, with the exception of tetrathionate, are mixtures containing the other polythionates; he deduced this from the n values, which he estimated to be from 4.29 to 4.34 for pentathionate and from 4.87 to 5.35 for hexathionate. However, his results do not seem reasonable, because these polythionates, as has been mentioned above, undergo a partial alkaline decomposition besides cyanolysis under the conditions of Urban's method.

From Table III, it may be seen that the n value, the mean number of sulfur atoms in the formula, $S_nO_6^{2-}$, for polythionate, could be sufficiently accurately determined by the present method.

The Evaluation of the Composition of Polythionates Simultaneously Present.—The composition of polythionates can be easily evaluated from the n value and Figs. 6 and 7 when two species of polythionates from among tetra-, penta- and hexathionate are simultaneously present. The experimental results are given in Table IV.

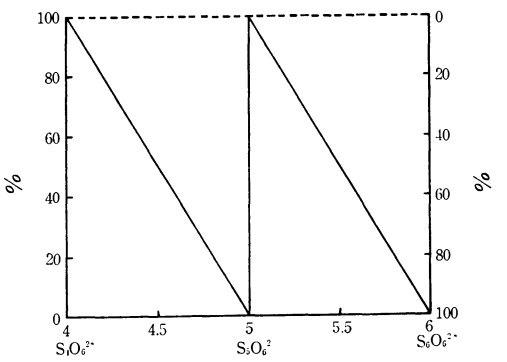

Fig 6.

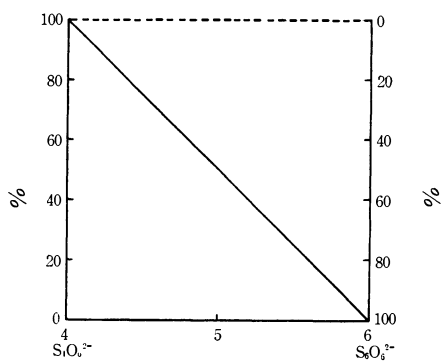

Fig. 7.

As may be seen in Table IV, there is a remarkable agreement between the experimental and the calculated compositions.

The Determination of Tetrathionate and Pentathionate Simultaneously Present.—The method consists of the determination of the different amounts of thiocyanate formed from Eqs. A and B on two separate aliquots of the sample; one is treated by the procedure A, and the other, by the procedure B. Then:

$$(S_4O_6^{2-}) = 2B-3A \text{ and } (S_5O_6^{2-}) = 2A-B,$$

where $(S_4O_6^{2-})$ and $(S_5O_6^{2-})$ indicate the absorbancy corresponding to the same concentration of thiocyanate as those of tetrathionate and pentathionate; A and B are the absorbancies obtained by the procedures A and B.

Tetrathionate and pentathionate simultaneously present can be readily determined by reference to the calibration curve in Fig. 1. The results listed in Table V show that this method can be accurately applied to the determination of tetrathionate and pentathionate simultaneously present at various ratios.

The Determination of a Tetrathionate-Hexathionate Mixture and a Pentathionate-Hexathionate Mixture.—The following equations can also be obtained: for a tetrathionate-hexathionate mixture, $(S_4O_6^{2-})=(3B-4A)/2$ and $(S_6O_6^{2-})=(2A-B)/2$; for a pentathionate-hexathionate mixture, $(S_5O_6^{2-})=3B-4A$ and $(S_6O_6^{2-})=3A-2B$. These polythionates can be determined in the same way as that used for a tetrathionate-pentathionate mixture, by using the above equations when two species of polythionates are simultaneously present. The results of the deter-

mination of polythionates mixed in various ratios are given in Tables VI and VII.

As will be seen in Tables V, VI and VII, the results are reproducible within an error of $\pm 0.2 \times 10^{-4}$ M of polythionates.

Summary

The photometric method for the determination of a small amount of thiosulfate has been investigated in greater detail; it is based on the formation of thiocyanate from the reaction of thiosulfate with cyanide in the presence of cupric ions, and on the determination of the thiocyanate with an excess of ferric iron.

The polythionates are first converted into thiocyanate with cyanide; one ion of thiosulfate is also thereby formed. The thiosulfate formed is then converted into thiocyanate by the addition of a cupric chloride solution. A method for the determination of micro amounts of polythionates mixed with each other has been devised; it is based on the determination of the different amounts of thiocyanate formed from the cyanolysis of polythionates in the presence of cupric ions and in their absence.

The present method was reproducible to $\pm 0.2 \times 10^{-4}$ M of polythionates when applied to the determination of polythionates simultaneously present at various ratios.

The authors wish to express their gratitude to Dr. Satori Utsumi of Nihon University, and to Mr. Takejiro Ozawa and Dr. Minoru Yoshida of the Tokyo Institute of Technology, for their valuable advice during this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 708—713 (1966)

The Reactions of Amido Phosphites. A New Synthesis of Oxazolidine, Imidazolidone and Thiazolidine Derivatives

By Oyo MITSUNOBU[†], Takashi OHASHI[††] and Teruaki MUKAIYAMA[†]

[†]*Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo*

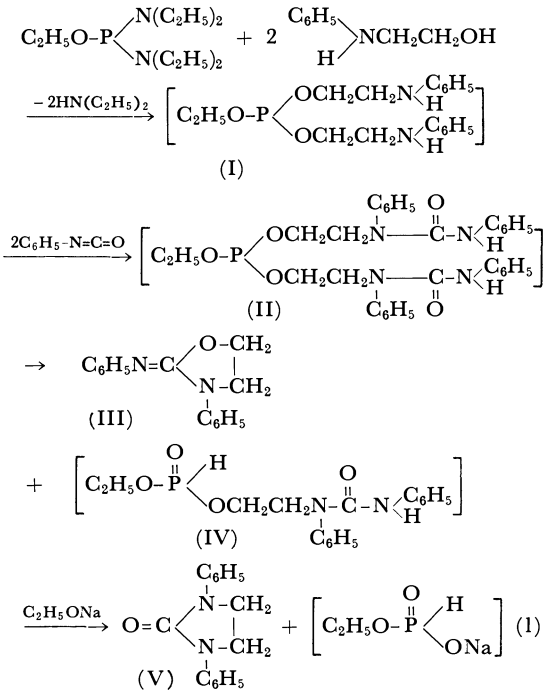
(Received July 28, 1965)

A new method for the preparation of various 2, 3-disubstituted oxazolidine, 2, 3-disubstituted thiazolidine and 1, 3-disubstituted imidazolidone derivatives from β-aminoethyl phosphites and either phenyl isocyanate or phenyl isothiocyanate has been developed. When 1 mol. of ethyl bis(β-anilinoethyl) phosphite, resulting from the reaction of ethyl bis(diethylamido) phosphite with *N*-phenyl ethanolamine, was treated with 2 mol. of phenyl isocyanate, 2-phenylimino-3-phenyl-1,3-oxazolidine was obtained in a 57% yield, along with an oily product. This oily product afforded a 36% yield of *N*, *N'*-diphenyl-2-imidazolidone when it was treated with sodium ethoxide. On the other hand, the pentavalent phosphorus compound, ethyl bis(β-*N*-phenyl-ureidoethyl) phosphate, did not afford an oxazolidine derivative but was converted to imidazolidone in the presence of sodium ethoxide. The reaction of β-anilinoethyl propylene phosphite with an equimolar amount of phenyl isocyanate gave only *N*, *N'*-diphenyl-2-imidazolidone in a 32% yield; 2-phenylimino-3-phenyl-1, 3-oxazolidine could not be obtained. These reactions were then extended to the preparation of exo-imino-thiazolidines. The reactions of β-aminoethyl phosphites with phenyl isothiocyanate resulted in the formation of 2-phenylimino-3-phenyl-1, 3-thiazolidine in fairly good yields.

It has been found in a previous paper[1] that bis(β-anilinoethyl) phenyl phosphonite reacts with phenyl isocyanate to form 2-phenylimino-3-phenyl-1, 3-oxazolidine in a fairly good yield. Exo-imino cyclic compounds, such as ethylene iminocarbonates, 2-iminotetrahydrofuranes and 2-imino-1, 3-oxazolidines, have been known to polymerize in the presence of cationic catalysts, giving polyurethanes, polyamides and polyureas respectively.[2-5]

Concerning the preperation of exo-imino oxazolidine and thiazolidine, several methods have been reported.[6-10]

In the present investigation, a new method for the preparation of various exo-imino oxazolidine and thiazolidine derivatives from β-aminoethyl phosphite and either phenyl isocyanate or phenyl isothiocyanate has been studied. When 1 mol. of ethyl bis(β-anilinoethyl) phosphite(I), the result of the reaction of 1 mol. of ethyl bis(diethylamido) phosphite with 2 mol. of *N*-phenyl ethanolamine, was treated with 2 mol. of phenyl isocyanate in benzene at room temperature, a considerable heat liberation was observed. After the reaction mixture had been refluxed for 3 hr., a highly viscous substance (II) was formed. Its infrared spectrum showed an absorption at 1670 cm^{-1} which was due to a carbonyl group of an urea linkage or to an exo-imino group of a five-membered ring, while the absorption peak at 2280 cm^{-1} which was due to an isocyanate group had disappeared. When this substance (II) was left to stand for a few days at room temperature, a crystalline product was obtained; this was identified as 2-phenylimino-3-phenyl-1, 3-oxazolidine (III) by a comparison of its infrared spectrum with that of an authentic sample[5] and by an elemental analysis. A 57% yield of the 2-phenylimino-3-phenyl-1, 3-oxazolidine was obtained by filtration. The infrared absorption spectrum of the filtrate showed characteristic bands attributed to P–H (2350 cm^{-1}) and to P=O (1260—1280 cm^{-1}). When the substance IV was treated with sodium ethoxide in benzene and *N*, *N'*-diphenyl-2-imidazolidone (V), cyclic urea was obtained in a 36% yield according to the following equation (1):



(1)

Similarly, the other substituted exo-imino oxazolidines and imidazolidones were obtained in fairly good yields (see Tables I and II).

Ethyl bis(β-anilinoethyl) phosphite, which had been obtained from the reaction of 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine (VI) and an equimolar amount of *N*-phenyl ethanolamine, was treated with phenyl isocyanate* to give 52.1% of the oxazolidine and 48.8% of the imidazolidone. On the other hand, the exo-imino compound could not be obtained by the reaction of β-anilinoethyl propylene phosphite (VII) with an equimolar amount of phenyl isocyanate under the same conditions. *N*, *N'*-Diphenyl-2-imidazolidone (V) resulted in a 40% yield when the above-mentioned reaction mixture VIII was treated with sodium ethoxide (Eq. 2):

* It has been proved that the isomerization reaction of 2-phenylimino-3-phenyl-1, 3-oxazolidine to *N*, *N'*-diphenyl-2-imidazolidone does not occur when the oxazolidine is treated with sodium ethoxide in refluxing ethanol for 1 hr. Eighty per cent of the oxazolidine is recovered.

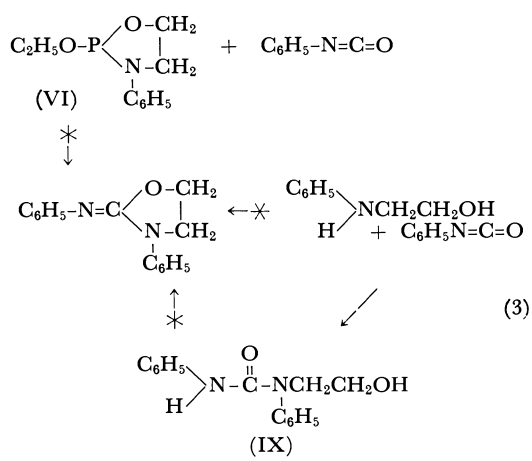
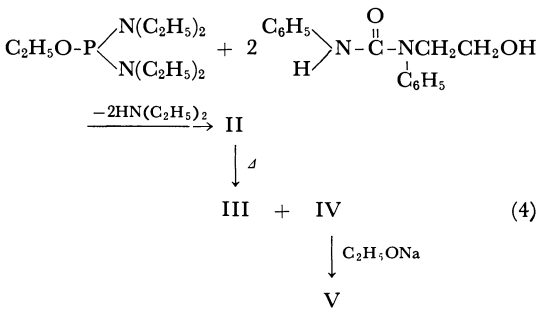
(2)

Also, it was found that 2-phenylimino-3-phenyl-1, 3-oxazolidine (III) could not be obtained by the treatment of either 2-ethoxy-3-phenyl-1,3,2-oxazaphospholidine or *N*-phenyl ethanolamine with phenyl isocyanate (Eq. 3):



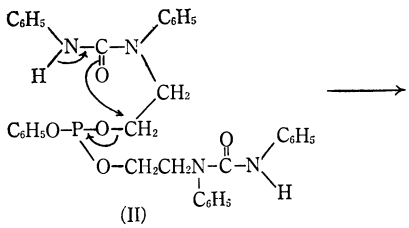
(3)

These results suggest that ethyl bis(β-*N*-phenylureidoethyl) phosphite (II) may be a necessary intermediate for the formation of oxazolidine. The proposed intermediate (II) may be expected to be analogously formed by the reaction of *N*-(β-hydroxyethyl)-*N*, *N'*-diphenyl urea (IX) with amido phosphite. Indeed, when the urea alcohol was treated with ethyl bis(diethylamido) phosphite, nearly quantitative yields of 2-phenylimino-3-phenyl-1, 3-oxazolidine and an oily product were formed. The oily product gave a 26.9% yield of *N*, *N'*-diphenyl-2-imidazolidone upon treatment with sodium ethoxide (Eq. 4):

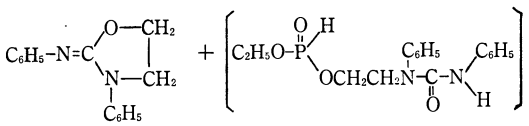


(4)

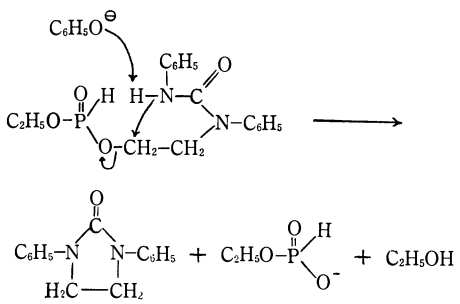
On the basis of these results, it can be considered that the reaction proceeds through a key intermediate II, which, on heating, is decomposed into IV and oxazolidine by an internal nucleophilic displacement of carbonyl oxygen to α-carbon (as is shown in Eq. 5):



(5)

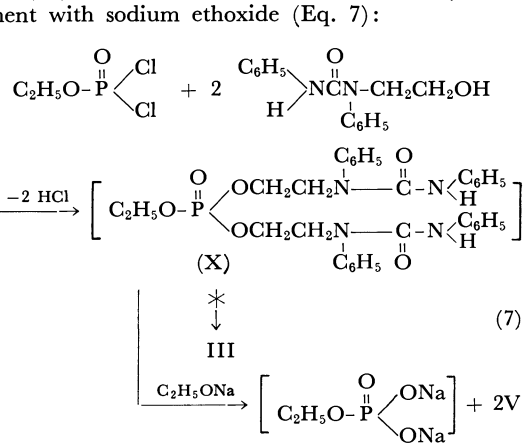


On the other hand, imidazolidone was formed by an internal nucleophilic attack of nitrogen on α-carbon when IV or VIII was treated with sodium ethoxide, as is shown in the following equation (Eq. 6):



(6)

It must be noted that when ethyl bis(β-*N*-phenylureidoethyl) phosphate (X) was used in place of the trivalent phosphorus compound, exo-imino oxazolidine could not be obtained, but a 85.7% yield of imidazolidone was obtained by treatment with sodium ethoxide (Eq. 7):

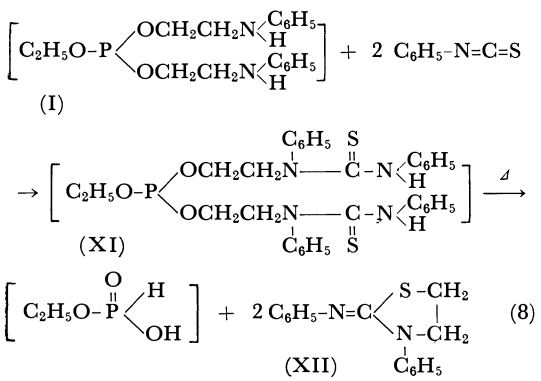


(7)

Further, for the purpose of extending the reaction to the preparation of exo-imino thiazolidine derivatives, 3.48 g. of ethyl bis(β-anilinoethyl) phosphite (I) was treated with 2.70 g. of phenyl isothiocyanate; 3.59 g. of 2-phenylimino-3-phenyl-1, 3-thiazolidine (XII) was thus obtained. Similarly, the other exo-imino thiazolidine derivatives

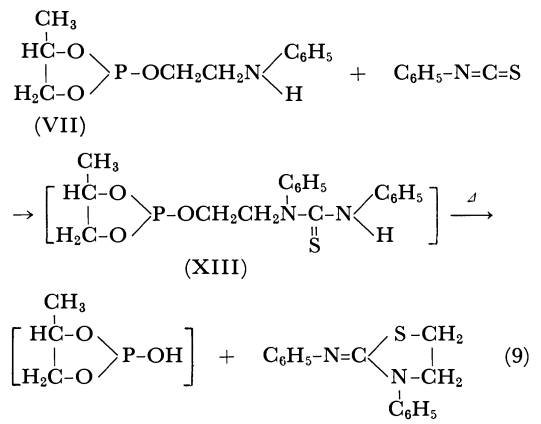
were obtained in good yields by the treatment of *N*-substituted ethanolamines with amido phosphite and phenyl isothiocyanate (see Table III).

Contrary to the case of ethyl bis(β-*N*-phenylureidoethyl) phosphite (II), this result shows that the decomposition of 1 mol. of ethyl bis(β-*N*-phenylthioureidoethyl) phosphite (XI) affords 2 mol. of thiazolidine (Eq. 8):



(8)

In this connection, it is interesting to note that the reaction of β-anilinoethyl propylene phosphite (VII) with an equimolar amount of phenyl isothiocyanate resulted in the formation of exo-imino thiazolidine (XII) in a fairly good yield (Eq. 9):



(9)

The predominant formation of thiazolidine from mono or bis(β-*N*-phenylthioureidoethyl) phosphite (XIII or XI) may be attributed to the high nucleophilicity of the sulfur.

Experimental

Materials. — Commercially - available *N* - phenyl ethanolamine, phenyl isocyanate and phenyl isothiocyanate were purified by distillation. *p*-Tolyl ethanolamine, *p*-anisyl ethanolamine and *p*-chlorophenyl ethanolamine were prepared from the corresponding aromatic amines, ethylenechlorohydrine and triethylamine. Ethyl bis(diethylamido) phosphite (b. p. 81—83°C/9 mmHg) was prepared in a manner analogous to that reported by Burgada.[11] *N*-(β-Hydroxyethyl)-*N*, *N'*-diphenyl urea[12] and ethyl phosphorodichloridate[13] were prepared according to literature procedures. Bis(β-anilinoethyl) phenyl phosphonite, ethyl bis(β-anilinoethyl) phosphite and β-anilinoethyl propylene phosphite were prepared as has been previously described.[1] The purification of ethyl bis(β-anilinoethyl) phosphite was difficult since it decomposes into *N*, *N'*-diphenyl piperazine during distillation. Therefore, the reaction mixture resulting from the reaction of 1 mol. of ethyl bis(diethylamido) phosphite with 2 mol. of *N*-phenyl ethanolamine was used as the starting material, ethyl bis(β-anilinoethyl) phosphite, in the following experiments.

The Reaction of Ethyl Bis(β-anilinoethyl) Phosphite with Phenyl Isocyanate.—A solution of phenyl isocyanate (2.38 g.; 0.02 mol.) in 10 ml. of dry toluene was added, drop by drop, into a solution of ethyl bis(β-anilinoethyl) phosphite, which had resulted from the reaction of 2.20 g. (0.01 mol.) of ethyl bis(diethylamido) phosphite with 2.74 g. (0.02 mol.) of *N*-phenyl ethanolamine, in 20 ml. of dry toluene at room temperature. After an exothermic reaction had ceased, the reaction mixture was refluxed for 3 hr. The solvent was then removed under reduced pressure, and a viscous oily substance was obtained. When the substance had been left standing for several days at room temperature, a small amount of a colorless crystalline compound appeared. After 5 ml. of 99.5% ethanol had been added to the mixture, a colorless crystalline compound, 1.35 g. (57%), m. p. 111-116°C, was obtained by filtration. After recrystallization from ethanol, the melting point rose to 115—116°C.

The infrared spectrum of the product was identical with that of authentic 2-phenylimino-3-phenyl-1, 3-oxazolidine.[5] (Found: C, 75.65; H, 5.96; N, 11.74%).

The filtrate was then concentrated to give an oily substance. A slurry of sodium ethoxide (from 0.23 g. of sodium) in 10 ml. of dry benzene was added to the oily substance, and the mixture was stirred at room temperature until it became homogeneous. After it had stood for a few days, a crystalline compound, *N*, *N'*-diphenyl-2-imidazolidone, was precipitated. This precipitate was filtered and washed well with benzene, 0.86 g. (35.9%); m. p. 208—211°C. After it had been recrystallized from ethyl acetate, the melting point rose to 216—218°C. The infrared absorption bands are at 1690 (s), 1420(s), 1230(s), 1100(m) and 893(m) cm^{-1}.

Found: C, 76.07; H, 5.97; N, 11.86. Calcd. for $C_{15}H_{14}N_2O$: C, 75.63; H, 5.88; N, 11.76%.

By an analogous procedure, the other oxazolidines and the corresponding imidazolidones were obtained. Their yields, melting points, analyses and infrared absorptions are summarized in Tables I and II.

The Reaction of 2-Ethoxy - 3 - Phenyl-1, 3, 2-Oxazaphospholidine with *N*-Phenyl Ethanolamine and Phenyl Isocyanate.—A mixture of 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine (2.11 g., 0.01 mol.) and *N*-phenyl ethanolamine (1.37 g., 0.01 mol.) in 5 ml. of dry toluene was refluxed for 3 hr. Then a solution of phenyl isocyanate (2.38 g., 0.02 mol.) in 15 ml. of dry toluene was added, drop by drop, into

11) R. Burgada, *Ann. Chim.*, 347 (1963).

13) B. C. Saunders, G. J. Stacey, F. Wild and I. G. E. Wilding, *J. Chem. Soc.*, **1948**, 699.

the reaction mixture at room temperature. When the reaction mixture was treated as in the above experiments, 2-phenylimino-3-phenyl-1, 3-oxazolidine 1.24 g. (52.1%); m. p. 111—114°C (after recrystallization from ethanol, the melting point rose to 116—118°C) and *N, N'*-diphenyl-2-imidazolidone 1.16 g. (48.8%); m. p. 208—210°C (after recrystallization from ethyl acetate, the melting point rose to 215—217°C) were obtained.

The Reaction of *N*-Phenyl Ethanolamine with Phenyl Isocyanate.—A solution of phenyl isocyanate (1.19 g.; 0.01 mol.) in 10 ml. of dry toluene was added, drop by drop, into a solution of *N*-phenyl ethanolamine (1.37 g., 0.01 mol.) in 10 ml. of dry toluene at room temperature. A slight heat liberation was observed. The reaction mixture was then refluxed for 3 hr. After the solvent had been completely removed under reduced pressure, the residue was solidified, 2.76 g.; m. p. 80—83°C. The infrared spectrum of this solid was identical with that of an authentic *N*-(β-hydroxyethyl)-*N, N'*-diphenyl urea.[12] Recrystallization from ethyl actate gave 1.50 g. (58.7%); m. p. 88—89°C. (Found: C, 69.92; H, 6.42; N, 11.23%).

The Reaction of Ethyl Bis(diethylamido) Phosphite with *N*-(β-Hydroxyethyl)-*N, N'*-diphenyl Urea.—A of ethyl bis(diethylamido) phosphite mixture (2.20 g.; 0.01 mol.) and *N*-(β-hydroxyethyl)-*N, N'*-diphenyl urea (5.12 g., 0.02 mol.) in 20 ml. of dry toluene was refluxed for 3 hr., by which time the theoretical amount of diethylamine had been distilled off. Then the reaction mixture was refluxed for an additional 7 hr. After the solvent had been completely removed, the residue was almost solidified. When 5 ml. of 99.5% ethanol was added to the mixture, a white crystalline compound was precipitated 2.31 g. (97%); m. p. 111—114°C. Recrystallization from ethanol gave 2-phenylimino-3-phenyl-1, 3-oxazolidine, m. p. 115—116°C. *N, N'*-Diphenyl-2-imidazolidone was obtained from the oily residue by treating it with sodium ethoxide as in the foregoing experiment, 0.56 g. (23.4%); m. p. 202—206°C. After recrystallization from ethyl acetate, the melting point rose to 217—218°C.

The Reaction of β-Anilinoethyl Propylene Phosphite with Phenyl Isocyanate.—A solution of phenyl isocyanate (1.19 g.; 0.01 mol.) in 10 ml of dry toluene was added drop by drop to a solution of β-anilinoethyl propylene phosphite (2.41 g.; 0.01 mol.) in 10 ml. of dry toluene at room temperature. After an initial slight exothermic reaction had ceased, the reaction mixture was refluxed for 3 hr. When the solvent was then removed under reduced pressure, an oily substance was obtained. The infrared absorption bands of the substance are at 3420(w), 1655(s), 1070(m) and 990(m) cm^{-1}. Although this oily substance was kept standing in a refrigerator for a few days, 2-phenylimino-3-phenyl-1, 3-oxazolidine could not be obtained. Then a solution of sodium ethoxide (from 0.23 g. of sodium) in 10 ml. of ethanol was added to the oily subtance and the mixture was refluxed for one hour. After the reaction mixture had cooled, a crystalline compound was precipitated, 0.77 g. (32.2%), m. p. 185—190°C. The crystalline compound was recrystallized from ethyl acetate, m. p. 218—219°C. The infrared spectrum and elemental analysis of this crystalline compound were identical with those of *N, N'*-diphenyl-2-imidazolidone.

Found: C, 75.76; H, 6.10; N, 11.76%.

The Reaction of Ethyl Phosphorodichloridate with *N*-(β-Hydroxyethyl)-*N, N'*-diphenyl Urea.—A solution of ethyl phosphorodichloridate with (1.63 g., 0.01 mol.) in 20 ml. of dry benzene was vigorously added, drop by drop, into a solution of *N*-(β-hydroxyethyl)-*N, N'*-diphenyl urea (5.12 g., 0.02 mol.) in 30 ml. of dry benzene at room temperature. After the addition had been completed, the mixture was refluxed for 7 hr. Hydrogen chloride was evolved copiously. When the solvent was removed under reduced pressure, an oily residue was obtained. When 99.5% of ethanol was added to the mixture, as has been mentioned in the above experiments, oxazolidine could not be obtained. On the other hand, when sodium ethoxide (0.46 g. of sodium in 15 ml. of ethanol) was added to the mixture, it was solidified with an evolution of heat, 4.66 g., m. p. 208—243°C. This solid was then recrystallized from ethyl acetate, 3.99 g. (84.0%), m. p. 209—210°C. The infrared spectrum of this crystalline compound was identical with that of authentic *N, N'*-diphenyl-2-imidazolidone (see Experimental Section, Part 1).

The Reaction of Ethyl Bis(β-anilinoethyl) Phosphite with Phenyl Isothiocyanate.—A solution of phenyl isothiocyanate (2.70 g.; 0.02 mol.) in 10 ml. of dry toluene was added, drop by drop, into a solution of ethyl bis(β-anilinoethyl) phosphite (3.48 g.; 0.01 mol.) in 10 ml. of dry toluene at room temperature. In this case an exothermic reaction was not observed. When the reaction mixture was refluxed for 3 hr., a red liquid was obtained. After the solvent had been removed, a yellow crystalline compound was precipitated, 3.59 g. (70.7%), m. p. 126—128°C. Recrystallization from ethanol gave white needles, m. p. 134—135°C. Its infrared spectrum shows 1620(s), 1375(m), 1307(s), 1140(m) and 1080(m) cm^{-1}. This crystalline compound was found to be identical with 2-phenylimino-3-phenyl-1, 3-thiazolidine by means of elemental analysis.

Found: C, 70.96; H, 5.71; N, 11.28. Calcd. for $C_{15}H_{14}N_2S$: C, 70.78; H, 7.51; N, 11.02%.

By a similar procedure, the other thiazolidines were obtained. Their yields, melting points, analyses and infrared absorptions are listed in Table III.

The Reaction of β-Anilinoethyl Propylene Phosphite with Phenyl Isothiocyanate.—A solution of phenyl isothiocyanate (1.35 g., 0.01 mol.) in 10 ml. of dry toluene was added drop by drop to a solution of β-anilinoethyl propylene phosphite (2.14 g., 0.01 mol.) in 10 ml. of dry toluene at room temperature. After the reaction mixture had been refluxed for 5 hr., a red color, accompanied by a slight isonitrile smell, appeared. The solvent was removed under reduced pressure, and a crystalline compound was precipitated.

The precipitate was filtered off, giving 1.0 g. (39.4%) m. p. 126—128°C of 2-phenylimino-3-phenyl-1, 3-thiazolidine. After recrystallization from ethanol, the melting point rose to 131—132°C.

The authors wish to thank Mr. Kunio Yasutake of the Bridgestone Tire Co., Ltd., for permission to publish this work, and also to acknowledge their gratitude to Mr. Yoshitake Kubota and the late Mr. Koshiro Fujiwara for much helpful advice given during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 714—716 (1966)

Organic Syntheses by Means of Noble Metal Compounds. XVIII. Friedel-Crafts Reaction Catalyzed by Rhenium Pentachloride[1]

By Jiro Tsuji, Tatsuo Nogi and Masanobu Morikawa

Basic Research Laboratories, Toyo Rayon Company, Kamakura

(Received July 30, 1965)

Rhenium pentachloride has been found to be a Lewis acid with an efficient Friedel-Crafts catalytic property. Aromatic rings have been alkylated smoothly with olefins or alkyl halides. By the reaction of ethylene with benzene in the presence of rhenium pentachloride, *s*-butylbenzene has been obtained as the main product. In the Friedel-Crafts acylation, a quantitative amount of the catalyst has been consumed in the reaction at a low temperature. On the other hand, the acylation reaction at a high temperature can proceed catalytically. Rhenium pentachloride is also active in the oligomerization of olefins, and in the cyclization and oligomerization of acetylenes.

Numerous metal halide-type Lewis acids, of which aluminum chloride is the most frequently used, are known as Friedel-Crafts catalysts. Until the present time, however, no definite report has appeared on the catalytic activity of group VII metal halides in the Friedel-Crafts reaction.[2] We have found, in the course of our studies of the catalytic activity of noble metal compounds, that rhenium pentachloride is a Lewis acid and that it is an efficient, though mild Friedel-Crafts catalyst, as has already been reported briefly.[3]

Experimental

Gas chromatographic analyses were carried out on a Silicone DC 550 on a Celite column, 2 m. in length, at 180°C or at 100°C. Molecular weights were determined in benzene by using a Mechrolab vapor pressure osmometer. Commercially-available rhenium pentachloride (purchased from Kanto Kagaku) was used without further purification.

Most of the products were purified by preparative gas chromatography and identified by infrared spectra (Hitachi infrared spectrometer, model EPI-S2, in a solution of carbon tetrachloride) and NMR spectra (Varian high resolution spectrometer, models DP 60 and HR 100). The boiling points and melting points were uncorrected.

Alkylation and Acylation.—The reaction conditions and results obtained are summarized in Tables I, III and IV.

The Isomerization of Alkylbenzenes.—The results obtained are summarized in Table II.

Oiligomerization and Cyclization.—The reaction conditions and results are given in Table V.

Results and Discussion

The Alkylation Reaction with Alkenes and Alkyl Halides.

—The alkylation reaction with olefins proceeded smoothly in the presence of a small amount of the catalyst, and in general a mixture of products was obtained, as is shown in Table I. The most characteristic feature of the catalytic action of rhenium pentachloride can be seen in the alkylation with ethylene. At 75°C and at an ethylene pressure of 47 kg./cm^2, a rapid pressure drop was observed, and ethylbenzene, *s*-butylbenzene and hexaethylbenzene were obtained in the ratio of 1 : 2 : 1. It is interesting to notice that *s*-butylbenzene was obtained as the main product, showing that the dimerization of ethylene to form *s*-butyl carbonium ions competes favorably with the direct attack of ethyl carbonium ions on the benzene ring. From anisole, only *p*- and *m*-*s*-butylanisoles were obtained. When a large excess of olefin was used, a considerable amount of the polymer was obtained. This means that the oligomerization of the olefin catalyzed by rhenium pentachloride is quite rapid.

When the reaction of propylene with benzene was carried out at 75°C for 24 hr., a mixed product composed of mono-, di-, tri- and tetraisopropylbenzenes was isolated. On the other hand, when the reaction was carried out with a large excess of benzene, cumene was the main product. It seems likely that some of these products were formed by the isomerization of the initial alkylation products. In order to test the isomerization of alkylbenzene catalyzed by rhenium pentachloride, several alkylbenzenes were heated with a catalytic amount of rhenium pentachloride. Table II indicates that rhenium pentachloride is active in the isomerization, as may be expected for a Friedel-Crafts catalyst.

Alkylation with alkyl halides also proceeded smoothly, as is shown in Table III. Isopropyl bromide gave the same distribution of products as that obtained from propylene.

Table I. Alkylation with olefin

Aromatic compound g.	Olefin	Product (g.)
Benzene 45	Ethylene (47 kg./cm²)	Ethylbenzene (0.8), *s*-Butylbenzene (1.5), Hexaethylbenzene (0.8)
Benzene 25	Propylene 30 ml.	Cumene (5.0), *m*- and *p*-Diisopropylbenzenes (4.0), 1,2,4-, and 1,3,5-Triisopropylbenzenes (3.5), 1,2,4,5-Tetraisopropylbenzene (1.5)
Benzene 25	1-Butene 30 ml.	*s*-Butylbenzene (11.5), *m*- and *p*-Di-*s*-butylbenzenes (5.0), 1,3,5-Tri-*s*-butylbenzene (1.0)
Ethylbenezene 45	Ethylene (50 kg./cm²)	*m*- and *p*-*s*-Butylethylbenezenes (2.5)
Anisole 25	Ethylene (50 kg./cm²)	*m*- and *p*-*s*-Butylanisoles (3.0)

The reactions were carried out in the 200 ml. autoclave for 24 hr. at 75°C. 1 g. of $ReCl_5$ was used.

Table II. Isomerization reaction

Aromatic compound g.	$ReCl_5$ g.	Product (%)
Cumene (5)	1	Benzene (44), Cumene (44), Diisopropylbenzene (10), Triisopropylbenzene (2)
1,2,4-Triisopropylbenzene (2)	0.5	Benzene (25), Cumene (30), Diisopropylbenzene (20), Triisopropylbenzene (25)
1,2,4-Triisopropylbenzene (2) and Benzene (10)	1	Cumene (85), Di- and Tri-isopropylbenzene (15)
o-Diethylbenzene (2)	0.5	Benzene (10), Ethylbenzene (20), Diethylbenzene (60), Triethylbenzene (10)

The reactions were carried out at 50°C for 8 hr.

Table III. Alkylation with alkyl halide

Aromatic compound g.	Alkyl halide ml.	Product (g.)
Benzene 12	Ethyl bromide 30	Ethylbenzene (2.5), *m*- and *p*-Diethylbenzenes (1.5)
Benzene 12	Isopropyl bromide 30	Cumene (3.0), *m*- and *p*-Diisopropylbenzene (2.0), 1,2,4- and 1,3,5-Triisopropylbenzenes (2.0), 1,2,4,5-Tetraisopropylbenzene (0.5)
Benzene 12	Cyclohexyl bromide 30	Cyclohexylbenzene (8.0), *p*-Dicyclohexylbenzene (2.5)
Benzene 25	Benzyl bromide 40	Diphenylmethane (21.0)

The reactions carried out at 50°C for 8 hr. 1 g. of $ReCl_5$ was used.

Acylation Reaction.—In the Friedel-Crafts acylation, it is generally known that an amount of catalyst equivalent to acyl halide is consumed as a result of the formation of a complex of metal halide with a ketonic compound formed by the acylation. The stability of the complex seems to vary with the kind of metal halide used. If the complex can be dissociated under certain conditions, especially by heating, then it might be possible to carry out the acylation reaction as a catalytic reaction. Actually this has been proved to be possible. For example, the benzoylation of toluene was found to be carried out in the presence of a catalytic amount of ferric chloride when the reaction temperature was kept between 135 and 150°C.[4] From this standpoint, the catalytic activity at a rather high temperature was compared by using chlorides of aluminum, iron(III), molybdenum and rhenium; the results are shown in Table IV.

Table IV. Benzoylation of toluene

Cayalyst	Temp.[a]	Yield 1[b]%	Yield 2[c]%
$ReCl_5$	125	850	10.5
$MoCl_5$	135	2300	29.0
$FeCl_3$	150	5000	60.0
$AlCl_3$	127	600	7.7

a) Maximum temperature, reached at the end of the reaction.
b) mol. %, based on the amount of the catalyst.
c) Based on benzoyl chloride.

As is apparent from the table, ferric chloride was the most efficient catalyst from this standpoint. As for rhenium pentachloride, the catalyst can not be recycled at 80°C; it then gives only 85%

4) A. Noguchi, T. Ikawa and Y. Shimada, *J. Soc. Org. Syn. Chem. Japan*, **21**, 377 (1963).

Table V. Oligomerization and cyclization

Olefin	Solvent ml.	Reaction		Product (g.)
		Temp., °C	Time, hr.	
Ethylene 50 kg./cm^2	Cyclohexane 30	70	20	C_4 olefins (1.5), C_6 (0.5), Higher than C_8 (0.5)
Propylene 20 ml.	Cyclohexane 20	70	20	C_6 olefin (2.0), C_9 olefin (4.5), C_{12} olefin (3.0), Higher olefins (2.0)
1-Butene 20 ml.	Cyclohexane 20	70	20	C_8-olefin (3.0), Higher olefins (2.0)
Propyne 20 ml.	*n*-Pentane 30	80	24	1,2,4- and 1,3,5-Trimethylbenezenes (1.0)

The reactions were carried out in the 200 ml. autoclave. 1 g. of $ReCl_5$ was used.

of the acylation product (based on rhenium chloride). On the other hand, a yield of 850% was obtained in the reaction carried out at 120—125°C. These results clearly show that the dissociation of the complex formed from certain metal halides and ketonic products is temperature-dependent, that at higher temperatures it is possible to carry out the acylation reaction in the presence of a catalytic amount of the metal halides.

The Oligomerization of Olefins and Acetylene.—It is known that Lewis acids can catalyze the oligomerization of olefins; rhenium chloride was tested for this activity. As is shown in Table V, a mixture of oligomers was obtained, but no selectivity was observed under the reaction conditions adopted. Therefore, no further studies were carried out. Acetylenes were found to be cyclized to form benzene derivatives in addition to a certain quantity of linear oligomers. For example, 1, 2, 4- and 1, 3, 5-trimethylbenzenes were obtained from propyne heated with rhenium pentachloride.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 716—720 (1966)

Studies of the Synthetic Inorganic Ion Exchanger. V.[1] The Separation of Zirconium-95 and Niobium-95 by Means of a Stannic Phosphate Cation Exchanger

By Akiko SATŌ, Yasushi INOUE and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received July 31, 1965)

With the aim of developing a method for the separation of ^{95}Zr and ^{95}Nb, various eluants were investigated, a sulfuric acid solution was found to be most suitable for this purpose. After the stannic phosphate exchanger column had been conditioned with 1 N nitric acid, the sample solution was passed through it to adsorb ^{95}Zr and ^{95}Nb. By using a 2 N sulfuric acid solution and a 3 N sulfuric acid - 0.01 N hydrofluoric acid solution as eluants, ^{95}Zr and ^{95}Nb could be eluted respectively. The separation was not quantitative, however, because of the unfavorable tailing of the elution curves. On the basis of the above results, the posibility of the total radiochemical separation of a long-lived fission product and the mechanism of the adsorption of these ions were discussed.

As one of the inorganic ion exchangers which may be expected to have radiation and thermal stability, stannic phosphate has previously been prepared[2,3] and its fundamental properties, such as its composition, its ion exchange capacity, its chemical stability,[2] its radiation and thermal stability, the nature of its ion exchange equilibrium, its exchange rate and its structure, were investigated.[3] Furthermore, this exchanger has been used for the separation of alkali metals,[2] the separation of individual nuclide contained in the fission products,[4] and the separation of uranium

3) Y. Inoue, This Bulletin, **36**, 1316 (1963).
4) Y. Inoue, ibid., **36**, 1324 (1963).

and fission products,[1] the results have been so successful that it was found to be an excellent material for the cation exchange separation.

In a nitric acid solution, this exchanger shows high distribution coefficients of zirconium and niobium, $2—4\times10^3$ ml./g., over a wide range of acidity. Therefore, in the process of the separation of fission products, these ions once adsorbed on the exchanger bed are not eluted at all with such eluants as ammonium chloride and nitric acid.[4]

With the aim of developing a method for the separation of ^{95}Zr and ^{95}Nb, various eluants, such as hydrochloric acid, hydrofluoric acid, sulfuric acid, oxalic acid, a mixture of hydrochloric acid and hydrofluoric acid and one of sulfuric acid and hydrofluoric acid, were investigated. Of those, oxalic acid, concentrated hydrochloric acid and hydrofluoric acid in a high acidity were not applicable because stannic phosphate could not resist these media. Sulfuric acid solution was found to be the most suitable for this purpose. Then the separation of zirconium and niobium with sulfuric acid eluants was investigated in detail. The results are described below.

Experiments

Reagents.—*Ion Exchanger.*—Stannic phosphate prepared by a method described previously was used.[2]

^{95}Zr-^{95}Nb Equilibrium Mixture.—This was obtained from the Oak Ridge National Laboratories (U. S. A.) and from the N. H. Philips-Roxane-Pharmaceutisch-Chemische Industries "Duphar" (Holland) as an about 1% oxalate solution. Prior to use, concentrated nitric acid was added to this solution and it was evaporated almost to dryness. This process was repeated several times in order to convert the nuclides into their nitrate forms completely. When either ^{95}Zr or ^{95}Nb was in need individually, they were separated from one another by the acetylacetone - benzene extraction method[5] immediately before use.

The other chemicals, such as sulfuric acid, hydrofluoric acid and acetyl acetone, were of the highest purity grade.

Apparatus.—The measurements of the β and γ activities were made by a Hitachi G. M. counter and Kobe Kogyo well-type scintillation counter respectively. For making elution curves in the column operation, a fraction collector, Toyo Kagaku Sangyo Model SF-200A, was used.

Procedures.—The experimental procedures were as follows, except otherwise noted.

The Determination of the Distribution Coefficients.—The batch distribution coefficients were determined after equilibrating 500 mg. of the ion exchanger (100—200 mesh or 200—350 mesh) in hydrogen form with 50 ml. of a suitable solution for about 100 hr. in a thermostat kept at 25°C. An aliquot of the supernatant liquid was then taken out in order to measure the radioactivity. The radioactivity on the exchanger was estimated from the difference between the total activity initially taken and that found finally in the solution.

In each case, the distribution coefficient was calculated by the following equation:

$$K_d=\frac{\text{Radioactivity on exchanger/g. of exchanger}}{\text{Radioactivity in solution/ml. of solution}}$$

Column Operation.—Into 2 g. of an air-dried exchanger in hydrogen form (100—200 mesh) a sufficient amount of distilled water was well stirred in order to expel any adhering air bubbles. After mixing, the slurry was poured into a glass column tube 7 mm. in internal diameter, in which glass wool had been put as a column support. The column thus prepared was 40 mm. high. Then the exchanger bed was conditioned by 1 N nitric acid, the sample solution was loaded on the bed to adsorb zirconium and niobium, and an elution was started. The flow rate of the influent was kept nearly constant, at 0.2—0.3 ml./min., throughout this experiment.

Results and Discussion

Distribution Coefficients. — In order to contribute to the establishment of the method of separation, the distribution coefficients of ^{95}Zr and ^{95}Nb were determined in sulfuric acid media; the results are shown in Table I. In contrast with the case of a nitric acid solution,[4] the distribution coefficients of these ions decrease with the increase in the acidity and a remarkable difference between zirconium and niobium is observed; that is to say, zirconium shows a distribution coefficient lower than niobium by one order. This indicates the possibility of separating zirconium

Table I. Distribution coefficient of zirconium and niobium in sulfuric acid solution

Concn. of H_2SO_4 N	Particle size Mesh	Distribution coefficient Zr	Nb
0.5	100—200	1.18×10^2	10.9×10^2
1.0	100—200	0.37×10^2	4.65×10^2
1.5	200—350	7.48×10^2	16.6×10^2
2.0	200—350	4.61×10^2	14.4×10^2
2.5	200—350	3.59×10^2	12.6×10^2
3.0	100—200	0.10×10^2	1.10×10^2
6.0	100—200	0.02×10^2	0.17×10^2

from niobium. However, the distribution coefficients of these ions vary with the particle size of the exchanger used. This phenomenon offers one reason for the ill-defined elution peak; it may also be considered to depend on the nature of the ion exchange reaction. This will be discussed in detail later.

The Separation of ^{95}Zr and ^{95}Nb.—In order to seek some good conditions for the selective elution of ^{95}Zr, the elution of zirconium and niobium by sulfuric acid solutions of various concentrations was carried out. The results are shown in Fig. 1. Although the elution curves of zirconium show remarkable tailing under any of the conditions

5) T. Shigematsu, M. Tabushi and M. Matsui, *Bull. Inst. Chem. Res., Kyoto Univ.*, **41**, 212 (1963).

examined, the higher the acidity, the sharper the elution curve. Corresponding to the shape of the elution curve, the yield of zirconium increases with the increase in the acidity of eluant. When the acidity is 1 N, the yield is only 20% with 100 ml.

of the eluant; when the acidity is 2 N, the yield is about 80% with 110 ml.; when the acidity is 2.5 N, the yield is about 90% with 100 ml. Niobium, however, is eluted a little with 2.5 N sulfuric acid solution, so this acid concentration is not desirable for the separation of zirconium from niobium, although the yield of zirconium is indeed high. From the above fact, a 2 N sulfuric acid solution seems to be most adequate for the selective elution of zirconium. In order to confirm this, the zirconium solution obtained after the elution was submitted to the drawing of a β-ray absorption curve by aluminum absorbers; it was confirmed that this solution contained a monoenergetic nuclide with a maximum energy of 0.40 MeV. This fact establishes the complete separation of zirconium from niobium.

From the values of the distribution coefficients, the sulfuric acid solution seems to be ineffective in the elution of niobium. Therefore, its elution was performed with a sulfuric acid solution containing a small amount of hydrofluoric acid. In this case the hydrofluoric acid concentration should be kept as low as possible because too many fluoride ions may dissolve the exchanger. As is shown in Fig. 2, the 3 N sulfuric acid - 0.01 N hydrofluoric acid mixture was effective in the elution of niobium. Tailing was observed in this curve as in the case of zirconium, but the shape of elution curve is comparatively sharp and the yield is about 80% with 75 ml. of the eluant.

As has been mentioned above, the separation of zirconium and niobium can be achieved by using a 2 N sulfuric acid solution at first for zirconium, and then a 3 N sulfuric acid - 0.01 N hydrofluoric acid solution for niobium. The niobium fraction, however, is partially contaminated with

zirconium because of the incomplete elution of the latter.

Discussion.—As has been stated in a preceding report,[4] in the separation of long-lived fission products, ^{95}Zr and ^{95}Nb in the nitric acid solution were not quantitatively adsorbed on the exchanger, but they could not be eluted at all by any eluants when they were once adsorbed. From the results of the present investigation, it may be considered that they can be separated from other fission products by eluting them with the eluants mentioned above after rare earths have been eluted according to the procedure described in the third part of this series.[4] This process is shown schematically in Fig. 3. It should be borne in mind that zirconium contaminates niobium to some extent because of the unfavorable tailing of its elution curve.

Many peculiar aspects of the behavior of zirconium and niobium in response to this ion exchanger have been observed. One of these aspects is the independency of the distribution coefficients on the concentration of nitric acid solution, as has been stated earlier.[4] It is clear from this observation that the adsorption of zirconium cannot be explained by the simple cation exchange reaction for which the mass action law holds. The other aspects are the intense tailing of the elution curve and the difference in the distribution coefficients obtained with the ion exchanger as its particle size varies. This behavior has not been observed in the case of the other ions, so it seems to characterize zirconium and niobium. In order to clarify this point, the adsorption of zirconium from 1 N nitric acid was examined by the column operation of the above-mentioned experimental procedure with the exchanger having various particle sizes, as is shown in Fig. 4. These curves do not show a S-shape, as is usually observed in an ion-exchange resin; rather, they composed of two parts, one of which represents rapid adsorption, while the other is a part of the long tailing. The effect of the particle size is remarkable; namely, when it is greater than 100 mesh, the exchanger is saturated with the passage of only 60 ml. of a 0.01 M zirconium solution. On the other hand, when the particle size is smaller than this, the exchange is not saturated with even more than 250 ml. of a 0.01 M solution. If we assume that one molecule of zirconium corresponds to four equivalents, the break-through capacity of the exchanger coarser than 100 mesh is calculated to be 0.096 meq./g. When the exchanger is 100—200 mesh, the amounts of zirconium adsorbed after the passage of 250 ml. of a 0.01 M solution is 0.44 meq./g. These values are extremely low compared with the hydrogen absorption capacity and the hydrogen liberation capacity of 1.3—1.4 meq./g. as defined in the first part of this series.[2] The tailing encountered in the elution step and the incomplete uptake of zirconium seem to be attributable to the slow rate of the adsorption-desorption reaction. This can also be reasonably explained by the fact that when adsorption is continued after an interruption of 10 hr. or more, the adsorption curve comes to be as if it were obtained with a new exchanger. From the above results it may reasonably be postulated that there are two kinds of adsorption sites. One is on the surface of the exchanger particle, while the other is in the inner part. On the surface, zirconium is adsorbed rapidly and reversibly, whereas in the inner part of the particle the adsorption is slow and irreversible. The adsorption in the inner part of the particle may proceed by one of the following two mechanisms. One is the formation of stable zirconium compounds with the phosphate because the presence of a lot of free phosphate groups close to each other in the inner part of the particle, unlike such a grouping on the surface of the materials, may facilitate the reaction. This argument is consistent with the property of zirconium, which easily forms sparingly-soluble compounds with phosphate, even in a strong acid solution. Another possibility is the exchange of tin, one of the elements constructing the exchanger net work, for the zirconium ion. At present it

cannot be decided conclusively which is the correct mechanism. Therefore, further investigations must be carried out.

Summary

The separation of zirconium and niobium has been carried out by means of a stannic phosphate cation exchanger. By using a 2 N sulfuric acid solution and a 3 N sulfuric acid-0.01 N hydrofluoric acid solution as eluants, zirconium and niobium could be eluted respectively. However, the separation was not quantitative because of the unfavorable tailing of the elution curves. From the above results, the possibility of the total radiochemical separation of long-lived fission products and the mechanism of the adsorption of these ions have been discussed.

Part of the expenses for this investigation have been defrayed by a grant-in-aid by the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 720—725 (1966)

The Heats of Mixing for Binary Mixtures. III. The Intermolecular Energy of Hydrogen Bonding between Alcohol and Several Other Polar Molecules

By Sachio MURAKAMI and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 31, 1965)

Calorimetric measurements of the heat of mixing have been made at 25.0±0.01°C for binary mixtures of *n*-butanol with polar liquids (acetonitrile, acetone, *n*-butyl ether, and *n*-butyl amine), and for binary mixtures of polar liquids with *n*-hexane. The calorimeter for measuring the heats of mixing was of twin type, and a thermomodule, HTM 0516 type (Sharp Electric Co., Ltd., Osaka) was used as the temperature-sensing device. By plotting the values of the heat of mixing, $\Delta H^{M}_{x_1}$, against the mole fraction of component 1, x_1, and by extrapolating the curve to an infinite dilution ($x_1 \rightarrow 0$) for each system, the heats of mixing per mole of component 1 at an infinite dilution ($\lim_{x_1 \rightarrow 0} \Delta H^{M}_{x_1}$) were obtained graphically. By using the values of $\lim_{x_1 \rightarrow 0} \Delta H^{M}_{x_1}$ obtained for these systems and by using the same treatment as that described in a previous paper [S. Murakami, K. Amaya and R. Fujishiro, This Bulltein, **37**, 1776(1964)], the intermolecular hydrogen bond energies between alcohol and polar molecules were estimated; it was found that the strength of the hydrogen bond was in the following order: *n*-butyl amine > *n*-butyl ether > acetone > acetonitrile. This agrees with the results obtained from the spectroscopic study.

In previous papers,[1,2] the heats of mixing for alcohol+ketone and alcohol+hexane solutions have been measured, and from these data the hydrogen bond energy between alcohol and ketone molecules has been estimated.

In the present paper, the same treatment will be applied to the *n*-butanol+polar liquid+hexane systems, and the hydrogen bond energies between butanol and polar molecules will be estimated. Acetonitrile, acetone, *n*-butyl ether and *n*-butyl amine will be used as the polar liquids.

Experimental

The apparatus for measuring the heats of mixing is the same as that used in the previous papers,[1,2] except for replacing a 7-junction copper-constantan

thermocouple with a thermomodule, type HTM 0516 (Sharp Electric Co., Ltd., Osaka), in order to detect a smaller temperature change. The mixing cell and other modifications are shown schematically in Fig. 1.

The experimental procedure was similar to that described in the previous papers.[1,2]

In order to check the accuracy of our calorimeter, the heat of mixing was measured for the benzene+carbon tetrachloride system, on which the fairly accurate data of the heat of mixing had previously been obtained by Larkin and McGlashan.[3] The results obtained are shown in Fig. 2, together with those obtained by Larkin and McGlashan; here x_1 is the mole fraction of carbon tetrachloride, and ΔH^M is the heat of mixing expressed in joule per mole of the mixture. Our results are found to agree with those of Larkin and McGlashan within an error of only a few percent.

Alcohol, acetone, and *n*-hexane were purified in the way described previously. *n*-Butyl ether was shaken with concentrated sulfuric acid, with a dilute aqueous solution of sodium carbonate, further with water and with mercury for a long time, and finally distilled

twice in a long column. A commercial *n*-butyl amine was fractionally distilled twice with sodium in a long column covered with aluminum foil in order to protect the amine from decomposition by light. The gas chromatographs of all the samples on polyethylene glycol and d-nonyl phthalate substrates showed a single peak.

Results and Discussion

The measurements of heats of mixing were carried out on the polar liquid+*n*-hexane systems and *n*-butanol+polar liquid systems at 25.0±0.01°C. The results obtained are given in Tables I to VIII and in Figs. 3 to 5, where x_1 is the mole fraction of component 1, and ΔH^M and $\Delta H^M_{x_1}$ are the heats of mixing expressed in cal. per mole of mixture and

those expressed in kcal. per mole of component 1 respectively.

In Fig. 3, the results we obtained for the *n*-butanol+*n*-hexane system are compared with those reported by Brown, Fock and Smith,[4] and also those reported by Wolf, Pahlke and Wehage.[5] A fairly good agreement is found between the present results and the previously published ones.

Plotting ΔH^M_x against x_1 and extrapolating the curve to an infinite dilution ($x_1 \to 0$) for each system, as is shown in Figs. 3 to 5, we can obtain the heats of mixing per mole of component 1 at the infinite dilution ($\lim_{x_1 \to 0} \Delta H^M_x$). They are as follows:

4) I. Brown, W. Fock and F. Smith, *Aust. J. Chem.*, **17**, 1106 (1964).

■: *n*-Butanol+acetonitrile
●: *n*-Butanol+acetone
▲: *n*-Butanol+*n*-butyl ether
▼: *n*-Butanol+*n*-butyl amine

2.25 kcal. for the *n*-butanol(1)+acetonitrile(2)

1.70 kcal. for the *n*-butanol(1)+acetone(2)

1.26 kcal. for the *n*-butanol(1)+*n*-butyl ether(2)

−1.98 kcal. for the *n*-butanol(1)+*n*-butyl amine (2)

1.27 kcal. for the *n*-butyl amine(1)+*n*-hexane(2)

0.10 kcal. for the *n*-butyl ether(1)+*n*-hexane(2)

For the *n*-butanol+*n*-hexane system, as is shown in Fig. 3, however, the extrapolation to $x_1=0$ is very difficult because the curve is very steep at small x_1 values and the measurements are accompanied with considerable errors at these concentration ranges. Fortunately, the value of $\lim_{x_1\to 0} \Delta H^{M}_{x_1}$ had been found by Pahlke[5] for this system to be 5.50 kcal. Therefore, we have adopted 5.50 kcal. for the $\lim_{x_1\to 0} \Delta H^{M}_{x_1}$ of this system.

Measurements of the acetonitrile+*n*-hexane system were also very difficult, because only a slight amount of acetonitrile dissolves into *n*-hexane at room temperature. The $\Delta H^{M}_{x_1}$ values obtained for this system have scattered from 2.2 to 2.9 kcal./mol. at $x_1\simeq 0.02$. The extrapolation to $x_1=0$, using only experimental data in the limited concentration range, gives 3 kcal., but its error may amount to ± 0.5 kcal.

In pure alcohol, all the molecules form hydrogen bonding with each other, while each alcohol molecule in the infinite dilution of alcohol in hexane is surrounded by hexane molecules and the hydrogen bonds are broken. Therefore, the value of 5.50 kcal. represents the energy sufficient to break the hydrogen bonds of pure alcohol. Similarly, the $\lim_{x_1\to 0} \Delta H^{M}_{x_1}$ values for the alcohol+polar liquid systems correspond to the energy change from the pure alcohol state to that in which each alcohol molecule makes a hydrogen bond with a polar molecule and in which such complexes are surrounded with a large amount of the polar-liquid medium. Roughly speaking, the difference between the $\lim_{x_1\to 0} \Delta H^{M}_{x_1}$ values for the alcohol + polar liquid systems and that for the alcohol + hexane system may correspond to the measure of the alcohol + polar liquid intermolecular hydrogen bonding. The results are as follows:

−2.25 kcal. for *n*-butanol+acetonitrile

−3.80 kcal. for *n*-butanol+acetone

−4.24 kcal. for *n*-butanol+*n*-butyl ether

−7.48 kcal. for *n*-butanol+*n*-butyl amine

It may be seen from these values that butanol forms the strongest hydrogen bond with *n*-butyl amine, while it forms the weakest hydrogen bond with acetonitrile. Strictly speaking, in the values mentioned above, the dipolar stabiiization energy must be included, because alcohol + polar liquid complex molecules are embedded in the polar medium.

In order to estimate the hydrogen bond energy more properly, we carried out the treatment described in previous papers,[1,2] applying the thermochemical cycle depicted in Fig. 6. The intermolecular hydrogen bond energy, ΔH_5, between alcohol and polar-liquid molecules is given by:

$$\Delta H_5 = -\Delta H_1 - x\Delta H_2 + \Delta H_3 + \Delta H_4 \qquad (1)$$

n-Butyl amine	(5.52)	5.34	5.16
n-Hexane	1.897	1.890	1.883

* μ, α and a are dipole moment, the polarizability and the molecular radius of the A-polar liquid complex, respectively. They are estimated in the same way as that described in the previous paper.[1]

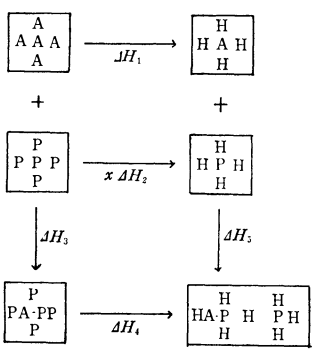

Fig. 6. The thermochemical cycle.

Here ΔH_1 is the energy of breaking the hydrogen bonds of pure alcohol by adding a large quantity of hexane; $x\Delta H_2$, the heat of the dilution of x mol. of polar liquid by a large amount of hexane and ΔH_3, the energy change accompanied by the dilution of the pure alcohol by a large amount of polar liquid; ΔH_4 consists of two parts; the first one is equal to $(x-1)\Delta H_2$, while the second one is due to the difference in the dipolar stabilization energy of a complex dipole arising from the reaction field by different media. This part of the energy change in ΔH_4 may be calculated by the previously-described method.[1,2] The results obtained are summarized in Table IX, together with the data necessary for this calculation.

By using the ΔH_4 value calculated above and the other measured values, the intermolecular hydrogen bond energies between the alcohol and polar molecules, ΔH_5, are found from Eq. 1 to be:

for *n*-butanol+acetonitrile (A-CN):

$$\Delta H_5 = -5.50 - 3x + 2.25 + 3.75 + 3(x-1)$$
$$= -2.50 \text{ kcal.}$$

for *n*-butanol+acetone (A-K):

$$\Delta H_5 = -5.50 - 2.15x + 1.70 + 2.23 + 2.15(x-1)$$
$$= -3.72 \text{ kcal.}$$

for *n*-butanol+*n*-butyl ether (A-E):

$$\Delta H_5 = -5.50 - 0.10x + 1.26 + 0.37 + 0.10(x-1)$$
$$= -3.97 \text{ kcal.}$$

for *n*-butanol+*n*-butyl amine (A-NH_2):

$$\Delta H_5 = -5.50 - 1.27x - 1.98 + 0.72 + 1.27(x-1)$$
$$= -8.03 \text{ kcal.}$$

The strength of the hydrogen bond between alcohol and polar molecules is in the following order:

A-NH_2>A-E>A-K>A-CN.

It is known from the spectroscopic study[6] that the shift in the frequency of the O–H bands, $\Delta\nu_s$, of alcohol in a variety of polar liquids is arranged in the order of:

$$A\text{-}NH_2 > A\text{-}E > A\text{-}K > A\text{-}CN.$$

Therfore, if $\Delta\nu_s$ is correlated with the energy of a hydrogen bond, the above-estimated intermolecular hydrogen bond energies agree with the results obtained from the spectroscopic study.

Summary

The heats of the mixing of *n*-butanol with polar liquids (acetonitrile, acetone, *n*-butyl ether, and *n*-butyl amine) and those of polar liquids with *n*-hexane have been measured calorimetrically. The results obtained for these systems have been compared with one another, and it has been found that the intermolecular hydrogen bond energies between alcohol and polar molecules are as follows:

−2.5 kcal. for *n*-butanol+acetonitrile

−3.7 kcal. for *n*-butanol+acetone

−4.0 kcal. for *n*-butanol+*n*-butyl ether

−8.0 kcal. for *n*-butanol+*n*-butyl amine

The authors wish to thank Dr. Ko Kimura for his kind advice. The expenses of this work have been partly defrayed by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 725—728 (1966)

Spectroscopic Studies of Dialkylaluminum Alkoxides and the Trialkylaluminum-Ether Complex. I. Structures and Symmetries*1

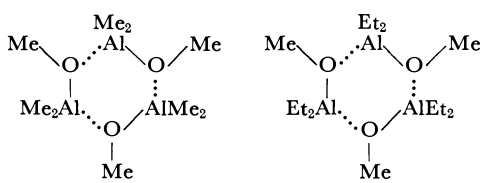
By Ryokichi TARAO

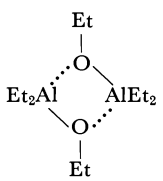
Research Center, Chisso Co., Ltd., Kanazawa-ku, Yokohama

(Received August 2, 1965)

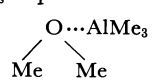
The infrared and Raman spectra of $[Al(CH_3)_2OCH_3)]_3$, $[Al(C_2H_5)_2OCH_3]_3$, $[Al(C_2H_5)_2 \cdot OC_2H_5]_2$, and $Al(CH_3)_3 \cdot (CH_3)_2O$ have been measured in the 3000—300 cm^{-1} region, and the infrared absorption bands and the Raman lines in the skeletal vibration region (720—300 cm^{-1}) have been compared. For $[Al(CH_3)_2OCH_3]_3$ and $[Al(C_2H_5)_2OCH_3]_3$, the results are consistent with trimeric structures with symmetry D_{3h}. For $[Al(C_2H_5)_2OC_2H_5]_2$, the results are consistent with a dimeric structure with symmetry V_h. Thus, the structures with the oxygen bridge proposed by Hoffmann for these polymeric compounds have been confirmed by spectroscopic measurements. The structures with alkyl bridges are very unlikely. For $Al(CH_3)_3 \cdot (CH_3)_2O$, the results do not contradict the postulated structure, with symmetry C_s.

It has been suggested, although there has been no direct experimental evidence, that dimethylaluminum methoxide $[Al(CH_3)_2OCH_3]_3$, diethylaluminum methoxide $[Al(C_2H_5)_2OCH_3]_3$, and diethylaluminum ethoxide $[Al(C_2H_5)_2OC_2H_5]_2$ have the molecular structures of the dimeric or trimeric bridge forms represented by[1,2]:





and that the trimethylaluminum - dimethyl ether complex, $Al(CH_3)_3 \cdot (CH_3)_2O$, has the structure with symmetry C_s represented by[3]:



Structures with the alkyl bridges, as in the case of trimethylaluminum, however, also appear to be possible for these three dialkylaluminum alkoxides. In the present study, in order to

obtain some positive evidences of these proposed structures, the infrared and Raman spectra of these three dialkylaluminum alkoxides and the trimethylaluminum - dimethyl ether complex have been measured, and the infrared absorption bands and the Raman lines in the skeletal vibration region (720—300 cm^{-1}) have been compared. Some conclusions have been reached from these spectra as to the structures of these compounds.

The infrared spectra of diethylaluminum ethoxide and the trimethylaluminum-dimethyl ether complex were reported in the previous paper,[3] but those of dimethylaluminum methoxide and diethylaluminum methoxide and the Raman spectra of these four compounds have not yet been reported as far as the author is aware.

Experimental

Dimethylaluminum methoxide was prepared by the reaction of trimethylaluminum with methanol. Diethylaluminum methoxide was prepared by the reaction of triethylaluminum with methanol. Diethylaluminum ethoxide was prepared by the reaction of triethylaluminum with ethanol. The trimethylaluminum - dimethyl ether complex was prepared by the reaction of trimethylaluminum with dimethyl ether. Table I shows the boiling points, aluminum contents, and molecular weights of these four compounds.*2

The infrared spectra were measured in the 3000—300 cm^{-1} region in the liquid state with a Japan Spectroscopic Co., Model DS-402G infrared spectrophotometer. The procedure described in the previous paper was used.[3] The Raman spectra were measured in the same region and in the liquid state with a Shimadzu GRS Raman spectrophotometer. All the samples were distilled into Raman tubes, which were then sealed off under reduced pressure to prevent contamination with air or moisture. Figure 1 shows the Raman spectra observed. The Raman spectrum of dimethylaluminum methoxide was also measured in a 10 volume per cent benzene solution. The spectrum obtained was merely a superposition of the spectrum of pure dimethylaluminum methoxide on that of benzene. No Raman line of dimethylaluminum methoxide shifted to either a higher or a lower frequency.

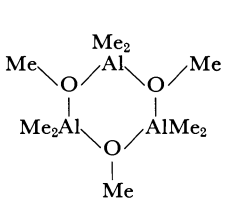
Dimethylaluminum Methoxide

Hoffmann found that this compound takes a trimeric structure in the benzene solution.[1] The similarity between the Raman spectrum in the liquid state and that in the benzene solution described above shows that the same trimeric structure remains also in the liquid state.

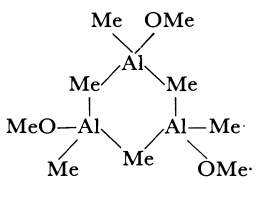
In the liquid state this compound has five infrared absorption bands and six Raman lines in the 720—300 cm^{-1} region; of those, four are both infrared and Raman active, as is shown in Table II.

There are two possible structural formulas, I and II, for this trimeric compound;

Formula I, with symmetry D_{3h}, has an oxygen bridge which would be formed by the coordination of lone-pair electrons in oxygen atoms with aluminum. Formula II, with symmetry C_{3v} or



I



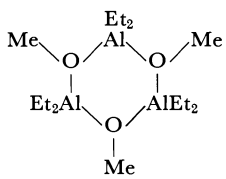
II

C_s, has an alkyl bridge which would be formed by the half bonds, as in the case of trimethylaluminum. Here the following postulations are made: the six atoms which constitute the oxygen bridge ring (model I) or the alkyl bridge ring (model II) are on a plane and occupy the six apices of a hexagon with D_{3h} symmetry; three methoxyl groups (model I) or three bridging alkyl groups (model II) lie on the ring plane, and

the plane containing two terminal alkyl groups (model I) or terminal methoxyl and alkyl groups (model II) and an aluminum atom is perpendicular to the ring plane. Model II requires that all skeletal vibrations be both infrared and Raman active. On the other hand, model I requires the skeletal vibrations of the species E' to be both infrared and Raman active, those of the species A_2'' to be infrared active and Raman inactive, and those of the species A_1' and E'' to be infrared inactive and Raman active. The results described above support model I.

Diethylaluminum Methoxide

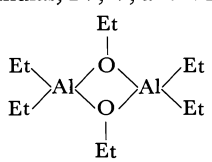
In the liquid state this trimeric compound has five infrared absorption bands and six Raman lines in the 720—300 cm^{-1} region; of these four are both infrared and Raman active, as is shown in Table II. These results are quite similar to those of dimethylaluminum methoxide. Analogous considerations lead to the conclusion that this compound is represented by the oxygen bridge model III:



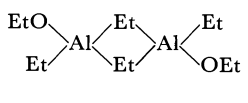
III

Diethylaluminum Ethoxide

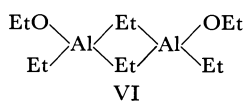
For this dimeric compound two infrared absorption bands and three Raman lines are observed in the liquid state in the 720—300 cm^{-1} region: the rule of mutual exclusion holds for these infrared absorption bands and Raman lines, as is shown in Table II. There are three possible structural formulas, IV, V, and VI, for this dimeric compound:



IV



V



VI

Formula IV, with symmetry V_h, has an oxygen bridge. For diethylaluminum chloride, bromide, and iodide, a dimeric bridge structure over the halogen atoms with symmetry V_h (which corresponds to model IV) has been established by Yamamoto.[4] Formula V, with symmetry C_{2h}, corresponds to the "trans" form, in which two ethoxyl groups are present on opposite sides of the bridge plane, while formula VI, with symmetry C_{2v}, corresponds to the "cis" form, where the ethoxyl groups are on the same side of the bridge plane. In the latter two formulas, the alkyl bridge would be formed by the half bonds. Here the following postulation is made: the plane containing two terminal ethyl groups (model IV) or terminal ethoxyl and ethyl groups (models V and VI) and an aluminum atom is perpendicular to the bridge plane, as in the case of diethylaluminum halides (see also Ref. 4). The results described above eliminate the possibility of model VI, because model VI would require a majority of skeletal vibrations species (A_1, B_1, and B_2) to be both infrared and Raman active. The spectral data cannot be used to determine which of the remaining two forms, model IV and model V, exist in the liquid state, because the rule of mutual exclusion should hold for the skeletal vibrations in either case. If, however, we consider the conclusion of the preceding section that dimethylaluminum methoxide is represented by the oxygen bridge model I, model IV seems preferable.

The Trimethylaluminum - Dimethyl Ether Complex

For this complex four infrared absorption bands and five Raman lines are observed in the 720—300 cm^{-1} region; all of them are both infrared and Raman active, with the exception of a weak Raman line at 576 cm^{-1} which does not agree with any infrared band, as is shown in Table II. Though the possibility of the structure with a lower symmetry can not be eliminated, these results at least do not contradict the postulated structure with symmetry C_s.

Summary

The infrared and Raman spectra of dimethylaluminum methoxide, diethylaluminum methoxide, diethylaluminum ethoxide and the trimethylaluminum - dimethyl ether complex have been measured in the 3000—300 cm^{-1} region. For the three dialkylaluminum alkoxides, the results are consistent with the dimeric or trimeric structures with the oxygen bridge proposed by Hoffmann. For the trimethylaluminum - dimethyl ether complex, the results do not contradict the postulated structure with symmetry C_s.

The author is indebted to Professor Takehiko Shimanouchi of the University of Tokyo and to Mr. Saburo Takeda for their valuable discussions throughout this work, and to Dr. Hiroshi Suzuki of the University of Tokyo for reading the manuscript and for advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 729—733 (1966)

The Copolymerization of the Vinyl Monomer with a Cyclic Compound. III. The Cationic Copolymerization of Styrene with Substituted Ethylene Oxides*

By Shuzo AOKI, Kazuo FUJISAWA, Takayuki OTSU and Minoru IMOTO

Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 7, 1965)

The copolymerization of styrene with substituted ethylene oxides catalyzed by boron trifluoride - diethyl ether has been investigated. In all cases, rather low-molecular-weight copolymers were obtained. The copolymerization reactivity of the substituted ethylene oxides with styrene varied with the substituents, in the order of: isobutene oxide>propylene oxide> styrene oxide>epichlorohydrin. This has been explained in terms of cross-propagation or the reaction of the growing oxide cation with styrene.

The styrene unit content of the copolymer of styrene and epichlorohydrin increases with an increase in the solvent polarity and with an increase in the temperature. It has been concluded from the experimental results that the copolymerizability of alkylene oxide toward styrene is increased by the introduction of electron-releasing substituents into the oxide and by the use of a polar solvent at a moderate temperature.

Recently the investigations of the cationic copolymerizations of some vinyl monomers with 3, 3-bis(chloromethyl)oxetane[1] and with β-propiolactone[2] have been reported. During the course of these investigations, it has been suggested that the structure of a growing terminal cation arising from the cyclic compound in its copolymerization reactivity is significant.

This work was undertaken in order to obtain information regarding the effect of the substituents in cyclic ethers on their cationic copolymerizations with styrene. Styrene (St) was copolymerized with substituted ethylene oxides, such as epichlorohydrin (ECH), propylene oxide (PO), isobutene oxide (IBO) and styrene oxide (StO), in the presence of a boron trifluoride - diethyl ether catalyst. The effects of the solvent and the temperature were also investigated.

Experimental

Materials.—Isobutene oxide was prepared from methallyl chloride through the corresponding chlorohydrin by the method described by Ishida.[3] B. p. 52°C, n_D^{20} 1.3732; lit.[3] b. p. 50.2—50.5°C, n_D^{20} 1.3730.

Styrene oxide was prepared from styrene through the corresponding iodohydrin, following the procedure used by Golumbic and Cottle.[4] B. p. 87°C/23 mmHg, n_D^{25} 1.5329; lit.[4] b. p. 87—88°C/23 mmHg, n_D^{25} 1.5331.

Epichlorohydrin, propylene oxide and styrene were obtained commercially. All of the monomers were distilled over calcium hydride before use.

The purifications of boron trifluoride - diethyl ether and methylene chloride were carried out as has been described in a previous paper.[1] Toluene and nitromethane were also purified by the usual methods.

Copolymerization Procedure.—The copolymerization was carried out in a glass stoppered-test tube. The initial concentrations of the total monomers and the catalyst in the copolymerization were kept constant at 3.0 and 0.07 mol./l. respectively. The reaction was stopped at a given time by the addition of ammoniacal methanol. Then the mixture was washed by pure water in order to remove the residual catalyst, and the volatile substances were evaporated under reduced pressure at a somewhat elevated temperature until the weight of residue became constant. The other procedures were the same as in a previous paper.[1]

The Analysis of the Resulting Polymer.—The copolymer composition was determined from the ele-

mentary analysis of the resulting polymer, except in the case of the styrene oxide copolymer. The composition of the styrene - styrene oxide copolymer was determined from its infrared spectrum, using the ratio of the optical densities at 1120 and 1495 cm^{-1}, which are the characteristic frequencies of the ether linkage and the benzene nucleus respectively. The calibration curve is shown in Fig. 1.

The copolymer formation was confirmed by the fractional extraction of the resulting polymer with hot methanol, in which the homopolyethers were soluble, while polystyrene was insoluble.

The molecular weight of the resulting polymer was determined with a Mechrolab. vapor pressure osmometer Model 301-A.

Results and Discussion

The Effect of the Substituents of the Oxides. —Styrene was copolymerized with the substituted ethylene oxides in the initial monomer mole ratio of 9/1 in methylene chloride at 0°C. The results are given in Table I, while the infrared spectra of the resulting polymers are shown in Fig. 2.

The polymers obtained above were separated by fractional extraction with hot methanol into soluble and insoluble fractions in order to confirm the copolymer formation. The data on hot methanol-insoluble fractions are also given in Table I.

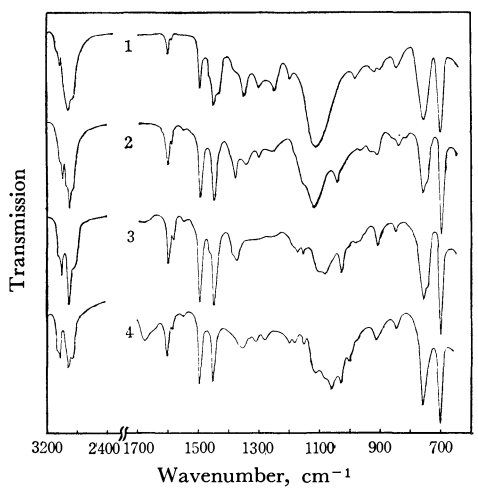

Fig. 2. Infrared spectra of the copolymer of styrene and substituted ethylene oxides.
1: St-ECH; 2: St-PO; 3: St-IBO; 4: St-StO

Furthermore, the copolymerizations of styrene with epichlorohydrin and with styrene oxide were carried out at different monomer mole ratios in methylene chloride at 0°C. The results are given in Tables II and III, while the monomer-copolymer composition curves are shown in Fig. 3.

From the infrared spectra (Fig. 2) and the elementary analyses (Table I), it was found that the

polymers obtained in the systems of styrene-substituted ethylene oxides contained both monomer units. The hot methanol-insoluble fractions of the resulting polymers also contained both monomer units (Table I). This indicates that the copolymers were obtained under the present conditions in every case.

Table I makes it clear that the cationic copolymerizability of the substituted ethylene oxides by styrene varied with their substituents, in the order of:

isobutene oxide > propylene oxide > styrene oxide > epichlorohydrin

The contents of the methanol-insoluble fraction in these copolymers and of styrene units in this fraction were also found to increase in the order given above (Table I).

The real values of the monomer reactivity ratios could not be evaluated in this work, because the molecular weights of the resulting copolymers were low. However, the following propagation reactions may reasonably be the most significant in determining the resulting copolymer composition, even though the initiation and the termination reactions have an influence on them:

$$\text{-St}^+ + \text{St} \xrightarrow{k_{11}} \text{-St·St}^+ \quad (1)$$

$$\text{-St}^+ + \text{Oxide} \xrightarrow{k_{12}} \text{-St·Oxide}^+ \quad (2)$$

$$\text{-Oxide}^+ + \text{Oxide} \xrightarrow{k_{22}} \text{-Oxide·Oxide}^+ \quad (3)$$

$$\text{-Oxide}^+ + \text{St} \xrightarrow{k_{21}} \text{-Oxide·St}^+ \quad (4)$$

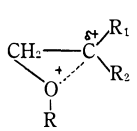
The k_{11} value is essentially constant as compared with the other constants. When both k_{12} and k_{22} decrease and k_{21} increases, the formation of a copolymer containing a large quantity of styrene units is encouraged. The values of k_{12} and also probably of k_{22} depend on the nucleophilicity of the oxides, which is to be expected from their basicity.[5] Thus the reactivity in their reaction is:

propylene oxide > styrene oxide > epichlorohydrin

This order is the reverse of that used to explain the experimental results given above. Therefore, the results should be explained by an increase in the value of the residual k_{21}.

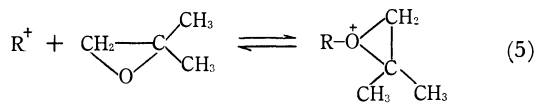
It has been discussed in the previous papers[1,2] how, in the cationic copolymerization of vinyl monomers with cyclic compounds, the structure of the growing terminal cation arising from the cyclic compound has a significant effect on the copolymer formation; a growing carbonium ion could react with a vinyl monomer, but an oxonium ion could not. Therefore, it is assumed that the substituted ethylene oxides which copolymerize with styrene give a carbonium ion in the propagation reaction, and that hence the cross-propagation becomes favorable.

In the cationic copolymerization of the substituted ethylene oxides and 3, 3-bis(chloromethyl)oxetane,[6] we proposed an intermediate structure (I) of both carbonium and oxonium ions for the growing oxide cation in the transition state. A similar structure:

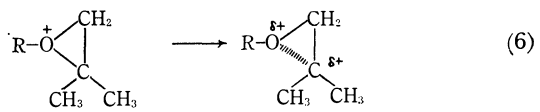


(I)

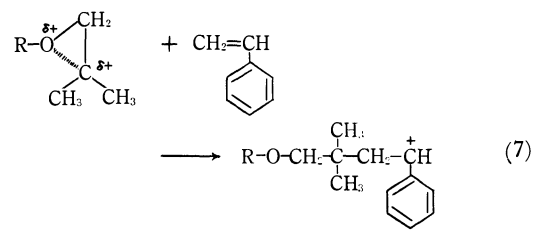
was postulated for the β-propiolactone growing cation.[2] The carbonium ion character of the ion I may be increased by the electron-releasing substituents and the ring strain. Thus, it may be assumed that, in this work, the oxides copolymerized with styrene in the order mentioned above, according to the following scheme:



(5)



(6)



(7)

Pritchard and Long[7] have reported on the hydrolysis of the substituted ethylene oxides in aqueous perchloric acid. The rate constant of this reaction, which proceeds through an S_N1-type mechanism, varied with the substituents, in the order of:

isobutene oxide > propylene oxide > epichlorohydrin

This order agrees with that of their copolymerization reactivities given above; it indicates the enhanced significance of carbonium ion participation in their propagations in the cationic copolymerization with styrene.

The Effects of the Solvent and the Temperature.—It may be expected that the extent of the partial charge distribution in the growing ion of the oxide I may be affected by both the solvent polarity and the temperature. The copolymerization of styrene and epichlorohydrin was carried out in the monomer mole ratio of 9/1 in toluene, methylene chloride and nitromethane at −30, 0 and 30°C. The results are given in Table IV.

The styrene unit content of the resulting polymer increased with an increase in the polarity of the solvent and with an increase in the temperature. This can be explained from the enhanced carbonium

ion character of the growing oxide cation I. However, if the k_{11} in Eq. 1 increases in a polar solvent and at a higher temperature more than the k_{22} in Eq. 3, this also affects the copolymer composition.

Studies of the Solution Properties of Co-polymer. I. Styrenepolysulfone*

By Ryūichi ENDŌ, Tomoyuki MANAGŌ and Masatami TAKEDA

Tokyo College of Science, Department of Chemistry, Faculty of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received August 9, 1965)

Styrenepolysulfone was polymerized and then, for its fractionation, tetrahydrofuran and methanol were used as solvent and precipitant respectively. The viscosities and osmotic pressures of fractions of this co-polymer were examined in tetrahydrofuran. The relation between the intrinsic viscosity and the molecular weight, $[\eta]=0.38_9\times10^{-4}\overline{M}_n^{0.78}$, was thus obtained. The unperturbed molecular dimension was calculated by the Fixman-Stockmayer method. The results were then compared with the calculated end-to-end distance of the hypothetical freely-rotating chain. The steric parameter, $\sigma=1.53$, was also obtained and compared with that of polystyrene.

The polymerization of styrene and sulfur dioxide has been reported by Staudinger[1] and others[2]; the co-polymers obtained were called styrenepolysulfones. The synthesis of the co-olymer was examined with various compositions of styrene and sulfur dioxide, and the form of combination of the monomeric units was studied in terms of the head-to-head or head-to-tail combination.[3] However, the solution properties of this co-polymer have not been examined as yet.

Recently, the solution properties of hexene-1 polysulfone were examined by Ivin et al.,[4] and the unperturbed molecular dimensions of this co-polymer were obtained by using two kinds of θ-solvents. Considerably different values of the unperturbed dimensions were obtained in the two θ-solvents. This was a new finding, in contrast to the prevailing view that the unperturbed dimension of flexible polymer chains was practically independent of the solvent nature; the solvent effect observed was interpreted as arising from the dipolar interaction between polar groups contained in the main chain of this molecule.

In the present work, the unperturbed molecular dimensions of styrenepolysulfone and polystyrene will be studied. The viscosities and osmotic pressures of fractions of this co-polymer and those of polystyrene will be examined in tetrahydrofuran as the solvent. The relations between the intrinsic viscosity and the molecular weight will be determined for both styrenepolysulfone and polystyrene. The unperturbed molecular dimensions will be calculated by the Fixman-Stockmayer method.[5] The results will be compared with the calculated end-to-end distance of the hypothetical freely-rotating chain.

Experimental

Materials and Fractionation.—Styrenepolysulfone was polymerized, with α, α'-azobis-isobutyronitrile as the catalyzer, from styrene and sulfur dioxide (mole ratio 1 : 1) at 30°C. On the basis of the chemical analysis, the composition of styrenepolysulfone was determined to be $(\text{Styrene})_2SO_2$. For the fractionation of styrenepolysulfone, tetrahydrofuran and methanol were used as the solvent and the precipitant respectively. The solvent and the precipitant were purified and distilled before use. Ten fractions were obtained by fractional precipitation from a tetrahydrofuran solution (concentration: 10 g./l.) upon the addition of methanol as the precipitant, with the system kept at 40°C. For the fractionation of polystyrene (commercial name: Styron 666), benzene and methanol were used as the solvent and the precipitant respectively. About ten fractions of polystyrene were prepared by fractional precipitation.

Viscosity and Osmotic Pressure Measurements.—Tetrahydrofuran was used as the solvent for viscosity and osmotic pressure measurements. The viscosity measurements were carried out with a dilution-type Ubbelohde viscometer at 30±0.005°C. Solutions with a wide variety of concentration were prepared from an

original stock solution by successive dilution with a definite volume of solvent and were then used in the measurements. The concentration of the original stock solution was determined by the evaporation method. The osmotic pressure measurements were made at 30±0.005°C by the semi-dynamic method with a modified Zimm-Meyerson-type osmometer fitted with gelcellophane. The intrinsic viscosities and molecular weights were determined by extraporating the viscosity and osmotic pressure data to zero concentration by the least-square method. The solution density measurements were made with an Ostwald-Sprengel pycnometer.

Results and Discussion

The Relation between Intrinsic Viscosities and Molecular Weights.—The results of the viscosity and osmotic pressure measurements for styrenepolysulfone and polystyrene fractions are collected in Table I. The intrinsic-viscosity-vs.-molecular-weight relationship is illustrated in Fig. 1, where the open circles represent log $[\eta]$ for polystyrene fractions plotted against log $\overline{M}_n$, and the closed circles those for styrenepolysulfones. Using these data, the Mark-Houwink equations were calculated by the least-square method. The results are shown by the straight lines in Fig. 1; they are:

$$[\eta] = 1.16_0 \times 10^{-4} \overline{M}_n^{0.73} \quad (1)$$

for polystyrene, and:

$$[\eta] = 0.38_9 \times 10^{-4} \overline{M}_n^{0.78} \quad (2)$$

for styrenepolysulfone.

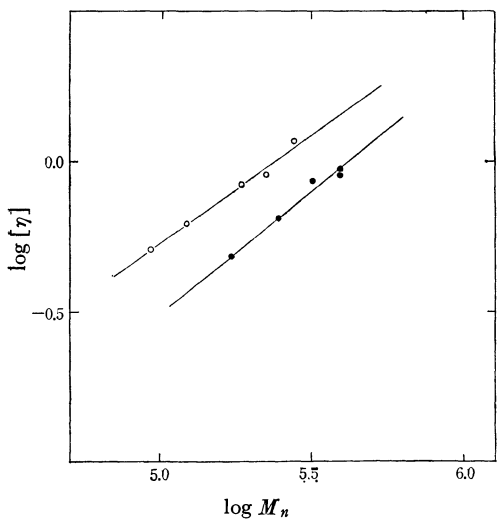

Fig. 1. Relationship between intrinsic viscosity and molecular weight.
○ Polystyrene fractions
● Styrenepolysulfone fractions

The Estimation of Unperturbed Molecular Dimension Parameters.—The unperturbed end-to-end distance, r_0, may be estimated from the $[\eta]$-vs.-M relationship with the aid of the Fixman-Stockmayer method. We first calculate $[\eta]M^{-1/2}$ and $M^{1/2}$ for each fraction. Then the values of $[\eta]M^{-1/2}$ are plotted against $M^{1/2}$, as is shown in Fig. 2, and a straight line is obtained for each polymer-solvent system.

Table I.

Polymer	Fraction	$[\eta]$	$\overline{M}_n \times 10^{-4}$
Styron 666	F_2	1.170	26.3
	F_4	0.902	22.3
	F_6	0.853	18.5
	F_8	0.618	12.1
	F_9	0.508	9.2
Styrenepoly-sulfone	F_1	0.939	39.0
	F_2	0.902	38.9
	F_3	0.861	31.8
	F_6	0.646	24.3
	F_7	0.480	17.1

According to Stockmayer and Fixman, the $[\eta]M^{-1/2}$ ratio is given by:

$$[\eta]M^{-1/2} = K + BM^{1/2} \quad (3)$$

where K and B are constant, relating to the unperturbed molecular dimension parameter and to the polymer and solvent interaction respectively. Thus, the value of K can be readily determined from the intercept of the straight line shown in Fig. 2. The results are given in Table II. As the value of K for polystyrene in a mixed θ-solvent is essentially identical with our data obtained with the Fixman-Stockmayer method, it seems most reasonable to assume that the value of K for styrenepolysulfone is accurate. The unperturbed end-to-end distance, r_0, for styrenepolysulfone and polystyrene can be calculated from

the experimental values of K by the following equation:

$$K = \Phi(\bar{r}^2_0/M)^{3/2} \tag{4}$$

where Φ is the universal viscosity constant. The results are also given in Table II, with other data given for the sake of comparison.

Table II shows that the molecular dimension of styrenepolysulfone is smaller than that of polystyrene in a tetrahydrofuran solution.

According to the results of chemical analysis and other evidence,[6] the molecular formula, $-CH_2CH(C_6H_5)SO_2CH_2CH(C_6H_5)-$, seems appropriate for the repeating units of styrenepolysulfone. To the distance from phenyl-to-phenyl groups in this molecule is larger than that in polystyrene, the steric interaction between phenyl groups, and consequently the hindrance to the rotation of the main chain, would be less significant than with the polystyrene chain. With the model defined by the above molecular formula or shown in Fig. 3, the mean-square end-to-end distance of free rotation for the monomer unit of styrenepolysulfone may be calculated by Flory's method as:[7]

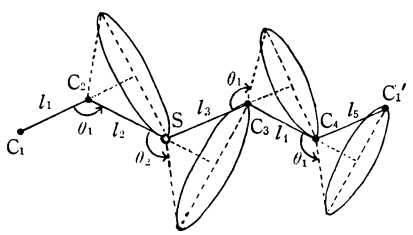

Fig. 3. Spatial representation of styrenepolysulfone monomer for free rotation.
l_1, l_4, l_5: C-C bond length 1.54 Å
l_2, l_3: C-S bond length 1.82 Å
θ_1: ∠C-C-C, ∠C-C-S 109.5°
θ_2: ∠C-S-C 115°

$$(\bar{r}^2_m) = \begin{vmatrix} \overline{l_1\cdot l_1} + \overline{l_1\cdot l_2} + \cdots\cdots + \overline{l_1\cdot l_5} \\ + \overline{l_2\cdot l_1} + \overline{l_2\cdot l_2} + \cdots\cdots + \overline{l_2\cdot l_5} \\ + \overline{l_3\cdot l_1} + \overline{l_3\cdot l_2} + \cdots\cdots + \overline{l_3\cdot l_5} \\ + \cdots\cdots\cdots\cdots\cdots\cdots \\ + \cdots\cdots\cdots\cdots\cdots\cdots \end{vmatrix} \tag{5}$$

where l_1, l_4 and l_5 are the bond lengths of C–C, and l_2 and l_3 are the bond lengths of C–S. The result is:

$$\begin{aligned}(\bar{r}^2_m) &= l_1^2[1+2(1-\cos\theta_1)(1-\cos^2\theta_1\cdot\cos\theta_2)] \\ &\quad +2l_2^2(1-\cos\theta_2) \\ &\quad -2l_1l_2\cos\theta_1(2-\cos\theta_1)(1-\cos\theta_2)\end{aligned} \tag{6}$$

where θ_1 is the bond angles of C–C–C and C–C–S, and θ_2 is the bond angle of C–S–C. For the polymer with the polymerization degree of x, the mean-square end-to-end distance of free rotation in the main chain is obtained as:

$$(\bar{r}^2_{0f}) = x\cdot(\bar{r}^2_m)(1-\cos\theta_1)/(1+\cos\theta_1) \tag{7}$$

where θ_1 is the bond angle of C–C–C (monomer)–(monomer). On the other hand, for the freely-rotating state of polystyrene, $\bar{r}^2_{0f}$ is given as:

$$(\bar{r}^2_{0f}) = n\cdot l^2(1-\cos\theta_1)/(1+\cos\theta_1) \tag{8}$$

where l is the bond length of C–C. Therefore, the steric parameter, $(\bar{r}^2_0/\bar{r}_{0f})^{1/2}$, can be calculated for styrenepolysulfone and for polystyrene by using Eq. 7 and Eq. 8 respectively. The results are shown in Table II. It is notable that the values of $(\bar{r}^2_0/M)$ and $(\bar{r}^2_0/\bar{r}^2_{0f})^{1/2}$ for styrenepolysulfone are considerably smaller than those of polystyrene. This clearly shows that the internal rotation around the bond axis in the main chain can occur with less hindrance in styrenepolysulfone than in polystyrene. Finally, if it is compared with that for hexen-1-polysulfone, the steric parameter for styrenepolysulfone is approximately identical with that for hexen-1-polysulfone obtained from mixed θ-solvent (ethyl methyl ketone and isopropylalcohol).

The Band Structure of Tetramethylammonium Pentaiodide*

By Shigekazu KUSABAYASHI** and Hiroshi MIKAWA**

The Institute of Scientific and Industrial Research, Osaka University, Sakai-shi, Osaka

(Received August 12, 1965)

The iodine framework in the crystal is constructed by repeated translations of a group of two pentaiodide ions (repeating unit). The wave function of a repeating unit is calculated by Hückel's approximation, the resonance integrals between iodine 5 p orbitals being estimated empirically from the data for the gaseous iodine molecule. The wave functions of the crystal are set up in the form of Bloch functions from the wave functions of the repeating unit. The energy is calculated by a tight-binding approximation, the values of the resonance integrals between nearest neighboring repeating units being estimated from the wave functions of the repeating unit. The band-gap energy thus calculated is 1.26 eV., satisfactorily near the experimental value of 1.36 eV. This finding supports our conclusion (This Bulletin, **37**, 811 (1964)) that the iodine framework is primarily important in the electrical conductivity. It is also supposed that the band model may satisfactorily be applied to the conduction mechanism. The interactions of the Bloch functions of different energies being very slight, the band-gap energy is influenced at most in the order of 10^{-2} eV. even when level interactions are taken.

In previous papers,[1] it was shown that the specific resistivities (20°C) and the band-gap energies of organic polyiodides decreased with the number of iodine atoms in the polyiodide anion. It was also shown that the iodine framework in the crystal structure was of primary importance in determining the electrical conductivity of polyiodides.

On the basis of the above discussion, we will now attempt to calculate the band structure of the tetramethylammonium pentaiodide crystal by the so-called tight-binding approximation, in order to see whether the band theory is applicable to the conduction mechanism of tetramethylammonium pentaiodide.

According to the X-ray analyses,[2,3] the tetramethylammonium pentaiodide crystal is end-centered monoclinic with a space group C2/c and with $a_0=13.34$, $b_0=13.59$, $c_0=8.90$ Å, $\beta=107°50'$, and $Z=4$. The coordinates of the iodine atoms and the tetramethylammonium cations are also reported. Five iodine atoms as a group form a planar V-shaped pentaiodide ion. Pentaiodide anions are arranged nearly parallel to (001). Thus, the layer structure of iodine atoms exists in the crystal, as is shown in Figs. 1 and 2.

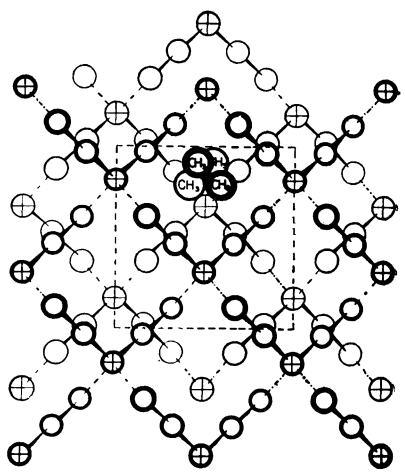

Fig. 1. Projection of the structure of tatramethylammonium pentaiodide along the c_0-axis onto the plane (001), showing the nets of iodine atoms in the upper plane and that in the lower plane. Nets are stacked so as to leave large holes for the cations. Only one is shown, upper center, though every hole is filled. The dashed line outlines the unit cell. (From Ref. 2)

The iodine framework in the crystal can be looked upon as being constructed simply by repeated translations of a group of two pentaiodide ions, as in Fig. 2. In order to calculate the band structure by tight-binding approximation, this repeating unit is first looked upon as a molecule and the wave function of the repeating unit is calculated as usual by the method of simple LCAO MO, the values of the resonance integrals between iodine atoms being estimated empirically from the data reported for the gaseous iodine molecule.

* Presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

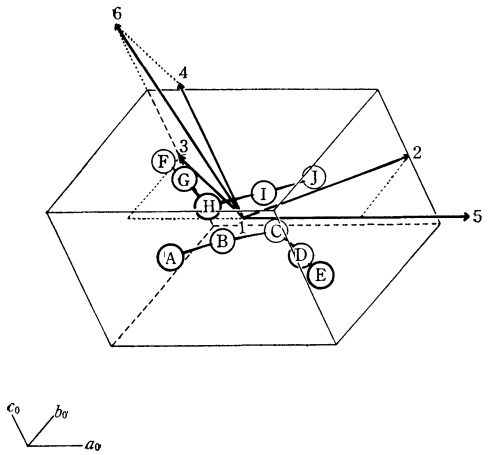

Fig. 2. Repeating unit consisting of two pentaiodide anions. Five vectors 2—6 connecting nearest neighboring repeating unit.

As the whole crystal is made up of simple repetitions of the three-dimensional translations of the repeating unit with the "molecular" wave functions thus calculated, the wave functions of the crystal can easily be set up in the form of Bloch functions from the "molecular" wave functions of the repeating unit. The energy band structure is next calculated by a tight-binding approximation as usual, the values of the resonance integrals between nearest neighboring repeating units needed for calculation being estimated from the "molecular" wave functions of the repeating unit.

The band structure thus calculated is shown in Fig. 4, the lower band being occupied and the upper vacant. The estimated band-gap energy is 0.455 β or 1.26 eV. This value is satisfactorily near to the experimental value of 1.36 eV.

Calculation

The Use of Only p Orbitals.—Several previous attempts have been made to explain the bonds in polyhalides by assuming the spd hybridization of the iodine atomic orbitals, the delocalization of the outer p orbital of the iodine atoms and so on.[4]

Pimentel[5] and Hach and Rundle[2] suggested the use of only the 5p orbitals; they based their argument on the linear form of triiodide ions. Havinga and Wiebenga[4] reviewed the structure of polyiodide ions and explained the observed configurations of atoms by means of the delocalization of the 5p orbitals, the valency angles being very close to 90° or 180° in all cases. Bersohn[6] and Rosenberg[7] have worked out the band structure of iodine on the assumption that only p orbitals are involved.

In such circumstances, only the 5p orbitals were used in the present calculation of the pentaiodide ion.

The Coordinates of the Iodine Atoms.—In our calculation of the band structure, the coordinates of the iodine atoms were estimated by the parameter reported in Ref. 3.

In order to set up the Bloch functions of an electron in a periodic field of the crystal, the repeating unit, which consists of two neighboring anions in a direction parallel to the c_0-axis, as has been stated before, must be examined first. The relation between neighboring repeating units in the crystal is drawn in Fig. 2; the numbers, 1, 2, ...,6, denote the nearest neighboring repeating units in the crystal. The ten iodine atoms in a repeating unit were named A, B, C,.., I and J. The distances between each two atomic centers were estimated as follows:

(a) Distances within the 1 repeating unit:
$A_1B_1=D_1E_1=F_1G_1=I_1J_1=2.81$ Å, $B_1C_1=C_1D_1=G_1H_1=H_1I_1=3.17$ Å, $B_1D_1=G_1I_1=4.67$ Å, $A_1G_1=D_1J_1=4.40$ Å, $A_1H_1=C_1J_1=4.73$ Å, $B_1G_1=D_1I_1=4.48$ Å, $B_1H_1=C_1I_1=4.74$ Å, $B_1I_1=4.68$ Å.

(b) Distances between the 1 and 2 repeating units:
$C_1A_2=J_1H_2=3.62$ Å, $D_1A_2=J_1G_2=4.91$ Å, $J_1A_2=4.59$ Å.

(c) Distances between 1 and 3:
$B_1E_3=F_1I_3=4.91$ Å, $C_1E_3=F_1H_3=3.62$ Å.

(d) Distances between 1 and 4:
$F_1B_4=I_1E_4=4.40$ Å, $F_1C_4=H_1E_4=4.73$ Å, $G_1B_4=I_1D_4=4.48$ Å, $G_1C_4=H_1D_4=4.74$ Å, $G_1D_4=4.68$ Å.

(e) Distances between 1 and 5:
$E_1A_5=J_1F_5=4.92$ Å.

(f) Distances between 1 and 6:
$F_1E_6=4.59$ Å.

Any distances between two atomic centers larger than 5.0 Å may be disregarded, for the overlap integrals decrease exponentially with the distance of two atomic centers.

The "Molecular Orbital" of a Repeating Unit.—The "molecular" orbital function of a repeating unit, φ, was approximated with a linear combination of 30 Slater-type 5p atomic orbitals, χ, belonging to the 10 iodine atoms in the unit. The energy and the coefficients of the "molecular" orbitals of the repeating unit were calculated by applying the variation principle and Hückel's approximation in the usual manner.

If χ_i is the wave function of the ith atomic orbital, the explicit parameters which enter the secular determinant are the Coulomb integral, $\alpha_i=\int\chi_i^*\boldsymbol{H}\chi_i d\tau$, and the resonance integral between adjacent orbitals, $\beta_{ij}=\int\chi_i^*\boldsymbol{H}\chi_j d\tau$, the overlap integrals being neglected. If all the orbitals are

4) E. E. Havinga and E. H. Wiebenga, *Rec. Trav. Chim.*, **78**, 724 (1959).
5) G. C. Pimentel, *J. Chem. Phys.*, **19**, 446 (1951).
6) R. Bersohn, ibid., **36**, 3445 (1962).
7) J. L. Rosenberg, ibid., **40**, 1707 (1964).

equivalent, the Coulomb integral will become an additive constant. $\boldsymbol{H}$ is a one-electron Hamiltonian. It is, therefore, necessary to evaluate the resonance integrals.

The resonance integrals were estimated by the familiar relation:

$$\beta' = \beta\frac{S'/(1+S')}{S/(1+S)} \qquad (1)$$

where β' and S' are, respectively, resonance and overlap integrals between the interesting orbitals, and β and S are, respectively, the resonance and overlap integrals for some standard. In our present calculation, β and S are the values for $(5p\sigma, 5p\sigma)$ at the interatomic distance, 2.68 Å, of an iodine molecule. The estimation of the numerical value of the basic parameter of our calculation, β, will be discussed later in detail.

The values of $S(5p\sigma, 5p\sigma)$ and $S(5p\pi, 5p\pi)$ between two iodine 5p atomic orbitals were calculated by Mulliken's special formulas[8] for Slater-AO overlap integrals for $t=0$. The formulas may be given as follows:

$$S(5p\sigma, 5p\sigma) = e^{-p}[-1-p-(29/70)p^2-(17/210)p^3 - (1/735)p^4+(1/294)p^5+(67/66150)p^6 + (13/66150)p^7+(1/33075)p^8]$$

$$S(5p\pi, 5p\pi) = e^{-p}[1+p+(33/70)p^2+(29/210)p^3 + (41/1470)p^4+(1/245)p^5 + (29/66150)p^6+(1/33075)p^7]$$

where $p=(\mu_a+\mu_b)R/2a_H$, $t=(\mu_a-\mu_b)/(\mu_a+\mu_b)$, R is the interatomic distance, a_H is the Bohr radius, and the $\mu_a=\mu_b$ value is 1.90 for the iodine-pair.

Next, in order to ascertain the overlap integral, S'_{ab}, between any two 5p iodine orbitals, $\boldsymbol{A}_a$ and $\boldsymbol{A}_b$, new orthogonal coordinates (X, Y, Z), in which the Z axis is parallel to the direction of the internuclear vector, are set up, and the interesting overlap integral, S'_{ab}, is estimated as follows:

$$S'_{ab} = -A_{az}\cdot A_{bz}\cdot S(5p\sigma, 5p\sigma) + (A_{ax}\cdot A_{bx} + A_{ay}\cdot A_{by})\cdot S(5p\pi, 5p\pi)$$

where $A_{ax}, A_{ay}, .., A_{bz}$ are the X, Y and Z components of the vectors of the atomic orbitals, $\boldsymbol{A}_a$ and $\boldsymbol{A}_b$.

In order to calculate the energy of the repeating unit, it is first assumed that the V-shaped pentaiodide ion is planar, that the I_B–I_C–I_D angle is 90° and that the arms are linear, the pentaiodide ion reported in Ref. 3 being planar within±0.09 Å, the I_B–I_C–I_D angle, 95°, and the angle of arms, 174.5°.

The sign and the numbering of the atomic p orbitals are as shown in Fig. 3. Thus, all the resonance integrals between any pairs of iodine atoms from A to J were estimated in β untis. Using these resonance integrals, a 30-order secular determinant was set up and solved by a computor. The energy levels of a repeating unit and the orbital coefficients for some levels are shown in Fig. 4 and Table I. The levels from 1 to 26 are filled; the levels from 27 to 30, lying much higher, are vacant.

* Orbital number from left to right, up to down.

Band Structure. — The band structure is calculated by the tight-binding approximation. We denote the unit cell vector by $\boldsymbol{a}_0$, $\boldsymbol{b}_0$ and $\boldsymbol{c}_0$, and define the new vector by $\boldsymbol{a}=(\boldsymbol{a}_0+\boldsymbol{b}_0)/2$, $\boldsymbol{b}=(-\boldsymbol{a}_0+\boldsymbol{b}_0)/2$ and $\boldsymbol{c}=\boldsymbol{c}_0$; therefore, $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$ connect the centers of the nearest-neighbor repeating units (Fig. 2).

The one-electron crystal wave functions, Ψ_k, are constructed from the linear combination of one-electron wave functions of the repeating unit, φ_j; since we are dealing with an electron in a periodic field, the wave function must be a Bloch function:

$$\Psi_k(\boldsymbol{r}) = \sum_{j=1}^{N}\exp(i\boldsymbol{k}\boldsymbol{r}_j)\varphi_j(\boldsymbol{r}-\boldsymbol{r}_j)$$

Here $\boldsymbol{r}_j$ locates the center of a repeating unit, j, and the sum extends over N repeating units in the crystal.

The application of periodic boundary conditions defines an elementary cell in $\boldsymbol{k}$ space, whose volume

8) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

is given by the conditions:

$$-\pi < \boldsymbol{ka},\ \boldsymbol{kb},\ \boldsymbol{kc} \leq \pi$$

The energy of one-electron with the wave vector $\boldsymbol{k}$ is calculated by the following expression:

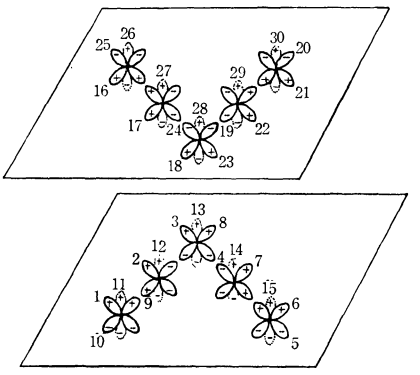

Fig. 3. The sign and the numbering of the atomic p-orbitals. 1—15 make a lower layer and 16—30 an upper layer. Lobes shown with dotted lines are perpendicular to each layer.

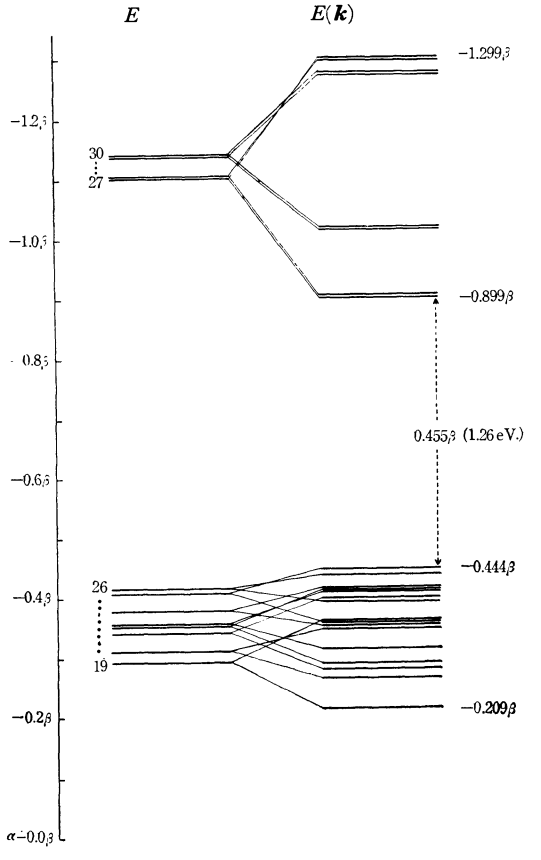

Fig. 4. Energy levels of a repeating unit, E, and energy bands of solid pentaiodide, $E(\boldsymbol{k})$. (Among 30 energy levels of a repeating unit only the levels 19—30 are shown.)

$$E(\boldsymbol{k}) = \frac{\int \Psi_k^* \boldsymbol{H} \Psi_k d\tau}{\int \Psi_k^* \Psi_k d\tau} = E_0 + 2\sum E_s \cdot \cos \boldsymbol{k r_s}$$

where $\boldsymbol{H}$ is the Hamiltonian for one electron in the crystal; E_0 is the molecular orbital energy of a repeating unit, and $\boldsymbol{r_s}$ is the primitive translation vector. The structure of the band is determined by the resonance integrals between repeating units, E_s. Each resonance integral between repeating units is a sum of the interatomic resonance integrals. Of the two-center atomic integrals in each E_s, only those involving a small interatomic distance and a large Hückel coefficient of a repeating unit are important.

The resonance integrals fall off rapidly with the distance between repeating units; only five nearest-neighbor interactions are found to be important. They are E_a, E_b, E_c, E_{a-b} and E_{b+c}, corresponding to $\boldsymbol{r_s} = \boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, $\boldsymbol{a}-\boldsymbol{b}$ and $\boldsymbol{b}+\boldsymbol{c}$ respectively.

The one-electron energy for each band is, therefore, given by:

$$E(\boldsymbol{k}) = E_0 + 2[E_a \cos \boldsymbol{ka} + E_b \cos \boldsymbol{kb} + E_c \cos \boldsymbol{kc} + E_{a-b} \cos \boldsymbol{k}(\boldsymbol{a}-\boldsymbol{b}) + E_{b+c} \cos \boldsymbol{k}(\boldsymbol{b}+\boldsymbol{c})] \quad (2)$$

The values of E_a, E_b,..., and E_{b+c} for the band corresponding to each nth "molecular" orbital are listed in Table II.

Results and Discussion

Using Eq. 2, the total width of each band was calculated. The energy levels of a repeating unit and the total width of each band are represented in Fig. 4.

As is shown in Fig. 4, the bands from 19 to 26 are all occupied by electrons and as a whole form a hole band, while the bands from 27 to 30 are all vacant and form an electron band. The band-gap energy is found to be 0.455 β.

In order to estimate the numerical value of β, as Rosenberg suggested,[7] the following assumption was made:

$$\beta(5p\sigma,\ 5p\sigma)-\beta(5p\pi,\ 5p\pi)=-1.71\ \text{eV}. \quad (3)$$

where β is the value for the interatomic distance, 2.68 Å, for the iodine molecule. This is the average value of T_e,[9] the pure electronic excitation, of the first two excited states, A and B, relative to the ground state, X, in the gaseous iodine molecule. The $X \rightarrow A$ and $X \rightarrow B$ transitions are the two spectroscopically-observed transitions of the vapor phase iodine corresponding to the orbital jump from π-antibonding to σ-antibonding orbitals.

The substitution of $\beta(5p\pi,\ 5p\pi)=0.381\beta$ from Eq. 1 into Eq. 3 gives $\beta=-2.76$ eV.

The band-gap energy is, therefore, calculated to be 1.26 eV. This value is in good agreement with the experimental value of 1.36 eV., reported in the previous papers,[1a,1b] for the band-gap energy of tetramethylammonium pentaiodide from the conductivity measurements.

As described before, the calculations have been performed on the assumptions that the V-shaped pentaiodide ion is planar, the I_B–I_C–I_D angle is rectangular, and the arms are linear. The calculations were also carried out with the pentaiodide ion, which has a more complicated geometry; the band gap energy thus calculated was found, however, to be almost the same as the above value (the difference was within 0.1 eV).

Although the treatment of the calculation is semiquantitative, this result may offer additional evidence in support of our previous conclusion that the iodine framework in the tetramethylammonium pentaiodide crystal structure is of primary importance in determining the electrical conductivity. It may also be supposed that the band model is satisfactorily applied for the conduction mechanism. Thereby, the experimental energy gap may be supposed to be the one of intrinsic conduction.

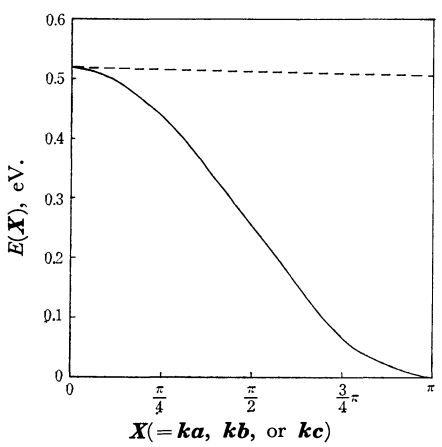

Fig. 5. The 27 band structure in the a^{-1} (solid line), b^{-1} (the same line as a^{-1}) and c^{-1} (dashed line) directions.

9) L. Mathieson and A. L. G. Rees, *J. Chem. Phys.*, **25**, 753 (1956).

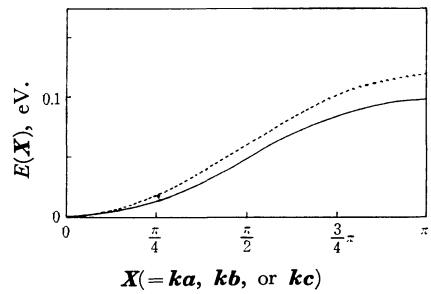

Fig. 6. The 25 band structure in the a^{-1} (solid line), b^{-1} (dotted line) and c^{-1} (the same line as a^{-1}) directions.

On examining the Hückel coefficients of the wave functions of the repeating unit, one finds that the electron band is mainly σ in character. No. 25 and 26 bands located at the top of the hole band are mainly π in character, perpendicular to the planar V-shaped pentaiodide ion.

In the reduced zone scheme given by $-\pi < ka, kb, kc \leq \pi$, the 27 and 25 band structures in the reciprocal crystal axis direction are as shown in Figs. 5 and 6. The origins of the energy scales are arbitrarily taken in both figures. The values of the bandwidths in the a^{-1}, b^{-1}, and c^{-1} directions are shown in Table III.

Table III. Bandwidths of 27 and 25 (eV.)

	27	25
a^{-1}	0.519	0.099
b^{-1}	0.519	0.121
c^{-1}	0.011	0.099

So far no mutual interactions of the Bloch functions of different energy have been taken into consideration; the interactions between the levels with different energies have thus been neglected.

In order to calculate the electron band, it is desirable to mix four vacant levels 27—30. The usual way to do this is to make a linear combination of these four functions and, next, set up a 4th order secular determinant by variation. It is, however, very difficult to solve the determinant thus obtained. To calculate the hole band in this way, it is desirable to interact eight levels at one time, leading to the 8th order secular determinant; these interactions are, however, impossible to solve.

We therefore attempted to see if there were pairs of levels which interact so strongly that the value of the energy gap estimated hitherto without level interactions must be changed. As will be shown below the level interactions were found to be so slight that the value of the energy gap changes at most in the order of 10^{-2} eV.

The interaction between two different Bloch functions, Ψ_p and Ψ_t, has been examined on the basis of a linear combination;

Table IV. E_s' from a pair of different Bloch functions

p, t	E_a'	E_b'	E_c'	E'_{a-b}	E_{b+c}'	cos or sin
27, 30	0.082	−0.080	0.000	0.000	−0.002	cos
27, 29	0.018	−0.016	0.000	−0.006	−0.002	sin
27, 28	0.000	0.000	0.000	0.000	0.002	sin
25, 26	0.000	0.000	0.004	−0.002	0.002	sin
24, 25	0.014	0.012	0.000	−0.002	0.008	sin
19, 25	0.014	−0.010	−0.014	−0.002	−0.008	cos

$$\Phi = c_1\Psi_p + c_2\Psi_t$$

By applying the variation principle, the secular determinant of the following form is obtained:

$$\begin{vmatrix} \int\Psi_p^*\boldsymbol{H}\Psi_p d\tau - E & \int\Psi_p^*\boldsymbol{H}\Psi_t d\tau \\ \int\Psi_t^*\boldsymbol{H}\Psi_p d\tau & \int\Psi_t\boldsymbol{H}\Psi_t d\tau - E \end{vmatrix} = 0$$

In solving the determinant, the band energy is written in explicit form as:

$$E_{p,t}(\boldsymbol{k}) = \frac{E_p(\boldsymbol{k}) + E_t(\boldsymbol{k})}{2} \pm \sqrt{\left(\frac{E_p(\boldsymbol{k}) - E_t(\boldsymbol{k})}{2}\right)^2 + |B|^2}$$

where

$$E_p(\boldsymbol{k}) = \int\Psi_p^*\boldsymbol{H}\Psi_p d\tau,\ E_t(\boldsymbol{k}) = \int\Psi_t^*\boldsymbol{H}\Psi_t d\tau,$$

$$B = \int\Psi_p^*\boldsymbol{H}\Psi_t d\tau = \int\varphi_p(\boldsymbol{r})\boldsymbol{H}\varphi_t(\boldsymbol{r})d\tau + \sum\{\exp(-i\boldsymbol{k}\boldsymbol{r}_s)\int\varphi_p^*(\boldsymbol{r})\boldsymbol{H}\varphi_t(\boldsymbol{r}-\boldsymbol{r}_s)d\tau - \exp(i\boldsymbol{k}\boldsymbol{r}_s)\int\varphi_p^*(\boldsymbol{r})\boldsymbol{H}\varphi_t(\boldsymbol{r}+\boldsymbol{r}_s)d\tau\}$$

$$B^* = \int\Psi_t^*\boldsymbol{H}\Psi_p d\tau,\ |B|^2 = (\sum E_s'\cos\boldsymbol{k}\boldsymbol{r})^2 \text{ or } (\sum E_s'\sin\boldsymbol{k}\boldsymbol{r})^2$$

Since $\varphi_p(\boldsymbol{r})$ and $\varphi_t(\boldsymbol{r})$ are orthogonal, $\int\varphi_p(\boldsymbol{r})\boldsymbol{H}\cdot\varphi_t(\boldsymbol{r})d\tau$ vanishes. The sum, $\sum$, is taken over the nearest-neighboring repeating units located in the five directions, $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, $\boldsymbol{a}-\boldsymbol{b}$ and $\boldsymbol{b}+\boldsymbol{c}$. One finds that, for some p, t pairs, $|B|^2$ contains only sine terms, $(\sum E_s'\sin\boldsymbol{k}\boldsymbol{r}_s)^2$ and for some other pairs, only cosine terms, $(\sum E_s'\cos\boldsymbol{k}\boldsymbol{r}_s)^2$. The E_s' values are listed in Table IV for several p, t pairs.

E_a' and E_b' in cosine terms are large but are opposite in sign. E_a and E_b are large and have the same sign. Hence, it is clear that when $\cos\boldsymbol{k}\boldsymbol{a} \fallingdotseq \cos\boldsymbol{k}\boldsymbol{b} \fallingdotseq \pm 1$, i. e., near the top and bottom of these bands, $|B|^2$ must be small, the interaction between p and t levels being very small for these $\boldsymbol{k}$ values. For the $E_{p,t}(\boldsymbol{k})$ bands with only sine terms in $|B|^2$, $|B|^2$ remains very small, irrespective of $\boldsymbol{k}$, very small interactions existing between p and t levels here also.

It may, therefore, be inferred that the position of the bottom of the electron band, as well as the position of the top of the hole band, will not change very much even when corrected for the interactions of the levels with different energies. Consequently, the band-gap energy will also remain unchanged, or will change at most in the order of 10^{-2} eV.

The authors wish to express their thanks to Professor Junjiro Kanamori of Osaka University for his kind discussion. They also wish to thank Professor Kenzo Jo of Osaka University and the members of his laboratory for their help in performing the calculations with an electronic computer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 742—749 (1966)

The Vibrational Spectra and Vibrational Assignments of Isotactic Polybutene-1

By Minoru UKITA

Government Industrial Research Institute, Osaka, Oyodo-ku, Osaka

(Received August 17, 1965)

The polarized infrared spectra of isotactic polybutene-1 in a hexagonal form will be measured in the region from 4000 to 700 cm^{-1}. The normal vibrations of this polymer, which takes a three-fold helical conformation, will be calculated by the use of the ***GF***-matrix method, with the modified Urey-Bradley force field. It will be found that the parallel and perpendicular bands correspond reasonably well to the calculated frequaencies of the A and E($2\pi/3$) symmetry species respectively. In accordance with these correspondences, the assignments of these bands will be made and their vibrational modes discussed.

In recent years, it has been reported that isotactic polybutene-1 exhibits three polymorphs, namely, a stable hexagonal form,[1-5,8] a stable orthorhombic form,[4,5,7-9] and an unstable tetragonal form,[2,4-9] and that these three crystalline forms exhibit significantly different infrared spectra in the region from 2000 to 400 cm^{-1}.[10-12] The spectral difference may depend upon the molecular conformations of the polymer, but the vibrational analysis of the correlation between the spectral difference and molecular conformations has not yet been dealt with.

On the other hand, the polarized infrared spectra of isotactic vinyl polymers, including the isotactic polybutene-1, were measured by Tadokoro et al.[13] in order to examine whether or not the bands associated with helical structures appear; the 1217 cm^{-1} band of isotactic polybutene-1 in the hexagonal form was proposed as the band to be associated with the helical conformation. Thereafter, the correlations of the infrared spectra with the crystallinity and the stereoregularity of the polybutene-1 samples were studied by Nishioka and Yanagisawa.[14] These studies showed that the absorption band at 1221, 1208, 1098, 1059, 1029, 922, 849, and 816 cm^{-1} in the hexagonal crystals are related to the crystallinity, while the absorption bands at 1220, 972, and 917 cm^{-1} in a carbon disulfide solution of the polymer are directly related to the stereoregularity. However, these bands have scarcely been assigned at all because of the complexity of this molecule.

Thus, in order to obtain some information about these problems, the normal vibrations for the isotactic polybutene-1 molecule of a three-fold helical conformation (hexagonal form) were calculated, using the force constants transferred from simple aliphatic hydrocarbons. The calculated frequencies will be compared with the observed frequencies, and the assignments of bands based on the calculated potential energy distributions will be given for the fundamental bands observed from 4000 to 700 cm^{-1}. The vibrational modes of the absorption bands characteristic of the three-fold helical conformation and other bands will also be discussed.

Experimental

A sample of isotactic polybutene-1 was prepared, with titanium-mercaptide as the catalyst, in the laboratory of the Toyo Soda Industrial Company. The sample was extracted with ethyl ether, and the insoluble part (ca. 75%) was used in this work. The film specimens for the measurement of the infrared spectra were obtained at about 40°C by casting a one percent solution in carbon tetrachloride on glass plates. The oriented film specimens were prepared by annealing the film at 90°C and by then elongating the film at 60°C. The polarized infrared spectra in the regions from 4000 to 2700 cm^{-1} and from 2700 to 700 cm^{-1} were taken

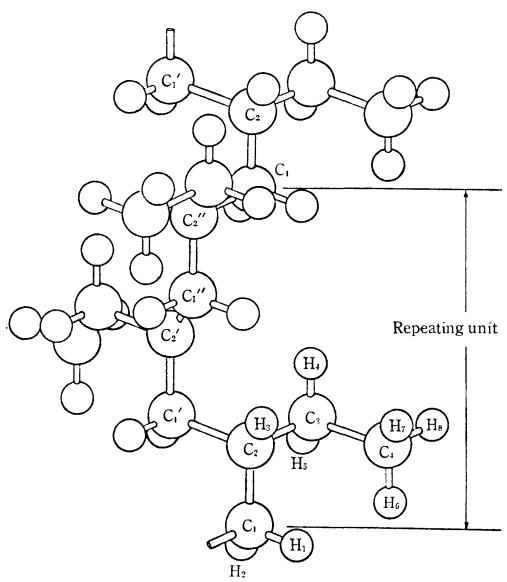

Fig. 2. Unit cell for three-fold helical structure of isotactic polybutene-1.

by using a Perkin-Elmer, model 221, grating spectrophotometer and a Hitachi Ltd., model EPI-S2, spectrophotometer respectively. The polarization measurements were carried out with a silver chloride polarizer. The observed spectra are shown in Fig. 1.

Normal Coordinate Treatment

The molecule of isotactic polybutene-1 in the hexagonal crystals contains three chemical unit, $-CH_2-CH(-CH_2-CH_3)-$, in one turn of the fiber identity period of 6.50 Å.[1-3] The unit cell for this structure is shown in Fig. 2. This model corresponds to the right-handed helix. This infinitely-extended helical structure belongs to the factor group, $C(2\pi/3)$, isomorphous with the point group, C_3; therefore, the molecular vibrations can be treated under the factor group $C(2\pi/3)$. The results of this treatment are given in Table I. Thirty-four of the modes listed in Table I belong to A species and are totally symmetric to the three-fold helical axis. Accordingly, the dipole-moment change for an A mode is parallel to the helical axis. On the other hand, the thirty-five degenerate modes belong to the E species, and the phase difference between adjacent chemical units is $2\pi/3$. The resultant dipole-moment change for an E mode is perpendicular to the helical axis.

*1 vs, very strong; s, strong; m, medium; w, weak.

*2 δ_a and δ_a', asymmetric deformations; δ_s, symmetric deformation; ν_s, symmetric stretching; ν_a, antisymmetric stretching; δ, bending; w, wagging; t, twisting; r, r_a, and r_a', rockings. The $(CH_2)_m$ and $(CH_2)_s$ represent methylene units of the main chain and the ethyl group, respectively.

The internal coordinates of a unit cell are expressed in vector notations, as in Eq. 1:

$$q = \begin{Vmatrix} q(j) \\ q(j') \\ q(j'') \end{Vmatrix} \quad (1)$$

where q(j), q(j'), and q(j'') represent the coordinates of unprimed, single-primed, and double-primed atoms, as is shown in Fig. 2. Table II lists the elements of the internal coordinate q(j). For the present coordinates, the freedom of internal rotation about CC bonds is ignored. These internal coordinates, q, were transformed into the local symmetry coordinates, S, as expressed in Eq. 2:

$$S = \begin{Vmatrix} S(j) \\ S(j') \\ S(j'') \end{Vmatrix} \quad (2)$$

The elements of the local symmetry coordinates, S(j), together with four redundant coordinates, are listed in Table III.

The $\boldsymbol{G}$ or $\boldsymbol{F}$ matrix based on the local symmetry coordinates may be factored into three matrices by the unitary transformation;[15] $\boldsymbol{G}$(A), $\boldsymbol{G}$(E), and

*1 The first row represents the calculated frequencies.

G(E*) or F(A), F(E), and F(E*). The resultant matrix, G(A) or F(A), is a real symmetric matrix of Order Thirty-two, while G(E) or F(E) is an Hermitian matrix of Order Thirty-two. G(E*) or F(E*) is the complex conjugated matrix of G(E) or F(E). Therefore, the symmetry coordinates of this helical structure are expressed as in Eq. 3:

$$\begin{aligned} S(A) &= 3^{-1/2}[S(j)+S(j')+S(j'')] \\ S(E) &= 3^{-1/2}[S(j)+S(j')e^{i\omega}+S(j'')e^{2i\omega}] \\ S(E^*) &= 3^{-1/2}[S(j)+S(j')e^{-i\omega}+S(j'')e^{-2i\omega}] \end{aligned} \quad (3)$$

where $\omega=2\pi/3$.

The force constants used in this work were transferred from the values of ethane, propane, and isobutane;[16] they are shown in Table IV. In the calculations, the bond lengths of R(C–C) and r(C–H) were taken as 1.54 and 1.09 Å respectively, and all the bond angles were assumed to be tetrahedral (109°28′) for the sake of simplicity. As an analytical method of calculating the normal vibrations, the GF-matrix method of Wilson was used.[17] The calculations of normal frequencies, L matrices, potential energy distributions, and phase angles were made with an OKITAC 5090A electronic digital compurter

*1 The first row represents the calculated frequencies.

(4000 core locations) using the programs described previously.[18,19] The calculated frequencies are shown in Tables V and VI, where they are compared with the observed frequencies. The vibrational assignments based on the potential energy distributions are shown in the last columns of Tables V and VI. The $\boldsymbol{L}$ matrix elements for the A and E symmetry species are listed in Tables VII and VIII respectively. In Table VII, the phase relations among the symmetry coordinates are represented by the signs plus and minus, which stand for in-phase and out-of-phase respectively. In Table VIII, each element for the E species is expressed by the amplitude, $|L_{jk}|$, and the phase angle (in parentheses), δ_{jk}, in degrees. The phase relations among the symmetry coordinates in a certain normal vibration are represented by the difference in phase angles (see Ref. 18).

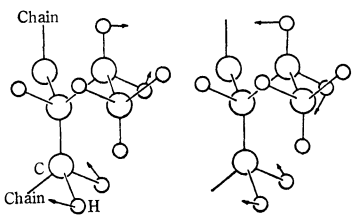
Discussion

The factor group analysis shows that the vibrational modes belonging to the A and E symmetry species have parallel ($\parallel$) and perpendicular ($\perp$) dichroisms respectively when the molecular chain is oriented along the stretching direction of the film specimen. As Tables V and VI show, the observed frequencies of parallel and perpendicular bands correspond reasonably well to the calculated frequencies of the A and E species respectively. The average deviations in this work are 1.29 (A species) and 1.12 (E species) %.

C–H Stretching Vibtations.—In the region from 3000 to 2800 cm^{-1} four perpendicular bands, at 2958, 2914, 2874, and 2851 cm^{-1}, and one parallel band at 2961 cm^{-1}, are observed. The assignments of these bands are given in Table V. All bands in this region are assigned to the overlapped modes of the A and the E species for each C–H stretching vibration. In addition to that, the CH_2 stretching vibrations for the main chain and the ethyl group are assigned to the same bands (see Table V).

CH_2 Bending and CH_3 Deformation Modes.—In the region from 1500 to 1370 cm^{-1}, three perpendicular bands, at 1463, 1439, and 1380 cm^{-1}, and two parallel bands, at 1458 and 1441 cm^{-1}, are observed. The strong bands at 1463 and 1458 cm^{-1} are assigned to the CH_3 asymmetric deformation modes, namely, $\delta'_a(CH_3)$(A, E) and $\delta_a(CH_3)$(A, E). The strong perpendicular band at 1380 cm^{-1} is easily assigned to the CH_3 symmetric deformation mode, $\delta_s(CH_3)$(A, E). The assignments of these bands related to the methyl group are consistent with those of isotactic polypropylene.[18,20-22]

The intense parallel band at 1441 cm^{-1} and the medium intensity band at 1439 cm^{-1} are assigned together to the CH_2 bending modes, but the CH_2 bending modes of the main chain and the ethyl group couple with each other in this polymer. The schematic representations of these CH_2 bending modes are shown in Figs. 3(a) and 3(b). On the basis of these normal modes, it may reasonably be understood that the 1441 cm^{-1} band has an intense parallel dichroism.



(a) (b)

Fig. 3. Vibrational modes for a chemical unit of the parallel band at 1441 cm^{-1} (a) and the 1439 cm^{-1} band (b).

CH_2 Wagging, CH_2 Twisting, CH Bending, and CH Wagging Modes.—In the region from 1370 to 1200 cm^{-1}, five perpendicular bands, at 1366, 1331, 1302, 1263, and 1207 cm^{-1}, and three parallel bands, at 1342, 1321, and 1222 cm^{-1}, are observed. As is shown in Table VI, all the bands observed from 1370 to 1300 cm^{-1} are assigned to the mixed modes of the CH_2 wagging, the CH bending, and the CH wagging. In this region, the medium intensity bands at 1331 and 1342 cm^{-1} appear in the spectra of a hexagonal form and are either extremely weak or do not appear in other crystalline forms.[12] The character of these bands may be due to the coupling of the CH_2 wagging (main chain), the CH bending, and the CH wagging modes (see Table VI).

The parallel band at 1222 cm^{-1} closely related to stereoregularity and crystallinity is observed in three crystalline forms.[12] This fact indicates that the 1222 cm^{-1} band is not affected by the molecular conformations. Therefore, it may easily be understood that this band is characteristic of stereoregularity. According to the present work, this band corresponds to the ν_{19}(A) vibration of the calculated frequency at 1235 cm^{-1}. The ν_{19}(A) vibration is associated with the CH_2 twisting, the CH bending, and the ethyl rocking modes. For this band, Tadokoro et al.[13] suggested that, in the mode assignable, the vibration

18) H. Tadokoro, M. Kobayashi, M. Ukita, K. Yasufuku, S. Murahashi and T. Torii, *J. Chem. Phys.*, **42**, 1432 (1965).

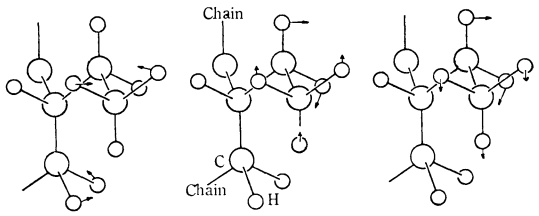
in the main chain would couple with that of the side group. This suggestion is clearly confirmed by the present work. The 1207 cm^{-1} band related to crystallinity appears only in the hexagonal form.[12] The character of this band may be due to the coupling of the CH_2 twisting (main chain) and the CH wagging modes.

CC Stretching, CH_2 Rocking, and CH_3 Rocking Modes.—In the region from 1200 to 1000 cm^{-1}, four perpendicular bands, at 1150, 1096, 1062, and 1015 cm^{-1}, and one parallel band, at 1028 cm^{-1}, are observed. The weak bands in this region are mainly assigned to the CC stretching modes, except for the 1062 cm^{-1} band, which is assigned to the coupling vibration of the CH_3 rocking and the CC stretching modes of the ethyl group. The CC stretching modes which are not localized in several CC symmetry coordinates are represented by ν(CC) in Table VI.

In the region from 1000 to 700 cm^{-1} five perpendicular bands, at 999,* 977, 924, 798, and 764 cm^{-1}, and three parallel bands, at 848, 816, and 758 cm^{-1}, are observed. The weak band at 977 cm^{-1} is assigned to the overlapped vibration (A and E species) of ν_{23}, which is associated with the coupling of the CC stretching modes of the main chain with the CH_3 rocking mode. The crystalline sensitive band at 924 cm^{-1} corresponds to the ν_{25}(E) vibration, which is associated with the coupling of the CH_2 rocking mode in the main chain with the CH_3 rocking mode. The schematic representation of this mode for a chemical unit is shown in Fig. 4(a). This mode has a transition moment perpendicular to the helical axis; therefore, the E vibration of this mode should have an intense perpendicular dichroism. This calculated result shows a good agreement with the observed result. The crystalline sensitive band at 848 cm^{-1} is assigned to the coupling vibration of the CH_3 rocking and the CC stretching modes. The medium intensity band at 816 cm^{-1} and the weak band at 798 cm^{-1} are assigned to the coupling vibration of the CH_2 rocking (main chain) and the CC stretching modes. Similar bands associated with the CH_2 rocking and the CC stretching modes have been observed at 841 ($\parallel$, medium) and 809 ($\perp$, weak) cm^{-1} in isotactic polypropylene.[18,20,22] It should be noted that similar bands are observed in this region.



(a) (b) (c)

Fig. 4. Vibrational modes for a chemical unit of the perpendicular bands at 924 cm^{-1} (a) and at 764 cm^{-1} (b), and the parallel band at 758 cm^{-1} (c).

With respect to ethyl rocking vibrations, Havey and Ketley[23] observed the infrared spectra for seven polymers with an ethyl group, and found that the ethyl rocking vibrations appear in the region from 785 to 760 cm^{-1}. According to the present work, the perpendicular band at 764 cm^{-1} and the parallel band at 758 cm^{-1} are to be assigned to the ethyl rocking modes, namely, ν_{27}(E) and ν_{27}(A) respectively. Therefore, the assignments by Havey et al. are consistent with the calculated results. The schematic representations of these modes for a chemical unit are shown in Figs. 4(b) and 4(c).

The dichroic properties of the observed bands can reasonably be explained by the normal modes. The molecular vibrations in the far infrared region will be reported on in the near future.

The author wishes to thank Professor Hiroyuki Tadokoro of Osaka University, and Dr. Isao Shiihara and Dr. Kazuo Nagai of this laboratory, for their kind guidance throughout the course of this work. He also wishes to thank Mr. Hiroshi Tamaoki of the Toyo Soda Industrial Company for supplying the sample, and Mr. Kiyohisa Imada of Kyushu University and Mr. Toshihide Ishikawa of this laboratory for supplying the routine programs.

* The weak perpendicular band at 999 cm^{-1} is observed in the spectra of three crystalline forms, and it is difficult to obtain a reasonable correspondence with a calculated frequency. Therefore, this band may be associated with the vibration of the atactic part or the end group of isotactic polybutene-1.

Dipole Moment and Molecular Structure of Copolymers. III. Dipole Moment of *p*-Methoxystyrene - Styrene Copolymers and *p*-Chlorostyrene - Styrene Copolymers

By Akira KOTERA, Keizo SUZUKI, Kimiyoshi MATSUMURA, Mikiko SHIMA and Etsuro JOKO

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received August 18, 1965)

The *p*-methoxystyrene monomer has been synthesized from anisole through *p*-methoxyacetophenone and *p*-methoxyphenyl methyl carbinol. Then copolymers of *p*-methoxystyrene and styrene have been prepared. The dielectric properties of the copolymers in a benzene solution have been measured, and it has been found that the value of the dipole moment, μ, of the *p*-methoxystyrene monomer unit in the copolymers increases with an increase in the styrene content, e. g., from 1.21 D (for poly-*p*-methoxystyrene) to 1.32 D (for the copolymer in which the mole fraction of *p*-methoxystyrene is 0.175) at 20°C. The variation in the value of μ has been discussed in view of the detailed arrangement of polar monomer units. The theory concenring the relation between the dielectric polarization and the detailed structure of the copolymer molecule developed in the preceding paper, Part I, has been applied to the experimental results. In addition, a similar analysis has been made for the dielectric polarizations of the *p*-chlorostyrene - styrene copolymers which had been measured previously by one of the authors.

The properties of copolymers should depend on the detailed arrangement of the monomer units as well as on their composition. For instance, there are three different arrangements that can be considered for a copolymer which contains equimoles of A and B monomer units:

(1) —AAAAAABBBBBBAAAAABBBBB—

(2) —ABABABABABABABABABAB—

(3) —AABBBAAABABAABBBABBAAA—

(1) The block arrangement, in which long sequences predominate. A copolymer having this structure is usually called a block copolymer.

(2) The regular alternating arrangement, in which the sequence length is always 1.

(3) The random arrangement, in which short sequences of A units alternate with short sequences of B units in an essentially random fashion. This arrangement may be considered the molecular structure of a normal copolymer.

The copolymers with these three structures can be expected to have different properties: they may be considered to be different chemical species, even though they have the same overall composition. The copolymer which has a structure of type 1 might be expected to resemble, in many respects, a simple mixture of the homopolymers of A and B. A short-sequence copolymer, on the other hand, would be expected to be unlike a mixture of the two homopolymers.

The reaction mechanism of copolymerization has been discussed in detail more than once.[1,2] From the basic theory of copolymerization, it is possible to calculate the number-average sequence length of monomer units and, hence, a statistically probable arrangement of individual monomer units in the copolymer molecular chain, the monomer reactivity ratios of which are known. However, as has already been mentioned,[3,4] there has yet been no convincing experimental evidence of the distribution of sequence lengths of individual monomer units in the copolymer molecule. A number of methods have been proposed in attempts to gain information about the detailed arrangement of individual monomer units in copolymers. They include the dechlorination of the vinyl chloride - vinyl acetate copolymer with zinc by Marvel et al.,[5] the intramolecular gamma-lactone formation in vinyl alcohol - acrylic acid copolymers,[6] and a study of the solution properties of partially-acetylated polyvinyl alcohol.[7] Recently developed methods have include the study of the dielectric properties of *p*-chlorostyrene-styrene copolymers in the solid state[8] and the

in which 39.7 cc. was used as the value of $(\mathrm{MR})_D$ for the *p*-methoxystyrene monomer unit.

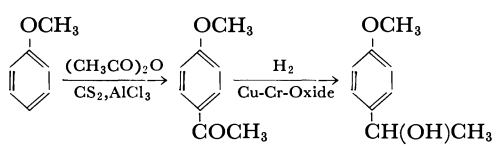
*b Polystyrene

infrared spectroscopic study of acrolein-acrylonitrile copolymers.[9] One of the present authors previously measured the dielectric properties of copolymers of methyl methacrylate - styrene[3] and methyl acrylate - styrene[4] in benzene solution, and developed a theory which connects the average dielectric polarization of copolymers with the detailed arrangement of monomer units in the copolymer molecule.

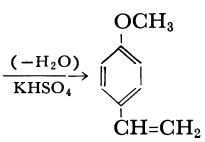
In this paper, we will work on the dielectric properties of copolymers of *p*-methoxystyrene and styrene, and will discuss the experimental results by applying the theory described in a preceding paper, Part I.[3] In addition, we will describe the results of a similar analysis for the *p*-chlorostyrene - styrene copolymers, the dielectric polarizations of which were measured previously by one of the present authors.[10]

Experimental

The Synthesis of the *p*-Methoxystyrene Monomer.—The *p*-methoxystyrene monomer was synthesized through the following three processes:



(I) (II)



(III)

p-Methoxyacetophenone (I) was prepared, by means of the Friedel-Craft reaction, from anisole and acetic acid anhydride in carbon disulfide, in the presence of anhydrous aluminum chloride.[11] *p*-Methoxyphenyl methyl carbinol (II) was obtained by the reduction of *p*-methoxyacetophenone with copper-chromium-oxide and hydrogen; this was carried out in an autoclave under a high pressure of more than 100 atm.[12,13] The reaction of the dehydration was carried out by heating *p*-methoxyphenyl methyl carbinol with acid potassium sulfate, and then distilling the *p*-methoxystyrene.

Copolymerization.—The *p*-methoxystyrene monomer was dried with anhydrous sodium sulfate and distilled three times under reduced pressure prior to polymerization; the b. p. was 84—86°C/8 mmHg. The styrene monomer used in these experiments was a commercial one, which was washed with a 10% aqueous solution of sodium hydroxide and water, dried with anhydrous sodium sulfate, and distilled under reduced pressure; the b. p. was 45—46°C/17 mmHg.

Monomer mixtures which total about 25 g. and which contain no catalyst were prepared over a whole range of composition and sealed in glass tubes. The polymerizations were carried out thermally by holding the tubes in an oil-bath at 100°C for about 120 hr. The

polymers were precipitated from a benzene solution into methanol and dried in a high vacuum.

Measurements of the Dielectric Polarization of Copolymers.—The experimental determination of the dielectric polarization of copolymers was carried out in the usual way by measuring the dielectric constants and the specific volumes of the copolymer solutions. The apparatus was similar to that described in Part I.[3] The cell is composed of three concentric platinum cylinders in a glass tube, and its capacity is about 35 $\mu\mu$F. The cell capacitance measurements were made by the heterodyne-beat method at a frequency of 500 kilocycles per second. The specific volumes were measured by "the mess-flask type" pycnometer, the volume of which was about 10 cc. The extrapolated values of the specific polarization of the copolymer at an infinite dilution were calculated according to the Halverstadt-Kumler equation[14]:

$$p_2 = \frac{3\alpha v_1}{\varepsilon_1+2} + (v_1 + \beta)\frac{\varepsilon_1-1}{\varepsilon_1+2} \qquad (1)$$

where ε_1 and v_1 are the dielectric constant and the specific volume of the solvent (benzene) respectively. α and β, denoting the dielectric constant and the specific volume of solution, ε_{12} and v_{12} respectively, are given as:

$$\varepsilon_{12} = \varepsilon_1+\alpha w_2, \quad v_{12} = v_1+\beta w_2$$

where w_2 is the weight fraction of the solute (the copolymer).

The dielectric constants and the specific volumes were measured on four solutions of different concentrations, from 1% to 9%, for each copolymer sample. The values of α and β obtained are given in Table I.

The specific polarization of copolymer, p_2, can be expressed as follows:

$$p_2 = w_A p_{MeO}+(1-w_A)p_{St} \qquad (2)$$

where w_A is the weight fraction of *p*-methoxystyrene in the copolymer, and p_{MeO} and p_{St} are the effective specific polarizations associated with *p*-methoxystyrene and styrene monomer units, respectively, in the copolymer molecule. As the styrene monomer is nonpolar, the value of p_{St} may not be very greatly influenced by the neighboring groups. Therefore, it was assumed that the value of p_{St} is the same as that of polystyrene. The average molecular polarization of *p*-methoxystyrene monomer units in the copolymer molecule, $P_{Av}(=M_A p_{MeO}$: M_A is the molecular weight of the *p*-methoxystyrene monomer unit) was calculated from Eq. 2. Further, the sum of electronic polarization and atomic polarization was assumed to be equal to the molecular refraction for the D line calculated from the atomic refractions of the constituent atoms. The dipole moment of the *p*-methoxystyrene unit was calculated by the equation:

$$\mu = 0.0128\times\{(P_{Av}-[MR]_D)T\}^{1/2} \qquad (3)$$

$[MR]_D$; the molecular refraction for the D line.

Results and Discussion

Experimental Results for *p*-Methoxystyrene-Styrene Copolymers.—The results of experiments are summarized in Table I. The tendency found in the cases of the copolymers of methyl methacrylate - styrene and methyl acrylate - styrene is also observed in the variation in μ value with the composition of the copolymers. The value of the effective dipole moment of the *p*-methoxystyrene monomer unit in the copolymers increased with an increase in the styrene content; i. e., the value of μ increased from 1.21 D for poly *p*-methoxystyrene ($x=1.000$) to 1.32 D for the copolymer of $x=0.1749$ at 20°C and from 1.24 D to 1.34 D at 50°C. This may be interpreted qualitatively as follows: the value of the dipole moment of the *p*-methoxystyrene monomer unit obtained from the measurement of the homopolymer is not the value of the isolated unit. Rather, it includes the effect of intramolecular interactions between the neighboring polar units along the chain, i. e., the influence of dipole-dipole interactions, steric hindrance, and so on. Because of the influence of these interactions, the value of μ in the poly-*p*-methoxystyrene should be smaller than that of the isolated equivalent unit. In the copolymer molecule, the influence of the dipole-dipole interactions may be reduced by the nonpolar styrene units separating the polar units. The increase in the styrene content should increase the isolated *p*-methoxystyrene units in the copolymer molecule, and, accordingly, the value of μ will approach that of the isolated unit.

The Relation between the Dielectric Polarization and a Detailed Arrangement of Polar Monomer Units in the Copolymer Molecule.—By applying the theory described in Part I,[3] to the experimental results, we shall attempt to treat quantitatively the relation between the dielectric polarization and the detailed arrangement of *p*-methoxystyrene units in the copolymer molecule. If it is assumed that the polar monomer units in a polar (A) - nonpolar (B) copolymer molecule can be classified into three types:

(1) two neighbors along the chain are the same polar units, A and A:

~~~ A Ⓐ A ~~~

(2) one neighbor is the polar unit A, and the other is the nonpolar unit B:

~~~ A Ⓐ B ~~~

(3) both neighbors are nonpolar units, B and B:

~~~ B Ⓐ B ~~~

and that these three types have different values of molecular polarization, P_{AA}, P_{AB} and P_{BB} respectively, then the average molecular polarization of the monomer unit, A, in the copolymer molecule, P_{Av}, may be given by the equation:

$$P_{Av} = P_{AA}F_{AA}+P_{AB}F_{AB}+P_{BB}F_{BB} \qquad (4)$$

where F_{AA}, F_{AB} and F_{BB} are the fractions of the polar monomer units A in the states of (1), (2) and (3) respectively. This equation can be transformed as follows, provided that f_{AA} is the

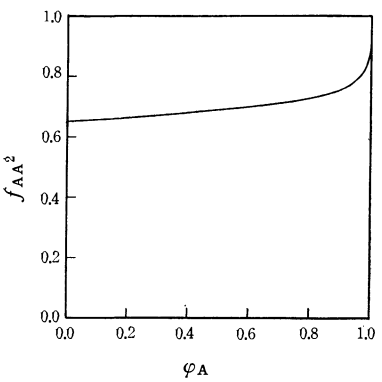
Conversion of *p*-methoxystyrene monomer



Conversion of *p*-methoxystyrene monomer

Fig. 2. Up, probability of AA sequence arising in copolymer; under, probability of double AA sequence arising in copolymer. $x_0=0.5799$

probability that a neighbor of the polar monomer unit A is polar:

$$P_{Av}=P_{AA}\overline{f_{AA}^2}+2P_{AB}(\overline{f_{AA}}-\overline{f_{AA}^2})+P_{BB}(1-2\overline{f_{AA}}+\overline{f_{AA}^2}) \quad (5)$$

The averages of f_{AA} and f_{AA}^2 can be calculated from the equations:

$$\overline{f_{AA}}=\frac{\int_0^{\varphi_A} f_{AA}\,d\varphi_A}{\int_0^{\varphi_A} d\varphi_A} \quad \text{and} \quad \overline{f_{AA}^2}=\frac{\int_0^{\varphi_A} f_{AA}^2\,d\varphi_A}{\int_0^{\varphi_A} d\varphi_A} \quad (6)$$

where φ_A is the conversion of the monomer A. f_{AA} and φ_A are related to each other through the mole fraction, x, of the A monomer in the monomer mixture, as is given by the equations:[1]

$$f_{AA}=\frac{r_1x}{r_1x+1-x} \quad \text{and}$$

$$(1-\varphi_A)=\left(\frac{x}{x_0}\right)^{1/(1-r_2)}\left(\frac{1-x}{1-x_0}\right)^{r_1/(1-r_1)}\times\left\{\frac{(r_1+r_2-2)x-(r_2-1)}{(r_1+r_2-2)x_0-(r_2-1)}\right\}^{r_1r_2-1/(1-r_1)(1-r_2)}$$

where x_0 is the x of the initial monomer mixture, and r_1 and r_2 are the monomer reactivity ratios. As f_{AA} and f_{AA}^2 can not be expressed as an explicit function of φ_A, we calculated the values of $\overline{f_{AA}}$ and $\overline{f_{AA}^2}$ by the numerical integrations of Eq. 6.

The Results of Calculation for Copolymers of *p*-Methoxystyrene - Styrene and *p*-Chlorostyrene - Styrene.—Figures 1—4 show f_{AA} and f_{AA}^2 as functions of the conversion, φ_A, of the A monomer for each sample of *p*-methoxystyrene - styrene copolymers. In this experiment, the monomers A and B referred to *p*-methoxystyrene and styrene respectively, and the values of $r_1=0.82$ and $r_2=1.16$[15] were employed in the calculation of f_{AA}. The values of $\overline{f_{AA}}$ and $\overline{f_{AA}^2}$ were obtained from the evaluation of the areas under the curves in these figures: they are given in Table III.

One of the present authors previously measured the dielectric properties of *p*-chlorostyrene - styrene copolymers in a benzene solution. Table II gives the results of these measurements.[16] We

as functions of the conversion of the *p*-chlorostyrene monomer. The monomer reactivity ratios for this copolymer system, $r_1=1.038$ and $r_2=0.786$, were employed[17]: the values of $\overline{f_{AA}}$ and $\overline{f_{AA}^2}$ calculated from these figures are shown in Table III.

By substituting the values of $\overline{f_{AA}}$ and $\overline{f_{AA}^2}$ and the experimental data of P_{Av} into Eq. 5, the values of P_{Av} and P_{BB} were obtained by the method of least squares. The last columns in Table I and Table II give the theoretical values of the average

molecular polarization obtained by Eq. 5 for the polar monomer unit in the copolymers. These values are also shown in Fig. 5 and Fig. 11 as a function of the composition of copolymers and compared with the experimental values. The good agreement of these results with the experimental values over the whole range of composition implies that the values of P_{AA}, P_{AB} and P_{BB} are practically constant and that the assumptions made in the theory are reasonable in the case of the copolymers of both *p*-methoxystyrene - styrene and *p*-chlorostyrene - styrene. The values obtained for P_{AA}, P_{AB} and P_{BB} are given in Table IV. The values of μ_{AA}, μ_{AB} and μ_{BB} were calculated by using Eq. 3.

The difference in the values of μ at 20°C and 50°C may be interpreted in terms of the internal rotation in the polymer molecule. It is known that in a chain molecule of polymer, the internal rotation around the C–C bonds of the chain skeleton is not free and that three energetically-favored positions persist, i. e., one "trans" and two "gauche" configurations.[18] The temperature dependence of the potential energy for the restricted rotation may explain the difference in values of μ at 20°C and 50°C.

It was noticed that the shape of the curves in Figs. 5 and 11 is not similar to that for the methyl methacrylate - styrene copolymers or methyl acrylate - styrene copolymers; i. e., in Figs. 5 and 11, the curve of P_{Av} seems to be almost linear with respect to x. This may be because, in the case of *p*-methoxystyrene - styrene copolymers and *p*-chlorostyrene - styrene copolymers, the difference between the values of P_{AA} and P_{BB} is rather small, the value of P_{AB} is close to the average of P_{AA} and P_{BB}, and the value of f_{AA} is almost equal to that of the mole fraction, x, therefore, Eq. 5 can be regarded as approximately a linear function of x.

According to the definition of P_{BB}, μ_{BB} is the dipole moment of the polar group which is separated by nonpolar groups from the influence of the interactions of the other polar groups in the same copolymer molecule; its value may be compared with that of the dipole moment of the polar group in an isolated state, which can be obtained from measurements in a nonpolar solvent. The experimental value of the dipole moment of *p*-methoxyethyl-benzene is not knwon, but by taking the

○ ; experimental values (at 25°C)

vector sum of the moment of anisole, 1.25 D,[19] and that of toluene, 0.37 D,[19] we can obtain 1.16 D as the calculated value. The value of μ_{BB} in the *p*-methoxystyrene - styrene copolymer was 1.35—1.37 D. The dipole moment of *p*-chlorotoluene is known to be 1.94 D,[19] which may be compared with the μ_{BB} values of 1.75—1.78 D in the *p*-chlorostyrene - styrene copolymer. In the above comparison, it can be seen that the values of μ_{BB} are always a little smaller than those of the moments of the polar groups in the isolated state. These differences may be due to the effect of the induced moments of the neighboring styrene monomer units, which are induced on benzene nuclei by the polar group under consideration. A comparison of the μ_{BB} value of the *p*-methoxystyrene unit with that of the *p*-chlorostyrene unit suggests that the inductive effect may be a little larger in the *p*-methoxystyrene - styrene copolymer than in the *p*-chlorostyrene - styrene copolymer, and that the average of the angle between the dipole moment of the polar group and the induced dipole moment may be nearer to 180° in the former than in the latter.

It was noticed that the values of μ_{AB} are very near the average value of μ_{AA} and μ_{BB} in both copolymers. The value of $(\mu_{BB}-\mu_{AB})/(\mu_{AB}-\mu_{AA})$ is 0.08/0.06 at 20°C and 0.08/0.05 at 50°C in the *p*-methoxystyrene - styrene copolymer, and 0.15/0.21 at 25°C and 0.16/0.20 at 50°C in the *p*-chlorostyrene - styrene copolymer. The difference between μ_{BB} and μ_{AB} gives the decrease in the moment caused by the interaction effect of one neighboring polar group, which was introduced as a neighbor instead of the nonpolar styrene group, while the difference between μ_{AB} and μ_{AA} is the further decrease in the moment caused by the replacement of the neighboring styrene with a polar group. It appears that, in the *p*-methoxystyrene - styrene copolymer, the first decrease in the moment is a little larger than the second decrease, while the reverse is true in the *p*-chlorostyrene - styrene copolymer. However, the difference between $(\mu_{BB}-\mu_{AB})$ and $(\mu_{AB}-\mu_{AA})$ is so small in these copolymers that these two values may be considered to be almost equal to each other. In the copolymer in which there is a possibility of internal rotation within the polar group, the value of $(\mu_{BB}-\mu_{AB})$ should be much larger than that of $(\mu_{AB}-\mu_{AA})$, which was found in previous considerations of the methyl methacrylate - styrene copolymer and the methyl acrylate - styrene copolymer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 758—761 (1966)

Copolymerization Characteristics of Methyl Acrylate and Methyl Methacrylate. II. Analysis of Methyl Acrylate-Methyl Methacrylate Copolymers by Infrared Spectroscopy

By Akira KOTERA, Mikiko SHIMA, Katsuo AKIYAMA, Masako KUME and Machiko MIYAKAWA

Department of Chemistry, Faculty of Science, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo

(Received August 18, 1965)

The infrared absorption spectra of polymers and copolymers of methyl acrylate and methyl methacrylate have been measured, and then used as the basis of a spectrophotometric method for the analysis of the copolymers. The 6.73 μ band, which may be due to methyl (–C–CH_3) vibration, was selected as the key band for measuring the methyl methacrylate component, while the 6.89 μ band was used as the standard. The monomer reactivity ratios for copolymerization of methyl acrylate - methyl methacrylate system have been determined to be $r_1=0.5\pm0.1$, and $r_2=2.3\pm0.4$ (M_1; methyl acrylate, M_2; methyl methacrylate) at 130°C. These values are in good agreement with those previously obtained by the deuterium tracer method. It has also been shown that the procedure used in this study is appropriate for the analyses of methyl acrylate - methyl methacrylate copolymers.

In a preceeding paper,[1] we have investigated the copolymerization kinetics of the methyl acrylate-methyl methacrylate system by using monomers containing deuterium as a tracer. As we mentioned in that paper, it is difficult to determine the composition of the copolymers of methyl acrylate and methyl methacrylate by using the conventional combustion analysis because of the similarity of the component monomers in chemical composition. In such a case, the spectrophotometric method may be useful.

When the infrared absorption spectra of the polymers and the copolymers of methyl acrylate and methyl methacrylate were measured, it was found that the ratio of the optical density of the absorption band at 6.73μ, which may be due to methyl (–C–CH_3) vibration, to that of the band at 6.89μ, which is probably due to methylene (–CH_2–) vibration, changes linearly with the change in the composition of copolymers. By using these two bands as the key bands for the analysis of the copolymer, the composition of the copolymers were determined; we also attempted to determine the monomer reactivity ratios for the copolymerization of this system.

Experimental

Copolymerization.—The methyl acrylate and methyl methacrylate monomers used in these experiments were supplied by the Mitsubishi Rayon Company. They were distilled twice under a reduced nitrogen atmosphere; the b. p.'s were 28°C/110 mmHg and 35.5°C/70 mmHg respectively. The polymerizations were carried out thermally in sealed pyrex tubes, each of which contained about 0.2 mol. of the monomer mixture and no catalyst. The tubes were kept in an oil-bath at 130°C and removed when the desired degree of conversion ($\leq 10\%$) had been reached. The polymers were precipitated from a benzene solution into methanol and dried in a high vacuum to a constant weight.

Measurements of Infrared Absorption Spectra.—The infrared spectra of the samples were measured by using a Nippon Bunko, Model SDl0l, double-beam spectrometer with a NaCl prism. All the samples were in the form of a solid film approximately 0.01 mm. thick; these films were prepared on a surface of mercury from the chloroform solution. The infrared spectra of polymethyl acrylate, polymethyl methacrylate, and copolymers are shown in Figs. 1—3.

In the 6—7 μ region, the spectra of polymethyl methacrylate and the copolymer show two absorption bands. The absorption band at 6.73 μ, which may be due to a methyl (–C–CH_3) deformation vibration,[2] decreases as the methyl methacrylate component in the copolymer decreases, and disappears in polymethyl acrylate. On the other hand, the intense band at 6.89 μ, which is probably due to a methylene (–CH_2–) vibration,[3] doesn't change appreciably with the change in the composition of the copolymers.

These two bands were used as a measure of methyl (–C–CH_3) groups and methylene (–CH_2–) groups respectively. The optical density at 6.73 μ, D_1 is, expressed as follows from the Beer-Lambert law:[4]

$$D_1=\log\frac{I_0^1}{I_1}=k_1^1c_1t+k_1^2c_2t \qquad (1)$$

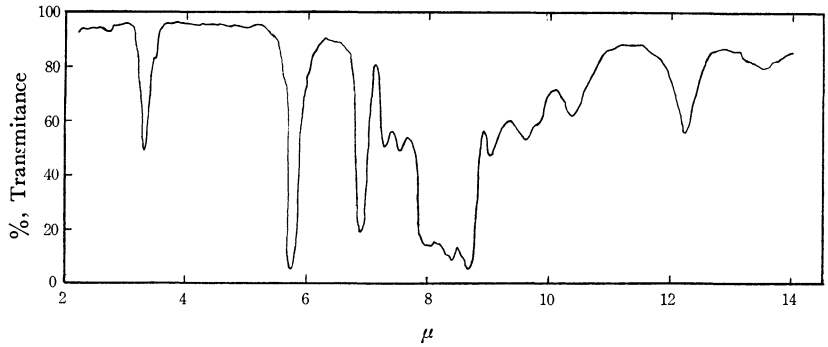

Fig. 1. Infrared spectra of polymethyl acrylate for ca. 0.01 mm. solid film.

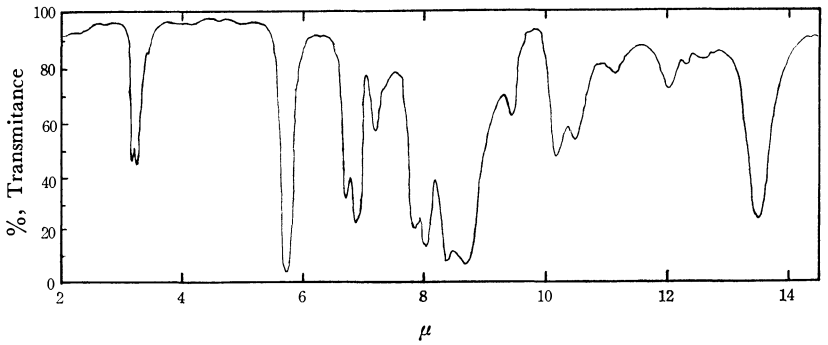

Fig. 2. Infrared spectra of polymethyl methacrylate for ca. 0.01 mm. solid film.

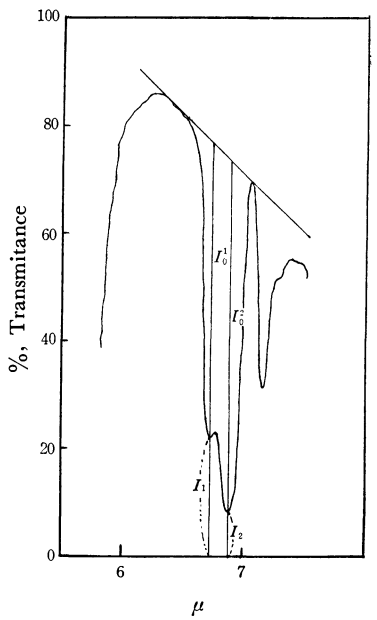

Fig. 3. The 6 to 7 μ region of a typical copolymer of methyl acrylate and methyl methacrylate.

where I is the transmission measured by the height of the absorption peak; k_1^1 and k_1^2 are the extinction coefficients of the 6.73 μ band and of the 6.89 μ band at 6.73 μ respectively; c_1 and c_2 are the number of methyl ($-C-CH_3$) groups and methylene ($-CH_2-$) groups per gram respectively, and t is the thickness of the film. The optical density at 6.89 μ, D_2, is given as:

$$D_2=\log\frac{I_0^2}{I_2}=k_2^2c_2t \tag{2}$$

where k_2^2 is the extinction coefficient of the 6.89 μ band at 6.89 μ. In order to eliminate the necessity of making an accurate measurement of the thickness of each sample, the ratio of the optical density of the 6.73 μ band, D_1, to that of the 6.89 μ band, D_2, was employed:

$$\frac{D_1}{D_2}=\frac{k_1^1c_1}{k_2^2c_2}+\frac{k_1^2}{k_2^2} \tag{3}$$

Therefore, if it is assumed that the Beer-Lambert law is valid in these samples and that the effect of methyl groups at chain ends can be neglected, a linear relationship should exist between D_1/D_2 and the mole fraction of methyl methacrylate in the copolymer, $f_2(=c_1/c_2)$.

The calibration curve was obtained from the measurements of the samples of a mixture of polymethyl acrylate and polymethyl methacrylate. All the samples were optically-uniform films which had been prepared from the chloroform solution of polymethyl acrylate and polymethyl methacrylate. The measurements for D_1/D_2 were repeated three to five times on each sample; the mean values of the measurements are shown in Table I. The data in this table are plotted in Fig. 4, where they prove the linear relation between D_1/D_2 and f_2. A least-square treatment of the points gives the following equation:

$$\frac{D_1}{D_2}=0.744(\pm0.0018)f_2+0.053(\pm0.012) \tag{4}$$

Using this equation, the composition of the copolymers in Table III was calculated.

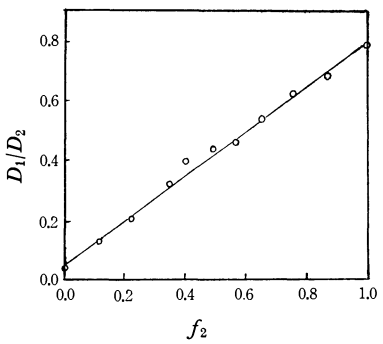

Fig. 4. Calibration curve for the composition of copolymers.

TABLE I. DATA FOR CALIBRATION CURVE

Sample	f_2	D_1/D_2
PMA	0.0000	0.0297
1	0.1133	0.129

f_2 is the mole fraction of methyl methacrylate in the sample. D_1 and D_2 are the optical densities of the absorption band at 6.73 μ and of the absorption band at 6.89 μ, respectively. The measurements for D_1/D_2 were repeated three to five times on each sample, and the mean values of the measurements are shown.

Results

The results of the experiments are summarized in Table II and Table III. The monomer reactivity ratios were determined by the method of Fineman and Ross.[5] The ratio of the molar concentrations of two monomers in the copolymer formed may be given by the following relation,[6]

TABLE II. COPOLYMERIZATION CONDITION

Expt. No.	F_2	Monomer g.	Polymer g.	Time min.	Conversion %

C6	0.0000	29.758	16.1247	50	54.19

F_2 is the mole fraction of methyl methacrylate in the initial monomer mixture.

5) M. Fineman and S. D. Ross, *J. Polymer Sci.*, **5**, 259 (1950).
6) T. Alfrey, Jr., J. J. Boher and H. Mark, "Copolymerization," Interscience Publishers, New York (1952), p. 10.

TABLE III. COMPOSITIONS OF COPOLYMERS

Sample	F_2	D_1/D_2	f_2
C2	0.7915	0.7047	0.876
C3	0.5912	0.5913	0.724
C4	0.3971	0.4732	0.565
C5	0.1998	0.2619	0.281

F_2 is the mole fraction of methyl methacrylate in the initial monomer mixture, and f_2 is the mole fraction of methyl methacrylate in the copolymer.

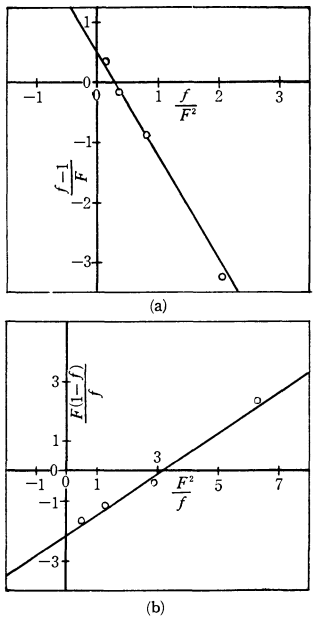

Fig. 5. Treatment of copolymer composition data by the method of Fineman and Ross. (a) using Eq. (5), (b) using Eq. (6).

provided the conversion is low;

$$\frac{m_1}{m_2}=\frac{M_1}{M_2}\cdot\frac{r_1M_1+M_2}{r_2M_2+M_1}$$

where M_1 and M_2 represent the molar concentrations of the respective monomers in the initial monomer mixture, and where r_1 and r_2 are the monomer reactivity ratios. Fineman and Ross made the $F=M_1/M_2$ and $f=m_1/m_2$ substitutions in the above equation, and so obtained the following equations:

$$\frac{f-1}{F}=\frac{-r_2f}{F^2}+r_1 \qquad (5)$$

$$\frac{F(f-1)}{f}=\frac{r_1F^2}{f}-r_2 \qquad (6)$$

Thus, a plot of $(f-1)/F$ against f/F^2 yields a straight line with a slope of r_2 and an intercept of r_1, while the latter equation yields r_1 as the slope and r_2 as the intercept. The data of Table III are plotted in Fig. 5 using both Eqs. 5 and 6.

A least-square treatment of the points yields:

$r_1 = 0.5 \pm 0.1$ using Eq. 5

$r_2 = 2.3 \pm 0.4$ using Eq. 6

(M_1: methyl acrylate; M_2: methyl methacrylate)

These values agree with those previously obtained by the deuterium tracer method, $r_1 = 0.47 \pm 0.09$ and $r_2 = 2.3 \pm 0.5$. This means that the procedure used in these experiments is quite appropriate for the analysis of methyl acrylate - methyl methacrylate copolymers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 761—766 (1966)

The Rotatory Dispersion and Stereochemistry of Organic Compounds. IX.[1] The Nitrates of Glucose

By Yojiro Tsuzuki, Koko Tanabe and Kikuhiko Okamoto

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received August 23, 1965)

We have measured the rotatory dispersion (RD) and the ultraviolet absorption of twelve nitrates of glucopyranosides carrying a nitrate chromophore, $-O-NO_2$, in the position of the carbon atoms 1, 2, 3, 4, and 6. On the basis of the experimental results and of those results already reported concerning four nitrates,[1] studies have been made as to the correlation between the configuration and the Cotton effect. The sign of the Cotton effect has been determined by the RD curve as well as by the dispersion constant as computed from the dispersion data. A regular relation has been found, namely, irrespective of the position of the nitrate group on the carbon atom, α-glucosides with a nitrate chromophore in the α- or (D)-configuration show negative Cotton effects, while the sign of the Cotton effects of the corresponding β-glucosides is positive. On the contrary, α-glucosides with a nitrate chromophore in the β- or (L)-configuration show positive Cotton effects, while the sign of the Cotton effects of the corresponding β-glucosides is negative.

In a previous preliminary report[1] it has been shown, with some nitrates of glucose, that the $-C-ONO_2$ (nitrate) chromophore has a feeble optically active absorption around 270 mμ ($\varepsilon \sim 20$) and gives rise to a Cotton effect at a region nearly 20 mμ longer than that of the ultraviolet absorption.

In this paper further studies will be reported; these studies were carried out with various nitrates of glucose (Table I) with the object of elucidating the correlation between the configuration and the sign of the Cotton effect, especially the optical rotatory contribution of the functional group attached to each asymmetric center.

Results and Discussion

Figure 1 shows the RD curves of the α- and β-anomers of C_1-nitrates (2, 3, 4, 6-tetraacetyl-α-D-glucopyranose-1-nitrate (I) and the β-anomer (II)). The compound I exhibits a positive Cotton effect which has a peak at 285 mμ, while the compound II shows a negative one, the trough of which lies at 298 mμ. The curve I is positively increased more than the background RD curve XVII (pentaacetyl-α-D-glucopyranose), indicating that the α-C_1-ONO_2 chromophore makes a larger positive rotatory contribution that the C_1-OH group, which is usually expected to make a positive rotatory contribution. (It should, however, be remarked that the C_1-xanthate chromophore has been found to exhibit a distinctly negative Cotton effect,[2] just the opposite effect.)

In a similar, inverse way, the β-C_1-ONO_2 group contributes to the negative rotation of the compound II (Fig. 1), just opposite in sign to the positive effect of the β-C_1-xanthate group.[2]

The compound I, with 1α-$C-ONO_2$, is of the R-configuration according to the rule of Cahn et al.[3]; this is in harmony with the positive Cotton effect, and the absolute configuration of the compound II with β-C_1-ONO_2 is s, in accordance negative effect.

Figure 2 gives the RD curves of a number of various anomers with a nitrate group at the C_2-position. The compounds III and IV in the α-configuration show a weak negative Cotton effect, as has already

Table I. Nitrates of glucose

Compound			Compound		
I	2,3,4,6-Tetra-*O*-acetyl-1-*O*-nitro-α-D-glucopyranose		X	Methyl 4:6-*O*-ethylidene-α-D-glucopyranoside 2:3-dinitrate	II	2,3,4,6-Tetra-*O*-acetyl-1-*O*-nitro-β-D-glucopyranose		XI	Methyl 4:6-*O*-ethylidene-β-D-glucopyranoside 2:3-dinitrate	III[1]	1,3,4,6-Tetra-*O*-acetyl-2-*O*-nitro-α-D-glucopyranose		XII[1]	Methyl 4:6-*O*-benzylidene-α-D-glucopyranoside 2:3-dinitrate	IV[1]	3,4,6-Tri-*O*-acetyl-2-*O*-nitro-α-D-glucopyranosyl chloride		XIII	Methyl 4:6-*O*-benzylidene-β-D-glucopyranoside 2:3-dinitrate	V	1,3,4,6-Tetra-*O*-acetyl-2-*O*-nitro-β-D-glucopyranose		XIV	Methyl 2,3,6-tri-*O*-acetyl-4-*O*-nitro-β-D-glucopyranoside	VI	3,4,6-Tri-*O*-acetyl-2-*O*-nitro-β-D-glucopyranosyl chloride		XV	Methyl 2,3-di-*O*-acetyl-4,6-di-*O*-nitro-β-D-glucopyranoside	VII	Methyl 4:6-*O*-ethylidene-β-D-glucopyranoside 2-nitrate		XVI	Methyl 2,3,4-tri-*O*-acetyl-6-*O*-nitro-α-D-glucopyranoside	VIII[1]	Methyl 4:6-*O*-benzylidene-α-D-glucopyranoside 3-nitrate		XVII[1]	Pentaacetyl-α-D-glucopyranose	IX	Methyl 4:6-*O*-ethylidene-β-D-glucopyranoside 3-nitrate		XVIII	Pentaacetyl-β-D-glucopyranose	
been reported,[1] while the corresponding β-anomers (compounds V and VI) show positive Cotton effects, with peaks at 295 and 300 mμ respectively. The ethylidene derivative (VII) of the β-configuration likewise exhibits a positive Cotton effect, with a peak at 300 mμ.

As may be seen from Fig. 2, all the β-anomers show relatively low rotations as a result of the background laevorotatory contribution of the β-glucosidic type (XVIII); this is consistent with the fact that the C_1–OH far surpasses the C_2–OH in rotatory contribution to glucose. A similar interpretation can be made of the RD curves of the nitrates of the α-form (III and IV) and the background α-pentaacetate (XVII), where the discrepancy in rotation is very little except the

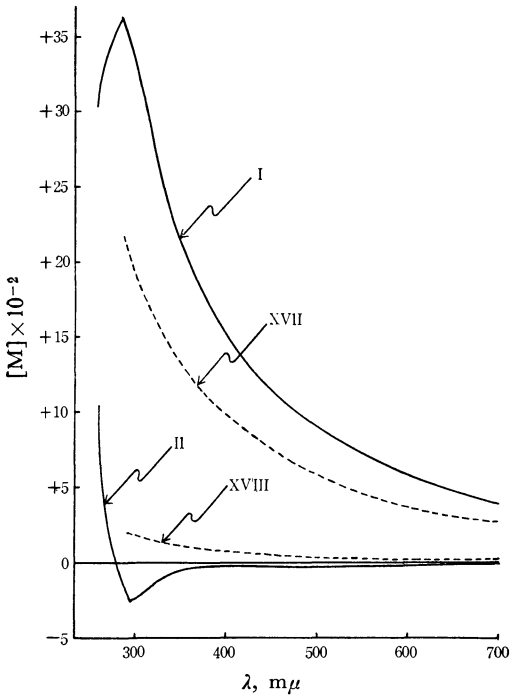

Fig. 1. RD of α- and β-1-nitrates of glucose.

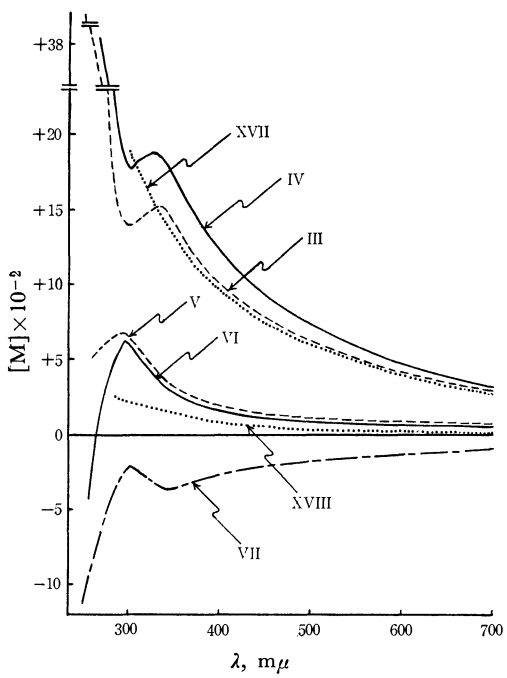

Fig. 2. RD of α- and β-2-nitrates of glucose.

feeble Cotton effects of the former due to the nitrate chromophore.

The rule of Cahn et al. does not appear to hold with the C_2-nitrates(R), since the α-forms (III and IV) show negative Cotton effects.

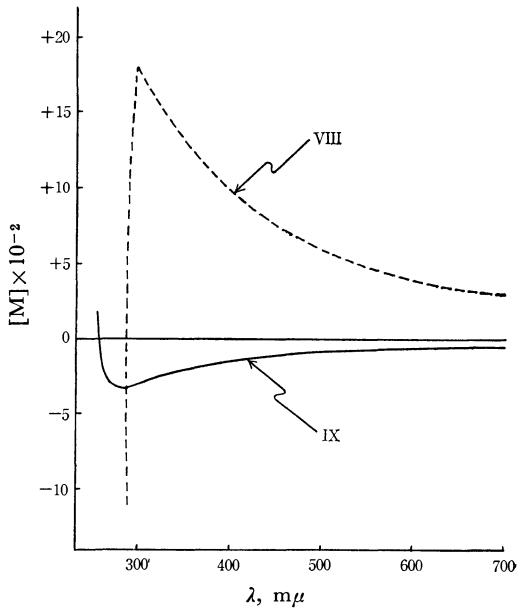

Fig. 3. RD of α- and β-3-nitrates of glucose.

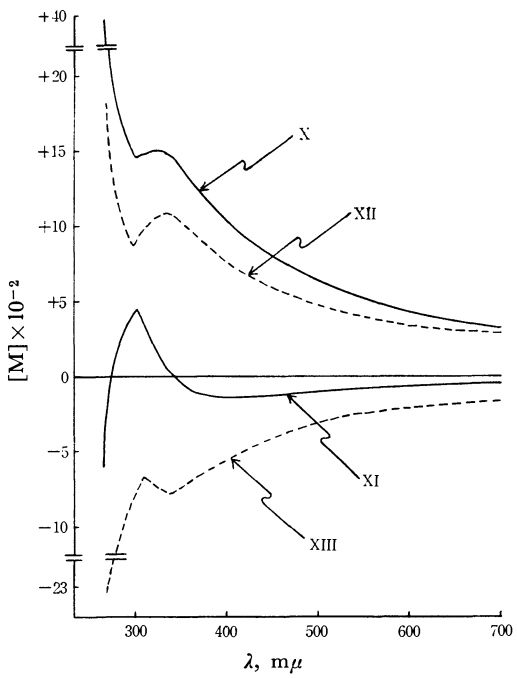

Fig. 4. RD of α- and β-2:3-dinitrates of glucose.

Figure 3 shows the RD curves of the anomers of the C_3-nitrates of glucose. While the α-anomer (VIII) clearly exhibits a positive Cotton effect,[1] quite in harmony with the R-configuration of the carbon 3, the β-glucoside (IX) shows an anomalous RD curve, and the Cotton effect with a trough at 290 mμ is indistinct in sign,

Figure 4 gives the RD curves of the 2 : 3-dinitrates

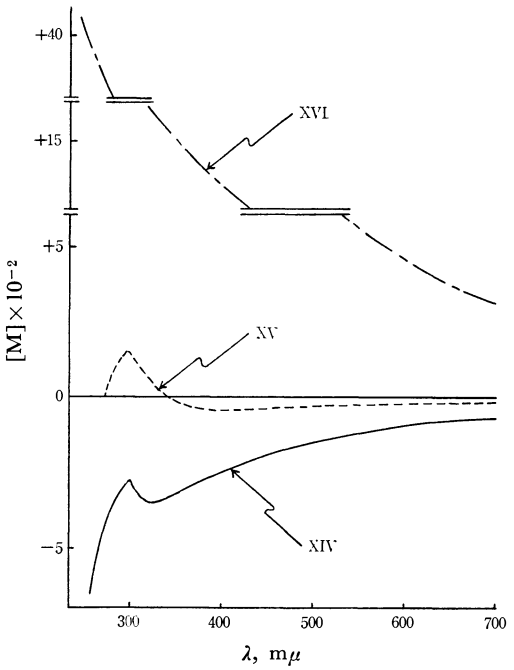

Fig. 5. RD of 4-, 6- and 4:6-dinitrates of glucose.

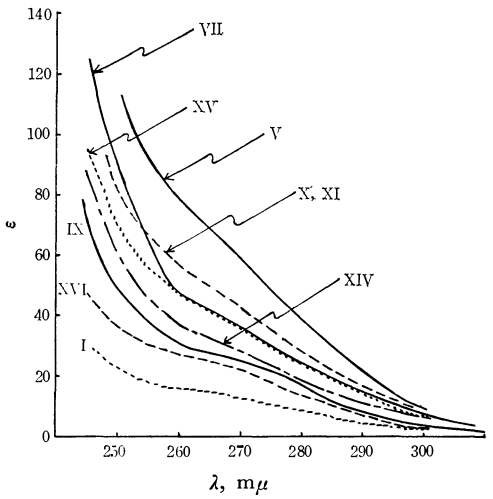

Fig. 6. UV absorption spectra of nitrates of glucose.

(X–XIII). The benzylidene derivatives (XII) show a negative Cotton effect, as has already been reported.[1] Here the rotatory contribution of the carbon 2 is greater than that of the carbon 3, so a negative Cotton effect results in the compound XII.

On the contrary, the β-anomer (XIII) shows a positive Cotton effect, indicating that the C_2-nitrate group also predominates over the C_3-chromophore. This is reasonable when we consider that the C_2-nitrates of the β-form (V–VII) all show positive Cotton effects.

A similar contrast in RD between the α- and β-

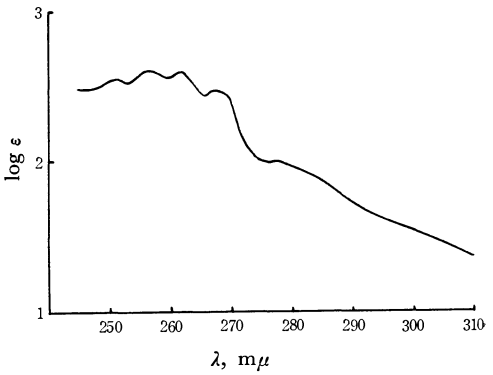

Fig. 7. UV absorption spectrum of XIII.

anomers can be seen in the α- and β-ethylidene derivatives (X and XI). It may, however, be seen in Fig. 4 that the ethylidene derivatives show more distinct Cotton effects than the benzylidene derivatives. Mention should also be made of how the sharper contrast between the former anomers can be used as a means of identification.

Figure 5 shows the RD curves of C_4-nitrate (XIV), 4, 6-dinitrates (XV) and 6-nitrate (XVI). The 4-nitrate exhibits a distinctly positive Cotton effect, even though in the negative domain, the peak of which is located at 300 mμ. The negative background rotation of IV undoubtedly arises from the β-methylglucoside. The RD curve of the compound XV shows a more strongly positive Cotton effect, thus showing the effect of the C_4–ONO_2 group. The 6-nitrate (XVI) does not appear to exhibit any Cotton effect, presumably because the carbon 6 is not asymmetric. The strongly positive background rotation is, naturally, due to the α-form of the glucoside.

The ultraviolet absorption spectra of these nitrates are assembled in Fig. 6, except for the spectrum of XI, which is shown in Fig. 7. As may be seen in Fig. 6, all the spectra show slightly visible shoulders in a region from 265 to 280 mμ, though they are not as distinct as those of alkyl nitrates.[4]

As in the case already elucidated,[1] in these cases a red shift of 5 to 25 mμ is also observed between the ultraviolet absorption and the peak of the Cotton effect. The ultraviolet absorption spectrum of the compound XI shows exceptionally a fine structure and relatively large extinction coefficients (Fig. 7), but it exerts almost no influence on the position of the Cotton effect.

Dispersion Constants

The dispersion data have been found to conform more suitably to the simplified two-term equation of Drude (1), than to the normal two-term equation (2).

XIV	+0.185	− 36.22	0.290	0.300	+	β
XV	+3.45	− 18.43	0.291	0.295	+	β

$$[M] = \frac{A}{\lambda^2-\lambda^2_0} + \frac{B}{\lambda^2} \quad (1)$$

$$[M] = \frac{A_1}{\lambda^2-\lambda^2_1} + \frac{A_2}{\lambda^2-\lambda^2_2} \quad (2)$$

The results of the computation are given in Table II, together with the sign of the Cotton effect.

As may be seen in Table II, the term A invariably agrees with the Cotton effect in sign, indicating that A represents the Cotton effect indeed, the values of λ_0 nearly coincide with the values of λ_{RD}, the optically active absorption maxima observed from the RD, although in some cases the former are 10 to 30 mμ shorter.

The term B without doubt represents the rotatory strength of the non-chromophoric contributions; its value is in general far greater than the corresponding A value. This means that the nitrate chromophore is a feeble contributor to the Cotton effect and, hence, to the optical rotation, and that the dominant rotation originates in the residue of the molecule, mainly in the asymmetry of the carbon 1.

As may be seen in Table II, the values of B are always positive with the α-anomers, while with the β-anomers they are negative in sign, with a few exceptions. However, even with these exceptions (II, V and VI), the positive values are comparatively small.

Conclusion

The results of the above studies are summarized in Table III, where some regular correlations can be seen between the configurations of the carbon atom carrying the nitrate chromophore, as well as the glucosidic carbon atom C_1, and the sign of the Cotton effect.

Table III. The Configurations and signs of the Cotton effect of nitrates

Configuration of C-O-NO_2	C_1-Configuration	Sign of the Cotton effect
D or α	α-anomer	negative
D or α	β-anomer	positive
L or β	α-anomer	positive
L or β	β-anomer	negative

Experimental

The nitrates of glucose were prepared according to the literature. The rotatory dispersion was measured with a Rudolph spectropolarimeter over the region from 250 to 700 mμ. The ultraviolet absorption was measured with a self-recording spectrophotometer of the Hitachi EPU-II type. The dispersion constants of the Drude equation were calculated from the data by means of the least-square method with an electronic computer of the Fuji FACOM 201 type.

2, 3, 4, 6-Tetra-*O*-acetyl-1-*O*-nitro-α-D-glucopyranose (Compound I).[5]—Colorless prisms and plates; m. p. 150.5—151°C. The RD was measured at 21°C in chloroform (c 1.0100). $[\alpha]^{21}_{700}$ +103°, $[\alpha]_{589}$ +151°, $[\alpha]_{500}$ +222°, $[\alpha]_{400}$ +382°, $[\alpha]_{300}$ +832°, $[\alpha]_{285}$ +921° (peak), $[\alpha]_{270}$ +844°, $[\alpha]_{260}$ +790°.

2, 3, 4, 6-Tetra-*O*-acetyl-1-*O*-nitro-β-D-glucopyranose (Compound II).[5]—Colorless needles; m. p. 86°C. The RD was measured at 21°C in chloroform (c 1.142). $[\alpha]^{21}_{650}$ −0.110°, $[\alpha]_{589}$ −1.37°, $[\alpha]_{500}$ −1.52°, $[\alpha]_{400}$ −4.50°, $[\alpha]_{300}$ −60.4° (trough), $[\alpha]_{280}$ +2.63°, $[\alpha]_{260}$ +262°.

1, 3, 4, 6-Tetra-*O*-acetyl-2-*O*-nitro-β-D-glucopyranose (Compound V).[6]—Colorless needles; m. p. 121—122°C. 3,4,6-Tri-*O*-acetyl-2-*O*-nitro-β-D-glucopyranosyl Chloride (Compound VI).[7]—Colorless needles; m. p. 138°C. The RD was measured at 21°C in chloroform (*c* 0.9006). $[\alpha]_{700}^{21}$ +14.0°, $[\alpha]_{589}$ +19.1°, $[\alpha]_{500}$ +27.9°, $[\alpha]_{400}$ +49.3°, $[\alpha]_{300}$ +159°, $[\alpha]_{295}$ +165°(peak), $[\alpha]_{270}$ +5.55°, $[\alpha]_{260}$ −100°.

Methyl 4:6-*O*-Ethylidene-β-D-glucopyranoside 2-Nitrate (Compound VII).[8]—Colorless needles; m. p. 143—144°C. The RD was measured at 21°C in chloroform (*c* 0.5880). $[\alpha]_{700}^{21}$ −34.1°, $[\alpha]_{589}$ −44.6°, $[\alpha]_{400}$ −101°, $[\alpha]_{340}$ −131° (broad extreme), $[\alpha]_{305}$ −83.7°(peak), $[\alpha]_{280}$ −183°, $[\alpha]_{265}$ −402°.

Methyl 4:6-*O*-Ethylidene-β-D-glucopyranoside 3-nitrate (Compound IX).[8]—Colorless needles; m. p. 145.5—146°C. The RD was measured at 21°C in chloroform (*c* 0.8740). $[\alpha]_{700}^{21}$ −19.3°, $[\alpha]_{589}$ −26.0°, $[\alpha]_{500}$ −37.9°, $[\alpha]_{400}$ −61.2°, $[\alpha]_{300}$ −111°, $[\alpha]_{290}$ −118°(trough), $[\alpha]_{260}$ −44.6°.

Methyl 4:6-*O*-Ethylidene-α-D-glucopyranoside 2:3-Dinitrate (Compound X).[9]—Colorless needles; m. p. 100—101°C. The RD was measured at 21°C in chloroform (*c* 2.492). $[\alpha]_{700}^{21}$ +98.6°, $[\alpha]_{589}$ +141°, $[\alpha]_{500}$ +201°, $[\alpha]_{400}$ +330°, $[\alpha]_{320}$ +494° (broad extreme), $[\alpha]_{300}$ +477°, (peak), $[\alpha]_{270}$ +1261°.

Methyl 4:6-*O*-Ethylidene-β-D-glucopyranoside 2:3-Dinitrate (Compound XI).[9]—Colorless prisms; m. p. 88—89°C. The RD was measured at 20.5°C in chloroform (*c* 1.0182). $[\alpha]_{700}^{20.5}$ −15.3°, $[\alpha]_{589}$ −21.6°, $[\alpha]_{500}$ −28.5°, $[\alpha]_{400}$ −38.7°(broad extreme), $[\alpha]_{330}$ +8.15°, $[\alpha]_{297.5}$ +142°(peak), $[\alpha]_{280}$ +19.6°, $[\alpha]_{270}$ −189°.

Methyl 4:6-*O*-Benzylidene-β-D-glucopyranoside 2:3-Dinitrate (Compound XIII).—This compound was obtained by the same procedure as was used in the case of compound XII,[1] but the reaction temperature was from −5 to −10°C. The compound was identified by means of its ultraviolet spectrum, its infrared spectrum and its analytical value. Colorless prisms; m. p. 163°C. The RD was measured at 21°C in tetrahydrofuran (*c* 1.2756). $[\alpha]_{700}^{21}$ −40.3°, $[\alpha]_{589}$ −59.0°, $[\alpha]_{500}$ −80.2°, $[\alpha]_{400}$ −140°, $[\alpha]_{337.5}$ −201° (broad extreme), $[\alpha]_{308}$ 178° (peak), $[\alpha]_{300}$ −192°, $[\alpha]_{270}$ −772°.

Methyl 2,3,6-Tri-*O*-acetyl-4-*O*-nitro-β-D-glucopyranoside (Compound XIV).[9]— Colorless needles; m. p. 113.5°C. The RD was measured at 20.8°C in chloroform (*c* 1.0644). $[\alpha]_{700}^{20.8}$ −19.8°, $[\alpha]_{589}$ −26.3°, $[\alpha]_{500}$ −39.8°, $[\alpha]_{400}$ −64.3°, $[\alpha]_{325}$ −90.5° (broad extreme), $[\alpha]_{300}$ −76.1°(peak), $[\alpha]_{280}$ −106°, $[\alpha]_{265}$ −181°.

Methyl 2,3-Di-*O*-acetyl-4,6-di-*O*-nitro-β-D-glucopyranoside (Compound XV).[10]—Colorless needles; m. p. 116°C. The RD was measured at 21°C in chloroform (*c* 1.7118). $[\alpha]_{700}^{21}$ −8.00°, $[\alpha]_{589}$ −10.2°, $[\alpha]_{500}$ −13.4°, $[\alpha]_{420}$ −16.2°(broad extreme), $[\alpha]_{350}$ −5.26°, $[\alpha]_{300}$ +77.7°, $[\alpha]_{295}$ +82.4°(peak), $[\alpha]_{275}$ +3.51°.

Methyl 2,3,4-Tri-*O*-acetyl-6-*O*-nitro-α-D-glucopyranoside (Compound XVI)[11]—Colorless prisms; m. p. 112—113°C. The RD was measured at 21°C in chloroform (*c* 1.1437). $[\alpha]_{700}^{21}$ +89.9°, $[\alpha]_{589}$ +131°, $[\alpha]_{500}$ +190°, $[\alpha]_{400}$ +316°, $[\alpha]_{300}$ +589°, $[\alpha]_{250}$ +1159°.

Pentaacetyl-β-D-glucopyranose (Compound XVIII).[12]—Colorless needles; m. p. 132°C. The RD was measured at 21°C in chloroform (*c* 2.1320). $[\alpha]_{700}^{21}$ +4.36°, $[\alpha]_{589}$ +6.47°, $[\alpha]_{500}$ +9.05°, $[\alpha]_{400}$ +16.8°, $[\alpha]_{300}$ +44.2°.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPNA VOL. 39 766—771 (1966)

The Electronic Structures and Electronic Spectra of Some Aliphatic Nitroso Compounds

By Masashi TANAKA*, Jiro TANAKA* and Saburo NAGAKURA

The Institute for Solid Physics, The University of Tokyo, Azabu, Tokyo

(Received August 28, 1965)

The electronic structures and electronic spectra of 1-chloro-1-nitrosocyclohexane, nitrosyl chloride, methyl nitrite and dimethylnitrosoamine were studied by making molecular orbital calculations and by measuring the electronic absorption spectra. Concerning 1-chloro-1-nitrosocyclohexane, the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ bands were observed at 650 and 160 mμ respectively. The conjugation effect of electron donors such as Cl, OCH_3 and $N(CH_3)_2$ upon the electronic spectrum of the nitroso group was studied. The intramolecular charge-transfer bands characteristic of the donor-acceptor interaction were found at 190, 210 and 230 mμ for nitrosyl chloride, methyl nitrite and *N*, *N*-dimethylnitrosoamine respectively. This shows that the intramolecular charge-transfer bands appear at longer wavelengths in the order of the increasing ability of the electron donors, $Cl<OCH_3<N(CH_3)_2$. On the other hand, the $n\rightarrow\pi^*$ bands shift to shorter wavelengths in the same order.

* Present address: Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya.

In a previous paper which studied the electronic absorption spectra of nitrosobenzene[1] and its derivatives, it was shown that the nitroso group is a strong electron acceptor, and that their ultraviolet absorption spectra are greatly different from that of benzene. Nitrosobenzene exhibits a new band characteristic of the charge-transfer interaction between the benzene ring as an electron donor and the nitroso group as an electron acceptor. Moreover, the maximum wavelength of the band is longer than the corresponding band of nitrobenzene. This seems to mean that the electron affinity of the nitroso group is greater than that of the nitro group. In view of the large electron-accepting ability of the nitroso group, the electronic structures of aliphatic nitroso compounds have been studied in the present paper by combining the experimental data of the absorption spectra with the theoretical results based on the molecular orbital calculations.

The electronic absorption spectra of aliphatic nitroso compounds have been studied by several workers from both experimental[2-7] and theoretical[8,9] points of view. In the present study, the electronic absorption spectrum of 1-chloro-1-nitrosocyclohexane was measured in order to obtain fundamental knowledge about the electronic structure of the nitroso group itself. Then the charge-transfer interaction of the nitroso group with electron donors such as Cl, OCH_3 and $N(CH_3)_2$ has been studied by the aid of the electronic absorption spectra in the vacuum ultraviolet region.

Experimental

Materials.—*Methyl Nitrite.*[2]—A sulfuric acid (12 N) solution was dropped on a mixture of methanol and a 45% aqueous sodium nitrite solution. The crude product was dried over calcium chloride and was purified by repeated low-temperature distillations in vacuo.

N, N-Dimethylnitrosoamine.[10]—A mixture of dimethylamine and sodium nitrite was heated for several hours. The oil layer was separated and the aqueous portion was extracted with benzene. The benzene was removed by distillation and the residue was fractionally distilled under reduced pressure. The nitrosoamine was obtained as a light yellow liquid; b. p. 104°C/ca. 10mmHg.

1-Chloro-1-nitrosocyclohexane.[5]—Cyclohexanone oxime was dissolved in diluted hydrochloric acid and the solution was cooled by ice water.

A fairly rapid stream of chlorine was passed through the solution until no more gas was absorbed. The separated blue oil was extracted with ether and then washed with an aqueous sodium bicarbonate solution and with water. After the extract had been dried with anhydrous sodium sulfate, the ether was removed. The nitroso compound was then distilled under reduced pressure as a purple oil with a very unpleasant smell; (b. p. 58°C/13 mmHg).

Measurements.—The absorption spectra of the

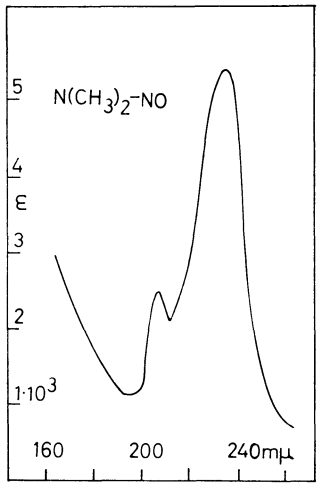

Fig. 3. The ultraviolet absorption spectrum of *N*, *N*-dimethylnitrosoamine.

above-mentioned samples were measured in the gaseous states. The ultraviolet absorption measurements down to 190 mμ were made with a Cary recording spectrophotometer, model 14 M, a quartz cell 10 cm. long being used. A vacuum ultraviolet spectrophotometer constructed in our laboratory was used for the measurements in the vacuum ultraviolet region. In this case, a gas cell 0.7 cm. long and equipped with lithium fluoride windows was used.

The results are shown in Figs. 1—3, together with the absorption spectrum of nitrosyl chloride, which was measured by Goodeve and Katz[6] down to 190 mμ and by Price and Simpson[7] down to 130 mμ.

The peak wavelengths and molar extinction coefficients are tabulated in Table I.

Table I. The Observed peak wavelengths and molar extinction coefficients for various aliphatic nitroso compounds

Sample	λ_{max}, mμ	ε_{max}
1-Chloro-1-nitroso-cyclohexane	(750	0.6)*[5]
	197	1200
	179	2800
	~160	>2600
Nitrosyl chloride[6,7]	(615	0.7)*
	197	2550
	145	2000
Methyl nitrite	(386	10)*
	212	1050
N, *N*-Dimethyl nitrosoamine	(377	50)*
	227	5200
	205	2350

* These absorptions have vibrational structures. The wavelengths given in this table are those for the longest wavelength bands which may be assigned to the 0—0 band.

Theoretical

The π-electron structures of nitrosyl chloride, methyl nitrite and *N*, *N*-dimethylnitrosoamine have been studied theoretically on the basis of the geometrical structures shown in Fig. 4. The geometrical structures of nitrosyl chloride and methyl nitrite were studied by Ketelaar and Palmer[11] and by Rogowski[12] respectively. However, the geometrical structure of *N*, *N*-dimethylnitrosoamine has not yet been studied experimentally. Therefore, we assume its structure to be as is shown in Fig. 4.

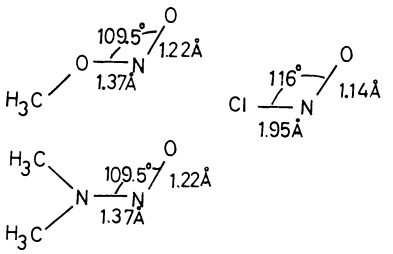

Fig. 4. The geometrical structures of nitrosyl chloride, methyl nitrite and *N*, *N*-dimethylnitrosoamine.

Calculation of the MO of the Nitroso Group. —First of all, the LCAO SCF MO's ϕ_i of the π-electron system of the nitroso group were evaluated by means of the usual equation[13]:

$$F\phi_i = \varepsilon_i\phi_i, \quad \phi_i = a\chi_N + b\chi_O$$

where χ_N and χ_O indicate the $2p\pi$ atomic orbitals of the nitrogen and the oxygen atoms of the nitroso group respectively. The details of the calculation will be given in the Appendix.

The resultant molecular orbitals, ϕ_i, and orbital energies, ε_i, are given below:

$$\varepsilon_1 = -17.70 \text{ eV.}, \quad \phi_1 = 0.5963\chi_N + 0.8028\chi_O$$

$$\varepsilon_2 = -0.61 \text{ eV.}, \quad \phi_2 = 0.8028\chi_N - 0.5963\chi_O$$

It is clear from these results that the μ-electron distribution in the ϕ_1 orbital of the nitroso group inclines toward the oxygen atom, and that the electron affinity of the nitroso group, $-\varepsilon_2 = 0.61$ eV., is larger than those of the nitro and carbonyl groups, 0.40 eV.[14] and −1.20 eV.[15] respectively.

The transition energy, $\Delta E(N \rightarrow V)$, and oscillator strength, f, were calculated as follows:

$$\Delta E(N \rightarrow V) = 7.96 \text{ eV.}$$

$$f = 0.475$$

For the purpose of checking the theoretical results,

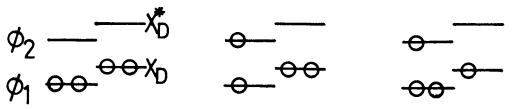
we measured the absorption spectrum of 1-chloro-1-nitrosocyclohexane. As may be seen in Table I, 1-chloro-1-nitrosocyclohexane shows absorption bands at 750, 197, 179 and ~160 mμ. The 750 mμ band may safely be regarded as the $n\rightarrow\pi^*$ transition band. The peak at about 160 mμ (7.75 eV.) may correspond to the N→V ($\pi\rightarrow\pi^*$) transition of the nitroso group, while the other two peaks, at 179 mμ and 197 mμ, seem to correspond to an $n\rightarrow\pi^*$ transition or a band of the Rydberg series.

Configuration Interaction Calculation.—The π-electron energy levels and the wave functions of nitrosyl chloride, methyl nitrite and *N*, *N*-dimethylnitrosoamine were calculated by taking into account the configurational interaction among several electron configurations. The respective molecules were separated into the two components, the electron donor, Cl–, CH_3O– or $(CH_3)_2N$– and the electron acceptor, NO–. The interaction between them was considered by means of the configurational interaction among π electron configurations which were constructed by putting the four π electrons into the appropriate orbitals of the components.

The electron configurations actually taken up in the present calculation are shown in Fig. 5.



ground config. | locally excited config. | charge-transfer config.

Fig. 5. The electron configurations of the nitroso compounds.

In addition to the ground configuration, G, a charge-transfer configuration, CT, caused by an electron transfer from the electron donor toward the electron acceptor, and a locally excited configuration, LE, were considered. The energy of the ground configuration, H_G, was taken as the standard. The energy of the locally excited configuration, H_{LE}, was set equal to 7.96 eV., the N→V transition energy of the nitroso group as evaluated theoretically by the present authors. The energy of the charge-transfer configuration, H_{CT}, was calculated by the following equation:

$$H_{CT} = I_D - A_{NO} - 0.5963^2(\mathrm{NN/DD}) - 0.8028^2(\mathrm{OO/DD})$$

Here the I_D's are the ionization potentials of the electron-donating groups, i. e., Cl–, CH_3O– and $(CH_3)_2N^-$. They were taken to be 12.84, 10.85 and 8.24 eV. for the chloro, methoxy and *N*, *N*-dimethylamino groups respectively from the ionization potentials of hydrochloric acid,[16] methanol[17] and dimethylamine[18]. A_{NO} is the electron affinity of the electron-accepting group, –NO; it was calculated to be 0.61 eV. by the present authors. D indicates the $2p\pi$ or $3p\pi$ atomic orbital for the lone pair electrons of the donor.

Two center Coulomb repulsion integrals like (NN/DD) were evaluated nonempirically, using Slater orbitals except for (NN/ClCl) and (OO/ClCl), which were calculated by Pariser and Parr's method.[19] The energies and wave functions of the configurations used in the present calculations are tabulated in Table II.

Table II. The energies and wave functions of the electron configurations

Energy, eV.	Wave function
$H_G=0$	$\Phi_G=\lvert\phi_1\bar{\phi}_1\mathrm{D}\bar{\mathrm{D}}\rvert$
$H_{LE}=7.96$	$\Phi_{LE}=1/\sqrt{2}\{\lvert\phi_1\bar{\phi}_2\mathrm{D}\bar{\mathrm{D}}\rvert + \lvert\phi_2\bar{\phi}_1\mathrm{D}\bar{\mathrm{D}}\rvert\}$
$H_{CT}=5.77$(NOCl) 2.58(CH_3ONO) −0.04($(CH_3)_2NNO$)	$\Phi_{CT}=1/\sqrt{2}\{\lvert\phi_1\bar{\phi}_1\phi_2\bar{\mathrm{D}}\rvert + \lvert\phi_1\bar{\phi}_1\mathrm{D}\bar{\phi}_2\rvert\}$

Table III. The off-diagonal elements used in the present calculation

$H_{GLE}=0$ $\quad H_{G\,CT}=\sqrt{2}\,b\beta_{ND}$ $\quad H_{LE\,CT}=-a\beta_{ND}$

$$\beta_{NCl}=\int\chi_N\boldsymbol{H}^{core}\chi_{Cl}d\tau=-1.40\ \mathrm{eV}.$$

$$\beta_{NO}=\int\chi_N\boldsymbol{H}^{core}\chi_{Cl}d\tau=-2.20\ \mathrm{eV}.$$

$$\beta_{NN}=\int\chi_N\boldsymbol{H}^{core}\chi_{Cl}d\tau=-2.10\ \mathrm{eV}.$$

The off-diagonal matrix elements of the total electronic Hamiltonian, each of which represents the magnitude of the interaction between two different configurations, were evaluated by the aid of the formulations by Pople[20] and by Longuet-Higgins and Murrell.[21] They are given in Table III in terms of the core resonance integrals, β_{NCl}, β_{NO} and β_{NN}. By solving the determinants constructed by the matrix elements given in Tables II and III with an electronic computer, Facom 202, in our Institute, the π electron energy levels and the wave functions for nitrosyl chloride, methyl nitrile and *N*, *N*-dimethylnitrosoamine were evaluated. The results are shown in Table IV. From these results, the dipole moments due to the π electrons in the ground state, the transition energies and the oscillator strengths were calculated for these nitroso compounds. The results are shown Table V, together with the observed results.

a) Observed oscillator strengths are uncertain.

Discussion

Nitrosyl Chloride.—As is shown in Fig. 2 and Table I, nitrosyl chloride shows three absorption bands in the visible and ultraviolet regions. The 615 mμ band may be ascribed to the $n \rightarrow \pi^*$ transition. The 197 mμ band can be assigned to the W_0-W_1 transition. From the wave function, Ψ_1, given in Table IV, it may be seen that the band has the character of the intramolecular charge-transfer band. The band at about 145 mμ is due to the W_0-W_2 transition, which has the property of the local excitation within the nitroso group. Therefore, the 160 mμ band of the nitroso group shifts to 145 mμ by conjugation with the nonbonding electrons of the chlorine atom.

It may be seen from Ψ_0 given in Table IV that the contribution of the charge-transfer configuration in the ground state of this compound is only 6%. The calculated dipole moment due to the π-electrons can explain the observed value satisfactorily (see Table V).

Methyl Nitrite.—Methyl nitrite shows two absorption peaks, at 386 mμ and 212 mμ. In addition, a strong band appears below 160 mμ (see Fig. 2). The 386 mμ band may be assigned to the $n \rightarrow \pi^*$ band of the nitroso group. The 212 mμ band, which corresponds to the $W_0' \rightarrow W_1'$ transition of methyl nitrite, may be regarded as an intramolecular charge-transfer band. This is because, as may be seen from Ψ_1' in Table V, the contribution of the charge-transfer configuration in the W_1' state amounts to 65%. The shorter wavelength band, the maximum of which does not appear until 160 mμ, may be ascribed to the $W_0' \rightarrow W_2'$ transition. This band may be interpreted as the blue-shifted band of the 170 mμ band of the nitroso group. It is known from Ψ_0' given in Table IV that the contribution of the charge-transfer configuration in the ground state is 28%.

***N*, *N*-Dimethylnitrosoamine.** — The absorption spectrum of *N*, *N*-dimethylnitrosoamine is similar to that of methyl nitrite. The 377 mμ band may be regarded as an $n \rightarrow \pi^*$ transition band, as may be the 386 mμ band of methyl nitrite. The strong band at 227 mμ corresponds to the 212mμ band of the methyl nitrite and may be interpreted as an intramolecular charge-transfer band. The absorption tail below 190mμ may be due to the local excitation within the NO group. A similar absorption tail was also observed with methyl nitrite. The peak at 205 mμ may be thought to be an extra band in the sense that the corresponding band was not observed with methyl nitrite. This may be regarded as the $n \rightarrow \pi^*$ transition band of the dimethylamino group.[25]

As may be seen from Table IV, the contribution of the charge-transfer configuration in the ground state

decreases in the following order; *N*, *N*-dimethylnitrosoamine>methyl nitrite>nitrosyl chloride. This means that the electron-donating power of the substituents decreases in the order of $N(CH_3)_2$> OCH_3>Cl.

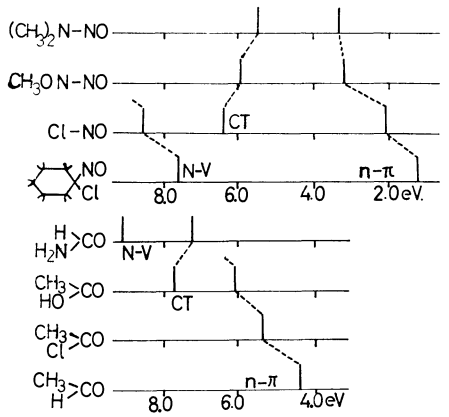

Fig. 6. The relation between the transition energy and the electron-donating ability of Cl, OCH_3 and $N(CH_3)_2$.

The Effect of the Electron-donating Group upon the Absorption Spectrum of the Nitroso Compounds.—The results obtained by the present authors are summarized in Fig. 6. This figure shows that the absorption spectra of XNO change regularly with the electron-donating power of X. That is, with the increasing electron-donating power of X, the $n\rightarrow\pi^*$ band shifts toward the shorter wavelengths, and the charge-transfer band toward the longer wavelengths. As is shown in Fig. 6, the same tendency was observed with the carbonyl compounds, O=CRX. The $n\rightarrow\pi^*$ transition band which appears at 280 mμ for acetaldehyde shifts to 232 mμ and to 205 mμ for acetylchloride and acetic acid respectively[26]. The band of acetamide shifts to a shorter wavelength than 200 mμ. On the other hand, the intramolecular charge-transfer band appears at 171.7 mμ and at 160 mμ for formamide and acetic acid respectively[15,27].

The authors' thanks are due to Dr. Michiya Itoh for his kind advice in preparing 1-chloro-1-nitrosocyclohexane, and also to Mr. Koji Kaya for his kind help in measuring the vacuum ultraviolet absorption spectra.

Appendix

The molecular orbital energies ε_i are solutions of the following secular determinant

$$\begin{vmatrix} F_{NN}-\varepsilon & F_{NO} \\ F_{NO} & F_{OO}-\varepsilon \end{vmatrix}=0$$

By the aid of the Pariser-Parr method,[19] the F_{NN}, F_{OO} and F_{NO} are given in the following

$$F_{NN} = \alpha_N + a^2(NN/NN) + 2b^2(NN/OO)$$
$$F_{OO} = \alpha_O + 2a^2(NN/OO) + b^2(OO/OO)$$
$$F_{NO} = \beta_{NO} - ab(NN/OO)$$

In this expression, one-center Coulomb repulsion integrals (NN/NN) and (OO/OO) are estimated by the aid of Pariser's approximation, namely averaging the I_p—A of the $2p\pi$ electron at various valance states, where I_p is the appropriate valence state ionization potential[28] and A the appropriate valence state electron affinity.[28] The two-center Coulomb repulsion integral was calculated by the use of the Slater orbitals[29] at the bond length r_{NO}=1.22 Å. Following the Pariser-Parr theory, the core integral β_{NO} was left as an adjustable parameter, and α_N and α_O were given by the following equations.

$$\alpha_N = -I_p(N) - (NN/OO)$$
$$\alpha_O = -I_p(O) - (NN/OO)$$

The above-mentioned various quantities are presented in Table VI.

Table VI. Integrals involving π-atomic orbitals (eV.)

$\alpha_N=-23.15$	$\alpha_O=-28.41$
$I_p(N)=14.51$	$I_p(O)=17.79$
$(NN/NN)=13.38$	$(OO/OO)=14.33$
$(NN/OO)=10.62$	
$\beta_{NO}=-3.10$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 772—776 (1966)

The Cation Effect on the Polarographic Reduction of *cis*-Dioxalatodiaquochromate(III) and Trioxalatochromate(III) Ions

By Nobuyuki TANAKA, Eiki ITABASHI* and Reita TAMAMUSHI**

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received September 3, 1965)

The cation effect on the polarographic reduction of *cis*-dioxalatodiaquochromate(III) and trioxalatochromate(III) ions has been reported. *cis*-Dioxalatodiaquochromate(III) ions give an irreversible wave corresponding to a three-electron reduction in the solutions of univalent electrolytes, while they give a double wave in the solutions of bivalent electrolytes, the first wave being of a one-electron reduction and the second wave, of a two-electron reduction. Trioxalatochromate(III) ions are reduced to chromium(0) in the univalent and the bivalent electrolyte solutions at more negative potentials than *cis*-dioxalatodiaquochromate(III) ions. The reduction potentials of these complex anions depend on the nature and the concentration of cations of electrolytes present in the solution, and shift to less negative potentials with increasing ionic charges of the cation and, at the constant ionic charge, with decreasing radii of the hydrated ion and increasing concentrations of the cation present. The cation effect was explained by taking into consideration of both the structure of the electrical double layer and the formation of ion-pairs.

In the previous papers[1-3] evidences have been presented that *cis*-dioxalatodiaquochromate(III) ions gave an irreversible wave corresponding to three-electron reduction with a half-wave potential of -1.52 V. vs. SCE in a 0.3 M potassium chloride solution,[1] and that trioxalatochromate(III) ions gave no reduction wave in a 0.1 M solution of tetramethylammonium bromide,[2] but gave a well-defined reduction wave in the solutions of other electrolytes such as potassium chloride or barium chloride.[3] This result seemed to differ from that of Pamfilov and his co-workers,[4] who reported trioxalatochromate(III) ions gave two irreversible waves with the half-wave potentials of -1.315 and -1.450 V. vs. NHE in a 1.0 N potassium chloride solution.

In the present paper are reported the detailed results of the effects of the nature and the concentration of supporting electrolytes on the polarographic reduction of *cis*-dioxalatodiaquochromate(III) and trioxalatochromate(III) ions. The cation effect is discussed on the basis of the formation of ion-pairs and the change in the structure of the electrical double layer.

Experimental

Current-potential curves were recorded with a pen-recording polarograph, a Yanagimoto Galvarecorder Model PR-2 with an automatic potential scanner. A Yanagimoto Y-GR 2 Galvarecorder was used for recording alternating current (a.c.) polarograms. Kalousek polarograms were recorded with the same circuit as has been described previously.[5] To determine the integral capacity in the double layer, the capacitance was measured using the same circuit as given in the previous report.[6]

The dropping mercury electrode had an m value of 1.84_7 mg./sec., and a drop time, t_d, of 3.1 sec. being measured in an air-free 1 M potassium chloride solution containing 0.005% galatin at -1.70 V. vs. SCE at 45 cm. of the mercury reservoir.

The cell equipment was the same as has been reported previously.[7] The potentials were referred to a saturated calomel electrode (SCE). The dissolved oxygen in the solution was removed by bubbling pure nitrogen gas through the solution. All measurements were carried out in a thermostat of 25.0°C. All current-potential curves presented in this paper are corrected for the residual current and the ohmic drop (iR) across the electrolysis cell.

Potassium *cis*-dioxalatodiaquochromate(III)[8] and potassium trioxalatochromate(III)[9] were prepared with the procedures given in the literatures. All other chemicals used were of a guaranteed reagent grade. In the case of lithium chloride, it was dissolved in redistilled water, a small amount of insoluble substance was

removed by decantation and pH of the solution was adjusted to about 7.0 by adding hydrochloric acid. Redistilled water was used to prepare the cell solution.

Results

The current-potential curves of *cis*-dioxalatodiaquochromate(III) and trioxalatochromate(III) ions were obtained in the solutions of various supporting electrolytes and at various concentrations of the electrolytes in the presence of 0.005% gelatin added as a maximum suppressor. The typical current-potential curves of *cis*-dioxalatodiaquochromate(III) ions are given in Figs. 1 and 2. Figure 1 shows the current-potential curves obtained in the solutions of univalent electrolytes.

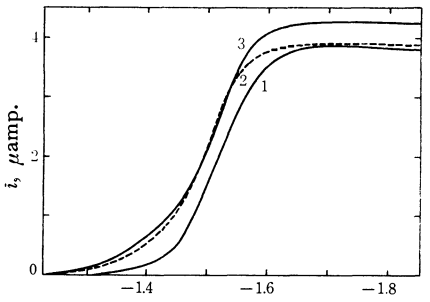

Fig. 1. Current-potential curves of 0.5 mM *cis*-dioxalatodiaquochromate(III) ions in the univalent electrolyte solutions containing 0.005% gelatin: (1) 1.0 M LiCl, (2) 1.0 M NaCl, (3) 1.0 M KCl.

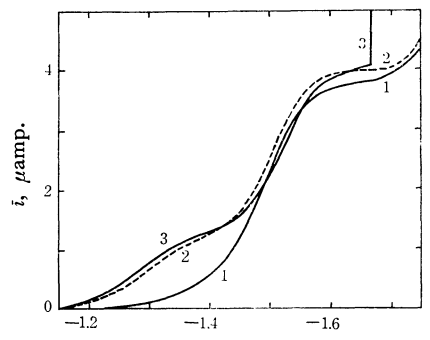

Fig. 2. Current-potential curves of 0.5 mM *cis*-dioxalatodiaquochromate(III) ions in the bivalent electrolyte solutions containing 0.005% gelatin: (1) 0.5 M $MgCl_2$, (2) 0.5 M $SrCl_2$, (3) 0.5 M $BaCl_2$.

The limiting current was found to be diffusion-controlled and proportional to the concentration of the complex ions. The current-potential curves obtained in the bivalent electrolyte solutions are reproduced in Fig. 2. In a solution of strontium chloride or barium chloride, especially, the wave was found to split into two steps; the first wave was observed in the potential range from −1.2 to −1.45 V. vs. SCE, which was not observed in the univalent electrolyte solutions. The limiting currents of both the first and the second wave are diffusion-controlled and proportional to the concentration of the complex ions. The gradual increase in the current was observed in the bivalent electrolyte solutions at more negative potentials than −1.75 V. vs. SCE. A maximum was observed at the potentials of the limiting current plateau when the measurement was made in a barium chloride solution, and the height of the maximum increases with increasing concentrations of barium chloride. The maximum was not suppressed by the addition of relatively high concentrations of gelatin, but suppressed by the addition of a small amount of hydrogen ion.

The diffusion current constants and the reduction potentials at $\bar{i}=\bar{i}_l/6$ and $\bar{i}=2\bar{i}_l/3$ on the reduction of *cis*-dioxalatodiaquochromate(III) ions which were obtained in the solutions of various electrolytes and at various concentrations of the electrolytes in the presence of 0.005% gelatin are given in Table I. The half-wave potential was not used because of the irregular shapes of the waves.

electrode process was considered to be of a three-electron reduction of chromium(III) to chromium(0), being compared with the reduction wave of *cis*-dioxalatodiaquochromate(III) ions previously reported.[1] The relation between E and $\log \bar{i}/(\bar{i}_l - \bar{i})$, Kalousek polarograms and a. c. polarograms indicated the electrode processes of trioxalatochromate(III) ions to be irreversible.

Table II shows the diffusion current constants, the half-wave potentials and the reciprocal slopes of log-plots obtained in the solutions of various supporting electrolytes and at various concentrations of the electrolytes.

Discussion

The polarographic reduction of *cis*-dioxalatodiaquochromate(III) and trioxalatochromate(III) ions was affected by the nature and the concentration of the cation of electrolyte present in the solution.

The reduction of *cis*-dioxalatodiaquochromate(III) ions at the DME in the solutions of univalent electrolytes proceeds irreversibly according to the equation,

$$cis\text{-}[Cr(ox)_2(H_2O)_2]^- + 3e \rightarrow Cr(0) + 2\,ox^{2-} + 2H_2O$$

In the solutions of bivalent electrolytes, on the other hand, two waves are observed as mentioned above. The electrode processes of these waves are considered as follows:

The first wave is of a one-electron reduction corresponding to the reaction,

$$cis\text{-}[Cr(ox)_2(H_2O)_2]^- + 2pH_2O + e \rightarrow [Cr(ox)_{2-p}(H_2O)_{2p+2}]^{(2-2p)-} + p\,ox^{2-}$$

The second wave is of a two-electron reduction, which proceeds as,

$$cis\text{-}[Cr(ox)_{2-p}(H_2O)_{2p+2}]^{(2-2p)-} + 2e \rightarrow Cr(0) + (2-p)ox^{2-} + (2p+2)H_2O$$

In the case of trioxalatochromate(III) ions, an irreversible wave corresponding to the reduction from chromium(III) to chromium(0) was found to appear at more negative potentials than those of *cis*-dioxalatodiaquochromate(III) ions in the solutions of both univalent and bivalent electrolytes. The result seems to contradict the result obtained by Pamfilov and his co-workers.[4]

The shifts of the reduction potential and the changes in the diffusion current constants given in Tables I and II indicate that the effect of the cations of electrolytes on the reduction potentials increases with the increase in the ionic charge, and at constant ionic charge, with the increase in the radius of the hydrated cation and the increase in the concentration of the electrolytes present in the solution. These facts may be explained by taking into account of both the structure of the

electrical double layer and the formation of ion-pairs.[10-12]

Since both *cis*-dioxalatodiaquochromate(III) and trioxalatochromate(III) ions are reduced at the negative side of electrocapillary maximum, the reduction of these complex anions are more difficult at lower concentrations of electrolytes because of greater electrostatic repulsion between the electrode surface and the electroactive complex anions. Trioxalatochromate(III) ions gave actually no reduction wave at lower concentrations of the univalent electrolytes in the solution.

If the potential difference across the diffuse double layer is decreased with increasing concentrations of electrolyte or by changing the nature of the cation of electrolyte, the electrostatic repulsion, which hinders the approach of the electroactive complex anions to the electrode surface, decreases so that the surface concentration of the complex anions increases. This and an increase in the effective potential difference in the Helmholtz double layer facilitate the reduction of the complex anions, as pointed out by Vlček[13] on the reduction of hexacyanocobaltate(III) ions. He reported that the reduction potential of hexacyanocobaltate(III) ions at the DME shifted to less negative potentials with increasing concentrations of potassium chloride and increasing radii of the univalent cation in the solution.

The shifts of the half-wave potential, $\Delta E_{1/2}$, with the change in the concentration of electrolyte is approximately given by the relationship,[14,15]

$$\Delta E_{1/2}=\frac{\alpha n_a - z_O}{\alpha n_a}\Delta(\phi_H-\phi_S)_{1/2} \qquad (1)$$

where α is the transfer coefficient, n_a the number of electron involved in the electron-transfer process, z_o the valency, with sign, of the reducible species and $\Delta(\phi_H-\phi_S)_{1/2}$ the change in the potential difference across the diffuse double layer at the half-wave potential of the reduction wave.

The relation between the electrode potential, E, and the value of $(\phi_H-\phi_S)$ can be calculated on the basis of the classical Gouy-Chapmann theory for the z-z type electrolyte,

$$K_i[(E-E_z)-(\phi_H-\phi_S)]=\left(\frac{2\boldsymbol{R}T\varepsilon C_t}{\pi}\right)^{1/2}\sinh\left\{\frac{|z|\boldsymbol{F}(\phi_H-\phi_S)}{2\boldsymbol{R}T}\right\} \qquad (2)$$

where K_i is the integral capacity of the Helmholtz double layer, E_z the potential at zero charge of the electrode, ε the dielectric constant, C_t the bulk concentration of ions with valence z.

In the calculation of Eq. 2, E_z and K_i which were determined from the electrocapillary curve and the capacitance measurements, respectively. The value of αn_a in Eq. 1 was obtained from the plot of E vs. $\log \bar{i}/(\bar{i}_d-\bar{i})$. The values of E_z and K_i obtained at varied concentrations of potassium chloride are given in Table III.

Table III. The potential of zero charge of the electrode (E_z) and the integral capacity in the Helmholtz double layer (K_i) obtained at varied concentrations of potassium chloride

2.0	-0.55_0	20.4_8
3.0	-0.60_0	20.7_5

* All solutions contain 0.005% gelatin.

Equation 1 was not able to apply to the electrode process of *cis*-dioxalatodiaquochromate(III) ions because no straight line was obtained in the log-plot analysis.

The experimental and the calculated values for the shift of the half-wave potential on the reduction of 0.5 mM trioxalatochromate(III) ions with varied amounts of potassium chloride are given in Table IV. The calculation was made with three different values of the valency of the complex anion participating in the electron-transfer process. Table IV shows that the experimental shifts of the half-wave potential agree to the calculated ones which were obtained with $z_O=-1$. This suggests that the species which is involved in the electron-transfer process is probably a $K_2[Cr(ox)_3]^-$ ion.

The concentration of the species, $K_2[Cr(ox)_3]^-$, in the bulk of the solution is estimated to be much smaller than that of the species, $K[Cr(ox)_3]^{2-}$, from the calculation with the association constants of these ion-pairs. Consequently, it is presumed that the species, $K_2[Cr(ox)_3]^-$ is present predominantly only at the electrode surface, and that one of the potassium ions of $K_2[Cr(ox)_3]^-$ plays a role of bridging the electrode surface and the electroactive species at the electron-transfer process. The formation of ion-pairs lessens the ionic charge of trioxalatochromate(III) ions, so that it facilitates their approach to the electrode surface. The electrode process for the reduction of trioxalatochromate(III) ions, therefore, may be written as follows:

$$K[Cr(ox)_3]^{2-} + K^+ \rightleftarrows K_2[Cr(ox)_3]^-$$

$$K_2[Cr(ox)_3]^- + 3e \longrightarrow Cr(0) + 3ox^{2-} + 2K^+$$

In conclusion, it may be said that the reduction processes of *cis*-dioxalatodiaquochromate(III) and trioxalatochromate(III) ions depend on the nature and the concentration of the cation of the electrolyte in the solution and that this cation effect may be understood by the consideration of the formation of ion-pairs as well as the change in the electrical double layer.

The Rheological Behavior of Suspensions of Ion-exchange Resin Particles

By Manabu SENŌ and Takeo YAMABE

The Institute of Industrial Science, The University of Tokyo, Azabu, Tokyo

(Received September 6, 1965)

The flow properties of the suspensions of ion-exchange resin particles, the highly-crosslinked polyelectrolyte gel particles, were examined, especially in relation to their charged state. The steady viscosities and the dynamic viscoelasticities of these suspensions were measured, and the results were interpreted in terms of the dispersion state of the suspended particles. The flow system of the highly-charged particles, such as Na-form resin particles, exhibits a high viscoelasticity and is in a well-dispersed state. On the contrary, the flow system of the lower-charged particles, such as Ba-form particles, is not viscoelastic, but viscous and dilatant. This behavior may be attributed to the variation in the electrical double layers around the suspended particles.

Ion-exchange resin particles are excellent model substances of the colloidal system for investigating its behavior in relation to the structure, because they have a well-defined polyelectrolyte structure and vary in the surface state according to the kind of counter-ions in their fixed dissociation groups. We have previously investigated the aggregation behavior of these particles[1] and measured their electro-kinematic potential.[2] As one extention of these investigations, we will now report on the rheological behavior of a suspension of these particles. This investigation will reveal how the rheological behavior of the suspension is affected by the charged state of the suspended particles.

2) M. Senō and T. Yamabe, *Nature*, **202**, 1110 (1964).

Experimental

The ion-exchange resin particles used were composed of Amberlite resin (Rohm & Haas), IR-120. This is a strongly-dissociated cation-exchange resin which had been prepared from polystyrene sulfonic acid crosslinked with divinylbenzene. The resin particles from commercial sources were ground in a wet state in a ball mill and sieved in water. The part which

TABLE I. THE CHARACTERIZATION OF SAMPLES OF SUSPENDING PARTICLES, AMBERLITE IR-120

Ionic form	Real density g./cm^3	Water content %	Apparent density g./cm^3
H	1.55	48.4	1.22
Na	1.64	46.2	1.26
Ca	1.60	42.8	1.27
Ba	1.88	36.3	1.56

had settled after 1—10 hr. was collected and washed thoroughly after conditioning; from this part the sample in various ionic forms was prepared. The ionic forms were the H–, Na–, Ca, and Ba–form. They are 2—20μ in size; their water contents and real densities were as shown in Table I.

The viscosity of the dilute suspensions was measured with an Ostwald-type capillary viscometer. The viscosity and the dynamic visco elasticity were measured with a rotational viscometer (McMichael type) and with a rheometer which was described in a preceding paper.[3]

Results and Discussion

The viscosities of the ion-exchange resin particle suspension in the range of relatively small concentrations are shown in Fig. 1 as a function of the volume fraction of particles. The rate of the increase in the viscosity with the increasing concentration is larger in the order; H->Na->Ca->Ba-form. The relationship between the relative viscosity and the volume fraction is ruled regularly by the following equation, proposed by Asbeck et al.[4]:

$$\ln \eta_{rel} = \frac{K\varphi}{\varphi_c - \varphi}$$

The linear relation of $1/\log \eta_{rel}$ and $1/\varphi$ is shown in Fig. 2, from which the parameters, K and φ_c, are obtained. The former is a shape factor, while the latter is a crowding factor which represents the extent of the packing of suspended particles or that of the immobilization of the dispersing media.[5] The results are shown in Table II.

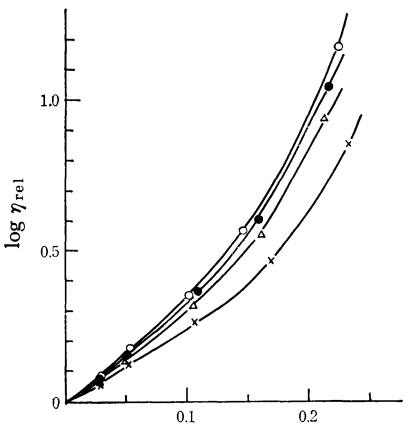

Fig. 1. Viscometric behavior of suspensions of ion-exchange resin particles.
○ H-form particles
● Na-form particles
△ Ca-form particles
× Ba-form particles

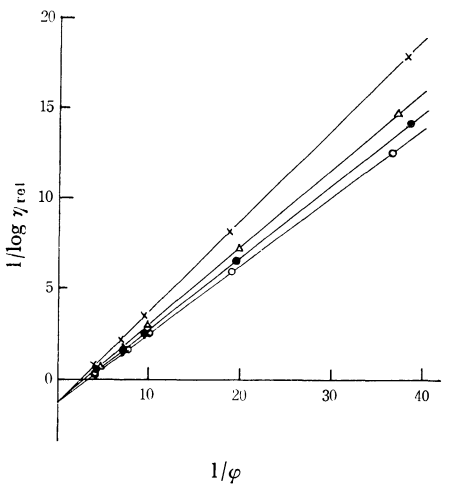

Fig. 2. Plots of $1/\log \eta_{rel}$ vs. $1/\varphi$. Symbols are the same as in Fig. 1.

From this table, the following important finding is derived. The shape factor, K, is identical for all suspensions, independently of their ionic forms, and approximately equals 2.5, which is the value for the spherical particles. On the contrary, the crowding factor, φ_c, is greatly dependent on the ionic forms of the suspending particles. This value is 0.502 for the Ba-form, which is the value for the cubic packing, the loosest closed-packing. The values for the other ionic forms are smaller than that for the Ba-form. This indicates either that these suspensions are in the looser packing state, or that the suspending medium is immobilized by the particles to a greater extent.

Table II. The analysis of the relation of viscosity and concentration by the equation $\ln \eta_{rel} = K\varphi/(\varphi_c - \varphi)$

Ionic form	K	φ_c
H	2.56	0.377
Na	2.56	0.391
Ca	2.56	0.427
Ba	2.56	0.502

This finding may be interpreted reasonably. For the sulfonate group, hydrogen and sodium ions are highly dissociated counterions, calcium ions are hardly dissociated, and barium ions are undissociated. The order of the degree of dissociation is in accordance with that of the interfacial electro-kinematic potential of the particles. That is, the ion-exchange resin particles of highly-dissociated counterions are accompanied by a highly-extended interfacial electrical double-layer. The same particles with a well-established electrical double-layer do not approach nearer to each other, since the electrical repulsion force is exerted between the double-layers with charges of the same sign. Therefore, such a suspending particle takes a loose packing state, accompanied

by the immobilization of the suspending medium.

The rheological properties of the suspension exhibit a more characteristic feature in the higher concentration region according to the variation in the charged state of the particles. One of the results is provided by the measurements using the rheometer of the forced-oscillation type. The coefficients of the dynamic viscoelasticity are given in Table III. The suspensions in which the particles have highly-dissociated counter-ions show large values of the dynamic viscosity and rigidity, and the suspension of the undissociated barium-ion form particles is nearly viscous. This establishes that the viscoelasticity of this suspension

TABLE III. THE DYNAMIC VISCOSITY AND RIGIDITY OF THE CONCENTRATED SUSPENSIONS
(30°C and 30—35 sec./cycle)

Ionic form	Volume fraction of particles	Dynamic viscosity poise	Dynamic rigidity dyn./cm^2
H	0.291	25.06	8.23
Na	0.295	9.91	3.70
Ca	0.304	3.06	0.44
Ba	0.328	0.76	0.09

results from the repulsion forces between the double-layers established around the suspending particles. The same has been proposed by Bolt.[6]

Another characteristic of the concentrated suspensions is revealed by the observation on the dilatancy behavior. It was clearly observed that the dilatancy of the suspensions the suspending particles of which have more undissociated counter-ions is more remarkable. Although no exact method for the estimation of the dilatancy has yet been established, an estimate is provided by the measurements using a rotational viscometer. The results are shown in Fig. 3.

TABLE IV. THE PROPERTIES OF THE SUSPENSIONS OF ION-EXCHANGE RESIN PARTICLES

Ionic form	Concentration range of characteristic flow	Characteri-zation	Volume fraction at settling
H	0.26~0.295	Viscoelastic	0.295
Na	0.27~0.30	Viscoelastic	0.302
Ca	0.27~0.31	Viscoelastic	0.315
Ba	0.28~0.33	Dilatant-viscous	0.394

No anomalous behavior is detected in the suspensions of H–, Na–, and Ca–form particles in the region of the measuring conditions, but, for the suspension of the Ba-form particles, an abrupt increase in the viscosity is observed, accompanied by the occurence of a turbulent flow, over the radial viscosity of 7.2 sec^{-1}. This value corresponds to values of 1.80 sec^{-1} for the rate of shear and of 3.0 for the Reynolds number. The latter is very small compared to the critical Reynolds number (about 1200—2000); therefore, it may be said that this suspension exhibits the anomalous turbulent flow which occurs at a very small Reynolds number. However, no exact interpretation of the relation of the dilatancy and the anomalous turbulent flow has yet been established, altough their intimate relation is recognized.[7] This suggests that the interfacial electrical double-layer reduces the friction between the particles as a result of the repulsive interaction of the double-layers, and that the Ba-form particle suspension, of which the double-layers are infant, is dilatant, while the H- and Na-form particle suspensions, the double-layers of which are well-established, are not dilatant. These characteristics are summarized in Table IV.

The suspensions of H- and Na-form particles are viscoelastic, the suspension of Ba-form particles is dilatant-viscous, and the suspension of Ca-form particles is intermediate in nature, in the characteristic concentration range covered in Table IV. In the lower concentration range, all the suspensions are purely viscous, while in the higher concentration range they are powdery solids.

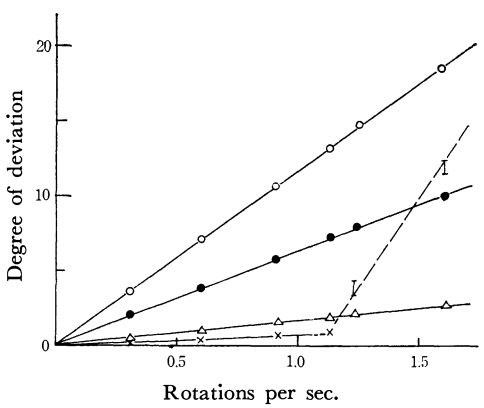

Fig. 3. Measurements using a rotational viscometer. Symbols are the same as in Fig. 1.

Table IV also shows the concentration of the sedimentation state of these suspensions. It is clear that the dispersed system with the lower-charged particles is in the more compact state at the settling; this accords with the generally accepted concept.

The Automatic Measurement of the Ohmic and Capacitive Components of the Impedance on a Platinum Electrode in Transient States

By Shigeo SHIBATA

Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Koshirakawa-cho, Yamagata

(Received September 6, 1965)

A new technique with an electronic circuit is described in which the ohmic and the capacitive components of the impedance of the electrode-solution interface may be registered simultaneously and continuously as a function of the time at a given frequency during polarization with a constant anodic or cathodic current. Impedance measurements were made on a smooth platinum in 2 N perchloric acid, 2 N sodium perchlorate and 2 N sodium hydroxide solutions in the region of oxygen deposition. According to the observed behavior of the impedance of the electrode, the oxide film on the electrode surface may be completed anodically through three stages; first, the adsorption of the hydroxyl radical; second, the formation of oxide (II), and finally, the conversion of this oxide to one of a higher grade. The dependence of the value of the electrode capacity at the first stage on the pH of the solution is discussed on the basis of the ion-exchange adsorption of cations and anions on the electrode surface covered by the hydroxyl radicals.

Much effort has been expended in the past on the study of platinum surface oxidation.[1-26] A chief concern of early investigations was the nature and the extent of surface coverage with oxygen species under a variety of conditions and using a variety of techniques. Early conclusions were based largely on the shape of the charging curve and on the value of the transition time between the onset of surface oxidation and the oxygen evolution.[10-26]

Measurements of the impedance of the electrode-solution interface yield information on the structure of the interface and on the kinetics of electrode reaction.[27-33] Therefore, it is useful in making clear the mechanism of the surface oxidation to measure the impedance change of the electrode during the anodic polarization.

Many methods for the quick measurement of the impedance have been reported.[34-40] All of them, however, appear to suffer from certain disadvantages for the continuous measurement of the impedance, which changes with time. Recently, a new technique has been described by Breiter,[41] in which the impedance of the electrode-solution interface may be obtained as a function of the potential during the anodic and the cathodic sweep of the electrode potential, which changes linearly with time. Baddy and Sundburg[42] and Krischer and Osteryoung[43] have also developed

methods for measuring the capacity continuously and rapidly.

A technique in which both the ohmic and the capacitive components of the impedance as a function of time during the galvanostatic polarization can be registered immediately and simultaneously on a suitable recorder has been developed and will be reported on this paper.

The technique will be applied to the determination of the impedance of a bright platinum electrode in the region of oxygen deposition in acid, neutral and alkaline solutions.

Principle of the Method

The impedance of the electrode-solution interface may be regarded as equivalent to a resistance, R_s, and a capacitacne, C_s, in series governed by the relation;

$$Z = R_s + 1/jwC_s \tag{1}$$

where Z is the impedance of the circuit. The a. c. current, i, passed through the circuit and the voltage drop, e, across a and b in Fig. 1 are represented as follows:

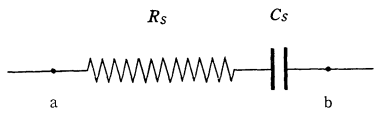

Fig. 1. Equivalent circuit of the electrode.

$$i = I\sin(\omega t+\theta) \tag{2}$$

$$e = E\sin\omega t \tag{3}$$

where I and E are the maximum values of the current and the voltage of the a. c. respectively; ω is the angular frequency, and θ, the phase difference between the current and the voltage. The values of the resistance and the capacitive reactance can be calculated by the following equations:

$$R_s = |Z|\cos\theta = |Z|\sin(\pi/2-\theta) \tag{4}$$

$$1/\omega C_s = |Z|\sin\theta \tag{5}$$

where $|Z|$ is the absolute value of the impedance. If the intensity of the current passed through the circuit is constant, the value of the potential drop, E, is proportional to the magnitude of $|Z|$. Consequently,

$$R_s \sim E\sin(\pi/2-\theta) \tag{6}$$

$$1/\omega C_s \sim E\sin\theta = E\sin(\pi-\theta) \tag{7}$$

The values of R_s and $1/\omega C_s$ are proportional to the instantaneous value of e at the times of $\omega t = \pi/2-\theta$ and $\pi-\theta$ respectively.

In measuring the value of the ohmic component, R_s, the phase of the current, i, was first shifted by $\pi/2$, as is shown in Fig. 2. The a. c. thus shifted is converted to a square-wave current and differentiated in order to make pulses. The sine wave voltage, e, from the cell is sampled with these positive pulses, which are generated at $\omega t = \pi/2-\theta$ in every half cycle. The peak voltage of the pulses thus sampled is proportional to the value of R_s. The value of the capacitive component, $1/\omega C_s$, can be obtained by sampling the value of e with pulses which are generated at $\omega t = \pi-\theta$, as is shown in Fig. 2.

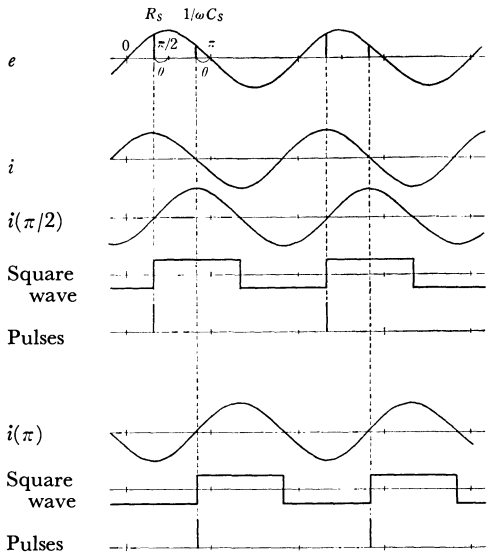

Fig. 2. Principle of the impedance measurement by sampling the signal, e, from the cell with pulses.

Apparatus

The measurements were carried out with an electronic circuit which was designed on the basis of a principle described earlier and constructed in this laboratory. A block diagram of the impedance meter is shown in Fig. 3. For the measurement of R_s, the signal of a given constant frequency from an oscillator is fed through a cathode-follower amplifier to the phase shifter, in which the phase of the signal is shifted by exactly $\pi/2$. The signal from this shifter is then converted with a Schmitt trigger circuit to square-wave a. c. with the same phase and frequency as the input sine wave signal. The rise time in the square wave a. c. was 0.2 μsec. The square wave is differentiated with a resistor and a capacitor in series, and the pulses thus obtained are rectified with a germanium diode. The signal, e, from the cell is sampled with these pulses using a vacuum tube, 6AS6, which has two separate control grids. The signal, e, is fed to one of these grids, while the vacuum tube is gated by the pulses introduced into the other grid. The peak voltage of the pulses from the sampler is proportional to the value of R_s. The

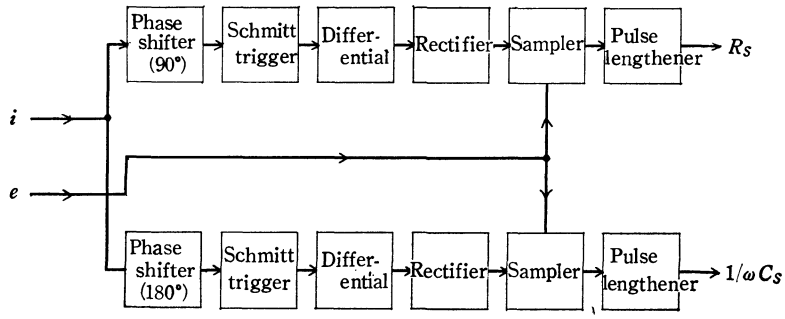

Fig. 3. Block diagram of the impedance measurement.

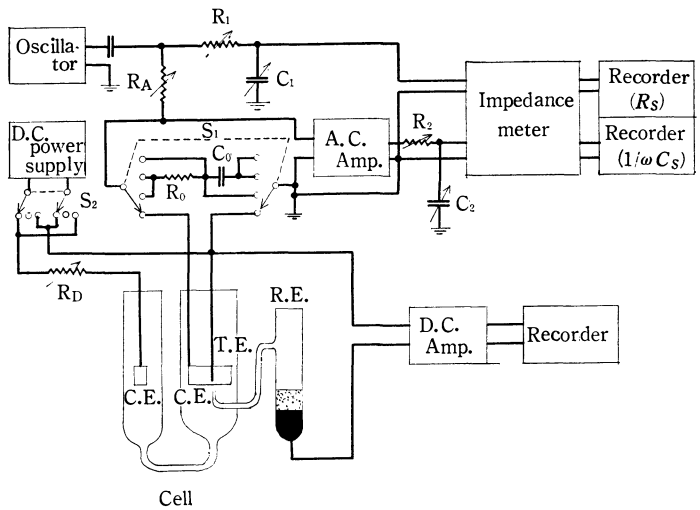

Fig. 4. Circuit diagram.

T. E., test electrode. C. E., counter electrode. R. E., reference electrode.

width of the pulses is broadened and made smooth through a pulse lengthener, because the width of the original pulse is so narrow that the direct measurement of its peak voltage is impossible with a usual recorder. The smoothed signal is amplified with a differential amplifier and then introduced to a pen recorder.

In order to measure the capacitive component, $1/\omega C_s$, the signal from the oscillator is fed, after its phase has shifted by π, to the square-wave converter. The subsequent electronical treatment of the signal is quite similar to that for the measurement of the ohmic component described above. The values of R_s and $1/\omega C_s$ as a function of the time are registered continuously and simultaneously on one chart of a two-pen recorder.

Procedure

A simplified schematic diagram of the measurement circuit is shown in Fig. 4. A constant a. c. of a small amplitude which is controlled by a variable resistor, R_A, in series with the cell was superimposed on the constant d. c. The output voltage from the oscillator was 20 V. p-p, while the d. c. voltage from the regulated power supply was 135 V. The intensity of the a. c. passed through the cell was so adjusted that the amplitude of the polarization voltage of the electrode resulting from its a. c. was below 2 mV. The a. c. signal from the cell was amplified with a high-gain a. c. amplifier and then introduced into the impedance meter. The phase of the a. c. signal was shifted through the a. c. amplifier; this is because of the small time constant or the stray inductance of the amplifier. In order to correct this phase shift, the cell in the measuring circuit was replaced with a noninductive standard resistor, and the variable resistor and capacitor, R_1, and C_1, or R_2 and C_2, were so adjusted that the difference in phase between the input signals of i and of e into the impedance meter was eliminated. The elimination of this phase difference was then checked by means of cathode-ray oscilloscopic observation. The impedance meter was calibrated with standard resistors, R_0, and capacitors, C_0, in series. When the applicability of the indicator was checked in the frequency range from 20 to

20000 c. p. s., the accuracy of the indicator was found to be ±2%.

The d. c. potential of the electrode was referred to a 1 N sulfuric acid - mercurous sulfate - mercury electrode for acid electrolytes or to a saturated calomel electrode for neutral and alkaline electrolytes. The values of the potential described in this paper are referred to the standard hydrogen scale. The stop-cock separating the reference electrode from the Luggin capillary was kept close in order to prevent any appreciable diffusion of the electrolyte of the reference electrode to the test electrode. Charging curves with the d. c. were registered by another pen recorder through a d. c. amplifier of a high-input impedance at the same time as the impedance measurement.

Experimental

The conductivity water was prepared by redistilling laboratory-distilled water from an alkaline permanganate solution in a Pyrex still, followed by triple redistillation with a quartz still. The electrolyte solutions used were 2 N perchloric acid, 2 N sodium perchlorate and 2 N sodium hydroxide solutions, all of which were prepared from guaranteed-grade reagents by appropriate dilution with the conductivity water. The electrolyte solutions were freed from dissolved oxygen by passing pure nitrogen gas through.

The test electrode was a platinum wire, 0.5 mm. in diameter and 10 mm. long. The counter electrode for the impedance measurement was a platinum gauze in the shape of a cylinder, 20 mm. high and 25 mm. in diameter, which was placed around the test electrode. A platinum plate in the other chamber of the cell served as a counter electrode for the d. c. galvanostatic polarization. The measurement was made in an all-glass vessel described previously[44] at the room temperature of 15±2°C. The test vessel had been in constant use for one year; it was, therefore, well aged. A hot chromic acid was used in order to clean the vessel at the beginning of this series of measurements, and the vessel was soaked in a test electrolytic solution for several days.

The correctness of the elimination of the ohmic potential drop which is caused by the electrolytic resistance between the test and the counter electrode in the a. c. measurement was checked with an R_s curve at 10000 c. p. s., according to the method described by Breiter.[45]

Results and Discussion

Figure 5 represents typical charging curves for each solution; the regions of β, γ and δ are attributed to the charging of the double layer, to the formation of oxygen layer, and to the evolution of oxygen respectively. The shapes of these curves have been discussed extensively. The quantities of electricity consumed in the γ regions of the solutions are nearly equal to one another. Figure 6 shows the curves of the corresponding ohmic component, R_s, while Fig. 7 shows those of the capacitive component, $1/\omega C_s$, of the impedance at 540 c. p. s. The three characteristic regions, i. e., γ', γ'' and γ''', are marked for these impedance curves corresponding to the γ region of the charging curves. The quantity of electricity consumed for each of those three regions is nearly the same, about 0.43 millicoulombs/cm².

In a previous paper,[45] it was suggested that the first step of the surface oxidation in acid solutions

is the formation of a layer of hydroxyl radicals adsorbed on the surface; this reaction takes place in the region from the initial potential of the region, γ, to 1.15 V. in the charging curve, which corresponds to the γ' region described here. If was also suggested that in the region above 1.15 V. definite oxide films are formed. If this suggestion is correct, the mechanism of the surface oxidation in acid solutions may be proposed as being by the following three stages in terms of the equal amount of electricity required in each of three regions.

The first stage, γ', is the adsorption of hydroxyl radicals on the platinum surface:

$$Pt+H_2O \rightarrow Pt\text{–}OH+H^+ +e \qquad (8)$$

The formation of Pt–OH species is reasonable, since it requires the transfer of only one electron.

In the second stage, γ'', the definite oxide layer is formed by the further oxidation of Pt–OH:

$$Pt\text{–}OH \rightarrow PtO+H^+ +e \qquad (9)$$

where the symbol PtO is used for the oxygen film instead of Pt–O, because it seems to be a monolayer of true oxide rather than an adsorbed layer of oxygen atoms.

The oxide layer thus formed is converted to a higher oxidized state in the final stage, γ''':

$$PtO+H_2O \rightarrow PtO_2H+H^+ +e \qquad (10)$$

Reactions in the neutral and the alkaline solutions may be similar to the reaction in the acid solution, except that not water molecules but hydroxyl ions are discharged.

Figure 8 shows the capacity, C_p, of the interfacial impedance in a parallel circuit as a function of the time for 4000 c. p. s. during the anodic polarization of each solution. The value of C_p was computed in the usual way from the measured values of R_s and $1/\omega C_s$. The values of C_p measured with such a high frequency may represent mainly the differential capacity of the ionic double layer, because these C_p curves resemble in shape the capacity curve[45] which was measured by the short pulse technique. In the acid solution the capacity exhibits a maximum value in the first region, γ'. The appearance of such a maximum is frequently explained in terms of an additional capacity in the inner double layer,[46-48] and it is assumed that the change in the double-layer capacity is brought about by the presence of an additional charge or dipolar species in the inner double layer.[48]

Various metal oxides with a hydrated surface generally have an ion-exchange property. The hydroxyl group which exists on a metal surface in aqueous solutions usually dissociates in one of two ways, depending on the pH of the solution[49]:

$$MOH \rightleftarrows M^+ +OH^- \text{ (in acid solutions)} \qquad (11)$$

$$MOH \rightleftarrows MO^- +H^+ \text{ (in alkaline solutions)} \qquad (12)$$

where M represents a metal atom on the surface. These OH^- or H^+ ions are held near the M^+ or OM^- ions respectively.

In order to understand the marked dependence of the capacity value of the platinum electrode in

46) D. C. Graham, *Chem. Revs.*, **41**, 441 (1947).
47) A. N. Frumkin, *J. Electrochem. Soc.*, **107**, 461 (1960).

49) C. B. Amphlett, L. A. Donald and M. J. Redman, *J. Inorg. and Nucl. Chem.*, **6**, 236 (1958).

the γ' region on the pH of the solution, the anion adsorption in acid solutions and the cation adsorption in alkaline solutions due to the ion exchange are assumed in the inner double layer:

$$Pt^+OH^- + ClO_4^- \rightleftarrows Pt^+ClO_4^- + OH^- \quad (13)$$

$$PtO^-H^+ + Na^+ \rightleftarrows PtO^-Na^+ + H^+ \quad (14)$$

The lower value of the capacity in the γ' region for the neutral solution is explained in terms of a small dissociation of Pt–OH on the surface. The large capacity value which appears in the first half of the γ' region in the alkaline solution is not fully understood, but it is not probably caused by the ion-exchange but by a specific adsorption of sodium ions. The capacity behavior resulting from the ion-exchange outlined above can be expected to hold for the formation of a Pt–OH surface, but it will not hold for surface oxidation to PtO and PtO_2H.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 784—790 (1966)

The Synthesis of Glycidylferrocenes and Related Compounds

By Hamao WATANABE, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 10, 1965)

Ferrocene derivatives with one or two glycidyl substituents, desired for the formation of polymeric ferrocene compounds, were synthesized by the epoxidation of chlorohydrin compounds obtained from the products of the addition of ferrocenyllithium to epichlorohydrin at −40——78°C. In the course of this synthesis, mono- and di-chlorohydrin compound and a disubstituted ferrocene with a 3-chloro-2-hydroxypropyl and a glycidyl substituent were isolated. All of them are stable liquid compounds. The investigation of the relationship between the reaction conditions and the yield of glycidylferrocenes revealed that the larger molar ratio of each reactant to ferrocene at each reaction step causes a higher conversion into glycidylferrocenes. In the epoxidation reaction of chlorohydrins with caustic alkali, a small amount of ethers, formed by the reaction of epoxides and the solvent ethanol, was obtained under some reaction conditions. In all cases, a small amount of biferrocenyl was isolated; the formation of this compound was considered to be attributable to the Wurtz-type coupling reaction of ferrocenyl radicals. The structures of all these products were confirmed by their infrared absorption spectra and, in part, by the NMR spectra.

In a previous communication[1] it was briefly reported that ferrocene derivatives with one or two glycidyl substituents were obtained by the epoxidation of chlorohydrins which had been derived from the products of the addition of ferrocenyllithium to epichlorohydrin. It seemed that these epoxy derivatives are promising monomers for the formation of various types of polymers. The present paper will deal with the synthesis of glycidylferrocenes and the related compounds in full detail.

The reaction of phenyllithium with epichlorohydrin has been reported by Gilman and his coworkers.[2] However, no reaction of this type on the ferrocene derivatives has yet been reported. In the present study a similar reaction was applied to the addition of ferrocenyllithium to epichlorohydrin in order to obtain the compounds which can lead to epoxy compounds.

Results and Discussion

The route and the products of the reactions are as follows:

Ferrocene (I) was converted into lithium derivatives (II and VI) by treatment with *n*-butyllithium in anhydrous ether under an atmosphere of nitrogen.[3] When a suspension of ferrocenyllithium was treated with epichlorohydrin at −40 to −78°C, a mixture of addition products (III, VII and IX) was obtained. The mixture was hydrolyzed to give chlorohydrin derivatives (IV, VIII and X). The chlorohydrin compounds were separated from the reaction mixture by adequate procedures, and each chlorohydrin compound was separated by means of vacuum distillation and/or chromatography on alumina. Each chlorohydrin was then epoxidized in an ethanol solution[4] by treatment with a 30% aqueous solution of potassium hydroxide. Monoglycidylferrocene (V) and diglycidylferrocene (XI) were thus obtained as dark red liquids. These epoxides were also obtained by a direct epoxidation of the chlorohydrin mixture (IV, VIII and X) without the previous separation of each chlorohydrin. Glycidylferrocenes (V and XI) were isolated from the reaction mixture by chromatography on alumina.

The Reaction of Ferrocenyllithium and Epichlorohydrin.—The preparation of ferrocenyllithium from ferrocene, followed by the addition reaction with epichlorohydrin, was attempted under various conditions, and the resultant lithium compounds were hydrolyzed. The reaction conditions and the results are listed in Table I, in which the yields of the final products are calculated on the basis of the ferrocene used. The addition reaction of ferrocenyllithium to epichlorohydrin could be accomplished at a low temperature, but not at an ordinary temperature, as has been shown by Gliman and his co-workers.[2] A similar reaction was also attempted with ferrocenylsodium[5] and epichlorohydrin. In this attempt also, no successful reaction

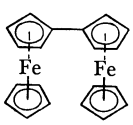
occurred without cooling, or when the mixture was heated in toluene, but the reaction may be expected to occur here also if it is undertaken at a low temperature. The conversion of ferrocene into ferrocenyllithium and its addition reaction with epichlorohydrin was facilitated by the increase in the molar ratios of *n*-butyllithium and of epichlorohydrin to ferrocene, and by the elongation of each reaction time. The reaction products were separated by vacuum distillation or chromatography on alumina. Besides two chlorohydrin compounds (IV and VIII), two epoxy compounds (V and XI) and a mixed epoxy-chlorohydrin compound (X) were isolated in significant amounts. These results indicate that the epoxy-ring formation from the compounds III, VII and IX occurred at least in part in the course of the addition reaction. When each step of the reaction was cut to a shorter reaction time (Exp. Nos. 207 and 208), however, the product was found to consist mainly of chlorohydrin derivatives.

Monochlorohydrin IV could be separated by vacuum distillation from the reaction product. It was found, however, that the reaction product was apt to decompose during the distillation, so the temperature must be carefully controlled under a high vacuum. Therefore, the method for separation and purification by means of alumina chromatography was recommended. A typical example is shown in Table II. Each product was successively eluted with benzene and other solvents.

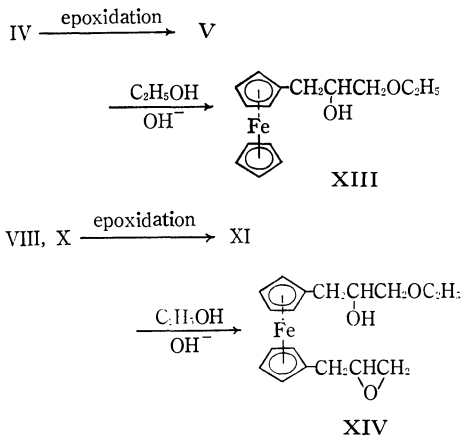
In the separation procedure of the chromatography, a small amount of orange crystals was isolated from the early-eluted fraction next to the ferrocene recovered. This compound was identified as biferrocenyl (XII), as has been reported in another communication by the present authors.[6] The mechanism of the formation of biferrocenyl in the course of the reaction was inferred to be as follows: ferrocenyllithium was subjected to homolytic fission between the ferrocenyl group and lithium to afford ferrocenyl radical, which then coupled to give biferrocenyl. Further investigations of this problem will be reported in a following paper.[7]



XII

By a comparison of the rate of elution in the chromatography, the adsorbability to alumina was estimated to be in the following order: I< XII<V<XI<IV<X<VIII.

Epoxidation Reaction.—*The Separate Epoxidation of Each Chlorohydrin.*—Each chlorohydrin separated by the chromatography was dissolved in ethanol and treated with a 30% aqueous solution of potassium hydroxide under cooling with ice water and high-speed stirring. After the epoxidation reaction was over, a large quantity of water and ether was added, and the crude epoxide (V or XI) was obtained from the ethereal layer and purified by alumina chromatography. The epoxidation of the chlorohydrin derivatives gave, in general, good yields of the corresponding glycidylferrocenes. In some exceptional instances, it was found that the reaction mixture was contaminated by a small amount of a liquid compound other than epoxy compound. These compounds were isolated after the separation of each product from the epoxidized mixture and purification by alumina chromatography. From the various analytical results, the compounds were found to be addition products of the glycidylferrocenes and ethanol used as the solvent.



Compounds XIII and XIV were supposed to be formed by the addition of ethanol to glycidylferrocenes during the epoxidation reaction in the presence of potassium hydroxide. This presumption was proved by an experiment, in which epoxide(XI) dissolved in ethanol was treated with a potassium hydroxide solution by a work-up similar to that described above; a part of the epoxide (XI) was converted into XIV, while most of it was recovered unchanged.

The yield of compound XIII or XIV was increased by the prolonged reaction time of epoxidation, as is shown in Table III. Compounds XIII and XIV are dark red liquids (n_D^{20} 1.5796 and 1.5711 respectively), the former being more viscous than the latter. It was shown that these compounds have slightly higher adsorbabilities than the corresponding epoxides.

The Direct Epoxidation of the Chlorohydrin Mixture.—The reaction product obtained by the reaction of ferrocenyllithium and epichlorohydrin was dissolved in ethanol without any further separation process, and directly epoxidized by treatment with

* Epoxy equivalent, 0.99 (HCl - dioxane method)

potassium hydroxide under the reaction conditions similar to those described in the above section. When the reaction mixture was submitted to a vacuum distillation, compounds V and XI were obtained, boiling at 111—115°C under 0.17—0.18 mmHg and at 160—161°C under 0.09—0.12 mmHg respectively. A small amount of biferrocenyl was also isolated from the residue of the vacuum distillation.

The chromatography to separate the products into each compound gave the results shown in Table IV. By the chromatographic separation, biferrocenyl was again isolated besides another unknown substance.

The Assignment of the Structures of the Products.—Compounds IV, V, VIII, X, XII, XIII and XIV were stable in air. These compounds were identified by means of their elemental analyses, infrared spectra and NMR spectra, and by a study of their chemical natures.

The physical properties of the various products are summarized in Table V. All of these products are dark red liquids. Mono- and di-chlorohydrin derivatives (IV and VIII) have higher viscosities than those of the corresponding glycidylferrocenes, which are fairly fluid. The viscosity of the compound X falls between those of VIII and XI. As a whole, the order of the viscosity of these compounds as determined by visual observation is: VIII$\geqq$IV$>$X$>$XI$>$V. The epoxy equivalent of monoglycidylferrocene (V) was determined by the hydrochloric acid - dioxane method,[8] using cresol red as an indicator, to be 0.99; this value agrees well with the theoretical value (1.00).

It has been shown in the previous paper[1] that when a mixture of glycidylferrocenes was treated with a hydrochloric acid - dioxane mixture in order to obtain the corresponding chlorohydrin mixture, only bischlorohydrin (VIII) was isolated by chromatography on alumina, and it was reconverted into diglycidylferrocene with potassium hydroxide. A similar ring-opening reaction was observed in the measurement of the epoxy equivalent of the

8) G. King, *Nature*, **164**, 706 (1949); "Organic Analysis," Vol. 1, 135; "Kobunshi Jikkengaku Koza," Vol. 9, Kyoritsu Shuppan, Tokyo (1958), p. 259.

compound V: a dark red, viscous liquid material obtained after the measurement was found to be identical with an authentic chlorohydrin compound IV. From these results it is obvious that a reversible epoxy-ring closure and opening reaction was effected between these compounds by alkali and hydrochloric acid.

It was substantiated that the disubstituted ferrocenes described above are heteroannularly-substituted compounds, from the fact that their infrared absorption spectra lack the absorption bands at 1100 and 1000 cm^{-1}. This assignment has been designated as the 9—10 rule.[9]

The infrared spectra of two chlorohydrins (IV and VIII) and two glycidylferrocenes (V and XI) exhibit essentially identical absorption bands in each pair, except for the region between 1100 and 1000 cm^{-1}. The characteristic peaks for the chlorohydrin group in IV and VIII appear at 3400 (ν_{C-H}), 1090—1050 (ν_{C-O}) and 760—690 cm^{-1} (ν_{C-Cl}), while the characteristic peaks for the epoxy group in V and XI appear at 3050 and 2970 cm^{-1} (ν_{C-H}) and at 1256, 960—900, and 845 cm^{-1} (epoxy ring). Compound X shows the absorption bands due to both the chlorohydrin group and the epoxy group.

Further confirmation was obtained by the examination of the NMR spectra of two glycidylferrocenes (V and XI). In the spectrum of the monoglycidylferrocene a singlet signal was observed at τ 6.[10] This is attributable to the overlapping of the signal of unsubstituted ring protons (5H) and that of monosubstituted ring protons (4H) because of the close resemblance of their chemical shifts. The signal was yet a sharp peak in spite of the overlapping. On the other hand, the NMR spectrum of diglycidylferrocene showed a singlet signal at τ 5.96 assignable to the heteroannularly-disubstituted ring protons (8H), and no other signals assignable to any homoannularly-disubstituted ring protons were observed. Two other complex signals, centered at τ7.0 and τ7.4, were assigned to the protons of glycidyl groups, the former due to the methine proton in the oxide group, and the latter to the two protons of methylene and two protons of oxide methylene.

Experimental

The temperatures in the reactions and measurements were uncorrected. The infrared spectra were determined on a Model EPI-S2 recording spectrometer (Hitachi Co.), and the NMR spectra were determined at 60 Mc. on a Model JNM-C-60 spectrometer (Japan Electron Optics Laboratory Co.), employing a room-temperature method in deuteriochloroform containing tetramethylsilane as an internal standard and ca. 30% (by volume) of the sample.

All column chromatographies were performed on Sumitomo Chemicals' activated alumina (150—250 meshes) which had previously been exposed to air for eigtht hours in order to diminish its adsorption ability. A benzene solution of the sample was placed on the alumina and developed with the same solvent.

1. The Reaction of Ferrocenyllithium and Epichlorohydrin.—The lithiations of ferrocene with *n*-butyllithium and the subsequent reactions of ferrocenyllithium with epichlorohydrin were carried out with stirring in anhydrous ether under an atmosphere of nitrogen. Three runs of the reaction were accomplished by essentially identical procedures except for the molar ratios of the reactants and the reaction times (Table I). A typical procedure for the preparation of ferrocenyllithiums and their reaction with epichlorohydrin is as follows (Exp. No. 210).

A solution of 0.6 mol. of *n*-butyllithium was prepared, according to the method described in the literature,[11] from 82.8 g. (0.6 mol.) of *n*-butyl bromide in 120 ml. of ether and 10.35 g. (1.5 g.-atom) of suspended lithium, cut into pieces as small as possible, in 240 ml. of ether, the temperature being kept at −30°C by cooling in a dry ice - acetone bath. In another vessel 55.8 g. (0.3 mol.) of ferrocene was dissolved in 650 ml. of ether and cooled to −20——30°C in a dry ice - acetone bath. The solution of *n*-butyllithium previously prepared was added to the ferrocene solution through a siphon, the inlet tube of which was covered with glass wool in order to filter off solid impurities. After the addition was complete, the mixture was allowed to warm up to room temperature with stirring over a 20-hr. period. Further stirring was continued for 94 hr. Since the spontaneous evaporation of the solvent under a stream of nitrogen was observed during this period, 400 ml. of ether was added in two portions (150 and 250 ml.).

The orange suspension of ferrocenyllithium thus obtained was cooled to ca. −65°C in a dry ice - acetone bath, and 138.8 g. (1.5 mol.) of epichlorohydrin (b. p. 115.0—115.4°C) in 100 ml. of ether was then added to the suspension during a 2-hr. period so as to maintain the temperature at −60°C or below. After the addition was complete, the mixture was kept at this temperature for 7 hr., and then allowed to warm up to −40°C over a 16.5-hr. period. Then, the cooling bath was removed and the mixture was allowed to come to room temperature, after which the contents were poured into a large amount of ice water in order to hydrolyze the lithium compounds.

The ethereal layer was separated, and the aqueous layer was extracted with ether. The combined ethereal solution was dried over magnesium sulfate and evaporated in order to remove the ether and the remaining epichlorohydrin. On concentration, a large quantity of unreacted ferrocene separated out as orange crystals; it was removed by filtration. The filtrate was placed in a Claisen-type flask fitted with a Vigraux-column and evaporated under 1.5 mmHg at 130°C on an oil bath, thus removing materials of a lower boiling point and/or a higher vapor pressure (the remaining ferrocene

11) "Organic Reactions," Vol. 6, 352 (1951).

sublimed inside the Vigraux-column). After the vacuum evaporation, 36.8 g. of the reaction product was obtained as a dark red, very viscous liquid.

2. The Separation of Each Compound from the Reaction Mixture.—*a) Vacuum Distillation.*—As has been reported in a previous communication,[1] a vacuum distillation of the reaction product (Exp. No. 207) gave a very viscous dark red liquid which was identified as the monochlorohydrin compound IV; b. p. 156—158°C/0.8—0.9 mmHg, or 144°C/0.52—0.53 mmHg; n_D^{20} 1.6102.

Found: C, 56.09; H, 5.33. Calcd. for $C_{13}H_{15}FeClO$: C, 56.05; H, 5.43%.

b) Separation by Means of Chromatography.—In order to make a more delicate separation, 9.2 g. of the reaction product described above (Exp. No. 210) was dissolved in a small amount of benzene and chromatographed on alumina using benzene as a developer. Elution was performed by successively changing the eluent. The results of the chromatography are shown in Table II.

The first elution with benzene gave ferrocene (0.03 g.).

The second elution with benzene yielded orange crystals (0.10 g.), which were then recrystallized from a mixture of benzene and petroleum ether; m. p. 233.8—234.5°C (in a sealed capillary). The compound was identified as biferrocenyl (XII); NMR spectrum, τ 5.68 (triplet), 5.85 (triplet), and 6.03 (singlet). These signals will be discussed in a following paper.[7]

Found: C, 64.78; H, 5.05. Calcd. for $C_{20}H_{18}Fe_2$: C, 64.91; H, 4.90%. Mol. wt. Found: 370(Rast) and 330 (vapor pressure osmometer method). Calcd. 370.

The third elution with benzene gave rise to monoglycidylferrocene (V, 1.48 g.; n_D^{20} 1.6093), whose identification was established as will be described below (3-a).

The fourth elution with benzene yielded diglycidylferrocene (XI, 0.90 g.) as a slightly viscous, dark red liquid; n_D^{20} 1.5968. The identification was established as will be described below (3-b).

A very viscous, dark red liquid obtained from the fifth band was the monochlorohydrin compound (IV, 1.80 g.). It was identified as the same compound as had been described above (2-a).

The sixth elution, with benzene-ether (1 : 1), gave a relatively viscous, dark red liquid (1.79 g.) which gave a pure material upon rechromatography. The compound was identified as a heteroannularly-substituted ferrocene (X); n_D^{20} 1.6014.

Found: C, 57.31; H, 5.12. Calcd. for $C_{16}H_{19}\cdot FeClO_2$: C, 57.43; H, 5.72%.

The seventh elution, with ether-methanol (9 : 1), gave rise to the dichlorohydrin compound (VIII, 1.89 g.); n_D^{20} 1.6069.

Found: C, 51.83; H, 5.26. Calcd. for $C_{16}H_{20}\cdot FeCl_2O_2$: C, 51.79; H, 5.43%.

The product from the last elution with methanol was presumed to be a mixture of many compounds (0.10 g.), but their separation and the identification were not attempted.

3. Epoxidation.—The separate epoxidation of each chlorohydrin (IV, VIII, X) was effected under common reaction conditions; 50 or 70 mol. of ethanol (used as solvent) and 10 mol. of potassium hydroxide were used per mole of the chlorohydrin function. The reaction conditions of epoxidation are shown in Table III.

a) The Epoxidation of IV to V.—A solution of 0.82 g. (2.94 mmol.) of IV in 80 g. (0.208 mol.) of ethanol was cooled to 0—10°C in an ice-water bath. Into the cold solution 5.6 g. of a 30% aqueous solution of potassium hydroxide (containing 29.4 mmol. of potassium hydroxide) was added with vigorous stirring. After the addition, the stirring was continued for 8 min., after which large amounts of water and ether were added. The ethereal layer was separated, and the aqueous layer was repeatedly extracted with ether. The combined ethereal solution was filtered and evaporated to give a crude epoxy compound (0.77 g.). The crude product was dissolved in benzene and chromatographed on alumina, using the same solvent as a developer. Elution with benzene yielded pure epoxide V (0.65 g., 91% yield); n_D^{20} 1.6093.

Found: C, 64.41; H, 5.57. Calcd. for $C_{13}H_{14}FeO$: C, 64.50; H, 5.83%. Epoxy equivalent, 0.99 (HCl-dioxane method).[8]

Vacuum distillation revealed the purity of the epoxide; b. p. 107-—113°C/0.13—0.16 mmHg: n_D^{20} 1.6093.

When a similar epoxidation reaction of the same chlorohydrin (IV) was carreid out for a elongated stirring period, as is shown in Table III, a subsequent fraction was obtained by elution with benzene-ether (1 : 1). This fraction gave rise to a small amount of a dark red, relatively viscous liquid, which was found to be an addition product (XIII) between V and ethanol; n_D^{20} 1.5796.

Found: C, 62.85; H, 6.97. Calcd. for $C_{15}H_{20}FeO_2$: C, 62.52; H, 7.00%.

b) The Epoxidation of VIII to XI.—The epoxidation reaction was accomplished according to the procedure described above. A solution of 1.34 g. (7.22 mmol.) of VIII in 16 g. (0.348 mol.) of ethanol was treated with 15 g. of a 30% aqueous solution of potassium hydroxide (containing 72.2 mmol. of potassium hydroxide). After the addition of the alkaline solution under cooling in an ice-water bath had been complete, a vigorous stirring was continued without cooling so as to allow the temperature of the mixture to rise from 10 to 25°C in 45 min. The reaction mixture was then extracted with ether. After the evaporation of the ether, a slightly viscous, dark red liquid (1.11 g.) remained. It was separated by alumina chromatography much as in procedure 3-a.

Elution with benzene yielded diglycidylferrocene (XI, 0.72 g., 66.9%); n_D^{20} 1.5968.

Found: C, 64.40; H, 6.18. Calcd. for $C_{16}H_{18}FeO_2$: C, 64.45; H, 6.09%.

The attempted purification of XI by vacuum distillation resulted in its boiling at 160—161°C/0.09—0.12 mmHg; n_D^{20} 1.5968.

Elution with benzene-ether (1 : 1) gave rise to a dark red, slightly viscous liquid (0.16 g.) which was identified as compound XIV; n_D^{20} 1.5711.

Found: C, 62.68; H, 6.91. Calcd. for $C_{18}H_{24}FeO_3$: C, 62.81; H, 7.03%.

When the epoxidation of VIII was accomplished in a short reaction time (Table III, 12 min. at 0—10°C), the yield of XI increased to 92%, while the compound XIV was not detected.

c) The Epoxidation of X to XI.—A solution of 0.84 g. (2.51 mmol.) of X in 8 g. (0.17 mol.) of ethanol was treated with 4.3 g. of a 30% aqueous solution of potassium hydroxide (containing 22.6 mmol. of potassium hydroxide). The products were separated by the

procedure described in 3-b.

Elution with benzene gave diglycidylferrocene (XI, 0.58 g., 77.3% yield) and compound XIV (0.10 g.).

d) The Reaction of Diepoxide XI with Alkali in Ethanol. —A solution of 1.27 g. (8.54 mmol.) of XI in 18 g. (0.348 mol.) of ethanol was vigorously stirred with 15 g. of a 30% aqueous solution of potassium hydroxide (containing 72.2 mmol. of potassium hydroxide) at 0—10°C for 25 min. The stirring was continued for further 40 min. without cooling. The following procedure was similar to that adopted for the epoxidation of chlorohydrin compounds. The product was chromatographed on alumina and eluted with benzene and benzene-ether.

Elution with benzene gave 1.03 g. of the recovered XI (81.1% recovery).

Elution with benzene-ether (1 : 1) gave a dark red, relatively viscous liquid (0.18 g.). The liquid was rechromatographed and identified as compound XIV by a comparison of its infrared spectrum and refractive index with those of an authentic material.

e) The Direct Epoxidation of the Chlorohydrin Mixture. —In the direct epoxidation of a mixture of chlorohydrins, it must be noted that a molar ratio calculation of the reactants was established on the basis of a composition analysis of the various components, which were determined from the results of alumina chromatography. The following example shows the epoxidation of the sample obtained by Exp. No. 210 (Table I); the composition of the sample is listed in Table II.

To a solution of 16.21 g. of the sample (containing 48.5 mmol. of chlorohydrin function) in 141 g. (3.06 mol.) of ethanol, 77.5 g. of a 30% aqueous solution of potassium hydroxide (containing 0.485 mol. of potassium hydroxide) was added under cooling in an ice-water bath, and the mixture was stirred for 10 min. After a treatment similar to that described above (3-a), 14.13 g. of a dark red liquid was obtained. The product was chromatographed on alumina. Five fractions were successively eluted with benzene and methanol, as is shown in Table IV.

The first elution with benzene gave rise to a mixture of ferrocene and biferrocenyl. Ferrocene (ca. 0.10 g.) was removed by vacuum sublimation, and the remaining red-brown solid material was purified by recrystallization from a mixture of benzene and petroleum ether to give 80 mg. of biferrocenyl (XII); m. p. 231.0—232.0°C (in a sealed capillary).

The second elution with benzene yielded 4.96 g. of monoglycidylferrocene (V).

The third elution with benzene gave a slightly viscous, dark red liquid (1.24 g.) on which no further analysis was attempted.

The fourth elution with benzene yielded 6.44 g. of diglycidylferrocene (XI).

The last elution, with methanol, gave a mixture (1.12 g.). Although it was supposed that the mixture might contain several compounds, such as XIII and XIV, no further attempt was made to separate and identify them.

Finally, as has been shown in a previous paper,[1] the epoxidized crude product was also purified by vacuum distillation to give V; b. p. 111—115°C/0.17—0.18 mmHg; n_D^{20} 1.6093. A small amount of biferrocenyl was separated as orange crystals by filtration from the residue of the vacuum distillation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 790—801 (1966)

The Direct Formation of Biferrocenyl and Polyferrocenyls from Ferrocenyllithium

By Hamao WATANABE, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 10, 1965)

In the presence or absence of *n*-butyl bromide, ferrocenyllithium and cobaltous chloride reacted to give various polyferrocenyls and butylated polyferrocenyls. They were isolated, mainly by alumina chromatography, and their structures were established, principally from the NMR spectra, to be heteroannularly-bonded ones. The formation of these compounds is considered to be due to the coupling reactions of the ferrocenyl radical, the ferrocenylene biradical and the butyl radical, which were formed by homolytic fissions of some reactive intermediate and butyl halide. The presence of the alkyl halide greatly affected the sorts and yields of the products. No cyclic polyferrocenylene was obtained. The "9—10 rule" concerning the infrared spectra of ferrocene derivatives was found not to apply to di-substituted biferrocenyls. It was found, by a study of the X-ray diffraction patterns and the infrared spectra, that terferrocenyl crystallizes in polymorphic forms according to the method and the solvent of crystallization. The polymorphism may be attributable to the rotational isomerism around the central ferrocene nucleus.

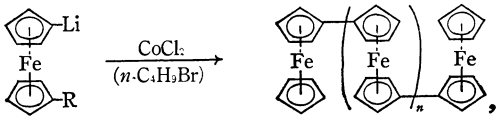
In connection with the synthesis of glycidylferrocenes and the related compounds,[1,2] the direct formation of biferrocenyl from ferrocenyllithium was previously reported by the present authors.[3] It was supposed that the formation of biferrocenyl is attributable to the Wurtz-type reaction,[4] in which the coupling of ferrocenyl radicals, produced by the homolytic fission of ferrocenyllithium molecules, gives rise to biferrocenyl. It has been shown by Kharasch and his co-workers[5] that small quantities of cobaltous chloride favor the formation of biphenyl from phenyllithium. Wittig and Lehmann[6] have also reported the coupling reaction of biphenyldilithium in the presence of cobaltous chloride. With reference to their experiments, the present authors attempted the reaction of ferrocenyllithium and cobaltous chloride in order to establish the radical mechanism. The mechanism has already been presumed from the results of the reaction which partly reported in a previous paper.[3]

Just after the present experiment was finished, Spilners and Pellegrini[7] reported a similar reaction of lithiated ferrocene and cobaltous chloride in ether-tetrahydrofuran. The reaction of ferrocenyl magnesium halide and cobaltous chloride to give biferrocenyl has also been reported by Shechter and Helling.[8] These investigators proposed the radical mechanism. However, no detailed description of a reaction of this type affording many sorts of polyferrocenyls has ever appeared.

The present paper will deal in full detail with the direct formation of biferrocenyl and polyferrocenyls from ferrocenyllithium. The reaction of ferrocenyllithium and cobaltous chloride was accomplished in dry ether under an atmosphere of nitrogen, in the presence or absence of an equimolar amount of alkyl halide, such as *n*-butyl bromide, to the ferrocene used. After the reaction of ferrocenyllithium and cobaltous chloride, the reaction mixture was poured into ice water in order to quench the reactive compounds. The organic layer was then separated from the inorganic aqueous layer. After the solvent has been removed from the organic layer, many products were isolated from the solid mixture by various procedures. The isolated crude products were then purified by rechromatography or recrystallization.

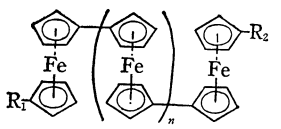
Results and Discussion

The reaction scheme and the products are as follows:



R=H or Li

I $n=0$
II $n=1$
III $n=2$
IV $n=3$
V $n=4$



VI $n=0$, $R_1=n\text{-}C_4H_9$, $R_2=H$
VII $n=0$, $R_1=R_2=n\text{-}C_4H_9$
VIII $n=1$, $R_1=n\text{-}C_4H_9$, $R_2=H$
IX $n=2$, $R_1=n\text{-}C_4H_9$, $R_2=H$

The reaction products in the presence of *n*-butyl bromide were found to be biferrocenyl (I), terferrocenyl (II), quaterferrocenyl (III), quinqueferrocenyl (IV), sexiferrocenyl (V), monobutyl-biferrocenyl (VI), dibutyl-biferrocenyl (VII), monobutyl-terferrocenyl (VIII), and monobutyl-quaterferrocenyl (IX). In the reaction without the halide, however, it was found that biferrocenyl, terferrocenyl and monobutyl-terferrocenyl were the main products. All of these products except biferrocenyl were confirmed to be hetero-annularly-bonded compounds. Their structures were established by means of their infrared, NMR and ultraviolet spectra, molecular weight determinations, elemental analyses, and by the behavior of these compounds in the chromatographic separation.

The Reactions of Ferrocenyllithium and Cobaltous Chloride.—The reaction conditions and the rate of the conversion of ferrocene into the condensation products are shown in Table I. The conversion rate in Run A was 36.2%, while in Run B it was 4.8%, in spite of the longer reaction period. This indicates that the presence of alkyl halide greatly affected the conversion of ferrocenyllithium into the condensation products. The reaction products, separated by chromatography, are listed in Table II.

In the reaction without the halide the present authors observed the formation of orange-red crystals which are apparently different from ferrocene and may be suspected to be an intermediate compound. Moreover, it is noticeable that, after the reaction was complete, a fine, almost black solid was found in the bottom of the flask. This solid was proved to be so sensitive to water that it rapidly changed

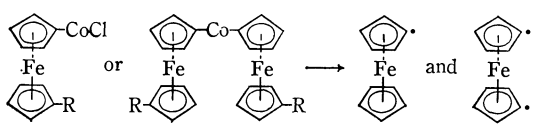
c) The yields, calculated on the basis of used ferrocene, are shown in parentheses.

into a fine orange solid, which seemed to be ferrocene, upon contact with water. Since ferrocenyllithium is yellow or orange, this reactive substance may be inferred to be an intermediate compound, something like X or XI, derived from ferrocenyllithium and cobaltous chloride. Probably, the homolytic fission of the intermediate affords the ferrocenyl radical (XII) and the ferrocenylene biradical (XIII), as has been reported in connection with phenyl derivatives by Kharasch and his co-workers[5] and by Wilds and McCormack.[9]



X XI XII XIII

R=H, Li or CoCl R=H, Li, CoCl, or -Co-

In the present experiment, however, it could not be elucidated from which intermediate, X or XI, the ferrocenyl and ferrocenylene radicals were derived. Nevertheless, it may be concluded that the formation of many polynuclear ferrocenes is attributable to the coupling reactions of these radicals, and that the presence of alkyl halide in the reaction system facilitates the formation of these radicals. Besides, alkyl halide itself is subjected to homolytic fission to give the alkyl radical, which then couples with ferrocenyl and ferrocenylene radicals to afford alkylated polyferrocenyls. The formation of some cyclic product was expected from the radical mechanism, as has been reported by Wittig and Lehmann[6] on biphenyl series, but no cyclic compounds such as biferrocenylene and polyferrocenylene were isolated at all from the reaction product. This is probably due to the steric inhibition of the radical coupling reaction and/or to the termination of the chain coupling by the ferrocenyl or the butyl radical.

Spectroscopic Behavior of the Products.— The structures of the products which were soluble in organic solvents were mainly assigned by means of their NMR spectra.

In the chromatographic separation of the products (Table II), the first elution gave rise to a red-orange compound (VII; m. p. 52.0—53.0°C), the NMR spectra of which is shown in Fig. 1. Three multiplet signals of eighteen protons, centered at τ 7.89, 8.73 and 9.14, are apparently due to the two butyl groups on the biferrocenyl nuclei. Nagai and his co-workers[10] pointed out that, in general, the four protons of the cyclopentadienyl ring with an alkyl group are subjected to the shielding effect from the alkyl group, and that a singlet signal appears at

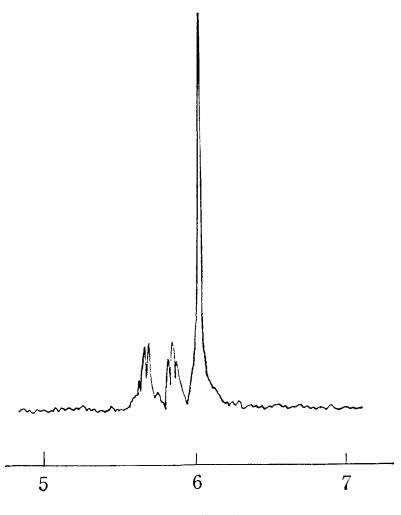


Fig. 3. NMR spectrum of biferrocenyl (I).

TABLE III. THE CHEMICAL SHIFTS OF THE PRODUCTS[1] (τ value)

Compound	$H_{u.r.}$[2]	$H_{\alpha,\beta}$[3]	$H_{s.r.}$[4]	$H_{b.}$[5]
FcH	5.85(10)	—	—	—
I	6.03(10)	5.68 (4); 5.85 (4)	—	—
II	6.03(10)	5.79 (8); 5.88 (8) 5.84[6]	—	—
VI	6.02 (5)	5.70 (4); 5.85 (4)	6.14 (4)	7.87, 8.85, 9.15 (9)
VII	—	5.73 (4); 5.85 (4)	6.13 (8)	7.89, 8.73, 9.14(18)
VIII	6.06 (5)	5.86[6](16)	6.18 (4)	7.95, 8.75, 9.18 (9)
IX	6.07 (5)	5.91[6](24)	6.18 (4)	8—9.5 (9)

1) The values in parentheses are relative intensities.
2) Unsubstituted ring protons.
3) Alpha and beta protons on directly bonded rings.
4) Protons on the ring substituted with one butyl group.
5) Protons of butyl group.
6) Value of the center of multiplet signal.

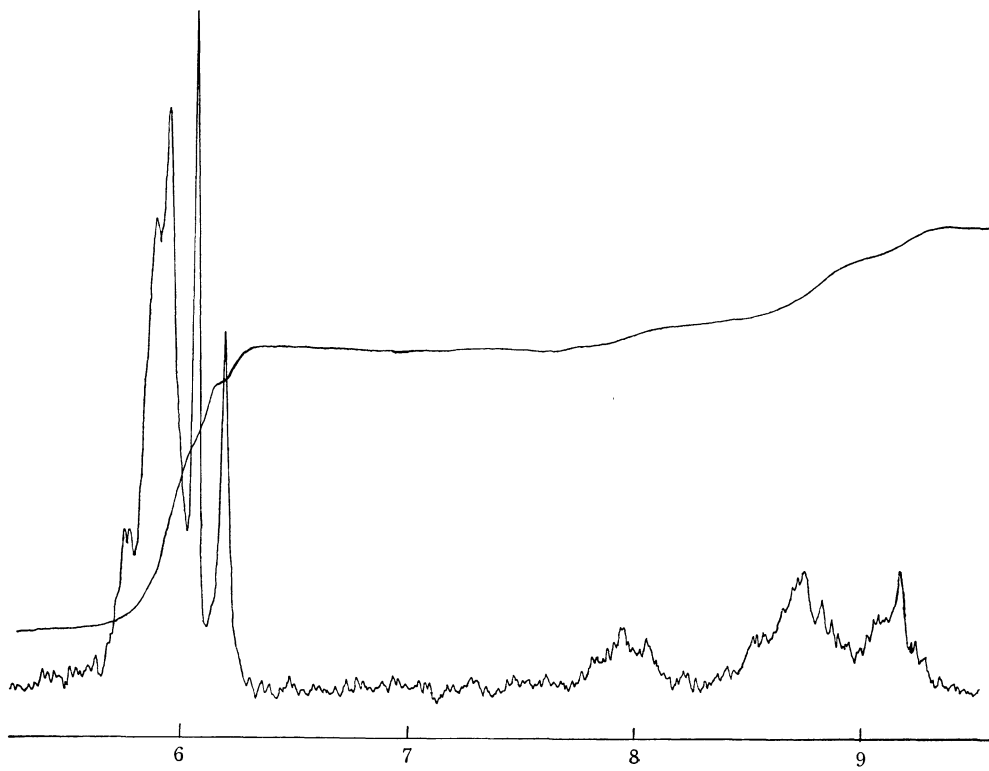

Fig. 4. NMR spectrum of monobutyl-terferrocenyl (VIII).

a higher field than that of the protons of the unsubstituted ring. Further, it is known that two directly-bonded ferrocene nuclei in biferrocenyl or its derivatives exert a strong mutual deshielding effect on the α and β protons in the bonded ring. From these facts, and by a comparison with the spectrum of monobutyl-biferrocenyl (Fig. 2. see below), the eight-proton singlet signal at τ 6.13 may be said to be due to the protons on the two rings respectively substituted with one butyl group, while the remaining two signals of four protons, centered at τ 5.73 and 5.85, are assignable to the α and β protons respectively. Therefore, this compound was determined to be heteroannularly-dibutylated biferrocenyl (VII).

The second elution gave a compound (VI; m. p. 68.2—70.2°C), the NMR spectrum of which is shown in Fig. 2. The singlet signal at τ 6.14 is due to the four protons on the substituted ring with a butyl group. The singlet signal at τ 6.02 is due to the five protons on an unsubstituted ring, and the two four-proton multiplet signals at τ 5.70 and

5.85 respectively to the α and β protons on the two directly-bonded rings. The signals of a butyl group appear at a higher field (centered at τ 7.87, 8.85 and 9.15). From these analyses this compound was identified as heteroannularly-monobutylated biferrocenyl (VI).

The NMR spectrum of biferrocenyl (I), obtained from the fraction of the third elution, shows only three signals (Fig. 3), as has been reported by Goldberg.[11] A singlet signal at τ 6.03 is attributable to ten protons on the two unsubstituted rings, and two triplet signals at τ 5.68 and 5.85 respectively to the α and β four protons on the directly-bonded rings.

The orange-red compound VIII melting at 113.0—115.0°C, obtained from the fraction of the fourth elution, shows a spectrum similar to that of monobutyl-biferrocenyl (see Fig. 4). By a compraison of the τ values of the signals and the intensities of the resonance peaks in Fig. 4 and Fig. 2, the compound VIII was identified as heteroannularly-bonded monobutyl-terferrocenyl.

The compound II, m. p. 226.5—227.2°C, obtained from the fraction of the fifth elution, was identified as terferrocenyl. Its NMR spectrum is shown in Fig. 5. A singlet signal at τ 6.03 is assignable to the ten protons on the two unsubstituted rings, while a multiplet signal centered at τ 5.84 is assignable to the sixteen protons on the four directly-bonded rings.

The orange-red compound IX melting at 177.4—179.4°C, obtained from the fraction of the sixth elution, exhibits the NMR spectrum shown in Fig. 6. By a treatment similar to that of monobutyl-terferrocenyl (VIII), the compound IX was presumed to be monobutylated quaterferrocenyl.

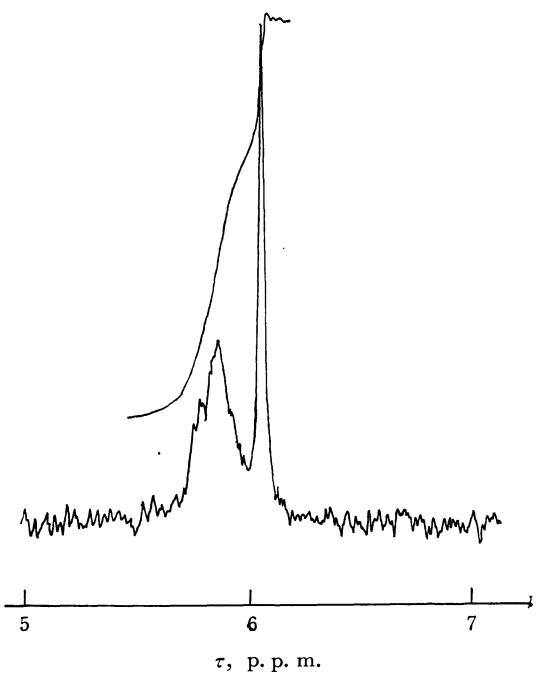

Fig. 5. NMR spectrum of terferrocenyl (II).

All of the peaks of the NMR spectra described above are summarized in Table III.

The NMR spectra of the remaining products, III, IV and V, were not available, for these compounds were insoluble in the solvent necessary for the observation of the spectra. The structures of these compounds were determined by other means to be heteroannularly-bonded quaterferrocenyl, quinqueferrocenyl and sexiferrocenyl.

As is shown in Figs. 7 and 8, the infrared absorption spectra of five polyferrocenyls (I—V) and of four butylated polyferrocenyls (VI—IX) are respectively very similar, while slight differences appeared mainly in the regions near 1100 and 900—800 cm^{-1}.

It is well known that the 9 and 10 μ bands are, respectively, due to unsubstituted ring breathing and to C–H bending in the plane. These absorption bands are very useful in distinguishing monosubstitution and heteroannular disubstitution in mononuclear ferrocene derivatives.[12] However, in the absorption spectra of heteroannularly-disubstituted biferrocenyl VII (Fig. 8), both 9 and 10 μ bands are observed in spite of the lack of an unsubstituted ring. Similar observations have been reported by several investigators.[13] Thus, it is obvious that the 9—10 rule is only applicable to mononuclear ferrocene derivatives.

By a careful comparison of the spectrum of compound VII with those of polyferrocenyls I—V, however, slight differences are found; there are two absorption bands in the latter in the 9 μ region (1105 and 1100 cm^{-1}). The band at 1105 cm^{-1} may be attributable to the directly-bonded ring breathing, and the band at 1100 cm^{-1}, to the unsubstituted ring breathing.

The ultraviolet absorption spectra of ferrocene, biferrocenyl (I) and terferrocenyl (II) in cyclohexane are shown in Fig. 9. As may be seen in the figure, the latter two compounds display the K-band at 220 and 225 mμ and the B-band in the region near 300 mμ, while ferrocene is inferred to show the K-band in a shorter wavelength region. The bathochromic shifts in this band are due to the increase in the conjugation in these polyferrocenyls. It is interesting that the position and the intensity of the absorption maxima of biferrocenyl are so

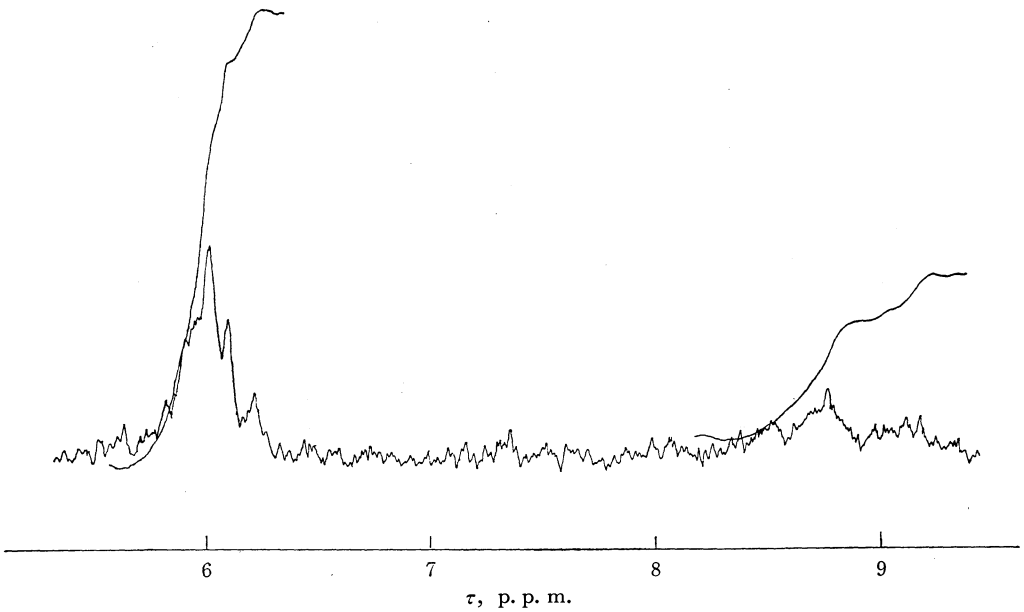

Fig. 6. NMR spectrum of monobutyl-quaterferrocenyl (IX).

similar to those of terferrocenyl that the effect of the accumulation of ferrocene nuclei on the spectra can hardly be recognized, while it is distinguished in para-polyphenyls.[14]

Chromatographic Behavior and Solubilities of the Products.—The order of the elution of the reaction products in the chromatographic separation (Table II) suggests that, in the series of polynuclear ferrocenes, the adsorbability on alumina increases according to the increase in the molecular weight, and that the increase in the number of butyl substituents on the polynuclear ferrocene nuclei causes a decrease in the adsorbability. Thus, as a whole, the order of the adsorbability on alumina is as follows: dibutyl-biferrocenyl < monobutyl-biferrocenyl < biferrocenyl < monobutyl-terferrocenyl < terferrocenyl < monobutyl-quaterferrocenyl < quaterferrocenyl < other polyferrocenyls (IV and V).

Among these compounds, alkylated polynuclear ferrocenes are soluble in common organic solvents, but polyferrocenyls without any alkyl group are less soluble than those of alkylated compounds. The solubilities of the series of polynuclear ferrocenes decrease with the increase in the molecular weight; quaterferrocenyl is almost insoluble, and quinque- and sexiferrocenyl are quite insoluble. Therefore, the latter two compounds could not be purified by the recrystallization method. In contrast, terferrocenyl was purified by recrystallization and chromatography on alumina.

The Polymorphism of Terferrocenyl.—It was found that, when the sample of terferrocenyl was crystallized from different solvents, the crystals were obtained in polymorphic forms, although no remarkable difference was observed between their melting points (around 226°C). The crystals obtained from benzene, ethanol, and ethyl acetate solution showed identical infrared absorption bands (Fig. 10). On the other hand, the spectrum of the crystals obtained by the crystallization from a large amount of petroleum ether (Fig. 11) was quite different in the region of the finger print from those of the former. The sample crystallized from the mixture of benzene and petroleum ether again showed a different spectrum (Fig. 12). The X-ray diffraction pattern of each crystal was also observed; the results were consistent with those of the infrared spectra, as is shown in Figs. 10—12. It was also found from the infrared spectra and X-ray diffraction patterns that the crystals obtained by the rapid cooling method in the crystallization are mixtures of the polymorphic forms described above, even when the same solvents were used.

The polymorphism of terferrocenyl may be accounted as a rotational isomerism (which belongs to the molecular polymorphism) about the central ferrocene nucleus, caused by rotation around the axis connecting the two cyclopentadienyl rings through an iron atom. It is also probable that the polymorphism is due to the variation in the arrangement of molecules in the crystal lattice caused by any hydrogen bonding possibly present.

Experimental

General.—Ferrocene was prepared according to the method previously reported by the present authors.[15]

The temperatures in the reactions and measurements were uncorrected, and each melting point was determined in a sealed capillary except for the case of the particular description. The NMR spectra were determined at 60 Mc. on a Model JNM-C-60 spectrometer (Japan Electron Optics Laboratory Co.) and a Model A-60 spectrometer (Varian Associates) in deuteriochloroform, containing tetramethylsilane as the internal standard. Molecular weight measurements with a vapor pressure osmometer were carried out on a Model 301-A (The Mechrolab Inc.). The infrared spectra were obtained on a Model EPI-S2 spectrometer (Hitachi Co.) by means of potassium bromide disks. The ultraviolet spectra were determined on a Model EPS-3 recording spectrometer (Hitachi Co.) in cyclohexane. Chromatographies were performed on Sumitomo Chemicals' activated alumina (150—250 meshes). After benzene solutions of the samples had been placed on alumina packed into a column with hexane, each component was developed and eluted with the appropriate solvent, as described below. The X-ray diffraction patterns[16] of terferrocenyl were obtained on a Model ADX-103 spectrometer (Toshiba Electric Co.) by the powder method. The differences among polymorphic forms from various crystallization methods were determined by a study of the X-ray diffraction patterns and infrared spectra.

The Reaction of Ferrocenyllithium and Cobaltous Chloride in the Presence of *n*-Butyl Bromide (Run A).—According to the method described in a previous paper,[2] a suspension of ferrocenyllithium was prepared by stirring 55.8 g. (0.3 mol.) of ferrocene and 0.6 mol. of *n*-butyllithium in anhydrous ether under an atmosphere of nitrogen. In this experiment, the lithiation took 72 hr. at room temperature.

Anhydrous cobaltous chloride (9.1 g., 0.07 mol.), obtained from its hydrate,[17] was added to the oragne suspension of ferrocenyllithium in an atmosphere of nitrogen, and then 14.4 g. (0.105 mol.) of *n*-butyl bromide was added at room temperature through a dropping funnel. An exothermic reaction took place with an evolution of gas and a vigorous refluxing, but the latter subsided when the flask was immersed into an ice-water bath. Then, the additional main part (26.70 g.; 0.195 mol.) of *n*-butyl bromide was added at one time. Immediately the vigorous refluxing of ether broke out again; it was again suppressed by cooling. After the mixture had been stirred for 44 hr. at room temperature, it was heated to reflux for another hour. The dark brown suspension thus obtained was poured into a large amount of ice water in order to hydrolyze the reactive compounds. On filtration, the reaction mixture was separated into two parts: (1) the filtrate, consisting of an ethereal layer and an aqueous layer, and (2) the residue on the filter. The following is the work-up for the two parts:

1) The ethereal layer was separated, and the aqueous layer was repeatedly extracted with ether. After the complete evaporation of ether from the combined ethereal solutions, the residue was submitted to sublimation in order to collect the unreacted ferrocene (35.6 g. recovery; the percentage of converted ferrocene: ca. 36.2%). After the sublimation, 15.5 g. of an orange-red solid (Substance A) remained; this was chromatographed on alumina.

2) The residue on the filter was washed with a sufficient amount of water and ether, and then left stand until it almost reached dryness in vacuo (water-jet pump). After it had been extracted with ether in a Soxhlet apparatus for ca. 100 hr., 14.7 g. of brown powder remained. This was further triturated with boiling benzene several times (total volume: 1.5 l.). After the trituration, 6.6 g. of a gray residue remained; this was interpreted as being an inorganic material derived from cobaltous chloride. Fine glittering orange-red crystals (0.67 g., Substance B), which separated when the hot benzene solution was cooled, were collected on a filter. The dark red mother liquor was evaporated to dryness in vacuo, and the solid was again dissolved in 600 ml. of boiling benzene. The undissolved material (0.44 g., Substance C) was collected by filtration while hot. After the hot solution had been cooled, 0.55 g. of an orange-red powder (Substance D) separated; this was collected on a filter. The filtrate was concentrated to about 200 ml. and cooled in order to separate

16) The present authors wish to express their thanks to Dr. M. Ichikuni for taking the X-ray patterns and his kind suggestion.
17) "Inorganic Syntheses," Vol. 5, 153 (1957).

additional crystals. Upon filtration, 0.98 g. of another orange-red powder (Substance E) was obtained. Finally the filtrate was evaporated to remove the benzene; 2.05 g. of a dark red-brown solid (Substance F) was thus obtained.

When the ethereal solution obtained by the Soxhlet-extraction described above was left to stand, 0.33 g. of an orange-red solid material (Substance G) separated. After the filtration, the mother liquor was evaporated to give rise to a red-orange solid material (1.79 g., Substance H).

The Chromatographic Separation and the Identification of Each Product.—*Substance A* (15.5 g.).—After the development with hexane, the elutions of the colored bands in the column were successively performed in the following order.

1) The first elution, with petroleum-benzene (3:1 by volume), yielded 1.0 g. of a yellow-orange liquid, which was then rechromatographed with the same eluent to afford two fractions. The first was an orange liquid (0.22 g.) which solidified to orange crystals upon standing. It was found to be dibutyl-biferrocenyl (VII), which is very soluble in common organic solvents; m. p. 52.0—53.0°C.

Found: C, 70.35; H, 6.96. Calcd. for $C_{28}H_{34}Fe_2$: C, 69.74; H, 7.11%.

The second fraction (0.22 g.) also solidified by itself, upon standing, to orange crystals, which were identified as monobutyl-biferrocenyl (VI) (see below).

2) The second elution, with the same solvent as in 1), yielded 1.95 g. of red-orange crystals which were very soluble in common organic solvents. This compound was identified as monobutyl-biferrocenyl (VI); m. p. 68.0—70.0°C.

Found: C, 67.61; H, 5.95%; mol. wt., 446 (Rast), 400 (vapor pressure osmometer method). Calcd. for $C_{24}H_{26}Fe_2$: C, 67.64; H, 6.19%; mol. wt. 426.

3) The third elution, also with the same solvent as in 1), yielded 5.78 g. of biferrocenyl (I), which melted at 225—234°C under decomposition (in an open capillary).

4) The fourth elution, with petroleum ether - benzene (1 : 1), yielded monobutyl-terferrocenyl (VIII, 0.34 g.), which was purified by rechromatography; m. p. 113.0—115.0°C.

Found: C, 67.07; H, 5.49%; mol. wt., 565 (v. p. o. method). Calcd. for $C_{34}H_{34}Fe_3$: C, 66.93; H, 5.62%; mol. wt., 610.

5) The fifth elution, with the same solvent as in 4), yielded orange crystals of terferrocenyl (II, 1.54 g.). The pure compound, recrystallized from a mixture of benzene and petroleum ether, had a m. p. of 226.5—227.2°C.

Found: C, 65.03; H, 4.73%; mol. wt., 554 (Rast). Calcd. for $C_{30}H_{26}Fe_3$: C, 64.89; H, 4.81%; mol. wt., 554.

6) The last elution, with methanol, gave rise to ca. 1.0 g. of a dark red glassy material. It was supposed to be still a mixture, but no attempt was made to separate and identify the components.

Substance B (0.67 g.).—Substance B melted at 252—256°C and was almost insoluble in common organic solvents. From the various analytical results, this compound was identified as sexiferrocenyl (V).

Found: C, 65.23; H, 4.87%; mol. wt., 1089 (Rast). Calcd. for $C_{60}H_{50}Fe_6$: C, 65.15; H, 4.56%; mol. wt., 1106.

Substances C, D and E (1.97 g. in total).—These substances are in fact the same compound, as is revealed by the identity of their infrared absorption spectra (Fig. 7). From the various analytical results, it was identified as quaterferrocenyl (III). It was insoluble in most common organic solvents, but it could be recrystallized from a large amount of hot benzene; m. p. 280°C.

Found: C, 65.76, 65.84, 65.63; H, 4.83, 4.84, 4.53%; mol. wt., 717, 729 (Rast; perylene being used instead of camphor because of the high melting point of this compond).[6] Calcd. for $C_{40}H_{34}Fe_4$: C, 65.09; H, 4.64%; mol. wt., 738.

Substance F (2.05 g.).—This substance was separated by chromatography into the following six fractions.

1) The first elution, with petroleum ether - benzene (1 : 1), yielded 0.2 g. of crude biferrocenyl; this was recrystallized from a mixture of benzene and petroleum ether to give a pure compound (I); m. p. 228.0—231.0°C.

2) The second elution, with the same solvent as in 1), gave ca. 90 mg. of monobutyl-terferrocenyl (VIII).

3) The third elution, with benzene, provided 0.57 g. of crude terferrocenyl (II, m. p. 214—220°C). The pure compound was obtained by the recrystallization from a mixture of benzene and petroleum ether.

4) The fourth elution, also with benzene, gave orange-red crystals (0.14 g., m. p. 170—173°C). The pure compound, obtained by recrystallization from a mixture of benzene and petroleum ether, had a m. p. of 177.0—179.0°C and was soluble in common organic solvents. The compound was found from the various analytical results to be monobutyl-quaterferrocenyl (IX).

Found: C, 66.24; H, 5.30. Calcd. for $C_{44}H_{42}Fe_4$: C, 66.54; H, 5.33%. The ultraviolet absorption spectrum (in cyclohexane) showed λ_{max} 228 ($\log \varepsilon$ 4.89), 305 (4.29) and 450 mμ (3.25).

5) The fifth elution, also with benzene, gave rise to quaterferrocenyl (III) as an orange-red powder (0.3 g., m. p. 280°C). This was found to be the same compound as Substances C, D and E.

6) The last elution, with methanol, yielded 0.29 g. of a dark red glassy solid. It was supposed to be a mixture, but further treatments were not attempted.

Substance G (0.33 g.).—This substance was repeatedly triturated with a sufficient amount of hot benzene. After the trituration, 55 mg. of a light brown powder remained; m. p. 240—245°C. From various analytical results this compound was identified as quinqueferrocenyl (IV). It is insoluble in common organic solvents.

Found: C, 61.83; H, 4.59%; mol. wt., 903 (Rast: perylene being used). Calcd. for $C_{50}H_{42}Fe_5$: C, 65.11; H, 4.59%; mol. wt., 922.

On the other hand, the evaporation of the benzene solution after the trituration gave 0.254 g. of a red-orange powder. This was dissolved in a small amount of benzene, and then chromatographed on an alumina column.

1) The first elution, with benzene - petroleum ether (4 : 1), yielded biferrocenyl (I) as orange leaflets (10 mg., m. p. 218.0—222.0°C).

2) The second elution, with the same solvent as in 1), gave rise to terferrocenyl (II) as orange crystals (0.77 g.).

3) The third elution, also with the same solvent as

in 1), yielded monobutyl-quaterferrocenyl (IX) as orange-red crystals (20 mg.).

4) The fourth elution, with benzene, gave rise to quaterferrocenyl (III) as orange-red crystals (56 mg., m. p. 278.0—279.5°C, recrystallized from a large amount of benzene).

5) The last elution, with methanol, afforded a dark red glassy solid (47 mg.). This was assumed to be a mixture of many compounds, but their separation and identification were not attempted.

Substance H (1.79 g.).—This substance was dissolved in a small amount of benzene and placed on alumina. The following is the work-up of the elution:

1) The first elution, with petroleum ether - benzene (3 : 1), gave rise to orange crystals (leaflets, 0.25 g.) which were found to be biferrocenyl (I).

2) The second elution, with petroleum ether - benzene (1 : 1), yielded 0.13 g. of fine yellow-orange crystals; these were rechromatographed by using petroleum ether - benzene (3 : 1) to give a pure substance. The compound had a m. p. of 113.0—115.0°C and was identified as monobutyl-terferrocenyl (VIII).

3) The third elution, with the same solvent as in 2), gave terferrocenyl (II, 0.78 g.).

4) A dark red glassy solid was obtained from the fraction of the last elution, but no further treatments were attempted.

The Reaction of Ferrocenyllithium and Cobaltous Chloride (Run B).—To an orange suspension of ferrocenyllithium, prepared from 55.8 g. (0.3 mol.) of ferrocene and 0.6 mol. of *n*-butyllithium according to the method described above, 9.1 g. (0.07 mol.) of anhydrous cobaltous chloride was added at one time. After the addition, a gentle refluxing occurred because of the exothermic reaction, but no cooling procedure was applied. The mixture was allowed to cool to room temperature over a period of 3 hr. The dark brown suspension was then stirred for 70 hr. under a stream of nitrogen at room temperature, and then for an additional hour under refluxing on a water bath. After cooling, the suspension was poured into a large amount of ice water in order to hydrolyze the reactive compounds. The total mixture was filtered to separate it into a solid and a liquid part.

The solid material which remained on the filter was repeatedly washed with a sufficient amount of water and benzene, dried in vacuo at room temperature, and extracted with ether for 8 hr. in a Soxhlet apparatus. The residual gray-black powder (7.77 g.) was conceived to be an inorganic substance derived from cobaltous chloride.

On the other hand, the liquid part from the reaction mixture consisted of an ethereal layer and an aqueous layer. The liquid part was combined with the washings of the solid part and the ethereal solution from the Soxhlet extraction. The combined organic layer was separated from the aqueous layer, and the aqueous layer was repeatedly extracted with ether. All the parts of the organic solution were combined, dried over magnesium sulfate, filtered, and evaporated to obtain an orange-red crystalline substance. It was submitted to vacuum sublimation at 100—120°C under 0.5 mmHg to collect the unreacted ferrocene (53.4 g., 95.5% recovery). The remaining dark red-brown solid (2.33 g.) was dissolved in a small amount of benzene and chromatographed on alumina. The solution of the sample was placed on alumina packed into a column with benzene - pertroleum ether (1 : 1), and the same solvent was used as the developer. Elution was performed as follows:

1) The first elution, with petroleum ether - benzene (1 : 1), gave rise to monobutyl-biferrocenyl (VI, 0.38 g., m. p. 67.0—69.0°C).

2) The second elution, with the same solvent as in 1), yielded biferrocenyl (I, 1.06 g., m. p. 228.5—233.0°C).

3) The third elution, also with the same solvent as in 1), gave an orange solid (59 mg.) which was found to be butyl-polyferrocenyl by a comparison of its infrared spectrum with those of other butyl-polyferrocenyls, such as monobutyl-biferrocenyl and monobutyl-terferrocenyl. It might be crude monobutyl-terferrocenyl, but no further treatments were attempted.

4) The fourth elution, with benzene, yielded terferrocenyl (II, 0.14 g., m. p. 215.0—218.0°C).

5) A dark red-brown glassy solid (0.20 g.) was obtained from the fraction of the elution with methanol. This was inferred to be a mixture which might contain some polyferrocenyls of a greater molecular weight than that of terferrocenyl. However, no further investigation was undertaken.

Thanks are due to the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 802—803 (1966)

Organic Sulfur Compounds. I. Reactions of Arylsulfinic Acids with Alkyl Chlorosulfites

By Michio KOBAYASHI, Miki TERAO and Asami YAMAMOTO

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received September 14, 1965)

The salts of arylsulfinic acids were found to react with alkyl chlorosulfite to form alkyl sulfinates. *p*-Toluenesulfinic acid-^{18}O was synthesized and treated with ethyl chlorosulfite to give ethyl *p*-toluenesulfinate-^{18}O, which retained half of the oxygen atoms existing in the original sulfinic aicd. A mechanism for this novel reaction was proposed.

The formation of carboxylic esters from the salts of carboxylic acids and chlorosulfites has previously been known.[1,2] The possibility of an analogous preparation of the sulfinic esters from the salt of sulfinic acids and chlorosulfites has now been investigated; the results will be described in this paper.

Ethyl chlorosulfite was added to the suspension of sodium *p*-toluenesulfinate in acetonitrile; this reaction mixture then warmed at 60°C for 2 hr. to form *p*-toluenesulfinate, as expected, in a 59% yield. When this reaction was carried out without a solvent, sulfur dioxide evolved vigorously and ethyl sulfinate was obtained in a 42% yield. Sodium *p*-bromobenzenesulfinate gave the ethyl ester in a 34% yield by a similar treatment.

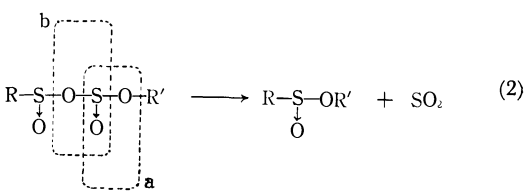
A solution of *p*-toluenesulfinic acid in pyridine reacted rapidly with ethyl chlorosulfite to give ethyl *p*-toluenesulfinate in a 21% yield. Since alkyl chlorosulfites are known to decompose very rapidly to alkyl chlorides and sulfur dioxide in the presence of pyridine, the above result suggests that the rate of the reaction of the sulfinate anion with alkyl chlorosulfite is also very high.

The formation of the mixed anhydride of sulfinic acid and monoalkyl sulfite (I) is suggested by these reactions, although the actual isolation of the intermediate was not possible.

$$RSO_2Na + ClS\text{-}OR' \rightarrow \underset{\underset{O}{\downarrow}}{R\text{-}S\text{-}O\text{-}S\text{-}OR'}_{\underset{O}{\downarrow}\quad\underset{O}{\downarrow}} \qquad (1)$$

(I)

There are two possibilities for the decomposition of the mixed anhydride (I), namely, the alkyl-oxygen cleavage (path a) and alkoxy-sulfur cleavage (path b):



(2)

When sodium *p*-toluenesulfinate-^{18}O, which had been prepared from *p*-toluenesulfinyl chloride and ^{18}O water, was treated with ethyl chlorosulfite, the resultant ethyl *p*-toluenesulfinate-^{18}O was found to contain about a half of the heavy oxygen atoms originally incorporated in the starting sulfinic acid. Therefore, the alkoxy-sulfur splitting (path b) may be chosen.

$$CH_3C_6H_4\text{-}S\text{-}Cl + H_2{}^{18}O \rightarrow \underset{\underset{O}{\downarrow}}{CH_3C_6H_4S^{18}O_2H} \qquad (3)$$

$$CH_3C_6H_4S^{18}O_2Na + \underset{\underset{O}{\downarrow}}{ClS\text{-}OC_2H_5} \rightarrow \underset{\underset{{}^{18}O}{\downarrow}\quad\underset{O}{\downarrow}}{CH_3C_6H_4\text{-}S\text{-}{}^{18}O\text{-}S\text{-}OC_2H_5} \qquad (4)$$

(Ia)

$$Ia \rightarrow CH_3C_6H_4S\text{-}OC_2H_5 + \underset{\underset{{}^{18}O}{\downarrow}}{SO} \qquad (5)$$

Between the following two mechanisms, a four-center mechanism (6) and a base-catalyzed ionic chain mechanism (7, 8, 9), which fit the above results equally well, there is no evidence to make a choice possible at present.

Experimental

Ethyl *p*-Toluenesulfinate.—*Reaction in Acetonitrile.*—Sodium *p*-toluenesulfinate dihydrate[3] was dehydrated by heating it at 130°C for a few hours in a vacuum to anhydrous salt. To a suspension of 5.8 g. of the fine powder of this salt in 20 ml. of acetonitrile there was added 4.5 g. of ethyl chlorosulfite (b. p. 45°C/55 mmHg) drop by drop. The reaction mixture was warmed at 60°C for 2 hr. and kept overnight. Extraction with ether and distillation in a vacuum gave ethyl *p*-toluenesulfinate (b. p. 115°C/5 mmHg) (3.6 g.) in a 59% yield of the theoretical.

Reaction without a Solvent.—When ethyl chlorosulfite was added to the fine powder of sodium *p*-toluenesulfinate at room temperature, sulfur dioxide evolved quickly (about 70% of the theoretical yield). The reaction mixture became jelly-like after being heated at 60°C for 2 hr. A work up similar to that above gave 2.8 g. of ethyl *p*-toluenesulfinate from 5.8 g. of the sodium salt in a 42% yield of the theoretical.

Ethyl *p*-Bromobenzenesulfinate.—To 8.0 g. of the finely-powdered sodium *p*-bromobenzenesulfinate there was added 6.0 g. of ethyl chlorosulfite. When the first exothermic reaction accompanying the evolution of 350 ml. (45%) of sulfur dioxide subsided, the reaction mixture was extracted with petroleum ether. Vacuum distillation gave ethyl *p*-bromobenzenesulfinate (2.8 g.) (b. p. 132°C/2 mmHg) in a yield 34% of the theoretical yield.

Ethyl *p*-Toluenesulfinate.—*Reaction in Pyridine.*—Four grams of *p*-toluenesulfinic acid was dried in a vacuum overnight and dissolved in 20 ml. of anhydrous pyridine. When 3.5 g. of ethyl chlorosulfite was added to this solution drop by drop, the reaction proceeded with the evolution of heat. After it had stood overnight, the mixture was diluted with water, acidified, and extracted with petroleum ether. The yield of ethyl *p*-toluenesulfinate was 1.0 g., 21% of the theoretical.

***p*-Toluenesulfinyl Chloride.**—Prepared from 15 g. of *p*-toluenesulfinic acid and 20 g. of thionyl chloride. The yield was 13.3 g (116°C/5 mmHg).

Sodium *p*-Toluenesulfinate-^{18}O.—To 13.3 g. of *p*-toluenesulfinyl chloride there was added 1.8 g. of $H_2{}^{18}O$ (^{18}O: 1.5 atom %) with cooling in an ice bath. The reaction started immediately, and white crystals of sulfinic acid were deposited. These crystals were vigorously stirred into an ice-cooled solution of sodium hydroxide (7 g.) in 30 ml. of water. The mixture was warmed to ensure a complete dissolution and then cooled in an ice bath in order to precipitate the sodium sulfinate. The salt filtrated was recrystallized once from the distilled water to give 9.0 g. of sodium *p*-toluenesulfinate-^{18}O dihydrate. The concentration of the mother liquid gave 6 g. of the second crop. The dehydration of the first crop in a vacuum afforded 7.5 g. of the anhydrous salt. It was confirmed in a separate experiment that no exchange of oxygen atoms occurred between sulfinic acid and water in neutral or basic conditions. The ^{18}O content of the anhydrous salt was 0.69, 0.70 atom %.

Ethyl *p*-Toluenesulfinate-[sulfinyl-^{18}O].—In 25 ml. of acetonitrile, 5.8 g. of sodium *p*-toluenesulfinate-^{18}O was treated with 4.5 g. of ethyl chlorosulfite. The mixture was then warmed at 60°C for one hour and left at room temperature for 2 days. A precipitated powder was filtered off, and the filtrate was evaporated under reduced pressure. The residue was extracted with petroleum ether, and the extract was washed with water and dried over magnesium sulfate. Vacuum distillation gave 2.4 g. of ethyl *p*-toluenesulfinate-^{18}O in a yield 41% of the theoretical. The ^{18}O atom % of this ester was 0.41%. The calculated ^{18}O atom %, based on the retention of half of the oxygen atoms, was 0.46%.

The infrared spectra of all the products in the above experiments were superimposable with those of an authentic specimen.

Thanks are due to Professor Shigeru Oae of Osaka City University for the donation of the heavy oxygen water. The authors are also grateful to Drs. Teijiro Kitao and Reiko Kiritani of the Radiation Center of Osaka Prefecture for their analyses of ^{18}O, and to Mr. Tadao Ohkusa of the Central Research Laboratories, Chisso Co., for his infrared measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 804—809 (1966)

The Magnetic Properties of Several *Pseudo*-Jahn-Teller Nonbenzenoid Aromatic Hydrocarbons

By Takeshi NAKAJIMA and Susumu KOHDA

Department of Chemistry, Ibaraki University, Mito

(Received September 15, 1965)

The effect of bond length alternation on the magnetic properties of several *pseudo*-Jahn-Teller nonbenzenoid aromatic hydrocarbons with 4ν carbon atoms will be investigated. The magnetic moment and the susceptibility of a cyclic polyene will first be formulated in terms of the bond alternation parameter. Appropriate cross-links for forming nonbenzenoid aromatic hydrocarbons, such as pentalene and heptalene, will then be treated as perturbations. It will be shown that the anomalously large paramagnetic susceptibilities of these molecules predicted by Pullman et al. ("Les Théories Electroniques de la Chimie Organique," Masson, Paris (1952), p. 527) arise mainly from the neglect of the bond alternation inherent in them. It will then be concluded that the magnetic susceptibility is a very sensitive indicator of the bond alternation, and that the diamagnetically-induced ring currents in these molecules are very much impeded.

The diamagnetic anisortopy of an aromatic hydrocarbon, attributable to induced ring currents in its π-electron network, is one of the important indications of π-electron delocalization. London[1] has developed a technique for calculating diamagnetic susceptibilities on the basis of the Hückel LCAO MO theory, and this method has since been used extensively for a variety of aromatic hydrocarbons.[2,3] The calculated diamagnetic anisotropies of benzenoid aromatic hydrocarbons are usually in quite good agreement with the experimental values.

As for nonbenzenoid aromatic hydrocarbons, on the other hand, the direct application of London's technique often brings about quite unsatisfactory results; Mayot et al.[4] and Pullman et al.[5] have, for instance, pointed out that the contribution to the magnetic susceptibility due to π-electron delocalization in the nonbenzenoid aromatic hydrocarbons with 4ν carbon atoms, such as pentalene and heptalene, turns out to be paramagnetic instead of diamagnetic. Wagnière and Gouterman[6] have recently interpreted such an anomalously-reduced diamagnetism as a quenched paramagnetism.

It has recently been shown that, as the result of a *pseudo*-Jahn-Teller distortion,[7] there exists a significant alternation in length in the peripheral C–C bonds of these nonbenzenoid aromatic hydrocarbons, the skew structure (C_{2h}) being more favorable energetically than the conventional symmetric structure (D_{2h}).[8-15] It is very probable that the unusually high paramagnetic susceptibilities obtained by the French authors are due mainly to the neglect of the bond alternation characteristic of these molecules.

The aim of this paper is to investigate the effect of bond length distortion on the magnetic susceptibilities of *pseudo*-Jahn-Teller nonbenzenoid aromatic hydrocarbons, such as pentalene, heptalene, *s*-indacene, and dibenzpentalene. The magnetic moment and the susceptibility of a cyclic polyene will first be formulated in terms of the bond alternation parameter, an external magnetic field being treated as a complex perturbation. The formulae will then be tested for cyclooctatetraene and [24]annulene. The formation of cross-links to yield the nonbenzenoid aromatic hydrocarbons will be considered further as a perturbation. The effect of this perturbation on the magnetic properties will then be investigated.

The Cyclic Polyenes, $C_{2n}H_{2n}$

In the presence of an external magnetic field, **H** assumed to be normal to the molecular plane,

the MO's of the π-electrons are constructed from the AO's, χ_r^m, given by:

$$\chi_r^m = \chi_r \exp\{-2\pi i(e/hc)\mathbf{A}_r \cdot \rho\} \tag{1}$$

where χ_r is the $2p\pi$ atomic orbital for the rth atom and $\mathbf{A}_r$ is the value of the magnetic vector potential at the rth atom. For a uniform magnetic field, $\mathbf{A}$ is given by $-(1/2)\rho \times \mathbf{H}$, while at the rth atom we have $\mathbf{A}_r = -(1/2)\mathbf{R}_r \times \mathbf{H}$. According to London, the secular problem for the MO's is different from that without the field merely in the form of the resonance integrals, which now include the field-dependent phase factor:

$$\beta_{rs}^m = \beta_{rs} \exp\{\pi i(e/hc)(\mathbf{A}_r - \mathbf{A}_s) \cdot (\mathbf{R}_r + \mathbf{R}_s)\} \tag{2}$$

Using simple geometry, Eq. 2 may be rewritten as:

$$\beta_{rs}^m = \beta_{rs} \exp\{2\pi i(e/hc) S_{rs} H\} \tag{3}$$

where S_{rs} is the singed area of a triangle formed by the origin (where $A=0$) and the bond $r \rightarrow s$ (S_{rs} is positive if the direction $r \rightarrow s$ is right-handed about the direction of the magnetic field). By expanding the exponential function and writing $(e/hc)S_{rs}H = f_{rs}$, we obtain the change in the resonance integral due to the presence of the field as:

$$\Delta_{rs} = \beta_{rs}(2\pi i f_{rs} - 2\pi^2 f_{rs}^2 + \cdots) \tag{4}$$

The total perturbation due to the presence of the field is represented by:

$$\Delta = \sum_{r<s} \Delta_{rs} \tag{5}$$

It is assumed that $\beta_{rs}=0$ if the atoms r and s are not bonded in a conventional structure.

Now let us consider a cyclic polyene, $C_{2n}H_{2n}$, the MO's of which are assumed to be expressed in the following form:

$$\left.\begin{aligned} \varphi_l &= a_l \varphi_l^o + b_l \varphi_l^e \quad (l=0, \pm 1, \pm 2, \cdots, n) \\ \varphi_l^o &= \frac{1}{\sqrt{n}} \sum_{r=1}^{n} \chi_{2r-1} \exp\{i\theta_l(r-1)\} \\ \varphi_l^e &= \frac{1}{\sqrt{n}} \sum_{r=1}^{n} \chi_{2r} \exp\left\{i\theta_l\left(r-\frac{1}{2}\right)\right\} \end{aligned}\right\} \tag{6}$$

where:

$$\theta_l = 2\pi l/n \tag{7}$$

Allowing for the possibility of a two-fold bond length alternation, we denote by β the resonance integrals for bonds between atoms $2r-1$ and $2r$, and by $k\beta$ ($k \leqq 1$), those for bonds between atoms $2r$ and $2r+1$, including the bond between the $2n$th atom and the first atom. Then we have:

$$\left.\begin{aligned} \int \varphi_l^{o*} \mathbf{H} \varphi_l^e dv &= (e^{i\theta_l/2} + k e^{-i\theta_l/2})\beta = \gamma_l \beta \\ \int \varphi_l^{e*} \mathbf{H} \varphi_l^o dv &= (e^{-i\theta_l} + k e^{i\theta_l/2})\beta = \gamma_l^* \beta \end{aligned}\right\} \tag{8}$$

$$\left.\begin{aligned} \int \varphi_l^{o*} \mathbf{H}_l^o dv &= \int \varphi_l^{e*} \mathbf{H} \varphi_l^e dv = \alpha \end{aligned}\right\}$$

By solving the quadratic secular equation, we obtain, for the orbital binding energies:

$$\begin{aligned} x_l^{(0)} &= (\varepsilon_l - \alpha)/\beta = \pm(1 + 2k\cos\theta_l + k^2)^{1/2} \\ &= \pm(\gamma_l^* \gamma_l)^{1/2} \end{aligned} \tag{9}$$

where + and − should be taken for the bonding and antibonding orbitals respectively.

The partial π-bond orders for the $2r-1$—$2r$ bonds (double bonds) and the $2r$—$2r+1$ bonds (single bonds) are given respectively by the forms[16]:

$$\left.\begin{aligned} p_{l,d} &= \frac{1}{n}(a_l^* b_l e^{i\theta_l/2} + a_l b_l^* e^{-i\theta_l/2}) \\ &= \pm \frac{1 + k\cos\theta_l}{n(1 + 2k\cos\theta_l + k^2)^{1/2}} \\ p_{l,s} &= \frac{1}{n}(a_l b_l^* e^{i\theta_l/2} + a_l^* b_l e^{-i\theta_l/2}) \\ &= \pm \frac{k + \cos\theta_l}{n(1 + 2k\cos\theta_l + k^2)^{1/2}} \end{aligned}\right\} \tag{10}$$

In order to take account of the imaginary perturbation due to an external magnetic field, we define in this connection the imaginary partial π-bond orders, which are given by:

$$\left.\begin{aligned} \bar{p}_{l,d} &= \frac{1}{n}(a_l^* b_l e^{i\theta_l/2} - a_l b_l^* e^{-i\theta_l/2}) \\ &= \pm \frac{ik\sin\theta_l}{n(1 + 2k\cos\theta_l + k^2)^{1/2}} \\ \bar{p}_{l,s} &= \frac{1}{n}(a_l b_l^* e^{i\theta_l/2} - a_l^* b_l e^{-i\theta_l/2}) \\ &= \pm \frac{i\sin\theta_l}{n(1 + 2k\cos\theta_l + k^2)^{1/2}} \end{aligned}\right\} \tag{11}$$

According to the LCAO perturbation theory, the first-order change in the energy of the lth MO due to the presence of a magnetic field is expressed in terms of bond orders. Using Eqs. 10 and 11, we obtain:

$$\begin{aligned} \delta x_l^{(1)} &= \langle \psi_l^* | \Delta | \psi_l \rangle \\ &= -2\pi i f n(\bar{p}_{l,d} + k\bar{p}_{l,s}) \\ &\quad -2\pi^2 f^2 n(p_{l,d} + k p_{l,s}) \\ &= \pm \left\{ \frac{2}{n} \frac{k\sin\theta_l}{(1 + 2k\cos\theta_l + k^2)^{1/2}} \omega \right. \\ &\quad \left. -\frac{1}{2n}(1 + 2k\cos\theta_l + k^2)^{1/2} \omega^2 \right\} \end{aligned} \tag{12}$$

where:

$$\omega = 2n\pi f = (e/hc)\pi SH \tag{13}$$

in which S is the total area of the molecular plane.

* The summation is over $l=0, \pm 1, 2$.
† The summation is over $l=0, \pm 1, \pm 2$.

McWeeny[17] has already shown that the second-order energy change of the lth MO due to complex perturbations is related to the imaginary partial mutual bond polarizability defined as:

$$\bar{\pi}_{l,rs,tu} = \pi_{l,rs,tu} - \pi_{l,rs,ut} + \pi_{l,sr,ut} - \pi_{l,sr,tu} \tag{14}$$

where:

$$\pi_{l,rs,tu} = \sum_{m(\neq l)} \frac{c_{rl}^* c_{sm} c_{tm}^* c_{ul}}{x_l^{(0)} - x_m^{(0)}} \tag{15}$$

The zero-field MO's are assumed to be $\psi_l = \sum_r c_{rl}\chi_r$. The second-order energy change in the lth MO due to the presence of a magnetic field is thus given by:

$$\begin{aligned}\delta x_l^{(2)} &= \sum_{m(\neq l)} \frac{\langle\psi_l^*|\Delta|\psi_m\rangle\langle\psi_m^*|\Delta|\psi_l\rangle}{x_l^{(0)} - x_m^{(0)}} \\ &= -4\pi^2 f^2 n(\bar{\pi}_{l,d,d} + k\bar{\pi}_{l,d,s} \\ &\quad + k\bar{\pi}_{l,s,d} + k^2\bar{\pi}_{l,s,s}) \\ &= \pm\frac{1}{2n^2}\left\{\frac{(1-k^2)^2}{(1+2k\cos\theta_l+k^2)^{3/2}}\right. \\ &\quad \left. + (n-1)(1+2k\cos\theta_l+k^2)^{1/2}\right\}\omega^2 \end{aligned} \tag{16}$$

We can now formulate the magnetic moment and the magnetic susceptibility associated with the lth MO. The shifts in orbital energies due to the magnetic field being very small, we may in general expand the energy of a given MO as a function of H in Taylor's series in H:

$$x_l = x_l^{(0)} + \lambda_l\omega + \mu_l\omega^2 + \cdots \tag{17}$$

where, using Eqs. 12 and 16 respectively, λ_l and μ_l are given by (in β units):

$$\lambda_l = \mp\frac{2}{n}\frac{k\sin\theta_1}{(1+2k\cos\theta_l+k^2)^{1/2}} \tag{18}$$

$$\mu_l = \pm\frac{1}{2n^2}\left\{(1+2k\cos\theta_l+k^2)^{1/2} - \frac{(1-k^2)^2}{(1+2k\cos\theta_l+k^2)^{3/2}}\right\} \tag{19}$$

The magnetic moment and the susceptibility, χ_l, associated with the lth MO are given, by $-\lambda_l(\omega/H)$ and $-2\mu_l(\omega/H)^2$, respectively. For the bonding MO's, the first term of Eq. 19 represents the pure diamagnetism (negative in β units), while the second term, which arises from the second-order perturbation, represents the induced paramagnetism (positive in β units).

Salem[18] has derived a formula similar to Eq. 19 for the effect of a bond alternation on the magnetic susceptibility of a cyclic polyene. However, the pure diamagnetic term and the second-order paramagnetic term are not separated in his expression, and the origin of the paramagnetic susceptibility is not clearly explained.

The usefulness of Eqs. 18 and 19 may also be demonstrated for cyclooctatetraene and [24]-annulene.

Cyclooctatetraene (C_8H_8).—The orbital energies and the magnetic contributions, λ_l and μ_l, calculated using Eqs. 9, 18, and 19 are presented in Table I. When $k=1$, all the MO's except for the lowest and the highest (vacant) ones are doubly degenerate. The bond alternation lifts the degeneracy of the nonbonding orbitals (with $l=\pm 2$), the top two electrons being both placed in the lower level. As we are concerned with the effect of the bond length distortion on the magnetic properties, we adopt for the case when $k=1$ the electron configuration in which the top two electrons are both placed into one of the degenerate nonbonding orbitals. This gives rise to a molecular paramagnetic moment due to the non-compensating orbital angular

17) R. McWeeny, *Mol. Phys.*, **1**, 311 (1958).

18) L. Salem, *Proc. Cambridge Phil. Soc.*, **57**, 353 (1961); H. C. Longuet-Higgins and L. Salem, *Proc. Roy. Soc.*, **A257**, 445 (1960).

momentum.* The magnetic moment of the occupied nonbonding orbital disappears if the bond alternation is introduced, and, at the same time, the magnetic susceptibility turns out to be paramagnetic. In other words, the first-order paramagnetism is quenched by the bond length distortion and transferred to the susceptibility as an induced paramagnetism. This second-order paramagnetism greatly predominates over the diamagnetism originating from all other, lower-lying electrons, giving rise to a molecular paramagnetic susceptibility. The molecular susceptibility is very sensitive to the value of k; the value of $2\sum_l \mu_l$ varies from ∞ to 0 as k varies from 1 to 0.

In the dianion of cyclooctatetraene that forms a closed electron shell when $k=1$, no such an anomalous paramagnetic susceptibility is predicted.

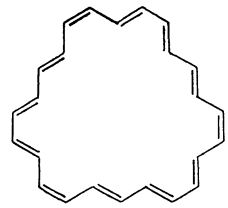
Hoarau[19] has recently made improvements on the London method by refining the calculation of the gauge factors. According to him, the molar magnetic anisotropy is given by:

$$\Delta K = (1/3)\Delta K_{\text{London}} + \text{A}\times 10^{-18}R \qquad (20)$$

where $\Delta K_{\text{London}}=N\chi_\pi$, in which N is Avogadro's number and $\chi_\pi=2\sum_l \chi_l$; R is the π-electron delocalization energy as calculated using the Hückel-type MO method. The value adopted for the proportionality constant, A, is 0.940.**

The magnetic susceptibilities as a function of the k of C_8H_8 calculated using Eq. 20 indicate that, within the range $0.2\geq k>0$, the susceptibility turns out to be diamagnetic, if only slightly so. Actually, it has been shown that the molecule exhibits a marked bond length alternation, as revealed by its tub form, and that it has a weak diamagnetism.[20] On the other hand, the $C_8H_8^{2-}$ dianion has been known to show the normal diamagnetism, as in benzenoid aromatic hydrocarbons, and no bond length alternation.[21]

[24]annulene ($C_{24}H_{24}$).—The molecule, if the molecular symmetry group is D_{3h}, possesses an open-shell electronic configuration in the sense that the top two degenerate MO's are filled with two electrons. The bond length distortion lifts the degeneracy of these MO's and results in the achievement of a closed electron shell, the situation being quite similar to the case of C_8H_8.



$C_{24}H_{24}$

In order to determine the equilibrium bond length alternation, we employ the minimum energy method, in which the effects of σ-bond compression are taken into account.[11] The total binding energies, V, taken to be the sum of the π-bond energy and the σ-bond energy, are calculated for a series of k values (1–0), and then the equilibrium bond alternation, $k_{\min}$, is given by the minimum of the V-k curve. The $k_{\min}$ value thus calculated for [24]annulene turns out to be 0.61, which indicates that in this molecule there exists a significant bond length alternation, one which is comparable in extent to that in butadiene (with $k_{\min}=0.55$).

The molar anisotropy, $\Delta K/\Delta K_{\text{benzene}}$, calculated for the skew form with $k=0.61$ turns out to be 0.012. This indicates that the induced diamagnetic ring current in this molecule is highly impeded. It has recently been shown that the proton NMR spectrum of this molecule consists of one single band at 3.16 τ, which is close to that observed for the olefinic protons of linear-conjugated polyenes, showing an absence of the ring current as in the benzenoid aromatic hydrocarbons.[22]

The Introduction of Cross-Links

Now let us consider a cata-condensed aromatic hydrocarbon formed by the introduction of certain cross-links into a cyclic polyene, the formation of cross-links being treated as a perturbation.

Let us consider the formation of a cross-link between the odd-numbered atoms, $2r-1$ and $2r'-1$, of a cyclic polyene, and let us denote the change in the π-electron Hamiltonian by $\mathbf{H}^o$. We then have:

$$\langle \varphi_l^{o*}|\mathbf{H}|\varphi_l^o\rangle = (2k^o\beta/n)\cos\theta_l(r'-r) = \delta_l^o\beta \qquad (21)$$

where we set $\int \chi_{2r-1}\mathbf{H}^o\chi_{2r'-1}dv=k^o\beta$. Similarly, for the cross-link between the even-numbered atoms, $2r$ and $2r'$, we have:

$$\langle \varphi_l^{e*}|\mathbf{H}^e|\varphi_l^e\rangle = (2k^e\beta/n)\cos\theta_l(r'-r) = \delta_l^e\beta \qquad (22)$$

where $\int \chi_{2r}\mathbf{H}^e\chi_{2r'}dv=k^e\beta$. Further, for the cross-

* We may place alternatively each of the top two electrons in one of the degenerate levels. This gives rise to a triplet spin paramagnetism.

19) J. Hoarau, *Ann. Chim.*, **1**, 544 (1956).

** The value of A has been determined so that the $\Delta K/\Delta K_{\text{benzene}}$ values calculated using Eq. 20 fit the experimental ones. Hoarau has proposed a value of 0.776 calculated using the experimental anisotropies of a number of aromatic hydrocarbons, including biphenyl and stilben, which show a remarkable bond length variation. We have re-examined the value using the experimental values of benzene, naphthalene, anthracene, phenanthrene, and naphthacene, which do not exhibit any significant bond length variation.

* The values in parentheses for x_l are calculated by solving the secular equation, and those for λ_l and μ_l are calculated by using London's method.

link between an odd-numbered atom, $2r-1$, and an even-numbered atom, $2r'$, we have:

$$\langle\varphi_l^{o*}|\mathbf{H}'|\varphi_l^{e}\rangle = (k'\beta/n)e^{i\theta_l(r'-r+1/2)} = \delta_l'\beta \quad (23)$$

where $\int \chi_{2r-1}\mathbf{H}'\chi_{2r'-1}dv = k'\beta$.

Assuming the perturbations due to the three types of cross-links to be additive, and solving the quadratic secular equation, we then obtain the energy of the $l$the MO as (in β units):

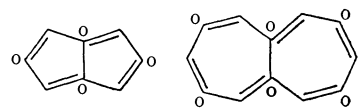
$$x_l = \frac{1}{2}\left[\left(\delta_l^o+\delta_l^e\right) \pm\left\{\delta_l^2+4\left(\gamma_l^*+\delta_l'^*\right)\left(\gamma_l+\delta_l'\right)\right\}^{1/2}\right] \qquad \left(\delta_l=\delta_l^o-\delta_l^e\right) \quad (24)$$

Using the LCAO perturbation theory generalized to take account of the imaginary perturbation due to a magnetic field, as described in the preceding chapter, we obtain the magnetic contributions, λ_l and μ_l, as:

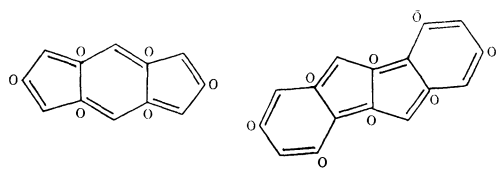
$$\lambda_l = \pm\{4k\sin\theta_l - i(e^{i\theta_l/2}-ke^{-i\theta_l/2})\delta_l'^* + i(e^{-i\theta_l/2}-ke^{i\theta_l/2})\delta_l'\}/n\{\delta_l^2 + 4(\gamma_l^*+\delta_l'^*)(\gamma_l+\delta_l')\}^{1/2} \quad (25)$$

$$\mu_l = \pm\frac{1}{2n^2}\left[\frac{2\gamma_l^*\gamma_l+\gamma_l^*\delta_l'+\delta_l'^*\gamma_l}{\{\delta_l^2+4(\gamma_l^*+\delta_l'^*)(\gamma_l+\delta_l')\}^{1/2}} - \frac{2}{\{\delta_l^2+4(\gamma_l^*+\delta_l'^*)(\gamma_l+\delta_l')\}^{3/2}} \times\{4(1-k^2)^2+(1-2k\cos\theta_l+k^2) \times(\delta_l^2+2\gamma_l^*\delta_l'+2\delta_l'^*\gamma_l+2\delta_l'^*\delta_l') + (e^{i\theta_l}-2k+k^2e^{-i\theta_l})(2\gamma_l^*\delta_l'^*+\delta_l'^{*2}) + (e^{-i\theta_l}-2k+k^2e^{i\theta_l})(2\gamma_l\delta_l'+\delta_l'^2)\}\right] \quad (26)$$

For the bonding MO's, the first term in the bracket of Eq. 26 represents the pure diamagnetism, while the second term, which arises from the second-order perturbation due to the magnetic field, represents the induced paramagnetism. Equations 25 and 26 will first be tested for pentalene, and then applied to heptalene, *s*-indacene, and dibenzpentalene.



(I) (II)



(III) (IV)

Pentalene (I).—The molecule is formed from cyclooctatetraene by the introduction of a cross-link between the atoms of a like parity with $r'-r=4$. The perturbation is given by $\delta_l^o=(k^o/2)-\cos\pi l$, the cross-linked atoms being assumed to be odd-numbered. The values of x_l, λ_l, and μ_l calculated using Eqs. 24—26 are presented in Table II. By comparing Table II with Table I, we can see how the introduction of the cross-link influences these quantities. By examining the figures of the case when $k(=k^o)=1$, it may be seen that the cross-link perturbation lifts the degeneracy of the non-bonding orbitals of the parent cyclic polyene. At the same time, the magnetic moment of the non-bonding orbitals is quenched and reproduced as the second-order susceptibility; namely, the first-order magnetic moment, λ_2, of the parent polyene is transferred to the second term of μ_2 as an induced paramagnetism. This paramagnetism greatly overshadows the diamagnetism from all other, lower-lying orbitals, giving rise to a large molecular paramagnetic susceptibility.

Table II includes the values of x_l, λ_l, and μ_l

for the case when $k(=k^0)=0.55$, which is the k_{min} value of the parent polyene. It may be seen that the susceptibility is very senstive to the value of k.

The values of x_l calculated by solving the secular equation, and those of λ_l and μ_l calculated by the direct use of London's method, are also included in Table II. For the molecular susceptibility, $2\sum_l \mu_l$, there is a good agreement between the present perturbation calculations and the complete MO calculations, though as to μ_1 and μ_{-1} there is a large difference.

Pentalene has not yet been synthesized.

Heptalene (II).—The k_{min} value of the perimeter of this molecule, dodecahexaene, was calculated to be 0.59. The cross-link perturbation used to yield heptalene from the cyclic polyene is $\delta_l^0=(k^0/3)\cos\pi l$. Assuming $k^0=0.59$ and using Eq. 26, one obtains $\chi_\pi=0.803\times10^{-17}\,\beta$. The $\Delta K/\Delta K_{benzene}$ value turns out to be -0.15 (cf. $\Delta K/\Delta K_{benzene}=-5.65$ when $k=k^0=1$). This indicates that, in heptalene, the magnetically-induced ring currents should be impeded considerably. A part of evidence for this conclusion is given by the proton NMR spectrum of this molecule, which exhibits the proton signals in the vinyl region (4–5τ).[23]

s-Indacene (III).—The cross-link perturbations used to form this molecule from the corresponding cyclic polyene are $\delta_l{}^0=(k^0/3)\cos(2\pi l/3)$. Assuming $k=k^0=0.59$, we obtain $\chi_\pi=0.377\times10^{-17}\,\beta$, which in turn yields $\Delta K/\Delta K_{benzene}=0.007$. The magnetically-induced ring currents should be considerably impeded in this molecule also. Comparing the $\Delta K/\Delta K_{benzene}$ values of heptalene and *s*-indacene, it may be expected that the NMR proton signals of the latter should appear at lower fields than do those of the former. It has experimentally been shown that *s*-indacene exhibits signals between 2.4 and 3.7 τ.[24]

Dibenzpentalene (IV).—The k_{min} value of the perimeter of this molecule, the 16-membered cyclic polyene, is calculated to be 0.60. The cross-link perturbations used to form dibenzpentalene from the cyclic polyene are $\delta_l^0=(k^0/4)\cos\pi l$ for the central cross-link (between atoms of a like parity) and $\delta_l'=(k'/8)\exp(5\pi il/8)$ for the other two cross-links (between atoms of a different parity). Assuming $k^0=k=0.60$ and $k'=(1+k)/2=0.80$, we obtain $\Delta K/\Delta K_{benzene}=0.99$. The calculated value is in good agreement with the observed value, 0.87, for dimethyldibenzpentalene.[19] The introduction of a methyl substituent would result in the reduction of the diamagnetic anisotropy.

In conclusion, it may be said that, in these catacondensed nonbenzenoid aromatic hydrocarbons with 4 ν carbon atoms, magnetically-induced ring currents are considerably impeded by the bond length alternation inherent in them, and that, hence, the π-electron delocalization is fairly restricted. In this sense these molecules can not be considered to belong to the "aromatic" category. They should have, rather, characteristics of a cyclic polyolefin.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 809—813 (1966)

The Intramolecular Interaction between the N–H Group and π-Electrons. IV.[1] The Energetics of the Interaction[2]

By Michinori Ōki and Kiyoshi Mutai

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 17, 1965)

The thermodynamic parameters for the intramolecular interaction between the N–H group and the π-electrons in *N*-benzylanilines were determined from the temperature dependence of the N–H stretching absorptions. A comparison of the $-\Delta H$'s with those for the O–H···π interaction indicates that there is no appreciable difference between the interactions involving the N–H and the O–H groups. The $-\Delta H$'s are less than 2 kcal./mol., this figure being considered to be a borderline differentiating the X–H···π interaction from the ordinary hydrogen bond. The wave number shift accompanying the interaction cannot be a measure of the $-\Delta H$ in the N–H group, nor be indicative of the difference between two groups. The $-\Delta H$ was found to be closely related with the equilibrium constant in these derivatives.

1) Part III of this series: This Bulletin, **38**, 393 (1965).

2) M. Ōki and K. Mutai, Presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

In the previous papers of this series,[1),3)] the existence of the interaction of the N–H group with π-electrons in *N*-(ω-phenylalkyl)anilines has been confirmed. A comparison of the chain lengths which permit the X–H$\cdots\pi$ interaction has shown that the N–H$\cdots\pi$ interaction is favored over the O–H$\cdots\pi$ interaction, contrary to the general expectation. Although this was presumed to be due mainly to the steric requirement of the phenyl group attached to the N–H nitrogen, it seemed that it would be interesting to compare the other characteristics of the interactions which involve the O–H and the N–H groups. The thermodynamic parameters are the most directly connected, and so they are most appropriate objects of comaprison. Thus the present paper is concerned with the determination of such parameters, on the basis of which the differences or the similarities of the two interactions may be discussed.

Experimental

Spectral Measurements.—A Perkin-Elmer, model 112G, double-pass high-precision grating infrared spectrometer, as has been described previously,[3)] was used. A carbon tetrachloride solution of a sample (ca. 0.004 mol./l.) was placed in a quartz cell (2 cm. long) covered with a heating coil protected with asbestos. The temperature of the solution was controlled by varying the current through the heating coil; the temperature was kept at each equilibrated temperature within an accuracy of 0.3°C and was read by a thermometer dipped in the solution. The spectrometer being of a single-beam type, a background trace was recorded every time immediately before or after scanning with the solution.

Calculation.—The band obtained was separated into its components and their integral intensities were calculated in a manner described before.[3)] The observed system can be regarded as being in the equilibrium expressed by Eq. 1, where K is an equilibrium constant:

$$\text{Free form} \overset{K}{\rightleftarrows} \text{Interacting form} \qquad (1)$$

Therefore, the well-known van't Hoff equation (2) can be used to obtain the energy difference between the two forms:

$$\ln K = \frac{\Delta H}{RT} + \frac{\Delta S}{R} \qquad (2)$$

K is given by spectral measurements:

$$K = \frac{c_i}{c_f} = \frac{A_i/a_i}{A_f/a_f} = \frac{a \cdot A_i}{A_f} \qquad (3)$$

where a_i and a_f represent the intensities per molecule for the interacting and the free N–H group respectively; a, their ratio, and the A's, the integrated intensities of each form.

By combining Eq. 2 with Eq. 3, Eq. 4 is obtained:

$$\ln\frac{A_i}{A_f} = \frac{-\Delta H}{RT} + \left(\frac{\Delta S}{R} - \ln a\right) \qquad (4)$$

Assuming that a_i and a_f, or their ratio, a, are independent of the temperature, at least within the 20—70°C range, the interaction energy ($-\Delta H$) can be determined from the slope of the $\ln(A_i/A_f)$ vs. $1/T$ polt by the least-squares treatment.

Results and Discussion

The effect of the temperature on the N–H stretching frequencies and the intensities of *N*-benzylanilines are summarized in Table I through V.

Some slight changes in the spectral characteristics with the temperature are observed. For instance, $\Delta\nu_{max}$ (the wave number shift accompanying the interaction) has a tendency to decrease with an increase in the temperature, though the shift is indefinite. The total integral intensity (A_i+A_f) also decreases. The latter phenomenon may be mainly due to the thermal expansion of the solvent, the effect resulting in a decrease of the concentration.

The spectrum of the *p*-nitro derivative (Table V) behaves unusually; the $\log(A_i/A_f)$ changes irregularly with the temperature, and a new, third band appears at a higher temperature, as shown in Fig. 1.[4)] The experiment was repeated twice for this case; the results were qualitatively similar, as is shown in Fig. 2 (the data given in Table V are those of one case). It may be supposed that the compound which is rather unstable in a solution would react with the solvent carbon tetrachloride, and that the product at this reaction would be the origin of the new band. However, the room temperature spectrum of the solution which had been heated to a high temperature showed no appreciable difference from that before heating.

For the origin of the new band at the high temperature, there are several possibilities: 1) the appearance of a new conformer, one which is unstable at room temperature; 2) the existence of a new product from the solute and the solvent which is

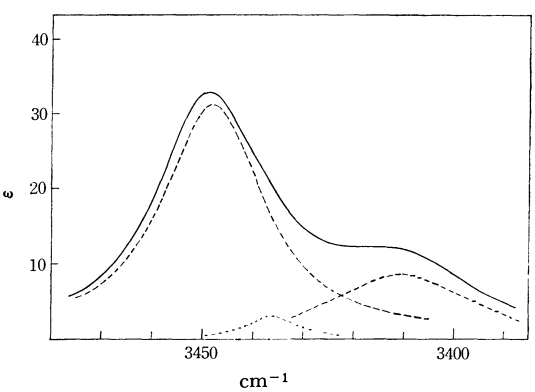

Fig. 1. ν_{N-H} Absorption of *N*-(*p*-nitrobenzyl)aniline at 74°C.

3) M. Ōki and K. Mutai, This Bulletin, 38, 387 (1965).

4) It is assumed that the curves are expressed by Lorentzian equation. This assumption is hold throughout this paper.

only present at the higher temperature; 3) a change in the absorption curve shape which allows a third band to find its place as a result of the somewhat indefinite calculation method (the trial and error method), etc. The band intensity, however, is very small, the position of its maximum is uncertain, and its existence is much limited by the compound and the temperature. Therefore, the authors have not yet tried to make a choice among the possibilities. It is difficult to determine whether the third band should be classified as the interacting or the free form, but it was temporarily assumed to be the free form. At any rate, the classification matters little to the intensity ratio.

Table VI summarizes the thermodynamic parameters obtained by applying Eq. 4 to the data in Tables I through V.

In Table VI it may be seen that the $-\Delta H$ values are all smaller than that for the ordinary hydrogen bond, which is more than 2 kcal./mol. In this connection it is interesting and significant that the N–H group is similar to the O–H group[5),6)] in the intramolecular interaction with π-electrons. The interaction energy ($-\Delta H$) of both groups is generally less than 2 kcal./mol., this small ΔH value may be the best criterion for differentiating the X–H···π interaction from the ordinary hydrogen bonding, not only for the O–H group but also for the N–H group.

In this connection, it would be interesting to examine the thermodynamic data for the intermolecular N–H···π interaction. Recently Whetsel and Lady[7)] reported that the energies of the intermolecular N–H···π interactions in *N*-methylaniline - benzene and aniline - benzene systems were 1.5 and 1.6 kcal./mol. respectively, the value being again in the range for X–H···π interaction. They also reported that the C–H···π interaction energy in a chloroform - benzene system was 2 kcal./mol. In conclusion, all the data so far available confirm the above criterion to be reliable. The small $-\Delta H$ values are probably due to the weak electron-donating power of the π-electron system of benzene.

With these values in mind, it may be easily explained why Moritz[8)] could not find any detectable change in the N–H stretching bands of *N*-benzylaniline with a varying temperature. Generally a small intensity change accompanying a small $-\Delta H$ is difficult to detect, especially when it is not the extinction coefficient but the half-band width that determines the value of the integral intensity.

In view of the $-\Delta H$ values and the frequency shifts ($\Delta\nu_{max}$) in Table VI, it is evident that there is no generally supposed linear relationship between the two. On the contrary, a large $-\Delta H$ value is accompanied by a small $\Delta\nu_{max}$ value (for instance, the $-\Delta H$ of the *p*-dimethylamino derivative is 1.7 kcal./mol. and the $\Delta\nu_{max}$, 30.4 cm^{-1}, whereas the $-\Delta H$ and $\Delta\nu_{max}$ of *p*-nitro derivatives are nearly zero and 38.1 cm^{-1} respectively). It should be emphasized that this anomaly is observed in a group of substituted benzylanilines, since in this group of compounds steric, electronic and other factors are nearly equal, and it may generally be expected that the stretching frequency of the N–H group would be predominantly affected by the strength of the interaction, namely, the energy of the interaction, $-\Delta H$. Considering this anomaly, it sould not be safe to discuss the interaction energies by using the $\Delta\nu_{max}$ value only.

On the other hand, the energy is closely related to the intensity ratio. As may be seen in Fig. 3,

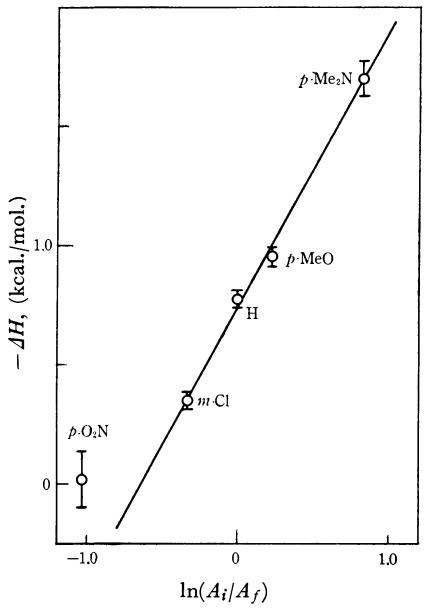

Fig. 3. Relation of $\ln(A_i/A_f)$ with interaction energy $(-\Delta H)$.

a plot of $-\Delta H$ against $\ln(A_i/A_f)$ shows a linear correlation, except for the value for the *p*-nitro derivative. In this group of compounds, it may safely be said that the equilibrium constant, K, is affected mainly by $-\Delta H$, with some part compensated for by the entropy.

The entropy change of the interaction (ΔS) could not be determined, because we do not know the a value. Strictly speaking, for the calculation of the entropy change another standard band, common in frequency and in molecular absorption coefficient with both interacting and free forms, must be used together with these two bands.[9] The value, $\Delta S/R - \ln a$, obtained as an intercept from the plot is, therefore, only a rough measure of the true ΔS, and no fruitful discussion can be expected from these data.

The $-\Delta H$ value of *p*-nitro derivative is nearly zero, and there remains a possibility of its being negative (ΔH is positive). This possibility is also supported by extending the line of the $-\Delta H$ vs. $\ln(A_i/A_f)$ plot (see Fig. 3), though the value obtained is obscured by large errors. Taking this into account, together with the N–H$\cdots\pi$ interaction which will cause some stability, it is suggested that there are some factors other than the N–H$\cdots\pi$ interaction which affects the total energy. The problem seems to be closely connected with the conformations of the two forms. An explanation for this phenomenon will be published in a forthcoming paper.

The authors are indebted to Professor Yoshiyuki Urushibara and Professor Takehiko Shimanouchi for their valuable discussions and encouragement. They are also indebted to the Ministry of Education for a grant-in-aid for Fundamental Scientific Research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 813—817 (1966)

Intramolecular Interaction between Hydroxyl Group and π-Electrons. XX.[1] Conformationally-fixed *o*-Vinylphenols

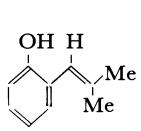
By Michinori Ōki, Hiizu Iwamura, Takeru Onoda and Michiko Nishida

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

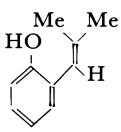
(Received September 17, 1965)

1, 2-Dihydro-5-hydroxy-8-methoxy-3-methylnaphthalene (III) was prepared, starting from 5, 8-dimethoxy-α-tetralone, via 8-hydroxy-5-methoxy-2-methyl-1-keto-1, 2, 3, 4-tetrahydronaphthalene. The O–H stretching absorptions (ν_{O-H}) and the ultraviolet absorptions of III, 1, 17 β-dihydroxy-4-methylestra-1, 3, 5(10), 9(11)-tetraene (IV), and the related naphthols were measured and compared with those of *o*-isobutenylphenol. IV showed a ν_{O-H} at 3532 cm^{-1} which is assigned to the hydroxyl group taking part in the strong interaction with the π-electrons on the ethylenic group; it corresponds well in its location to the lowest frequency band of *o*-isobutenylphenol. The previous assignment of this band to the conformer II with the double bond *syn* to the hydroxyl was thus confirmed. III showed only a symmetric band at 3618 cm^{-1}, which was assigned to the free ν_{O-H}, and could not be a model for the conformer with a ν_{O-H} at 3576 cm^{-1}, presumably because of the more planar structure for the overlap between the orbitals of the hydroxyl group and the ethylenic group.

In the foregoing paper,[1] the doublet O–H stretching absorption bands (ν_{O-H}) at 3576 and 3539 cm^{-1} of *o*-isobutenylphenol were assigned to the hydroxyl groups interacting with the π-electrons in conformations expressed approximately by I and II respectively. In an attempt to verify this tentative assignment, the model compounds conformationally fixed as in I and II have now been prepared and their ν_{O-H} absorptions examined. They are α-naphthol, 5-hydroxy-1, 2-dihydronaphthalene,[2] 1, 2-dihydro-5-hydroxy-8-methoxy 3-methylnaphthalene (III), and 1, 17-β-dihydroxy-4-methylestra-1, 3, 5(10), 9(11)-tetraene(IV)[3];

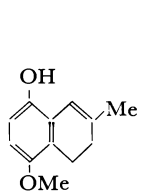


I

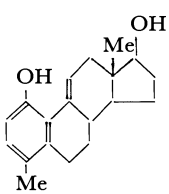


II

all are known compounds except III, whose preparation started from 5, 8-dimethoxy-α-tetralone and was analogous to the route to equilenin developed by Bachman et al.[4]



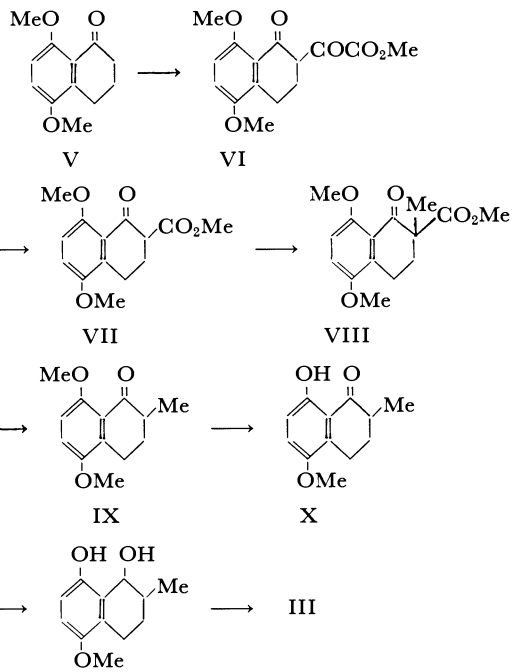
III



IV

The α-tetralone (V) was condensed with methyl oxalate by the action of sodium methoxide under nitrogen, and the methoxalyl derivative (VI) was heated in order to effect decarbonylation and to give the 2-methoxycarbonyl derivative (VII) of the α-tetralone. The sodio-derivative of the latter was methylated with methyl iodide. Saponification, followed by decarboxylation, gave 5, 8-dimethoxy-2-methyl-α-tetralone (IX). Gentle refluxing with constant boiling hydroiodic acid demethylated the 8-methoxyl group preferentially. The hydroxy-ketone (X) was reduced to the corresponding diol (XI) with lithium aluminum hydride. Refluxing with acetic anhydride, followed by saponification, gave III with a m. p. of 92—93°C.

The Diels-Alder reaction between toluquinone and isoprene has been shown to afford 3, 4-dihydro-



V VI VII VIII IX X XI III

5, 8-dihydroxy-2, 7-dimethylnaphthalene after acid-catalyzed rearrangement.[5] The diol (XII) similarly obtained from the reaction between benzoquinone and isoprene was dissolved in aqueous sodium hydroxide and partially methylated with dimethyl sulfate. Through chromatography on alumina, a fraction of a mono-methyl ether was obtained. Recrystallization gave pure mono-methyl ether, which was different from III. Since further methylation afforded the common dimethyl ether (XIV), the latter mono-methyl ether must be the 5-methoxy-8-hydroxy isomer (XIII).

Experimental

Spectral Measurements.—Those were carried out as described previously.[1]

Materials.

Methyl 5, 8-Dimethoxy-1-keto-1, 2, 3, 4-tetrahydronaphthalene-2-glyoxalate (VI).—In 100 ml. of anhydrous methanol was dissolved 9.2 g. of sodium and the excess methanol was evaporated to dryness at 100°C under diminished pressure. To the white solid were added 47.2 g. of dimethyl oxalate and 200 ml. of dry benzene. The mixture was refluxed under dry nitrogen for half an hour in order to dissolve the solid. To the cooled solution was added 41.2 g. (0.2 mol.) of 5, 8-dimethoxy-α-tetralone (V)[6] dissolved in 300 ml. of benzene. After it had stood for four hours at room temperature with occasional shaking, the mixture was hydrolyzed with 500 ml. of water. The aqueous layer was then drawn off, the benzene layer was extracted twice with 100 ml. of a 5% sodium hydroxide solution, and the combined aqueous solution was carefully acidified with dilute hydrochloric acid. The yellow crystalline deposit was collected and recrystallized from methanol to give 50.5 g. of the glyoxalate (VI), m. p. 108—109°C, corresponding to a yield of 95%.

Found: C, 61.83; H, 5.63. Calcd. for $C_{15}H_{16}O_6$: C, 61.64; H, 5.52%.

Methyl 5, 8-Dimethoxy-1-keto-1, 2, 3, 4-tetrahydro-2-naphthoate (VII).—The methyl glyoxalate (VI) (26.7 g.) was mixed with 20g. of 200 mesh glass powder in a Claisen flask, and the mixture was carefully heated under diminished pressure. A vigorous evolution of carbon monoxide commenced at about 160°C. After half an hour at 180°C, the evolution of the gas stopped and, as the pressure inside the flask dropped, refluxing took place. The temperature of the oil bath was then raised to 240°C and an oil boiled at 180—190°C under ca. 3 mmHg was collected. The viscous oil was dissolved in benzene and recrystallized to give colorless prisms (20.5 g.; yield, 85%), m. p. 86°C.

Found: C, 63.54; H, 6.28. Calcd. for $C_{14}H_{16}O_5$: C, 63.63; H, 6.10%.

Methyl 5, 8-Dimethoxy-1-keto-2-methyl-1, 2, 3, 4-tetrahydro-2-naphthoate (VIII).—To 23 g. of sodium dissolved in 500 ml. of anhydrous methanol was added 23.9 g. of VII dissolved in 200 ml. of benzene. After this mixture had been refluxed for fifteen minutes on a water bath, 50 ml. of methyl iodide was added over a five-minute period. Another 50 ml. of methyl iodide was added after an exothermic reaction had ceased, and the mixture was refluxed for an hour. After neutralization with acetic acid, the solvents were evaporated nearly to completion, and the residue was treated with 500 ml. of benzene and 300 ml. of water. The organic layer was washed with 5% sodium hydroxide and then with water, and dried over sodium sulfate. After the solvent had then been evaporated, the residue was crystallized from carbon tetrachloride (yield, 20 g.; 80%) m. p., 63—63.5°C.

Found: C, 64.92; H, 6.73. Calcd. for $C_{15}H_{18}O_5$: C, 64.74; H, 6.52%.

5, 8-Dimethoxy-2-methyl-1-keto-1, 2, 3, 4-tetrahydronaphthalene (IX).—A mixture of 100 ml. of 45% aqueous potassium hydroxide and 300 ml. of methanol was mixed with 30 g. of VIII, refluxed on a water bath for two hours, and diluted with water in order to collect the resulting solid. Recrystallization from methanol gave colorless prisms, m. p. 69°C.

Found: C, 70.99; H, 7.46. Calcd. for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

8-Hydroxy-5-methoxy-2-methyl-1-keto-1, 2, 3, 4-tetrahydronaphthalene (X).—IX (20 g.) was heated under reflux with 200 ml. of 52% hydroiodic acid for 2 hr. The mixture was then diluted with water, and the product was triturated with a 20% aqueous sodium hydroxide solution to give the insoluble sodium salt, which was collected and washed with aqueous alkali and then with water. The residue was then suspended in 50 ml. of water and acidified with 1 N hydrochloric acid. The oil was extracted with ether, and the solution was dried over anhydrous sodium sulfate. After evaporation, the residue was crystallized from methanol to give pale yellow needles (yield, 16 g.; 85.4%), m. p. 46.5—47°C.

Found: C, 69.93; H, 6.84. Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84%.

The NMR spectra[7] of 5% $CDCl_3$ solution consisted of the following signals; 1.26 ($C_{(2)}$'-Me, doublet), 1.8—3.1 (aliphatic, multiplet), 3.81 (O'Me), 6.70, 6.85, 7.01 and 7.16 (the AB quartet of the aromatic protons), and 11.99 (chelated OH).

1, 8-Dihydroxy-5-methoxy-2-methyl-1, 2, 3, 4-tetrahydronaphthalene (XI).—To a slurry of 4 g. of lithium aluminum hydride in 100 ml. of ether was added, drop by drop, a solution of 10.3 g. of the hydroxyketone (X) in 70 ml. of ether. After the reaction had subsided, the mixture was refluxed for an hour. The excess reagent was decomposed with ethyl acetate and then treated with 2 N sulfuric acid. The combined ether extracts were washed with 1 N sodium bicarbonate and dried over anhydrous potassium carbonate. The solvent was evaporated, and the residue was recrystallized from carbon tetrachloride to give needles, m. p. 125°C (yield, 9.5 g.; 91.3%).

Found: C, 68.91; H, 8.02. Calcd. for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.

1, 2-Dihydro-5-hydroxy-8-methoxy-3-methylnaphthalene (III).—A solution of 5 g. of the above diol (XI) in 50 ml. of acetic anhydride was refluxed for an hour. When, after the solvent had been evaporated, the dehydrated acetate was distilled under diminished pressure, a fraction boiling at 120—130°C/1.5 mmHg was collected. The distillate was dissolved in 50 ml. of 5% ethanolic sodium ethoxide, and the mixture was refluxed for thirty minutes. The volume of the solvent was reduced to half, and the residue was diluted with water. The solution was treated with a small portion of active charcoal and filtered while hot. The filtrate was acidified and the product crystallized from carbon tetrachloride to give needles, m. p., 92—93°C; the yield was 2.8 g. (61.3%).

Found: C, 75.78; H, 7.66. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

1, 2-Dihydro-5, 8-dihydroxy-3-methylnaphthalene (XII).—A solution of 12 g. of *p*-benzoquinone and 7 g.

6) M. Crawford and V. R. Supaneka, *J. Chem. Soc.*, **1960**, 1985.

7) Determined at 60 Mc./sec. on a model A-60 spectrometer (Varian Associates, Palo Alto, Calif., U. S. A.) at the normal operating temperature (36.5°C) and reported in units of δ in p.p.m., from the signal of TMS used as the internal standard.

of isoprene in 50 ml. of acetic acid was kept at room temperature for 24 hr. The solid was then collected on a Buchner funnel and washed several times with water. To a suspension of the crude adduct in 50 ml. of chloroform, 20 ml. of concentrated hydrochloric acid was added, and the mixture was heated under reflux for 12 hr. The solid mass was filtered when it had cooled, washed several times with chloroform, and finally recrystallized from chloroform-acetone to give needles, m. p. 175°C.

Found: C, 75.10; H, 6.99. Calcd. for $C_{11}H_{12}O_2$: C, 74.97; H, 6.86%.

1, 2-Dihydro - 8 - hydroxy - 5 - methoxy-3-methylnaphthalene (XIII).—To a solution of 8.8 g. of the diol (XII) in 200 ml. of 10% aqueous sodium hydroxide was added, drop by drop, 7 g. of dimethyl sulfate with cooling and shaking. The dark solution was washed twice with ether, and the aqueous layer was acidified with dilute hydrochloric acid. The heavy oil was dissolved in ether, and the ether solution was dried over anhydrous sodium sulfate. After the solvent had evaporated, the residue was dissolved in benzene - petroleum ether (b. p. —60°C) (1 : 1 in volume) and chromatographed on alumina. Following a fraction of an oil, a series of fractions was obtained and found to be homogeneous. The residue obtained after the evaporation of the solvent was recrystallized from carbon tetrachloride to give needles (1.2 g.; 12%), m. p. 124.5—125°C.

Found: C, 76.01: H, 7.34. Calcd. for $C_{12}H_{14}O_2$: C, 75.76; H, 7.42%.

The ethereal layer yielded a small amount of a dimethyl ether which was identical with the specimen whose preparation is described below.

1, 2-Dihydro - 5, 8 -dimethoxy -3 - methylnaphthalene (XIV).—To a solution of 3.8 g. of III in 50 ml. of 10% aqueous sodium hydroxide, 3 g. of dimethyl sulfate was added; the mixture was then shaken for ten minutes. The oil was extracted in ether, and the ether solution was dried over anhydrous potassium carbonate. The residue obtained after the evaporation of the solvent was recrystallized from petroleum ether to give needles (3.8 g.; 93%), m. p. 66°C.

Found: C, 76.56; H, 8.10. Calcd. for $C_{13}H_{16}O_2$: C, 76.44; H, 7.90%.

Results and Discussion

In Fig. 1 are shown the apparent ν_{O-H} absorptions of III and IV, while in Table I all of the ν_{O-H} data concerned are collected.

The band at the highest frequency of IV is due to the secondary alcoholic hydroxyl group at the 17-position of the steroid skeleton; it is outside the present discussion. Judging from its location, the absorption maximum at 3606 cm^{-1} can be assigned to the free ν_{O-H} of the phenolic hydroxyl group.[1,8] The lowest-frequency band, at 3532 cm^{-1}, may consequently be assigned to the phenolic hydroxyl group interacting with π-electrons on the ethylenic group. Compared with the interacting ν_{O-H}'s of *o*-isobutenylphenol, the location of the

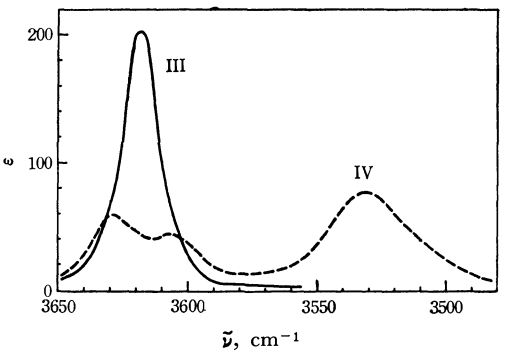

Fig. 1. ν_{O-H} absorptions of 1, 2-dihydro-5-hydroxy-8-methoxy-3-methylnaphthalene (III) and 1, 17β-dihydroxy-4-methylestra-1, 3, 5(10), 9(11)-tetraene (IV).

last band of IV corresponds well to the lower one at 3539 cm^{1-} of *o*-isobutenylphenol; therefore, it may be concluded that this band should be assigned to the hydroxyl group in conformation II. The Dreiding model of IV suggests that the angle between the benzene ring and the plane made by the ethylenic linkage is ca. 10°. Table II lists the ultraviolet absorption maxima of these *o*-vinylphenol derivatives. The K-band in *n*-hexane of IV is shifted to the red side by 20 mμ from that of *o*-isobutenylphenol, and it is even comparable to those of the more planar *o*-vinylphenol and *o*-(*trans*-propenyl)phenol.[1] Although a part of the effect may be attributed to the auxochromic effect in IV of the additional alkyl groups attached to the chromophore, the UV data indicate that the benzene ring and the ethylenic group in IV are mutually more co-planar than those of *o*-isobutenylphenol. It is not yet clear why this molecule shows a strong interaction despite its near co-planarity, but it is interesting to note that the compound IV and *o*-isobutenylphenol show essentially the same ν_{O-H} values at the lower frequencies. It is possible that the ν_{O-H} in conformation II is rather insensitive to the angle between the benzen ring and the plane of the ethylenic group.

The ν_{O-H}'s of 5-hydroxy-1, 2-dihydronaphthalene and III are, contrary to the expectation, singlets, like those of α-naphthol and XIII. The apparently unusually high ν_{O-H} of III and XIII is due to the electronic effect of the methoxyl substitution.[8] No absorption of any degree indicative of the presence of intramolecular interaction between the hydroxyl group and the π-electrons was detected. It is not unreasonable to assume, however, that there is no interaction in α-naphthol and XIII, since there is no π-electron available for the interaction in the latter, and since in the former the hydroxyl group must point to the node of the π-orbitals. The Dreiding models of 5-hydroxy-1, 2-dihydronaphthalene and III suggest that the angle between the benzene

ring and the plane made by the ethylenic group is ca. 25°. Since there is no interaction even in III, in which the proton-accepting power of the ethylenic group is enriched by methyl substitution, it may be concluded that III does not reflect the conformation I of o-isobutenylphenol, but that the dihedral angle made by the plane of the ethylenic group and the plane of the benzene ring must be much larger than that in III in order to have interaction with the hydroxyl group.

The effects of conformations, including the dihedral angles made by the benzene ring and the ethylenic linkage and the relative location of the double bond, remain to be fully explored. However, one possible reason for the poor interaction in the compound III may be that two *p*-orbitals are available for the interaction in conformation II, while only one is available in conformation I. The former is expected to be the preferable interacting form, on analogy with the benzene-silver ion complex.[9,10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 818—826 (1966)

The Crystal Structure of 1, 2, 3, 4-Tetrachlorobenzo[g]sesquifulvalene

By Yoriko NISHI, Yoshio SASADA, Tamaichi ASHIDA and Masao KAKUDO

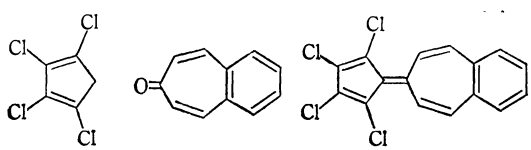
Institute for Protein Research, Osaka University, Joancho, Kita-ku, Osaka

(Received September 20, 1965)

The molecular structure of 1, 2, 3, 4-tetrachlorobenzo[g]sesquifulvalene has been ascertained by X-ray crystal analysis. The crystal of this substance is monoclinic, with four molecules in a unit cell of dimensions: $a=21.31$, $b=16.88$, $c=3.83$ Å, and $\beta=93.3°$, the space group being $P2_1/a$. The crystal structure was determined by the Harker-Kasper inequality and the Sayer's method. The atomic coordinates and the anisotropic temperature factors of each atom were refined by the block-diagonal-matrix least-squares method. The average length of the C–Cl bonds is 1.705 Å, a value which is in good agreement with those of several chlorobenzenes. In the sesquifulvalene skeleton, longer and shorter bonds are disposed as may be expected from the conventional chemical formula. The average length of the longer bonds is 1.461 Å, while that of the shorter ones is 1.354 Å. The mean C–C bond length in the benzene ring is 1.413 Å. The whole molecule is not on a plane, although the component ring systems are nearly planar. The five-membered ring and the seven-membered ring twist to each other by an angle of about 31° around the bond connecting these two rings. This might be due to the repulsion forces between chlorine and hydrogen atoms which approach each other closely. The plane of the seven-membered ring makes an angle of about 5° with that of the six-membered ring.

In attempting to synthesize some derivatives of sesquifulvalene (cycloheptatrienylidenecyclopentadiene), Kitahara, Murata, Funamizu and Asano[1] have found that there action of tropone with 1, 2, 3, 4-tetrachlorocyclopentadiene (I) in methanol results in a mixture of 1, 2, 3-trichloro-6-(*o*-methoxyphenyl)fulvene and the corresponding para-isomer. This is an entirely new type of rearrangement reaction, in which the methoxy group enters the seven-membered ring (a six-membered ring after the rearrangement) and in which a chlorine atom in the five-membered ring is liberated. This chemical conclusion was confirmed by an independent crystal structure determination of an analogous product containing bromine atoms.[2]

Such a kind of rearrangement could be avoided by using benzo[d]tropone (II) instead of tropone; the product, in the form of fine violet needles, may be supposed to be 1, 2, 3, 4-tetrachlorobenzo-[g]sesquifulvalene (III).[3]



(I) (II) (III)

The results of the elementary analysis of the substance also supported this formula. For an independent verification of the structure by means of X-ray analysis, a sample of the compound was supplied to us by Professor Yoshio Kitahara of Tohoku University.

The stereochemistry of this compound is also interesting. If the molecule is planar, or nearly so, as may be expected from the chemical formula, much steric hindrance should be exerted between Cl(1) and the hydrogen atom bonded to C(10), and between Cl(4) and the hydrogen bonded to C(5). In addition to the establishment of the chemical formula, this investigation has been carried out in order to clarify the molecular configuration and the features of the steric hindrance.

The present paper will describe the structure determination of this compound by the three-dimensional Fourier and least-squares methods.

Experimental

The crystals of 1, 2, 3, 4-tetrachlorobenzo[g]sesquifulvalene are deep violet needles elongated along the c axis.

The crystallographic and physical data found are as follows:

1, 2, 3, 4-Tetrachlorobenzo[g]sesquifulvalene, $C_{16}H_8Cl_4$.

M.p.: 234°C.

Monoclinic: $a=21.31\pm0.05$, $b=16.88\pm0.03$, $c=3.83\pm0.02$ Å, $\beta=93.3\pm0.3°$.

Volume of the unit cell: 1375.3 Å^3.

Density observed by the floatation method; 1.64 g.cm^{-3}

Density calculated; 1.65 g.cm^{-3}

Number of molecules in the unit cell: 4

3) Y. Kitahara, I. Murata and S. Katagiri, *Angew. Chem.*, **77**, 345 (1965).

Absent spectra: $(h0l)$ when h is odd,
$(0k0)$ when k is odd
Space group: $P2_1/a$.

The crystal was found to be twin; the X-ray photographs showed that the twinning occurred with a common (100) plane. The crystals were so thin along the c axis that it was impossible to obtain a single crystal. Therefore, we selected a few crystals in which one component of the twin was as small as possible.

Copper $K\alpha$ radiation was used with a nickel filter. The intensity data were collected only for the $(hk0)$, $(hk1)$ and $(hk2)$ zones by means of equi-inclination Weissenberg photographs. In order to correlate strong and weak reflections, the multiple-film technique was applied, the relative intensities being ranged between 3300 and 1 for $(hk0)$, between 5000 and 1 for $(hk1)$, and between 350 and 1 for $(hk2)$. The maximum $(2\sin\theta)$'s of the observed reflections were 1.98, 1.66 and 1.75 for $(hk0)$, $(hk1)$ and $(hk2)$ respectively. 277 independent reflections out of 418 possible $(hk0)$, and 428 out of 935 $(hk1)$ and $(hk2)$, were observed within the above-mentioned ranges.

Precession photographs were also taken for the $(h0l)$ zone in order to determine the relative scale factors among the three layers of the Weissenberg photographs. The crystal used had a cross section of about 0.1×0.03 mm.

The intensities were estimated visually by comparison with a standard intensity scale prepared using the same crystal. Corrections for Lorentz and polarization factors were applied as usual, while the absorption effect was neglected because of the small size of the crystal used in the experiment. The observed structure factors were then put onto a tentative absolute scale by means of Wilson's statistics.[4]

Structure Determination

Structure Projected along the c Axis.— Since the c axis of the crystal is short, the molecule was supposed to be approximately planar and almost parallel to the (001) plane. In order to locate the four chlorine atoms, the sharpened Patterson projections on the (001) plane were synthesized with several degrees of sharpening. It was difficult to interpret the maps so obtained, however, because of the heavy overlappings of peaks due to chlorine-chlorine and chlorine-carbon interactions.

In the next attempt, the direct sign-determination methods were applied to $F(hk0)$'s. The Harker-Kasper inequality[5] was used;

$$(U_{\mathrm{H}}\pm U_{\mathrm{H}'})^2 \leq (1\pm U_{\mathrm{H}+\mathrm{H}'})(1\pm U_{\mathrm{H}-\mathrm{H}'})$$

where U_{H} etc., are the unitary structure factors for the $(hk0)$ plane. Signs for 76 out of 277 observed reflections were obtained by this method. Further sign-determinations were made by using Sayre's relation,[6]

$$S_{\mathrm{H}}=S_{\mathrm{H}'}S_{\mathrm{H}+\mathrm{H}'}$$

where S_{H} denotes the sign of F_{H}. The relation gave signs of 50 more reflections. After the final refinement of the structure, it was found that only two out of the 126 signs determined by the direct methods were incorrect.

The projection of the electron-density distribution along the c axis was then synthesized using these 126 reflections. The map showed not only the four chlorine atoms, but also a rough layout of the carbon skeleton, as may be seen from Fig. 1. The structure was then refined by the usual Fourier technique, after which the anisotropic temperature factors in the form of $\exp\{-(h^2B_{11}+k^2B_{22}+hkB_{12})\}$ were assigned to each non-hydrogen atom, and the least-squares refinement method was applied with a block-diagonal-matrix approximation. The atomic scattering factors given by Berghuis, Haanappel, Potters, Loopstra, MacGillavry and Veenendaal[7] for carbon and chlorine and by McWeeny[8] for hydrogen were used throughout this structure determination. After three cycles of refinement, the discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, decreased to 0.091 for all the observed reflections ($R=0.145$ if unobserved reflections were included).

Using the coordinates so determined, the (F_o-F_c) synthesis was computed. Several peaks of residual electron density were observed, as is shown in Fig. 2; some of these might be due to the hydrogen atoms. Among them, two peaks corresponding to H(5) and H(10) were also included; those two hydrogen atoms are involved in the steric hindrance mentioned above. Therefore, all the hydrogen atoms were located geometrically at a distance of 1.0 Å outward from the carbon atoms.

Three more least-squares refinement cycles, including those hydrogen atoms with isotropic temperature factors, were carried out. The final discrepancy factor was 0.081 for all the observed reflections ($R=0.133$ including the unobserved reflections). The final x- and y-coordinates and temperature factors are given in Tables I and II respectively, while the observed and calculated structure factors, $F(hk0)$, are listed in Table III. The final electron density projection along the c axis is shown in Fig. 3.

The Determination of the z-Coordinates.— Although no complete three-dimensional intensity data were collected, the Harker section, $P(u, 1/2, w)$, was synthesized, using $F(hk0)$, $F(hk1)$ and $F(hk2)$, in order to obtain the z-coordinates of the atoms. The peaks on the Harker section, as is shown in Fig. 4, were interpreted rather easily by assuming that the chlorine atoms attached to the five-membered ring are coplanar. As the y-coordinates of Cl(2) and Cl(4) are nearly

equal, the non-Harker peak due to these atoms should be placed at the mid-point of their Harker peaks,[9] the Harker peak of each chlorine being indicated in Fig. 4. Near this non-Harker peak, the Harker peak of Cl(3) appears accidentally. This is the reason why the peak corresponding to Cl(3) is higher than those of the other chlorine atoms.

A three-dimensional Fourier synthesis was carried out using the structure factors based on the four chlorine atoms. The electron density

C (4)	4.81	C (12)	5.25
C (5)	5.35	C (13)	6.25
C (6)	5.47	C (14)	6.79
C (7)	5.23	C (15)	6.01
C (8)	6.07	C (16)	6.25

distribution so obtained showed up all the carbon atoms clearly. After one more three-dimensional Fourier synthesis, the structure was subjected to the least-squares refinement. Since the three-dimensional intensity data were incomplete, not only in number but also in their accuracy, only the z-coordinates and temperature factors of non-hydrogen atoms were refined, while anisotropic temperature factors for chlorine and isotropic temperature factors for carbon atoms were assigned. The final R factor for the set of $F(hk1)$ and $F(hk2)$ is 0.136 for the observed reflections.

The final z-coordinates of all the atoms are included in Table I, while the final temperature factors are listed in Table IV. The observed and calculated structure factors, $F(hk1)$ and $F(hk2)$, are tabulated in Table V.

All the numerical computations in this study were done on the NEAC-2101 of the Institute, the NEAC-2206 of the Computing Center of Osaka University and the IBM 7090 of the "UNICON" project, with programmes written by the authors and their collaborators.

A Description of the Structure and Discussion

From the first electron density distribution, which was obtained without any assumption regarding the structure, it was concluded exclusively that the chemical formula deduced from the synthetic process was valid as a whole. This conclusion was confirmed by the subsequent refinement, which gives a fairly good agreement between the observed and calculated structure factors

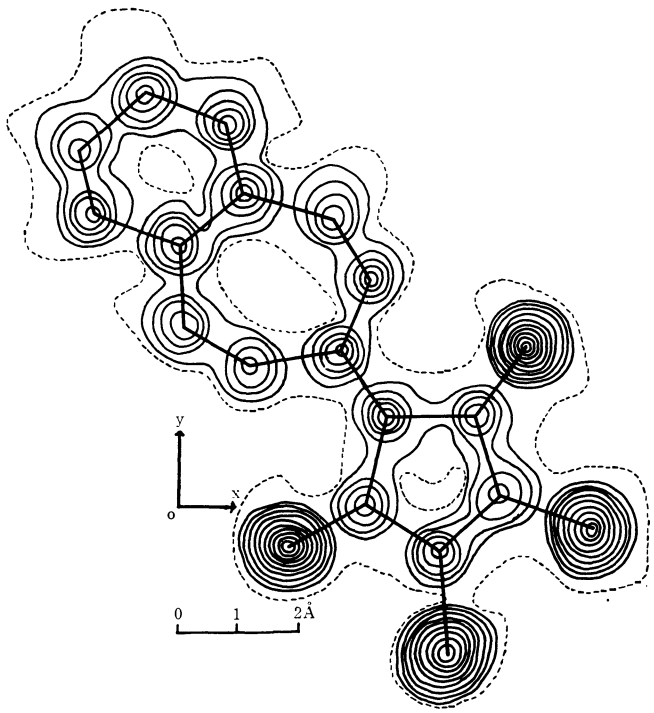

Fig. 3. The final electron density projection along the c axis. Contours are drawn at intervals of 1 e. Å^{-2} with broken contour of 1 e. Å^{-2}. For chlorine atoms, contours are drawn at intervals of 2 e. Å^{-2} beginning with 2 e. Å^{-2}.

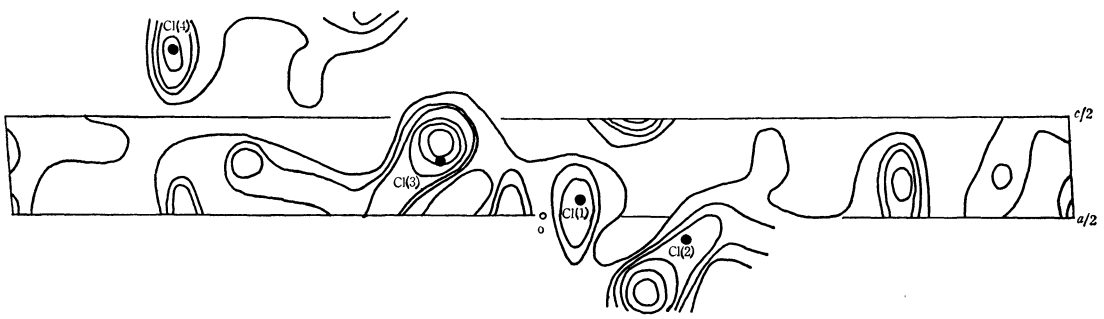

Fig. 4. Harker section $P(u, 1/2, w)$. Contours are drawn at equal intervals on an arbitrary scale. Harker peaks corresponding to the chlorine atoms are indicated.

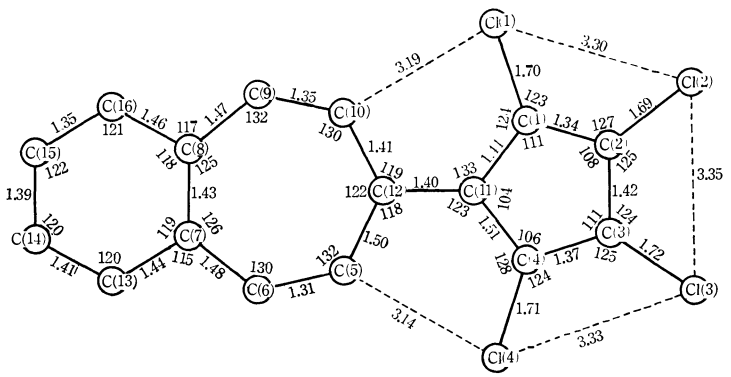

Fig. 5. Bond lengths (Å) and bond angles (°) in the molecule of 1,2,3,4-tetrachlorobenzo[g]-sesquifulvalene.

and which results in quite reasonable intra- and intermolecular distances.

All the bond lengths and angles are shown in Fig. 5. The average standard deviations of the atomic coordinates are 0.011 and 0.036 Å for chlorine and carbon atoms respectively. Therefore, the estimated standard deviation of a C–C bond length is 0.05 Å, while that of a C–Cl bond length is 0.04 Å.

The mean length of C–Cl bonds is 1.705 Å, a value which is in good agreement with the average value of those in several chlorobenzenes (1.70 Å).[10] In the benzene ring of the present molecule, the mean C–C length is 1.413 Å.

In the sesquifulvalene skeleton, longer and shorter bonds are disposed alternately, as could be expected from the chemical formula (III). The average of the longer bond lengths is 1.461 Å, while that of the shorter is 1.354 Å. These values may be compared with those observed in some similar compounds; 1.451 and 1.373 Å in 8, 8-dicyanoheptafulvene,[11] 1.446 and 1.358 Å in 7, 7, 8, 8-tetracyanoquinodimethane,[12] 1.477 and 1.322 Å in *p*-benzoquinone,[13] 1.477 and 1.342 Å in tetrachloro-*p*-benzoquinone,[14] and 1.470 and 1.322 Å in cyclooctatetraenecarboxylic acid.[15]

Murata[16] deduced the bond orders in benzo[g]-sesquifulvalene from a molecular orbital treatment by assuming the planarity of the molecule and the presence of a mirror plane perpendicular to the molecular plane through C(11)-C(12). Table VI shows the theoretical bond lengths converted from the bond orders. It can be said that the observed lengths of the bonds related to each other by the mirror do not differ significantly in the present molecule. Therefore, the average lengths of the equivalent bonds (Table VI) may be compared with the theoretical values. The agreement between them is fairly good, although the assumption of the planarity of the molecule does not hold, as will be described below .

Table VI. Theoretical and observed bond lengths (Å)

Bonds	Theoretical	Observed
C(1)-C(2) and C(3)-C(4)	1.36	1.355
C(2)-C(3)	1.46	1.420
C(1)-C(11) and C(4)-C(11)	1.45	1.475
C(11)-C(12)	1.37	1.400
C(10)-C(12) and C(5)-C(12)	1.46	1.455
C(9)-C(10) and C(5)-C(6)	1.36	1.330
C(8)-C(9) and C(6)-C(7)	1.46	1.475
C(7)-C(8)	1.41	1.430
C(8)-C(16) and C(7)-C(13)	1.46	1.450
C(15)-C(16) and C(13)-C(14)	1.39	1.380
C(14)-C(15)	1.40	1.390

The equations of the best planes of the five-, seven- and six-membered rings (A, B and C respectively) were derived by the least-squares method. In the final evaluation of the coefficients of the equations, the C(1) and C(12) atoms were excluded, because they were significantly off the planes. The equations of these best planes are:

$$-4.786X-Y-16.984Z+26.139=0 \quad (A)$$

$$-0.002X-Y+2.238Z+1.342=0 \quad (B)$$

$$-0,008X-Y+1.842Z+1.947=0 \quad (C)$$

where $X=x\sin\beta$, $Y=y$, and $Z=z+x\cos\beta$.

The perpendicular displacements of the atoms from each mean plane are shown in Table VII. The C(1) atom is shifted from the mean plane by 0.12 Å. Except for this, the five-membered ring might be thought to be planar. Some of the chlorine atoms are significantly off from the five-membered ring. In the seven-membered ring, the C(12) atom which is linked to the five-membered ring deviates from the mean plane by 0.22 Å. The other atoms in the ring lie on the plane. The six-membered ring also seems to be planar within the limit of error.

Table VII. Deviation of the atoms from the mean planes (Å)

Atoms	From the plane A (The five-membered ring)	From the plane B (The seven-membered ring)	From the plane C (The six-membered ring)

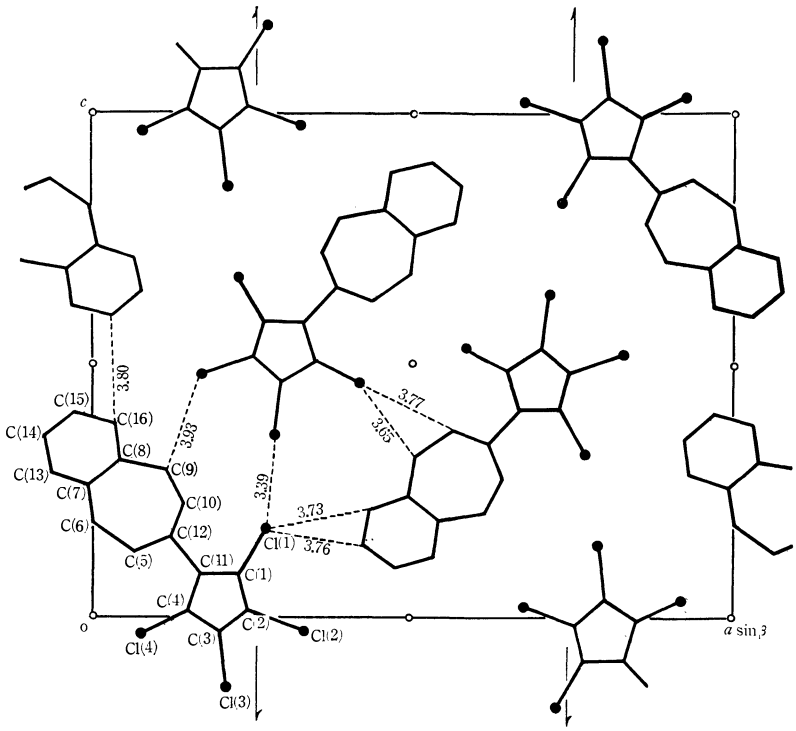

Fig. 6. Arrangement of the molecules in the crystal viewed along the c axis. Short intermolecular distances are indicated.

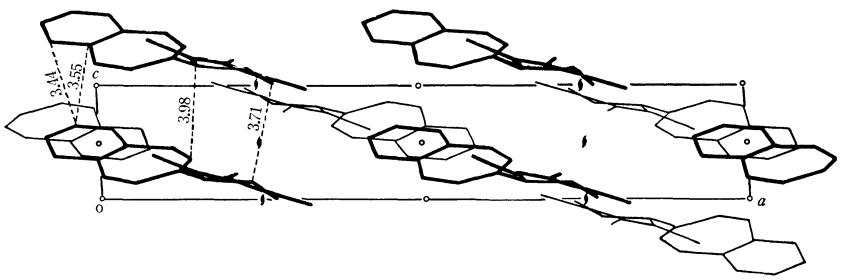

Fig. 7. Arrangement of the molecules in the crystal viewed along the b axis. Short intermolecular distances are indicated.

The five- and seven-membered rings twist around the C(11)–C(12) bond by an angle of about 31° to each other. This might be due to repulsion forces between Cl(1) and H(10) and between Cl(4) and H(5). If the hydrogen atoms are assumed so as to be located at a distance of 1.0 Å outward from the carbon atoms, the distances between the chlorine and hydrogen atoms may be computed to be 2.45 Å for the former and 2.57 Å for the latter.

The seven- and six-membered rings are not coplanar; these two planes make slight angles (of about 5°).

The arrangement of the molecules in the crystal is shown in Figs. 6 and 7, where the short intermolecular distances are given. There is observed one short intermolecular approach, 3.39 Å between Cl(1) in a molecule and Cl(3) in the neighboring molecule related by the screw axis to it. All the other intermolecular separations are equal to or larger than the sums of the van der Waals radii of the corresponding atoms.

As may be seen from Figs. 6 and 7, two molecules related by a center of symmetry to each other make a pair; the dipole moment of this compound (5.20 D)[3] is compensated for by this pairing. Such pairs are packed together in the manner found in the crystals of typical aromatic molecules.

The authors would like to express their deep thanks to Professor Yoshio Kitahara and Dr. Ichiro Murata of Tohoku University for supplying material and for their continued interest. Thanks are also due to the staff of the University Computing Center for their kind help. The computing time of the IBM 7090 was made available to the authors through the "UNICON" project.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 827—828 (1966)

The Oxidation of Chloromethyl Compounds with Lead Tetraacetate

By Yasuhide YUKAWA and Mitsuru SAKAI

Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received September 20, 1965)

In studying the reaction of styrene, olefins, vinyl ethers and vicinally-substituted compounds with lead tetraacetate, it was shown that the methyl group of 9-chloro-9-methylfluorene was easily acetoxylated with lead tetraacetate. This novel reaction was then applied to 1, 1-diphenylethyl chloride, 1-phenylethyl chloride and *t*-butyl chloride. In every case the methyl group of chlorides with an α-methyl group was acetoxylated preferentially.

The authors have, in recent years, been studying the reactions of lead tetraacetate with various unsaturated compounds, such as styrene, olefins, vinyl ethers and vicinally-substituted compounds.[1] In this paper we wish to report the novel acetoxylation of a methyl group with lead tetraacetate. It has been found that the methyl group of 9-chloro-9-methylfluorene, 1, 1-diphenylethyl chloride, 1-phenylethyl chloride and *t*-butyl chloride is preferentially acetoxylated by the reactions with lead tetraacetate. Table I shows the results of these reactions.

The yield of the acetoxylated products has been slightly raised by the addition of a small amount of anhydrous sodium acetate. The formation of tarry by-products has been suppressed when the reaction is carried out at a moderate temperature, below 70°C.

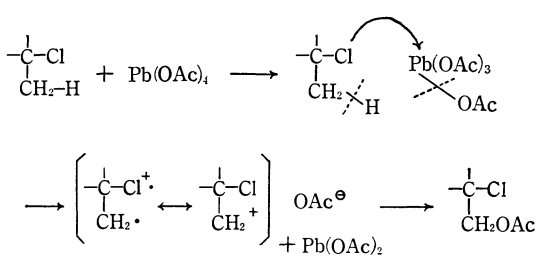
The lead tetraacetate could be used without any special precautions for its purification, since it has been found that these acetoxylation reactions are not influenced by the presence of the 10 to 15% of lead dioxide which could be a major impurity of lead tetraacetate.

The structures of the products were assigned by their conversion to the respective glycols. The hydrolysis of the 2-chloro-acetate was carried out by sodium hydroxide in methanol. The resulting glycols were shown to be III, VI, IX and XII by a comparison of these infrared spectra and the retention times in gas chromatography (on two different columns, silicon grease and apiezon grease on firebrick) with those of the authentic samples. The migration of the chlorine atom was rejected in the oxidation of IV. The structures for the two isomers of V and XIII were assigned by Summerbell.[2] The melting points of V and XIII were 76 and 30°C respectively. XIII was synthesized from ethyl chloroacetate and phenylmagnesium bromide, followed by acetylation with acetic anhydride. The product in the oxidation of IV showed a marked depression of melting point when mixed with XIII.

$$\begin{matrix} Ph_2\text{-}C\text{-}CH_2Cl \\ | \\ OAc \end{matrix}$$
(XIII)

Neither 2-phenylethyl halide nor cyclohexyl halide was acetoxylated, even under more drastic conditions. Bromides with an α-methyl group gave similarly acetoxylated products. Iodides gave mainly tarry products. Thus it has been demonstrated that chlorides and bromides in which the methyl group and halogen atoms are joined to the same carbon atom react with lead tetraacetate to give halohydrin acetates in fairly good yields.

Although the mechanism of this reaction has not yet been settled, there can be little doubt, in view of the radical mechanism in lead tetraacetate oxidation, that the reaction involves a one electron-transfer from chlorine to lead (Pb^{IV}) and a concurrent hydrogen abstraction from the methyl group by an acetoxyl radical. The following mechanism is tentatively suggested:



The oxidation of chloromethyl compounds with lead tetraacetate in acetic acid provides a useful route for the synthesis of pure chlorohydrin acetate.

Experimental

The melting points were determined on a Yanagimoto hot bench melting point apparatus and are corrected. The elementary analyses were performed by the Microanalytical Laboratories of Osaka University. The

infrared spectra were determined using a Hitachi double-beam spectrophotometer.

Materials.—Lead tetraacetate was prepared from red lead oxide and acetic acid.[3] The following reagents were commercial materials and were redistilled before use; acetic acid, butanol, *t*-benzaldehyde, β-phenylethyl alcohol and ethyl chloroacetate. The following commercial reagents were used without further purification; benzophenone, fluorenone, cyclohexanol and methyl iodide. 9-Chloro-9-methylfluorene,[4] 1, 1-diphenylethyl chloride,[5] *t*-butyl chloride[6] and 1-phenylethyl chloride[7] were prepared by the methods described in the literature.

General Procedure.—In order to avoid needless repetition, the experimental conditions for carrying out these reactions have been generalized. A stirred solution of 0.1 mol. of the substituted chloride and 0.1—0.12 mol. of lead tetraacetate in 100 ml. of a solvent, under a slight pressure of dry nitrogen, was maintained at 60 to 70°C for about 0.5—1 hr. From the resulting clear solution, about a half of the acetic acid was removed under a vacuum below 65°C. The residue was then dissolved in ethyl ether (100 ml.) and washed with water (80 ml.) three times in order to remove the inorganic lead compounds. The etheral solution was treated with anhydrous sodium sulfate filtered, and vacuum-distilled.

9-Acetoxymethyl-9-chlorofluorene (II).—Under the general procedure, with acetic acid as the solvent, 9-chloro-9-methylfluorene and lead tetraacetate gave a 50% yield of II, m. p. 118°C (from ethanol).

Found: C, 70.17; H, 4.76; Cl, 13.16. Calcd. for $C_{16}H_{13}O_2Cl$: C, 70.46; H, 4.80; Cl, 13.00%.

The hydrolysis of II gave 9-hydroxymethyl-9-fluorenol (III), m. p. 105—106°C (from benzene), lit.[8] m. p. 105—108°C.

Found: C, 79.31; H, 5.84, Calcd. for $C_{14}H_{12}O_2$: C, 79.22; H, 5.70%.

2-Chloro-2, 2-diphenylethyl Acetate (V).—Under the general procedure, with acetic acid as the solvent, 1, 1-diphenylethyl chloride and lead tetraacetate gave a 50% yield of V, m. p. 75—76°C (from ethanol).

Found: C, 69.85; H, 5.61; Cl, 13.07. Calcd. for $C_{16}H_{15}O_2Cl$: C, 69.95; H, 5.50; Cl, 12.90%.

The hydrolysis of V gave asym-diphenylethylene glycol (VI), m. p. 122°C (from benzene); lit.[9] m. p. 121°C.

2-Chloro-2, 2-dimethylethyl Acetate (VIII).—Under the general procedure, with acetic acid as the solvent, *t*-butyl chloride and lead tetraacetate gave a 45% yield of VIII, b. p. 95—97°C/35 mmHg.

Found: Cl, 23.83. Calcd. for $C_6H_{11}O_2Cl$: Cl, 23.54%.

The hydrolysis of VIII gave asym-dimethylethylene glycol (IX) (diphenylurethan, m. p. 140°C).

2-Chloro-2-phenylethyl Acetate (XI).—Under the general procedure, with acetic acid as the solvent, 1-phenylethyl chloride and lead tetraacetate gave a 45% yield of XI, b. p. 110°C/4.0 mmHg.

Found: Cl, 17.54. Calcd. for $C_{10}H_{11}O_2Cl$: Cl, 17.85%.

The hydrolysis of XI gave styrene glycol (XII), m. p. 67°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 829—833 (1966)

The Electrical Resistivity of Carbon Black under Compression

By Tokiti NODA, Hajime KATO, Toshihiko TAKASU, Akihide ŌKURA and Michio INAGAKI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 21, 1965)

The electrical resistivity of carbon blacks was measured under compression (up to 9 kilobars) at room temperature using a pressure vessel of the piston-cylinder type. The slope of the log ρ vs. log P relation was about -0.5 for all the carbon black specimens except the original channel black. For the thermal blacks heat-treated above 2100°C, i. e., the graphitized thermal blacks, the linear relation between logarithms of resistivity, ρ, and of pressure, P, broke at about 2.5—4.5 kilobars. After the break the slope of the log ρ vs. log P relation for the graphitized thermal blacks had the same value as that for natural graphite. The original channel black had a value of the slope as high as -0.9, but the 1300°C-treated channel black had a value similar to that of the other samples. This was probably due to the removal of the high-resistance film on the particle surface by the heat treatment. The first stage of the decrease in electrical resistivity with an increase in the pressure seems to be due to the yielding deformation of carbon black particles caused by the increased packing of the particles, while the second stage may be due mainly to the increase in the contact of crystallites in the particles by the elastic deformation, accompanied by a change in the preferred orientation of crystallites with the pressure.

The measurement of the electrical resistivity of carbon black under compression has been carried out by a number of investigators with both technical and scientific interests. However, the measurements under pressures above 2 kilobars (kb) have been very few. According to Adelson and Austin,[1] the resistance versus pressure curves of a number of carbon blacks broke relatively sharply at approximately 30 kb; this break was assumed to be caused by the change from the elastic to the yielding deformation of carbon black particles. In their work, however, there might have been a considerable pressure gradient in the radial direction of the compressed specimen, because they used opposed anvils of a flat face as the pressure apparatus.

In the present work, the electrical resistivity of carbon black under compression was investigated under a pressure of up to 9 kb at room temperature using a pressure vessel of the piston-cylinder type. In this pressure vessel, the gradient of the pressure is negligibly small, in both the radial and the longitudinal directions of the compressed specimen, if the specimen is appropriately thin, as will be described below. Not only original carbon blacks but also heat-treated carbon blacks were used as samples.

Experimental

The materials used in the present work were two kinds of thermal black, a channel black, their heat-treated specimens and a pulverized natural graphite. The thermal blacks have no "structure"; the particle size of one of them is quite uniform, about 1000 Å on the average, while the other's is not so uniform, its average particle size being 3000 Å. The carbon blacks were heat-treated in an induction furnace at various temperatures under a reduced pressure of 10^{-2} Torr for 30 min. The natural graphite powder was also heated at 2700°C for 10 min. under 10^{-2} Torr in the same furnace. The polyhedral form of the particles of thermal blacks heat-treated above 2100°C was observed in their electron micrographs.

The density measured by the pycnometric method,[2] d_p; the density calculated from lattice constants, d_x, and the porosity, 100 $(d_x-d_p)/d_p$, of the carbon blacks are given in Table I.

The pressure vessel of the piston-cylinder type is shown schematically in Fig. 1. The piston and the cylinder were made of tool steel. The surfaces of the upper and lower pistons were plated with copper and silver in order to decrease the contact resistance between the piston and the specimen. This vessel could be used under pressures of up to 10 kb. The dimensional change of the cylinder by the elastic compression at the pressure of 10 kb was found to be negligible for the measurement of the resistivity. As an insulator between the pistons and the cylinder, a polyethylene sheet, a phenol resin pipe and a pipe made of epoxy resin reinforced with glass fibre were tested. A polyethylene sheet 0.04 mm. thick was proved to be the best among them and could be used for the measurement of the resistivity under pressures of up to 10 kb. The phenol and reinforced epoxy resin pipes, which were 2.5 mm. thick, fractured when the specimen was compressed to about 6 kb. Also, the dimensional

3000°C HT	2.167±0.006	2.24	3.2
Natural graphite	2.254±0.006	2.26	—

change in the resin pipes by compression could not be neglected in the measurement of the resistivity when the thick pipes were used. In the case of the polyethylene sheet, however, its dimensional change was negligible because it was very thin compared with the diameter of the compressed specimen. The pressure applied to a specimen was calibrated by the measurement of the volume change of NH_4F transition (3.8 kb.) The pressure loss for friction between the piston and the cylinder was found to be 5%.

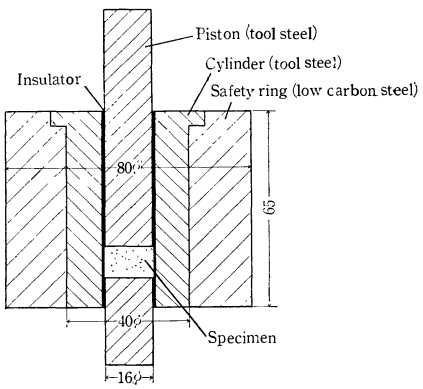

Fig. 1. The pressure vessel of piston-cylinder type.

The electrical resistance under compression was measured as a function of the thickeness of the specimen by a Kelvin bridge using the pistons as electrodes. The very good linear relation between the measured resistance and the thickness of specimen was observed, as is shown in Fig. 2. When the thickness of the specimen became too high, the measured resistance of the specimen deviated upwards from this line as a result of the non-uniformity of the pressure in the specimen. Accordingly, the thickness of the specimen was limited to about 4 mm. The electrical resistivity was determined from the inclination of this line using the least-squares calculation.

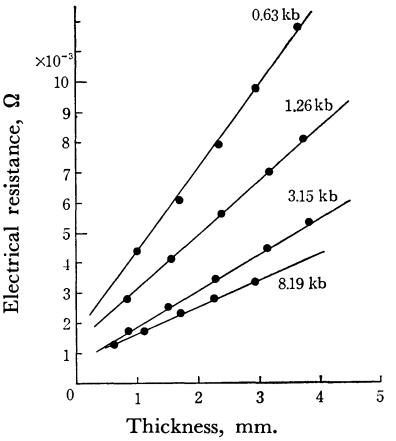

Fig. 2. Dependence of the measured electrical resistance on the thickness of the 2680°C-treated thermal black (Miike #20).

Results

The changes in the electrical resistivity, ρ, of the thermal blacks (Miike #20) and of the natural graphite with the pressure, P, are shown on logarithmic plots in Fig. 3; that of the channel black (Spheron-9), in Fig. 4 and that of the thermal black (N. G. C.), in Fig. 5.

●: 2680°C-treated thermal black (TBM-2700)
Figures in parentheses along lines are slopes of these lines.

The relation between $\log \rho$ and $\log P$ can be said to be linear. For the 2100°C-, 2700°C- and 3000°C-treated thermal blacks, the $\log \rho$ vs. $\log P$ relations break relatively sharply at the pressure of about 4.5—3.0 kb. The pressure of the break point decreases with the increase in the heat treatment temperature. However, the original and 1300°C-treated thermal blacks do not show

any break within the limits of the pressure applied in the present work. In other words, the 2100°C-, 2700°C- and 3000°C-treated or graphitized thermal blacks show the change in resistivity with the pressure in two stages, while the original and 1300°C-treated thermal blacks show only the first stage of the change in resistivity. The slopes of the thermal blacks at the first stage are about −0.5, scattering somewhat from specimen to specimen. At the second stage, the relation between $\log \rho$ and $\log P$ has almost the same slope, −0.23, for all graphitized thermal blacks. This value of slope agrees with that for natural graphite.

The relation between $\log \rho$ and $\log P$ for the channel black shows no break. The original channel black has quite a high resistivity and a high slope of the $\log \rho$ vs. $\log P$ relation.

Discussion

The change in the electrical resistivity with the pressure results from the process of packing the carbon black particles. Takahashi[3] reported the dependence of the electrical resistivity of carbon black on pressures up to 200 kg./cm² to be $\rho = A/P + B$ for hard spheres and $\rho = C/P^{1/2} + D$ for deformable particles as derived from Holm's contact resistance theory. Akamatu and Inokuchi[4] observed the relation $\rho = a/P + b$ (3) for various carbon blacks in the 11—160 kg./cm² pressure range. Honda, Ouchi and Toyoda[5] reported that there was, in general, the relation $\rho = AP^{-2} + B$, where $n \approx 1$—2 for heat-treated coals, cokes and charcoals in the 400—2000kg./cm² pressure range. They also derived the relation from the relations of the void ratio to the pressure and of the void ratio to the resistivity, and deduced $n = 2$ for plastically-undeformable particles. Ōtani[6] found $n = 1$—0.5 for various carbons in the 500—2200 kg./cm² pressure range. According to Mrozowski,[7] the electrical resistivity of the powder

$$\rho \cong 0.34\bar{\rho}E^{1/3}/(P^{1/3}\varphi^{1.0})$$

for a purely elastic deformation (4)

and

$$\rho \cong 0.445\bar{\rho}H^{1/2}/(P^{1/2}\varphi^{3/4})$$

for a purely yielding deformation (5)

where $\bar{\rho}$ = the real resistivity; E = the elastic modulus, H = the hardness of the material of the particles, and φ = the fraction of the volume occupied by the particle. From the experimentally-established relation for the volume of a definite amount of material, $\log V = -m \log P$[7] and $\varphi \cong 1/V$,

$$\rho = k_1/(P^{(1/3+m)}) \text{ for elastic deformation} \quad (4')$$

and

$$\rho = k_2/P^{(1/2+3m/4)} \text{ for yielding deformation} \quad (5')$$

The pressure dependence of the resistivity caused by the change in packing is very small and leads to a small correction in the slope of the $\log \rho$ vs. $\log P$ relation. The slopes of the first stage of all the curves for $\log \rho$ vs. $\log P$ are alsmost equal to −0.5 except for the original channel black. Therefore, the first stage of the $\log \rho$ vs. $\log P$

relation may mainly correspond to the yielding deformation process of the packing of the particles, although the elastic deformation process may play some part. One can see a slight increase in the slope for the thermal black with the increase in the heat treatment temperature. As can be seen from Table I, carbon black particles are porous and are, therefore, deformable, especially when they are heat-treated at higher temperatures and become softer. The slope of the $\log \rho$ vs. $\log P$ relation for the original channel black is -0.9. This is due to the surface film on the carbon black particles.[7,8] The film on the particle surface can be removed by heat treatments at high temperatures. Therefore, the 1300°C-treated channel black has a slope similar to those of the other samples.

The pressure of the break point of the $\log \rho$ vs. $\log P$ relation for the graphitized thermal blacks conincided with the pressure at which the bulk density of the compressed mass is almost equal to the density of carbon black particles; i. e., the void ratio is almost zero (Fig. 6).

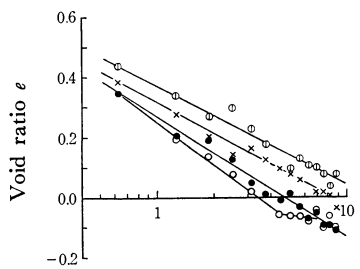

Fig. 6. Dependence of void ratio e of thermal black on pressure P.
⦶: original thermal black (TBM)
×: 1340°C-treated thermal black (TBM-1300)
●: 2120°C-treated thermal black (TBM-2100)
○: 2680°C-treated thermal black (TBM-2700)

From this point on, the particles themselves are compressed and the bulk density of particles finally reaches almost the same density as that calculated from the lattice constants, d_x. In the case of the channel black and the original and calcined (1370°C treated) thermal blacks, the bulk densities never exceeded their particle densities (Figs. 6 and 7). The plots $\log \rho$ vs. $\log P$ for these blacks had only the first stage, and not the second stage. In the second stage the dependence of the electrical resistivity on the pressure may mainly be represented by the elastic deformation mechanism, although the experimental slope, -0.23, is rather smaller than the predicted value, -0.33. There may be an increase in the preferred orientation of crystallites in the compressed

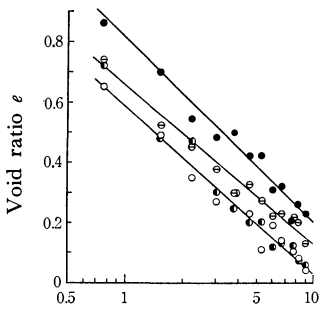

Fig. 7. Dependence of void ratio e of channel black on pressure.

⊖: 1270°C-treated channel black (CB-1300)
◐: 2020°C-treated channel black (CB-2000)
○: 2610°C-treated channel black (CB-2600)

mass with the increase in compression. When the distribution function of crystallite orientation is assumed to be $\sin^n \Phi$,[9] where Φ is the angle between the normal to the basal plane of crystallite and the normal to the direction of compression, the resistivity, $\bar{\rho}$, can be taken to be approximately $\rho_{\parallel c} \sin^n \Phi$, because $\rho_{\parallel c} \gg \rho_{\perp c}$, where $\rho_{\parallel c}$ and $\rho_{\perp c}$ are the resistivities of single crystals of graphite parallel to and perpendicular to the c-axis respectively. The distribution function may be related to the pressure of compression as $\sin^n \Phi = a P^b$; therefore,

$$\bar{\rho} = a \cdot \rho_{\parallel c} \cdot P^b \tag{6}$$

From Eqs. (4) or (4′) and (6)

$$\bar{\rho} \cong 0.34a \cdot \rho_{\parallel c} E^{1/3}/(P^{1/3-l}\varphi^{1.0}) \cong k_3/(P^{1/3+m-l}) \tag{7}$$

Thus the increase in the preferred orientation decreases the slope of the $\log \rho$ vs. $\log P$ relation.

From Eq. 5 one can calculate the hardness, H, from the applied pressure, P, and the bulk density of the carbon black powder at the pressure. The resistivity at 9 kb was taken as $\bar{\rho}$, because the change in the resistivity with the increase in the pressure in the high pressure range was very small. Mrozowski[7] obtained 8×10^5 lb/in^2 = 56×10^3 kg./cm^2, which is an unreasonably high value for calcined soft carbons of coarse powder. However, he suggested the use of the calculated hardness in estimating relative values. Our results were about the same order as his value, i. e., very high. For example, the hardness was estimated to be 51×10^3 kg./cm^2 for the original thermal black, 38×10^3 kg./cm^2 for the 1340°C-treated thermal black, 28×10^3 kg./cm^2 for the 2120°C-treated thermal black, and 24×10^3 kg./cm^2 for the 3000°C-treated thermal black.

8) S. Mrozowski, A. Chaberski, F. E. Loebner and H. T. Pinnick, ibid., p. 211.

9) G. E. Bacon, *J. Appl. Chem.* (*London*), **6**, 477 (1956).

The original carbon blacks have about the same hardness as calcined soft carbons, and the hardness of the carbon blacks decreases to about half when they are graphitized, i. e., heat treated above 2000°C. Therefore, the graphitized carbon black particles deform easier than the original and calcined particles. In the case of the graphitized thermal black, all space in the compressed mass is filled up with material of the density of the carbon black particle at about 3—5 kb. At higher pressures the compression can be achieved only by increasing the density of the particle material, thus increasing the contact between crystallites in the particle by the elastic deformation mechanism. At the final stage of compression, the density reached 2.2 g./cm^3. This value is very near to the true density, d_x=2.24. The shape of the carbon black particles did not change even when the particles were compressed at pressures of 9 kb or above, where the bulk density of the carbon black was 2.2 g./cm^3 or above. The shapes of the carbon black particles before and after the compression are shown in Plate 1.

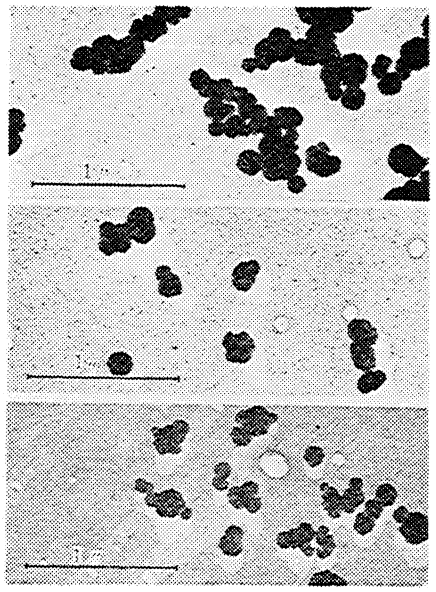

Plate 1. Electron micrographs of 2680°C-treated thermal black (Miike #20) Al-shadowed.
(a) before compression
(b) after compression at 8.8 kb
(c) after compression at 25 kb

In conclusion, the change in the electrical resistivity of carbon black particles with the pressure proceeds in three stages. In the lower pressure range, where the packing proceeds by filling voids by the rearrangement of carbon black particles, the resistivity changes with the number of contact points between particles. It has been reported that the resistivity changes with $1/P$—$1/P^{1/2.3,4}$. However, the dependence of the resistivity of carbon black on the pressure seems to be proportional to $1/P^{1/2}$, even in a very low pressure range.[10] In the medium and high pressure ranges, where the contact area increases with an increase in the deformation of the particles, the resistivity, ρ, changes with $1/P^{1/2}$. In the very high pressure range, the elastic deformation, accompanied by the change in the preferred orientation with the pressure, is the main process in determining the change in the resistivity with the pressure, $\rho \propto 1/P^{1/3-t}$. No change in the shape of carbon black particles after compression under a very high pressure could be observed.

Thanks are due to Mr. Etsuro Kato for his discussion. The authors are also indebted to the Tokai Electrode Mfg. Co. for the supply of specimens, and to the Mitsubishi Chem. Co. and the Onoda Cement Co. for taking electron micrographs.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 833—837 (1966)

Kinetic Studies of the Oxidation of Aldopentoses: L-Arabinose and D-Xylose Oxidized by Hexacyanoferrate(III) in an Alkaline Medium

By Rajendra Kumar SRIVASTAVA, Narendra NATH and M. P. SINGH

Department of Chemistry, University of Allahabad, Allahabad, India

(Received May 13, 1965)

The kinetic studies of the oxidation of L-arabinose and D-xylose have been carried out using potassium ferricyanide in the presence of sodium hydroxide and sodium carbonate. The order of the reaction has been found to be zero with respect to ferricyanide and first with respect to the reducing sugar. The reaction rate is also directly proportional to the hydroxide ion concentration. The reaction also has a very small induction period.

Kinetic studies of reactions in solutions have achieved commendable importance during the last few decades, especially in explaining the mechanism of the reactions. So far as the kinetics of oxidation of these reducing sugars is concerned, however, this field has not been studied for several years. Most of the works in this direction were first carried out by using halogens[1] as oxidising agents in alkaline and acidic media. Ingels and Israel[2] studied the kinetics of the oxidation of simple monosaccharides as well as of disaccharides by alkaline hypoiodide; they reported the order of the reaction with respect to each reactant to be unity. They also observed that the rates of the oxidation of D-galactose and D-arabinose are greater than those of D-glucose and D-xylose respectively.

Systematic studies of the kinetics of oxidation of several hexoses and pentoses by cupric tartrate and cupric citrate in the presence of sodium hydroxide were made in this laboratory by Singh, Krishna and Ghosh.[3,4] They reported that the reaction is of the first order with respect to the cupric complex and that it is catalysed by the free hydroxide ion. There is also an autocatalysis due to the cuprous oxide produced in the system. Recently Nath and Singh[5,6] studied the kinetics of the oxidation of several aldo and keto hexoses by potassium ferricyanide in an alkaline medium. The advantage of taking potassium ferricyanide as the oxidant lies in the value of its redox potential, which is large compared to that of copper. They have observed that the reaction rate is of the zero order with respect to ferricyanide and of the first order with respect to reducing sugar. Further, the reaction rate is directly proportional to the concentration of hydroxide ions, and the reaction has a small induction period, which is probably due to the presence of oxygen. The present work will deal with the kinetics of the oxidation of L-arabinose and D-xylose by potassium ferricyanide in an alkaline medium; such a study will give more evidence on the mechanism.

Experimental

Potassium ferricyanide was of B. D. H. (AnalaR)-grade sample. The standard solution of reducing sugar was prepared just before starting the reaction. The sugar and the sodium hydroxide used were of E. Merck grade.

The volumetric procedure developed by Lang[7] which depends upon the precipitation of complex zinc-ferrocyanide to complete the reaction between potassium ferricyanide and iodine is not very accurate because it does not give a very clear end point due to the appearance of a bluish colour in the end. Therefore, the present method of estimating ferricyanide was slightly modified by increasing the overall strength of potassium iodide to a great extent instead of by adding zinc sulphate.

The mixture of potassium ferricyanide and alkali was kept in a black-coated jena bottle at a constant temperature (±0.1°C); the fresh solution of reducing sugar was kept separately in the same bath. When the solutions have attained the temperature of the bath, the requisite quantity of reducing sugar was added to a solution containing potassium ferricyanide and alkali. The progress of the reaction was followed by sucking out an aliquot (10 or 5 ml.) and pouring it into a beaker containing 10 ml. of a strong fresh solution of potassium iodide (40%) and 5 ml. of 4 N sulphuric acid of B. D. H. (AnalaR) grade. The function of the sulphuric acid was to check the reaction by neutralising the alkali as well as to help in the liberation of iodine. The liberated iodine was immediately titrated by a standard solution of sodium thiosulphate (hypo), using starch as an indicator and with the help of micro-burette.

Results

The Determination of the Order of Reaction with Respect to Ferricyanide Ions.—In order to find out the order of the reaction with respect to ferricyanide ions, the concentration of the reducing sugar was kept high. If the concentration of the reducing sugar is in a large excess as compared to the concentration of ferricyanide ions, the variation in the velocity of the reaction will mainly be determined by the concentration of the latter. The results given below consistently show that the reaction is of the zero order with respect to ferricyanide ions.

A perusal of the above tables will show that the zero order velocity constants assume practically constant values after a certain induction period. Below each table the mean value of standard zero order velocity constant (k_s) has been given; each has been calculated by taking the mean zero order velocity constant (k_0) and multiplying it by the factor S/V, where S is the strength of the hypo used in the estimation and V, the volume of the aliquot taken;

$$k_s = k_0 \times (S/V)$$

A further confirmation of the order of reaction with respect to ferricyanide can be seen from Tables V and VI.

The Effect of Varying the Ferrcyanide Ion Concentration—From Table V, it is evident that though the concentration has been varied from 25×10^{-4} M to 100×10^{-4} M, with the concentrations of other reactants kept the same, the zero order rate constants are practically the same. Table VI confirms the above statement in the case of D-xylose. Thus Tables V and VI also confirm that the reaction is of the zero order with respect to potassium ferricyanide in the concentration range of alkali and potassium ferricyanide studied.

to determine the order of reaction with respect to reducing sugar, the concentration of reducing sugar was varied, while the concentration of other reactants was kept constant. It has been shown that the reaction is of the zero order with respect to ferricyanide ions; therefore, the average velocity ($\Delta x/\Delta t$), the instantaneous velocity (dx/dt), and the specific rate constant are identical. If, therefore, the average velocity (the velocity in the case of a zero order reaction) increases in direct proportionality with the increase in the concentration of reducing sugar, it proves that the reaction is of the first order with respect to reducing sugar. The table given below shows the effect of varying the reducing sugar concentration on the zero order velocity constant.

From Table VII it is evident that k_s/[sugar] gives practically a constant value, which indicates that the reaction rate is directly proportional to the reducing sugar concentration. Thus, it is evident that the order of reaction with respect to reducing sugar is unity.

The Effect of Varying the Hydroxyl Ion Concentration.—A perusal of Table VIII will show that the zero-order velocity constant increases proportionally with the increase in the concentration of hydroxide ions.

Discussion

A careful study of the kinetics of the oxidation of the above sugars shows that the rate of expression is of the form:

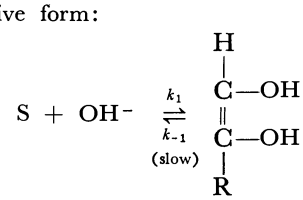
$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = k[sugar][OH^-]$$

which implies that the rate of reaction is independent of the concentration of ferricyanide ions, while the reaction is of the first order both with respect to reducing sugar as well as to alkali. In cases where the concentration of the sugar as well as of alkali is large as compared to the concentration of ferricyanide, the rate expression takes the form:

$$-\frac{d[Fe(CN)_6^{3-}]}{dt} = k_s = \frac{\Delta\chi}{\Delta t}$$

where $k_s = k[sugar][OH^-]$

Further, on the basis of the above experimental results, it appears that the first slow step involves a reaction between hydroxide ions and the reducing sugar, leading to the formation of an intermediate reactive form:



(1st step)

(1, 2 enediol)

where S represents the reduing sugar. The fact that this step is slow explains how the order of the reaction is unity with respect to reducing sugar. Further, this intermediate reactive form, which

is called "1, 2 enediol," is subsequently oxidised by ferricyanide to give ferrocyanide and other reaction products:

$$\text{en} + [Fe(CN)_6^{3-}] \xrightarrow[\text{fast}]{k_2} [Fe(CN)_6^{4-}] + \text{other reaction product}$$

(2nd step)

where "en" represents "1, 2 enediol." The fact that the second step is fast explains the zero order of the reaction with respect to ferricyanide ions. Further work on the kinetics of the oxidation of several more reducing sugars is now in progress; the details will be published later.

NOTES

Amperometric Titrations of Thorium with Alkali Tungstate

By C. M. GUPTA

Department of Chemistry, University of Rajasthan Jaipur, India

(Received March 29, 1965)

In view of the interesting results reported[1] in the amperometric studies of rare metal molybdates and tungstates, it was considered that it would be of interest to make a detailed study of the similar reaction between thorium nitrate and alkali tungstate from an analytical point of view. A perusal of the literature, however, revealed that no amperometric investigation seems to have been carried out on the thorium nitrate - alkali tungstates system. Only the preparation of thorium tungstate has been described long ago by Berzelius,[2] who mixed a solution of each of these salts.

Reagent-grade thorium nitrate and sodium tungstate were used. The strengths of these solutions were checked by the standard gravimetric methods.

Much anomalous polarographic behaviour of thorium at d. m. e. has been reported.[3] Amperometric titrations of thorium have also been described.[4,5] In view of this, it was considered worthwhile to investigate for analytical purposes the nature of the reduction wave produced by Th^{4+}. In this investigation the current voltage curves were obtained as usual by means of a manual polarograph with a lamp and scale galvanometre. The capillary had the following characteristics: ($m=2.416$ mg./sec., $t=3.6$ and $m^{2/3}\ t^{1/6}=2.235$ at -1.0 V.). Polarograms were run on 0.2 to 2 mM Th^{4+} solutions in a supporting electrolyte (1 M with respect to LiCl). Gelatin (0.01%) was used as a maximum suppressor. After making a correction for the residual current, the value of the limiting current at each concentration was determined at an applied potential $=-1.60$ versus SCE. The values of i_e/C were calculated; it was found that these values are fairly constant from a 1 mM to a 2 mM concentration of Th^{4+}. Though the wave seems to be catalytic, it may serve our purpose for carrying out amperometric titrations between a thorium salt and an alkali tungstate in this narrow range of Th^{4+} concentrations.

Twenty-five milliliters of a solution containing 1 mM of thorium as thorium nitrate is pipetted into the supporting electrolyte, 1 M lithium chloride, contained in the titration vessel. Oxygen is removed by passing nitrogen through for ten minutes. A standard solution of sodium tungstate is then added in small increments, and nitrogen is bubbled through the solution for one minute. The current is read at a potential value of -1.60 V. one minute after being diverted over the tip of the solution. The readings thus obtained are then plotted against the volume of the titrant after correcting for the volume added. The equivalence point is obtained in the usual manner from the point where the straight lines interesect.

In direct titration, where sodium tungstate is used as the titre, it is noted that at $E_{de}=-1.60$ V. versus SCE the WO_4^{2-} ion yields no measurable diffusion current, because, as is well known, this ion gives no polarographic wave in a neutral or an alkaline medium.[6] Little change in the value of current was observed on the addition of

thorium salt until the stoichiometric end point is reached; after this point, however, it is found to increase linearly with the addition of the titrant. In the case of inverse titrations, the current falls. It falls as more of the precipitant is added; this continues until all of the Th^{4+} in the test solution is precipitated. Beyond the equivalence point, it reaches the residual current value. The amperometric titration curves have an L shape and feature a break at the point where the molecular ratio of Th:W is 1 : 2; this corresponds to the formation of normal tungstate of thorium $ThO_2 \cdot 2WO_3$ in the pH range from 3.5 to 7.5.

The accuracy and reproducibility of these titrations are found to be quite satisfactory, even at low concentrations of thorium salt (1 mM) or alkali tungstate. The titrations can be easily completed in twenty minutes. Cations which form a precipitates with alkali tungstate, e. g., silver, cadmium, cerium, mercury(I) and mercury-(II), and anions which react with Th^{4+}, e. g., vanadate, chromate, molybdate, tellurite, selenite and oxalate, interfere and so must be excluded.

The above results have been corroborated by making pH measurements on a battery-operated Cambridge pH meter. Direct and reverse pH titrations show a sharp break at the 1 : 2 (Th : W) ratio. The pH titrations indicate a sharp change in pH value from the acidic to the neutral side of the end point. These titrations suggest the possibility of estimating metal thorium within a 2% error.

The Racemization of Optically Active α-Phenylethyl Alcohol in Liquid Sulfur Dioxide

By Niichiro TOKURA and Fuminori AKIYAMA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received April 23, 1965)

It has been reported that optically active α-phenylethyl alcohol is racemized in an aqueous solution by the catalysis of perchloric acid; carbonium ion is presumed to be formed during the reaction.[1] In the present communication we should like to report on the racemization of the alcohol in liquid sulfur dioxide in the absence of any proton donor; this is supposedly a somewhat different kind of racemization.

As may be seen in Fig. 1, the optical rotation of the solution first increases, reaches a maximum, and then tends to decrease very slowly, thus resulting in the complete racemization. Such a phenomenon may be presumed to be typical of the series of consecutive reactions involving an intermediate formation:

$$\underset{[A]}{ROH} + SO_2 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} \underset{[C]}{\text{Intermediate}} \xrightarrow{k_2} \underset{[R]}{\text{Racemic ROH}}$$

There are three possible intermediates, I, II and III.

$$ROH + H^+ \rightarrow \underset{I}{ROH_2^+} \rightarrow R^+ + H_2O \qquad (1)$$

$$ROH + SO_2 \rightarrow \underset{II}{ROH\cdot SO_2} \rightarrow R^+ + {}^-OH\cdot SO_2 \qquad (2)$$

$$ROH + SO_2 \rightarrow \underset{III}{ROSO_2H} \rightarrow R^+ + {}^-HSO_3 \qquad (3)$$

They are a protonated alcohol (I), a SO_2–ROH complex (II), and an ester of sulfurous acid (III), respectively.

It might be considered that the trace of water present in liquid sulfur dioxide is the source of a proton which could combine with the alcohol as I and racemize via the route 1. This mechanism is unlikely, however, since the acid- or proton-catalyzed racemization ordinarily results in a smooth descending curve vs. the time plot, with no maximum of the rotation at all, as has been shown in the literature.[1] Moreover, the water content in dehydrated (by phosphorus(V) oxide) liquid sulfur dioxide is as low as 48 p. p. m., thus showing practically no effect of the catalyst.

As for the interaction between an alcohol and liquid sulfur dioxide, several papers have appeared lately. Hoyer[3] has observed that the sulfur dioxide molecule can neither permit hydrogen bonds among alcohol molecules themselves nor make hydrogen bridges with the hydrogen atoms of the alcohol by

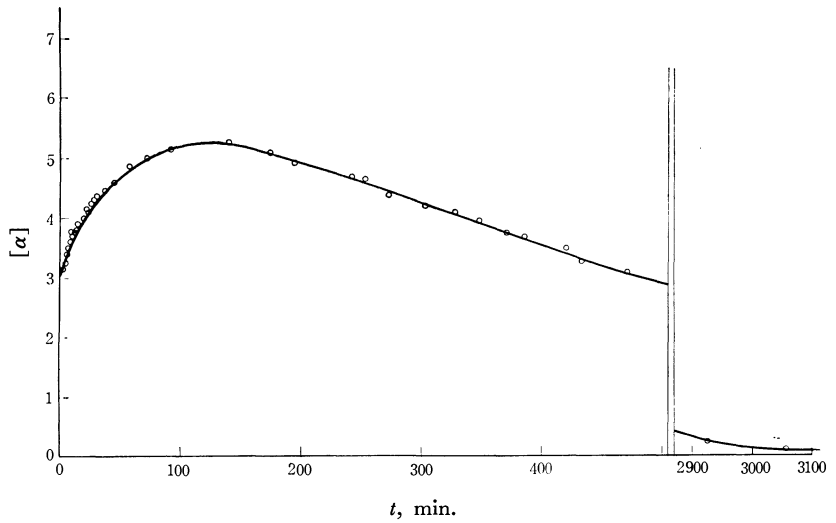

Fig. 1. Optical rotation of *l*-α-phenylethyl alcohol in liquid sulfur dioxide.

using oxygen atoms of the sulfur dioxide molecules. Only a very small amount of $RO{\cdot}SO_2H$ has been found in the mixture of ethyl alcohol and sulfur dioxide,[4] and Guss[5] has revealed that, by the colorimetric titration, a sulfite or an ester like III might partly be formed from the alcohol and sulfur dioxide.

Since the optical rotaion of an alcohol is generally enhanced when it is converted to an ester, as is the case in *l*-menthol,[2] the rise in the rotation might be suspected to result from an ester-formation such as III. The recovered residue of the racemization was not the sulfurous acid ester of the α-phenylethyl alcohol, but the racemized alcohol itself. However, the present authors are not sure whether the intermediate of the reaction is the complex II or the sulfite III, the stoichiometry of the two being the same. A complex formation like II has already been indicated by Dietzel and Galanos.[6] However, we cannot distinguish the complex from the ester like III, since the ester is also very unstable, as was reported by Zimmermann.[7]

The over-all racemization process may be deemed to be the result of the consecutive reactions, the reversible formation of the intermediate and the dissociative racemization of the intermediate, II or III.

Actually, the experimental curve in Fig. 1 has a maximum of rotation, α_{max}; this fact may be fairly reconciled with the consecutive (series) reaction mechanism consisting of intermediate formation and racemization, where $k_2 \gg k_{-1}$. The alternative route, viz., a preliminary reversible formation of the intermediate C, $k_2 \ll k_{-1}$, may thus be ruled out, as will be elucidated below. I $k_2 \gg k_{-1}$, for the A→C→R series,

$$-d(A)/dt = k_1(A) \quad (4)$$

$$d(C)/dt = k_1(A) - k_2(C) \quad (5)$$

$$d(R)/dt = k_2(C) \quad (6)$$

and $(C)_0$ and $(R)_0$ are zero, where the suffix zero indicates the initial concentration. The solution of the series reactions is:

$$(C) = \frac{(A)_0 k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t}) \text{ and } (A) = (A)_0 e^{-k_1 t} \quad (7)$$

and a variable vs. time plot should be a curve with a maximum.[8] Since $\alpha = [\alpha]_A \cdot (A) + [\alpha]_C \cdot (C)$, where $[\alpha]_A$ and $[\alpha]_C$ are the specific rotations of the alcohol and the intermediate, respecively, in liquid sulfur dioxide at the temperature, by rearranging and substituting Eq. 8 one gets:

$$\alpha = (A)_0 \left\{ [\alpha]_A e^{-k_1 t} + [\alpha]_C \frac{k_1}{k_2 - k_1}(e^{-k_1 t} - e^{-k_2 t}) \right\} \quad (8)$$

By differentiating Eq. 8 and putting $d\alpha/dt = 0$ at α_{max} and t_{max} on the curve in Fig. 1, the value of $[\alpha]_C$ can be estimated; this will give the ultimate equation with regard to α.

As a first approximation, the complication of the calculation may be alleviated by the following procedures. The expressions are derived from the above discussion as:

$$d(C)/dt = k_1(A)_0 \left\{ e^{-k_1 t} - \frac{1}{1 - k_1/k_2} e^{-k_1 t}(1 - e^{(k_1 - k_2)t}) \right\} \quad (9)$$

5) L. S. Guss, *Chem. Abstr.*, **39**, 4278 (1945).
6) R. Dietzel and S. Galans, *Z. Elektrochem.*, **31**, 466 (1925).
7) M. R. Zimmermann, *Angew. Chem.*, **15**, 898 (1902).
8) A. A. Frost and R. G. Pearson, *Kinetics and Mechanism*, John Wiley, New York (1953), pp. 153—154.

and:

$$d(R)/dt = k_2 \frac{(A)_0}{k_2/k_1 - 1} e^{-k_1 t}(e^{(k_2-k_1)t} - 1) \quad (10)$$

where (R) is the concentration of the racemized alcohol. In the region where t is zero to t_{max}, especially when t is very small, i. e. at the initial stage of the reaction, $e^{(k_1-k_2)t}$ is approximately unity and $1/e^{k_1 t} < 1$, so the second term in parentheses in Eq. 9 may be eliminated;

$$d(C)/dt = k_1(A)_0 e^{-k_1 t} \quad (11)$$

Since, in the reaction stage from t_{max} to t, $k_2/k_1 \fallingdotseq 0$, and $e^{(k_2-k_1)t} = 0$, Eq. 10 reduces to:

$$d(R)/dt = k_2(A)_0 e^{-k_2 t} \quad (12)$$

Consequently, the rate constants, k_1 and k_2, can be estimated from the ascending and the descending parts of the curves in Fig. 1 respectively:

$$\ln \frac{\alpha_{max} - \alpha_0}{\alpha_{max} - \alpha} = k_1 \cdot t \quad (13)$$

$$\ln \frac{\alpha_{max}}{\alpha} = k_2 \cdot t \quad (14)$$

where α, α_0 and α_{max} are the optical rotations of the reaction mixture at time t, at time zero, and at the time when the rotation was at the maximum respectively. Both plots were linear, as may be seen in Figs. 2 and 3, and both obey the first-order rate law derived in the above discussion.

The constants, k_1 and k_2, are estimated to be as in Table I.

Table I

Experimental

Materials.—Liquid sulfur dioxide was dehydrated by phosphorus(V) oxide and distilled. Optically active α-phenylethyl alcohol was prepared by the fractional crystallization of the brucine-complex salt of hydrogen monophthalate of the alcohol; b. p. 76.5°C/6 mmHg, $[\alpha]_D^{25} = -45°$ degree. $dm^{-1}g^{-1}ml.$ in benzene.[1]

Polarimetry.—A Shimadzu-Lippich type, model II, polarimeter equipped with a glass pressure cell coupled with an inlet joint was used.[6]

A Typical Run of the Racemization of α-Phenylethyl Alcohol in Liquid Sulfur Dioxide.—Into 18.2 ml. of liquid sulfur dioxide in a pressure cell (the length of which was 22 cm.[2]) there was dissolved 0.503 g. of optically-active *l*-α-phenylethyl aclohol; the solution was then allowed to stand for over 10 hr.

The Reactions of Hydrogen Atoms with Methylamine Initiated by Ionizing Radiation

By Setsuo TAKAMUKU and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Sakai-shi, Osaka

(Received June 30, 1965)

In a previous paper[1] dealing with the radiolysis of methylamine in the gas phase, it has been shown that the main volatile products are hydrogen, ammonia and methane, and that the most important primary process is the formation of hydrogen atoms by the dissociation of the N–H bond, though there is a small amount of unscavengeable hydrogen formation. Even after the study, however, there was still uncertainty concerning the position of the abstractable hydrogen atoms (the N–H and C–H hydrogen) in the secondary process. It became desirable, therefore, to clarify this step by an investigation using isotopic methylamines (CH_3ND_2 and CD_3NH_2) or by the measurement of the activation energy of the process.

The activation energy of the hydrogen abstraction from ethyleneimine by methyl radicals produced photochemically was found to be 4.8 kcal./mol. by Brinton and Volman;[2] this value is much lower than the values for any C–H type abstraction, found by Trotman-Dickenson and Steacie.[3] Therefore, they suggested that it is the N–H hydrogen atoms which are active in methane formation. Thynne[4] has also studied the reaction of methyl radicals with a deuterated methylamine, CH_3ND_2; he observed a very low activation energy (5.7 kcal./mol.) for the N–H abstraction, while the value was 9.0 kcal./mol. for the C–H abstraction.

The present paper is concerned with the activation energy of the reaction of hydrogen atoms with methylamine; we used ethylene as a hydrogen atom scavenger in the radiolysis of methylamine.

Experimental

The preparation and purification of methylamine and ethylene have been previously described.[1] Gaseous samples, involving 300 mmHg of methylamine and various amounts of ethylene, were irrradiated in a 500 ml. Pyrex cyrindrical vessel fitted with a breakable seal and graphite-coated electrodes in order to measure the saturation ion current during γ-irradiation.

Irradiations were carried out using a 5000-curie ^{60}Co source at various temperatures up to 152°C. The conversion was kept lower than 0.1%. A conventional vacuum line was used to degas the irradiation samples and to analyze the products.

The other experimental details have been described previously.[1]

Results and Discussion

On the basis of the mechanism elucidated for the radiolysis of methylamine at room temperature,[1] the following main reactions appear to be acceptable representations of the initial steps:

$$CH_3NH_2 \xrightarrow{\sim\sim} H + CH_3NH\cdot \quad (1)$$

$$\xrightarrow{\sim\sim} H_2 + CNH_3 \quad (2)$$

$$\xrightarrow{\sim\sim} \cdot CH_3 + \cdot NH_2 \quad (3)$$

$$H + CH_3NH_2 \rightarrow H_2 + CNH_4 \quad (4)$$

$$2CNH_4 \rightarrow NH_3 + C_2NH_5 \quad (5)$$

Reaction 3 was supposed not to be important at room temperature, because of the low yields of methane and ethane.

The yield of methane, however, increased at higher temperatures, as is shown in Fig. 1 while the ion-pair yield of hydrogen decreased. These temperature dependencies of the products may be interpreted as showing that the precursors, which will give hydrogen atoms or molecules at lower temperatures, prefer to dissociate to amino and methyl radicals (reaction 3), thus leading to

the formation of methane at high temperatures. Another possibility is that the precursors are collisionally deactivated as the pressure increases at a high temperature (the pressure of the irradiation sample was kept constant, 300 mmHg, at room temperature). The increase in methane yield may be explained as due to the thermal degradation of the primary radicals, thus producing methyl radicals.

As was pointed out earlier,[1,5-7] when a radical scavenger (C_2H_4) is present in the system, it competes with methylamine (reaction 4) for hydrogen atoms:

$$H + C_2H_4 \rightarrow C_2H_5\cdot \qquad (6)$$

The following equation was obtained by the steady-state kinetic treatment of hydrogen atom production:

$$\frac{1}{\Delta(M/N)_H} = \frac{1}{(M/N)_{H(1)}} \cdot \frac{k_4[CH_3NH_2]}{k_6[C_2H_4]} + \frac{1}{(M/N)_{H(1)}} \qquad (I)$$

where $\Delta(M/N)_{H_2}$ is the difference in the ion-pair yield of hydrogen, without and with ethylene, and $(M/N)_{H(1)}$ is the ion-pair yield of hydrogen produced by reaction 1. Figure 2 shows that the results here obtained obey Eq. 1, even at high temperatures.

The rate constant ratios, k_4/k_6 and $(M/N)_{H(1)}$, calculated from these straight lines are summarized in Table I. From these results it is obvious that the relative importance of the radical process in the hydrogen formation is independent of the temperature, though the total hydrogen yield decreases slightly with the temperature.

Arrhenius plots of the rate constant ratios, k_4/k_6, give a fairly good straight line, as is shown in Fig. 3. This result is expressed by the equation:

$$\frac{k_4}{k_6} = 3.2 \exp(-2.3/\boldsymbol{R}T) \qquad (II)$$

By assuming the activation energy of the reaction 6 to be 1.9 kcal./mol.[7] and the log A value to be 12.9,[7] the following relation is obtained:

$$k_4 = 10^{13.4} \exp(-4.2/\boldsymbol{R}T) \qquad (III)$$

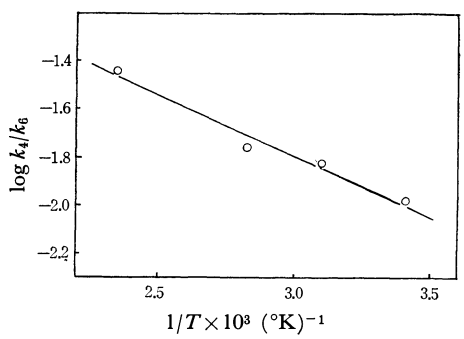

Fig. 3. Arrhenius plot of values of k_4/k_6.

The activation energy, 4.2 kcal./mol., estimated for the reaction 4 is considerably lower than the others reported for the C–H type abstractions. For example, the activation energies of the hydrogen abstraction from methane, ethane, propane and neopentane by hydrogen atoms were reported by

5) R. A. Back, *J. Phys. Chem.*, **64**, 124 (1960).
6) T. J. Hardwick, ibid., **65**, 101 (1961).
7) K. Yang, *J. Am. Chem., Soc.*, **84**, (1961).

Steacie[8] to be 13, 9.5, 8.5 and 9.3 kcal./mol. respectively.

The present observation, therefore, supports the suggestion that the N–H bond is the acitive participant in the reaction 4, on analogy to the low activation energy for the abstraction of N–H hydrogen by methyl radicals.

Summary

The radiolysis of methylamine with and without ethylene has been investigated at various temperatures up to 152°C.

The relative importance of the radical process (80%) in the hydrogen formation is independent of the temperature, though there are a slight decreases in the total hydrogen formation at high temperatures.

The thermal hydrogen atoms thus formed in the primary process may be supposed to abstract mainly the N–H hydrogen atoms of methylamine, because the activation energy for the process has been observed to be 4.2 kcal./mol., much lower than any C–H type abstraction.

A Relationship between the Binding Energy and the Scattering Intensity of Electrons from Gas Molecules

By Takao Iijima

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo, Hokkaido

(Received August 3, 1965; in revised form November 24, 1965)

The effect of chemical bond formation on the scattering intensity has been investigated in several recent theoretical and experimental studies[1-8] of the scattering of fast electrons from gas molecules. The results of these studies have indicated that the intensity of electrons scattered by molecules shows a decrease, or at least a difference, from the calculated intensity based on *the independent atom model*[6] in the region of small scattering angles. This decrease in intensity has been attributed to a change in the effective volume occupied by a fixed percentage of electrons due to chemical binding, and thus qualitatively related to the binding energy of the system.[6-8] The present communication is intended to show that this decrease in intensity is directly and quantitatively related to the binding energy of the molecule. The theoretical prediction of the binding effect for the H_2 molecule[6] has been found to be consistent with this relationship. Also, a preliminary value of the binding energy of methane has been obtained by the use of the same relationship.

Tavard and Roux[4] have recently presented the following suggestive integral formula:

$$\left\langle \psi \left| \sum\sum_{i<j} \frac{Z_i Z_j}{r_{ij}} - \sum\sum_{i,\mu} \frac{Z_i}{r_{i\mu}} + \sum\sum_{\mu<\nu} \frac{1}{r_{\mu\nu}} \right| \psi \right\rangle = \frac{1}{\pi} \int \mathrm{d}s [s^4 I^T(s) - \sum_i Z_i^2 - \sum_i Z_i] \quad (1)$$

where Z_i is the atomic number of the ith atom, and r_{ij}, $r_{i\mu}$, $r_{\mu\nu}$ are the nuclear-nuclear, nuclear-electron and electron-electron distances respectively. The electronic wave function of the system is denoted by ψ; s is the scattering parameter $(4\pi/\lambda)\sin(\theta/2)$, and $I^T(s)$ is the total intensity of electrons scattered by the system involved in the first Born approximation. By noting that the left-hand side of Eq. 1 is the potential energy and by using the virial theorem, the total molecular energy, E_M, may be related to the total intensity of the electrons scattered by the molecule $I_M{}^T(s)$ through the expression:

$$E_M = \frac{1}{2\pi} \int_0^\infty \mathrm{d}s [s^4 I_M{}^T(s) - \sum_i Z_i^2 - \sum_i Z_i] \quad (2)$$

When all the internuclear distances, r_{ij}, are infinitely large, Eq. 1 is reduced to:

$$E_A = \frac{1}{2\pi} \int_0^\infty \mathrm{d}s [s^4 I_A{}^T(s) - \sum_i Z_i^2 - \sum_i Z_i] \quad (3)$$

where E_A is the sum of the atomic energies and $I_A{}^T(s)$ is the atomic background. By subtracting Eq. 2 from 3, the binding energy, E_b, is obtained as:

$$E_b = \frac{1}{2\pi} \int_0^\infty \mathrm{d}s [s^4 I_A{}^T(s) - s^4 I_M{}^T(s)] \quad (4)$$

8) T. Iijima, R. A. Bonham, C. Tavard, M. Roux and M. Cornille, This Bulletin, **38**, 1757 (1965).

This relationship can be rewritten in a more convenient form by using the intensity calculated by the independent atom model, $I_{IAM}{}^{T}(s)$:

$$E_b=\frac{1}{2\pi}\int_0^\infty ds[s^4I_{IAM}{}^{T}(s)-s^4I_M{}^{T}(s)] + \frac{1}{2\pi}\int_0^\infty ds[s^4I_A{}^{T}(s)-s^4I_{IAM}{}^{T}(s)] \quad (5)$$

The integrand of the first term corresponds to the decrease in intensity discussed earlier,[6-8] while the second integrand is simply the molecular term calculated by the independent atom model.*

For the H_2 molecule, the right-hand side of Eq. 5 was evaluated by the use of the $I_M{}^{T}(s)$ value which was calculated with the Weinbaum(ionic) wave function and reported previously.[6,7] Because the calculated $I_M{}^{T}(s)$ values were available only up to $s=10$, the integration of the first term had to be terminated at $s=10$. The second integration was evaluated with a simple analytical expression:

$$\frac{1}{2\pi}\int_0^\infty ds[s^4I_A{}^{T}-s^4I_{IAM}{}^{T}(s)] = -\frac{e^{-2D}}{D}\left[1+\frac{5}{8}D-\frac{3}{4}D^2-\frac{1}{6}D^3\right] \quad (6)$$

(D: the H-H distance)

for the case of H_2.[9] The first term amounted to 0.267 Ry (Rydberg), and the second term, to 0.002 Ry; thus total binding energy was calculated to be 0.269 Ry, while the binding energy of the Weinbaum(ionic) function is 0.296 Ry. The discrepancy may reasonably be understood as due to the termination error, which may be estimated to be 0.03 Ry by the graphical extrapolation of the $s^4(I_{IAM}{}^{T}-I_M{}^{T})$ curve.

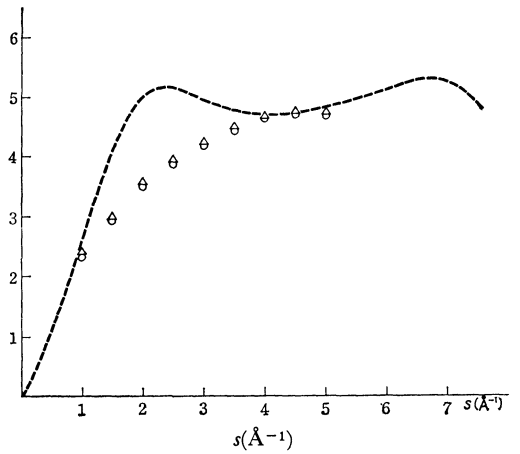

Fig. 1. The $s^3I_{IAM}{}^{T}(s)$ (--) and the observed scattering intensity with an s^3-sector of methane in an arbitrary scale. The results from two different plates are indicated by ○ and △. The difference in the scattering intensity shown in this figure which corresponds to the first integrand of Eq. 5, must be multiplied by s prior to integration.

The relationship given by Eq. 5 was used to analyze the diffraction data for methane** reported elsewhere.[8] Because of the lack of the sufficiently accurate experimental data in the region of large s values, there remains some ambiguity in the choice of a normalizing factor to make $I_M{}^{T}(s)$ fit the $I_{IAM}{}^{T}(s)$ intensity at large s values. On the assumption that no appreciable binding effect would appear in the range beyond $s=5$, the plausible normalization shown in Fig. 1 was made***; the intergration of Eq. 5 for this choice gave 1.06 Ry† as the binding energy of CH_4, a value which is in good agreement with the reported value of E_b, 1.34 Ry.[10] Both the first and the second term were integrated numerically.

It appears possible that a careful diffraction experiment could give the total binding energy of many molecules. This might be especially useful in cases where the determination of E_b by ordinary methods is difficult. Moreover, the known value of the binding energy might be used with the experimental intensity data to help provide estimates of such higher order effects on the scattering intensity as polarization and multiple scattering, by taking advantage of the relationship between the tatal intensity and the binding energy.

The author is greatly indebted to Professors Masao Kimura, Kimio Ohno, Kozo Kuchitsu and Russell A. Bonham, and also to Dr. Claude Tavard for reading the manuscript and giving helpful comments.

* The formulae equivalent to Eqs. 4 and 5 have also been obtained by Tavard; private communication via Professor R. A. Bonham; C. Tavard, to be published.

9) C. Tavard, private communication.

** The diffraction patterns for CH_4 were obtained in the Electron Diffraction Laboratory of Indiana University, Bloomington, Indiana. The author wishes to thank Professor R. A. Bonham for letting him use his apparatus.

*** The data beyond $s=5$, although not shown on the figure, are not in coincidence with the $s^3I_{IAM}{}^{T}$ curve. The inconsistency in this portion of data must be due to experimental error. A project to obtain more accurate intensity data is under way.

† The coherent and incoherent scattering factors used in the present calculation are based on the Hartree-Fock SCF wave functions.[11] Accordingly the value (1.37 Ry) thus obtained by Eq. 5 should be corrected for by the amount of the difference between the true atomic energy and the Hartree-Fock energy of carbon, namely, by about 0.31 Ry.[12,13]

10) G. Glockler, *J. Chem. Phys.*, **21**, 1242 (1953). The value reported by Glockler, 1.25 Ry, was corrected for the zero point energy by 0.09 Ry.

The Dipole Moments and Polarizabilities in the Excited States of Naphthalene from Spectral Solvent Shifts

By Takehiro ABE,

College of General Education, Tohoku University, Kawauchi, Sendai

and

Yoshito AMAKO, Tadashi NISHIOKA and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 23, 1965)

Several attempts have been made to estimate dipole moments in excited states of aromatic compounds on the basis of the solvent effects on their electronic spectra.[1-5] Recently Abe[6] has evolved a theory for solvent effects by means of the application of the van der Waals interaction and has estimated the dipole moment and polarizability in the excited state of nitrobenzene. In the present paper, the dipole moments and polarizabilities in the $^1B_{1u}$- and $^1B_{2u}$-excited states of naphthalene will be estimated by the application of the general expression derived by Abe to the solvent shifts for naphthalene.

The general expression presented by Abe can be written as:

$$\{(\mu_i^u)^2-(\mu_0^u)^2\} + A\cdot\alpha_i^u = B \qquad (1)$$

where:

$$A = \left\{\frac{2}{3kT}\cdot(\mu_0^v)^2+\alpha_0^v\right\}^{-1} \times\left\{(\mu_0^v)^2+\frac{3}{2}\cdot(\alpha_0^v)\cdot I_0^v\cdot\frac{I_0^u-hc\nu^0_{i0}}{I_0^v+I_0^u-hc\nu^0_{i0}}\right\}$$

and:

$$B = \left\{\frac{2}{3kT}\cdot(\mu_0^v)^2+\alpha_0^v\right\}^{-1} \times\left[\left\{(\mu_0^v)^2+\frac{3}{2}\cdot(\alpha_0^v)\cdot I_0^v\cdot\frac{I_0^u}{I_0^v+I_0^u}\right\}\cdot(\alpha_0^u) -\left\{1.007\times10^{65}(\mathrm{erg^{-1}cm^{-1}})\times\left(\frac{d^v}{M^v}\right)^{2/3}\right\}^{-1} \times\left\{\left(\left(\frac{M^u}{d^u}\right)^{1/3}+\left(\frac{M^v}{d^v}\right)^{1/3}\right)^{-4} +\left(\left(\frac{M^u}{d^u}\right)^{1/3}+3\left(\frac{M^v}{d^v}\right)^{1/3}\right)^{-4} +\left(\left(\frac{M^u}{d^u}\right)^{1/3}+5\left(\frac{M^v}{d^v}\right)^{1/3}\right)^{-4}\right\}^{-1}\times(\nu_{i0}-\nu^0_{i0})\right]$$

Here ν^0_{i0} and ν_{i0} are the maximum wave numbers in the vapor and in the solution respectively in an absorption transition from the ground state to the ith excited state of an isotropic solute molecule. All the notations refer to Abe's original paper. The notations of μ_i^u and α_i^u are the dipole moment and the polarizability in the ith excited state. The values of A and B can be calculated from the observed values, so the plot of B against A should be linear; the slope of the straight line will be equal to α_i^u, and the intersection of the line at $A=0$ will be equal to $\{(\mu_i^u)^2-(\mu_0^u)^2\}$.

Experimental

Measurements were made with a Hitachi EPS-2 recording spectrophotometer or a Shimazu GE-100

7	Acetonitrile	32190	34730	3.94	44.166**	12.39[11]

* These values were calculated by the use of the observed values[8] for deformation polarizations.
** This value was calculated from the sum of bond refractions.

grating spectrophotograph at room temperature. The results of the measurements of the $^1B_{1u}$ and $^1B_{2u}$ bands of naphthalene in polar solvents are given in Table I. Usually the first reasonably intense vibration band of a transition was measured.

Naphthalene was purified by sublimation after being recrystallized four times, alternately from ethyl ether and from ethanol. Ethanol was twice distilled after being refluxed with 12 N sulfuric acid and with potassium hydroxide and silver nitrate, dried over calcium chloride, and fractionated. Ethyl ether was refluxed with 10% sodium carbonate, distilled, dried over calcium chloride, and distilled over sodium. Acetonitrile was of spectroscopic grade and had been obtained from the Eastman Co.

Results

The first intense vibration bands of the $^1B_{1u}$ and $^1B_{2u}$ transitions in naphthalene and the other data used are listed in Table I. The densities of d at 20°C taken from Lange's table[12] and from another source were used. On the assumption that the temperature is 20°C, that is, that $2/3kT$ is 1.647×10^{13} erg^{-1}, the present authors calculated the values of A and B and plotted B against A, as is shown in Fig. 1. It may be seen in Fig. 1 that the points fall close to the straight lines which approximately pass through the point of origin. The values of $\{(\mu_i^u)^2-(\mu_0^u)^2\}$ are, therefore, estimated to be zero. Accordingly, both the dipole moments in the $^1B_{1u}$- and $^1B_{2u}$-excited states of naphthalene are estimated to be zero, because the observed value of μ_0^u is zero. From the slopes of the lines in Fig. 1, the polarizabilities in the $^1B_{1u}$- and $^1B_{2u}$-excited states of naphthalene are found to be 345.8×10^{-25} and 556.2×10^{-25} cm^3 respectively.

The Electron Spin Resonance Spectra of Nitrobiphenyl Radical Anions

By Yasuto NAKAI, Katsuyuki KAWAMURA, Kazuhiko ISHIZU, Yasuo DEGUCHI and Hideo TAKAKI

Department of Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received August 30, 1965)

In a study of series of substituted biphenyls, several nitro derivatives have been synthesized and the ESR spectra of their anion radicals investigated. The analysis of the spectra is quite straightforward for the mononitrobiphenyls. Although the hyperfine splitting constant for the nitrogen atom is distinct, those for the hydrogen atoms can not be assigned unequivocally. These splittings can, however, be assigned with reasonable certainty, as shown in Table I, by using the theoretical estimates of the spin density distribution and by comparing the splitting constants of a related series of radicals, including halogenated nitrobenzene and hydrogenated nitrobiphenyl. The results seem to sustain the view that the frame-work of mononitrobiphenyls is similar to that of nitrobenzene as far as the frontier electronic orbital level is concerned. Although they are phenylated, the effect of the conjugation of ortho- and meta-substituents is small because of the sterically-induced decoupling and the small spin density respectively. This observation is contrary to that made of alkyl-[1], methoxyl-,[2] or cyanobiphenyls.[3] For paraphenylnitrobenzene, however, the electron-withdrawing nitro group does not entirely dominate the mesomeric interaction effect of the additional aromatic ring; this results in somewhat smaller splitting constants for the main ring atoms.

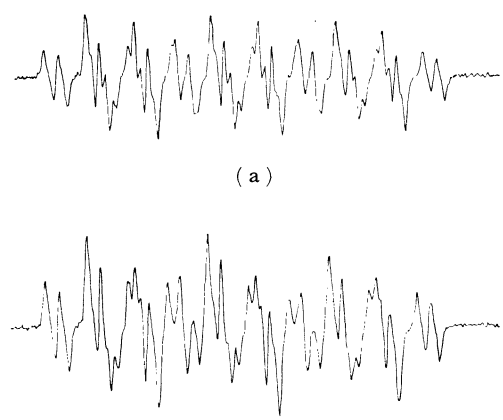
(c) Interaction with two protons

Dinitrobiphenyls all give substantially different spectra depending upon the method of reduction used to produce anion radicals. The spectra of electrolytically-generated radicals could be readily interpreted on the basis of symmetry considerations alone. When reduced by alkali metals, the contiguity of the small cation to the nitro group seems to destroy the molecular symmetry, so the unpaired electron tends to localize exclusively only one of the two nitrogens in a molecule, as in the case of dinitrobenzene.[4] A striking feature of the spectra exhibited in Fig. 1(a) and (b) is that the spectrum of metadinitrobiphenyl closely resembles that of metanitrobiphenyl.



(a)

(b)

Fig. 1. The electron spin resonance spectra of *m*-nitrobiphenyl (a) and *m*,*m'*-dinitrobiphenyl (b) anion radicals.

When the spin density calculations based on the simple Hückel LCAO approximation for these compounds are compared with the experimental data, we find that the internal rotation rather than the cation-induced polarization of the nitro group in dinitrobiphenyl is the more probable model. The *o*,*o'*-dinitrobiphenyl anion forms a

stable ion-pair[5] with the alkali metal cation. The metal hyperfine splittings are 0.35 gauss for lithium and 0.18 gauss for sodium. Since one of the benzene rings possesses most of the unpaired spin during the formation of a stable ion pair, the nitrogen in the other ring shows a very small hyperfine splitting, 0.38 gauss.

We have not been able to detect anion radicals with alkali metals in *p,p'*-dinitrobiphenyl.

Sterol Constituents of *Daedalea quercina* L. (Fr.)

By Yoshiaki TANAHASHI and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received September 7, 1965)

In the course of our studies of higher terpenoids, we have examined the ethyl acetate extract of *Daedalea quercina* L. (Fr.) and isolated a mixed crystal of ergosterol and 5-dihydroergosterol, together with 5-dihydroergosterol (ergosta-7, 22-dien-3β-ol) and ergosterol peroxide (5, 8-epidioxyergosta-6, 22-dien-3β-ol).[1]

The sources of *D. quercina* were as follows; (1) Commercially supplied; living on beech; 380 g. (2) Commercially supplied; generally called "Baikisei" and used as a herb medicine; living on Prunus Mume Sieb. et Zucc.; 2.5 kg. (3) Living on beech. Collected in April and May, 1962, at Tanzawa in Kanagawa Prefecture; 15 kg.

The first sample gave a neutral alcoholic compound, named DQ-ol A_1. The ultraviolet spectrum of DQ-ol A_1 was very similar to that of ergosterol, but its intensities were slightly weaker. The concentrated extract of the second, "Baikisei," gave DQ-ol A_2, which was found to be identical with DQ-ol A_1. The mother liquor furnished, on chromatographic separation, DQ-ol B and DQ-ol C, which were later identified as 5-dihydroergosterol and ergosterol peroxide respectively. The third sample afforded DQ-ol A_3 which showed much weaker absorptions in the ultraviolet spectrum than those of DQ-ol A_1.

The constants of DQ-ol A_1 were found to be very similar to those of "neosterol," which was first considered by Wieland et al.[2] to be a new sterol isolated from yeast fat. Barton et al.[3] have established, however, that neosterol consists of 75.5% of ergosterol and 24.5% of 5-dihydroergosterol, and have found that "synthetic neosterol" and its benzoate can not be separated by recrystallization. Table I shows the constants of neosterol, "synthetic neosterol", DQ-ol A_1, and ergosterol.

From these data, it seems probable that DQ-ol A_1 is a mixed crystal of ergosterol and 5-dihydroergosterol, as in the case of neosterol, and that DQ-ol A_3 contains much more 5-dihydroergosterol. The chemical evidence for these conclusions is as follows:

a) On catalytic hydrogenation over platinum oxide in acetic acid, DQ-ol A_1 absorbed 1.89 mol. of hydrogen, while ergosterol absorbed 2.01 mol. of hydrogen under the same conditions.

b) DQ-ol A_3 acetate gave only 5-dihydroergosteryl acetate on hydrogenation over Raney nickel in benzene; 0.49 mol. of hydrogen was absorbed.

c) The photosensitized oxidation of DQ-ol A_3 afforded 5-dihydroergosterol in a 60% yield and a small amount of ergosterol peroxide.

d) 3β-Acetoxy-Δ^7- and -$\Delta^{5,7}$-steroids are well known to show their C-18 methyl signals at τ 9.43 and τ 9.37 respectively.[4] The NMR spectrum of DQ-ol A_3 acetate consisted of two signals of an approximately equal intensity at τ 9.36 and 9.46,*1 and the whole spectrum could be interpreted as the sum of those of ergosteryl acetate and of 5-dihydroergosteryl acetate.

e) The infrared spectra of DQ-ol A_1 and A_3 may be well interpreted as a sum of the spectra of ergosterol and 5-dihydroergsoterol.

Table II shows the estimated compositions of DQ-ol A_1 and of DQ-ol A_3.

TABLE I. CONSTANTS OF NEOSTEROL, "SYNTHETIC NEOSTEROL," DQ-OL A_1 AND ERGOSTEROL

Substance	M. p. °C	$[\alpha]_D$	ε at λ_{max} 271 mμ	282 mμ	293 mμ
Neosterol[2]	164—165	−105°	11400	11400	6900
"Synthetic neosterol"[3]	164—165	−107°	9500	10100	5000
DQ-ol A_1	160—161	−103°	9100	9450	5300
Ergosterol	162—163	−119°	11500	12100	7050

Table II. Ergosterol in DQ-ol A*2

Estimated from the data in:	DQ-ol A_1	DQ-ol A_3	DQ-ol A_3 acetate
$[\alpha]_D$	74%	30%	—
UV	79%	35%	50%
Hydrogenation	80%	—	49%

Experimental*3

Isolation.—*DQ-ol A_1*.—Chopped, air-dried fungus (100 g.) was extracted with ethyl acetate (800 cc.). After filtration, the ethyl acetate extract was concentrated to a small volume and crude crystals (330 mg.), m. p. 153—160°C, were separated out; these gave white needles after filtration through the column of alumina, m. p. 160—161°C (from ethyl acetate), $[\alpha]_D$ −103° (*c* 1.72), λ_{max}^{EtOH} 271 mμ (ε 9100), 282 mμ (ε 9450) and 293 mμ(ε 5300), ν_{OH} 3622.1 cm^{-1} *4 (in CCl_4 soln., secondary hydroxyl group), ν^{Nujol} (cm^{-1}) 1664, 1605, 1050, 968, 846(sh.), 835, 802.

Found: C, 82.93, 83.06, 82.09; H, 11.39, 11.41, 11.18. Calcd. for $C_{28}H_{44}O\cdot\frac{1}{2}H_2O$: C, 82.90; H, 11.18: for $C_{28}H_{46}O\cdot\frac{1}{2}HO$: C, 82.61; H, 11.62%.

DQ-ol A_2.—Powdered, air-dried fungus "Baikisei" (2.5 kg.) was extracted with ethyl acetate (10 l.). The extract, worked up as above, gave crude crystals; these in turn yielded DQ-ol A_2 (11 mg.), as white needles, m. p. 160—161°C, virtually identical with that of DQ-ol A_1.

The dark brown residue of the mother liquor was dissolved in benzene and adsorbed on alumina (600 g.). The column was eluted with (i) benzene, (7 l.), (ii) benzene-ether (9 : 1) (7 l.), (iii) benzene-ether (3 : 1) (5 l.), (iv) benzene-ether (1 : 1) (3 l.) and (v) ether (4 l.). Fraction (ii) gave 400 mg. of DQ-ol B (characterized as its acetate; m. p. 172—174°C, identical with that of 5-dihydroergosteryl acetate). Fraction (v) gave 80 mg. of DQ-ol C, m. p. 171—173°C, identical with that of an authentic sample of ergosterol peroxide.

DQ-ol A_3.—Fifteen kilograms of *Daedalea quercina* L. (Fr.) was extracted by the same method. After purification, DQ-ol A_3 (4.51 g.), m. p. 162—163°C, $[\alpha]_D$ −54° (*c* 1.53), λ_{max}^{EtOH} 271 mμ (ε4550), 282 mμ (ε 4600) and 293 mμ(ε 2700) was obtained. (Mixed m. p. with DQ-ol A_1: 158—162°C). The infrared spectrum of DQ-ol A_3 is virtually identical with that of DQ-ol A_1, except for the two peaks at 835 and 802 cm^{-1}, which are weaker than in the case of A_1.

On acetylation DQ-ol A_3 gave its acetate, m. p. 172—174°C (from methanol), λ_{max}^{EtOH} 271 mμ (ε 6100), 282 mμ(ε 6400) and 293 mμ(ε 3800).

The Photosensitized Oxidation of DQ-ol A_3.—A hot solution (about 60°C) of DQ-ol A_3 (500 mg.) in 95% ethanol (200 cc.), containing eosin (3 mg.), was aerated with a dry air-stream for 9 hr. under irradiation by a 200-watt lamp. After cooling, white crystals (305 mg.) were separated from the reaction mixture. Recrystallization from ethanol gave 5-dihydroergosterol, m. p. 172—173.5°C; identified with an authentic sample prepared by the hydrogenation of ergosterol.

After the concentration of the mother liquor, a small amount of the crystalline product was obtained. Its infrared spectrum was completely superimposable upon that of ergosterol peroxide.

The Hydrogenation of DQ-ol A_3 Acetate.—DQ-ol A_3 acetate (440 mg.) in thiophene-free benzene was hydrogenated over Raney nickel at room temperature. Within 10 min., 13.2 cc. of hydrogen was absorbed. The reaction mixture was then worked up in the usual manner, and the crystallization of the product from ethyl acetate gave 5-dihydroergosteryl acetate (350 mg.), m. p. 173°C, $[\alpha]_D$ −17.6° (*c* 2.7)

Under the same conditions, ergosteryl acetate (440 mg.) absorbed 27.2 cc. of hydrogen to yield 5-dihydroergosteryl acetate (320 mg.), m. p. 174°C, $[\alpha]_D$ −16.2° (*c* 1.85).

We are greatly indebted to Dr. Hiizu Iwamura of The University of Tokyo for his IR and NMR measurements.

*2 The other component is 5-dihydroergosterol.

*3 All the m.p.'s are measused in the capillary and are uncorrected. The specific rotations are for chloroform solutions.

*4 Run on a Perkin-Elmer 112G spectrometer.

The Electric Properties of Metallocenes and Their Derivatives

By Hamao WATANABE, Izumi MOTOYAMA and Kazuo HATA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 10, 1965)

It is well known that electron acceptors, such as tetracyanoethylene, tetracyanoquinodimethane, and *p*-chloranil, form various types of charge transfer complexes with many donor compounds, and that some of these complexes have the properties of semiconductors. Although a great number of ferrocene derivatives have already been synthesized and their chemical properties have been elucidated, only a few reports on the properties of semiconductors in the field of metallocene derivatives have appeared.[1] As has been reported by the present authors,[2] ketazine polymers derived from diacetylferrocene and hydrazine have an interesting property, i. e., their electric resistivities are near to those of organic semiconductors.

Now the present authors wish to report on the electric properties of some metallocenes, polyferrocenyls, and two sorts of charge transfer complexes which consist of one mole of metallocene and two moles of *p*-chloranil.

Samples.—Ferrocene and nickelocene were prepared by the method reported in a previous paper.[3] Terferrocenyl, quater-ferrocenyl and sexiferrocenyl are products of the reaction of ferrocenyllithium and cobaltous chloride reported in previous papers.[4]

The Nickelocene-*p*-chloranil (1 : 2) Charge Transfer Complex.—This complex was prepared by the method reported by Goan and his co-workers.[5] A solution of 2.6 g. of *p*-chloranil in 250 ml. of dry benzene and a solution of 1.0 g. of nickelocene in 10 ml. of dry benzene (2 : 1 in mole ratio) were mixed; the complex immediately precipitated as a crystalline solid. After it had stood for several minutes, it was collected on a filter, washed with benzene, and dried in vacuo at room temperature. Thus 1.7 g. of the complex was obtained (ca. 47% yield) as dark brown glittering fine needles which did not melt at 300°C in air (on Kofler apparatus) nor at 250°C in nitrogen (in a sealed capillary). The ESR observation in acetonitrile gave no signal in the spectrum. (Found: C, 38.72; H, 1.75; Cl, 41.74, 41.69. Calcd. for $(C_{10}H_{10}Ni)(C_6Cl_4O_2)_2$: C, 38.82; H, 1.47; Cl, 41.67%).

The Cobaltocene-*p*-chloranil (1 : 2) Charge Transfer Complex.—According to a method similar to that described above, ca. 1.9 g. of the complex was obtained by mixing a solution containing 2.6 g. of *p*-chloranil in 250 ml. of benzene and a solution of cobaltocene (ca. 1.0 g.) in 50 ml. of benzene under an atmosphere of nitrogen in a dry box. This complex was a brown solid which melted at 150—155°C in nitrogen in a sealed capillary. It decomposed at 125—128°C in air and also after standing for a long period at room temperature. The solution of this complex in acetonitrile gave a sharp ESR signal corresponding to one spin per formula weight, the *g* value being estimated to be 2. (Found: C, 38.64; H, 2.19; Cl, 38.83, 38.78. Calcd. for $(C_{10}H_{10}Co)(C_6Cl_4O_2)_2$: C, 38.81; H, 1.49; Cl, 41.66%).

As is shown in Fig. 1, the infrared spectra of the two complexes show very similar absorption bands, while both are vastly different from that of *p*-chloranil.

Specific Resistivity.—The specific resistivities of the samples were measured in a vacuum with pellets prepared by pressing them at more than 7000 kg./cm^2. For the pellets of the three polyferrocenyls, aluminum foils prepared by vacuum evaporation on thier surfaces were used as electrodes. For the pellets of ferrocene, nickelocene and the two complexes, the electrodes were prepared with an electroconductive paint, "Dotite paint, Type S-1",[6] because of the failure of the application of the aluminum evaporation method. In the latter cases, after the painting of the electrodes on the surfaces of the pellets, they were evacuated under a high vacuum in order to exclude any solvent which might have remained in them.

The relationship between the logarithm of the specific resistivity and the reciprocal of the temperature is shown for three polyferrocenyls in Fig. 2. The specific resistivities at room temperature are listed in Table I. The energy gap, ΔE_g, was determined from the temperature dependence of the resistivity according to the following equation:

1) a) L. R. Melby, R. J. Harder, W. R. Hertler, W. Mahler, R. E. Benson and W. E. Mochel, *J. Am. Chem. Soc.*, **84**, 3374 (1962); b) I. M. Pauskin, L. S. Polak, T. P. Vishnyakova, I. I. Patalakh, F. F. Machus and T. A. Sokolinskaya, *Doklady Akad. Nauk S. S. S. R.*, **149**, 856 (1963); *J. Polymer Sci.*, Part C, No. 4, 1481 (1964).

2) K. Hata, I. Motoyama and K. Azuma, to be published in this Bulletin; read before the 16th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1963.

3) H. Watanabe, I. Motoyama and and K. Hata, This Bulletin, **38**, 853 (1965).

4) K. Hata, I. Motoyama and H. Watanabe, ibid., **37**, 1719 (1964); **39**, 790 (1966).

5) J. C. Goan, E. Berg and H. E. Podall, *J. Org. Chem.*, **29**, 975 (1964).

6) A product of Fujikura Kasei Co.

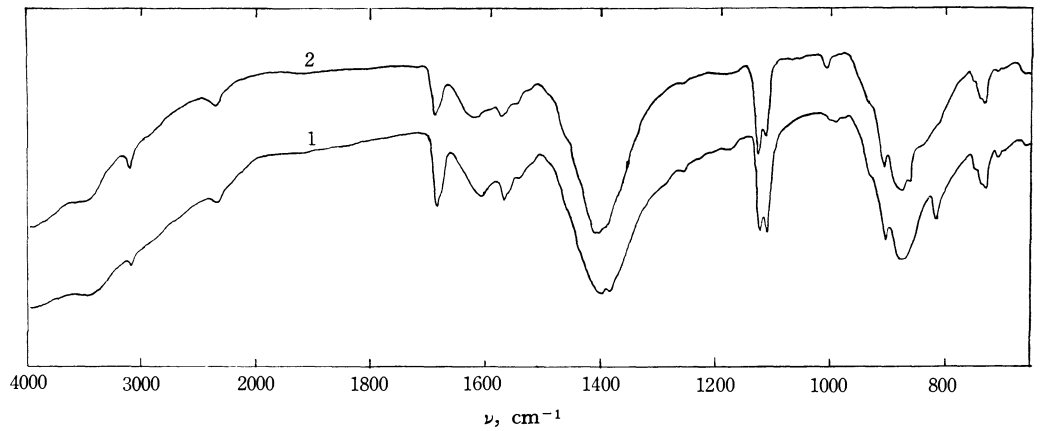

Fig. 1. Infrared spectra of the charge transfer complexes in KBr disk.
1: $(C_{10}H_{10}Ni)(C_6Cl_4O_2)_2$ 2: $(C_{10}H_{10}Co)(C_6Cl_4O_2)_2$

$$\rho = \rho_0 \exp(\Delta E_g/2kT)$$

All of these metallocene derivatives have higher electric conductivities than those of the original metallocenes. The two metallocene-*p*-chloranil complexes have especially high electric conductivities, but they are apt to decompose during the measurements. The electric resistivity shows a minimum at 40—45°C, indicating decomposition at this temperature. Therefore, the energy gaps could not be determined for these substances.

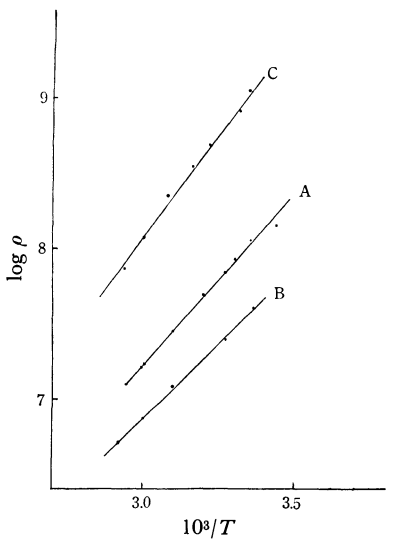

Fig. 2. Temperature dependence of the resistivity.
A: terferrocenyl B: quaterferrocenyl
C: sexiferrocenyl

Table I. Electric properties of the samples

Sample	Specific resistivity at room temperature, Ω·cm.	Energy gap ΔE_g, eV.
Ferrocene	10^{12}	—
Nickelocene	10^{11}	—
Terferrocenyl	10^{8}	0.8
Quaterferrocenyl	10^{7}	0.9
Sexiferrocenyl	10^{9}	1.1
Nickelocene-*p*-chloranil complex	10^{5}	—
Cobaltocene-*p*-chloranil complex	10^{6}	—

A solution of the cobaltocene-*p*-chloranil complex in acetonitrile gave a sharp ESR signal, while the nickelocene-*p*-chloranil complex gave no signal. From these facts it may be concluded that the former is present in the form of a charge transfer anion radical, $[C_{10}H_{10}Co^+][C_6Cl_4O_2]_2^{\cdot-}$, in the solution, and the latter, in the form of a charge transfer anion, $[C_{10}H_{10}Ni^{2+}][C_6Cl_4O_2]_2^{2-}$, as has been pointed out by Goan and his coworkers,[1a,5] and by other investigators.[7] Finally, it can be concluded that these polyferrocenyls and charge transfer complexes have the properties of semiconductors.

The authors are indebted to Professor Shu Kambara of the Tokyo Institute of Technology for his measurement of the specific resistivities. Thanks are also due to the Ministry of Education for the financial support granted for this research.

SHORT COMMUNICATIONS

The Catalytic Hydrolysis of Esters by Amidines

By Eiichi HARUKI, Toshikazu FUJII and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received December 20, 1965)

It has been well recongnized that α-chymotrypsine catalyzes the hydrolyses of esters and that its esteratic activity is due to the imidazolyl group of the histidine residue in α-chymotrypsine. In fact, imidazoles effectively hydrolyze many kinds of esters.

We have now found that amidines, which are considered to be a part of the imidazole ring, catalyze the hydrolyses of esters more effectively than do imidazole and its derivatives. For example, ethyl acetate and γ-butyrolactone were hydrolyzed very easily with benzamidine or acetamidine, but they were not hydrolyzed with imidazole. When a solution of an ester in ethanol-water was mixed with a solution of an amidine in the same solvent at room temperature, the ester was quickly hydrolyzed to the corresponding acid and the acid did form the salt with free amidine, although the salts of amidines do not catalyze the reaction. The kinetics of the reaction were followed by measuring the amount of the residual amidine, which was determined by titration with hydrochloric acid, using phenolphthalein as an indicator. Kinetic studies were carried out starting with about 0.02 mol. solutions of both amidines and esters in a 85% ethanol-water solvent. The reactions were of the second order; the initial second-order rate constants, which were determined from the data for the first 40% of the reaction, are summarized in Table I.

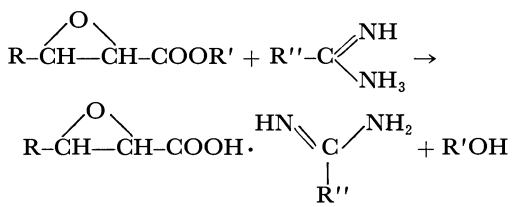
TABLE I. RATE CONSTANTS FOR HYDROLYSIS OF VARIOUS ESTERS BY FORMAIDINE, ACETAMIDINE, BENZAMIDINE AND GUANIDINE IN 85% ETHANOL-WATER AT 30°C

Ester	Catalyst	Second order rate constant $1\ mol^{-1}\ sec^{-1}$
Ethyl acetate	Formamidine	1.82×10^{-2}*
	Acetamidine	2.82×10^{-3}*
	Guanidine	3.75×10^{-3}
	Hydroxide ion	1.09×10^{-2}
γ-Butyrolactone	Formamidine	very fast
	Acetamidine	5.42×10^{-3}*
	Benzamidine	1.43×10^{-3}
	Guanidine	2.90×10^{-2}
Phenyl acetate	Formamidine	very fast
	Acetamidine	3.40×10^{-2}
	Benzamidine	2.37×10^{-2}
	Imidazole	1.80×10^{-3}**
p-Cresyl acetate	Benzamidine	2.44×10^{-2}
	Imidazole	8.83×10^{-3}**

* These values include the rate of the self-decomposition of amidines.

** Determined in a 60% acetone-water solvent at 25°C by T. C. Bruice and G. L. Schmir, *J. Am. Chem. Soc.*, **79**, 1663 (1957).

N-Substituted amidines seem to be very weak catalysts. The relations between the reactivities and the structures of amidines and of esters will be reported on later. However, it must be noted here that the glycidic esters are hydrolyzed without opening the epoxide ring to form the amidinium salts of the glycidic acids.



Further study is now in progress.

The Rearrangement of Acid Anhydride by a *t*-Amine. The Preparation of Glycylglycine from *N*-Benzyloxycarbonylglycine Anhydride

By Hiroshi KOTAKE and Tomoo SAITO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa

(Received January 7, 1966)

In a previous paper,[1] it was reported that β-hydroxy-α-amino acid *N*-carboxy anhydrides rearrange to 2-oxazolidone-4-carboxylic acid 5-derivatives in the presence of triethylamine. The reaction presumes the possibility of an analogous rearrangement reaction between other acid anhydrides and a *t*-amine.

In this communication, a new method for the preparation of dipeptide via the rearrangement reaction of *N*-benzyloxycarbonylamino acid anhydride with *t*-amine, followed by reduction, will be described. *N*-Benzyloxycarbonylglycine anhydride (I) (m. p. 122—123°C, IR: $\nu_{C=O}$ 1825 cm^{-1} and 1765 cm^{-1}), prepared from *N*-benzyloxycarbonylglycine (m. p. 120°C) by the use of dicyclohexylcarbodiimide,[2,3] was rearranged by the reaction of a *t*-amine, e. g., triethylamine in an inactive solvent such as dioxane or tetrahydrofuran at room temperature, to *N'*-(*N*-benzyloxycarbonylglycyl) *N'* - benzyloxycarbonylglycine (II) (yield 85%; m. p. 135°C, IR: $\nu_{C=O}$ 1685 cm^{-1}, 1720 cm^{-1}, and 1745 cm^{-1}. Found: C, 60.00; H, 4.94; N, 6.91; equiv. wt. 398, Calcd. for $C_{20}H_{20}O_7N_2$: C, 59.99; H, 5.04; N, 7.00%; equiv. wt. 400.4).

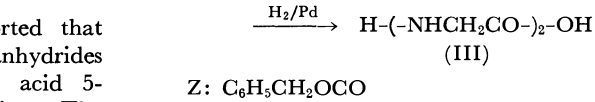
2) I. Muramatsu, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **82**, 83 (1961).

3) H. Schüssler and H. Zahn, *Chem. Ber.*, **95**, 1076 (1962).



(III)

Z: $C_6H_5CH_2OCO$

Even if the amount of the base added was less than the equivalent of I (1—1/10 mol. per mol. of I), the reaction gave satisfactory yields (about 85%). This result indicates that the base reacted with I as a catalyst. Since II has the molecular formula, $C_{20}H_{20}O_7N_2$, which agreed with that of I, it should be an isomer of I. The product II dissolved when a portion of it was heated with aqueous sodium hydrogen carbonate. On acidification, a crystalline product, which was found to be identical with the starting material (II) by means of a mixed melting point procedure (m. p. 135°C), was deposited from the solution. Therefore, II must contain a free carbonyl group. The fact mentioned above led us to conclude that II must be a rearranged product. Another piece of evidence relating to the II structure was also obtained by the reduction producing glycylglycine (III) (yield 97%; m. p. 215—220°C (decomp.), Found: C, 36.51; H, 5.99; N, 21.03; equiv. wt. 134, Calcd. for $C_4H_8O_3N_2$: C, 36.36; H, 6.10; N, 21.20%; equiv. wt. 132.1) from II with palladium black in ethanol.

The infrared spectrum of III was identical with that of an authentic sample in all regions. Thus, this reaction will be extended as a new method of preparing dipeptides. One further investigations of the rearrangement reaction will be reported in the future.

The Synthesis of Nitriles From Aldehydes

By Akira MISONO, Tetsuo OSA and Seiichiro KODA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received January 14, 1966)

Recently, the ammoxidation reaction in a liquid phase has attracted interest because it may be carried out under mild conditions. While studying some aspects of liquid-phase ammoxidation reactions, we have discovered a one-step method of synthesizing nitriles from aldehydes and ammonia in the presence of iodine.

Previously-reported methods for the production of nitriles from the corresponding aldehydes involve the application of a thoria catalyst at about 440°C to a mixture of aldehyde and ammonia,[1] the reaction of phenyl-imidophosgene with benzaldoxime,[2] or other methods using such selective reagents as *O*, *N*-bis-(trifluoroacetyl)-hydroxylamine,[3] hydroxylamine and sodium formate,[4] hydroxylamine and sodium acetate,[5] or nitropropane and ammonium dibasic phosphate.[6] Brackman and Smit[7] obtained nitriles by stirring a methanolic solution of aldehydes, ammonia, a complexed copper salt, and a strong base under oxygen. Parameswaran and Friedman[8] found a method using lead tetraacetate as an oxidizing agent.

It was found in the present study that iodine is a more convenient oxidizing agent than oxygen and a copper complex or lead tetraacetate. By this method, benzonitrile (reaction time: 1.5 hr.; yield: 50%), heptanenitrile (0.15 hr.; 26%), cinnamonitrile (1.5 hr.; 10%) anisonitrile (2 hr., 50%), and *p*-chlorobenzonitrile (1.5 hr., 68%) can be prepared from the corresponding aldehydes at room temperature.

A typical procedure is the preparation of benzonitrile.

Benzonitrile.—Thirty-two grams (0.3 mol.) of benzaldehyde and 16 g. (0.3 mol.) of sodium methoxide were added to 400 ml. of methanol saturated with ammonia. After the sodium methoxide had been dissolved 76 g. (0.3 mol.) of iodine (in 100 ml. of methanol) was added to the solution. Ammonia gas was continuously bubbled into the mixture during the reaction at room temperature. When the color of the solution became a light yellow (in 1.5 hr.), the bubbling in of ammonia gas was stopped. After the volatile reactants had then been removed from the reaction solution in vacuo, the residual oil was extracted with ether. The ethereal solution was treated with an aqueous solution of sodium bisulfite and distilled. Benzonitrile was thus obtained in a yield of 50% (16 g.); b. p. 83°C/20 mmHg; n_D^{20} 1.526.

When hydrobenzamide was used as the starting material in place of benzaldehyde, benzonitrile was again obtained, though in a small yield. This fact supports the theory that benzilideneimine is a possible intermediate.

The simplicity, rapidity, and mildness of this method make it apparent that it can be a convenient method for the preparation of nitriles,[9] especially aromatic nitriles.

Detailed results and a discussion of the possible mechanism will be published in the near future.

Rearrangement in the Substitution Reaction of 3-Keto-4β-bromo-5β-steroids

By Yasuo SATOH, Masaaki MUKOH, Yuichi OGAKI, Tomoyoshi TAKAHASHI
Takako KIMURA, Hiromitsu AOKI and Akira HAGITANI

Department of Chemistry, St. Paul's University (Rikkyo Daigaku), Toshima-ku, Tokyo

(Received January 18, 1966)

The authors wish to report on a new rearrangement in the substitution reaction of 3-keto-4β-bromo-5β-steroids with potassium acetate.

4β-Bromo-5β-chloestan-3-one (8 g.) in acetic acid (280 ml.) was refluxed with potassium acetate (56 g.) in a nitrogen atmosphere for 6 hr. The reaction mixture was then evaporated under reduced pressure, and the residue was extracted with ether. The ethereal extracts were washed with an aqueous sodium bicarbonate solution and water, dried, and evaporated. Two crystallizations of the residue from ethanol gave needles (2.6 g.), m. p. 149—151°C. Found: C, 78.37; H, 10.85. Calcd. for $C_{29}H_{48}O_3$: C, 78.33; H, 10.88%. IR (KBr disk): 1765 ($\nu_{C=O}$), 1743 ($\nu_{C=O}$) and 1224 cm^{-1} (ν_{C-O-C}); ORD in dioxane (*c* 1.00) at 18°, $[\alpha]_{589}$ +8.0°, $[\alpha]_{400}$ +8.0°, $[\alpha]_{308}$ −195.0°, $[\alpha]_{285}$ +205.0°; NMR δ: 5.24 (one proton, quartet) (=C_2H–OAc), 2.15 (three protons, singlet) (C_2–OOCCH_3).

By treating a mixture of methyl 4β-bromo-3-ketocholanate (2 g.), potassium acetate (11 g.) and acetic acid (55 ml.) as described above, needles (1.3 g.), m. p. 168.5—170°C were obtained. Found: C, 72.68; H, 9.50. Calcd. for $C_{27}H_{42}O_5$: C, 72.61; H, 9.48%. IR (KBr disk): 1750 ($\nu_{C=O}$), 1722 ($\nu_{C=O}$), 1227 (ν_{C-O-C}), 1150 cm^{-1} (ν_{C-O-C}); ORD in dioxane at 19°: $[\alpha]_{589}$ +5.5°, $[\alpha]_{380}$ +9.0, $[\alpha]_{309}$ −190.0°, $[\alpha]_{285}$ +230.0°; NMR δ: 5.24 (one proton, quartet) (=C_2H–OAc), 3.68 (three protons, singlet) (C_{23}–COOCH_3), 2.15 (three protons, singlet) (C_2–OOCCH_3).

Both products of this reaction are 2β-acetoxy-3-keto-5β-steroids, not 4-substituted isomers. This has been confirmed by the signs of the Cotton effect and its specific rotations in ORD, and by the patterns of the splitting and its coupling constants in NMR spectra (Fig. 1).[1,2]

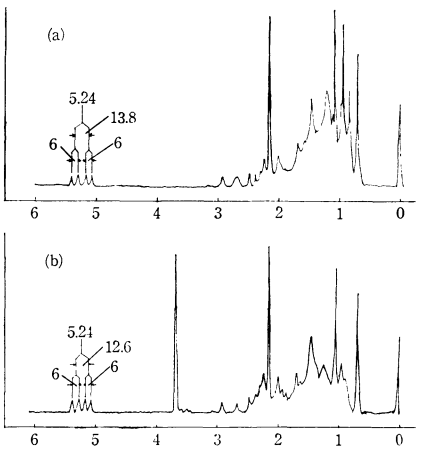

Fig. 1. Nuclear magnetic resonance spectra.
(a) 2β-Acetoxy-5β-cholestan-3-one
(b) Methyl 2β-acetoxy-3-ketocholanate

We may conclude that the substitution reaction of 4β-Br in 3-keto-5β-steroids with potassium acetate is accompanied by the rearrangement of C_4 to C_2.

This result is contrary to that reported by Fieser and Romero concerning the C_2—C_4 rearrangement of 2α-bromo-5α-chloestan-3-one with potassium acetate.[3]

Further details will be published later.

Medium-sized Cyclophanes. II. The Stereoselective Synthesis and Optical Resolution of 4, 14-Dimethyl[2.2]metacyclophane[1]

By Takeo SATO,† Sadatoshi AKABORI,† Masatsune KAINOSHO†† and Kazuo HATA†

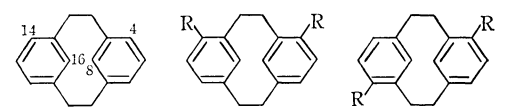
†*Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo*

††*The Ajinomoto Co., Ltd., Kawasaki*

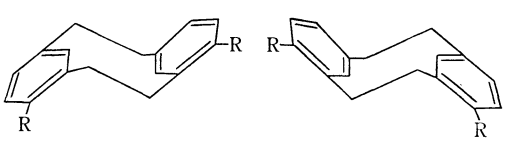
(Received January 25, 1966)

Among the medium-sized ring compounds, [2.2]metacyclophane (I) is unique in that it represents one of the few examples in which the conformations have been elucidated by X-ray measurements.[2] It has a step-like structure, containing two distorted benzene rings arranged in two parallel planes. The structural features of compound I have also been shown to be reflected in the NMR spectra.[3] In addition to an AB_2-type absorption of aryl protons at δ 7.18 and 6.97, a triplet appeared at δ 4.23; it is assignable to the intraannular aryl protons at C_8 and C_{16}, which are shifted to a higher magnetic field as they are extended over the ring current of the opposite benzene rings. An A_2B_2-type absorption centered at δ 2.55 indicates the presence of non-equivalent methylene protons. Since the ten-membered ring in compound I exists in a chair conformation, it is quite natural to assign these to axial and equatrial protons.

Our interest in the possible inversion of compound I prompted us to study the high-temperature NMR spectra. The spectra determined at 67 (in CCl_4), 126 and 190°C (both in hexachloro-1, 3-butadiene) were compared with those taken at room temperature and at a low temperature (ca. −80°C). It was not possible, however, to find any appreciable temperature dependence in the spectra. Especially, the A_2B_2 absorption was surprisingly held unchanged throughout the range of the temperature studied, indicating that the molecule is frozen in the chair conformation (e. g., IIa, b: R=H).



I II III



IIa IIb

These results were taken as an indication that there is a substantial conformational barrier between the inverted isomers. It is, then, to be expected that suitably-substituted cyclophanes, such as II, would become optically resolvable, IIa and IIb being the optical antipodes. The Wurtz reaction of 2, 4-bis(chloromethyl)toluene using disodium tetraphenylethane as a condensing agent in tetrahydrofuran afforded 4, 14-dimethyl-[2.2]metacyclophane, m. p. 68—69°C (Found: C, 91.34; H, 8.34%; mol. wt., 235 in a 21% yield. High-dilution conditions were realized by the combination of a slow addition (68 hr.) and a low reaction temperature (−60—70°C). The generation of the metacyclophane structure was confirmed by the NMR spectra, which consisted of four sets of absorption and which were consistent with the structure II (R=CH_3); an AB-type absorption of aryl protons at δ 6.90, a doublet for intraannular aryl protons at δ 4.18, A_2B_2 patterns centered around δ 2.43, and a singlet for the methyl group at δ 2.31.

The preferential formation of the II-type compound over the III-type compound, which should be the *meso* compound, due to the extremely mild reaction conditions used, was also encountered in the preparation of the methoxyl analog. By the coupling reaction described above, 2, 4-bis-(chloromethyl)anisole afforded compound II (R=OCH_3), m. p. 132—134°C (Found: C, 80.65; H, 7.45%; mol. wt., 260, as a major product, together with a small amount of a higher melting isomer, possibly II (R=OCH_3), m. p. 182°C (Mol. wt. Found: 278). The structure was determined by a comparison of the NMR spectra of methylene signals.

The optical resolution of compound II (R=CH_3) was achieved by using (−)-α-(2, 4, 5, 7-tetranitro-9-fluorenylideneaminooxy)-propionic acid[4] as a complex-forming reagent. A levorotatory isomer, $[\alpha]_{578}^{26}$ −3.4, and a dextrorotatory isomer, $[\alpha]_{578}^{26}$ +4.2 (ethanol), both with identical infrared spectra with a racemic compound, were obtained by the liberation of hydrocarbon by passing through an alumina column.

A Delayed Excimer Fluorescence of Acriflavine Stretched PVA Sheet

By Masao SATO, Tohru AZUMI and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received January 29, 1966)

A delayed excimer fluorescence of (the excimer fluorescence of long-lived) acriflavine has been observed. Acriflavine, absorbed into a stretched polyvinylalcohol (PVA) sheet, was irradiated by a high-pressure xenon lamp; the long-lived emission was then observed by means of a Shimadzu spectrograph. At a dilute concentration, the long-lived emission is composed of α-phosphorescence and β-phosphorescence.[1] At a high concentration, a new, previously-unobserved band arises about 1400 cm^{-1} to the red of the α-phosphorescence; this band increases in intensity as the concentration increases. (See Fig. 1.) The absorption spectra of these samples as recorded by a Hitachi EPU-2 absorption spectrometer exhibit no change in spectral distribution. On this ground, the newly-observed long-lived emission may be ascribed to an excimer species.

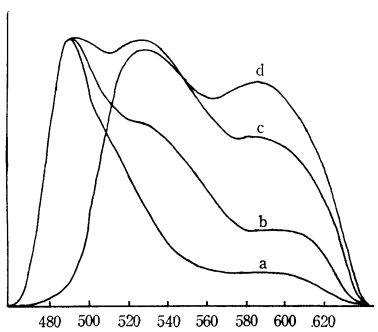

Fig. 1. Microphotometer tracings of the long-lived emission of acriflavine in streched PVA sheets. Samples were prepared by immersing PVA sheets in solutions of acriflavine at concentrations of: a: 5×10^{-5}; b: 9×10^{-5}; c: 4.6×10^{-3}; 10^{-2} mol./l. The ordinates are approximately normalized.

A long-lived excimer fluorescence has previously been observed for a limited number of polyacenes in liquid solutions[2,3] and in solid solutions.[4] In all the cases investigated, the delay of the emission has been ascribed to triplet-triplet annihilation. In the present case, however, the delayed excimer fluorescence is interpreted to be the excimer α-phosphorescence, consisting of thermal excitation from the triplet state to the excimer state followed by emission. The mechanism can be represented by the following reaction scheme:

$$S_0 + S_1 \rightleftarrows E \rightarrow 2S_0 + \text{(excimer fluorescence)}$$
$$\downarrow \quad T_1 \rightarrow S_0 + \text{(phosphorescence)}$$
$$S_0 + \text{(fluorescence)}$$

where S_0 and S_1 are, respectively, the ground state and the first-excited singlet state, and where T_1 is the lowest triplet state. The parentheses indicate that there are both radiative and radiationless transitions. No distinction is made between the triplet state of the monomer and that of the excimer, since the exciton band width of the triplet state may very well be equated with zero. According to this reaction scheme, the Arrhenius plots of ϕ_f/ϕ_p and ϕ_e/ϕ_p should yield the activation energies for the $T_1\rightarrow S_1$ and $T_1\rightarrow E$ processes, respectively, where ϕ_f, ϕ_p, and ϕ_e are the quantum yields of the monomer α-phosphorescence, the β-phosphorescence, and the delayed excimer fluorescence, respectively. The experiments were performed between -20°C and -44°C; the activation energies obtained were 10 and 4.5 kcal./mol. for the $T_1\rightarrow S_1$ and $T_1\rightarrow E$ processes, respectively. These values are in agreement with the energy differences of the corresponding peaks of emission spectra. These kinetic treatments substantiate the above identification of the newly-observed band is being the excimer α-phosphorescence.

The fact that the spectrum of dimeric species is observed in a stretched PVA sheet is another point of interest. This will facilitate the polarization measurements of dimeric species, which has not hitherto been attempted.

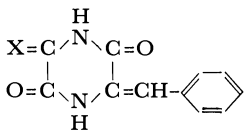
The Synthesis of 3-Isopropylidene-2, 5-dioxopiperazines

By Chung-gi SHIN, Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received February 16, 1966)

Albonoursin, isolated from the culture filtrates of Streptomyces noursei and Streptmyces albus var. fungatus, has been concluded to be 3-benzylidene-6-isobutylidene-2, 5-dioxopiperazine (I) by Khokhlov et al.,[1] Vondráček et al.,[2] and Brown et al.[3]



X: CH_3>CH_3>CHCH= (I)

CH_3>CH_3>C= (II)

Dioxopiperazine has been known to condense with aromatic aldehyde in the presence of acetic anhydride and sodium acetate, yielding mono- or di-benzylidene derivatives.[4,5] However, the synthesis of 3-alkylidene or 3, 6-dialkylidene derivatives of dioxopiperazine has never been reported.

In connection with a program directed toward a total synthesis of albonoursin, we have sought a method of synthesizing of 3-alkylidene dioxopiperazine. We wish to report in the present paper a synthesis of 3-isopropylidene dioxopiperazine and a homolog of albonoursin, 3-benzylidene-6-isopropylidene-2, 5-dioxopiperazine (II) by a new method.

Methyl α-amino-β, β-dimethylacrylate (III), obtained by the reduction of the corresponding nitro compound, was treated in an aqueous solution of sodium bicarbonate with phthaloylglycyl chloride; it thus gave methyl α-phthaloylglycylamino-β, β-dimethyl acrylate (IV) as colorless needles with a m. p. of 234—235°C in a quantitative yield (Found: C, 60.50; H, 5.38; N, 8.95. Calcd. for $C_{16}H_{16}N_2O_5$: C, 60.75; H, 5.10; N, 8.86%). The hydrolysis of IV with 1 N sodium hydroxide afforded α-phthaloylglycylamino-β, β-dimethyl acrylic acid (V) in a 31.8% yield, colorless fibrous needles from methanol, m. p. 258—259°C (decomp.) (Found: C, 59.21; H, 4.82; N, 9.44. Calcd. for $C_{15}H_{14}N_2O_5$: C, 59.60; H, 4.67; N, 9.27%). By treatment with hydrazine hydrate, V was converted into α-glycylamino-β, β-dimethylacrylic acid (VI) in an almost quantitative yield, colorless prisms with a m. p. of 232—234°C (decomp.) from a 50% aqueous ethanol (Found: C, 49.05 H, 7.09; N, 16.31. Calcd. for $C_7H_{12}N_2O_3$: C, 48.83; H, 7.03; N, 16.27%), which was then esterified with methanol - hydrogen chloride to give the corresponding methyl ester hydrochloride (VII) as colorless prisms with a m. p. of 178—180°C (Found: N, 12.58. Calcd. for $C_8H_{14}N_2O_3 \cdot HCl$: N, 12.58%).

When VII was heated with an aqueous solution of an equivalent mole of sodium bicarbonate on a boiling water bath for 30 min., a cyclization reaction occured and 3-isopropylidene-2, 5-dioxopiperazine (VIII) was obtained in a 70% yield. Recrystallization form boiling water afforded colorless prismatic needles with a m. p. of 260—261°C (decomp.) (Found: C, 54.52; H, 6.83; N, 18.16. Calcd. for $C_7H_{10}N_2O_2$: C, 54.53; H, 6.54; N, 18.17%), λ_{max}^{EtOH} 230 mμ (ε=22800), 240 mμ (ε=23000), ν_{max}^{KBr} 3200, 3050, 1680, 1665 and 1625 cm^{-1}. VIII was also obtained in a 54% yield by heating IV with hydrazine hydrate in a small amount of methanol.

The condensation reaction of VIII with benzaldehyde was carried out by heating it in acetic anhydride in the presence of sodium acetate at 120—130°C for 8 hr.; II was thus obtained in a 77% yield. Recrystallization from boiling acetic acid afforded colorless needles with a m. p. of 283—284°C (decomp.) (Found: C, 69.45; H, 5.72; N, 11.81. Calcd. for $C_{14}H_{14}N_2O_2$: C, 69.40; H, 5.83; N, 11.56%), λ_{max}^{DMF} 321 mμ (ε=21600), ν_{max}^{KBr} 3250, 3050, 1680 and 1635 cm^{-1}. These data of the ultraviolet and infrared absorption spectra are very similar to those of albonoursin.

III was heated in a sealed tube at 180—190°C for 48 hr.[6] to yield 3, 6-diisopropylidene-2, 5-dioxopiperazine in a 27% yield, colorless needles with a m. p. of 264—265°C (decomp.) (Found: N, 14.43. Calcd. for $C_{10}H_{14}N_2O_2$: N, 14.42%).

The details of the present communication and the methods of preparing the starting meterials will be described shortly in a further publication.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 859—863 (1966)

Effects of Pressure on the Chemical Properties of the Solid Surface. III. The Catalytic Activity and the Structure of the Compressed Tungstic Acid

By Yoshisada OGINO, Takeshi KAWAKAMI and Toru MATSUOKA

Department of Chemical Engineering, Faculty of Engineering, Tohoku University, Sakura-koji,, Sendai

(Received May 14, 1965)

In order to investigate the surface properties of tungstic acid samples which had been compressed at pressures of 640—3840 kg./cm^2, experimental studies concerning the catalytic activity for the vapor-phase hydration of propylene, the specific surface area, the pore structures, the surface acidities and the crystal structures were carried out. According to the experimental results, both the catalytic activity and the surface acidity became higher as the compressing pressure of the sample was increased, whereas the specific surface area remained practically constant. Further, a relation between the surface acidity and the crystal structure was deduced from X-ray diffraction studies. Namely, the crystal structure of the reduced sample approached the structure of $H_{0.1}WO_3$ from a WO_3-like structure as the compressing pressure was increased. In other words, samples with higher compressing pressures had crystal structures of a higher proton content. In addition to the above results, the total pore volume, the mean pore radius, the apparent activation energy, and the frequency factor became smaller as the compressing pressure was increased. On the basis of these experimental results, it was deduced that the catalytic activities of the compressed samples are affected by intra-particle diffusion.

The previous works[1,2] in this series have shown the special effects of pressures on the surface acidity of several metal sulfates. Further, by the use of potassium bisulfate as a sample it has been revealed that both acid strength distributions and catalytic acitvities varied with the degree of compression. These findings seem to suggest that the surface properties of other substances might be altered by manipulating the compression; this might then be a useful procedure for improving catalytic activities.

In the present research, tungstic acid was used as the sample material in order to test the surface property and the structure in the compressed state. In testing the catalytic activity, the yields of isopropanol from water and propylene were measured. The surface acidity was measured by a conventional indicator method. Information about pore structures and crystal structures in the compressed state was also obtained. This paper will present the detailed results of the present work; these results will demonstrate the actual occurrence of the anitcipated effect.

Experimental

The Preparation of the Sample.—Powders of commercial tungstic acid were packed into the sample space of the apparatus shown in Fig. 1. Then the apparatus was sandwiched between the stationary bed and the moving bed of an oil press, by which means a desired amount of load was applied on the piston head for 10 min. period. Thus cylindrical pellets of 4×4 mm. were prepared. The compacting pressures,

2) Y. Ogino, T. Kawakami and K. Tsurumi, ibid., to be published.

which were estimated by a conventional means of calculation,[1] were 640, 1280, 1920, 2560, 3200 and 3840 kg./cm^2.

Catalytic Activity.—The vapor-phase hydration of propylene over 5 ml. of sample pellets was carried out with the apparatus shown in Fig. 2. Prior to the activity test, catalyst pellets were reduced during a 0.5 hr. period with a mixed vapor of water and propylene ($H_2O/C_3H_6=2.0$, S.V.$=4.8\times10^3$ hr^{-1}) at 200°C and 1 atm. After the reduction, the temperature of the catalyst bed was adjusted to a desired value, and, after the stationary state had been reached, liquid products were collected. Except for the temperature, the reaction conditions were the same as those of the reduction. The isopropanol content in the liquid products was determined by the gas chromatographic analysis.

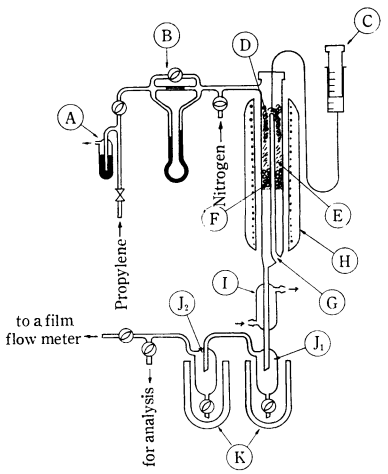

Fig. 2. The apparatus for the activity test.
A: Buffer, B: Flow meter, C: Water injector, D: Glass wool, E: Copper granules, F: Catalysts, G: Thermo-couple well, H: Electric furnace, I: Condenser, J_1, J_2: Separators, K: Ice bath

The conversion (x%) of propylene to isopropanol was evaluated from simple material-balance considerations based on the assumptions that no side reaction occurs and that the vapors of water and isopropanol are completely condensed in the separator.

After the activity test, the residual propylene was purged from the catalyst bed by the water vapor; then dry nitrogen was passed through the bed untill the reactor was cooled to room tmperature. The catalyst pellets which were taken out from the reactor were stored in an evacuated ampule.*

Surface Area, Pore Volume, Pore Radius and Particle Diameter.—The specific surface area (S, m^2./g.) was measured by means of a B. E. T. adsorption isotherm with n-butane at 0°C. The mercury displacement valume (V_{Hg}, ml./g.), as well as the water displacement volume (V_w, ml./g.), were also measured by a simple pycnometric method.[3] The difference between these volumes, $V_{Hg}-V_w$, was defined as the total pore volume (V_g, ml./g.) of the sample pellet.

The mean pore radius, $\bar{r}$, was evaluated by Eq. 1[4]

$$\bar{r} = 2V_g/S \quad (1)$$

while the mean particle diameter, $\bar{d}$, was evaluated by Eq. 2

$$\bar{d} = 6V_w/S \quad (2)$$

All the experiments described in this section were carried out with the reduced sample.

Surface Acidity.—Pellets of the reduced sample were pulverized and dried for 6 hr. in a desiccator; immediately after the drying, the surface acidity of the powder was measured. Essentially the same method as that of Benesi[5] was adopted in this measurement. Since the blue color of the sample powder masks that of the indicator adsorbed on the sample surface, a given weight (W, g.) of silica-alumina powder of a known acidity (A_0, mmol./g.) was mixed with the sample, and the total quantity of n-butylamine (A, mmol.) needed to neutralize the acid on the mixture was determined. Then, the surface acidity (A_s, mmol./g.) of the sample powder was evaluated by Eq. 3

$$A_s = (A-A_0W)/W_s \quad (3)$$

where W_s is the weight of the sample powder.

In the present work, three indicators, i. e., p-dimethylaminoazobenzene ($pK_a=3.3$), benzeneazodiphenylamine ($pK_a=1.5$) and dicinnamalacetone ($pK_a=-3.0$), were used.

Crystal Structure.—Powder X-ray diffraction patterns of the reduced sample as well as of the unreduced sample were obtained with an X-ray diffractometer. The Cu$K\alpha$ radiation (Ni filter) at 30 kV. and at 15 mamp. was adopted.

Results

Catalytic Activity.—The relations between the conversion of propylene to isopropanol per unit weight of the catalyst pellet and the reaction temperature are given in Fig. 3. As may be seen in this figure, the conversion increases with the compacting pressure of the catalyst.

Surface Area, Pore Structure.—The values of the specific surface area of the compressed samples (reduced samples) are given in Table I. In the

Table I. Specific surface areas of compressed samples

Compacting psess., kg./cm^2	640	1920	3200	3840
Surface area, m^2/g.	21.5	23.7	21.8	22.6

table, no systematic dependency of the surface area upon the compacting pressure can be seen, and the surface area seems to be roughly constant.

In Fig. 4, the total pore volume, the mean pore radius and the mean particle diameter are given as functions of the compacting pressure. It may be seen that the pore volume and the pore radius decrease with the compacting pressure, while the mean particle diameter stays at a constant

* In this paper, samples which were treated in this manner will be called reduced samples.

level.

Surface Acidity.—The relations between the compacting pressure and the surface acidity at various H_0 values[6] are given in Fig. 5. As may be seen in this figure, the surface acidity increases with the compacting pressure.

Crystal Structure.—The powder X-ray diffraction patterns of reduced samples compressed at different pressures are given in Fig. 6(a)—(c). These patterns are supplemented by Miller's notations of WO_3 and $H_{0.1}WO_3$.[7] They show

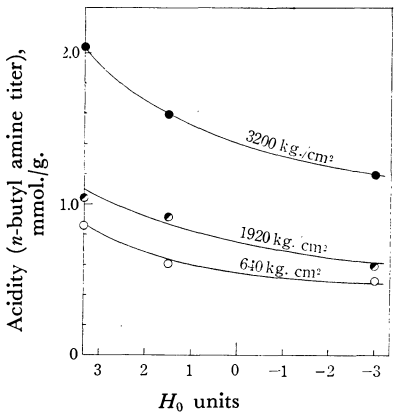

Fig. 5. Variations of the surface acidity on compression.

that, at the lower compacting pressure, the crystal structure of the sample closely approximates the structure of WO_3, while at the higher compacting pressure it approximates the structure of $H_{0.1}WO_3$.

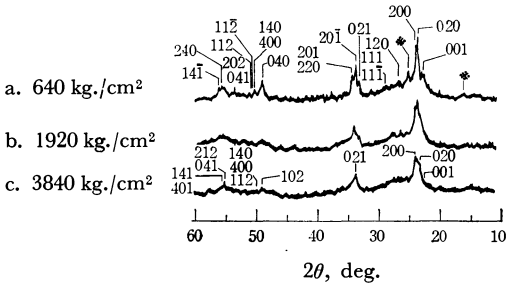

Fig. 6. X-ray diffraction patterns of reduced samples, together with Miller's notations for WO_3 (a) and $H_{0.1}WO_3$ (c).
The symbol * in (a) indicates residual peaks of H_2WO_4.

On the contrary, few changes due to the compression were observed in the X-ray diffraction patterns of unreduced samples.

Discussion

Catalytic Activity and Surface Acidity.—One of the most important results obtained in the present work may be the fact that the catalytic activity of tungstic acid can be increased by the compression of the catalyst (cf. Fig. 3). From this fact, it may be said that the effect of compression suggested in the previous paper has actually appeared.

The activity increase on compression might be due to the increase in the surface acidity. It is well known[8] that the hydration of propylene is catalyzed by acidic solids, and that increases

6) L. P. Hammett and A. J. Deyrup, *J. Am. Chem. Soc.*, **54**, 2721 (1932).

in the surface acidity make the catalyst more active. Therefore, from Fig. 5, which shows the acidity increase on compression, the increase in the catalytic activity can be understood.

Further effects of the compression on the catalytic activity were revealed by analyzing the conversion-temperature relationship with a rate equation which had been derived by one of the present authors[9] under the assumption that the rate-controlling step is a surface reaction on a sparsely-covered surface. The results of the analysis are given in Fig. 7 and Table II. These results show

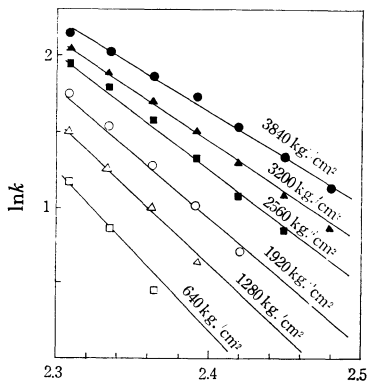

Fig. 7. Arrhenius plots.

TABLE II. FREQUENCY FACTORS AND APPARENT ACTIVATION ENERGIES FOR VARIOUS CATALYSTS COMPRESSED AT DIFFERENT PRESSURES

Compacting pressure kg./cm²	Frequency factor* ml./hr.g.-cat.	Activation energy kcal./mol.
640	1.39×10^{11}	21.2
1280	1.22×10^{10}	18.6
2560	2.88×10^{8}	15.1
3200	4.14×10^{7}	13.3
3840	1.02×10^{7}	12.1

* The rate constant whose frequency factor is given in this table was defined by the following equation

$$k=(273\boldsymbol{R}C_{\mathrm{m}}P^2/1\ \mathrm{atm.})\{(m)/(1+n+m)^2\}k_0$$

where R is gas constant, C_{m} is the mean compressibility factor of the mixed vapor at the standard state (N. T. P.), $m=C_3H_6/H_2O$ (mole ratio), $n=$inert gas/H_2O (mole ratio) and k_0 is the rate constant defined by the following rate equation

$$r(\text{rate of reaction, mol./hr. g.-cat.})=k_0p_{H_2O}p_{C_3H_6}-k_*p_{C_3H_7OH}$$

where k_* is the rate constant of the reverse reaction.

that both the frequency factor of the rate constant and the apparent activation energy were decreased by the compression. In other words, the so-called compensation effect holds among the activities of catalysts compressed at different pressures. This shows that the effect of compression on the catalytic activity is not a simple one.

At first sight, it seems possible to explain the compensation effect on the basis of the theory[10] of the inhomogeneity in active centers. Since the experimental results indicated in Fig. 5 showed the existence of acid centers of different strength, if it is assumed that all acid centers are effective as active centers, the theory might be applicable. However, it has previously been shown[9] that the rate of the hydration of propylene is nearly proportional to the acidity of a limited strength. Therefore, the application of the theory upon the basis of the present data is inadequate.

The Catalytic Activity and Pore Structure. —The interferences of the intra-particle diffusion of reactants and products with the intrinsic activity, which is considered to be dependent purely on the surface acidity, seem to be a cause of the compensation effect. Generally, the interference becomes more evident when the intrinsic activity is higher and when the pore radius is smaller. The experimental results show the higher surface acidity and the smaller pore radius at the higher compacting pressure. Therefore, when a highly-compressed catalyst is used for the activity test, retardations due to the diffusion process should be serious in the over-all reaction process. Further, the size of the catalyst pellet used in the present work was quite large, i. e., 4×4 mm. This would enhance the retardation. Thus, the low activation energy and the low frequency factor, both of which were found when a highly-compressed catalyst was used, might be attributed to the low activation energy of the diffusion process and to the retardation due to the diffusion respectively.

According to the explanation presented above of the compensation effect, it is necessary to consider that both the surface reaction and the intra-particle diffusion control the rate of the over-all reaction. Usually, in such cases, the experimental rate constant, k_{exp}, is regarded as a product of the true rate constant, k_{t}, and the effectiveness factor, E_{f}. Although details of the pore structure of the sample are not yet clear and although a rigorous evaluation of E_{f} is not possible, a rough estimation under suitable assumptions showed that the E_{f} value for the catalyst compressed at 3840 kg./cm² is about 0.8* at 435°K. This shows that the effect of the intra-particle diffusion on the over-all reaction is considerable. Further, if it is assumed that, at the lowest reaction temperature, the reaction is purely kinetic, the activation energy for the catalyst compressed at 3840 kg./cm² is corrected to 16 kcal./mol. Although this

9) Y. Ogino, *J. Catalysis Soc. Japan* (Shokubai), **4**, 73 (1962).

10) S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Process," McGraw-Hill Book Company, New York and London (1941) p. 394.

value of activation energy is yet lower than the value for the catalyst compressed at a lower pressure, e. g., 640 kg./cm^2, the simple consideration described above seems sufficient to show that, if the pore structure of the compressed sample is clarified and the effect of intra-particle diffusion is correctly taken into account, the observed compensation effect might be explained.

Crystal Structure. — Among many works concerning the crystal structure of the reduced tungsten oxide, the work of Glemser[11] seems to contain much information relevant to the present work. Glemser observed that the reduction of WO_3 with atomic hydrogen resulted in a systematic change in the crystal structure. Namely, the crystal structure of H_xWO_3, which is the formula employed to express the composition of the reduced tungsten oxide, was varied by the reduction from the skewed structure of WO_3 (monoclinic) to the symmetrical structure of $H_{0.5}WO_3$ (cubic) by way of $H_{0.1}WO_3$ (orthorhombic) and $H_{0.33}WO_3$ (tetragonal). These results were explained by him as follows. Namely, hydrogen atoms in the crystal of H_xWO_3 are protonized; the contrapolarization effect of these protons then releases repulsions among oxygen ions in the crystal, and, as a consequence of this release, a closer packing of oxygen ions in the crystal becomes possible.

The experimental results obtained in the present work seem to be consistent with the results of Glemser. The acidity increase, which was thought to be the main cause of the activity increase on compression, seems to be related to the change in the crystal structure of the reduced tungstic acid. In the present work, it was found that the crystal structure of the reduced sample was transformed from a WO_3-like structure to a $H_{0.1}WO_3$-like structure by the compression. Therefore, the sample would contain many more protons in the highly-compressed state than in the less-compressed one. Further, the surface-area measurement showed that, irrespective of the compacting pressure, the surface area remained constant. Therefore, the probability of the appearance of protons on the surface of the sample might be higher in the highly-compressed state than in the less-compressed state. Thus, the acidity increase on compression can be understood.

The observed effect of the compression on the crystal structure might be attributed mainly to pressures.* According to high-pressure chemistry,[12] some orderings resulting from compression can be expected in microscopic structures of substances. By applying this principle to the present case, it might be expected that pressures would make some contributions to the progress of the following reactions:

$$H_2WO_4 \rightarrow WO_3 + H_2O \qquad (I)$$

$$WO_3 \xrightarrow{+H} H_{0.1}WO_3 \xrightarrow{+H} H_{0.33}WO_3 \xrightarrow{+H} H_{0.5}WO_3 \qquad (II)$$

(A loose packing of oxygen ions→ A closer packing of oxygen ions)

Indications showing the occurrence of some of these reactions have appeared in X-ray diffraction patterns of reduced samples, while they have not appeared in the patterns of unreduced samples.

These results seem to show that, in addition to the compression, the subsequent reduction of the sample was a necessary condition for the occurrence of those reactions. This is reasonable, because the progress of the reaction II may be assumed to require some proton donors. Further, the incomplete progress of the reaction II, i. e., the occurrence of the reaction $WO_3 \rightarrow H_{0.1}WO_3$ only, may be attributed mainly to the existence of water in the reducing vapor (propylene and water). According to the work of Glemser et al.,[7] highly-reduced oxides of tungsten, e. g., $H_{0.5}WO_3$ are oxidized very easily by water.

Summary

It has been established that the compression of tungstic acid is effective in increasing the catalytic activity in the vapor-phase hydration of propylene. The activity increase on compression is thought to be dependent upon the acidity increase resulting from the compression. The increase in the surface acidity has been attributed to the change in the crystal structure. Namely, it is thought that the compression and the subsequent reduction of the catalyst force the crystal structure to transform from a WO_3-like structure to a $H_{0.1}WO_3$-like structure, which is capable of containing many protons and so giving the high surface acidity.

On the other hand, the increase in the compacting pressure resulted in a considerable decrease in the pore radius of the catalyst. This fact supports the explanation that the observed compensation effect among catalytic activities of compressed catalysts is due to the interference of the intra-particle diffusion with the intrinsic activity.

* The estimation was carried out by the method of Kubota et al. (*Chem. Eng., Japan* (Kagaku Kōgaku), **23**, 284 (1959).) under the following assumptions:

1. Since the conversion is low, reverse reaction can be neglected, and the concentration of the reactant approximates to the inlet value.
2. The diffusion coefficient of the reactant is approximated by the value of the Knudsen diffusion coefficient of propylene at 435°K.
3. The mean pore radius, $\bar{r}$, is 80 Å, and the porosity, θ, is 0.3.
4. The labyrinth factor, χ, for the uncompressed catalyst is 0.1, but by the compression of 3840 kg./cm^2 the value of χ is reduced to 0.01. (This assumption is based on the experimental result of D. van Zoonen et al. (*J. Inst. Petrol.*, **49**, 383 (1963)), who showed that, by the pelleting pressure, the diffusivity of the Co-Mo-Al_2O_3 is reduced to about 1/10 of the initial value.)

11) O. Glemser, *Angew. Chem.*, **73**, 785 (1961).

* The increase in temperature due to the compression was less than 5°C, which might have little influences on the surface property of the sample. In this measurement, a thermocouple was inserted directly into the sample.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 864—867 (1966)

A Phase Study of the Iron(III) Sulfate, Sodium Sulfate and Sodium Chloride System

By Kohzoh SUGIYAMA and Takehiko TAKAHASHI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received June 8, 1965)

A phase diagram was drawn by using the results of a differential thermal analysis of the samples sealed in vicolglass and X-ray diffraction techniques undertaken in connection with the study of chlorine formation by the reaction of sodium chloride with sulfur dioxide and oxygen in the presence of iron compounds. In the two-component sodium sulfate - iron(III) sulfate system, the eutectic point was found at 562°C, the peritectic point, at 780°C, and the peritectoid point, at about 380°C. The former two values differ from those found by K. A. Bol' shakov et al. (*Zhur. Neorg. Khim.*, **8**, 2577 (1963)). In the trigonal diagram, two eutectic points were found, one at 465°C with a composition of about 13.5 mol.% iron sulfate, 53.5 mol.% sodium chloride and 33.0 mol.% sodium sulfate, and the other at 454°C with 15.0 mol.% iron(III) sulfate on the line of sodium chloride - iron(III) sulfate. It was confirmed that the peritectic point corresponding to the $Fe_2(SO_4)_3+Na_2SO_4(l)=2NaFe(SO_4)_2$ reaction shifted from 780°C on the line of sodium sulfate - iron(III) sulfate to 680°C on that of sodium chloride - iron(III) sulfate. From the diagram, the retarding tendency of the reaction rate of the final period of chlorine formation was attributed to diffusion control coming from the formation of solid phases.

The formation reaction of chlorine represented by the equation $2NaCl+SO_2+O_2=Na_2SO_4+Cl_2$ has previously been studied by the authors of this paper.[1] It was observed that the presence of iron compounds extremely accelerated the reaction rate and easily converted the system into the melt. This paper will give information about the phase change as the reaction proceeds. The phase diagram of the titled system is also expected to give fundamental data on the deposits produced at the medium temperature range in an oil furnace.

The titled system is a half of the four-component system iron(III) sulfate - sodium sulfate - sodium chloride - iron(III) chloride, which must be considered in the above-mentioned formation reaction of chlorine.

In order to draw the phase diagram, the differential thermal analysis (DTA) was performed in sealed cells, as it was inevitable in open apparatus for the composition of samples to change spontaneously, as a result of the decomposition, to form sulfur dioxide, sulfur trioxide and chlorine at temperatures above 600°C.

Apparatus and Experimental Methods

Reagents.—Chemically-pure sodium sulfate and sodium chloride were used after drying, while iron(III) sulfate was prepared from chemically-pure $Fe_2(SO_4)_3 \cdot xH_2O \cdot yH_2SO_4$ by double drying processes; the first process involved drying at 180°C for two or three hours in an open vessel, and the second, drying at 450°C for an hour in a test tube, in which the dead space over the reagent was made as small as possible. The composition of the reagent prepared by these methods corresponded to $Fe_2(SO_4)_3 \cdot 0.016Fe_2O_3$, and the X-ray diffraction pattern accorded with that in the literature.[2] The DTA cells were made of vicolglass; they were 40 mm. long, 4.7 mm. in inner diameter, and 0.7 mm. thick. Alumel-chromel thermocouples were used for the measurement of the differential temperature, and alumina powder was used as the standard substance. The temperature scale was calibrated at three points: the melting point of sodium chloride (801°C), the α, β transition point of potassium sulfate (583°C), and the transition point of silver chloride from $\alpha+\beta$ to γ (143°C). The ascending and descending speeds of the temperature were adjusted to 3°C per min. by the use of a photoelectric programmer. Generally, the first ascending curves were abandoned, and after holding at 900°C for an hour, the descending curves were recorded. From the temperatures under 150°C, the ascending curves were recorded again. Some samples which had the composition of iron(III) sulfate above 40 mol.% were heated up to 1000°C on account of their hard melting properties.

The compositions of samples were selected on the lines of 0, 3.3, 6.6, 10, 15, 20, 30, 40 and 50 mol.% iron(III) sulfate in the triangular diagram; these lines are close enough in composition that the nearest two compositions have difference of less than 10 mol.% for every component. Many samples were also taken up on the lines of sodium chloride - iron(III) sulfate and sodium sulfate - iron(III) sulfate.

The analysis of DTA was carried out as usual; the temperature of the phase change was decided by the point of intersection of the build-up tangent and the corresponding ground line. After the DTA measurements, the samples were analyzed to give X-ray diffraction diagrams by Co K_α at room temperature.

Results and Discussion

The Sodium Sulfate and Iron(III) Sulfate System.—From the results shown in Fig. 1, the eutectic point B is found to be 562°C at 17.5 mol.% of iron(III) sulfate. The peritectic point, DF, at which the $Fe_2(SO_4)_3+Na_2SO_4(l)=2NaFe\cdot(SO_4)_2$ reaction occurs, is about 780°C, and the peritectoid point, KMN, is also found to be about 380°C (here the $NaFe(SO_4)_2+Na_2SO_4(l)=Na_3Fe(SO_4)_3$ reaction occurs).

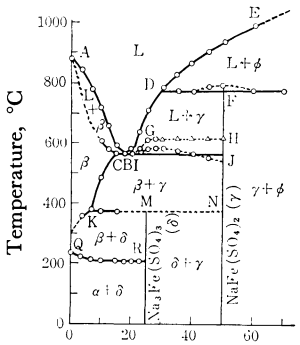

Fig. 1. The system Na_2SO_4-$Fe_2(SO_4)_3$.
GH and IJ lines refer to irreversible changes, and α, β refer to α and β sodium sulfate solid solutions respectively.

On the line of GH, the peaks of DTA curve were observable only in the run of ascending temperature, except for a few points near G. On the contrary, the peaks of the DTA curve on the line of IJ were observed only in the run of descending temperature, except for a few points near I.

According to Bol'shakov et al.,[3] who have reported on the same system, this system has the eutectic point at 620°C, the peritectic point at 680°C, the peritectoid point at 420°C, and the α, β transition point of a sodium sulfate solid solution at 220—228°C. Considerable discrepancies are found between Bol'shakov's results and those of the present paper. Though little description of the apparatus and experimental methods appeared in Bol'shakov's report, it is likely that the discrepancies arise from the dependence of the phase transition temperature on the pressure in the present experiment, or from the change in the composition of the sample on account of the decomposition in Bol'shakov's experiment.

In Fig. 2, the X-ray diffraction diagrams of the sodium sulfate - iron(III) sulfate system are drawn. The patterns of tri-sodium iron(III) tri-sulfate are found above 6.6 mol.% iron(III) sulfate; they increase in intensity up to 25 mol.%, above which the patterns of sodium iron(III) di-sulfate gradually increase to 50 mol.% iron-(III) sulfate.

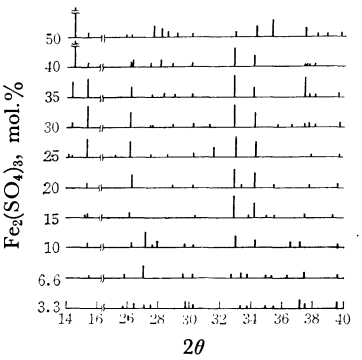

Fig. 2. X-ray diffraction diagrams of the system Na_2SO_4-$Fe_2(SO_4)_3$.

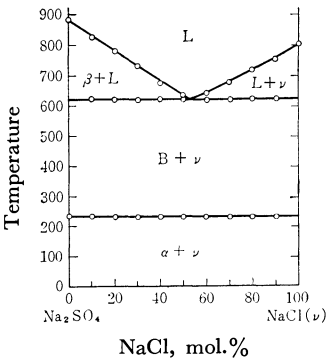

Fig. 3. The system Na_2SO_4-NaCl.

The Sodium Chloride and Sodium Sulfate System.—The phase diagram of this system, indicated in Fig. 3, is in good accordance with the results reported by Fedorov et al.[4]

The Inner Territory of the Sodium Sulfate, Sodium Chloride and Iron(III) Sulfate System.—To represent variations in temperature as well as in composition, the sectional diagrams, which are cut along various mol.%'s of iron(III) sulfate, are indicated in Figs. 4 to 10. The phase boundary between the phase containing β-sodium sulfate, tri-sodium iron(III) tri-sulfate and sodium chloride and the phase containing tri-sodium iron(III) tri-sulfate, sodium iron(III) di-sulfate and sodium chloride was determined from the peaks of the

α, β transition of sodium sulfate in DTA curves, as is shown in Figs. 4 to 6 by vertical dotted lines. The presence of iron(III) sulfate, tri-sodium iron-

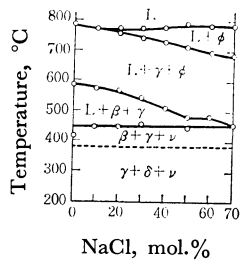

Fig. 8. Sectional diagram cut along the composition of 30 mol.% $Fe_2(SO_4)_3$.

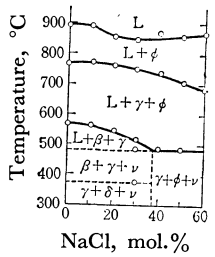

Fig. 9. Sectional diagram cut along the composition of 40 mol.% $Fe_2(SO_4)_3$.

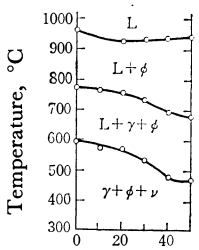

Fig. 10. Sectional diagram cut along the composition of 50 mol.% $Fe_2(SO_4)_3$.

(III) tri-sulfate and sodium iron(III) di-sulfate was detected by X-ray diffraction, in which the most distinct peaks by which to identify the respective compounds were found at 2θ values of 16.9°, 15.1° and 14.3° respectively.

From Figs. 7 to 10, it seems that the liquidus planes of the samples containing above 20 mol.% of iron(III) sulfate are influenced slightly by the variation in the mixing ratio of sodium sulfate and sodium chloride. The phase containing iron(III) sulfate is found over 30 mol.% of iron(III) sulfate at a high temperature and over 40 mol.% at room temperature, as is shown in Figs. 8 to 10. It may clearly be seen in Figs. 8 and 9 that the peritectic point, where the $Fe_2(SO_4)_3 + Na_2SO_4 = 2NaFe(SO_4)_2$ reaction occurs, varies from the sodium sulfate and iron(III) sulfate side to the sodium chloride and iron(III) sulfate side, and that the maximum temperature difference of the both sides reaches about 100°C.

The first solid phase which separates on cooling

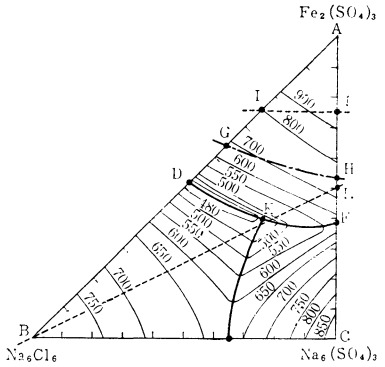

Fig. 11. Liquidus plane indicated by contour method.

is indicated by thick lines (DK, KF and KE) and a broken line (GH) in Fig. 11, in which the corners of the triangle are taken as 6 equivalent compounds—for example, Na_6Cl_6 instead of NaCl. The inner zone of AGH corresponds to the phase separating iron(III) sulfate first; GDKFH, to that separating sodium iron(III) di-sulfate; DBEK, to that separating sodium chloride, and EKFC, to that separating a β-sodium sulfate solid solution.

In Fig. 11, the dotted lines indicate the phase boundaries which are stable at room temperature; the inner zone of AJI corresponds to the phase containing sodium chloride, iron(III) sulfate and sodium iron(III) di-sulfate; IBHJ, to that containing sodium chloride, tri-sodium iron(III) tri-sulfate and sodium iron(III) di-sulfate; and LBC, to that containing sodium chloride, tri-sodium iron(III) tri-sulfate and α-sodium sulfate. The slender zone near the line of Na_6Cl_6 - $Fe_2(SO_4)_3$ is inferred to contain iron(III) chloride because of the stoichiometric discrepancy, but its presence could not be detected by DTA and X-ray diffraction.

In Fig. 11, the liquidus plane is also indicated by the method of the isothermal contour, and thick lines correspond to the ternary eutectic curves. It is found that the eutectic point, K, is 465°C, with a composition of about 13.5 mol.% iron(III) sulfate, 53.5 mol.% sodium chloride and 33 mol.% sodium sulfate. Another eutectic is also found at 454°C on the line of Na_6Cl_6-$Fe_2(SO_4)_3$, which has about 15 mol.% iron(III) sulfate. The characteristic low melting zone (450—490°C) distributes from the central region of the triangle to the Na_6Cl_6-$Fe_2(SO_4)_3$ line.

In the reaction of sodium chloride with sulfur dioxide, 20 to 40 wt.% pyrite was effectively added to sodium chloride in order to accelerate the reaction rate. When the composition containing 30 wt.% pyrite is considered, it corresponds to the liquidus point of about 660°C on the Na_6Cl_6-$Fe_2(SO_4)_3$ line in Fig. 11. In the course of the reaction, the composition will vary from the Na_6Cl_6-$Fe_2(SO_4)_3$ to the $Na_6(SO_4)_3$-$Fe_2(SO_4)_3$ line, parallel with the Na_6Cl_6-$Na_6(SO_4)_3$ line. If the temperature of the reaction is above 560°C, the whole system will be changed into the melt as the reaction proceeds. However, the system will have deposits of the β-sodium sulfate solid solution in the final step of the reaction if a temperature below 600°C is selected. These deposits of β-sodium sulfate are susceptible to interference with the diffusion of gas and liquid, as has been established by the previous data of the present authors.[1] On the other hand, the higher concentration of iron compounds will spread the attainable extent of the reaction, since the eutectic point of the $Na_6(SO_4)_3$-$Fe_2(SO_4)_3$ system is as low as 562°C. This is again supported by the previous results of the present authors.

As a whole, the state of the reaction system may be explained as being in close relation to the attainable extent and the velocity of the formation reaction of chlorine through the oxidation of sodium chloride and sulfur dioxide in the presence of iron compounds.

The authors wish to thank Mr. Katsuhiko Kitagawa for his assistance in the experimental work.

The Charge-transfer Complex and the Photochemical Reactions of Anthracene with Sulfur Dioxide in Various Solvents

By Toshikazu NAGAI, Kenichi TERAUCHI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Miyakojima-ku, Osaka

(Received June 26, 1965)

The equilibrium constant, K, of the 1 : 1 charge-transfer complex formation of anthracene with sulfur dioxide has been estimated by spectrophotometric measurements to be 0.33 in carbon tetrachloride at 15°C. The values of ΔH (-4.8 kcal.mol^{-1}) and $\Delta S°$ (-19 cal.deg^{-1}mol^{-1}) have been derived. The K value is nearly zero when estimated in the longer wavelength region, indicating that a contact charge-transfer complex is involved. A sort of contact charge-transfer complex of anthracene-SO_2 is also observed in benzene. Irradiations by a high-pressure mercury lamp of anthracene with sulfur dioxide in various solvents have been carried out. In solvents such as *n*-hexane and carbon tetrachloride, which have no interaction with sulfur dioxide, anthracene gives sulfur-containing substances, such as anthracene-9-sulfonic acid (I) and dianthranyl-(9.9')-sulfonic acid-(10) (II). On the contrary, in benzene or in carbon disulfide, no product such as the sulfonic acid, the dimer or the endoperoxide of anthracene is produced, indicating that the interaction of anthracene with sulfur dioxide is diminished by the solvent - sulfur dioxide interaction. A suggestion was made that the activated intermediate which induced the formation of I and II was of a singlet character.

Comprehensive studies have been made of the photochemical reactions of anthracene, especially of dimerization and oxidation in solutions.[1-3] According to these studies, in such hydrocarbon solvents as benzene and hexane anthracene affords its dimer through an excited singlet state ($^1A^*$), whereas in a heavy atom containing such solvents as carbon tetrachloride, chloroform and carbon disulfide, a transition from $^1A^*$ to ^3A (a triplet state) results in the formation of a cyclic endoperoxide in the presence of oxygen.

Such behavior of anthracene in various solvents has prompted the present authors to investigate the solvent effects of a photochemical reaction in the presence of sulfur dioxide, since the interaction of anthracene and sulfur dioxide has been the subject of considerable interest lately.[4,5]

Weiss[4] has concluded that the complex between anthracene and sulfur dioxide is an ion pair as the result of a complete electron transfer. Lichtin et al.,[5] however, have found that the complex in liquid sulfur dioxide is not a very good conductor, and no evidence has been provided for the ionic nature of the complex, either by conductometry or ultraviolet spectrometry.

In this paper, the electronic spectra of anthracene in various solvent systems involving liquid sulfur dioxide have been examined in order to obtain a greater understanding of the nature of the charge-transfer complex of anthracene - sulfur dioxide, our results will be discussed, together with the photochemical outcomes of the reaction of anthracene with sulfur dioxide in various solvents.

Experimental

Materials.—Liquid sulfur dioxide was dehydrated with phosphorus pentoxide and distilled. Carbon tetrachloride, benzene, *n*-hexane, and ethanol were purified by ordinary methods. A chromatographically-purified anthracene, m. p. 215—215.5°C, was used.

The Measurement of Electronic Spectra. — A Hitachi EPU 2 A-type spectrophotometer equipped with a thermostat was used. A pressure cell made of quartz was used to ensure the measurement in a sulfur dioxide solution; the width of the cell could be adjusted to 0.706 mm. by the insertion of a spacer. Lambert-Beer's law was satisfactorily obeyed throughout the range of the measurements.

The Calculation of the Equilibrium Constant of the Complex-Formation.—The Benesi-Hildebrand equation[6] was used for the estimation of the equilibrium constant.

Since the formation of the complex is shown as:

$$A + SO_2 \rightleftarrows A{\cdot}SO_2 \text{ (Complex)} \qquad (1)$$

the equilibrium constant can be expressed as:

$$K = \frac{[A{\cdot}SO_2]}{([A]_0-[A{\cdot}SO_2])([SO_2]_0-[A{\cdot}SO_2])} \qquad (2)$$

where $[A{\cdot}SO_2]$ = the molar concentration of the complex, $[A]_0-[A{\cdot}SO_2]$ = the molar concentration of free anthracene, and $[SO_2]_0-[A{\cdot}SO_2]$ = the mole fraction of

free sulfur dioxide. [A·SO_2] in the last term is expressed in terms of the mole fraction.

Under the experimental conditions,

$$[SO_2]_0 \gg [A\cdot SO_2]$$

and

$$[SO_2]_0 - [A\cdot SO_2] \fallingdotseq [SO_2]_0$$

The Benesi-Hildebrand equation is derived as:

$$\frac{l[A]_0}{D} = \frac{1}{\varepsilon_c \cdot K[SO_2]_0} + \frac{1}{\varepsilon_c} \qquad (3)$$

where ε_c, D and l are the molecular extinction coefficient of the complex, the optical density of the solution, and the light-path length of the cell respectively. A linear plot of $l[A]_0/D$ vs. $1/[SO_2]_0$ will give $1/\varepsilon_c \cdot K$ and $1/\varepsilon_c$ by the slope and the intercept of the line respectively. K can thus be estimated.

The Estimation of $\Delta G°$, ΔH and $\Delta S°$. — The thermodynamic values, $\Delta G°$ (free energy change), ΔH (enthalpy change), and $\Delta S°$ (entropy change), were calculated by the following relation:

$$R \ln K = \Delta S° - \frac{\Delta H}{T}$$

Apparatus.—The vessel used for the reaction is illustrated in Fig. 1.

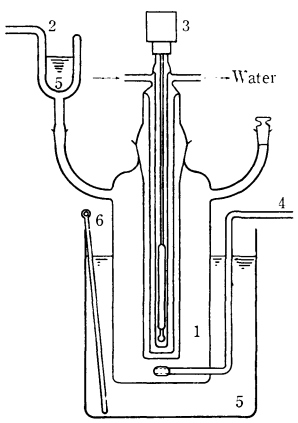

Fig. 1. Reaction vessel.

(1) reaction vessel, (2) cooler, (3) high pressure mercury lamp (which is equipped with double layered surrounding tubes made of quartz to be useful for low temperature experiment), (4) gas-inlet tube, (5) dry ice-trichloroethylene, (6) thermometer

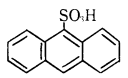
A reaction vessel (1), equipped with a dry ice cooler (2), a 300-Watt high-pressure mercury lamp (3) inside the vessel and an inlet tube for nitrogen or oxygen gas (4), was chilled with dry ice - triclene bath in a Dewar vessel (5) equipped with thermometer (6).

The Procedure of the Reaction.—Anthracene (0.11—1.5 g.) was dissolved in a solvent (liquid sulfur dioxide, carbon tetrachloride, benzene, *n*-hexane or ethanol) in the reaction vessel; then a measured amount of liquid sulfur dioxide was charged into this solution. The atmosphere in the vessel was replaced by pure nitrogen gas several times, under cooling with the dry ice - triclene bath, the temperature of the vessel being kept at −25°C. The mixture was then irradiated for a definite time (1.5—8 hr.) by the mercury lamp. After the reaction, the solvent and /or liquid sulfur dioxide was distilled, and the residue was triturated with ethanol.

The ethanol-soluble part was evacuated to dryness and extracted with benzene in order to remove the unreacted anthracene. The residual part was added and digested with alcoholic sodium hydroxide until the pH of the solution became 7. The precipitated sodium salt was filtered and dried; thus it was identified as the sodium salt of I.

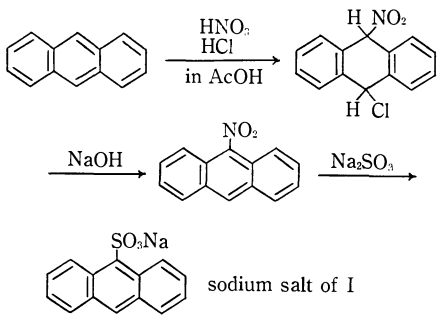
The ethanol-insoluble part was again extracted with benzene, since the extracts still contained some unreacted anthracene. The benzene-insoluble substance was in the form of dark brown crystals (II).

The Identification of the Products.—*Anthracene-9-sulfonic Acid (I).*—I was a hygroscopic substance containing sulfur; it was insoluble in a non-polar solvent



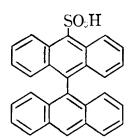
(I)

and soluble in methanol, ethanol and aqueous alkali, and it formed alkaline salts readily. The properties are coincident with the results described in the literature[7] for anthracene-9-sulfonic acid. IR (KBr disk), 3400 cm^{-1} (ν_{OH}), 1140—1220 cm^{-1} ($\nu_{as.SO_2}$ of SO_2OH) and 1040 cm^{-1} ($\nu_{s.SO_2}$ of SO_2OH). An authentic specimen was synthesized by the method of Minajew and Fedorow[8] by the following scheme:



The ultraviolet spectra of the sodium salt of I and the authentic sample in an aqueous solution were entirely superimposable upon each other: λ_{max} 256 ($\log \varepsilon$ = 4.61), 335 (3.12), 351 (3.37), 370 (3.55) and 390 mμ (3.52). The R value of the salt as determined by thin-layer chromatography (adsorbent, Wako-silica gel B-5, 0.63 mm., elution with water), R=0.56., was coincident with that of the authentic specimen.

Dianthranyl-(9.9)'-sulfonic Acid-(10) (II). — II had a m. p. above 300°C and was sparingly soluble in ordinary solvents. Its infrared spectrum was almost identical with that of anthracene-9-sulfonic acid.



(II)

8) W. Minajew and B. Fedorow, *Ber.*, **62**, 2489 (1929).

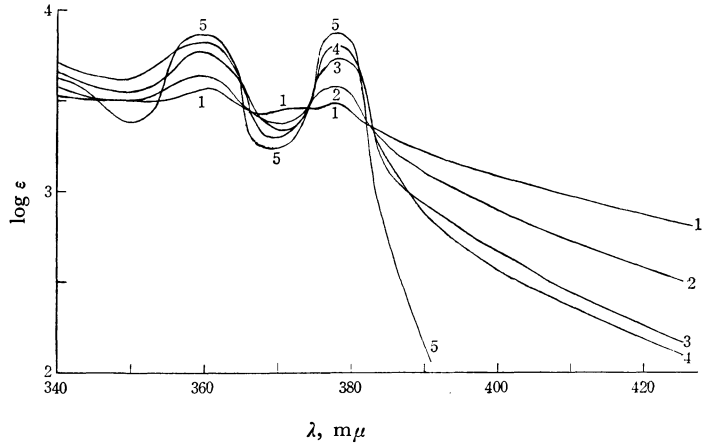

Fig. 2. The electronic spectra of anthracene, CCl_4-SO_2 system, 30°C.

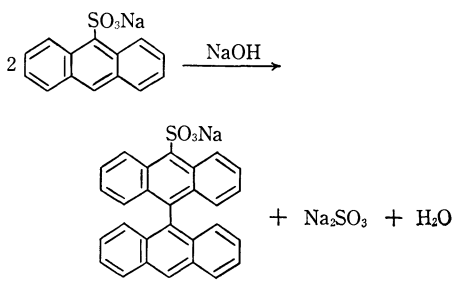
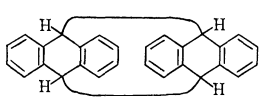
ν_{max}^{KBr} 3400 cm^{-1} (ν_{OH}), 1160—1220 cm^{-1} and 1030 cm^{-1} (sulfur dioxide stretching of sulfonic acid), which disappeared when this compound was heated in a crucible. The sulfur content, 7.36% (calcd., 7.36%), shows that the molar ratio of the SO_3H group to the anthracene ring is 1 : 2. This ratio was confirmed by the alkali titration of II (neutral equivalent 409; calcd., 434). Moreover, the mass spectrum shows the presence of a dianthranyl ring, *m/e*, 354, 178, 127, 80, 64 and 48. The properties obtained here are coincident with the results described in the literature,[9] and so II was confirmed to be dianthranyl-(9.9')-sulfonic acid-(10).

An authentic specimen was synthesized by the following method:[10]



The infrared spectrum and *R*-value (0.81) as determined by the thin-layer chromatography (adsorbent, Wako-silica gel B-5, 0.30 mm.; elution with 1 : 1 ethanol-water) of the sodium salt of II were coincident with those of the authentic specimen.

9, 9', 10, 10'-Dianthracene(III).—This compound was sparingly soluble in an organic solvent, m. p. 255—257°C, and a mixed melting point determination with



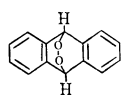
(III)

an authentic dianthracene[11] showed no depression. At the melting point, this compound dissociated to the anthracene-monomer (m. p. 211—212°C). These properties are coincident with those of the photodimers of anthracene derivatives reported by Greene et al.[12] The 725 cm^{-1} band due to the out-of-plane C–H deformation vibration of *ortho*-di-substituted aromatics which is observed in anthracene itself is replaced by a band at 760 cm^{-1} in this compound similar to that proposed for 9.10-dihydroanthracene.[13]

Found: C, 94.26; H, 5.52. Calcd. for $C_{28}H_{20}$: C, 94.38; H, 5.63%.

III was thus confirmed to be 9, 9', 10, 10'-dianthracene.

9.10-Anthracene-endo-cyclicperoxide (IV).—IV decomposed at 120°C (reported, m. p. (decomp.) 120°C[14]). The active oxygen was analyzed by the spectrophotometric determination of iodine which had been liberated



(IV)

from the ethanolic solution of IV by the addition of potassium iodide. The infrared spectrum showed no absorption at 3450 cm^{-1} due to the ν_{OH} of hydroperoxide. This compound was confirmed by reexamining the method of Bowen and Tanner[8] in the absence of sulfur dioxide.

Results and Discussion

The Interaction of Anthracene with Liquid Sulfur Dioxide. Solvent Effects.—In Fig. 2, the electronic spectra of the anthracene - liquid sulfur dioxide - carbon tetrachloride system are compared at different molar ratios of sulfur dioxide vs. carbon tetrachloride, where a constant amount of anthracene (6.3 mg.) was dissolved in 10 ml. of carbon tetrachloride.

As is shown in Fig. 2, the characteristic fine structure of the absorption of anthracene disappears

as the molar fraction of sulfur dioxide increases, while the absorption of the longer-wave-length region (as far as 470 mμ) of the broad absorption increases. The absorption bands above 400 mμ may obviously be identified as a charge-transfer complex[15] between anthracene and sulfur dioxide, since the absorptions of both anthracene and sulfur dioxide are below 400 mμ in carbon tetrachloride.

Figure 3 shows the Benesi-Hildebrand plot at 0°C; it indicates a 1 : 1 complex formation. This complex formation is also confirmed from the linear Benesi-Hildebrand plots at 15 and 30°C, and by the linear plot in Fig. 4, where a linear correlation between $\ln K$ vs. $1/T$ is visualized.

The equilibrium constants, K, for the complex formation estimated at various wavelengths are listed in Table I.

Table I. Equilibrium constant of the complex formation

Wavelength	0°C	15°C	30°C
400 mμ	0.581	0.327	0.216
410 mμ	0.188	0	0
420 mμ	0	0	0

The K values are different depending on the wavelengths. The null-values of the K's at the higher wavelengths are of some interest, because these values mean that the interactions are principally due to the contact charge-transfer complex[16] and that the effects of many complexes with different orientations are overlapping to show a broad absorption band.

The small values of the equilibrium constants, K, are due to the fact that there are various mixtures, from the loose forms of the 1 : 1 complexes to the contact-type form. In contrast to this, the K value for the A–I_2 complex in carbon tetrachloride is estimated to be $K_c=52$ (1./mol.)[17] and $K_c=3.7$ (1./mol.).[18] The same tendency is also shown in the K's at 15 and 30°C.

The apparent enthalpy and entropy changes calculated from these K values at 400 mμ are as follows:

$\Delta G^\circ=0.64$ kcal. mol^{-1}, $\Delta H=-4.8$ kcal. mol^{-1} and $\Delta S^\circ=-19$ cal. deg^{-1} mol^{-1}.

The spectra of liquid sulfur dioxide in various solvents indicate the interaction of the solvents with sulfur dioxide. The maximum of the absorption of sulfur dioxide is observed at 290 mμ (ε 383)[19]; the λ_{max} and ε were almost the same in such solvents as *n*-hexane and carbon tetrachloride,

The yields of the products are in mole percent.

* O_2 was bubbled into the solution.

** m. p. >300°C (sinters at ca. 135°C), IR, 1680 cm^{-1} ($\nu_{C=O}$), 1160 and 1310—1340 cm^{-1} (ν_s and ν_{as} SO_2), UV, λ_{max} 252 mμ. Sulfur content 14.88%. The yield was very small and the structure was not identified.

(280—274 mμ) and the molecular extinction coefficient, ε, also increases (for example, 1390 in benzene),[20] indicating an interaction of some extent. In carbon disulfide, an absorption which might be due to a charge-transfer complex with sulfur dioxide appears. The same trend is seen in benzene, as is shown in Fig. 5, which indicates that the anthracene-sulfur dioxide complex is affected by benzene. The Benesi-Hildebrand plot is scattered, indicating that the anthracene-sulfur dioxide interaction in benzene results in a sort of contact charge-transfer complex.

In ethanol, despite the supposed EtOH - sulfur

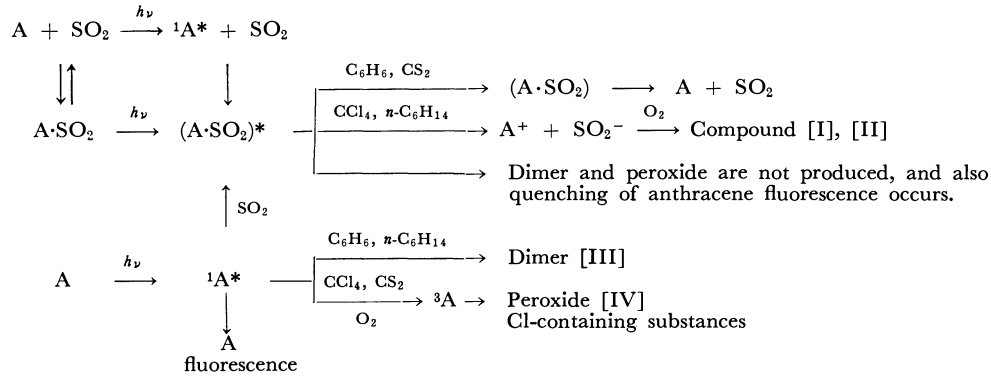

Fig. 6. Reaction schemes.

dioxide interaction, a linear Benesi-Hildebrand plot was observed, indicating that either a loose 1 : 1 complex or a complicated, anthracene - sulfur dioxide - EtOH (for example, a 1:1:1 complex) complex might be formed. Moreover, the absorptions at 610—680 mμ of anthracene due to the S–T transition[21] of anthracene in an approximately saturated solution were not observed in such systems as carbon tetrachloride, carbon disulfide and carbon disulfide - oxygen.

The Irradiation of Anthracene - Sulfur Dioxide Solutions by a High-pressure Mercury Lamp.—In order to obtain further information about the effects of solvents on the interaction between sulfur dioxide and anthracene, irradiation by a high-pressure mercury lamp was attempted. The results are listed in Table II.

The yields of I and II were higher in the presence of *n*-hexane and carbon tetrachloride. According to the findings of Bowen et al., the irradiation of anthracene in carbon tetrachloride gave chlorine-containing compounds,[22] whereas in this anthracene - sulfur dioxide - carbon tetrachloride system sulfur-containing compounds were produced in place of chlorinated compounds.

It has been already established that, in benzene, anthracene dimerizes by an irradiation through an excited singlet state (Exp. No. 5). By the addition of a small amount of sulfur dioxide, regardless of its quantity or the reaction time, the dimerization reaction was inhibited (Exp. No. 6, 7 or 8). In addition, no sulfur compounds were found in the reaction mixture. The results are interpreted as being the consequence of the formation of an anthracene - sulfur dioxide - benzene contact complex. In an ethanol solution (Exp. No. 4), the sulfur content in the products was greatly decreased. In carbon disulfide (Exp. No. 11), also, no sulfur-containing compound was found in the reaction mixture. The previously-recognized formation of endocyclic peroxide through a triplet state by the bubbling of oxygen gas into a carbon disulfide solution of anthracene (Exp. No. 9) was inhibited by the addition of sulfur dioxide in the presence of oxygen; it was replaced by the formation of a small amount of a sulfur compound.

With regard to the influence of oxygen addition to sulfur dioxide (Exp. No. 12), it was demonstrated that formation of I and II was not affected. Thus, it can be assumed that the activated intermediate which induces the formation of I and II is of a singlet character. This assumption is supported by the following facts. i) Neither the disulfone nor the disulfonic acid of anthracene was produced, though expected, if the intermediate was of a triplet state as a result of its radical character. In fact, Squire et al.[23] obtained diphenyl disulfone by the thermal reaction of benzene and sulfur dioxide in the presence of a radical source such as benzoyl peroxide. ii) As has been described above, the sulfur-containing substances were produced in preference to chlorinated compounds in the anthracene - sulfur dioxide - carbon tetrachloride system, though a Cl-radical-abstracting reaction might be expected if the intermediate had a triplet character. Actually, under irradiation by a low-pressure mercury lamp (2537 Å), chlorinated compounds were produced in preference to sulfur-containing compounds, even in the anthracene - sulfur dioxide - carbon tetrachloride system which is similar to that of the photoreaction of anthracene in carbon tetrachloride without sulfur dioxide undertaken by Bowen et al.[22] (A low-pressure mercury lamp does not emit the radiation of the wavelength required for the excitation of anthracene-sulfur dioxide complex.) This behavior differs from the behavior under the irradiation of a high-pressure mercury lamp. iii) Moreover, the absorption at 610—680 mμ of anthracene due to S–T transition was not observed.

21) In a $CHCl_3$ solution of anthracene containing acetylacetonate of Fe^{3+}, the absorptions at 610—680 mμ due to the S–T transition of anthracene have been recognized by Chaudhuri et al. (J. N. Chaudhuri and S. Basu, *Trans. Faraday Soc.*, **54**, 1605 (1958)).

22) E. J. Bowen and K. K. Rohatgi, *Discussions Faraday Soc.*, **14**, 146 (1953).

23) J. M. Squire and W. A. Waters, *J. Chem. Soc.*, **1962**, 2068.

As has been described above, the photochemical reactions in solutions, the reaction of anthracene with sulfur dioxide are seriously influenced by the solvents used, the interaction between the solvent and sulfur dioxide being of the greatest importance. The reaction schemes are illustrated in Fig. 6. As is shown in the scheme, the various reaction courses in the photochemical influence are presumably founded on the excited anthracene - sulfur dioxide complex $(A \cdot SO_2)^*$, which may be produced by the photo-activation of a charge-transfer complex or by the interaction of sulfur dioxide with photoactivated anthracene rather than by the photoactivated sulfur dioxide.[24]

Dimerization in a benzene solution is thus inhibited, and the quenching[25-28] of anthracene fluorescence occurs by the addition of a small amount of sulfur dioxide. Moreover, in benzene or a carbon disulfide solution, in the presence of sulfur dioxide, I and II are not formed, indicating that the interaction of anthracene with sulfur dioxide is diminished by the solvent-sulfur dioxide interaction.

On the contrary, in a *n*-hexane or in carbon tetrachloride solution, which has no interaction with sulfur dioxide, anthracene interacts with sulfur dioxide as much as in liquid sulfur dioxide, where the electron - transferred complex is stabilized in the excited state by solvation with the surrounding sulfur dioxide. The sulfur-containing compounds, such as sulfonic acid of the aromatic compound, will thus be produced from the excited anthracene-sulfur dioxide complex and an atmospheric oxygen which is probably present slightly in the reaction system. The photochemical formation of sulfonic acid of the aromatic compound gives a new synthetic method.

The authors wish to express their thanks to Mr. Hiroshi Takeuchi of our laboratory for his help in the experimental work.

24) In the photochemical gas-phase reactions between sulfur dioxide and olefin or paraffin, the formation of sulfinic acids due to the excitation of sulfur dioxide has been reported by Dainton and Ivin (F. S. Dainton and K. J. Ivin, *Trans. Faraday Soc.*, **46**, 374, 382 (1950)). Thereby, the photochemical products, such as dibenzyl disulfone and benzyl-sulfinic acid, may be expected from sulfur dioxide and toluene if sulfur dioxide is excited, but no photochemical formation is observed under the present conditions. Therefore, the interaction of the photo-activated free anthracene with sulfur dioxide is predominant, rather than that by photo-activated sulfur dioxide, since greater amounts of anthracene than the quantity of the complexed anthracene expected from the calculated value of the equilibrium constant, *K*, are brought into the reaction or inhibition for dimerization. It would be very interesting to know if there is a possibility of a singlet-triplet intersystem crossing of the photo-activated anthracene by sulfur dioxide, due to the spin-orbit coupling. However, no evidence for such a conversion has been obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 874—879 (1966)

The Electron Spin Resonance of Oxovanadium Sulfate Dispersed on Porous Materials

By Hazime TANAKA and Akira MATSUMOTO

The Central Research Laboratory, Showa Denko K.K., Haramati, Ohta-ku, Tokyo

(Received August 18, 1965)

Oxovanadium sulfate was fixed on silica and alumina gel bases as a model of the oxidation catalyst. On silica gel the ESR spectra showed an exchange narrowing without hyperfine lines as a result of the formation of small crystallites. In this case, axially-symmetrical g factors were obtained: $g_{\perp}=1.969\pm0.001$ and $g_{\parallel}=1.915\pm0.005$. When sulfuric salts of alkali metals were added to the system, the dispersion of VO^{2+} ions became homogeneous and a hyperfine structure was observed in the ESR spectra. On an alumina gel base the spectrum resembled that of the frozen aqueous solution of $VOSO_4$ and showed the hyperfine structure, $A_{\perp}=(7.0\pm0.2)\times10^{-3}cm^{-1}$ and $A_{\parallel}=(1.85\pm0.05)\times10^{-2}\,cm^{-1}$. It may be considered that VO^{2+} ions are distributed homogeneously in the surfase layer of alumina. In the alumina gel and silica gel with alkali sulfate, the decrease in the V^{4+} ions with heat treatment was slower than in the silica gel system.

Vanadium complexes which are fixed on various base materials have been used for oxidation catalysts. The mechanism of their catalytic reaction and the effects of added materials have been investigated

by many authors from the point of view of kinetics or of structure.[1-10]

Recently some investigators[11-14] have analyzed the electronic structure of V^{4+} or VO^{2+} in the catalyst system. The V^{4+} ion has a single unpaired electron in the 3d orbital and shows the ESR spectrum with eight hyperfine lines as a result of V^{51} ($I=7/2$). Fortunately, the studies about V^{4+} and VO^{2+} have been stored up from the theoretical point of view in the relation of the ESR spectra from various states.[15-24]

In this paper, the circumstances of the VO^{2+} ions in a catalytic system with silica or alumina gel bases will be investigated by the ESR method. The interaction between oxovanadium sulfate and base materials will be discussed, as well as the effects of the addition of the sulfates of alkali metals.

Experimental

Sample Preparation. — Oxovanadium sulfate, $VOSO_4 \cdot 3H_2O$, was prepared by the reduction of vanadium(V) oxide with sulfur dioxide. Silica and alumina gels were immersed in an aqueous solution at varying concentrations of oxovanadium sulfate and sulfuric acid. They were then dried and kept in an air bath at 120°C for 10 hr. Five kinds of alkali sulfate, lithium sulfate, sodium sulfate, potassium sulfate, cesium sulfate and ammonium sulfate, were added to aqueous solutions of $VOSO_4$.

Table I. Samples

Base material	$VOSO_4$ content	Alkali sulfates added to the system
Silica gel Alumina gel	5—40% of base materials	Li_2SO_4; Na_2SO_4; K_2SO_4; Cs_2SO_4; $(NH_4)_2SO_4$

ESR Measurements. — The ESR spectra were measured at two frequencies, the X and K bands. The K-band spectrometer was a super-heterodyne type constructed by the Oyo Denki (Applied Electric) Laboratory Co., Ltd., while the X-band spectrometer was made in the authors' laboratory. The magnetic field was monitored with the proton resonance at an accurately known frequency. As a standard of the signal intensity, a small ruby crystal and calcium oxide powder containing Mn^{2+} were employed.

Results and Discussion

The ESR of VO^{2+} in Aqueous Solutions.— The ESR signals of the VO^{2+} ions in aqueous solutions were measured as a function of the concentrations of VO^{2+} and sulfuric acid in order to examine the ionic configuration of VO^{2+}. In the concentration range from 0.1 to 3 mol./l. of VO^{2+}, a typical hyperfine structure of eight lines was observed. The width of the hyperfine components changed with the nuclear spin quantum number, m_I. At a more concentrated solution of VO^{2+}, it became impossible to observe the separate hyperfine structure. When sulfuric acid was added to the solutions where the hyperfine components were distinguished, however, the individual hyperfine width became broad, probably because of an increase in the viscosity. The addition of alkali metal ions did not affect the spectra.

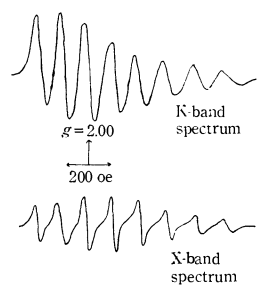

Fig. 1. ESR spectrum of $VOSO_4$ in aqueous solution (0.1 mol./l.).

Kivelson,[15] Rogers and Pake[16] have given the following equation for the width of the hyperfine components of VO^{2+} in solutions:

$$\Delta H = a_0 + a_1 m_I + a_2 m_I^2 \qquad (1)$$

where ΔH is the width, m_I is the nuclear spin quantum number, and a_0, a_1, a_2 are as follows:

$$a_0=\alpha+\tau_c[4/45(\Delta\gamma H_0)^2+3/40I(I+1)b^2] \quad (2a)$$

$$a_1=\tau_c[4/15(b\Delta\gamma H_0)] \quad (2b)$$

$$a_2=\tau_c[1/8b^2] \quad (2c)$$

where α is the contribution from unspecified sources, τ_c is correlation time, $H_0=\omega_0/\gamma$, $\Delta\gamma=\beta(g_\perp-g_\parallel)$, and $3b=2(A_\parallel-A_\perp)$. In Eqs. 2a, 2b and 2c the small terms are neglected.

The values of α and the $\Delta\gamma H_0/b$ ratio have been calculated; they are listed in Table III. The values of α are not in good agreement, as the line shapes of the hyperfine components are not symmetric and the theory is not sufficient to describe the broadening mechanism. The $\Delta\gamma H_0/b$ ratio should be 2.5 times larger in the K-band spectra than in the X-band spectra. Actually, however, the results obtained are from 1.9 to 2.8 times larger in the former.

It may be considered from these data that the electronic structure around VO^{2+} does not change greatly in the solution at from 0.1 to 1.0 mol./l. VO^{2+} concentration nor upon the addition of up to 3 N of sulfuric acid. A distorted octahedral structure of $VO(OH_2)_5$, which has been proposed for dilute aqueous solutions of VO^{2+} ions, can be considered.[24] When the concentration of VO^{2+} ions or that of sulfuric acid increases, not only the change in viscosity but also the change in the structure of coordination around VO^{2+} must occur.

sulfate dispersed on silica gel shows an ESR spectrum of an axial symmetrical g anisotropy without a hyperfine structure (Fig. 2), which resembles the ESR spectra of $VOSO_4$·$3H_2O$ and of $VOSO_4$·H_2SO_4 in powder. In these systems, the exchange narrowing becomes dominant and the hyperfine interaction is negligible as compared with the g

k) K-band measurement. x) X-band measurement.

anisotropy for the K-band measurements. The VO^{2+} ions seem to form small crystallites of $VOSO_4 \cdot nH_2O$. Therefore, if each individual csystallite is distributed in random orientation and gives Lorentzian line shape, the ESR spectrum may be expressed approximately as follows:[25]

$$I(H) = \int K \sin\theta \cdot \frac{d\theta}{(H-H_0)^2+b^2} \qquad (3)$$

where H_0 is the resonance field, θ is the angle between the applied field H and the crystal axis, $K=1/8\, g_\perp{}^2[(g_\parallel/g_\perp)^2+1]$, and b is the half-width at the half-power of each crystallite.

The values of $g_\perp$, $g_\parallel$ and b can be estimated from the experimental data, if b remains constant throughout the θ range. The results are listed in Table IV.

Table IV. ESR constants of $VOSO_4$ on silica gel base

The quantity of $VOSO_4$: 10 mol.% of base material.

The quantity of alkali sulfate: 10 mol.% of base material.

* Measured after heat treatment at 300°C.

** Without base material.

When the sample was heated in a stream of air, the ESR signal decreased in intensity, while the width was increased. As the symmetry of the spectrum increased, only an apparent value of g could be obtained. The exchange narrowing, therefore, seems to become weak as a result of the decrease in the concentration of VO^{2+} ions, while the ill-resolved hyperfine structure seems to cause the inhomogeneous broadening.

When alkali sulfates were added to the system, the hyperfine structure appeared in the ESR spectrum. This effect was influenced by the quantity of alkali sulfate as well as by its kind. In Fig. 4 the change in the hyperfine splitting of the system with various concentrations of cesium sulfate is shown. When the mole ratio of cesium sulfate to the silica gel base reached about 0.4, the width of each individual hyperfine component was about

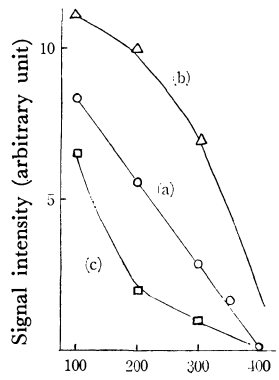

Fig. 3. The Variation of the ESR intensity of $VOSO_4$ on silica gel with heat treatment; (a) without additional material, (b) with Na_2SO_4, (c) with $(NH_4)_2SO_4$. The content of $VOSO_4$ and of additional materials are 10 mol.% to base.

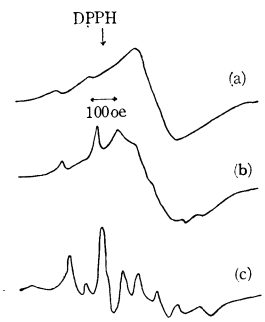

Fig. 4. The variation of ESR spectra of $VOSO_4$ on silica gel as a function of the additional quantity of Cs_2SO_4; 1) 10 mol.%, 2) 20 mol.%, and 3) 40 mol.%. $VOSO_4$ content is about 10 mol.%.

40 oe. and the splitting between the components had the value noted.

The samples containing alkali sulfate gave complicated spectra as a result of the anisotropy of g as well as that of the hyperfine structure. From the figure of the narrowing spectrum, it may be assumed that the axial symmetry exists for both g and hyperfine tensors, with $g_\perp > g_\parallel$ and with $A_\perp < A_\parallel$. Some hyperfine components which appear in the low magnetic field have highly-distorted signal shapes in the K-band measurements. On the other hand, in the X-band measurements, it is easy to obtain the value of $A_\parallel$, but difficult to determine $g_\perp$, $g_\parallel$ and $A_\perp$.

If both g and hyperfine tensors have an axial symmetry and if each ion is distributed at rondom, the ESR spectrum may be expressed as follows:[26]

25) J. A. Ibers and D. Swalen, *Phys. Rev.*, **127**, 1914 (1962).

26) T. Vänngard and R. Aasa, *Proc. First Int. Conf. Paramagnetic Resonance*, Jerusalem, 1962, Academic Press, New York (1963), p. 509.

$$I(H) = \frac{1}{(2I+1)} \sum_{m_I=-7/2}^{7/2} \int_0^1 K(\theta) \cdot S(H-H_0)^2 \cdot dz \tag{4}$$

where $z=\cos\theta$, θ and $K(\theta)$ have meanings given in Eq. 3, $S(x)$ is the shape function, and $S(H-H_0)=1/\{(H-H_0)^2+b^2\}$ for Lorentzian. Including the magnetic hyperfine interaction to the second order, the resonance field is given approximately by:

$$\begin{aligned} H_0 = {} & H_c - Km_I/g\beta - (4H_c)^{-1}(g\beta)^{-2}A_\perp{}^2 \\ & \times (A_\parallel{}^2 + K^2)K^{-2}[I(I+1) - m_I{}^2] \\ & - (2H_c)^{-1}(g\beta)^{-2}(A_\parallel{}^2 - A_\perp{}^2)^2 \\ & \times K^{-2}g_\perp{}^2g_\parallel{}^2g^{-4}z^2(1-z^2)m_I{}^2 \end{aligned} \tag{5}$$

where $H_c = h\nu/g\beta$, $g^2 = g_\perp{}^2 + (g_\parallel{}^2 - g_\perp{}^2)z^2$ and

$$K^2g^2 = A_\parallel{}^2g_\parallel{}^2z^2 + A_\perp{}^2g_\perp{}^2(1-z^2)$$

$A_\perp$ and $A_\parallel$ are hyperfine-structure constants in energy units.

By comparing the K-band spectra to the above expressions, we can obtain $g_\perp$, $A_\perp$, and $A_\parallel$, because the K-band spectra shows the characteristic signal from those crystallites which have orientations perpendicular to the magnetic field. When $z=0$, Eq. 5 becomes:

$$\begin{aligned} H_0(m_I) = {} & H_\perp - A_\perp m_I/g_\perp\beta - (4H_\perp)^{-1}(g_\perp\beta)^{-2} \\ & \times (A_\perp{}^2 + A_\parallel{}^2)(63/4 - m_I{}^2) \end{aligned}$$

where $H_\perp = h\nu/g_\perp\beta$. The results are listed in Table V.

When the quantity of alkali sulfate remains only ten percent of the base materials, the values of $g_\perp$ and $g_\parallel$ can not be determined separately, but they give an apparent value of $g : \langle g\rangle = (2g_\perp + g_\parallel)/3$. When the hyperfine splitting is so large that Eq. 5 is applicable, the values of g obtained are slightly greater than those of the sample without alkali sulfate, The values of $A_\perp$ appear to be 6.3×10^{-3} cm^{-1} for the sample with 20% cesium sulfate, and 7.5×10^{-3} cm^{-1} for that with 40% cesium sulfate.

The decrease in the ESR intensity with heat treatment is slower for the systems containing alkali sulfates than for the system without them, except for the case of ammonium salt. Alkali sulfates make the ESR of VO^{2+} insensitive to the heat treatment. They prevent the oxidation of vanadium ions from 4+ to 5+ and the formation of crystallites of vanadium(V) oxide,

VO^{2+} on an Alumina Gel Base.—Oxovanadium sulfate on an alumina gel base showed ESR spectra closely resembling those of the system of a silica base with alkali sulfate in the concentration range from 5 to 10 percent of $VOSO_4$. The addition of alkali sulfates did not have any remarkable effects. Table V shows the results obtained by the method described in the preceding section. As the concentration of $VOSO_4$ increased, the width of each hyperfine component exceed the hyperfine splitting. The ESR spectrum was observed as a broad single line which had a good symmetry.

TABLE V. ESR CONSTANTS OF $VOSO_4$ IN ALUMINA GEL AND IN SILICA WITH ALKALI SULFATES

Sample		g	Hyperfine constant

VO^{2+} Ions in an Aqueous Solution at 77°K.—The ESR spectra of $VOSO_4$ in aqueous solution at 77°K are shown in Fig. 5. In aqueous solutions

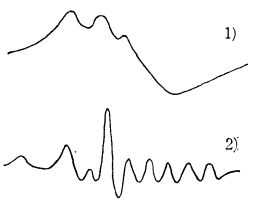

Fig. 5. ESR spectra of $VOSO_4$ in aqueous solutions observed at 77°K. 1) VO^{2+}: 0.1 mol./l., 2) VO^{2+}: 0.1 mol./l., H_2SO_4: 1 N.

containing under 0.1 N sulfulic acid, the hyperfine lines show a broadening in spite of the low concentration of $VOSO_4$. In the solutions containing over 1.0 N sulfuric acid, on the contrary, the sharp hyperfine components were clearly separated. This system can be considered to be a typical model of the random distribution of VO^{2+} ions. The values of $g_\perp$, $A_\perp$, $A_\parallel$ can be calculated by using Eq. 5; they are listed in Table VI. They are in good agreement with the results obtained from the data on an alumina gel base.

From the variation in spectra with the different concentrations of sulfuric acid, the existence of

TABLE VI. ESR CONSTANTS OF $VOSO_4$ IN AQUEOUS SOLUTIONS AT 77°K

0.1	1.0		2.9	7.37
0.1	3.0	1.965	2.3	7.05
0.1	10.0	1.966	2.3	7.16

excess SO_4^{2-} ions may be considered to change the circumstances around VO^{2+} ion, or the coordination state of VO^{2+}.

The Effects of Base Materials and Alkali Sulfates.—Silica gel has a weaker interaction with transition metal oxides dispersed on it than has alumina gel.[27] Oxovanadium sulfate is deposited as small crystallites on silica gel, and so the ESR of VO^{2+} on silica shows the exchange narrowing.

When alkali sulfates are added to the system, double salts, $M_2 \cdot V_2O_2(SO_4)_3$, are formed[28] and the exchange between VO^{2+} ions is prevented. An excess addition of alkali sulfates bring about a dilution of the double salt and a decrease in the width of the hyperfine lines in the ESR spectrum. If the random dispersion of VO^{2+} ions is realized at an adequate concentration, an ESR with a hyperfine structure can be observed. Frozen sulfuric acid solutions of VO^{2+} are good models for this state. The spectra obtained with an alumina base are similar to those of the frozen sulfuric acid solutions. VO^{2+} ions may be considered to be combined strongly with an alumina base and to be dispersed homogeneously in the surface layers of almuina.

Summary

The electron spin resonance spectra of oxovanadium sulfate has shown an exchange narrowing on a silica gel base as a result of the formation of small crystallites. In this case, the g factor has an axial symmetry of $g_\perp = 1.969 \pm 0.001$ and $g_\parallel = 1.915 \pm 0.005$. When alkali sulfates are added to the system, the dispersion of VO^{2+} ions on the base materials becomes homogeneous and ESR spectra with hyperfine lines appear.

On an alumina gel base, VO^{2+} ions seems to be dispersed homogeneously in the surface layers of the base, and ESR spectra show the hyperfine structure with the parameter of $A_\perp = (7.0 \pm 0.2) \times 10^{-3}\,cm^{-1}$ and $A_\parallel = (1.85 \pm 0.05) \times 10^{-2}\,cm^{-1}$. These values are slightly smaller than the value of $\langle A \rangle$, $(1.20 \pm 0.03) \times 10^{-2}\,cm^{-1}$ which has been obtained from aqueous solutions of VO^{2+}.

The authors are indebted to Messieurs Nobuhisa Goto, Kunihiko Nakamura and Hiroshi Fukunaga for their kind help in the ESR measurements and for their discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 879—882 (1966)

The Reactions of the Benzil - Triethyl Phosphite Adduct

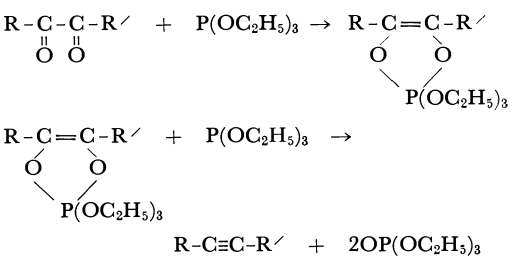
By Teruaki MUKAIYAMA and Takanobu KUMAMOTO

Tokyo Institute of Technology, Ookayama, Tokyo

(Received August 26, 1965)

The decomposition of benzil - triethyl phosphite adduct in the presence of copper powder or cupric sulfate has been studied. When benzil, triethyl phosphite and cupric sulfate were treated in boiling toluene, *cis*-dibenzoylstilbene and triethyl phosphate were obtained. When the reaction was carried out in the presence of active hydrogen compounds, such as alcohol, carboxylic acid and amine, the corresponding benzoin derivatives were obtained. Further, when the adduct was decomposed in the presence of phenyl isocyanate or dicyclohexylcarbodiimide, 3, 4, 5-triphenyl-4-oxazoline-2-one or 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline was obtained, along with triethyl phosphate.

It has recently been found that the decomposition of the adducts of α-diketones and triethyl phosphite[2] gives disubstituted acetylenes and triethyl phosphate in good yields.[1] The reactions take place at a comparatively high temperature, that is, above 215°C.



In the present experiment, several catalysts, such as copper powder and cupric sulfate, were

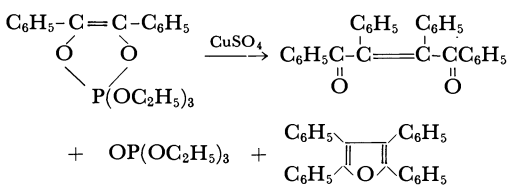
* As the isolation of ethers of benzoin from reaction mixture was difficult, the yields of the ethers were comparatively low.

examined in order to carry out the decomposition of the adduct of benzil and triethyl phosphite at a lower temperature.

When a mixture of benzil and triethyl phosphite was refluxed in anhydrous toluene for five hours under nitrogen in the presence of anhydrous cupric sulfate, disubstituted acetylene could not be obtained, contrary to the case of the decomposition of the adduct in the absence of a catalyst. Instead, *cis*-dibenzoylstilbene and triethyl phosphate were obtained in 41% and 81% yields respectively, along with a small amount of tetraphenyl furan (18% yield).



Similarly, when copper powder or mercuric chloride was used as a catalyst, *cis*-dibenzoylstilbene was obtained in a 32% or a 14% yield respectively.

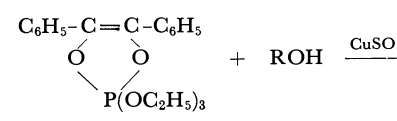
These results may be explained by considering an initial formation of triethyl phosphate and phenyl benzoyl carbene[3] by the decomposition of the adduct. The carbene thus formed may in turn dimerize to form dibenzoylstilbene.

Usually, α-ketocarbene[4] is known to be unstable and to yield disubstituted ketene by a Wolff rearrangement. On the other hand, Yater[5] reported that α-ethoxy acetophenone was produced when α-diazoacetophenone was decomposed in the presence of alcohol and copper powder, but the rearranged product, the ester of phenylacetic acid, could not be obtained.

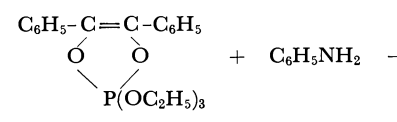
The intermediate of the decomposition of the adduct, carbene, may be demonstrated by the formation of benzoin derivatives when the adduct is decomposed in the presence of active hydrogen compounds.

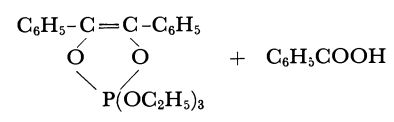
Indeed, when a mixture of benzil, triethyl phosphite and ethanol was refluxed in toluene for five hours under nitrogen in the presence of anhydrous cupric sulfate, benzoin ethyl ether (30% yield) and triethyl phosphate (69% yield) were obtained, along with a small amount of *cis*-dibenzoylstilbene (5% yield) and dibenzoyldiphenyl ethane (3% yield).

Similar reactions were observed in the cases of the other alcohols and phenol (see Table I).



By the same method, anilino desoxybenzoin (63% yield) and benzoin benzoate (29% yield) were obtained when the adduct was treated with aniline and benzoic acid respectively.





In connection with the reaction of the α-diketone - tertiary phosphite adduct with active hydrogen compounds, Ramirez et al. have

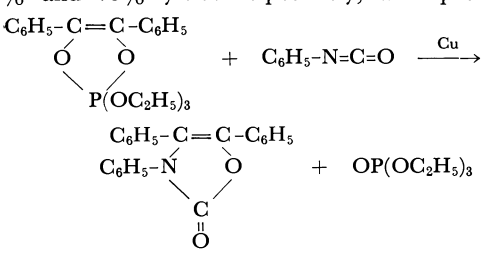
Table II. Reactions of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline and protonic acid

Acid	Yield, %	Salt of oxazoline: Formula of salt	Analysis Found (Calcd.) C	H	N	M. p., °C (Decomp. p.)
Hydrogen chloride	100	$C_{27}H_{32}N_2O \cdot HCl$	73.66 (74.11	7.82 7.56	6.26 6.41)	(234—236)
Phenylphosphonic acid	86	$C_{27}H_{32}N_2O \cdot C_6H_5PO(OH)_2$			4.90 (5.02)	191—192
p-Toluenesulfonic acid	89	$C_{27}H_{32}N_2O \cdot C_7H_7SO_3H$	70.84 (71.30	7.30 6.99	5.01 4.89)	178—180
Monochloroacetic acid	81	$C_{27}H_{32}N_2O \cdot ClCH_2CO_2H \cdot H_2O$	67.24 (67.85	7.45 7.22	5.68 5.47)	(115—120)

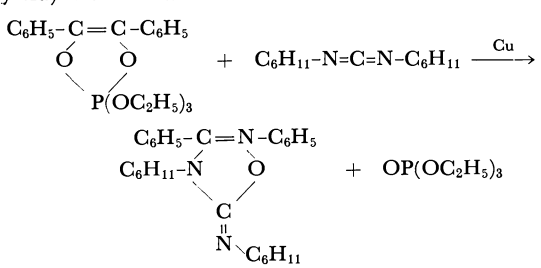
reported[6] that α-ketol-monophosphates resulted when α-diketone - trimethyl phosphite adducts reacted with hydrogen chloride. On the other hand, desyl chloride was obtained when the benzil - triphenyl phosphite adduct was treated with hydrogen chloride.

Also, it has recently been reported[7] by Ramirez et al. that the hydrolysis of the biacetyl - trimethyl phosphite adduct in boiling benzene gave trimethyl phosphate.

The carbene, 1, 3-dipolar intermediate, was further demonstrated by the formation of 3, 4, 5-triphenyl-4-oxazoline-2-one when benzil, triethyl phosphite and phenyl isocyanate were allowed to react in the presence of copper powder. By the above reaction, 3, 4, 5-triphenyl-4-oxazoline-2-one and triethyl phosphate were obtained in 23% and 79% yields respectively, as expected.



Furthermore, when the adduct was treated with dicyclohexylcarbodiimide in boiling toluene in the presence of copper powder under nitrogen, 2 - cyclohexylimino - 3 - cyclohexyl - 4, 5 - diphenyl - 4 - oxazoline (72% yield) and triethyl phosphate (89% yield) were obtained.



6) F. Ramirez, R. B. Mitra and N. B. Desai, ibid., **82**, 2652 (1960).

7) F. Ramirez, O. P. Madan and C. P. Smith, ibid., **87**, 670 (1965).

Next, several reactions of the oxazoline were studied. 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline reacts with protonic acids, such as hydrogen chloride, *p*-toluenesulfonic acid, monochloroacetic acid and phenylphosphonic acid, to form the corresponding salts in high yields (see Table II).

On the other hand, 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline is very stable towards hydrolysis in both basic and acidic media. Further study of the reaction of the oxazoline is now in progress.

Experimental

The Decomposition of the Benzil - Triethyl Phosphite Adduct in the Presence of Cupric Sulfate.—A mixtrue of benzil (4.20 g., 0.02 mol.), triethyl phosphite (3.32 g., 0.02 mol.) and cupric sulfate (2.00 g.) was refluxed in anhydrous toluene (15 cc.) under nitrogen for 5 hr. The removal of the solvent gave a white precipitate. Its recrystallization from benzene gave *cis*-dibenzoylstilbene, 1.12 g., m. p. 215—217°C.

Found C, 86.37; H, 5.24. Calcd. for $C_{28}H_{20}O_2$: C, 86.57; H, 5.19%.

The fractional distillation of filtrate gave triethyl phosphate, 2.89 g. (81%); b. p. 113—115°C/28 mmHg. The addition of a small amount of ether to the residue also gave *cis*-dibenzoylstilbene. It was recrystallized from benzene, 0.48g., m. p. 214—216°C. The total yield of *cis*-dibenzoylstilbene was 41%.

Further, a crystalline was isolated from the residue. Its recrystallization from acetic acid gave tetraphenyl furan, 0.66 g. (18%), m. p. 173—174°C.

Found C, 90.03; H, 5.38. Calcd. for $C_{28}H_{20}O$: C, 90.29; H, 5.41%.

The Decomposition of the Benzil - Triethyl Phosphite Adduct in the Presence of Ethanol and Cupric Sulfate.—A mixture of benzil (2.10 g., 0.01 mol.), triethyl phosphite (1.66 g., 0.01mol.), ethanol (0.46 g., 0.01mol.) and cupric sulfate (1.00 g.) was refluxed in toluene (10 cc.) for 5 hr. under nitrogen. After the cupric sulfate had then been filtered off, the solvent was removed. Then a white precipitate was obtained. Recrystallization from benzene gave dibenzoyldiphenyl ethane, 0.05 g. (3%), m. p. 253—254°C. The residue was distilled in vacuo giving triethyl phosphate, 1.25 g. (69%), 114—116°C/30

mmHg, and another fraction, 1.45 g., 141—144°C/0.4 mmHg. This was a mixture of benzil and benzoin ethyl ether. By the addition of a small amount of petroleum ether, benzil was recovered, along with benzoin ethyl ether; recrystallization from ligroin gave 0.72 g. (30%); m. p. 59—61°C.

Found C, 79.63; H, 6.98. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

When to the residue of fractional distillation there was added a small amount of diethyl ether, a white precipitate was obtained. It was recrystallized from benzene to give *cis*-dibenzoylstilbene, 0.10 g. (5%); m. p. 213—215°C.

By a similar procedure, various benzoin ethers were obtained from the reactions of benzil, triethyl phosphite and alcohols.

Analogously, anilino desoxybenzoin or benzoin benzoate was obtained from the reaction of benzil, triethyl phosphite and corresponding aniline or benzoic acid (see Table I).

The Decomposition of the Benzil-Triethyl Phosphite Adduct in the Presence of Phenyl Isocyanate and Copper Powder.—A mixture of benzil (2.10 g., 0.01 mol.), triethyl phosphite (1.66 g, 0.01 mol.), phenyl isocyanate (1.19 g., 0.01 mol.) and copper powder (0.50 g.) was refluxed in toluene for 5 hr. under nitrogen. The removal of the solvent gave a white precipitate. This was recrystallized from benzene to give 3, 4, 5-triphenyl-4-oxazoline-2-one, 0.73 g. (23%); m. p. 212—213°C; mixed m. p. 213°C. The filtrate was distilled in vacuo to give triethyl phosphate, 1.43 g. (79%), b. p. 103—105°C/20 mmHg.

The Decomposition of the Benzil-Triethyl Phosphite Adduct in the Presence of Dicyclohexylcarbodiimide and Copper Powder.—A mixture of benzil (4.20 g., 0.02 mol.), triethyl phosphite (3.32 g., 0.02 mol.), dicyclohexylcarbodiimide (4.12 g., 0.02 mol.) and copper powder (1.00 g.) was refluxed in toluene (15 cc.) for 5 hr. under nitrogen. After copper powder was filtered, the solvent was removed.

The fractional distillation of the residue gave triethyl phosphate, 3.24 g. (89%); b. p. 103—106°C/18 mmHg. The addition of a small amount of ethanol to the residue gave a white precipitate. Recrystallization from ethanol gave 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline, 5.76 g. (72%); m. p. 133—134°C.

Found C, 80.73; H, 8.28; N, 7.10. Calcd. for $C_{27}H_{32}N_2O$: C, 80.96; H, 8.05; N, 6.99%. ν_{max}^{KBr} 2925, 2855, 1673, 1648, 1595, 1500, 1444, 1363, 1342, 1047, 1020, 984, 736, 698 and 683 cm^{-1}.

The Reaction of 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline with Hydrogen Chloride.—Anhydrous hydrogen chloride was passed through a solution of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline (2.00 g., 0.005 mol.) in anhydrous ether. A white precipitate was thus obtained. This was recrystallized from ethyl acetate giving 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline hydrochloride, 3.83 g. (100%); m. p. 234—236°C (decomp.).

By a similar procedure, various salts of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline were obtained from the oxazoline and *p*-toluenesulfonic acid, phenylphosphonic acid and monochloroacetic acid respectively (see Table II).

The authors wish to express their hearty thanks to Mr. Takenori Nagaoka for his help during the course of this experiment.

The Syntheses of Peptides Related to the *N*-Terminal Structure of Corticotropin. VII. The Synthesis of Peptide Derivatives Corresponding to Positions 11 to 18 in the Corticotropin Molecule

By Hideo Otsuka, Ken Inouye, Makoto Kanayama and Fusako Shinozaki

Biochemistry Division, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received August 27, 1965)

The derivatives of lysyl-prolyl-valyl-glycyl-arginyl-arginine, lysyl-prolyl-valyl-glycyl-lysyl-arginyl-arginine and lysyl-prolyl-valyl-glycyl-lysyl-lysyl-arginyl-arginine, which correspond to the amino acid sequences in positions 11—14 plus 17—18, 11—14 plus 16—18, and 11—14 plus 11—18 of the corticotropin molecule respectively, have been obtained as intermediates for the synthesis of adrenocorticotropically active peptides.

As a step toward our synthesis of the adrenocorticotropically active peptides involving a hexadecapeptide $\alpha^{1-14,17-18}$-Gly^{1}-ACTH,[1] a heptadecapeptide $\alpha^{1-14,16-18}$-Gly^{1}-ACTH-18-amide,[2] and octadecapeptides α^{1-18}-ACTH and α^{1-18}-ACTH-18-amide,[3] we prepared the peptide intermediates

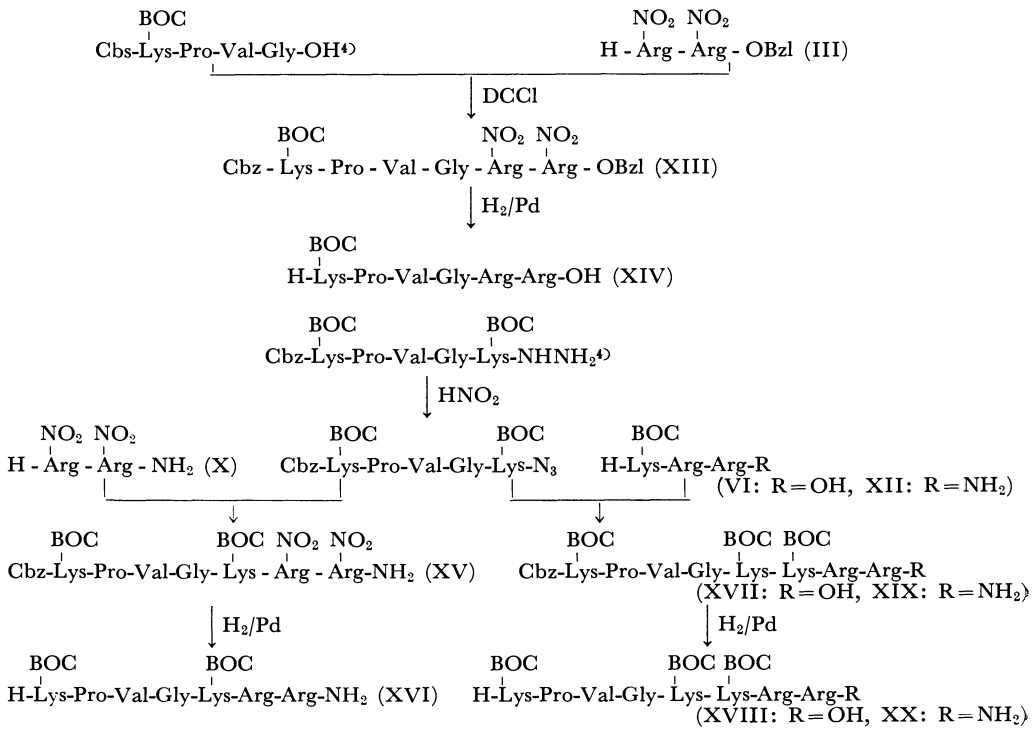

Fig. 1. Outline of the synthetic procedure for the hexapeptide, heptapeptide and octapeptide derivatives. Cbz, carbobenzoxy; BOC, *t*-butyloxycarbonyl; Bzl, Benzyl; DCCl, *N*, *N'*-dicyclohexylcarbodiimide.

corresponding to the natural and the partially-altered sequences of positions 11 to 18 in the corticotropin (ACTH) structure; namely, N^{ε}-*t*-butyloxycarbonyl - lysyl - prolyl-valyl-glycyl-arginyl-arginine (XIV), N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl - N^{ε} - *t* - butyloxycarbonyl- lysyl-arginyl-arginine amide (XVI), and N^{ε}-*t*-butyloxycarbonyl-lysyl - prolyl - valyl - glycyl - N^{ε}- *t* -butyloxycarbonyl-lysyl -N^{ε}- *t* - butyloxycarbonyl -lysyl-arginyl-arginine (XVIII) and its amide (XX).*1

An outline of the synthetic procedure is shown in Fig. 1. The heptapeptide (XV) and the octapeptides (XVII and XIX) were built by the idea of the coupling of Lys-Pro-Val-Gly-Lys with Arg-Arg and with Lys-Arg-Arg respectively, while the hexapeptide (XIII) was prepared from Lys-Pro-Val-Gly and Arg-Arg. The synthesis of the sequences of Lys-Pro-Val-Gly and Lys-Pro-Val-Gly-Lys has already been reported.[4] Therefore, we wish to describe here the synthesis of arginyl-arginine and lysyl-arginyl-arginine fragments. We wish also to describe in detail the procedures for preparing the longer peptides from them.

The Synthesis of the Hexapeptide Derivative (XIV).—Attempts to synthesize the nitroarginine benzyl ester were made by three different methods as follows:

(1) H-Arg(NO_2)-OH + $C_6H_5CH_2OH$
$\xrightarrow{CH_3C_6H_4SO_3H}$ H-Arg(NO_2)-OBzl·$CH_3C_6H_4SO_3H$

(2) BOC-Arg(NO_2)-OH + $C_6H_5CH_2Cl$
$\xrightarrow{\text{triethylamine}}$ BOC-Arg(NO_2)-OBzl
$\xrightarrow{CF_3COOH}$ H-Arg(NO_2)-OBzl·CF_3COOH

(3) Cbz-Arg(NO_2)-OH
$\xrightarrow[\text{in dioxane}]{PCl_5}$ NH-Arg(NO_2)-CO (CO—O)
$\xrightarrow{HCl/C_6H_5CH_2OH}$ H-Arg(NO_2)-OBzl·HCl

In each case, no salt of the ester was crystallized. Of these methods, the first one was found to be the most convenient and to give a moderate yield. The *t*-butyloxycarbonyl-nitroarginine benzyl ester, which was obtained as an intermediate in the second method, was homogeneous in thin-layer chromatography (R_f=0.61, ethyl acetate - methanol (95 : 5)), but it also resisted all attempts at crystallization. In the third method, it seemed that the nitroguanidino function did not decompose upon the treatment with phosphorus pentachloride.

The nitroarginine benzyl ester *p*-toluenesulfonate (I) was, after having been converted into the free

*1 All amino acid residues are of the L-configuration, with the exception of glycine.

4) H. Otsuka, K. Inouye and Y. Jono, This Bulletin, **37**, 1471 (1964).

base, combined with *t*-butyloxycarbonyl-nitroarginine to give the *t*-butyloxycarbonyl-nitroarginyl-nitroarginine benzyl ester (II), which failed to crystallize. Compound II was, however, found by thin-layer chromatography to be homogeneous. The *t*-butyloxycarbonyl group was removed with the trifluoroacetic acid treatment; the nitroarginyl-nitroarginine benzyl ester trifluoroacetate (III) was thus obtained. This was then coupled with N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycine[4] by the *N*, *N'*-dicyclohexylcarbodiimide (DCCl) procedure, thus affording a hexapeptide derivative, the N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-nitroarginyl-nitroarginine benzyl ester (XIII). Compound XIII crystallized with a 90 per cent yield. The catalytic hydrogenolysis of XIII gave a partially protected hexapeptide N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-arginyl-arginine diacetate (XIV), which was homogeneous in paper chromatography.

The Synthesis of the Heptapeptide Amide Derivative (XVI).—Carbobenzoxy-nitroarginine was treated with ethylchloroformate and tri-*n*-butylamine in a tetrahydrofuran solution in order to convert it into a mixed anhydride, which was then allowed to react with a small excess of aqueous ammonia to produce carbobenzoxy-nitroarginine amide (VII) in an 81 per cent yield. Compound VII crystallized readily from aqueous ethanol and had a melting point of 220—221°C. Van Orden and Smith gave a m. p. of 219—220°C for the same compound.[5] The treatment of VII with hydrogen bromide in acetic acid gave the crystalline monohydrobromide of nitroarginine amide (VIII) in an 85 per cent yield. Carbobenzoxy-nitroarginine and VIII were coupled by the mixed anhydride procedure to produce carbobenzoxy-nitroarginyl-nitroarginine amide (IX), which crystallized from dimethylformamide, combining two molecules of the solvent. The carbobenzoxy group was removed from compound IX by hydrogen bromide in acetic acid. The resultant dipeptide amide nitroarginyl-nitroarginine amide monohydrobromide (X) failed to crystallize, but it was found by paper chromatography to be homogeneous. Compound X was then added to an aqueous tetrahydrofuran solution of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysine azide, which was derived from the corresponding hydrazide;[4] they were then allowed to react in the presence of sufficient triethylamine to produce a hyptapeptide derivative N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-nitro-arginyl-nitroarginine amide (XV). A pure sample of compound XV, which was easily obtained by reprecipitation from *n*-butanol in a moderate yield (66%), was found by thin-layer chromatography to be homogeneous. The catalytic hydrogenolysis of XV yielded the partially protected heptapeptide amide N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine amide triacetate (XVI), which had no absorption in the 250—390 mμ region and which gave a single ninhydrin and Sakaguchi reactive spot on paper.

In our previous communication, N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysine methyl ester was synthesized from the carboxyl terminal by a step-by-step procedure.[4] Now this protected pentapeptide has also been obtained in an excellent yield (86%) by the DCCl-mediated condensation from N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycine[4] and the N^{ε}-*t*-butyloxycarbonyl-lysine methyl ester.[5] The product was found to be identical with that obtained previously.

The Synthesis of the Octapeptide Derivatives (XVIII and XX).—The N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysine *N*-hydroxysuccinimide ester (XI), which had been prepared from the diacyllysine and *N*-hydroxysuccinimide by the DCCl-mediated reaction,[6] was utilized for the synthesis of the Lys-Arg-Arg sequence. Compound XI was allowed to react with III and with X, each of which had been neutralized with triethylamine, in aqueous tetrahydrofuran to yield, respectively, the benzyl ester (V) and the amide (XI) of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-nitroarginyl-nitroarginine in 70 per cent yields. Compound XI was also obtained by the mixed anhydride procedure, and the product was identical in optical rotation to that obtained by the active ester method. Compounds V and XI were hydrogenolyzed to obtain the partially deblocked tripeptides, N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine diacetate (VI) and N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine amide triacetate (XII) respectively. Both of these were found by paper chromatography to be homogeneous.

The reaction of the pentapeptide azide with the partially deblocked tripeptide VI or XII proceeded smoothly, affording an octapeptide, N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valylglycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine (XVII) or its amide (XIX). The octapeptides XVII and XIX, which were purified by simple extraction (see "Experimental") were, found to be homogeneous to ninhydrin and Sakaguchi reagent in thin-layer chromatography. Judging from the number of positive charges, compounds XVII and XIX would form the monoacetate and the diacetate, respectively, if they were isolated from the aqueous acetic acid solutions. It was, however, a fact that compound XVII combined with one molecule of acetic acid, whereas the acid was not detected in XIX, when

5) H. van Orden and E. L. Smith, *J. Biol. Chem.*, **208**, 751 (1954).

6) G. W. Anderson, J. E. Zimmerman and F. M. Callahan, *J. Am. Chem. Soc.*, **86**, 1839 (1964); **85**, 3039 (1963).

they had been dried ordinarily (at 60°C in vacuo). Compounds XVII and XIX were then submitted to catalytic hydrogenolysis, which gave N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine (XVIII) and its amide (XX) respectively. Compound XX was obtained as the triacetate, but XVIII did not contain so much acetic acid as had been expected theoretically. This anomalous phenomenon, which has been observed only with the octapeptides, may suggest that they possess a certain kind of unusual conformation within their molecules. Compound XX was homogeneous in paper chromatography, but XVIII was found to be contaminated by a trace of impurity, which had a little higher R_f value than that of XVIII.

Table I. Compositions of basic amino acids in acid hydrolysates of the hexapeptide (XIV), heptapeptide(XVI) and octapeptides (XVIII and XX)

Acid hydrolysate of	Molar ratio of basic amino acids		
	Lys	Arg	NH_2
Compound XIV	1.00 (1)	1.99 (2)	0.17 (0)
Compound XVI	2.00 (2)	1.96 (2)	1.13 (1)
Compound XVIII	3.00 (3)	1.96 (2)	0.33 (0)
Compound XX	3.00 (3)	2.11 (2)	1.23 (1)

Numbers in parentheses are theoretical values.

The compositions of basic amino acids in the acid hydrolysates of the synthesized peptide derivatives (XIV, XVI, XVIII and XX) were determined by an automatic analyzer.[7] The results are shown in Table I, where it may be found that the heptapeptide (XVI) and the octapeptide (XX) each contain one amide group per molecule, as was expected.

Experimental

All melting points are uncorrected.

Nitroarginine Benzyl Ester *p*-Toluenesulfonate (I).—A mixture of 10.96 g. (0.05 mol.) of nitroarginine and 14.25 g. (0.075 mol.) of *p*-toluene-sulfonic acid monohydrate in 100 ml. of benzyl alcohol was stirred at 100°C. To this solution 50 ml. portions of carbon tetrachloride were added at about 40-min. intervals and then allowed to distill out. After five hours the reaction mixture was cooled, and 500 ml. of anhydrous ether was introduced. The supernatant was removed by decantation, and the sirupy residue was thoroughly washed with ether and dried in vacuo, thus affording 25.3 g. of the crude ester *p*-toluenesulfonate.

A 5 g. sample of the crude product was dissolved in 20 ml. of *n*-butanol, which had been saturated with water, and the solution was washed three times with water and evaporated at 45°C in vacuo to give an oily residue. The pure material was precipitated by the addition of ether; 4.36 g. (91.7% based on nitroarginine used); a highly hygroscopic powder, $[\alpha]_D^{25.5}$ $-1.4\pm1°$ (*c* 1.970, methanol). A single ninhydrin reactive spot was visible on paper, at $R_f=0.83$ (BAPW).*2

Found: C, 49.98; H, 5.71; N, 12.77; S, 7.06. Calcd. for $C_{13}H_{19}N_5O_4\cdot C_7H_8O_3S$: C, 49.89; H, 5.65; N, 14.54; S, 6.65%.

***t*-Butyloxycarbonyl-nitroarginyl-nitroarginine Benzyl Ester (II).**—Compound I (4.10 g., 8.5 mmol.) in water-*n*-butanol-ethyl acetate (1 : 1 : 4) was cooled in an ice-bath; to this 5 ml. of ice-cold 50% potassium carbonate was added, and the mixture was shaken vigorously. The aqueous phase was extracted again with *n*-butanol-ethyl acetate (1 : 4). The organic extracts were combined, washed with water, dried over anhydrous sodium sulfate, and concentrated in vacuo. The nitroarginine benzyl ester (free base) was precipitated by the addition of ether; 1.88 g. (71.6%).

This free ester (1.88 g.) and 1.815 g. (5.0 mmol.) of *t*-butyloxycarbonyl-nitroarginine[9] were dissolved in 10 ml. of dimethylformamide. To this solution there was then added 1.03 g. (5.0 mmol.) of *N*, *N'*-dicyclohexylcarbodiimide (DCCl), dissolved in 15 ml. of methylene chloride, and the reaction mixture was allowed to stand in a refrigerator overnight. After the *N*, *N'*-dicyclohexylurea (DCU) had been removed, the filtrate was evaporated at 40—45°C in vacuo. The resultant sirupy residue was dissolved in *n*-butanol-ethyl acetate (1 : 2), and the solution was washed successively with water, ice-cold N hydrochloric acid, M sodium bicarbonate and water, dried over anhydrous sodium sulfate, and evaporated in vacuo. The desired dipeptide was then precipitated from *n*-butanol as an amorphous solid; 2.42 g. (79.2%), $[\alpha]_D^{25}$ $-18.1\pm1°$ (*c* 2.487, methanol). A single spot was visible in thin-layer chromatography, at $R_f=0.40$ (Silica-gel G, methanol-ethyl acetate (15 : 85)).

Found: C, 47.68; H, 6.78; N, 21.42. Calcd. for $C_{24}H_{38}N_{10}O_9$: C, 47.21; H, 6.27; N, 22.94%.

Nitroarginyl-nitroarginine Benzyl Ester-Trifluoroacetate (III).—Compound II (0.916 g., 1.5 mmol.) was dissolved in trifluoroacetic acid, and the solution was allowed to stand at room temperature for 60 min., after which time the dipeptide ester trifluoroacetate was precipitated by the addition of anhydrous ether; 0.892 g. (95.2%).

Found: C, 40.76; H, 5.80; N, 21.57. Calcd. for $C_{19}H_{30}N_{10}O_7\cdot CF_3COOH$: C, 40.39; H, 5.00; N, 22.43%.

***N*$^{\alpha}$-Carbobenzoxy-*N*$^{\varepsilon}$-*t*-butyloxycarbonyl-lysine *N*-Hydroxysuccinimide Ester (IV).**—To a solution of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysine (prepared from 5.62 g. (0.01 mol.) of the dicyclohexylamine-salt)[4] and 1.15 g. (0.01mol.) of *N*-hydroxy-succinimide in acetonitrile 2.06 g. (0.01 mol.) of DCCl was added, and the mixture was kept in a refrigerator overnight. After the urea had been removed by filtration, the filtrate was evaporated in vacuo to give a sirupy residue. An ethyl acetate solution of the residue was washed succesively with ice-cold N hydrochloric acid, water, M sodium bicarbonate and water, and dried over anhydrous sodium sulfate. The removal of the solvent yielded a sirupy residue, which crystallized from ethyl

acetate - isopropyl ether; 4.58 g. (95.8%), m. p. 91—94°C. Recrystallization from the same solvent gave 4.00 g. (83.7%); m. p. 94.5—95.5°C, $[\alpha]_D^{27.5}$ −14.8 ±1° (*c* 1.770, dioxane).

Found: C, 57.73; H, 6.73; N, 8.93. Calcd. for $C_{23}H_{31}N_3O_8$: C, 57.85; H, 6.54; N, 8.80%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-nitroarginyl-nitroarginine Benzyl Ester (V).—The dipeptide ester trifluoroacetate (III, 0.843 g., 1.35 mmol.) was dissolved in 10 ml. of 90% tetrahydrofuran, and then 0.38 ml. (2.7 mmol.) of triethylamine was added. After this solution had been cooled in an ice bath, 0.645 g. (1.35 mmol.) of IV was added, and the mixture was kept in a refrigerator overnight. After the solvent had been removed, the residue was redissolved in *n*-butanol - ethyl acetate - water (3 : 2 : 1) and the organic phase was washed successively with ice-cold N hydrochloric acid, water, 5% sodium bicarbonate and saturated sodium chloride, dried over anhydrous sodium sulfate, and evaporated in vacuo to give a gelatinous mass. This was reprecipitated from hot acetonitrile to give the desired tripeptide as an amorphous solid; 0.88 g. (74.5%), $[\alpha]_D^{24}$ −20.3 ± 1° (*c* 2.112, methanol).

Found: C, 51.99; H, 6.84; N, 19.00. Calcd. for $C_{38}H_{56}N_{12}O_{12}$: C, 52.28; H, 6.47; N, 19.26%.

N^{ε}-*t*-Butyloxycarbonyl-lysyl-arginyl-arginine Diacetate (VI).—Compound V (0.740 g.) was hydrogenolyzed in a 90% acetic acid solution in the presence of palladium catalyst at room temperature and at atmospheric pressure for 6.5 hr. After the catalyst had been removed by filtration, the filtrate was evaporated in vacuo to give a sirupy residue, which was lyophilized to afford a colorless powder; 0.578 g., $[\alpha]_D^{24}$ +5.3±1° (*c* 2.132, 50% acetic acid). A single ninhydrin and Sakaguchi reactive spot was visible on paper, at R_f= 0.51 (BAPW).

Carbobenzoxy-nitroarginine Amide (VII).—Carbobenzoxy-nitroarginine (17.67 g., 0.05 mol.) and 13.1 ml. (0.055 mol.) of tri-*n*-butylamine were dissolved in 130 ml. of anhydrous tetrahydrofuran. To this solution 5.3 ml. (0.055 mol.) of ethyl chloroformate was added drop by drop at an ice-salt bath temperature. After 10 min. aqueous 28% ammonia (9.6 ml.) was introduced, and the mixture was stirred for 2 hr. at 0°C. The precipitates which formed were filtered off, washed with tetrahydrofuran and ether, and dried in vacuo (19.31 g.). These precipitates crystallized from aqueous ethanol to give pure VII; 14.26 g. (80.9%), m. p. 217—219°C. A sample was recrystallized from the same solvent for analyses; there was a recovery of 92.4%, m. p. 220—221°C, $[\alpha]_D^{24}$ +4.9 ± 1° (*c* 1.946, dimethylformamide). The lit.[5] m. p. 219—220°C, $[\alpha]_D$ not given.

Found: C, 47.40; H, 5.75; N, 24.10. Calcd. for $C_{14}H_{20}N_6O_5$: C, 47.72; H, 5.72; N, 23.85%.

Nitroarginine Amide Hydrobromide (VIII).—To 1.06 g. of VII there was added 8 g. of 40% (w/w) hydrogen bromide in acetic acid; the mixture stood at room temperature for 30 min., after which time anhydrous ether (30 ml.) was introduced. The resultant precipitates were filtered off, washed with anhydrous ether, and dried to give the dihydrobromide as a hygroscopic powder (1.18 g.), which changed to the monohydrobromide upon crystallization from aqueous ethanol; 0.764 g. (85.2%), m. p. 237—239°C. Recrystallization from the same solvent did not alter the melting point; $[\alpha]_D^{26}$ +13.7±0.5° (*c* 2.550, water). A single ninhydrin reactive spot was visible on paper, at R_f=0.38—0.39 (BAPW).

Found: C, 24.09; H, 5.22; N, 28.21; Br, 26.83. Calcd. for $C_6H_{14}N_6O_3$·HBr: C, 24.09; H, 5.05; N, 28.10; Br, 26.71%.

Carbobenzoxy-nitroarginyl-nitroarginine Amide (IX).—Carbobenzoxy-nitroarginine (7.07 g., 0.02 mol.) was converted into the mixed anhydride in a tetrahydrofuran solution by the same procedure as was employed for the preparation of compound VII. After 20 min. an ice-cold solution of 5.99 g. (0.02 mol.) of VIII and 4.77 ml. (0.02 mol.) of tri-*n*-butylamine in 20 ml. of water and 140 ml. of dioxane was added, and the mixture was stirred for 2 hr. at 0°C. The separated precipitates were filtered off, washed with dioxane and ether, and dried in vacuo to give 13.2 g. (92.1%) of the crude dipeptide amide; m. p. 116—119°C. Recrystallization from hot dimethylformamide gave fine needles which seemed to combine two molecules of dimethylformamide as the crystallization solvent; 9.49 g. (66.1%), m. p. 115—115.5°C, $[\alpha]_D^{25}$ −6.2±1° (*c* 2.165, 50% acetic acid).

Found: C, 43.40; H, 6.75; N, 25.42. Calcd. for $C_{20}H_{31}N_{11}O_8$·2HCON$(CH_3)_2$·H_2O: C, 43.51; H, 6.60; N, 25.37%.

Nitroarginyl-nitroarginine Amide Hydrobromide (X).—To 5.74 g. (8.0 mmol.) of compound IX there was added 70 g. of 40% (w/w) hydrogen bromide in acetic acid; the mixture stood at room temperature for 40 min., after which time anhydrous ether (150 ml.) was introduced. The resultant precipitates, which were highly hygroscopic, were reprecipitated from aqueous ethanol; 4.21 g. (96.4%), m. p. 147—155°C (decomp.). Reprecipitation from the same solvent gave 3.95 g. (90.5%) of a colorless powder; m. p. 153.5—156°C (decomp.), $[\alpha]_D^{23.5}$ +14.1±1° (*c* 2.026, water). A single ninhydrine reactive spot was visible in paper chromatography, at R_f=0.33 (BAPW).

Found: N, 28.83; Br, 14.24. Calcd. for $C_{12}H_{25}N_{11}O_6$·HBr·C_2H_5OH: N, 28.25; Br, 14.65%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-nitroarginyl-nitroarginine Amide (XI).—*By the N-Hydroxysuccinimide Ester.*[6]—To a solution of 1.41 g. (2.5 mmol.) of compound X and 1.16 ml. (6.25 mmol.) of tri-*n*-butylamine in a mixture of 3.5 ml. of water and 9 ml. of tetrahydrofuran, 1.19 g. (2.5 mmol.) of the *N*-hydroxysuccinimide ester (IV) was added ; the mixture was then left to stand at room temperature for 4 hr. The solvent was removed by evaporation in vacuo, and the residue was dissolved in a mixture of water, *n*-butanol and ethyl acetate (2 : 1 : 2). The organic phase was washed successively with ice-cold N hydrochloric acid, water, and M sodium bicarbonate, and dried over anhydrous sodium sulfate. After the solvent had been removed by evaporation, a sirupy residue was redissolved in hot *n*-butanol. The protected tripeptide, which separated upon cooling, was collected, washed with cold *n*-butanol and ether, and dried; 1.75 g. (87.4%). Reprecipitation from hot *n*-butanol gave 1.44 g. (71.8%) of a pure material; m. p. 111—114°C, $[\alpha]_D^{25.5}$ −15.4±1° (*c* 2.092, methanol). Thin-layer chromatography gave a single ninhydrin reactive spot when the chromatographed plate had been treated with hydrochloric acid, at R_f=0.45

(Silica-gel G, methanol - ethyl acetate (25 : 75)).

Found: C, 46.83; H, 6.88; N, 22.51. Calcd. for $C_{31}H_{51}N_{13}O_{11}\cdot H_2O$: C, 46.55; H, 6.68; N, 22.77%.

By the Mixed Anhydride Procedure.—To a solution of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysine (prepared from 1.12 g. (2.0 mmol.) of the dicyclohexylamine salt)[4] and 0.48 ml. of tri-*n*-butylamine in 10 ml. of anhydrous tetrahydrofuran, 0.19 ml. (2.0 mmol.) of ethyl chloroformate was added at an ice-salt bath temperature (ca. −10°C). After the mixture had been stirred for 15 min., a solution of nitroarginyl-nitroarginine amide hydrobromide and 0.57 ml. (2.4 mmol.) of tri-*n*-butylamine in 2 ml. of water and 14 ml. of tetrahydrofuran was added. The reaction mixture was stirred for one hour at 0°C and then allowed to stand at room temperature for 3 hr. The solvent was removed by evaporation in vacuo to give a sirupy residue, to which were added 5 ml. of *n*-butanol, 10 ml. of ethyl acetate and 5 ml. of water. The aqueous phase was extracted twice with *n*-butanol - ethyl acetate (1 : 2). The organic extracts were combined, washed successively with ice-cold N hydrochloric acid, M sodium bicarbonate and water, dried quickly over anhydrous sodium sulfate, and evaporated in vacuo at 40—45°C. The residue was reprecipitated from hot *n*-butanol to give the desired tripeptide; 1.05 g. (65.6%), m. p. 110—120°C, $[\alpha]_D^{24.5}$ −15.5±1° (*c* 2.046, methanol), homogeneous in thin-layer chromatography.

Found: C, 46.19; H, 6.74; N, 22.27. Calcd. for $C_{31}H_{51}N_{13}O_{11}\cdot H_2O$: C, 46.55; H, 6.68; N. 22.77%.

N^{ε}-*t*-Butyloxycarbonyl-lysyl-arginyl-arginine Amide Triacetate (XII).—Compound XI (1.00 g.) in 90% acetic acid was hydrogenolyzed in the presence of a palladium catalyst at room temperature and at atmospheric pressure for 5 hr. After the catalyst had been removed by filtration, the filtrate was evaporated in vacuo and the residue was lyophilized to give a colorless powder; 0.913 g., $[\alpha]_D^{23.5}$ +2.7±2° (*c* 1.318, 50% acetic acid). A single ninhydrin and Sakaguchi reactive spot was visible on paper, at R_f=0.51 (BAPW).

Found: C, 46.73; H, 8.06; N, 19.99; CH_3CO. 16.24. Calcd. for $C_{23}H_{47}N_{11}O_5\cdot 3CH_3COOH\cdot 2H_2O$: C, 45.01; H, 8.21; N, 19.91; CH_3CO, 16.69%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-nitroarginyl-nitro-arginine Benzyl Ester (XIII).—The dipeptide benzyl ester trifluoroacetate (III) (1.29 g., 2.0 mmol.) in *n*-butanol - methylene chloride (1 : 1) was treated with 50% potassium carbonate at 0°C. The organic phase was, after being dried over anhydrous sodium sulfate, concentrated in vacuo. The free ester of the dipeptide solidified upon the addition of ether. The dipeptide ester thus obtained and 1.11 g. (1.75 mmol.) of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycine[4] were dissolved in dimethylformamide, and to this solution there was added a methylene chloride solution of 0.361 g. (1.75 mmol.) of DCCl at 0°C. The reaction mixture was then allowed to stand in a refrigerator for 40 hr. The DCU which formed was filtered off and the filtrate was evaporated in vacuo. The residue was dissolved in 2 ml. of *n*-butanol and 20 ml. of ethyl acetate, and the solution was washed with ice-cold N hydrochloric acid, water, M sodium bicarbonate and with saturated sodium chloride, dried over anhydrous sodium sulfate, and evaporated in vacuo at 40—45°C. The resultant foamy residue crystallized from acetonitrile and ethyl acetate; 1.62 g. (92.8%), m. p. 113—115°C. Recrystallization from the same solvent system gave the pure hexapeptide derivative; 1.49 g. (85.2%), m. p. 114—115°C, $[\alpha]_D^{25}$ −49.4±1° (*c* 1.986, methanol). A single spot was detected in thin-layer chromatography, at R_f=0.36 (Silica-gel G, methanol - ethyl acetate (15 : 85)).

Found: C, 52.54; H, 6.49; N, 18.52. Calcd. for $C_{50}H_{75}N_{15}O_{15}\cdot H_2O$: C, 52.48; H, 6.78; N, 18.36%.

N^{ε}-*t*-Butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-arginyl-arginine Diacetate (XIV).—Compound XIII (0.687 g.) was hydrogenolyzed in 90% acetic acid in the usual manner for 8 hr. After the catalyst had been removed, the solvent was removed by evaporation in vacuo, and the residue was then lyophilized; 0.586 g. (100%), $[\alpha]_D^{26.5}$ −50.1±1.5° (*c* 1.565, 50% acetic acid).

Found: N, 19.51; CH_3CO, 9.68. Calcd. for $C_{35}H_{65}N_{13}O_9\cdot 2CH_3COOH$: N, 19.54; CH_3CO, 9.24%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-nitroarginyl-nitroarginine Amide (XV).—A solution of 0.876 g. (1.0 mmol.) of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysine hydrazide[4] in 10 ml. of 90% tetrahydrofuran was chilled in an ice-salt bath, and to this 2.5 ml. of ice-cold N hydrochloric acid and 0.55 ml. of ice-cold 2M sodium nitrite were added. After five minutes the mixture was made neutral by the addition of 0.35 ml. of triethylamine. To this mixture there was then added an ice-cold solution o 0.569 g. (1.0 mmol.) of compound X and 0.168 ml. (1.2 mmol.) of triethylamine in 1.5ml. of water and 7.5 ml. of tetrahydrofuran; the reaction mixture was stirred at 0—4°C for 40 hr. After most of the solvent had been removed by evaporation at 30°C, 10ml. of water, 10 ml. of ethyl acetate and 5 ml. of *n*-butanol were added and the mixture was shaken vigorously. The organic phase which separated was cooled in an ice-bath, washed successively with ice-cold N hydrochloric acid, water, and M sodium bicarbonate, dried quickly over anhydrous sodium sulfate, and evaporated at 40—45°C in vacuo. The residue was dissolved in about 20 ml. of hot *n*-butanol, and the solution was refrigerated overnight. The precipitates which separated were collected, washed with cold *n*-butanol, ethyl acetate and ether, and dried in vacuo to give the pure heptapeptide derivative; 0.856 g. (65.6%), m. p. 133—135°C, $[\alpha]_D^{25.5}$ −40.4±1° (*c* 1.751, methanol). A single spot was detected in thin-layer chromatography, at R_f= 0.42 (Silica-gel G, methanol - ethyl acetate (25 : 75)).

Found: C, 49.76; H, 7.29; N, 19.31. Calcd. for $C_{54}H_{90}N_{18}O_{17}\cdot 2^1/_2H_2O$: C, 49.57; H, 7.32; N,19.27.

N^{ε}-*t*-Butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine Amide Triacetate (XVI).—Compound XV (0.75 g.) was hydrogenolyzed in 90% acetic acid in the presence of palladium black for 8 hr. After the catalyst had been removed, the filtrate was evaporated in vacuo to give an oily residue. In order to remove the remaining acetic acid, this residue was dissolved in *n*-butanol and evaporated again in vacuo. The resultant residue was dissolved in water, and the aqueous solution was concentrated to a small volume in order to remove a trace of *n*-butanol, and then lyophilized to give a colorless fluffy powder; 0.747 g. (100%), $[\alpha]_D^{24}$ −44.8

$\pm 1°$ (c 1.530, 50% acetic acid). A single ninhydrin and Sakaguchi reactive spot was visible on paper, at $R_f=0.69$ (BAPW).

Found: N, 17.79; CH_3CO, 11.10. Calcd. for $C_{46}H_{86}N_{16}O_{11}\cdot 3CH_3COOH\cdot 2H_2O$: N, 17.85; CH_3CO, 10.29%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine Monoacetate (XVII).—To a solution of the protected pentapeptide azide (prepared from 0.876 g. (1.0 mmol.) of N^{α}-carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysine hydrazide[4] by the procedure described in the synthesis of compound XV) there was added an ice-cold solution of 0.527 g. (0.76 mmol.) of compound VI, which had been dissolved in 1.5 ml. of water and 6.0 ml. of tetrahydrofuran containing 0.21 ml. (1.52 mmol.) of triethylamine. The reaction mixture was then stirred at 0—4°C for 56 hr. After the solvent had been removed by evaporation, the residue was dissolved in 10 ml. of N acetic acid, and the solution was extracted four times with ethyl acetate. The ethyl acetate extracts were then combined and concentrated to about 20 ml. in vacuo. The resultant concentrate was extracted four times with N acetic acid. The equeous extracts were combined and concentrated to about 10 ml. at 40—45°C in vacuo. The resultant aqueous solution was extracted four times with *n*-butanol which had been saturated with water. The butanol extracts were pooled, dried over anhydrous sodium sulfate, and evaporated at 40—45°C in vacuo. The foamy residue was then lyophilized to give a colorless fluffy powder; 0.587 g. (52.8%), $[\alpha]_D^{25.5}$ $-46.1\pm 2°$ (c 1.044, 50% acetic acid). Paper chromatography, $R_f=0.92$ (BAPW).

Found: C, 50.66; H, 8.32; N, 15.32; CH_3CO, 2.80. Calcd. for $C_{65}H_{111}N_{17}O_{17}\cdot CH_3COOH\cdot 7H_2O$: C, 50.65; H, 8.18; N, 14.99; CH_3CO, 2.71%.

N^{ε}-*t*-Butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxy-carbonyl-lysyl-arginyl-arginine Acetate (XVIII).—Carbobenzoxy octapeptide (XVII) (0.300 g.) was hydrogenolyzed in 15 ml. of 90% acetic acid over a palladium black catalyst for 4.5 hr. in the usual manner. The catlyst was then filtered off, and the filtrate was evaporated at 40—45°C in vacuo. The residue was treated as was compound XVI in order to remove the remaining acetic acid, and then lyophilized; 0.275 g. (98.9%), $[\alpha]_D^{25.5}$ $-41.6\pm 2°$ (c 1.007, 50% acetic acid). Paper chromatography gave a main spot and a faint minor one reactive to both ninhydrin and Sakaguchi reagents, at $R_f=0.86$ (BAPW) and 0.94 (BAPW) respectively.

Found: C, 47.44; H, 8.54; N, 16.71; CH_3CO, 2.42. Calcd. for $C_{57}H_{105}N_{17}O_{15}\cdot {}^3/_4CH_3COOH\cdot 7H_2O$: C, 48.80; H, 8.54; N, 16.54; CH_3CO, 2.24%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine Amide (XIX).—To a solution of the protected pentapeptide azide (prepared from 1.313 g. (1.5 mmol.) of the hydrazide[4] by the procedure described in the synthesis of compound XV) there was added a solution of 0.756 g. (1.0 mmol.) of compound XII, which had been dissolved in 2.0 ml. of water and 8.0 ml. of tetrahydrofuran, together with 0.28 ml. (2.0 mmol.) of triethylamine. The reaction mixture was then stirred at 0—4°C for 40 hr., and evaporated at 30°C in vacuo. The residue was purified exactly as was compound XVII. The purified product was then lyophilized to give a colorless fluffy powder; 1.292 g. (84.2%), $[\alpha]_D^{22.5}$ $-43.7\pm 1°$ (c 1.745, 50% acetic acid). Thin-layer chromatography gave a Sakaguchi reactive spot, at $R_f=0.76$ (Silica-gel G, dimethylformamide - ethyl acetate - acetic acid (15 : 10 : 2)).

Found: C, 50.85; H, 8.54; N, 16.33; CH_3CO, 0.0%. Calcd. for $C_{65}H_{112}N_{18}O_{16}\cdot 7{}^1/_2H_2O$: C, 50.80; H, 8.33; N, 16.41; CH_3CO, 0.0%.

N^{ε}-*t*-Butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-N^{ε}-*t*-butyloxycarbonyl-lysyl-arginyl-arginine Amide Triacetate (XX).—A sample of carbobenzoxy-octapeptide amide (XIX) was hydrogenolyzed for 3 hr. in 15 ml. of 90% methanol containing 0.1 ml. of acetic acid in the presence of palladium black. The catalyst was then removed by filtration, and the filtrate was evaporated in vacuo. The lyophilization of the resultant residue gave a colorless fluffy powder; $[\alpha]_D^{24}$ $-41.0\pm 2°$ (c 1.210, 50% acetic acid). A single ninhydrin and Sakaguchi reactive spot was visible on paper, at $R_f=0.80$ (BAPW).

Found: C, 50.22; H, 8.22; N, 16.83; CH_3CO, 8.37. Calcd. for $C_{57}H_{106}N_{18}O_{14}\cdot 3CH_3COOH\cdot 2H_2O$: C, 51,00; H, 8.29; N, 16.99; CH_3CO, 8.70%.

N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycyl-N^{ε}-*t*-butyloxycarbonyl-lysine Methyl Ester.—N^{α}-Carbobenzoxy-N^{ε}-*t*-butyloxycarbonyl-lysyl-prolyl-valyl-glycine (3.17 g., 5.0 mmol.)[4] and the N^{ε}-*t*-butyloxycarbonyl-lysine methyl ester (prepared from 1.76 g. (5.5 mmol.) of the acetate)[4] were dissolved in methylene chloride, and to this solution a methylene chloride solution of 1.135 g. (5.5 mmol.) of DCCl was added. The mixture was then allowed to stand in a refrigerator overnight. After the DCU which separated had been removed, the filtrate was evaporated in vacuo and the residue was redissolved in ethyl acetate. This solution was then washed successively with ice-cold N hydrochloric acid, 5% sodium bicarbonate and water, and dried over anhydrous sodium sulfate. The gelatinous precipitates separated from the concentrated ethyl acetate solution upon the addition of ether; 4.14 g. (94.6%), m. p. 92—94°C. The amorphous solid was reprecipitated from acetone-ether to give fine crystals with a m. p. of 101—104°C; 3.75 g. (85.5%), $[\alpha]_D^{25}$ $-56.6\pm 1°$ (c 2.017, methanol). Lit.[4] m. p. 105—107°C, $[\alpha]_D^{25}$ $-55.2\pm 1°$ (c 2.126, methanol).

Found: C, 58.72; H, 7.98; N, 11.13. Calcd. for $C_{43}H_{69}N_7O_{12}$: C, 58.95; H, 7.94; N, 11.19%.

Grateful acknowledgement is made to Dr. Mitsuo Ebata and staff for amino acid analyses, to Dr. Kaoru Kuriyama and staff for optical rotation measurements, and to Dr. Satoshi Mizukami and staff for elemental microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 889—892 (1966)

The Attempted Cationic Polymerization of 1, 1-Dimethylcyclopropane and Phenylcyclopropane

By Shuzo AOKI, Yoshiyuki HARITA, Takayuki OTSU and Minoru IMOTO

Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received August 30, 1965)

1, 1-Dimethylcyclopropane and phenylcyclopropane gave the oligomer by aluminum bromide-catalyzed polymerization in *n*-hexane or in methylene chloride at 0°C. The polymerization reactivity of 1,1-dimethylcyclopropane was lower than that of styrene, and the content of cyclopropane units in their copolymers was decreased by a lowering of the temperature. The polymerization of 1,1-dimethylcyclopropane in the presence of polystyrene gave a graft polymer by chain transfer reaction. The polymerization of the cyclopropanes by a coordinated catalyst, $C_2H_5AlCl_2/TiCl_3$, in *n*-heptane at room temperature gave polymers with molecular weights of above 1200. The results are discussed in comparison with those of the polymerization of the corresponding vinyl monomers.

Cyclopropyl compounds polymerize in the presence of Lewis acids to give an oligomer.[1-3] The polymerizations of 1, 1-dimethylcyclopropane and phenylcyclopropane catalyzed by Lewis acids and a coordinated catalyst will be attempted in this work as an experiment preliminary to the copolymerization of the vinyl monomer with a cyclopropyl compound. 1, 1-Dimethylcyclopropane will be referred to isobutene in terms of their structures, especially, as growing terminal cations, while phenylcyclopropane will be referred to styrene. The results will be discussed in comparison with those of the polymerization of the corresponding vinyl monomers.

Experimental

Materials.—1, 1-Dimethylcyclopropane was prepared from 1, 3-dibromo-2, 2-dimethylpropane according to the method given by Shortridge et al.[4] B. p. 20.8°C; lit.[4] b. p. 20.63°C.

Phenylcyclopropane was obtained following the method of Dale et al.[5] B. p. 68.5—69.0°C/12 mmHg, n_D^{20} 1.5320; lit.[5] b. p. 69°C/12 mmHg, n_D^{20} 1.5320.

The monomers and solvents were carefully purified by the usual methods. Boron trifluoride - diethyl etherate, and stannic and titanic chlorides were distilled prior to use. The other catalysts, obtained commercially, were used without further purification.

Procedure.—*Polymerization by Lewis Acid.*—Into a glass stoppered test tube the monomer and solvent were taken and chilled to a given temperature. Then the catalyst solution was added. After a given time, ammoniac or acidic methanol was added to the reaction system in order to stop the polymerization. The resulting product was precipitated by the addition of a large amount of methanol, or, in some cases, it was fractionally distilled from the reaction system.

Polymerization by Coordinated Catalyst.—The polymerization was carried out in *n*-heptane in a sealed tube at room temperature, using a catalyst which had been aged for an hour. After a given time, the contents of the tube were poured into a large amount of isopropanol containing hydrochloric acid in order to precipitate the resulting polymer and remove the residual catalyst. The polymer was washed several times with pure methanol, and then dried under reduced pressure.

Results

The Polymerization of 1, 1-Dimethylcyclopropane.—In order to examine the catalytic activity, 1, 1-dimethylcyclopropane was polymerized in methylene chloride at 0°C by using various Lewis acids, such as aluminum bromide, aluminum chloride, stannic chloride, titanic chloride and boron trifluoride - diethyl etherate. Aluminum bromide-catalyzed polymerization afforded an oligomer with the molecular weight of 390, whereas no product was obtained by using the other Lewis acids.

The effects of the solvents are shown in Table I. In alkane (*n*-hexnane) the reaction proceeded very fast and gave an oligomer. The fast reaction in toluene, however, gave a liquid product. The infrared spectra of the products obtained in *n*-hexane and in toluene are shown in Fig. 1. The spectrum of the product obtained in *n*-hexane agreed with that of poly-1, 1-dimethylcyclopropane,[3] whereas the spectrum of the product obtained in toluene contained aromatic absorption bands. The absorptions at 1890, 1780 and 810 cm^{-1} indicated that the para-substitution of toluene by attacking the alkyl cation. Thus aromatic compounds

seem to be unsuitable as solvents for the cyclopropane polymerization.

The Copolymerization of 1, 1-Dimethylcyclopropane with Styrene.—The copolymerization of 1, 1-dimethylcyclopropane with styrene was attempted in the presence of aluminum bromide. The results are given in Table II.

The rate of the polymerization of 1, 1-dimethylcyclopropane was markedly lower than that of styrene, and the copolymer containing the higher concentration of styrene units resulted from the equimolar mixture of the monomers. The cyclopropane unit content of this copolymer decreased with a lowering of the temperature.

The infrared spectrum of the copolymer agreed with that of polystyrene, and no evidence for the presence of the para-substituted styrene units was obtained.

The Graft Polymerization of 1, 1-Dimethylcyclopropane onto Polystyrene.—1, 1-Dimethylcyclopropane was polymerized in the presence of polystyrene to produce a graft polymer by the attack of the growing cyclopropane cation on the benzene nucleus of polystyrene. Table III shows the results of the graft polymerization. *n*-Hexane-insoluble polystyrene, obtained by radical polymerization, was used as the backbone. The entire polymer recovered after the polymerization of cyclopropane was soluble in *n*-hexane. This indicates that the high-molecular-weight polystyrene initially used was modified. The rubbery polymer recovered was fractionated by the *n*-hexane - isopropanol system (Table III). The infrared spectra

* $[M_1+M_2]_0=3.0$ mol./l., $[AlBr_3]_0=0.007$ mol./l.

Table III. Polymerization of 1,1-dimethylcyclopropane in the presence of polystyrene

Polymerization condition and result:

Polystyrene: 0.1170 g., 1,1-Dimethyl cyclopropane: 5.0 ml., CH_2Cl_2: 8.0 ml., $AlBr_3$: 0.49 g., Reaction time: 75 hr., Reaction temp.: 0°C. Whole polymer recovered: 0.4200 g., Content of polystyrene in the polymer: 27.9%.

Fractionation of the polymer recovered:

Sample initially used: 0.3963 g.

First fraction (Precipitate in *n*-hexane 20 ml. - isopropanol 30 ml.): 0.1510 g. (38.1%). Rubbery substance.

Second fraction (Precipitate in *n*-hexane 20 ml. - isopropanol 40 ml.): 0.0544 g. (13.7%). Rubbery substance.

Third fraction (Methanol insoluble): 0.1819 g. (45.9%). Viscous liquid.

of the first and the second fractions contained a strong absorption at 820 cm^{-1} (Fig. 2). This indicates the presence of the para-substituted styrene units, an evidence of grafting. The third fraction was found from its infrared spectrum to be the homopolycyclopropane (Fig. 2).

The Polymerization of Phenylcyclopropane.—The polymerization of phenylcyclopropane (3.0 mol./l.) was attempted in the presence of aluminum bromide (0.07 mol./l.) in *n*-hexane at 0°C. After 15 sec., the exothermic reaction gave a viscous liquid at about a 90% conversion. About 60% of the product was distilled off below 200°C/1.5 mmHg. The molecular weight of the distillate at 200°C/1.5 mmHg was 320. The infrared spectrum of this fraction is shown in Fig. 3. The absorptions at 2000—1700 cm^{-1} indicated the presence of 1,2-disubstituted benzene units. The

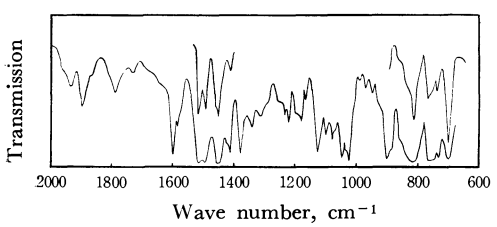

Fig. 3. Infrared spectrum of the reaction product from phenylcyclopropane.

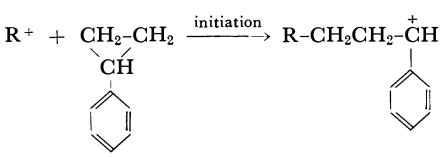
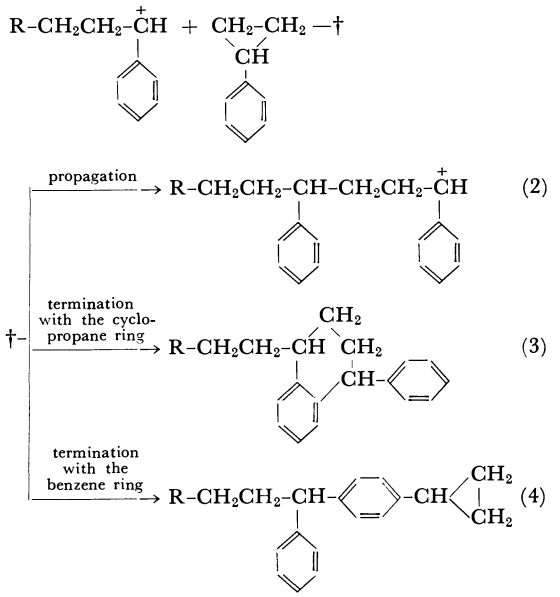
presence of 1,4-disubstituted benzene units was also confirmed by the absorption at 810 cm^{-1}.

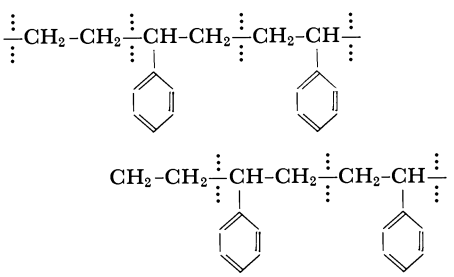
Thus the reaction scheme may be expressed as follows:





The Coordinated Polymerization of Cyclopropanes.—The polymerization of 1,1-dimethylcyclopropane with $C_2H_5AlCl_2/TiCl_3$ catalyst (Al/Ti=2) in *n*-heptane at room temperature for 18 days gave a waxy polymer with the molecular weight of 1240 in a 66% conversion. Phenylcyclopropane also gave a resinous polymer, this one with the molecular weight of 1480 in a 45% conversion. The other catalyst systems, $(C_2H_5)_2AlCl/TiCl_3$ and $(C_2H_5)_3Al/TiCl_3$, did not show any catalytic activity for the cyclopropane polymerization.

The degradation temperature of the polyphenylcyclopropane was found by the differential thermal analysis to be 430°C. If the polyphenylcyclopropane has the following structure (I), the thermal degradation of this polymer may give styrene and ethylene in the ratio of 2/1;



(I)

Styrene and ethylene in the degradation products at 450°C of this polymer were detected on a gas chromatogram, though the quantitative analysis was unsuccessful because of the complexity of the by-products.

The infrared spectrum of this polymer, shown in Fig. 4, contained the absorption band at 820 cm^{-1}, showing the presence of 1,4-disubstituted benzene

units arising from chain transfer reaction, besides the structure I.

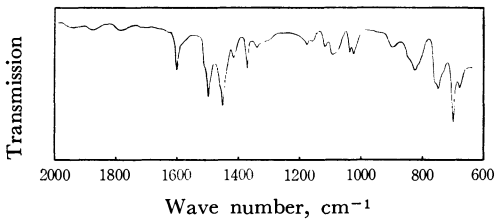


Fig. 4. Infrared spectrum of polyphenylcyclopropane.

Discussion

Dainton, Devlin and Small,[6] using the semi-empirical method, evaluated the heat of polymerization as 13.7 kcal./mol. for isobutene and 20.4 kcal./mol. for 1, 1-dimethylcyclopropane. These values suggest that the reactivity of 1, 1-dimethylcyclopropane is higher than that of isobutene. However, the results of the Lewis acid-catalyzed polymerizations of the cyclopropanes mentioned above indicate that the polymerization reactivity of the cyclopropanes is lower than that of the corresponding vinyl monomers.

1, 1-Dimethylcyclopropane was less reactive than styrene in the homopolymerization and in the copolymerization (see Table II), though, in general, isobutene was more reactive than styrene.[7] The content of cyclopropane units in the 1, 1-dimethylcyclopropane-styrene copolymer was influenced by the reaction temperature, for it decreased with a lowering of the temperature. This may be explained by the difference in the activation energies of the propagation reaction, as in the other copolymerization.[8,9]

The graft polymer was obtained in the polystyrene-1, 1-dimethylcyclopropane system, though the polystyrene-isobutene system did not give the graft polymer.[10] If the reactivities of the growing terminal cations of 1, 1-dimethylcyclopropane and isobutene are similar because of the similarity in the structure of their cations, this also indicates the lower reactivity of the cyclopropane monomer as compared with that of the vinyl monomer.

Phenylcyclopropane did not afford a high polymer under the conditions under which styrene gives a high polymer. This can be explained by the fact that the termination proceeds much further than the propagation in this polymerization because of the lower reactivity of the cyclopropane.

The cationic polymerization of vinylcyclopropane gave results which indicate that the cyclopropyl group has a lower reactivity than the vinyl group.[11]

A more quantitative study will be published later.

The authors wish to thank the Osaka Research Laboratory of the Japan Gas Chemical Co. for supplying the raw material and for the differential thermal analysis and the gas chromatographic measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 892—898 (1966)

The Radiation-Induced Addition of Hydrogen Chloride to Ethylene

By Akira TERAKAWA, Jun NAKANISHI and Toru HIRAYAMA

Central Research Laboratory, Showa Denko K. K., Ota-ku, Tokyo

(Received August 31, 1965)

In a stainless steel autoclave, ethylene and hydrochloric acid or dried hydrogen chloride were irradiated with cobalt-60 gamma-rays. *n*-Butyl chloride and ethyl chloride were thus produced efficiently, unlike as when an ultraviolet light or catalyst was used. The products were quantitatively analyzed by gas chromatography. This reaction was supposed to be a vapor-phase radical chain reaction; the proposed reaction mechanism agreed well with our results. The selectivity of ethylene to the products was considered to be practically 100%. The *G* values of ethyl chloride, *n*-butyl chloride and the ethylene consumed, using the ratio of the total absorbed dose to ethylene, were calculated to be 16000, 10000 and 35000 respectively at 50°C and at a dose rate of 1.10×10^4 r./hr. The ratios of the rate constants for ethyl chloride and *n*-butyl chloride were 366, 499 and 580 at 50, 40 and 15°C respectively, and the apparent activation energies for ethyl chloride and *n*-butyl chloride were calculated from the reaction rates to be 6.94 and 8.95 kcal./mol. respectively.

Although the chain addition of hydrogen bromide to olefins is readily brought about by peroxide[1] or by radiation,[2] it has been generally recognized that the analogous reaction of hydrogen chloride is much less likely. There are only a few articles which are concerned with this reaction. One of them is by Ford and Hanford,[3,4] who reported the formation of mixtures of straight-chain primary alkyl chlorides, ranging from ethyl chloride to greases and waxes, by the reaction between ethylene and hydrogen chloride in the presence of catalysts and water at a high temperature and a high pressure.

Another article is that by Raley, Rust and Vaughan,[5] who recognized that the vapor-phase addition of hydrogen chloride to ethylene, as initiated by ultraviolet light or di-*t*-butyl peroxide, yielded ethyl chloride and small amounts of hydrogen and ethane (both 0.1% or less).

The general methods of preparing alkyl chlorides include one working from corresponding *n*-alcohol using zinc chloride and concentrated hydrochloric acid,[6] and one working from the chlorination of the corresponding alkyl hydrocarbons with hydrogen chloride.[7] However, it is generally considered that the selective preparation of *n*-alkyl chlorides from the chlorination of olefins is rather difficult; besides, there is no report on such a reaction using actinic radiation. The authors found that both *n*-butyl chloride and ethyl chloride were efficiently formed from a gamma-ray-induced reaction between ethylene and hydrogen chloride; the results of this process will be given in the present paper.

Experimental

Materials.—Ethylene and dried hydrogen chloride were obtained from the Nihon Sekiyu Kagaku Co., Ltd. (Kawasaki), and the Dow Chemical Co. (Matheson Co., Inc., U. S. A.) respectively, and were used without further purification. Reagent-grade concentrated hydrochloric acid (sp. gr. 1.184, 20°C) was obtained from the Kanto Kagaku Co., Ltd. (Tokyo), or the Wako Junyaku Co., Ltd. (Osaka), and all chemicals and materials used for analysis and identification were guaranteed reagents.

Apparatus and Procedures.—Dried hydrogen chloride or 15 ml. of concentrated hydrochloric acid in a glass vessel was introduced into a stainless steel autoclave with a capacity of 50 ml. After that, ethylene was compressed at pressures ranging from 25 to 65 kg./cm^2 and irradiated with cobalt-60 gamma-rays at a does rate of 1.10×10^4 r./hr. or 3.82×10^4 r./hr. After irradiation for 0—160 hr., the gaseous components in the autoclave were absorbed in toluene. The absorbants, as well as the liquid components, were then stored in a refrigerator for analysis. The autoclave was washed and cleaned with ethyl alcohol and ethyl ether after each reaction in order to avoid the effects of any impurities.

Dosimetry.—The intensity of the cobalt-60 source used was about 230 curies. The dose rates were determined with a Fricke dosimeter, using $G(Fe^{3+})=15.6$. The does absorbed by ethylene was calculated by the following equation[8]:

$$D_{C_2H_4} = D_{H_2O}\times\frac{(a/\rho)_{C_2H_4}}{(a/\rho)_{H_2O}} = D_{H_2O}\times\frac{(Z/A)_{C_2H_4}}{(Z/A)_{H_2O}}$$

where $D_{C_2H_4}$ and D_{H_2O} represent the doses absorbed by ethylene and by water in the system. (a/ρ) denotes the mass energy absorption coefficient, and Z and A represent the atomic number and the molecular weight of the substances in the system respectively.

Analytical.—The products, ethyl chloride and *n*-butyl chloride, were identified by comparing them with pure materials, by flame tests, by boiling point and refractive index measurements, by examining the infrared spectrum, and by gas chromatography. Hydrogen and chlorine were identified by gas chromatography. The products were quantitatively analyzed by gas chromatography using Kotaki Gu-12 model equipment. A 5-m. column of tri-*m*-cresyl phosphate on cerite was used at an operating temperature of 65°C and at a flow rate of 80 ml./min. of helium (Southern Oxygen Co.).

A known volume of the toluene absorbant of the gaseous products was taken for gas chromatography. As to the liquid products, known volumes of the toluene phase from the product of the extraction and of the aqueous hydrochloric acid phase were analyzed by gas chromatography.

Results

Products and *G* Values.—Table I shows the results obtained without irradiation and with and without the addition of the $AlCl_3$ catalyst, which is commonly employed in the production of ethyl chloride. No ethyl chloride, or only a small amount of it, was produced, and no *n*-butyl chloride was detected in any case. The pressure of hydrochloric acid in Table I represents the partial pressure of

his co-workers[5] reported that their synthesis of ethyl chloride by ultraviolet light was a vapor-phase reaction. From these results, it is reasonable for us to conclude that the present reaction, using aqueous hydrochloric acid, is a vapor-phase radical reaction rather than a liquid one. G values were calculated on the basis of the assumption that this reaction is vapor-phase one, using total dose absorbed by ethylene.

Table III shows the relation between the yields and the initial pressure of ethylene. The reaction time was 66 hr. 15 ml. of aqueous hydrochloric acid were used in this series. It is evident from these relations that the mole ratios of the products are

controlled by the temperature and by the ratio of the initial pressures of ethylene to hydrogen chloride.

The relation between the irradiation time by cobalt-60 gamma-rays and the yields at 50, 40 and 15°C are shown in Figs. 1 and 2. Tables IV, V and VI show the G values against the total dose absorbed. The results obtained when the dose rate is changed are given in Table VII.

Since the energy absorbed during the induction period is included, the G values in the above results are naturally small when the conversion rate is low. Above $1—2\times10^6$ r., a wax-like or a solid polymer was produced; these were confirmed to be polyethylene by means of a study of their infrared spectra.

When the reaction temperature was above 60°C, viscous decomposition products were found in addition to ethyl chloride and *n*-butyl chloride. This is considered to be attributable to the fact that the reaction, being due to a high temperature, makes the walls of the autoclave tend to corrosion.

Although the selectivity of ethylene to ethyl chloride and *n*-butyl chloride is not quite 100% in some cases in Tables V, VI and VII, it is considered to be practically 100% in all cases, because no product other than ethyl chloride and *n*-butyl chloride was observed. Furthermore, the mole ratio of ethyl chloride to *n*-butyl chloride becomes smaller with an increase in the reaction time. This observation indicates that the partial pressure of hydrogen chloride with respect to the total pressure is decreased more rapidly than that of ethylene in spite of the feeding of hydrogen chloride from the aqueous hydrochloric acid.

The after-effects of the irradiation on yields were practically negligible in the case of 15°C.

The Effect of the Dose Rate on G Values.—Effects of the dose rate on the yields can be seen by comparing Tables VI and VII or Figs. 1 and 2. According to the curves in the figures, the G values of the consumed ethylene depend on the reaction time. If the logarithm $G(-C_2H_4)$ is plotted against the logarithm of the dose rate at each time, we find that G values are proportional to -0.54 powers of the dose rate, as is shown in Fig. 3.

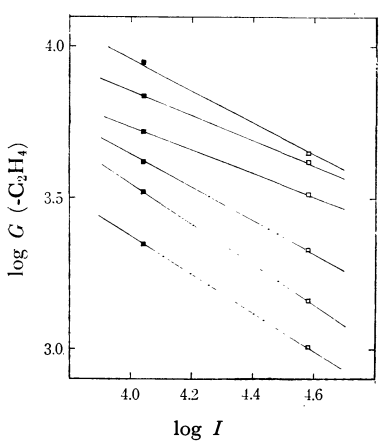

Fig. 3. Dependency of $G(-C_2H_4)$ on dose rate (I).

Discussion

Reaction Mechanism.—Since the investigated reaction is guessed to be a vapor-phase radical reaction, it may be presumed that hydrogen and chlorine radicals are initially formed from hydrogen chloride by irradiation and that the reaction proceeds in accordance with the following chain mechanism:

$$HCl \xrightarrow{f(I)} H\cdot + Cl\cdot \quad (1)$$

$$C_2H_4 + Cl\cdot \xrightarrow{k_2} C_2H_4Cl\cdot \quad (2)$$

$$C_2H_4Cl\cdot + HCl \xrightarrow{k_3} C_2H_5Cl + Cl\cdot \quad (3)$$

$$C_2H_4Cl\cdot + C_2H_4 \xrightarrow{k_4} C_4H_8Cl\cdot \quad (4)$$

$$C_4H_8Cl\cdot + HCl \xrightarrow{k_5} C_4H_9Cl + Cl\cdot \quad (5)$$

$$C_4H_8Cl\cdot + C_2H_4 \xrightarrow{k_6} C_6H_{12}Cl\cdot \quad (6)$$

$$C_6H_{12}Cl\cdot + HCl \xrightarrow{k_7} C_6H_{13}Cl + Cl\cdot \quad (7)$$

$$Cl\cdot + Cl\cdot \xrightarrow{k_8} Cl_2 \quad (8)$$

$$H\cdot + C_2H_4 \xrightarrow{k_9} C_2H_5\cdot \quad (9)$$

$$C_2H_5\cdot + HCl \xrightarrow{k_{10}} C_2H_6 + Cl\cdot \quad (10)$$

The addition reaction of the $C_6H_{12}Cl$ radical to C_2H_4 in this reaction mechanism need not be considered, since no products beyond *n*-butyl chloride were obtained.

By applying the stationary-state method, the following equation is obtained:

$$\frac{d(C_2H_5Cl)}{d(n\text{-}C_4H_9Cl)} = \frac{k_3(HCl)}{k_4(C_2H_4)} + \frac{k_3k_6}{k_4k_5} = m \quad (11)$$

This equation shows that the ratio of the reaction rate (m) of ethyl chloride to that of *n*-butyl chloride is proportional to the pressure ratio of hydrogen chloride to that of ethylene; that its slope is equal to the ratio of rate constants, k_3/k_4, and that k_6/k_5 is derived from the intercept of the line.

The rates of formation were calculated on the basis of the differential of the formation curves in Figs. 1 and 2, while the depression of ethylene pressure was measured with a gauge. The partial pressure of hydrogen chloride, not being subjectable to direct measurement, was calculated by the use of both Perry's data[9] and the concentration of

9) J. H. Perry, "Chemical Engineering Handbook," McGraw-Hill, New York (1950), pp. 166—167.

hydrogen chloride, which in turn was calculated from the yields of ethyl chloride and *n*-butyl chloride. The relation represented by Eq. 11 is illustrated in Fig. 4; the values of k_3/k_4 obtained with a dose rate of 1.10×10^4 r./hr. at 50, 40 and 15°C were 366, 499 and 580 respectively. In the case of a dose rate of 3.82×10^4 r./hr. at 15°C, a value of 568 was obtained.

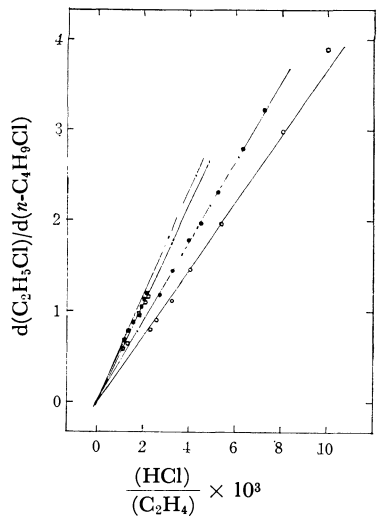

Fig. 4. The relation between ratio of reaction rate (m) and pressure ratio $(HCl)/(C_2H_4)$.
○: 50°C, Dose rate 1.10×10^4 r./hr.
●: 40°C, Dose rate 1.10×10^4 r./hr.
■: 15°C, Dose rate 1.10×10^4 r./hr.
□: 15°C, Dose rate 3.82×10^4 r./hr.

From the fact that these straight lines practically pass through the origin, the value of k_3k_6/k_4k_5 is practically zero; thus, k_6/k_5 approximately equals zero. This calculation agrees well with the fact that nothing beyond *n*-butyl chloride was actually obtained. The logarithms of k_3/k_4 against $1/T$ (T: absolute temperature) gave a straight line according to the Arrhenius equation, as is shown in Fig. 5. From its slope, the difference between activation energies, E_4-E_3, was calculated; its value was 2.29 kcal./mol.

In the case of a dose rate of 1.10×10^4 r./hr., the energies absorbed by ethylene were nearly equal in all cases up to the reaction time of 30 hr.; at this point, a value of 7×10^{19} eV. was obtained. After the pressures of hydrogen chloride and ethylene had been equalized in three cases, the relation between the reaction rates of ethyl chloride and *n*-butyl chloride was found to be as shown in Fig. 6. From the slopes of these straight lines, the apparent activation energies for ethyl chloride and *n*-butyl chloride were calculated to be 6.94 and 8.95 kcal./mol. respectively. The difference between them is 2.01 kcal./mol., which is in good agreement with $E_4-E_3=2.29$ kcal./mol. Evans[10] calculated the

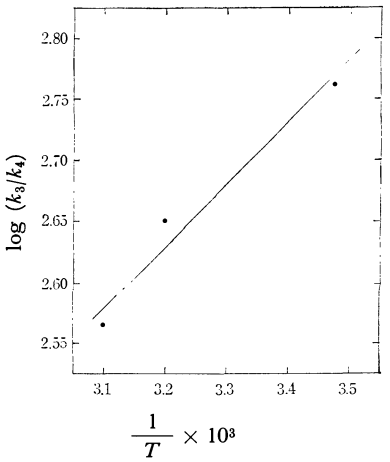

Fig. 5. Logarithms of k_3/k_4 against $1/T$°K.

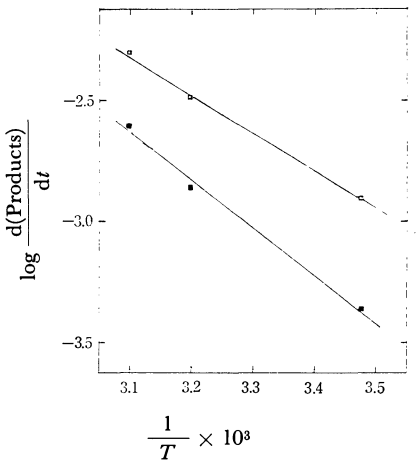

Fig. 6. Logarithms of reaction rates of C_2H_5Cl or n-C_4H_9Cl against $1/T$°K.

■: n-C_4H_9Cl, Dose rate 1.10×10^4 r./hr.

activation energy, $E_2=4.5$ kcal./mol., from the distance between atomic centers. Walling and his co-workers[11] calculated the ΔH values in Eqs. 2 and 3 to be −26 and +5 kcal./mol. respectively, and suggested that the value of E_3 is a little greater than +5 kcal./mol. Our results agree fairly well with these data.

Although Vaughan[5] established the formation of ethane, we could not find ethane under our experimental conditions as long as the reaction temperature was kept below 60°C. However, above the reaction temperature of 60°C, small amounts of ethane were observed.

Since the activation energies for the reactions between the H radical and chlorine gas or hydrogen

10) M. G. Evans, J. Gergely and E. C. Seaman, *J. Polymer Sci.*, **3**, 866 (1948).
11) C. Walling, "Free Radicals in Solution," John Wiley & Sons, New York (1957), p. 241.

chloride are rather small, the following equations, 12 and 13, may have occured in the system:

$$H\cdot + Cl_2 \cdots\cdots HCl + Cl\cdot \quad (12)$$

$$H\cdot + HCl \cdots\cdots H_2 + Cl\cdot \quad (13)$$

Usually no products from the reaction between ethylene and ethyl chloride and *n*-butyl chloride except polymers were observed, but there were a few cases where small amounts of *s*-butyl chloride were observed. This is presumably due to the isomerization of *n*-butyl chloride to *s*-butyl chloride.

Summary

Ethyl chloride and *n*-butyl chloride have been selectively prepared by the cobalt-60 gamma-ray-induced addition of hydrogen chloride to ethylene. The *G* values of consumed ethylene reached 35000. This reaction has been presumed to be a vapor-phase radical chain reaction, and the proposed reaction mechanism show a good agreement with our experimental results. The activation energies for the production of ethyl chloride and *n*-butyl chloride have been calculated from the rate constants to be 6.94 and 8.95 kcal./mol. respectively.

The Barium Content of Barite-forming Hydrothermal Waters as Exemplified by Tamagawa Hot Spring Waters

By Masami ICHIKUNI

Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received September 3, 1965)

An estimation of the barium concentration in Tamagawa Hot Spring water was made on the basis of the partition of lead between spring waters and barite deposits precipitated from the waters. As the lead content of the waters and the chemical composition of the deposits are already known, the barium concentration can be computed by the use of the following relation:

$$D=\left(\frac{\mathrm{Pb}}{\mathrm{Ba}}\right)_{\mathrm{S}}\Big/\left(\frac{\mathrm{Pb}}{\mathrm{Ba}}\right)_{\mathrm{L}}$$

where D is the partition coefficient of lead, and where S and L denote the solid and liquid phases respectively. A value of 2 ± 1 mg./l. was obtained for the barium concentration in the water issuing from the vents. It was pointed out that the water is supersaturated with barium sulfate. This supersaturation may be due to the addition of a considerable amount of sulfates, probably formed by supergene processes, to the original thermal water. The genesis of hydrothermal barite deposits was also discussed.

The determination of the barium content of thermal waters presents a considerable difficulty, its concentration being in general very small. The accumulation of data on the barium concentration in natural waters, especially of hydrothermal origin, will therefore provide useful information on the genesis of ore deposits containing barium minerals. It is of particular importance to define the range of its concentration in various hydrothermal waters producing barite or related minerals.

As one spring indicating a high barium content, we may refer to the Tamagawa Hot Springs, where a continuous deposition of plumbian barite, or so-called hokutolite, occurs on the bed of the stream. The barite originates from the principal spring, called "Obuki," and from other small springs located nearby.

In the studies of the genesis of plumbian barite, Suganuma[1] gave a value of 1.1 mg./l. as the barium sulfate content of Obuki Spring water. This value is, however, very questionable, as compared with the lead content of the same spring water, which has recently been reported by Minami et al.[2] Admittedly, Watanuki,[3] assuming the saturation of the spring water with barium sulfate, recommended a value of 1 mg./l. as its barium concentration. However, this value is possibly a lower limit of barium content, because the water issuing from the vents may be supersaturated with barium sulfate. On the other hand, Minami et al.[4] gave the following values for the barium concentration in the same spring water: 2.9 mg./l.

(sample collected on May 5, 1954) and 5.7 mg./l. (collected on July 14, 1956). It is obvious that more extensive works must be done in order to obtain a reliable value for the barium content.

This report will propose another approach to estimating the concentration of this element. It is a method developed on the basis of the partition equilibrium of a minor element between the liquid and solid phases. As we have a useful review on this subject,[5] it would be unnecessary to give the full details of this method. Minami et al.[6] outlined the same approach, but they did not make any accurate calculations.

Method of Calculation

From the experiments on the partition of lead between the solution and the barium sulfate precipitate, Kolthoff and Noponen[7] determined the partition coefficient, D, to be as follows: 0.027 at 95°C, and 0.026 at 26°C. The coefficient D is defined by Eq. 1:

$$D=\left(\frac{\mathrm{Pb}}{\mathrm{Ba}}\right)_{\mathrm{S}}\Big/\left(\frac{\mathrm{Pb}}{\mathrm{Ba}}\right)_{\mathrm{L}} \qquad (1)$$

where (Pb/Ba) designates the weight ratio of the two elements, and the subscripts S and L refer to the solid and liquid phases respectively. They examined the precipitates with compositions ranging from 0.025 to 0.302 in a Pb/Ba ratio. The composition of plumbian barites from the Tamagawa Hot Springs falls entirely within this range. It was also shown that perchloric acid had no effect upon the partition coefficient; thus, the value is not affected by a high acidity of spring water. The presence of chloride ions in spring water may modify the coefficient slightly as a result of the complex-formation of lead, but as a first approximation, the reported value can be used here without correction.

In the Tamagawa Hot Springs, the plumbian barite precipitates from waters ranging in temperature from 90°C to 40°C; therefore, a partition coefficient of 0.027 may be accepted in this calculation. Special emphasis must be placed on a small variability of the coefficient with the temperature. From Eq. 1, the barium concentration in the solution $(\mathrm{Ba})_{\mathrm{L}}$ is given by the following equation:

$$(\mathrm{Ba})_{\mathrm{L}}=\frac{0.027(\mathrm{Pb})_{\mathrm{L}}}{\left(\frac{\mathrm{Pb}}{\mathrm{Ba}}\right)_{\mathrm{S}}} \qquad (2)$$

where $(\mathrm{Pb})_{\mathrm{L}}$ is the lead concentration in the stream water from which the plumbian barite is precipitating. Since the lead concentration appears to be roughly constant in the stream, a value of 1.2 mg./l. for the stream water[2] is inserted into Eq. 2. In reality this is not true, however, it will be seen later that the correction due to a decrease in lead concentration does not affect the results of calculation. The lowering of the lead concentration resulting from the confluence of some streamlets with the main stream can be equally neglected, their discharge being small compared with that of the latter.

Results and Discussion

Table I indicates the chemical composition of several plumbian barites[8,9] and the calculated barium contents of the waters which are in equilibrium with these minerals. Figure 1 represents the locality of the barites. It is well known that the deposits formed in the lower course of the stream are rich in lead, while those formed in the upper course are deficient in this element. The change in chemical composition can be attributed to the selective incorporation of barium into the deposits. Thus, the Pb/Ba ratio in the

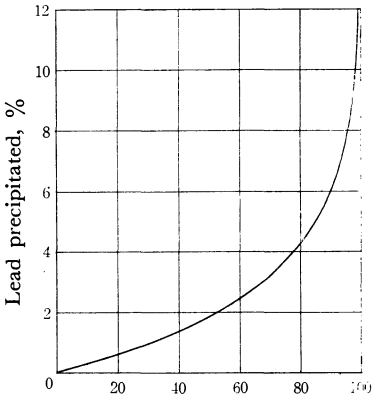

Fig. 3. Relation between the portion of barium precipitated and that of lead precipitated.

waters is evidently the lowest at the vents of the springs, and increases gradually with the flowing of the stream. In Fig. 2, the calculated barium concentration in the stream water is plotted against the distance from the Obuki Spring. The figure shows that 2 ± 1 mg./l. may be a reasonable value for the barium concentration in the water issuing from the vent of the Obuki Spring. This leads to the rather surprising conclusion that the major portion of the barium contained in the original water precipitates within 100 m. of the Obuki Spring.

The quantity of lead coprecipitated with barium can be computed if we assume that the precipitate once formed has no further interaction with the solution. Starting from Eq. 1, we have:

$$\frac{-(\Delta\mathrm{Pb})}{-(\Delta\mathrm{Ba})} = D\frac{(\mathrm{Pb})}{(\mathrm{Ba})} \tag{3}$$

where $(\Delta\mathrm{Pb})$ and $(\Delta\mathrm{Ba})$ represent small portion of these elements incorporated into the precipitate, and where (Pb) and (Ba) refer to their concentrations in the solution from which the precipitate was formed. The integration of the above equation gives:

$$\frac{(\mathrm{Pb})}{(\mathrm{Pb})_0} = \left\{\frac{(\mathrm{Ba})}{(\mathrm{Ba})_0}\right\}^D \tag{4}$$

where $(\mathrm{Pb})_0$ and $(\mathrm{Ba})_0$ denote their initial concentrations. Equation 4 indicates the relation between lead and barium concentrations in the solution during the formation of the precipitate. From Eq. 4, the portion of lead coprecipitated is given by:

$$1 - \frac{(\mathrm{Pb})}{(\mathrm{Pb})_0} = 1 - \left\{\frac{(\mathrm{Ba})}{(\mathrm{Ba})_0}\right\}^D$$

Figure 3 shows the relation between the portion of barium precipitated and the corresponding value for lead. In order to calculate the total amount of plumbian barite deposited on the bed of the stream extending over 700 m. from the Obuki Spring to the Yudaki Fall, we need only the lead and the barium concentrations in the water at both points and the discharge of the stream in this area. As is shown in Fig. 2, the amount of barium precipitated on the bed under consideration corresponds to approximately 95% of its initial amount. In this case, a value of 8% may be expected for the coprecipitated portion of lead. Consequently, one liter of spring water may precipitate 1.9 mg. of barium and 0.096 mg. of lead, or 3.37 mg. of mixed sulfate (Ba, Pb) SO_4. Using a discharge value of 75.4 l./sec. or 2.4×10^9 l./yr. (both as given by Miura[10]), we can estimate the annual production of deposits as 8.09×10^9 g.

If the bed of the stream between the Obuki Spring and the Yudaki Fall were covered with crustal deposits of a uniform thickness, the rate of the growth of the crustal deposits would be of 0.86 mm./yr.* This value is extremely high compared with the results obtained by Saito et al.[11] A spectrochemical investigation by Nakagawa[12] showed that some sulfurous sinters occuring in the Tamagawa Hot Springs contain a considerable amount of barium and lead, so the above-mentioned disagreement means simply that the precipitate exists mainly in the form of minute crystals buried in sulfurous sinters, and not in the form of crustal deposits.

The formation of abundant microcrystals of plumbian barite presents a direct evidence that the spring water issuing from the vents is supersaturated with barium sulfate. It is well known that the greater the degree of supersaturation,

* This calculation was made on the assumption that the bed occupies an area of 2100 m^2 and that the barite deposits have a density of 4.5 g./cm^3.

the greater will be the number of nuclei formed. We will discuss here briefly the possible causes of this phenomenon. It may be attributed to a rapid decrease in the temperature or to an abrupt change in the chemical composition of the original thermal water. As a cause of the decrease in the temperature, the mixing of the original water with some groundwater of a low temperature may be considered. However, the addition of groundwater of a low mineralization cannot always result in the precipitation of barium sulfate, for the water may be effective not only in cooling the original solution, but also in diluting it. Therefore, no separation of solid barium sulfate takes place unless the water is accompanied by a considerable quantity of sulfates. It may be generally admitted that the increase in sulfate concentration is indispensable for the formation of barite deposits. This hypothesis is in accord with the present author's interpretation of the formation of the Tamagawa Hot Springs.[13]

From the foregoing discussion, we can schematize the genesis of hydrothermal barite deposits as follows: the original ore solutions are relatively deficient in sulfate ions and contain at least 1 mg. of barium per liter. When the ore solutions encounter some subsurface waters which are rich in sulfates, the precipitation of barite will take place because of the decrease in the solubility of the barium sulfate. The sulfates may be formed by the oxidation of sulfides contained in the same ore solutions or by some other supergene processes.

The author wishes to express his gratitude to the Matsunaga Science Foundation for its support of this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 901—909 (1966)

Electronic Spectra of Trivalent Metal Complexes of 3-Phenyl- and 3-Benzyl-2, 4-pentanedione*

By Yukito MURAKAMI and Katsuyuki NAKAMURA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received September 3, 1965)

The 3-phenyl- and 3-benzyl-2, 4-pentanedione complexes of trivalent aluminum, chromium, iron and cobalt were prepared, and their electronic absorption spectra measured in the 220—900 mμ range. The spectral data were interpreted in detail in terms of the $\pi_3 \rightarrow \pi_4$, the electron transfer ($d_\varepsilon \rightarrow \pi_4$) and the $d \rightarrow d^*$ transitions of the various components. In this series of complexes, an inter-ring π-interaction between a phenyl ring and a chelate ring is expected to remain to a limited extent in the metal complexes of 3-phenyl-2, 4-pentanedione, although the twist of both rings from the coplanarity is significant. For the aluminum complexes, π-electrons in the ligand part remain delocalized in a manner similar to that which holds in the corresponding enolate ion. On the other hand, each kind of $\pi_3 \rightarrow \pi_4$ transition in the transition metal complexes of the 2, 4-pentanedione derivatives was found to depend on the number of d_ε electrons of the central metal ion and to appear in this increasing order of energy: Cr < Fe < Co. In addition, the metal-ligand π-interaction has a major effect on the $\pi_3 \rightarrow \pi_4$ transition, and it seems to increase with respect to the ligands in the order: 2, 4-pentanedione, 3-phenyl-2, 4-pentanedione, and 3-benzyl-2, 4-pentanedione. The two major substituent (at the 3-position of 2, 4-pentanedione) effects which may affect the $\pi_3 \rightarrow \pi_4$ transitions were identified.

Much work has been done on the interpretation of the absorption spectra of 2, 4-pentanedione complexes from various aspects.[1-6] In two of these studies, Barnum applied the Hückel LCAO-MO calculation to the 2, 4-pentanedione chelate systems in order to estimate the effect of metal-ligand π-bonding on the electronic transition energies; he also successfully analyzed $\pi_3 \rightarrow \pi_4$ and $d_\varepsilon \rightarrow \pi_4$ transition bands.[4,5]

In the present study, the 3-phenyl- and 3-benzyl-2, 4-pentanedione complexes of trivalent aluminum, chromium, iron and cobalt have

been prepared, and their electronic spectra interpreted in terms of the $\pi_3 \rightarrow \pi_4$ transition which is characteristic of the ligand molecules and of the electron transfer transition in the chromium, iron and cobalt complexes. The $d \rightarrow d^*$ transitions characteristic of the nuclear metals have also been assigned for the transition metal complexes.

Experimental

Preparation of Materials. — 3-Phenyl-2,4-pentanedione was prepared from phenylacetone and acetic anhydride in the presence of boron trifluoride and of *p*-toluenesulfonic acid in the 0—5°C temperature range, following the method described in the literature[7]; b. p. 110—115°C at 17 mmHg; m. p. 58.0—59.0°C (reported[7] b. p. 116—118°C at 20 mmHg; m. p. 58.5—59.5°C). 3-Benzyl-2,4-pentanedione was obtained by the reaction of sodium acetylacetonate with excess benzyl chloride[8]; b. p. 115—118°C at 4 mmHg; n_D^{25} 1.5236 (reported b. p. 140—146°C,[8] 143—146°C[9] at 10 mmHg; n_D^{25} 1.5250[9]); a yield of 43%.

The methods of preparation employed for the trivalent metal complexes of acetylacetonate were used in this study with some modification for the syntheses of 3-phenyl- and 3-benzyl-2,4-pentanedione complexes of the corresponding trivalent metals. The procedure has been described in detail elsewhere.[10] The results of analysis, along with the values of the melting point, are listed in Table I.

Spectral Measurements.—The ultraviolet and visible spectra of the metal complexes were measured by standard methods, using a Hitachi ESP-2 type recording spectrophotometer. Ethanol, *n*-hexane and chloroform were used as solvents in this study.

Results and Assignments

The absorption spectra of 3-phenyl- and 3-benzyl-2, 4-pentanedione and of the corresponding enolate ions are illustrated in Fig. 1, along with that of 3, 3-dibenzyl-2, 4-pentanedione. The spectra of the trivalent metal complexes of 3-phenyl- and 3-benzyl-2, 4-pentanedione are shown in Figs. 2 through 5. It may be seen that these absorption spectra of metal complexes are generally similar to the corresponding 2, 4-pentanedione complexes. The significant peaks of the absorption spectra of the ligands and the metal complexes are listed in Tables II and III respectively.

Ligands.—The $\pi_3 \rightarrow \pi_4$ transition band of acetylacetone was observed to shift to a longer wavelength upon replacement of the γ-hydrogen with either phenyl or benzyl group. Besides this profound band, several indistinct shoulders, which are due to $\pi \rightarrow \pi^*$ transitions in a benzene ring system, were observed. Among several shoulders which appeared in the 249—274 mμ range in the spectrum of 3-benzyl-2,4-pentanedione, 263 and 269 mμ bands were noticed as being most intense. On the other hand, in 3, 3-dibenzyl-2, 4-pentanedione there are three distinct bands, of nearly identical intensity, at 253.3, 258.9 and 264.7 mμ in ethanol; this is because of the absence of its enol form. These $\pi \rightarrow \pi^*$ bands are located on the longer wavelength side relative to the secondary bands (^1L_b) of benzene itself.

Although 3-phenyl-2, 4-pentanedione seems to demonstrate shoulder bands due to a similar electronic transition in approximately the same range, the definite position of these bands could not be detected clearly. In 3-phenyl-2, 4-pentanedione, several indistinct shoulders were also observed in the 227—243 mμ range; they may

Shoulder bands are given in parentheses.
* log ε, 4.61

be attributed to the primary bands (^1L_a) in the benzene π-system.

The $n \rightarrow \pi^*$ forbidden transition in the ketonic forms of the present ligands is expected to appear on a longer wavelength side of the $\pi \rightarrow \pi^*$ transition band. Nevertheless, this band of a rather low intensity seems to be hidden by the intense $\pi \rightarrow \pi^*$ bands. On the other hand, the $n \rightarrow \pi^*$ band with a maximum at 301 mμ in *n*-hexane was clearly observed in 3, 3-dibenzyl-2, 4-pentanedione, and it demonstrated a significant solvent effect, which resulted in a blue shift to 294 mμ in ethanol.

In the presence of sodium ethoxide, the enolate ions are formed, and the $\pi \rightarrow \pi^*$ transition bands shift to longer wavelengths, i. e., to 306.5 mμ in the 3-phenyl derivative and to 309 mμ in the 3-benzyl; also, their intensities increase.

Aluminum Complexes.—The general appearance of the absorption spectra is quite similar to that of the respective free ligand species. The $\pi_3 \rightarrow \pi_4$ band upon chelation shifts to a wavelength shorter by 850 cm^{-1} with respect to the enolate ion. Also, the γ-substituent tends to shift the $\pi_3 \rightarrow \pi_4$ transition band to a longer wavelength with respect to the acetylacetonate complex; 1670 cm^{-1} with a benzyl group and 1400 cm^{-1} with a phenyl, while the benzyl group obviously has a greater effect on the π-energy level. The secondary bands (^1L_b) of the benzene ring appear in the 3-benzyl-2, 4-pentanedione complex as shoulders located at 264 and 270 mμ, while the phenyl derivative demonstrates in its spectrum the first primary band (^1L_a) of a phenyl substituent at 231.5 mμ.

Chromium Complexes.—The general appearance of the absorption spectra of transition metal complexes is quite different from those of non-transition metal complexes, such as aluminum complexes. The splittings of the $\pi \rightarrow \pi^*$ band

caused by the π-interaction between metal and ligand, and the appearance of electron transfer bands ($d_\varepsilon \rightarrow \pi^*$) and of $d_\varepsilon \rightarrow d_\gamma$ bands brought about by a ligand field are characteristic of the absorption spectra of transition metal complexes. The general trend of the absorption spectra of trivalent metal complexes of the present ligands is quite similar to that of the corresponding acetylacetonate complexes. Therefore, the results of

the Hückel LCAO-MO calculation carried out by Barnum[5] are referred to in the assignment of absorption bands in this work.

The 3-phenyl derivative shows extremely broad bands in the ultraviolet region of its electronic spectrum due to the presence of $\pi\rightarrow\pi^*$ transition bands of a phenyl ring. Thus, the assignment of $\pi_3\rightarrow\pi_4$ bands would involve some uncertainty due to the lack of an exact resolution of absorption bands. The 258 mμ band in ethanol is tentatively assigned to the $\pi_3(e)\rightarrow\pi_4(a_1)$ transition. In the range of $\pi_3(e)\rightarrow\pi_4(a_1)$ transition for the 3-benzyl-2,4-pentanedione complex, three absorption bands appeared at 257, 265 and 270 mμ; of these, the first one was found to be a weak shoulder. Some of these bands (most likely the latter two) are presumably due to the $\pi\rightarrow\pi^*$ secondary bands (^1L_b) of the benzene ring. The 289 and the 310 mμ bands in the phenyl derivative, and the 285 and the 318 mμ bands in the benzyl (when ethanol is used as a solvent), all of which appeared as shoulders, were assigned to the $\pi_3(e)\rightarrow\pi_4(e)$ overlapped with $\pi_3(a_2)\rightarrow\pi_4(a_1)$ and the $\pi_3(a_2)\rightarrow\pi_4(e)$ transitions respectively. All these $\pi_3\rightarrow\pi_4$ bands shifted to longer wavelengths upon replacement at the 3-position, with reference to those of the 2,4-pentanedione complex.

Electron transfer ($d_\varepsilon\rightarrow\pi_4$ transition) bands were also observed to shift to longer wavelengths upon replacement of the 3-position, relative to the parent complex. The overlapping $d_\varepsilon(a_1)\rightarrow\pi_4(e)$ and $d_\varepsilon(e)\rightarrow\pi_4(a_1)$ transitions are attributed to the 348 mμ band and the 352 mμ band, while the $d_\varepsilon(e)\rightarrow\pi_4(e)$ transition are attributed to the 395 mμ shoulder band and the 400 mμ shoulder band in the phenyl and the benzyl derivative respectively.

The first $d\rightarrow d^*$ ($^4A_{2g}$—$^4T_{2g}$) transition lies at 575 and 565 mμ in the phenyl and the benzyl derivative respectively. On the other hand, a shoulder lying in 410—440 mμ for the phenyl derivative and one in 420—445 mμ for the benzyl are assigned to the second $d\rightarrow d^*$ band. Since 2,4-pentanedione has been shown to be placed in the spectrochemical series[11] in the neighborhood of oxalate and water, the second $d\rightarrow d^*$ ($^4A_{2g}\rightarrow{}^4T_{1g}$) transition is expected to lie close to the 416 mμ band of the oxalate complex[12] or to the 407 mμ band of the aqueous complex.[12] In addition, Sone[13] suggested that the following relationship holds among the first and the second bands for the chromium(III) complex:

$$\nu_2 = 1.117\,\nu_1 + 13.06$$

where ν_1 and ν_2 represent the first and the second bands in the frequency unit (10^{13} sec^{-1}) respectively. From this equation, the second bands for both the phenyl and benzyl derivatives may be expected to appear in the vicinity of 420 mμ. Thus, the above assignment for the second $d\rightarrow d^*$ band seems reasonable.

Cobalt Complexes.—The $\pi_3(e)\rightarrow\pi_4(a_1)$, $\pi_3(e)\rightarrow\pi_4(e)$ overlapped with $\pi_3(a_2)\rightarrow\pi_4(a_1)$, and the $\pi_3(a_2)\rightarrow\pi_4(e)$ transitions are believed to lie, respectively, at 228.5, 253, and 308 mμ (as a slight shoulder) in the phenyl derivative, and at 227, 248.5, and 300 mμ (as a slight shoulder) in the benzyl derivative. The first and second transition bands are shifted to shorter wavelengths with reference to those of the 2,4-pentanedione complex. On the longer wavelength side of the $\pi_3(e)\rightarrow\pi_4(e)$ and $\pi_3(a_2)\rightarrow\pi_4(a_1)$ bands in both complexes, there exist several shoulder bands, among which the 263 mμ and the 270 mμ band are most likely to be ascribed to the secondary band (^1L_b) of a benzene.

The $d_\varepsilon\rightarrow\pi_4$ ($a_1\rightarrow e$, $e\rightarrow a_1$) band in the phenyl and benzyl derivatives shifted to longer wavelengths, at 338 (shoulder) and 341 mμ respectively, with reference to that in the 2,4-pentanedione complex. On the longer wavelength side of these $d_\varepsilon\rightarrow\pi_4$ bands, there were observed very broad shoulders in which the $d_\varepsilon(e)\rightarrow\pi_4(e)$ charge transfer band and the second $d\rightarrow d^*$ ($^1A_{1g}\rightarrow{}^1T_{2g}$) band are expected to be involved. According to the LCAO-MO calculation for the 2,4-pentanedione complex,[5] the $d_\varepsilon(e)\rightarrow\pi_4(e)$ band for this complex

11) Y. Shimura and R. Tsuchida, This Bulletin, **29**, 311 (1956).
12) J. S. Griffith, "The Theory of Transition Metal Ions," Cambridge University Press, Cambridge (1961), p. 425.
13) K. Sone, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zassi*), **71**, 271, 316 (1950).

is expected to lie around 400 mμ, although only a shoulder was observed in this range. Meanwhile, Shimura and Tsuchida[11] assigned the 405 mμ band in the 2, 4-pentanedione complex to the second $d \rightarrow d^*$ transition. On the other hand, Sone[13] has proposed a relationship which may correlate the first $d \rightarrow d^*$ band with the second:

$$\nu_2 = 1.189\,\nu_1 + 13.31$$

(ν_1 and ν_2: frequency in $10^{13}\,\mathrm{sec}^{-1}$ unit)

The first band ($^1A_{1g} \rightarrow {}^1T_{1g}$) for the 2, 4-pentanedione complex, and the 3-phenyl- and 3-benzyl-2, 4-pentanedione complexes were observed at 595, 608 and 596 mμ (in chloroform) respectively. Thus, the second bands for these complexes are expected to lie in the 410—420 mμ range. Nevertheless, no unambiguous assignment was made because of the broadness of the absorption spectra in this range, as has been mentioned above.

Iron Complexes.—All the absorption bands in the 3-phenyl- and the 3-benzyl-2, 4-pentanedione complexes were observed to shift to longer wavelengths with reference to the corresponding bands in the 2, 4-pentanedione complex, as is shown in Table III and Fig. 4. The $\pi_3(e) \rightarrow \pi_4(a_1)$ and the $\pi_3(e) \rightarrow \pi_4(e)$ and $\pi_3(a_2) \rightarrow \pi_4(a_1)$ bands are believed to be located at 247 and 284 mμ in the phenyl derivative, and at 240 (shoulder) and 286 mμ in the benzyl derivative, respectively. Two distinct bands appear in the visible region for each iron complex of 2, 4-pentanedione derivatives. The absorption bands lying around the 370 mμ range are assigned to the $d_\varepsilon(a_1) \rightarrow \pi_4(e)$ and $d_\varepsilon(e) \rightarrow \pi_4(a_1)$ transitions. Barnum[4,5] has not made any assignment for the 437 mμ band in the 2, 4-pentanedione complex. The corresponding bands in the phenyl and benzyl derivatives are, respectively, at 445 and 450 mμ in ethanol. The magnitudes of these spectral shifts from the corresponding band in the 2, 4-pentanedione complex are 400 and 700 cm^{-1} for the phenyl and the benzyl derivatives respectively. Although the direction of the band shift is the same as that of the $d \rightarrow \pi^*$ bands, its magnitude is smaller than that of the latter (1100 cm^{-1} for the phenyl derivative, and 1400 cm^{-1} for the benzyl). In addition, as the polarity of a solvent increases, the band tends to shift to a shorter wavelength; there is also a decrease in its intensity. This solvent effect seems to be, in general, characteristic of an electronic transition involving a nonbonding electron, while $d \rightarrow \pi$ bands do not show such a strong solvent-dependency. Thus, a band appearing in the 450 mμ range is considered to be due to the $n \rightarrow d_\gamma$ transition, in which oxygen n-electrons are involved.

The $d \rightarrow d^*$ transitions ($^6A_{1g} \rightarrow {}^4T_{1g}$, and $^6A_{1g} \rightarrow {}^4T_{2g}$) are expected to lie in a region with much longer wavelengths; they were not observed in the present measurements.

Discussion

Ligands.—An absorption band characteristic of β-diketones is generally subject to the solvent effect which controls their keto-enol isomerism. This absorption band consists of two components: a $\pi \rightarrow \pi^*$ transition of an enol form, and a $n \rightarrow \pi^*$ forbidden transition of the corresponding keto-form, which appears on the longer-wavelength side of the former. 3-Phenyl-2, 4-pentanedione shows an absorption band at 284 mμ in n-hexane which shifts to a slightly longer wavelength with a somewhat decreased intensity in ethanol. As far as the spectral shift is concerned, the same solvent-dependency was observed for 3-benzyl-2, 4-pentanedione. However, the absorption intensity for this ligand decreases in ethanol to a greater extent than for 3-phenyl-2, 4-pentanedione. This suggests that the enol component of the latter diketone may be predominant in ethanol,* though in general polar solvents stabilize a keto-form. On the other hand, the 3-benzyl derivative increases its keto component when the solvent is changed from n-hexane to ethanol.

$\pi \rightarrow \pi^*$ Bands.—The spatial configuration of a phenyl ring relative to the chelate ring in a 3-phenyl-2, 4-pentanedione complex seems to control the extent of π-interaction among these groups. Such a π-interaction among these two groups would not be as strong as among the two phenyl groups in biphenyl, or as among olefinic and phenyl groups in styrene, since the latter two molecules show an absorption band in the range around 250 mμ,[14] while in a 3-phenyl-2, 4-pentanedione complex no such band exists in that range. In 2,6-dimethyl-biphenyl the inter-ring resonance may be reduced to a certain extent by the twist of both rings from coplanarity. Such a diminished π-interaction makes the absorption band appear in the 240 mμ range[15] as a shoulder, which is assigned to the first primary band (^1L_a) of a benzene ring in this substituted biphenyl. Meanwhile, in the aluminum complex of 3-phenyl-2, 4-pentanedione the steric interaction among a phenyl ring and two methyl groups on the chelate ring tends to twist both phenyl and chelate rings. However, such a fairly large deviation from coplanarity will not destroy all of the inter-ring resonance interaction, since the aluminum complex shows a $\pi \rightarrow \pi^*$ transition band at 231.5 mμ. In other transition metal complexes of the same ligand, absorption bands are broad and intense in the 240—250 mμ range in comparison with those of the corresponding metal complexes of 2, 4-pentanedione and of 3-benzyl-2, 4-pentanedione. The breadth of absorption bands in such a range

* This keto-enol isomerism was studied in this laboratory by means of infrared and NMR spectroscopies. These results will be described in a forthcoming paper.

14) H. E. Ungnarde, Ed., "Organic Electronic Spectral Data," Vol. II, Interscience Publishers, New York (1957), pp. 130, 295.

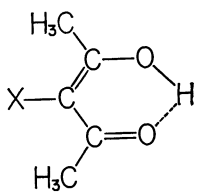
may be ascribed to the existence of the primary band (^1L_a) of a benzene ring in addition to the $\pi \rightarrow \pi^*$ bands of the chelate ring. From the observations mentioned above, the inter-ring π-interaction remains to a limited extent in the metal complexes of 3-phenyl-2, 4-pentanedione. Meanwhile, this inter-ring π-interaction may help to raise the π_3 orbital of the chelate ring to a higher energy, thus shifting the $\pi_3 \rightarrow \pi_4$ band to a longer wavelength.

In the metal complexes of 3-benzyl-2, 4-pentanedione, both the hyperconjugation and inductive effects of the methylene group may raise the π_3 level to a higher energy.

The enolate ions of β-diketones decrease their delocalization energy upon chelation with either hydrogen or aluminum. The enol-forms of β-diketones show their $\pi \rightarrow \pi^*$ band at shorter wavelengths relative to the corresponding enolate ions. The magnitude of such a spectral shift follows the sequence:

2, 4-pentanedione ($2700\ cm^{-1}$) > 3-phenyl-2, 4-pentanedione ($2400\ cm^{-1}$) > 3-benzyl-2, 4-pentanedione ($2250\ cm^{-1}$)

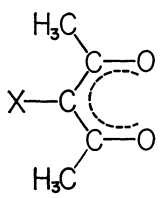
Such a great loss of delocalization energy in the enol forms of β-diketones (structure I) is consistent



(I)

X = H, phenyl, benzyl

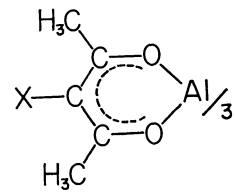
with the fact that an enolic proton is located closer to one oxygen than the other, that the two C–C bonds are not equivalent to each other in bonding character, and that neither are the two C–O bonds. Meanwhile, an identical bond character is expected for the C–C bonds and also for the C–O bonds in the enolate ion, as is illustrated by structure II.



(II)

X = H, phenyl, benzyl

On the other hand, upon chelation with the aluminum ion, the $\pi \rightarrow \pi^*$ band shifts to a wavelength lower by $850\ cm^{-1}$ than that of the corresponding enolate ion, regardless of the ligand species. The substituent effect on the chelate ring, therefore, seems parallel to that on the enolate ion. This leads one to the conclusion that π-electrons in the ligand part remain delocalized much like those in the corresponding enolate ion, even when the coordinate bonds are formed among an aluminum ion and carbonyl oxygens. The structure of such a chelate ring of the aluminum complexes may be represented by III.



(III)

X = H, phenyl, benzyl

The metal-ligand π-interaction in transition metal complexes results in a splitting of the $\pi_3 \rightarrow \pi_4$ band, and in a shift of these $\pi_3 \rightarrow \pi_4$ transitions to higher energies. The magnitude of the spectral shift to a lower wavelength was found to depend on the number of d_ε electrons that the central metal ion possesses, as has been observed in the 2, 4-pentanedione complexes.[4,5] Thus, the $\pi_3 \rightarrow \pi_4$ transitions in the trivalent metal complexes of the present 2, 4-pentanedione derivatives have been found to appear in this increasing order of energy:

$$Cr < Fe < Co$$

In the iron and chromium complexes, each $\pi_3 \rightarrow \pi_4$ transition band was observed to shift to a longer wavelength as the ligand varies in this order: 2,4-pentanedione, 3-phenyl-2, 4-pentanedione, and 3-benzyl-2, 4-pentanedione. On the other hand, both the $\pi_3(e) \rightarrow \pi_4(a_1)$ band, and the $\pi_3(e) \rightarrow \pi_4(e)$ combined with $\pi_3(a_2) \rightarrow \pi_4(a_1)$ band in the cobalt complexes shift in the reverse direction in the same order. In the transition metal complexes, the metal-ligand π-interaction has a major effect on the $\pi_3 \rightarrow \pi_4$ transition, and it seems to increase with respect to the ligands in this order: 2, 4-pentanedione, 3-phenyl-2, 4-pentanedione, and 3-benzyl-2, 4-pentanedione. As each $\pi_3 \rightarrow \pi_4$ transition band in a complex shifts to a shorter wavelength with reference to the enolate ion of the correspond ing ligand, the comparison of the size of these spectral shifts may give the extent of metal-ligand π-interaction. Thus, a 3-benzyl-2, 4-pentanedione complex in general shows the greatest spectral shift among the corresponding metal complexes of three different 2, 4-pentanediones, while a metal complex of the 3-phenyl derivative comes next. For example, the $\pi_3(e) \rightarrow \pi_4(a_1)$ band in cobalt complexes shifts to a wavelength shorter from the

15) G. H. Beaven, "Steric Effects in Conjugated Systems," Butterworths, London (1958), Chapter 3.

enolate ion by 9500 cm^{-1} with 2, 4-pentanedione as the ligand, by 11000 cm^{-1} with 3-phenyl-2, 4-pentanedione, and by 12000 cm^{-1} with the 3-benzyl derivative.

It may be concluded that the $\pi_3 \rightarrow \pi_4$ transition is affected by either or both of the two major effects of a substituent at the 3-position of 2, 4-pentanedione:

(1) A substituent tends to raise the π_3 level of the chelate π-orbitals to a higher energy, either through the π-interaction with the chelate ring or its inductive effect on the chelate ring. As a result, a $\pi_3 \rightarrow \pi_4$ band shifts to a longer wavelength.

(2) Such π_3-orbitals that were raised to a higher energy may interact with the d_ε-orbitals. This interaction lowers the energy of the π_3-orbitals on the one hand and raises that of the d_ε-orbitals on the other. This effect results in a shift of the $\pi_3 \rightarrow \pi_4$ transition to a higher energy.

In the transition metal complexes, both of the substituent effects may come into play in the $\pi_3 \rightarrow \pi_4$ transitions, while the first effect is expected to be predominant in the aluminum complexes and the enolate ions. Upon substitution at the 3-position of 2, 4-pentanedione, the spectral shift toward a longer wavelength was observed to be greater in the aluminum complexes and the enolate ions than in the transition metal complexes. This experimental fact can be understood from the above point of view.

Meanwhile, the greatest metal-ligand π-interaction is expected in the cobalt complexes as a result of the presence of the largest number of d_ε electrons. In this instance, the second substituent effect may prevail over the first one and $\pi_3 \rightarrow \pi_4$ transition bands may tend to shift to a lower wavelength upon substitution.

In general, the solvent effect tends to shift the $\pi \rightarrow \pi^*$ band to a longer wavelength in a solvent with a higher polarity. In fact, the $\pi \rightarrow \pi^*$ bands of the ligands (the enol form) appear on the longer wavelength side in ethanol relative to those measured in *n*-hexane, as is shown in Table II. On the other hand, it is interesting to note that the reverse spectral shifts were observed in the metal complexes when the solvent was changed from chloroform to ethanol.

$d_\varepsilon \rightarrow \pi_4$ Bands.—These transition bands tend to shift to lower energies upon substitution at the 3-position of 2, 4-pentanedione. The magnitudes of such spectral shifts in metal complexes are approximately 1100 cm^{-1} with a phenyl group and 1350—1450 cm^{-1} with a benzyl with reference to the corresponding bands in 2, 4-pentanedione complexes, regardless of the metal ions employed. These phenomena are most likely caused by electronic interaction among d_ε and π_3 orbitals, which raises d_ε orbitals to a higher energy. As for the metal species concerned, the $d_\varepsilon \rightarrow \pi_4$ transition energy is greatest for the cobalt complexes and least for the iron complexes.

$d \rightarrow d^*$ Bands.—From the first $d \rightarrow d^*$ bands observed for the cobalt and chromium complexes, 2, 4-pentanedione and its 3-benzyl derivative may be inferred to occupy a higher position relative to 3-phenyl-2, 4-pentanedione in the spectrochemical series. However, the strength of the coordinate bonds may not be directly related to the value of Δ, the energy difference between the d_ε and the d_γ orbitals, as the crystal field theory would predict. Since the metal-ligand π-interactions are involved[4,5] in these transition metal complexes, it is rather difficult to estimate the hypothetical crystal field effects of these ligands which may be expected in the absence of π-interaction.

Infrared and NMR studies of these trivalent metal complexes, as well as similar spectroscopic studies of some divalent metal complexes, are now in progress in this laboratory; these results will be described in a forthcoming paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 910—916 (1966)

Asymmetric Synthesis with Sugar Derivatives. I. The Conjugate Additions of Grignard Reagents to α, β-Unsaturated Esters of Sugar Derivatives

By Masajiro KAWANA and Sakae EMOTO

The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

(Received September 3, 1965)

Partial asymmetric syntheses were carried out in the reaction of Grignard reagents with crotonic and cinnamic esters of 1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose, 1, 2 : 5, 6-di-*O*-isopropylidene-D-glucose, 1, 2-*O*-isopropylidene-5-deoxy-D-xylose and (−)-menthol. The reaction of 3-*O*-crotonyl-1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (Ic) with phenylmagnesium bromide, followed by the hydrolysis of the resulting ester, gave (−)-3-phenylbutyric acid (III) in 33% optical and 12% synthetic yields, while in the presence of cuprous chloride as a catalyst, III was obtained in 74% and 58% yields respectively. The reaction of 3-*O*-crotonyl-1, 2-*O*-isopropylidene-5-deoxy-D-xylose (Ie) with phenylmagnesium bromide gave (+)-acid (III) without cuprous chloride in 16% optical and 32% synthetic yields and (−)-acid (III) with cuprous chloride, in 58% and 61% yields respectively. The reaction of 3-*O*-cinnamoyl-1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (IVc) with benzylmagnesium chloride, followed by the saponification of the resulting ester, gave (−)-3, 4-diphenylbutyric acid (VI) in 18% optical and 62% synthetic yields without cuprous chloride, and in 17% and 58% yields with cuprous chloride. In the formation of acid (VI), cuprous chloride seemed to have no effect on optical and synthetic yields nor on the change in the sign of optical rotation. The steric courses of these reaction are discussed.

Numerous partial asymmetric syntheses have been made in an attempt to introduce a new asymmetric center into a carbon chain of organic acid under the influence of an optically active alkoxy group on the carbonyl carbon of the carboxylic ester. For example, 2-hydroxy-2-phenylpropionic acid (atrolactic acid) was asymmetrically synthesized by Grignard reaction from (−)-menthyl,[1] (+)-1-(2′, 4′, 6′-tricyclohexylphenyl) - ethyl[2] and (+)-α-phenyldihydrothebaine-isomethine[3] phenylglyoxylates, respectively, in 17, 66 and 91% optical yields. In these asymmetric syntheses, it is evident that the esters' asymmetric centers derived from the naturally-occurring terpenes or alkaloids play an important role in making one transient comformation of esters predominant over the others. However, sugar derivatives have been utilized as the alcohol to only a negligible extent in this field. Many oxygens on the asymmetric carbons of a sugar derivative are supposed to show a particular stereoselectivity in such reactions when organometallic compounds or metal catalysts are used. Thus, the authors were interested in the stereoselective addition of metallic compounds to the α, β-unsaturated esters of sugar derivatives.

Recently, Inouye and Walborsky[4] reported that a partial asymmetric synthesis of (+)-3-phenylbutyric acid (III) was achieved (5.4% optical yield) by the addition of phenylmagnesium bromide to (−)-menthyl crotonate (Ia), followed by the hydrolysis of the adduct (IIa) (Eq. 1); moreover, when the catalytic amount of cuprous chloride was added to the reaction mixture, the optical rotation of the acid III obtained had an opposite sign and its synthetic yield was somewhat increased, compared with the case of the absence of cuprous catalyst. However, the stereochemical course of the reactions has never been established. As to the conjugate addition of Grignard reagent to

crotonate, Munch-Petersen[5] described that (±)-*s*-butyl crotonate (Ib) with phenylmagnesium bromide gave (±)-*s*-butyl 3-phenylbutyrate (IIb) in a 67% yield in the presence of cuprous chloride, which had been known to catalyze predominantly a 1, 4-addition over a 1, 2-addition in the α, β-unsaturated carbonyl system (Eq. 1). He and his co-workers[6] also found that (—)-*s*-butyl cinnamate (IVb) with benzylmagnesium chloride gave (±)-*s*-butyl 3, 4-diphenylbutyrate (Vb) in a 63% yield; in this case, cuprous chloride has no catalytic effect (Eq. 2).

The present authors have studied[7] the partial asymmetric syntheses achieved by the 1, 4-addition of phenylmagnesium bromide to crotonic esters (Ic, Id and Ie) and of benzylmagnesium chloride to cinnamic esters (IVc, IVd and IVe), using three kinds of sugar derivatives, 1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (VII),[8] 1, 2 : 5, 6-di-*O*-isopropylidene-D-glucose (VIII)[9] and 1, 2-*O*-isopropylidene-5-deoxy-D-xylose (IX),[10] in the presence or absence of a cuprous catalyst.

Procedure and Results

The crotonic ester of each sugar derivative (Ic, Id and Ie) was prepared by the addition of crotonyl chloride to a solution of the sodium alcoholate of each sugar derivative in toluene, according to a modification of the method of Otey et al.[11] This method gave a better yield than the general reaction of the free hydroxy-group of a sugar with crotonyl chloride in pyridine-chloroform. The cinnamic ester of each sugar derivative (IVc, IVd and IVe) was obtained in a fairly good yield by the reaction of each sugar derivative with cinnamoyl chloride in pyridine-chloroform.

Their yields, physical properties and analyses are listed in Table III.

The Grignard reactions were carried out in ether at temperature from −17°C to −15°C by a method based on the procedure of Munch-Petersen.[12] A catalytic amount of cuprous chloride was added in four portions at regular intervals during the addition of the esters to the Grignard reagents. The adducts were not purified but were completely saponified by refluxing them with a large excess of potassium hydroxide in aqueous alcohol for 16 hr. The racemization of the asymmetric carbon atoms of 3-phenylbutyric acid (III) and 3, 4-diphenylbutyric acid (VI) did not occur during saponification (See Ref. 4 and the Experimental Section). 1, 2 : 5, 6-Di-*O*-cyclohexylidene-D-glucose (VII) and 1, 2 : 5, 6-di-*O*-isopropylidene-D-glucose (VIII) were recovered in 60—85% yields, but the recovery of 1, 2-*O*-isopropylidene-5-deoxy-D-xylose (IX) was poorer because the compound was readily soluble in water.

The 3-phenylbutyric acid (III) obtained was identified by a comparison of its infrared spectrum with that of an authentic sample.[4] Elemental analysis of the crystalline anilide of III was performed. The optical[13] and synthetic yields of III are shown in Table I.

In this reaction, Ic gave (−)-acid (III) in 33% optical and 12% synthetic yields without cuprous chloride (Exp. 3), while in the presence of cuprous chloride, it gave III with the same sign of optical rotation as that in the case of no catalyst in increased optical and synthetic yields, 74% and 58% respectively (Exp. 4). The effect of cuprous chloride on the reaction of Id (Exp. 6 and 7) showed a same tendency as that on the reaction of Ic. On the contrary, it is noteworthy that the reaction of Ie (Exp. 8) gave (+)-acid (III) in 16% optical and 32% synthetic yields without cuprous chloride, but (−)-acid (III) was afforded in much better optical (58%) and synthetic (61%) yields with cuprous chloride (Exp. 9). However, Ia gave (+)-acid (III) without cuprous catalyst in poor optical yields under the conditions of both Inouye[4] and us.

The 3, 4-diphenylbutyric acid (VI) obtained by the reaction of each sugar ester (IVc, IVd and IVe) or (−)-menthyl cinnamate (IVa) with benzylmagnesium chloride was identified by a comparison

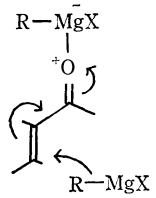
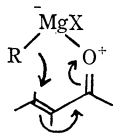
of its infrared spectrum with the sample prepared from an authentic ester (Vb).[6] Optically pure VI, $[\alpha]_D -60°$, was obtained for the first time by the resolution of quinine salt in the present experiment. The optical[14] and synthetic yields of VI are shown in Table II. The reactions of IVc, IVd and IVe all gave (−)-acid (VI) in a 18% optical yield in the absence of cuprous chloride (Exp. 12, 15 and 17) and in 17, 22 and 17% yields respectively in the presence of cuprous chloride (Exp. 14, 16 and 18). The reaction of IVa gave (−)-acid (VI) in a 32% optical yield without cuprous chloride (Exp.10). It is interesting that cuprous chloride seems to have no effect on the optical and synthetic[6] yields in the reactions of cinnamates with benzylmagnesium chloride.

Discussion

Recently Munch-Petersen et al.[15] suggested that there were two types of mechanisms in the addition of Grignard reagents to conjugated esters, depending on the natures of the substrate and the Grignard reagent, i. e., the carbanion mechanism, A, and the cyclic mechanism, B. These mechanisms have



A



B

been considered to be irreversible. They also reported that the mode of the catalytic action of cuprous chloride was still obscure, but that it exerted its effect by way of complex formation between the cuprous ion and the carbon-carbon double bond.

The results may be explained by the following

M=Mg or Cu

assumptions. If Prelog's rule[16] can be applied to these asymmetric syntheses, on the reaction of (−)-menthyl crotonate (Ia) the phenyl group in the Grignard reagent would preferrably enter from the least-hindered side of the double bond in the mechanism A to give s-(+)-acid (III) predominantly, as is shown in Eq. 3, because the absolute configurations of (−)-menthol[17] and III[18] have been established to be as depicted in Eqs. 3 and 4. In the presence of cuprous chloride, the initial attack of the phenyl copper[15,19] prepared from cuprous chloride and the Grignard reagent would be towards the least hindered side of the double bond to form a complex (X); then the phenyl group of the Grignard reagent or phenyl copper would enter from the other side to give R-(−)-acid (III) predominantly (Eq. 4).

On the reaction of both the sugar esters, Ic and Id, the model XI is expected to be most stable, since Prelog's model XII has the steric hindrance of the substituent at C-4 of the furan ring against the ester carbonyl. Furthermore, magnesium or copper could coordinate[20] with the unshared electron pairs of oxygen to make this model XI more rigid. This force is very useful in preventing free rotation between the sugar part and the acid part. Consequently, the attack of the phenyl group from the front side of the double bond according to the mechanism A would be sterically hindered by the 5, 6-*O*-cyclohexylidene group of Ic or the 5, 6-*O*-isopropylidene group of Id, and R-(−)-acid (III) would be more predominantly produced. When cuprous chloride is present, the oxygen at C-5 of glucose would contribute to form a copper complex which would fix the conformation as is shown in XIII.[21] This model (XIII) predicts not only that R-(−)-acid (III) will predominate, but that the optical yield will be high.

On the reaction of Ie, it is considered that the model XII (R=CH_3) would be rather stable because of the decrease of the bulkiness of the substituent at C-4 of the furan ring. Thus, the phenyl group would attack from the front side of the double bond, as a result of the steric effect of the methyl group, to give s-(+)-acid (III) predominantly by the mechanism A. Although the mode of action of cuprous chloride is not clear in this case, the increase in the optical yield with cuprous chloride suggests that the oxygen at C-2 of the furan ring participates in the formation of the similar chelation, as is shown in XIII. The acid III obtained, therefore, has a R-(−)-configuration in a good optical yield.

Meanwhile, the absence of any catalytic effect of cuprous chloride on the formation of 3, 4-diphenylbutyric acid (VI) suggests that the esters of cinnamic acid would react with the Grignard reagent according to the mechanism B. Though the absolute configuration of VI has not yet been established, the formation of VI, which has the same sign of optical rotation in every synthesis, may be attributed to the steric effect of the isopropyl group in (−)-menthol (XIV: Prelog's model), the 1, 2-*O*-cyclohexylidene or the 1, 2-*O*-isopropylidene group (XV: the most stable model) in IVc and IVd, and the methyl group (XVI: Prelog's model) in IVe, which block the backside-attack of the benzyl group on the double bond. In these models, the optical yields of VI prepared from the sugar esters would be lower than that of VI prepared from (−)-menthyl cinnamate (IVa), because there is no fixation between the ester carbonyl and the sugar part.

Experimental[22]

The Sugar Ester of Crotonic Acid.—The esters were prepared by a modification of the method of Otey et al.[11] Into a solution of 0.075 mol. of the sugar derivative, 1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (VII), 1, 2 : 5, 6-di-*O*-isopropylidene-D-glucose (VIII) or 1, 2-*O*-isopropylidene-5-deoxy-D-xylose (IX), in 100 ml. of dry toluene, there was stirred 6.0 g. of sodium powder in three portions over a 2 hr. period at room temperautre; the stirring was then continued overnight. To the solution, decanted from excess sodium, there was then stirred, drop by drop, a solution of 0.075 mol. of crotonyl chloride in 20 ml. of toluene

21) H. B. Henbest and B. Nicholls (*J. Chem. Soc.*, **1959**, 227) reported a similar phenomenon in the methoxy-mercuration of 4-substituted cyclohexenes.
22) All melting points and boiling points are uncorrected. The infrared spectra were taken with a Perkin-Elmer 521 grating infrared spectrophotometer. The optical rotations were performed with a Hitachi No. 070-1 polarimeter, using a 1 dm. tube. Elemental analyses were performed by the Institute of Physical and Chemical Research.

at 0—5°C until the reaction mixture became acidic, a large excess of crotonyl chloride being avoided. Saturated aqueous sodium bicarbonate (ca. 40 ml.) was then added immediately with vigorous stirring to the reaction mixture, which was then extracted with ether and the ether layer was washed with water, dried over sodium sulfate and distilled. The residue was dissolved in chloroform-ligroin (1 : 1 v./v.) and chromatographed on a column of activated alumina. Elution with the same solvents first gave the pure sugar ester. The yield, physical properties and analytic results are recorded in Table III.

The Sugar Ester of Cinnamic Acid.—Into a solution of 0.20 mol. of the sugar ester, 1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (VII), 1,2 : 5,6-di-*O*-isopropylidene-D-glucose (VIII) or 1, 2-*O*-isopropylidene-5-deoxy-D-xylose (IX) in a mixture of 100 ml. of dry pyridine and 100 ml. of dry benzene, there was stirred a solution of 0.22 mol. of cinnamoyl chloride in 50 ml. of dry benzene for about 0.5 hr. at −5—0°C. After it had been stirred for 1 hr., the reaction mixture was allowed to stand overnight at room temperature and then poured into ice water. The mixture was then extracted with ether (or chloroform for VII). The extract was washed with ice water, mixed with ice, washed succesively with iced 3% aqueous sulfuric acid, cold water, saturated aqueous sodium bicarbonate and water, and dried over sodium sulfate. After the solvent had been removed, the residue was dissolved in chloroform-ligroin (1 : 1 v./v.) and chromatographed on a column of activated alumina. Elution with the same solvents first gave the pure sugar ester, except for IVc, which was recrystallized from ligroin. The yield, the physical properties and the analytical results are recorded in Table III.

The Asymmetric Synthesis of 3-Phenylbutyric Acid (III).—A solution of Grignard reagent was prepared from 1.82 g. (0.075 g.-atom) of magnesium and 11.8 g. (0.075 mol.) of bromobenzene in 60 ml. of dry ether. Into this solution of phenylmagnesium bromide, there was added, drop by drop, a solution of 0.03 mol. of the ester Ia,[13] Ic, Id or Ie, in 60 ml. of dry ether (dry tetrahydrofuran for Ic) at −17——15°C for 1 hr. After the addition had been completed, the stirring was continued at the same temperature for 0.5 hr. and then at room temperature for 0.5 hr. The reaction mixture was poured into saturated aqueous ammonium chloride (250 ml.) with vigorous shaking. The ether layer was separated, and the water layer was extracted with ether. The combined ether layers were washed with water, dried over sodium sulfate, and removed. The residual oil, the infrared spectrum of which did not show the presence of the starting ester, was not purified but was hydrolyzed by reflux with 16.8 g. (0.3 mol.) of potassium hydroxide in a solution of 10 ml. of water and 70 ml. of ethanol for 16 hr. After the ethanol had been removed, the resulting solution, diluted with 50 ml. of water, was extracted with 100 ml. of ether and then with 100 ml. of chloform. The combined ether-chloroform extracts were treated as will be descrived below. The water layer was acidified with 6 N hydrochloric acid on cooling and extracted with ether. After the ether had been removed, 50 ml. of saturated aqueous sodium bicarbonate was added with vigorously shaking. The resulting solution was extracted with ether, and the water layer was acidified with 6 N hydrochloric acid and extracted with ether. The ether layer was washed with water, dried over sodium sulfate and then removed. The residue, the optical rotation of which had been measured, was distilled to give pure 3-phenylbutyric acid (III). Its infrared spectrum was identified with that of an authentic sample.[4] The yield and physical properties for III are recorded in Table I.

The ether-chloroform extracts were washed with water, dried over sodium sulfate, and removed. The residue, which had no absorption of ester carbonyl in the infrared spectrum, gave 1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (VII) or 1, 2 : 5, 6-di-*O*-isopropylidene-D-glucose (VIII) by recrystallization from ligroin in a 60—85% yield. 1, 2-*O*-Isopropylidene-5-deoxy-D-xylose (IX) was recovered in a 30—50% yield by extracting the residue with 23 ml. of water, and then extracting it with 150 ml. of ether.

In the case of the addition of cuprous chloride to the reaction mixture, the experiment was carried out similarly except that when the ester (0.03 mol.) was added, 107 mg. (1.4 mol. percent with respect to Grignard reagent) of cuprous chloride was added concurrently in four portions at the interval of 15 min., the first portion being added just before the addition of the ester and the last one, just after.

The Anilide of 3-Phenylbutyric Acid (III). — A mixture of 500 mg. (0.0030 mol.) of the acid III obtained by each of the above asymmetric syntheses and 1.0 g. (0.0084 mol.) of thionyl chloride was refluxed for 0.5 hr. To the solution there was added a solution of 2.0 g. (0.0215 mol.) of aniline in 15 ml. of dry benzene on cooling, and the mixture was refluxed for 2 min. After cooling, 20 ml. of ether was added and the mixture was washed successively with 5 ml. of water, 5 ml. of 6 N hydrochloric acid, 5 ml. of water, 5 ml. of 3 N sodium hydroxide, and 10 ml. of water. The organic solvents were removed, and the residue was recrystallized once from 50% aqueous ethanol, with treatment of charcol, to give anilide in a 80—95% yield. The physical properties and the results of the analysis for anilide are recorded in Table I.

(±)-3, 4-Diphenylbutyric Acid (VI).[23] — (±)-*s*-Butyl-3, 4-diphenylbutyrate (Vb), b. p. 150—155°C/1 mmHg, n_D^{20} 1.5356 (lit.[6] b. p. 157°C/1 mmHg, n_D^{20} 1.5333) was prepared by the method described by Munch-Petersen et al.[6] A mixture of 2.0 g. (0.0067 mol.) of Vb, 20 ml. of ethanol and 5.0 g. (0.089 mol.) of potassium hydroxide in 5.0 ml. of water was refluxed for 3 hr. After it had then been concentrated, 50 ml. of water was added and the solution was extracted with chloroform. The water layer was acidified with 6 N hydrochloric acid and extracted with ether. The ether which dried over sodium sulfate was removed, and the resulting product was recrystallized from ligroin - ethyl acetate (1 : 1 v./v.), with treatment of charcol, to give 1.2 g. of (±)-acid (VI), m. p. 94—96°C (lit.[23] m. p. 95—96°C).

Found: C, 79.70; H, 6.60. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

IR λ_{max}^{KBr}: 3030, 2920, 1709, 1435, 1414, 1245 cm^{-1}.

IR ν_{max}^{CHCl}: 3033, 2916, 1708, 1413 cm^{-1}.

The Asymmetric Synthesis of 3, 4-Diphenylbutyric Acid (VI).—A solution of Grignard reagent was prepared from 1.82 g. (0.075 g.-atom) of magnesium

23) S. Ruhemann, *J. Chem. Soc.*, **1910**, 460.

and 9.5 g. (0.075 mol.) of benzylchloride in 60 ml. of dry ether. Into this solution of benzylmagnesium chloride there was then stirred, drip by drop, a solution of 0.03 mol. of the ester IVa,[24] IVc, IVd or IVe in 60 ml. of dry ether (dry tetrahydrofuran for IVc) at −17——15°C for 1 hr; the stirring was then continued at the same temperature for 0.5 hr. and then at room temperature for an additional 0.5 hr. The reaction mixture was poured into saturated aqueous ammonium chloride (250 ml.) with vigorous shaking. The ether layer was separated, and the water layer was extracted with ether. The combined ether layer were washed with water, dried over sodium sulfate, and removed. The residual oil, the infrared spectrum of which did not show the presence of the starting ester, was not purified but was hydrolyzed by refluxing it with 6.2 g. (0.11 mol.) of potassium hydroxide in 5 ml. of water and 75 ml. of ethanol for 16 hr. After the ethanol had been removed and water had been added, the solution was extracted with 100 ml. of ether and 100 ml. of chloroform. The removal of organic solvents gave 1, 2 : 5, 6-di-*O*-cyclohexylidene-D-glucose (VII), 1, 2 : 5, 6-di-*O*-isopropylidene-D-glucose (VIII) or 1, 2-*O*-isopropylidene-5-deoxy-D-xylose (IX) in 80%, 70%, and 55% yields respectively, in the same manner described in the asymmetric synthesis of 3-phenylbutyric acid. The water layer acidified with 6 N hydrochloric acid on cooling and extracted with ether. The ether was washed with water, dried over sodium sulfate, and removed. The residue, the optical rotation of which had been measured, was distilled to give pure 3, 4-diphenylbutyric acid (VI). Its infrared spectrum (in chloroform) was identified with that of a racemic sample prepared from an authentic ester (Vb).[6] The yield, the physical properties and the results of the analysis for VI are recorded in Table II.

In the case of addition of cuprous chloride, the experiment was carried out in the same way described as asymmetric synthesis of 3-phenylbutyric acid (III).

The Resolution of 3, 4-Diphenylbutyric Acid (VI).—A mixture of 4.8 g. (0.02 mol.) of VI, m. p. 89—95°C, $[\alpha]_D^{28}$ −9° (*c* 2.25, benzene) which had been obtained by the above asymmetric synthesis, 6.5 g. (0.02 mol.) of quinine, and 70 ml. of ethanol was boiled until dissolution was complete. After the mixture had stood overnight at 0°C, the crystalline product was separated and washed with small quantities of ethanol. Weight of the dried product, 4.0 g.; $[\alpha]_D^{25}$ −95° (*c* 1.82, chloroform), m. p. 160—162°C. Three further recrystallizations from the same solvent gave 1.8 g. of quinine salt as needles, m. p. 165—166°C, $[\alpha]_D^{25}$ −101° (*c* 1.72, chloroform), as was indicated by its constant rotation when subjected to further recrystallization.

Found: C, 76.61; H, 7.07; N, 4.96. Calcd. for $C_{36}H_{40}N_2O_4$: C, 76.56; H, 7.14; N, 4.96%.
Decomposition in the usual manner gave a specimen of (−)-acid (VI) with a m. p. of 84—86°C, $[\alpha]_D^{28}$ −67° (*c* 0.81, chloroform), which after four recrystallizations from ligroin, had a m. p. of 87—88°C, $[\alpha]_D^{28}$ −60° (*c* 1.92, benzene). Yield, 280 mg. Further recrystallization led to no change in the optical rotation.

Found: C, 80.03; H, 6.50. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

The mother liquors containing the (+)-acid were concentrated and allowed to stand overnight at room temperature. After the precipitate had been filtered out, the filtrate was concentrated to dryness. The re-resulting solid (4.0 g.), which had a m. p. of 65—100°C, $[\alpha]_D^{25}$ −57° (*c* 1.63, chloroform), was recrystallized three times from 50% aqueous ethanol to give quinine salt of (+)-acid (VI) as needles, m. p. 110—111°C, $[\alpha]_D^{25}$ −66° (*c* 1.47 chloroform).

Found: C, 75.13; H, 7.14; N, 4.75. Calcd. for $C_{36}H_{40}N_2O_4 \cdot 1/2H_2O$: C, 75.36; H, 7.20; N, 4.88%.
Decomposition gave (+)-acid (VI) with a m. p. of 82—88°C, $[\alpha]_D^{27}$ +46° (*c* 1.24, benzene), which, after three recrystallizations from ligroin, had a m. p. of 86—88°C, $[\alpha]_D^{28}$ +59° (*c* 1.85, benzene). Yield, 200 mg. Further recrystallization led to no change in the optical rotation.

Found: C, 80.25; H, 6.64. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.

IR_{max}^{KBr}: 3023, 2914, 1711, 1659, 1407, 1279 cm^{-1}.
Its infrared spectrum (in chloroform) was identified with that of racemic acid (VI).

Examination for the Optical Stability of (—)-3, 4-Diphenylbutyric Acid (VI) in an Alkaline Solution.—A mixture of 253 mg. of VI, m. p. 87—88°C, $[\alpha]_D^{28}$ −60° (*c* 1.92, benzene), 200 mg. of potassium hydroxide in 0.1 ml. of water and 2.5 ml. of ethanol was treated under the same conditions as that of saponification in the asymmetric synthesis of VI. (−)-Acid (VI) was recovered in a 93% yield; it had a m. p. of 86.5—89.0°C, $[\alpha]_D^{28}$ −61° (*c* 1.61, benzene).

Found: C, 80.24; H, 6.65. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.71%.
The infrared spectrum was identical in every respect with that of the starting material.

The authors wish to express their thanks to Dr. Hiroyoshi Kuzuhara for his useful suggestions, to Dr. Haruo Homma and his co-workers for microanalyses, and to Mr. Teruo Kurihara for measurement of infrared spectra. The authors also wish to thank Miss Kimiko Noda and Miss Suzue Ishikawa for their helpful assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 917—920 (1966)

A Preliminary Study of the Carboxylation and Decarboxylation of Some Sulfides[1)]

By Waichiro TAGAKI, Kenji UEYAMA, Isao MINAMIDA, Yong He KIM
Yoshinori IKEDA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 3, 1965)

Some sulfides with benzylic hydrogen have been carboxylated by carbonating the respective carbanions generated with dimsylsodium in dimethyl sulfoxide. The resulting mercaptocarboxylic acids have then been found to have considerably-enhanced rates of decarboxylation reaction.

The ability of divalent sulfide groups to stabilize the α-carbanion has been disclosed in a number of reactions.[2)] The Dieckmann condensation of α, β-dicarboxy methyl ethyl sulfide, the tautomeric double-bond migration between vinyl and allyl sulfides, the alkylation at the α-carbon of mercaptal, and the hydrogen isotopic exchange reaction, are a few typical examples of these reactions. Recently we have suggested that the electron-accepting 3d orbital resonance of the divalent sulfur atom is the major factor in the facile base-catalyzed D–H hydrogen isotopic exchange reactions of a number of mercaptals and related compounds.[2b,3)]

$$R\text{-}\ddot{S}\text{-}\overset{\ominus}{\underset{|}{C}}\text{-} \leftrightarrow R\text{-}\overset{\ominus}{\ddot{S}}\text{=}C\text{-} \qquad (1)$$

Base-catalyzed decarboxylation is also considered to be a reaction involving the carbanion intermediate which is similar to the base-catalyzed hydrogen exchange reaction.[4)] However, no systematic investigation of the decarboxylation reaction of α-substituted mercapto-carboxylic acids has been known. If the carbanion is relatively stable and if, hence, its equilibium concentration is substantial in a basic solution, it would not be difficult to trap the carbanion by reacting it with carbon dioxide. In the case of the hydrogen exchange or the decarboxylation reaction, a rapid reaction does not necessarily mean a high equilibrium concentration of carbanion. Only a few examples are known which indicate an appreciable concentration of the carbanion of divalent sulfide in an equilibrating system. Fröling and Arens found that mercaptals were metalated in liquid ammonia, and they observed an increased electrical conductivity in the reaction mixture.[5)] Truce and Roberts found that benzaldehyde diphenylmercaptal was readily metalated in dimethylformamide, and that the resulting carbanion was alkylated with alkyl halide.[6)] Therefore, the study of the decarboxylation of mercapto-carboxylic acids and the carboxylation of sulfides is quite significant for the evaluation of the effects of the divalent sulfide group on the stabilization of the carbanion.

$$R\text{-}\ddot{S}\text{-}\overset{|}{C}\text{-}CO_2^{\ominus} \rightarrow R\text{-}\ddot{S}\text{-}\overset{\ominus}{\underset{|}{C}}\text{-} + CO_2 \qquad (2)$$

$$R\text{-}\ddot{S}\text{-}\overset{\ominus}{\underset{|}{C}}\text{-} + BH^{\oplus} \rightarrow R\text{-}\ddot{S}\text{-}\overset{|}{C}\text{-}H + B \qquad (3)$$

During the course of the investigations aimed at finding some appropriate base and solvent systems for the generation of carbanions of various sulfides at an appreciable equilibrium concentration, we have found that some sulfides with benzylic hydrogen can be successfully carboxylated by quenching, with carbon dioxide, solutions of the sulfides in dimsylsodium - dimethyl sulfoxide. The resulting carboxylic acids have all been found to have enhanced rates of decarboxylation. This paper will describe the preliminary results of these carboxylation and decarboxylation reactions.

Results and Discussion

Carboxylation Reactions.—A sulfide was dissolved in an excess of 0.5 N dimsylsodium in dimethyl sulfoxide[7)] under an air-free nitrogen atmosphere. When a sulfide was dissolved, the initial brilliant red color of the dimsylsodium solution due to the addition of an indicator amount of triphenylmethane turned a dark yellowish brown, dark green, or dark purple depending on the kind of sulfide dissolved.

7) E. J. Corey and M. Chaykovsky, *J. Am. Chem. Soc.*, **84**, 866 (1962).

The carboxylation was then performed by quenching the reaction mixture with or an ether suspension of solid carbon dioxide. The results are shown in Table I.

As is indicated in Table I, none of the carboxylic acids were obtained from the sulfides, VI and VII, with only the aliphatic C–S bonds. In the case of 1, 3-dithian (VI), the starting sulfides was largely recovered alone with a small amount of resinous product. The bicyclic sulfide (VII) also gave mainly a resinous product. These resinous products were probably formed by the cleavage of C–S bonds, similar to the cases where mercaptals were cleaved by some such metalating agents as Grignard reagents, phenyllithium, or *n*-butyllithium.[2a,8,9]

Although qualitative, it seems that the yield of the carboxylic acid in Table I can be explained on the basis of the stability of the carbanion formed by the dissociation of the α-proton of sulfide. The rates of hydrogen exchange reaction have been found to increase dramatically with the increase in the number of the substitution of the mercapto group at the α-carbon atom.[3] Similarly, Table I indicates that the yield of the carboxylic acid from benzaldehyde diethylmercaptal (II) is much higher than that from the benzyl ethyl sulfide (I). Table I also indicates that the yield of the carboxylic acid from benzyl phenyl sulfide (III) is much higher than that from benzyl ethyl sulfide (I). This appears to indicate that the phenylmercapto group is more effective than the ethylmercapto group in the stabilization of carbanion, this is confirmed by the results of the subsequent decarboxylation reactions shown in Table II.

Decarboxylation Reaction.—As Table I shows, the acids, XII and XI, obtained from the sulfides, II and IV, were readily decomposed when their crystals were heated at around 140°C in a glass tube, there was also a vigorous evolution of carbon dioxide. The corresponding sulfides, II and IV, were quantitatively obtained. The acids from the III and V sulfides, are relatively stable, and their decomposition was not observed below 200°C. These acids were then subjected to the base-catalyzed decarboxylation reaction. The results are shown in Table II, although the methods of the kinetics will be reported in detail elsewhere.

Table II appears to disclose the following three points: (1) The rate of diethyl mercapto acetic acid (VIII) is much smaller than those of the other acids. (2) The rates of the decarboxylation of the disubstituted acids, IX and X, are smaller than those of the trisubstituted acids, XI and XII. (3) The rates of the decarboxylation of phenylmercapto-substituted acids (XI and IX) are greater than that of ethylmercapto-substituted acids, (XII and VIII). These observations can be explained by assuming that the ability to stabilize α-carbanion is greater for phenyl and phenylmercapto groups than for the aliphatic mercapto (RS) group, and that the stability of the carbanion is increased with the increasing substitution of mercapto groups.

The products of the decarboxylation reaction were analyzed, the results are shown in Table III. The most plausible mechanism for the present decarboxylation reaction is the formation of carbanion at the rate determining slow step, followed by the fast protonation of the carbanion. However, such other mechanisms as the formation of a methylene intermediate are also possible, in which different kinds of products may be expected.[10] Although the analyses were preliminary and were not thoroughly enough to exclude the formation of a very small quantity of unknown products, it was found that more than 90% of the mercapto acids were decomposed to give carbon dioxide and that the corresponding mercaptals were obtained in high yields; the direct analyses of the reaction mixtures by gas chromatography did not indicate the formation of products other than dimethyl sulfoxide and the mercaptals. The products of the decomposition of diphenoxyacetic acid other than carbon dioxide are not clear. The infrared spectra of the product, however, showed the presence of phenol. This suggests a possibility that the mechanism of the decarboxylation of RO-substituted acid is different from that of RS-substituted acetic acids.

Experimental

The Preparation of Sulfides.—Benzyl ethyl sulfide (I) and benzyl phenyl sulfide (III) were prepared by the reaction of benzyl chloride with the corresponding sodium mercaptide in ethanol (I, b. p. 110°C/20 mmHg; II, b. p. 167—168°C/15 mmHg, m. p. 40—42°C). Benzaldehyde diphenylmercaptal (IV) was prepared by saturating the mixture of benzaldehyde and phenyl mercaptan with dry hydrogen chloride (b. p. 183—184°C/1 mmHg; m. p. 50—51°C). Similarly, formaldehyde diphenylmercaptal (V) was prepared by the acid (HCl)-catalyzed condensation of formaldehyde with phenylmercaptan (b. p. 164—167°C/3 mmHg). The preparations and the properties of benzaldehyde diethylmercaptal (II) and the cyclic mercaptals, VI and VII, have been reported in previous papers.[11]

Carboxylation Reaction.—Commercial dimethyl sulfoxide was dried with calcium hydride under 50°C and vacuum-distilled (below b. p. 55°C). Sodium hydride (7 g.) in a 50% oily suspension was dissolved in 590 ml. of the above dimethyl sulfoxide below 60°C under an air-free nitrogen atomosphere to give a pale brown dimsylsodium solution,[7] the solution was then

connected to an air-tight automatic buret.[12] Sulfide (2.0 g.) was weighed in a glass tube, dissolved in 25 ml. of a dimsylsodium solution which had been transferred from the above automatic buret, and sealed under an air-free nitrogen atmosphere. The reaction mixture was then left at room temperature for 17 hr., after which the tube was opened and the contents poured into an excess suspension of solid carbon dioxide in ether to give a salt suspension. Water was added to the salt suspension, and the water layer was extracted with ether twice. The ether layers were combined, washed with water, dried and concentrated, and the residue was vacuum-distilled to give the unreacted sulfide. The water layer was acidified with hydrochloric acid and then extracted with ether three times. The ether extract was dried and concentrated to give the mercapto acid. The results are shown in Table I. An air-free nitrogen atomsphere is not necessarily required for the purpose of the carboxylation, and the reaction time can be shortened by increasing the reaction temperature to 50°C.

Decarboxylation Reaction.—*Kinetics.*—The carboxylic acid and triethylamine or triethanolamine were dissolved in anhydrous dimethyl sulfoxide and heated in a constant temperature bath under an air-free nitrogen stream. Carbon dioxide was absorbed in dilute solutions of sodium hydroxide and back-titrated with dilute sulfuric acid. While the kinetic procedures will be reported in detail elsewhere, the results are shown in Table II. The relative rates were calculated from the apparent activation energy of the decarboxylation reaction of the acid (X) (29.2 kcal./M) obtained from Arrhenius plot.

The Product Analysis of the Decarboxylation.—In a 100-ml. two-necked flask with a nitrogen gas inlet tube and a reflux condenser there was placed 0.01 mol. of an acid and 50 ml. of dimethyl sulfoxide. The reaction mixture was then heated on an oil bath under the bubbling of air-free nitrogen gas. The carbon dioxide evolved was led through a dry ice - cooled trap to an absorbing trap containing 0.2 M barium hydroxide. The heating was then continued, by replacing the absorbing trap with another one, until the evolution of carbon dioxide was no more observed. The reaction mixture was cooled and analyzed by gas chromatography and finally subjected to a fractional distillation. The results are shown in Table III.

Chronopotentiometry of Tris(ethylenediamine)chromium(III) Ions in Various Supporting Electrolyte Solutions

By Nobuyuki TANAKA and Akifumi YAMADA

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received September 8, 1965)

The reduction of tris(ethylenediamine)chromium(III) ions at the dropping mercury electrode has been studied chronopotentiometrically in various supporting electrolyte solutions. The electrolysis at constant cathodic current in an acid solution gives a well-defined chronopotentiogram which corresponds to the one-electron reduction of chromium(III) to chromium(II). The anodic chronopotentiogram which is obtained by the current-reversal techniques is clearly separated from the cathodic one. Two cathodic steps are obtained in alkaline ethylenediamine solutions, and two anodic steps, at the current reversed. No chemical reaction involving hydrogen ions or ethylenediamine takes place prior to the electron transfer. The presence of very small amount of surface-active substances was found to improve the shape of chronopotentiograms. In the presence of EDTA, the one-electron cathodic chronopotentiogram splits into two steps.

In a previous paper,[1] the present authors reported on the chromopotentiometric behavior of hexamminechromium(III) ions in acetate buffer solutions. Since only a little work has been reported on the electroreduction of tris(ethylenediamine)-chromium(III) ions,[2-4] it seems worthwhile to carry out the polarographic or chronopotentiometric study of this complex.

The present paper is concerned with the chronopotentiometry of tris(ethylenediamine)chromium-(III) ions in various supporting electrolyte solutions. The observations in the cathodic chronopotentiometry and in the anodic chronopotentiometry by the current-reversal techniques will be presented, and the mechanism of the electrode processes will be discussed.

Experimental

Tris(ethylenediamine)chromium(III) chloride was

prepared according to the method of Pfeiffer[5]; the chromium and nitrogen contents were determined by the usual methods.

Found: Cr, 12.79; N, 20.4. Calcd. for $[Cr(en)_3]Cl_3 \cdot 3^1/_2\ H_2O$: Cr, 12.94; N, 20.9%.

As the complex is sensitive to light and not very stable in aqueous solutions[6-9] precautions were taken when it was used. All other chemicals used were of analytical reagent grade. Redistilled water was used for the preparation of the solutions of desired concentrations. Polyoxyethylene laulyl ether (LEO), $C_{12}H_{25}O(C_2H_4O)_n$-OH (n=ca. 15), was used for a maximum suppressor. The contamination of the solution with surface-active substance was carefully avoided.

Chronopotentiometric measurements were carried out in general by following the procedure given in the previous paper.[1] A dropping mercury electrode of a long drop time was used for the working electrode; it had an m value of 0.1164 mg./sec. and a drop time, t_d, of 61 sec., being measured in a deaerated solution containing 0.1 M acetate buffer and 0.9 M ammonium chloride at open circuit at 25 cm. of the mercury reservoir. The auxiliary electrode was a platinum wire, which was isolated in a compartment provided with a sintered glass disk. A saturated calomel electrode (SCE) was used for the reference electrode. Dissolved oxygen in the electrolytic solution was removed by bubbling purified nitrogen gas through the solution. All measurements were carried out at 25±0.1°C.

Results

In the polarographic measurements, tris(ethylenediamine)chromium(III) was found not to give a well-defined polarographic wave in neutral unbuffered solutions, but to give a well-defined wave in acetate buffer or acid solutions.[10] Similar observations were made in the chronopotentiometric measurements. Typical examples are shown in Fig. 1.

The characteristics of the potential-time curve for the reduction of tris(ethylenediamine)chromium-(III) ions in neutral media were studied in a 1 M ammonium chroride solution. No linear relation was found between the concentration and the square root of the transition time. An example of the potential-time curves, which were obtained by the electrolysis at a constant cathodic current followed by the electrolysis at the constant anodic current of the same magnitude is given in Fig. 2. The values of τ_c/τ_a, $E^c_{t=0}$ and $E^a_{t=0}$ were determined to be 3.2, −0.94 V. vs. SCE and −0.75 V. vs. SCE respectively, where τ_c and $E^c_{t=0}$ mean the transition time and the potential at t=0 of the cathodic chronopotentiogram respectively, and τ_a and $E^a_{t=0}$, those of the anodic chronopotentiogram obtained by the current-reversal techniques respectively.

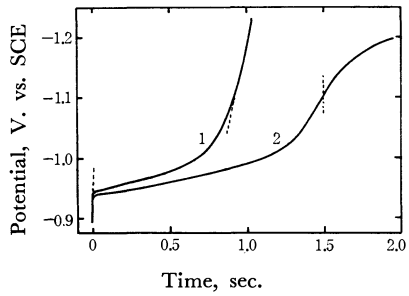

Fig. 1. Chronopotentiograms of 1 mM $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ (1) in 0.9 M NH_4Cl+0.1 M acetate buffer (pH 4.6) and (2) in 1 M NH_4Cl at 25°C at current densities of (1) 0.231_4 and (2) 0.165_5 mamp.cm^{-2}. The measurements were started at 40 sec. after the beginning of the growth of mercury drop.

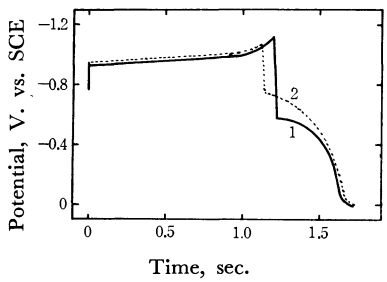

Fig. 2. Chronopotentiograms for the reduction and the subsequent reoxidation of 1 mM $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ (1) in 0.9 M NHCl+0.1 M acetate buffer (pH 4.6) and (2) in 1 M NH_4Cl at 25°C. Current densities are (1) 0.181_7 mamp. cm^{-2} and (2) 0.186_0 mamp.cm^{-2}.

In acetate buffer solutions, well-defined chronopotentiograms were observed (see curve 1 in Figs. 1 and 2). The transition time (τ) was determined at various current densities (i) ranging from 0.179 to 0.508 mamp. cm^{-2}. The results showed that the product $i\tau^{1/2}$ was independent of the current density, indicating clearly that tris(ethylenediamine)chromium(III) ions are directly reduced at the electrode without any preceding chemical reaction prior to the electron-transfer process. The average value of $i\tau^{1/2}/C_O$, where C_O represents the concentration of the complex in the bulk of the solution, was obtained to be 0.211 mamp. sec$^{1/2}$ cm^{-2} mM^{-1}.

Measurements were also made at various concentrations of the complex. The results showed that the square root of the transition time was proportional to the concentration of the complex up to 1.5 mM, but at higher concentrations the transition time abnormally increased. The average value of $i\tau^{1/2}/C_O$ was obtained to be 0.211 mamp.

$sec^{1/2}\,cm^{-2}\,mM^{-1}$ in the range of the concentration up to 1.5 mM. According to Sand[11] the value of $i\tau^{1/2}/C_O$ is expressed as

$$i\tau^{1/2}/C_O = \frac{\pi^{1/2}}{2} nFD_O^{1/2} = 85.51nD_O^{1/2} \qquad (1)$$

where F is the Faraday, C_O the bulk concentration expressed in mM, D_O the diffusion coefficient expressed in $cm^2\,sec^{-1}$, i the current density expressed in mamp. cm^{-2} and n the number of electrons involved in the electrode reaction. The transition time constant $i\tau^{1/2}/C_O$ is correlated to the polarographic diffusion current constant I, which is given by the equation,

$$I = 607\,nD_O^{1/2} \qquad (2)$$

when the original form of the Ilkovic equation and the average current during the life of a mercury drop are employed. Hence, one obtains

$$i\tau^{1/2}/C_O = 0.1409\,I \qquad (3)$$

Introducing 1.47 μamp. $sec^{1/2}\,mg^{-2/3}\,mM^{-1}$ for I, which was determined by the polarographic measurement, the theoretical value of $i\tau^{1/2}/C_O$ was caluclated to be 0.207 mamp. $sec^{1/2}cm^{-2}mM^{-1}$. This value was in a satisfactory agreement with the experimental one.

The potential at $t=0$ ($E_{t=0}$) was found to be dependent on the current density and to change linearly with log i as shown in Fig. 3. Chronopotentiograms were obtained at various pH's in acetate buffer solutions, when the potential at $t=0$, the slope of the log-plot (log $(\tau^{1/2}-t^{1/2})$ vs. E) and the transition time constant were found to be independent of pH of the solution. The transition time constant, the potential at $t=0$ and the slope of the log-plot which were obtained at varied ionic strengths and in various supporting electrolyte solutions are given in Tables I and II, respectively. The effect of LEO on the chronopotentiogram of tris(ethylenediamine)-chromium(III) ions is shown in Table III. The transition time was not affected unless the concentration of LEO exceeded 5×10^{-4} M, whereas the potential at $t=0$ is affected by the addition of 5×10^{-6} M LEO.

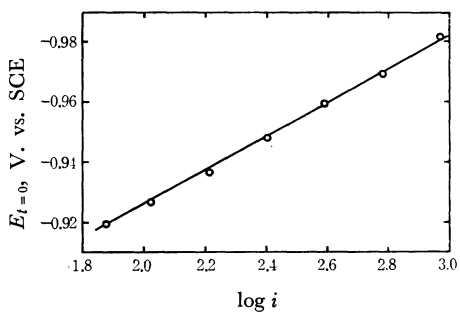

Fig. 3. Relation of $E_{t=0}$ with log i for the reduction of 1 mM $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ in 0.9 M NH_4Cl+0.1 M acetate buffer. Ohmic drop is corrected.

When a small amount of disodium ethylenediaminetetraacetate (EDTA) is added to the solution, the one-electron cathodic chronopotentiogram of the tris(ethylenediamine)chromium(III) ions split into two steps. A typical example of the

chronopotentiogram is shown in Fig. 4.

Chronopotentiograms in alkaline ethylenediamine solutions were not so simple as in acid solutions. As shown in Fig. 5, two cathodic steps were observed in a solution containing 0.5 M ethylenediamine dihydrochloride and 1 M sodium hydroxide, and two anodic steps at the current reversed.

Discussion

Tris(ethylenediamine)chromium(III) ion gives no well-defined chronopotentiogram in neutral unbuffered solutions, because it contains basic ligands and, when reduced, it forms an insoluble film on the surface of the electrode, as has already been reported in the case of the polarographic reduction of some chromium(III) complexes.[12-14] In an acid solution the ethylenediamine molecules which the reduced chromium(II) species liberate are neutralized by hydrogen ions diffusing from the bulk of the solution; consequently, the formation of an insoluble film is prevented. It may be concluded from the results obtained at various current densities and at various concentrations of the complex that tris(ethylenediamine)chromium-(III) ions are directly reduced at the dropping mercury electrode without any preceding chemical reaction prior to the electron-transfer process. The anodic chronopotentiograms obtained by the current-reversal techniques indicate that the overall process of the reduction of tris(ethylenediamine)chromium(III) to chromium(II) species proceeds irreversibly at the dropping mercury electrode:

$$[Cr(en)_3]^{3+} + e + 2p\ H_3O^+ \rightarrow [Cr(H_2O)_{2p}(en)_{3-p}]^{2+} + p\ H_2en^{2+} \quad (4)$$

In alkaline ethylenediamine solutions, the first cathodic and the first anodic chronopotentiogram appeared in approximately the same potential region. This observation agrees with the result which was obtained by Fischerovâ and Fischer[4] in their oscillograph-polarographic study on the reduction of the same complex.

The potential of the cathodic chronopotentiogram is dependent on the ionic strength of the solution; the potential at $t=0$ ($E^c_{t=0}$) shifts to more negative potentials as the ionic strength increases (Table I). Such a shift is also observed in the reduction of other chromium(III) complexes.[13-15]

A plot of $E_{t=0}$ versus log i yielded a straight line with a slope of 55 mV. The plot of $\log(\tau^{1/2}-t^{1/2})$ versus E in various supporting electrolyte solutions, however, did not always yield a straight line as given in Table II. This makes the theoretical analysis of the potential-time curve less feasible. According to the theoretical treatment of potential-time curves reported previously,[1] the slope of these plots is equal to $2.3\,\boldsymbol{R}T/n\boldsymbol{F}$ for a reversible electron-transfer and $2.3\,\boldsymbol{R}T/\alpha n\boldsymbol{F}$ for an irreversible electron-transfer, where α represents the transfer coefficient and $\boldsymbol{R}$ the gas constant. At the moment, however, it seems impossible to decide, from the experimental results, by which process the reduction of tris(ethylenediamine)chromium(III) ions takes place, because of the insufficient knowledge on

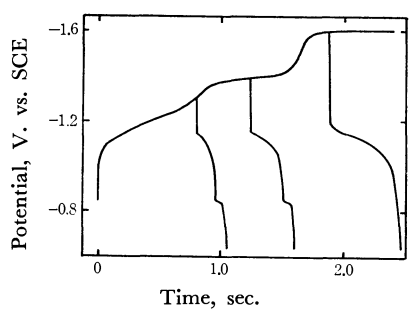

Fig. 5. Chronopotentiograms for the reduction and the subsequent reoxidation of 1 mM $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ at current density of 0.223_6 mamp. cm^{-2} in the solution containing 0.5 M en·2HCl and 1 M NaOH (pH 7.9).

the reactivity of chromium(II) complexes.

The ratio of τ_c/τ_a fluctuates around 3, i. e., the theoretical value that is expected when the reduced species is soluble and the current densities at the forward and the reverse process are equal in magnitude.[16] The value of τ_c/τ_a in potassium nitrate solutions was found to increase as τ_c increased, as seen in Table IV. This suggests the interaction between the reduced chromium(II) complex and nitrate ions.

TABLE IV. TRANSITION TIME FOR THE REOXIDATION PROCESS OF 1mM $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ RECORDED AT CURRENT DENSITY OF 0.182_0 mamp.cm^{-2} IN 0.9M KNO_3+0.1M ACETATE BUFFER

0.88_0	0.25_0	3.5_2		
0.68_0	0.25_0	3.4_0		

The transition time constant of tris(ethylene diamine)chromium(III) ions (0.211 mamp.sec$^{1/2}$ cm^{-2}mM^{-1}) obtained in the solution containing 0.1 M acetate buffer and 0.9 M ammonium chloride was smaller by 20 per cent than that of hexammine-chromium(III) ions obtained under the same condition. The difference is considered to be due to a larger size of the ethylenediamine complex ion. The transition time constant obtained in the ammonium sulfate solution was found to be smaller by some 10 per cent than that obtained in other supporting electrolytes. This is considered as due to the ion-pair formation of tris(ethylene-diamine)chromium(III) with sulfate ions, the details of which will be reported elsewhere.

It is known that the transition time decreases more or less markedly when a strongly adsorbable substance is present in the solution.[17-19] In the case of the reduction of tris(ethylendiamine)-chromium(III) ions, in contrast, the addition of a very low concentration of surface-active substances improved the shape of the potential-time curves (see Fig. 6). In the absence of surface-active substance, no satisfactory chronopotentiogram was obtained; a sudden change or a drift in potential occurred, immediately before the transition time is attained. Table III indicates that the addition of LEO up to 5×10^{-7} M in concentration gives satisfactory chronopotentiograms of tris(ethylene-diamine)chromium(III) ions. A similar example of the improvement of a chronopotentiogram by the addition of a small amount of surface-active substance has been reported for the reduction of copper(II) ions in the presence of polyacrylamide.[19]

In the presence of EDTA, the cathodic chrono-potentiogram of tris(ethylenediamine)chromium-(III) ions splits into two steps; the potential of the first step is almost the same as that of the chronopotentiogram obtained in the absence of EDTA, while the potential of the second step corresponds to the oxidation-reduction potential of chromium(II)- and chromium(III)-EDTA complexes. The first step decreases in the transition time with the increase in the EDTA concentration, and it vanishes when the EDTA concentration exceeds a critical value. A plot of $\tau_1^{1/2}$ versus [EDTA]/C_O yields a nearly straight line as is seen in Fig. 7, where τ_1 is the transition time of the first step, [EDTA] the concentration of EDTA and C_O the concentration of the complex. These phenomena were considered as being caused by the electrode process given as follows [20,21]:

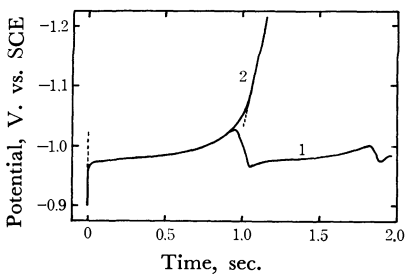

Fig. 6. Chronopotentiograms of 1 mM $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ obtained at current density of 0.238_6 mamp.cm^{-2} in the solution containing 0.9 M KSCN and 0.1 M acetate buffer (1) in the absence and (2) in the presence of 5×10^{-9} M of LEO.

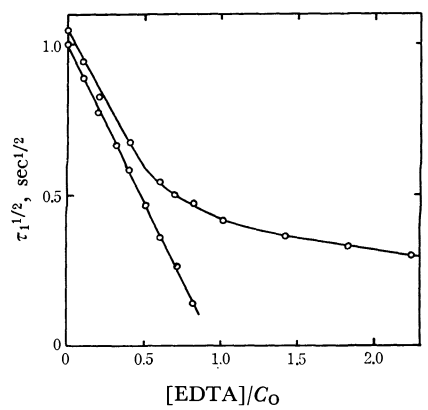

Fig. 7. Relation of $\tau_1^{1/2}$ with [EDTA]/C_O obtained at various concentrations of $[Cr(en)_3]Cl_3 \cdot 3^1/_2H_2O$ in the solution containing (1) 0.1 M acetate buffer and 0.9 M NH_4Cl and (2) 0.1 M acetate buffer and 0.3 M $CaCl_2$. $$[Cr(en)_3]^{3+} + e \rightarrow [Cr(en)_3]^{2+}$$

$$[Cr(en)_3]^{2+} + EDTA \rightleftharpoons Cr(II)\text{-}EDTA + 3en \quad (5)$$

$$Cr(II)\text{-}EDTA \rightarrow CrY(H_2O)^- + e$$

where Y^{4-} represents a quadrivalent EDTA anion and Cr(II)-EDTA, either $[CrYH_2O]^{2-}$ or $[Cr(HY)(H_2O)]^-$ according to the pH of the solution.[22] As is seen in Fig. 7, when a large excess of calcium ions is present in the solution, the decrease in transition time of the first step is much smaller than that observed in the absence of calcium ions. This is considered to be due to the decrease in the activity of free EDTA anions because a large excess of calcium ions reacts with free EDTA anions to form stable calcium-EDTA complexes. The details will be reported elsewhere.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 925—928 (1966)

Chemical Studies of Minerals Containing Rarer Elements from the Far East District. LX.*,[1] Thalenite from Suishoyama, Kawamata-machi, Fukushima Prefecture, Japan

By Kozo NAGASHIMA**

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

and Akira KATO

Department of Geology, National Science Museum, Ueno Park, Taito-ku, Tokyo

(Received September 10, 1965)

Chemical studies of thanlenite from Suishoyama pegmatite, Fukushima Prefecture, showed its composition to be very close to the ideal formula, $Y_2Si_2O_7$, and to a selective distribution pattern of rare earths belonging to the thortveitite-type as defined by Goldschmidt and Thomassen. The X-ray powder studies disclosed a metamict state hitherto unknown in this species, and the original state could be recovered by thermal treatment. Optical and other properties: color, colorless to light gray; luster, resinous; optical properties, $\alpha=1.709\pm0.002$, $\beta=1.716\pm0.002$, $\gamma=1.723\pm0.002$, $(-)2V\sim70°$, $\rho<v$; specific gravity, 4.16, hardness; $6^1/_2$. Chemical analysis: SiO_2, 30.68%; Al_2O_3, 0.10%; Fe_2O_3, 0.17%; $\sum Y_2O_3$, 64.89%; UO_2, 1.12%; ThO_2, 0.20%; CaO, 0.35%; MnO, 0.38%; MgO, 0.33%; Na_2O, 0.02%; $H_2O(+)$, 1.56%; $H_2O(-)$, 0.11%; total, 99.91%.

The rare yttrium sorosilicate mineral thalenite, $Y_2Si_2O_7$, was first described by Benedicks[2] in 1898 on the basis of a specimen from a granite pegmatite at Österby, Sweden; then it was described on the basis of samples found at Askagen, Sweden,[3] and from Hundholmen and other places, Norway.[4] The localities of this mineral added thereafter include Kofu, Japan,[5] Arizona[6] and Colorado[7], U. S. A., and Siberia, U. S. S. R.[8]

Suishoyama pegmatite, Kawamata-machi, Fukushima Prefecture, is found in a Mesozoic biotite granite body, which also contains several other pegmatites, smaller than the Suishoyama one. This pegmatite has a well-developed zonal arrangement of felsic minerals and has been worked for quartz and feldspar for many years. It is also very famous for the occurrences of many rare element-bearing minerals, such as abukumalite

(type locality),[9] yttrialite,[10] fergusonite,[11] tengerite,[12] thorogummite,[13] allanite,[14,15] uraninite,[16] zircon,[17] gadolinite,[18] keilhauite[19] and some secondary uranium minerals, such as autunite, torbernite and zeunerite.[20] Most of these minerals are found in aggregates of large blades of a lepidomelane containing a small amount of lithium.[21] Abukumalite, allanite, a fergusonite-uraninite mixture and zircon also occur as larger crystals in the intermediate zone composed of large crystals of microcline, albite and quartz. It is in this zone that the thalenite here described was found together with a fergusonite-uraninite mixture. The largest thalenite crystals are fist-size and weigh about 1 kg. Some of them display a few crystal faces, though they are not goniometrically measurable due to their ruggedness.

The mineral thalenite also provides an example of the selective assemblage of rare earth elements in which dysprosium is dominant and which is known under the name "thalenite-type", by Goldschmidt and Thomassen.[22] The mode of the distribution of rare earth elements in the thalenite we have studied is not of the "thalenite-type" but rather of the "thortveitite-type," in which the maximum content of rare earth is in ytterbium. It is worthy to note that another Japanese thalenite, from Kofu, Yamanashi Prefecture, shows the same tendency.

Physical Properties

The outer parts of the thalenite grains are white and have a clouded, porcelain-like appearance, while the inner parts range from colorless to a very light gray or are transparent. The X-ray powder studies showed the former to be a mixture of more or less metamictized thalenite and tengerite, and the latter, to be thalenite itself, but more metamictized than the former. The physical properties, including the optical properties, of the core part are given in Table I. Among them, the refractive indices which are lower than those of thalenite from other localities are so significant as to constitute one of the characteristics of the metamictized minerals (e. g., $\alpha=1.725$, $\beta=1.746$, and $\gamma=1.762$ for thanlenite from Kofu, Japan[5]). However, the conoscopic figure is unexpectedly sharp irrespective of the broader and weaker X-ray diffraction peaks, as will be established in the succeeding.

Table I. Optical and other prorerties

Color	colorless
Luster	resinous to glassy
X-Ray powder diffractions	broad and weak
Optical property	α 1.709±0.002
	β 1.716±0.002
	γ 1.723±0.002
	$(-)2V\sim70°$, $\rho<v$
Specific gravity	4.16
Hardness	$6\,1/2$

X-Ray Powder Studies

The X-ray powder studies were made on unheated and heated materials from the inner parts using a Norelco X-ray Diffractometer. The former gives a few, broad diffraction peaks, as is shown in Table II. After the material has been heated for one hour at about 900°C in the air, the diffraction peaks become very sharp and the powder data are very similar to those for thalenite (non-metamict) obtained from Snowflake pegmatite,[7] Colorado, U. S. A., as is shown in Table II. The positions of all the diffraction peaks of the unheated material shift to the high angle side when heated, without any significant changes in their relative intensities. This means a complete recovery from the metamict to the crystalline state after thermal treatment up to about 900°C; the recovered crystalline state is crystallographically identical with that of ordinary nonmetamict thalenite. Also, the metamictization of this mineral yields the expansion of the unit cell, which is substantially responsible for the lowering of the refractive indices.

Chemical Composition

Chemical analyses were carried out on hand-picked material from the inner part. The average atomic weight of the rare earth elements was determined by titrating the weighed mixed oxides with EDTA after first dissolving them in hydrochloric acid. The water content was determined by igniting the sample and by then absorbing the liberated water in calcium chloride. Sodium and potassium were determined by flame-photometry.

The results of the chemical analyses are given in Table III, together with the molecular ratios of the components. The higher uranium content and the presence of thorium that characterize

this material are responsible for the metamict state.

As is shown in Table III, the experimental formula of the thalenite from Suishoyama is $(Y, Yb, Er, Dy, U, Ca, etc.)_{2.012}(Si, Al)_{2.009}O_{7.000}\cdot 0.38H_2O$, which is very close to the ideal formula, $(Y, Yb)_2Si_2O_7$, except for an additional 0.38 mol. of H_2O.

The crystallochemical nature of the water in thalenite is still unknown. In Doelter's handbook,[23] the formula is given as $Y_2Si_2O_7\cdot{}^1/_2H_2O$; this has lately been revised to $Y_2Si_2O_7$. However, judging from the results of a survey of the literature concerned, no significant study has hitherto been made of the water in this mineral.

Proton magnetic resonance studies[24] of water molecules in this material proved that they are not in a merely absorbed state, but that they combine with the mineral rather tightly at room temperature, and that they (more precisely, the protons) do not exist as isolated OH^- ions, either. Nearly 10% water (by weight) has been found in the white outer part of the mineral, which is in a less metamictized state than the inner part, according to the X-ray powder study. Even though the presence of a small amount of tengerite in the outer part is taken into consideration, a considerable amount of water should be in thalenite itself; it is responsible for the less metamictized state.

The Distribution Pattern of Rare Earth Elements

The distribution pattern of rare earth elements was determined by the X-ray fluorescent method; yttrium, neodymium, samarium, gadolinium, terbium, dysprosium, erbium and ytterbium were thus found. Lutetium may be present, but its presence was not confirmed due to the overlapping diffractions of other spectra with stronger intensities. A quantitative estimation is given in Table IV, in which the total of the detected oxides is calculated to be 100% and is compared with those for the Siberia thalenite.[8] The present material has predominances of dysprosium, erbium and ytterbium among the lanthanides, and a very high concentration of yttrium in rare earths. The concentration of cerium-group lanthanides is too low to be detected. The average atomic weight calculated by adopting the values rendered by the X-ray fluorescent analysis was 108, which coincides rather well with that determined by the ordinary chemical method shown in Table III.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 929—932 (1966)

The Structure of a Yellow Pigment from the Mutant *lemon* of *Bombyx mori*

By Miki GOTO, Masaki KONISHI and Katsura SUGIURA

Department of Chemistry, Gakushuin University, Mejiro, Toshima-ku, Tokyo

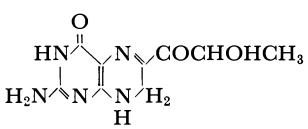
and Motoo TSUSUE

Department of Biology, Tokyo Metropolitan University, Setagaya-ku, Tokyo

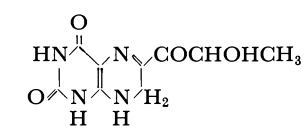
(Received September 11, 1965)

The structure of N_8-methylsepiapterin was previously postulated for a new pteridine from *Bombyx mori lemon* (This Bulletin, **38**, 503 (1965)). This structure must, however, be modified on the basis of some new experiments. We will now present the 7, 8-dihydro-6-lactyllumazine structure for this compound.

Hirata, Nakanishi and Kikkawa[1] have reported the isolation of a yellow pigment, named xanthopterin-B, from the epidermis of the mutant *lemon* of *Bombyx mori*. Nawa and Taira[2] have reported that xanthopterin-B is indistinguishable from a yellow compound found in comparatively large quantities in the eyes of the *sepia* mutant of *Drosophila melanogaster*. Aruga, Kawase and Akino[3] have shown, by chromatographic techniques, the presence of two yellow, yellow-fluorescent compounds (xanthopterin-B_1 and xanthopterin-B_2) in the epidermis of *B. mori lem.* Tsusue and Akino[4] have succeeded in isolating a small amount of xanthopterin-B_1, which is by far the major component, in a pure state and have demonstrated that it has the same structure as sepiapterin, i. e., 2-amino-4-hydroxy-7, 8-dihydro-6-lactylpteridine I.[5] The second component, xanthopterin-B_2, is present in extremely small amounts, and it is very sensitive to light. In a preliminary report,[6] we described some degradations of this compound and postulated a structure for it. This structure must, however, be modified in the light of some new experiments which will be described here. We now wish to propose the structure II for this compound.



(I)



(II)

Experimental

The Isolation of Xanthopterin-B_2.—The epidermis of silkworms (*B. mori*, mutant *lemon*) was treated with acetone, filtered, and pulverized. The pteridines were extracted by boiling the epidermis (100 g., wet) with 800 ml. of 50% ethanol for 20 min.; the solution was then filtered. The extraction with 50% ethanol was repeated twice, after which the yellow filtrates were combined and evaporated to dryness in vacuo. The residue was dissolved in water, and the solution was passed through an Ecteola cellulose column (7×12 cm.). The yellow fluorescent material (xanthopterin-B_2) was concentrated in a band at the top of the column; after the column had been throughly washed with water, this band was eluted with 0.01 N acetic acid. The eluate was concentrated, and the solution was again passed through an Ecteola cellulose column (3×10 cm.). The yellow eluate obtained by washing this with a 1% ammonium chloride solution was evaporated to a small bulk. The extract was then passed through a Filtrol (grade 58) column (2×7 cm.). After the column had been thoroughly washed with water, the band was eluted with 10% aqueous acetone. The eluate was concentrated to dryness in vacuo. All the above procedures were carried out in the dark in order to avoid photolysis. Four hundred grams of the epidermis gave 15 mg. of the crude product in a repetition of this procedure. From this about 2 mg. of the pure material was obtained by crystallization from methanol and water. The ultraviolet absorption spectra of the compound are shown in Fig. 1.

Air Oxidation in a Borax Solution.[5]—A small amount of the compound was dissolved in 5% aqueous borax and then shaken at 35°C for 24 hr. in the dark in order to avoid photodecomposition; the yellow color of the solution thereby gradually changed to a weak yellowish green, and the yellow fluorescence, to green. The product was purified by paper chromatography using as solvents *n*-propanol - 1% ammonia (2 : 1) and *n*-butanol - acetic acid - water (4 : 1 : 1). The absorption spectra, R_f-values and electrophoretic behavior

of the product were identical with those of an authentic sample of 6-hydroxylumazine[7] (Table I).

The Characterization of Lactic Acid.[8]—An aqueous solution of the compound (xanthopterin-B_2) (0.28 ml., c=41.0 μg./ml.) was treated with 5% borax (0.1 ml.) and shaken at 35°C for 24 hr. in the dark. The solution was then diluted with water to 1 ml. and heated at 100°C for 5 min. with 6 ml. of sulfuric acid and 0.05 ml. of 2% copper(II) sulfate. After cooling, 0.1 ml. of a 1.5% *p*-hydroxybiphenyl reagent was added; the mixture was allowed to stand at 30°C for 30 min. and then heated at 95°C for 1—2 min. The color which developed was estimated at 570 mμ (Hitachi spectrophotometer EPS-3). From a standard curve obtained with known amounts of lithium lactate, 41.0 μg. (1 ml. of the reaction mixture) was estimated to give 13.1 μg. of lactic acid (84% of the theoretical yield).

Potassium Permanganate Oxidation.—An aqueous solution of the sample (0.04 ml., c=5 mg./ml.) was treated with a saturated solution of potassium permanganate in 0.1 N sodium hydroxide (0.08 ml.) at 95°C for 30 min. The excess permanganate was then destroyed with alcohol, and the solution was filtered

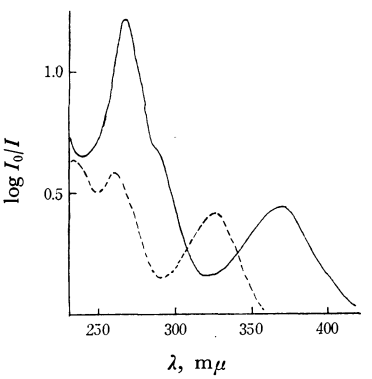

Fig. 2. The ultraviolet absorption spectra of the pteridine obtained by permanganate oxidation of xanthopterin-B_2: ——, at pH 12; and ·····, at pH 1.

in order to remove the manganese(IV) oxide. The product was identical with lumazine-6-carboxylic acid[9] (Table I and Fig. 2).

Periodate Oxidation.—A small amount (enough for paper chromatography) of an aqueous solution of the sample was treated with sodium metaperiodate at 30°C for 24 hr. and then submitted to paper chromatography and electrophoresis. The product was identical with lumazine-6-carboxylic acid.

Reduction with Sodium Borohydride.—An aqueous solution of the compound (xanthopterin-B_2) (0.1 mg./10 ml.) was treated with sodium borohydride (1 mg.); the greenish yellow fluorescence of the solution

7) A. Albert, J. H. Lister and C. Pedersen, *J. Chem. Soc.*, **1965**, 4621.

thereby almost disappeared. When the reaction mixture was shaken in air, its fluorescence became blue. The paper chromatography of this solution showed the presence of three fluorescent compounds. The major spot was lumazine-6-carboxylic acid and the intermediate lumazine; this was confirmed by the ultraviolet absorption spectra and the electrophoretic migration (Table I).

The Reaction of 2, 5-Diamino-4-hydroxy-6-methylaminopyrimidine with Glyoxal.—2-Amino-4-hydroxy-6-methylamino-5-nitropyrimidine was prepared from 2-amino-6-chloro-4-hydroxy-5-nitropyrimidine and aqueous methylamine.[10] The product (6.0 g.) was purified by dissolution in 8% aqueous ammonia (100 ml.) (charcoal) and by reprecipitation with hydrochloric acid (6 N).

Found: C, 27.6; H, 3.3; N, 30.6. Calcd. for $C_5H_7N_5O_3 \cdot HCl$: C, 27.3; H, 3.6; N, 31.5%.

The pyrimidine hydrochloride (2 g.) in hot 3% ammonia (5 ml.) was treated with sodium dithionite. The solution was neutralized with acetic acid (pH 6), 8 ml. of glyoxal (40%) was added, and the whole was refluxed for 30 min. under nitrogen. The precipitate was collected by centrifugation and purified by chromatographic methods using a cellulose column (9×50 cm.; developer: isopropanol/1% ammonia=2 : 1) and a Dowex 1X8 column (5×24 cm.; $HCOO^-$; developer: 0.03 M formic acid/ammonia, the pH value being changed continuously from 9.4 to 7.0). The effluent containing the main fluorescent band was acidified with hydrochloric acid (pH 2—3), and the compound was adsorbed on Darco G-60, which was then washed well with water. The pteridine was eluted with 2% ammonium hydroxide-ethanol (3 : 1), the eluate evaporated to dryness in vacuo, and the residue crystallized from water to give a faint yellow product (20 mg.).

Found: C, 43.3; H, 2.3; N, 33.9. Calcd. for $C_6H_4N_4O_2$: C, 43.9; H, 2.5; N, 34.1%.

The product was indistinguishable from synthetic lumazine on the basis of ultraviolet, infrared and mass spectral data and R_f-values.

The Reaction of 2, 5-Diamino-4-hydroxy-6-methylaminopyrimidine with Monochloracetone.—2-Amino-4-hydroxy-6-methylamino-5-nitropyrimidine hydrochloride (2 g.) in hot 16% ammonia (50 ml.) was treated with sodium dithionite (8 g.), and then the solution was adjusted to pH 5 with acetic acid. After the addition of monochloracetone (6.0 ml.) it was refluxed for 1 hr. and concentrated to a small bulk in vacuo. By the use of a Dowex 1X8 column ($HCOO^-$), two main products (A and B) were separated from the reaction mixture.

Product A (24 mg.): colorless needles; m. p. 246—248°C (decomp.).

Found: C, 47.5; H, 3.3; N, 31.2. Calcd. for $C_7H_6N_4O_2$: C, 47.2; H, 3.4; N, 31.5%. λ_{max} mμ ($E^{1\%}_{1cm.}$) 248 (842), 360 (408) in 0.1 N sodium hydroxide and 327 (560) in 0.1 N hydrochloric acid.

Product B (14 mg.): faint yellow needles; m. p. 266—268°C (decomp.).

Found: N, 31.7. Calcd. for $C_7H_6N_4O_2$: N, 31.5%. λ_{max} mμ ($E^{1\%}_{1cm.}$) 256 (995), 368—372 (349) in 0.1 N sodium hydroxide and 232 (724), 333 (480) in 0.1 N hydrochloric acid.

Product A was indistinguishable from authentic 7-methyllumazine, while product B was identical with 6-methyllumazine, as determined by a study of the ultraviolet, infrared and mass spectral data and the R_f values. On oxidation compounds A and B gave lumazine-7-carboxylic acid and lumazine-6-carboxylic acid respectively.

Discussion

The new naturally-occurring compound described above gives ultraviolet spectra similar to those of sepiapterin. The presence of the parent lumazine ring system was demonstrated by reduction with $NaBH_4$ and by the reoxidation of the reduction product. This yielded lumazine. The production of lumazine-6-carboxylic acid by oxidation (potassium permanganate and sodium periodate) showed that there was a substituent on the 6-position, while its nature was demonstrated by the fact that the pteridine, on air oxidation in a borax solution, yielded 6-hydroxylumazine and lactic acid. From these findings, it may be concluded that the compound is a 6-lactyllumazine. No direct evidence for the presence of the reduced ring system was obtained; however, the similarity of the chemical properties and ultraviolet spectra (in basic, acidic and neutral media) to those of sepiapterin strongly suggests that it is 7, 8-dihydro-6-lactyllumazine. The 7, 8-dihydro structure of sepiapterin was proved by its nuclear magnetic resonance spectrum*.

In 1962 Kaufman[11] reported that sepiapterin functions as a cofactor in the enzymatic transformation of phenylalanine to tyrosine (the activity is 25 times that of folic acid). The activity of the compound (xanthopterin-B_2) as the cofactor was, however, only one-fourth that of sepiapterin.**

The question then arises as to the origin of this compound. A possible explanation is that it is produced enzymatically from reduced lumazine in exactly the same way that sepiapterin or isosepiapterin can be synthesized from reduced 2-amino-4-hydroxypteridine and an active C_3-compound.[12,13] Current theory supposes that the pteridine ring arises from guanosine or guanosine-5'-phosphate. The first step of the reaction involves the opening of the imidazole ring of the guanine moiety and the elimination of the carbon-8 of the purine.[14] The resulting 2, 5-diamino-4-hydroxy-6-D-ribofuranosylaminopyrimidine could then undergo transformation to lumazine in the presence of a two-carbon unit in just the same way

as lumazine can be synthesized from 2, 5-diamino-4-hydroxy-6-methylaminopyrimidine and glyoxal in vitro. Attempts to obtain 6-lactyl-7, 8-dihydrolumazine from reduced lumazine and α-keto-β-hydroxybutyric acid in the presence of thiamine, were, however, fruitless. An alternative pathway, in which xanthopterin-B_2 is derived enzymatically from xanthopterin-B_1, is more probable. The presence of sepiapterin-deaminase in *B. mori lem* was actually demonstrated by one of us (M. T.). This finding will be reported on elsewhere.

In a preliminary communication,[6] we reported that the oxidation product of the compound (xanthopterin-B_2) (potassium permanganate and potassium poriodate) is indistinguishable from the synthetic "2-amino-4-hydroxy-8-methyl 4, 8-dihydropteridine-6-carboxylic acid" obtained by the condensation of 2, 5-diamino-4-hydroxy-6-methylamino-pyrimidine with β-bromopyruvic acid, and that a reduction product ($NaBH_4$) is identical with the "2-amino-4-oxo-8-methyl 4, 8-dihydropteridine" prepared by the condensation of the pyrimidine with glyoxal.[15] From these observations and its behavior upon air-oxidation in a borax solution, the N_8-methylsepiapterin structure was tentatively postulated. However, the present investigation has proved that the condensation of 2, 5-diamino-4-hydroxy-6-methylaminopyrimidine with β-bromopyruvic acid or glyoxal under the conditions described here does not give the desiredp roducts, but, that unexpectedly, lumazine-6-carboxylic acid or lumazine is formed. In the same way, the condensation of the pyrimidine with monochloracetone yields 6-methyllumazine and its 7-isomer. Previously, we were not aware of this unusual reaction; this led to an incorrect formulation of xanthopterin-B_2. We now wish to present the structure II for this compound.

The Chemiluminescence of Acyl Luminols

By Yoshimori OMOTE, Takeo MIYAKE, Seiya OHMORI and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received September 11, 1965)

From a study of the chemiluminescence spectra of acyl luminols (e. g., 3-acetylaminophthalhydrazide, 3-propanoylaminophthalhydrazide and 3-undecenoylaminophthalhydrazide) and of the corresponding fluorescence spectra of the reaction products, it is tentatively assumed that the emitting species of the chemiluminescence of acyl luminols in dimethylformamide-water (3 : 1 in vol.) is the corresponding 3-acylaminophthalate ion in the excited state.

Since Albrecht[1] first described the bright chemiluminescence of luminol (3-aminophthalhydrazide) (I), the synthetic approach to a clarification of the mechanism of the chemiluminescence had been attempted by several groups of workers.[2] Recently White et al.[3] showed that the 3-aminophthalate ion might be the light emitting species in the chemiluminescent reaction of luminol in water or in dimethylsulfoxide.

As a part of the investigation of the synthesis of chemiluminescent polymers,[4] the present authors have studied the synthesis and chemiluminescence of acyl luminols. The object of this paper is to present a convenient modified method for the acylation of luminol and to describe the relation between the chemiluminescence spectra of acylated luminols and the corresponding fluorescence spectra of the chemiluminescent reaction products.

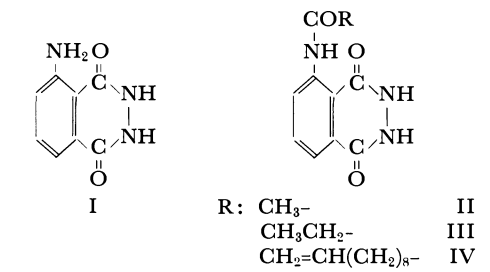
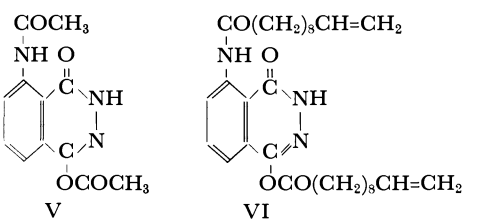
Results and Discussion

The Acylation of Luminol.—It has been found in this laboratory that dimethylformamide is a suitable solvent for the acylation of luminol, which is sparingly soluble in most organic solvents. Monoacyl derivatives of luminol were prepared by the action of several acyl chlorides on luminol dissolved in dimethylformamide in the presence of pyridine.

The ultraviolet absorption spectra of luminol and its three acyl derivatives, 3-acetylaminophthalhydrazide (II), 3-propanoylaminophthalhydrazide (III) and 3-undecenoylaminophthalhydrazide (IV), are shown in Fig. 1. The absorption maximum about 330 nm* was useful for the identification of the acyl derivatives.





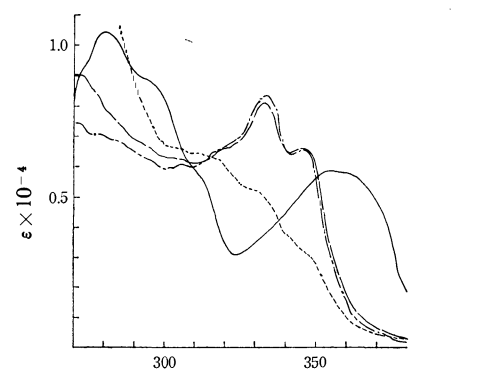


Fig. 1. Ultraviolet absorption spectra of luminol and acyl luminols.

* Following the IUPAC rule, the new notation nm (nanometer) is used instead of mμ.

When luminol was treated with an excess of several acyl chlorides, diacyl derivatives of luminol were obtained. Those were tentatively deduced to be V and VI from their infrared absorption spectra, which have the strong absorption at 1760 cm^{-1} characteristic of the carbonyl group of the enol ester type.

The Chemiluminescence Spectra of Luminol and Acyl Luminols.—The color of the chemiluminescence of luminol was bright blue, with a spectral maximum at 470 nm, while acyl derivatives showed a greenish blue chemiluminescence, with a maximum at about 480 nm. The chemiluminescent spectra spread over a broad region between about 400 nm and 600 nm.

Concn.: 7.5×10^{-4} mol. in DMF-water mixture (vol. 3 : 1) respectively.

Figure 2 shows the change in chemiluminescence intensity with time. The chemiluminescence intensity strikingly decreases with the acylation of the amino group of luminol. This suggests that both the inductive and steric effects of the acylamino group serve to decrease the chemiluminescence of luminol, as has been reported by earlier investigators.[5] The spectra of the chemiluminescence of acyl luminols show the emission maximum at a little longer wavelength than luminol, as is shown in Table I. This fact is likely to show that the energy difference between the emitting species and the emission products of acyl derivatives is smaller than that of luminol. Moreover, a comparison of the wavelengths and intensities at the maximum of emission spectra of

II, III and IV shows that the acylamino group with a longer alkyl chain is more unfavorable to the emission than that with a shorter one (Table I and Fig. 2).

The Relation of Chemiluminescence and Fluorescence.—The fluorescence spectra in various conditions are useful in deciding the emitting species in the chemiluminescent reaction.[6] First, the authors have examined the fluorescence spectra of luminol and its acyl derivatives in dimethylformamide or in the mixed solvent of dimethylformamide and water (3 : 1 in vol.). The results are summarized in Table I. During the measurement of the fluorescence spectrum of luminol, it was found that the intensity at the maximum of 410 nm decreased with the increase in the intensity at the new maximum, 470 nm, as is shown in Fig. 3. The spectral change seemed to be accelerated by adding water. Also, acyl luminols showed a similar phenomenon, which is likely to be related to the photochemical reaction with oxygen in the solvent.[6d] A more precise experiment investigating this phenomenon is now in progress.

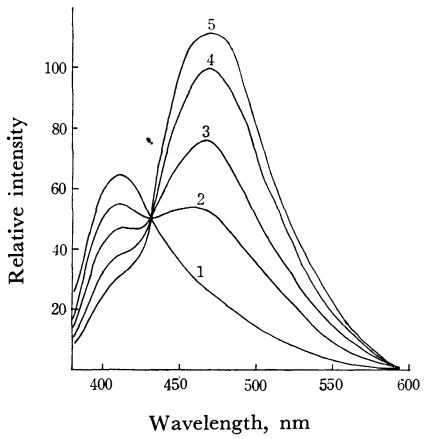

Fig. 3. The change of fluorescence spectrum of luminol in dimethylformamide with time 1—5, 5 min. interval.

Next, the fluorescence spectrum of the total reaction product of the chemiluminescent reaction of each compound was measured after chemiluminescence. The results are summarized in Table I, while the typical chemiluminescence spectra of I and II are shown in Figs. 4 and 5 respectively.

White et al.[3] reported, that in the chemiluminescence of luminol in dimethylsulfoxide and also in water, a good match had been found in the wavelength distribution in chemiluminescence, the

6) In addition to luminol (cf. Ref. 3), other chemiluminescent compounds, such as lucigenin (a), lophine (b, c, d) and 7-dialkylamino-naphthalin-1, 2-dicarboxylic acid hydrazide (e) have been recently treated by the similar approach. a) F. McCapra and D. G. Richardson, *Tetrahedron Letter*, **1964**, 3167. b) J. Sonnenberg and D. M. White, *J. Am. Chem. Soc.*, **86**, 5686 (1964). c) E. H. White and M. J. C. fluorescence of the total reaction product, and the fluorescence of sodium aminophthalate. The present observation of luminol in a dimethylformamide-water mixture (3 : 1 in vol.), shown in Fig. 4, led to the same conclusion as that of White et al.,[3] who concluded that the 3-aminophthalate ion is the light-emitting species.

In the case of acyl luminols a rough coincidence between the maximum of the chemiluminescence spectrum and the fluorescence maximum after chemiluminescence was observed (Table I). Considering that the wavelength distribution of the chemiluminescence spectrum is similar to that of the corresponding fluorescence spectrum after chemiluminescence, the authors tentatively assume that 3-acylaminophthalate ion in the excited state is mainly the light emitting species of the chemiluminescent reaction of 3-acylaminophthalhydrazide.

Experimental*

3-Acetylaminophthalhydrazide (II).—To the solution of luminol (0.9 g.) in dimethylformamide (20 ml.), pyridine (0.4 ml.) was added; then acetyl chloride (0.4 ml.) in dimethylformamide (1 ml.) was slowly stirred in under cooling. After the reaction mixture had been allowed to stand overnight, water was carefully poured into the mixture. The fine crystals which formed were collected, washed with water, and recrystallized from dimethylformamide and water successively to give faint yellow needle crystals, m. p. 315°C. The authentic sample, which was synthesized from 3-acetylaminophthalic anhydride and hydrazine, showed a m. p. of 320°C (decomp.).[2a]

Found: C, 54.38; H, 4.32; N, 19.20. Calcd. for $C_{10}H_9O_3N_3$: C, 54.79; H, 4.14; N, 19.17%.

UV: λ_{max}^{DMF} 333 nm (ε=8400), IR: ν^{KBr} 3420, 1530 cm^{-1} (-NH).

3-Acetylamino-*O*-acetylphthalhydrazide (V). — When the treatment as described in the preparation of II was carried out with an excess of acetyl chloride (4 ml.), 3-acetylamino-*O*-acetylphthalhydrazide was obtained. The compound was soluble in dimethylformamide to a much smaller extent than luminol, and was reprecipitated from dimethylformamide and water as light yellow crystals, m. p. 251°C (decomp.).

Found: C, 54.75; H, 4.22; N, 16.16. Calcd. for $C_{12}H_{11}O_4N_3$: C, 55.17; H, 4.21; N, 16.09%.

UV: λ_{max}^{DMF} 332 nm (ε=9600), IR: ν^{KBr} 3420, 1760, 1530 cm^{-1}.

3-Propanoylaminophthalhydrazide (III).—Luminol (0.9 g.) in dimethylformamide (20 ml.), pyridine (0.4 ml.), and propanoyl chloride (0.5 ml.) were treated as in the case of II. The product formed was then reprecipitated from dimethylformamide and water as a pale yellow powder, m. p. 278°C (decomp.).

Found: C, 56.18; H, 4.74; N, 18.21. Calcd. for $C_{11}H_{11}O_3N_3$: C, 56.55; H, 4.75; N, 18.02%.

UV: λ_{max}^{DMF} 333 nm (ε=8200), IR: ν^{KBr} 3420, 1530 cm^{-1}.

3-Undecenoylaminophthalhydrazide (IV). — Luminol (0.9 g.) and undecenoyl chloride (0.6 ml., prepared from undecenoic acid and thionyl chloride) brought to reaction according to the procedure used in the preparation of II. A light yellow powder resulted, m. p. 275°C.

Found: C, 66.73; H, 7.13; N, 12.22. Calcd. for $C_{19}H_{25}O_3N_3$: C, 66.45; H, 7.34; N, 12.24%.

UV: λ_{max}^{DMF} 300 nm (ε=6700, shoulder), IR: ν^{KBr} 3420, 2925, 2850, 1530 cm^{-1}.

3-Undecenoylamino-*O*-undecenoylphthalhydrazide (VI).—The procedure used in the preparation of IV but with an excess of undecenoyl chloride (about 6 ml.) gave a diundecenoyl derivative as a faint yellow powder, m. p. 142°C.

Found: C, 70.56; H, 8.22; N, 8.30. Calcd. for $C_{30}H_{43}O_4N_3$: C, 70.69; H, 8.50; N, 8.25%.

UV: λ_{max}^{DMF} 329 nm (ε=8300), IR: ν^{KBr} 3420, 2950, 2850, 1760, 1540 cm^{-1}.

The Chemiluminescence Spectra.—The chemiluminescence spectra of luminol and its acyl derivatives in the dimethylformamide-water system were measured with an Hitachi recording spectrophotometer, EPS-2 type. The procedure for the measurement of the chemiluminescence spectrum was as follows: To a 10^{-3} mole. solution of luminol or acyl luminols in dimethylformamide (3 ml.), 1 ml. of a 1 *N* sodium hydroxide solution containing potassium ferricyanide (10^{-2} mole./l.) was added. The final concentrations of the components in the chemiluminescent system were: luminol or acyl luminols, 7.5×10^{-4} mol., the hydroxide ion, 2.5×10^{-1} mol., and the ferricyanide ion, 2.5×10^{-3} mol./l. The mixture gave a brilliant chemiluminescence. The decrease in the chemiluminescence of luminol and acyl luminol with time was measured in a dimethylformamide-water mixture (3 : 1 in vol.), at the maximum of the chemiluminescence spectrum at 38—40°C.

The Fluorescence Spectra.—The fluorescence spectra were measured at 30°C with a spectrophotometer equipped with an attachment for measuring the fluorescence spectrum. The 365 nm line of a high-pressure mercury lamp was used for excitation, and the spectra were measured at concentrations of 10^{-5}—10^{-4} mol./l.

* All melting points are uncorrected.

The Dipole Moment and Polarizability in the n-π^* Excited State of Acetone from Spectral Solvent Shifts

By Takehiro ABE

College of General Education, Tohoku University, Kawauchi, Sendai

(Received September 11, 1965)

This paper has presented the expression for the frequency shift, including the solvent refractive index and the dielectric constant; the expression has been determined on the basis of a previous paper (This Bulletin, **38**, 1314 (1965)). According to the present theory and E. G. McRae's theory (*J. Phys. Chem.*, **61**, 562 (1957)), the excited state dipole moment of acetone has been estimated to be 0.86 and 1.84 *D* respectively, both being smaller than the ground state value. The results calculated by the present theory show that the excited state polarizability is 163.1×10^{-25} cm^3 and that the solvation energies in the solvents of *n*-heptane, cyclohexane, carbon tetrachloride, ethyl ether, and methyl acetate are less in the ground states than in the excited states.

McMurry[1] has identified the 280 mμ band of acetone as a forbidden n-π^* transition involving the excitation of a non-bonding electron of the oxygen atom to an anti-bonding π-orbital between the carbon and oxygen atoms of the carbonyl group. The band shifts to the blue in polar solvents compared with the case in non-polar solvents.[2,3] Bayliss and McRae[3,4] have stated that the transfer of the electronic charge away from the oxygen will cause the permanent dipole moment to be decreased in the excited state, since the acetone molecule has a dipole with the negative end directed toward the oxygen.

In the present paper, an attempt has been made to estimate the dipole moment and isotropic polarizability in the n-π^* excited state of acetone by the applications of McRae's expression[5] and of a new expression, which has derived by the same procedure as in the previous paper,[6] to the frequency shifts of the n-π^* transition of acetone.

Theoretical

On the assumption that there are no strong dipole orientation strains among the spherical solute and the spherical solvent molecules, one may obtain the expression for the frequency shift of an absorption spectrum in a very dilute solution by the same procedure as was used in a previous paper[6] as follows: Considering an unperturbed solute molecule and the solvent molecules already interacting with one another in the zeroth order approximation, one may write the solvation energy in erg in the ith excited state of the solute as:

$$E'_i = -2.378\times10^{25}\times\left(\frac{M^v}{d^v}\right)^{1/3}\times\left[\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+3\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+5\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}\right]$$
$$\times\left[\frac{2}{3}\cdot\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}\cdot(\mu_i^u)^2+1.380\times10^{-16}(\mathrm{erg\cdot deg^{-1}})\times T\times\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}\cdot(\alpha_i^u)+\frac{1}{3}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot(\mu_i^u)^2+\frac{1}{2}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot\frac{I_i^u\times I_0^v}{I_i^u+I_0^v}\cdot(\alpha_i^u)\right] \quad (1)$$

where M is the molecular weight; d, the liquid density; ε, the dielectric constant; n, the refractive index; I, the ionization potential; T, the absolute temperature; μ, the permanent dipole moment, and α, the isotropic polarizability. Throughout this paper the notations u and v will refer to the solute and the solvent respectively. Here E'_i is taken as negative if the ith excited state energy of the solute is decreased in solution. The solvation energy for the ground state of the solute is obtained by replacing i by 0 in Eq. 1. It is obvious from Fig. 1 that the frequency shift $\Delta\nu_{i0}=\nu_{i0}(\mathrm{soln})-\nu^0_{i0}$ (gas) is given by $\Delta\nu_{i0}=E'_i-E'_0$, as is found by Bayliss and McRae.[3] The frequency shift in cm^{-1} is given by:

$$\Delta\nu_{i0} = -1.198\times10^{41}(\mathrm{erg^{-1}cm^{-1}})\times\left(\frac{M^v}{d^v}\right)^{1/3}\times\left[\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}\right.$$

$$+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+3\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}$$
$$+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+5\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}\Bigg]$$
$$\times\Bigg[\frac{2}{3}\cdot\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}\cdot\{(\mu_i^u)^2-(\mu_0^u)^2\}+\boldsymbol{k}T$$
$$\times\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}\cdot\{(\alpha_i^u)-(\alpha_0^u)\}$$
$$+\frac{1}{3}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot\{(\mu_i^u)^2-(\mu_0^u)^2\}$$
$$+\frac{1}{2}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot I_0^v\cdot\left\{\frac{I_0^u-\boldsymbol{hc}\nu_{i0}^0}{I_0^v+I_0^u-\boldsymbol{hc}\nu_{i0}^0}\cdot(\alpha_i^u)-\frac{I_0^u}{I_0^v+I_0^u}\cdot(\alpha_0^u)\right\}\Bigg] \quad (2)$$

where $\boldsymbol{h}$ is the Planck constant; $\boldsymbol{c}$, the velocity of light, and $\boldsymbol{k}$, the Boltzmann constant. For a non-polar solvent the first and second terms in the second square brackets in Eq. 2 are zero. Equation 2 can be further written in the following form:

$$\{(\mu_i^u)^2-(\mu_0^u)^2\}+(\alpha_i^u)\cdot A=B \quad (3)$$

where

$$A=3\times\left[\frac{2\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}+\frac{(n^v)^2-1}{(n^v)^2+2}\right]^{-1}$$
$$\times\left[\boldsymbol{k}T\cdot\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}+\frac{1}{2}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot\frac{I_0^v(I_0^u-\boldsymbol{hc}\nu_{i0}^0)}{I_0^v+I_0^u-\boldsymbol{hc}\nu_{i0}^0}\right]$$

and

$$B=3\times\left[\frac{2\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}+\frac{(n^v)^2-1}{(n^v)^2+2}\right]^{-1}$$
$$\times\left[\boldsymbol{k}T\cdot\frac{\{\varepsilon^v-(n^v)^2\}\{2\varepsilon^v+(n^v)^2\}}{\varepsilon^v\{(n^v)^2+2\}^2}+\frac{1}{2}\cdot\frac{(n^v)^2-1}{(n^v)^2+2}\cdot\frac{I_0^v\times I_0^u}{I_0^v+I_0^u}\right]\cdot(\alpha_0^u)$$
$$-8.351\times10^{-42}(\text{erg}\cdot\text{cm.})\times\left(\frac{d^v}{M^v}\right)^{1/3}\times\Delta\nu_{i0}$$
$$\times\left(\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+3\left(\frac{M^v}{d^v}\right)^{1/3}\right\}^{-4}+\left\{\left(\frac{M^u}{d^u}\right)^{1/3}+5\left(\frac{M^u}{d^u}\right)^{1/3}\right\}^{-4}\right)^{-1}\Bigg]$$

The values of A and B can be calculated from the observed values, so the plot of B against A should be linear; the slope of the straight line will be equal to α_i^u, and the intersection of the line at $A=0$ will be equal to $\{(\mu_i^u)^2-(\mu_0^u)^2\}$.

The general expression derived by McRae is written in the approximate form:[5]

$$\Delta\nu_{i0}=(aL_0+b)\cdot\frac{(n^v)^2-1}{2(n^v)^2+1}+c\left[\frac{\varepsilon^v-1}{\varepsilon^v+2}-\frac{(n^v)^2-1}{(n^v)^2+2}\right] \quad (4)$$

where a, b and c are constants characteristic of the solute molecule. Assuming that Onsager's reaction radius is equal to $(3M^u/4\pi\boldsymbol{A}_0d^u)^{1/3}$, where $\boldsymbol{A}_0$ is the Avogadro number, one may have:

$$c=2.541\times10^{40}(\text{erg}^{-1}\text{cm}^{-1})\times(d^u/M^u)\cdot\mu_0^u(\mu_0^u-\mu_i^u) \quad (5)$$

Therefore, one can obtain the value of μ_i^u from Eq. 5 by the same procedure that Robertson, King and Weigang have used for azulene.[7] By taking L_0 to be approximately a constant characteristic of the solute molecule, they first found the value of (aL_0+b) from the plot of $\Delta\mu_{i0}$ against $\{(n^v)^2-1\}/\{2(n^v)^2+1\}$ in the case of non-polar solvents, because the second term in Eq. 4 is zero in this case. Then, in the case of polar solvents they found the value of c that best reproduced the observed value of $\Delta\nu_{i0}$.

In Eqs. 2 and 4, the important effect of hydrogen bonding found by Nagakura and Baba[8] has not been considered.

Results and Discussion

The n-π^* transition bands of acetone in several solvents and the other data to be used are listed in Table I. The observed value of α_0^u for acetone is 63.3×10^{-25} cm^3.[9]

Assuming that the temperature is 20°C, the author has applied Eq. 3 to acetone. The plot of B against A is shown in Fig. 2. It may be

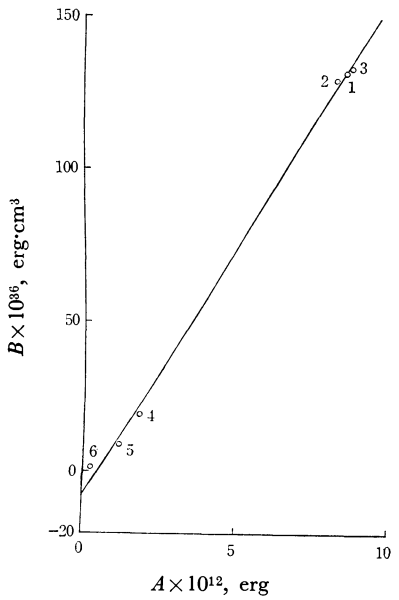

Fig. 2. The plot of B against A.

seen in Fig. 2 that all the points except for the point 6 fall close to the straight line. It may be expected that there are strong orientation strains between the acetone and the acetonitrile molecules, because acetonitrile has the large dipole moment of 3.94 D. Equations 1—3 are limited for use in solutions in which no strong dipole orientation strains occur between solutes and solvent molecules. Equation 3, therefore, will not hold sufficiently for the case of acetonitrile. On account of the strain, the point 6 is likely to deviate from the line. From the intersection of the line in Fig. 2 the value of $\{(\mu_i^u)^2-(\mu_0^u)^2\}$ is estimated to be -7.3267×10^{-36} erg·cm^3. Accordingly, the dipole moment in the excited state due to the n-π^* transition is estimated to be 0.86 D, because the observed value of μ_0^u is 2.84 D. From the slope of the line the excited state polarizability is estimated to be 163.1×10^{-25} cm^3.

By applying Eq. 4 in the way mentioned above, the author has obtained the values of -2156 and 983 cm^{-1} for (aL_0+b) and c respectively. From Eq. 5, then, the excited-state dipole moment is obtained as 1.84 D. The frequency shifts calculated are compared with the observed shifts in Fig. 3.

The excited state dipole moment of 0.86 D obtained by Abe's method is considerably smaller than that obtained by McRae's method. This seems to be due to the inclusion of the ground

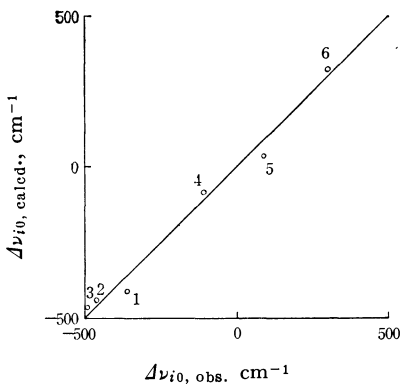

Fig. 3. Calculated vs. observed frequency shifts in n-π^* band of acetone (McRae's method)

and excited state polarizabilities in the Abe expressions, while the polarizabilities have not been considered explicitly in McRae's expression. The excited state polarizability plays an important role in the frequency shift, because the polarizability is much larger than that for the ground state.

According to the above two methods, the n-π^*

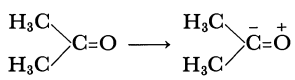
excited-state dipole moment of acetone is considerably smaller than that for the ground state. On the basis of McRae's theory, Ito, Inuzuka and Imanishi[13] have also mentioned that the excited-state dipole moments of ketones are much smaller than their ground-state values. In the ground state of acetone the π electronic charges are distributed more at the oxygen atom than at the carbon in the carboxyl group, because the absolute value of the Coulomb integral for the oxygen atom is larger than that for the carbon atom. The n–π^* transition in acetone transfers a non-bonding electron of the oxygen atom to a π^* orbital distributed over C=O,[3] especially at the carbon atom. The transition is probably represented by:



Consequently, the dipole moment is considerably decreased in the excited state, since the ground-state dipole has the negative end directed toward the oxygen atom.
