The x, y, z, components of the charge density and the bond order matrix (Eq. 9) can be represented in terms of electron densities, q_r, as follows if we take x, y and z axes to be as shown in Fig. 1:

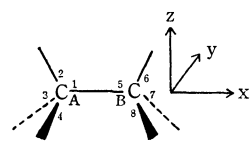

Fig 1.

$$P_{xx} = (3/4)q_1 + (1/12)(q_2 + q_3 + q_4)$$
$$P_{yy} = (1/6)(q_2 + q_4) + (2/3)q_3$$
$$P_{zz} = (1/2)(q_2 + q_4)$$
$$(P_{yy})_{AB} = 2\sum_i^{occ}[-1/\sqrt{6}\,(C_{i2} + C_{i3}) + \sqrt{2/3}C_{i4}]$$
$$\times[-1/\sqrt{6}\,(C_{i6} + C_{i7}) + \sqrt{2/3}C_{i8}]$$

The calculated values of P_1, P_2, P_3, $\langle r^{-3}\rangle_{2p}$ and σ_p, together with the observed[3] δ ^{13}C and calculated $\delta^{13}C$ values, are summarized in Table I for several compounds.

When we take ΔE as 10 eV. for Eq. 8, we have:

$$\sigma_p = (44.8Q_{2p\sigma} - 138.1)(P_1 - P_2 - P_3) \quad (11)$$

where $Q_{2p\sigma}$ designates $(P_1 - 3)$. The values of $(P_1 - P_2 - P_3)$ is almost constnat $(P_1 - P_2 - P_3 = 1.498)$. Therefore, if we take $(P_1 - P_2 - P_3)$ as 1.498 for Eq. 11, the total shielding constant, $\sigma(= \sigma'_d + \sigma_p)$, due to the valence electrons of the carbon atom A in a saturated hydrocarbon is, from Eq. 7 and Eq. 11:

$$\sigma = 87.8Q_{2p\sigma} - 1.6Q_{2p\sigma}{}^2 - 207.2 \text{ (p.p.m.)} \quad (12)$$

In order to test the validity of Eq. 12, which was derived theoretically, we plot in Fig. 3 the observed carbon-13 chemical shift against the excess charge density of 2p electrons for several compounds. We thus find an approximate proportionality between $Q_{2p\sigma}$ and $\delta^{13}C$.

Discussion

Theoretical considerations predict the same simple linear relationship between the excess charge density and the carbon-13 chemical shifts for saturated hydrocarbons as has been exhibited in the aromatic compounds. However, Fig. 3 shows a fairly large scattering.

This is mainly due to the failure of the theoretical interpretation of the anomalous β-effect suggested by Paul and Grant,[4] which gives an unexpectedly large down-field contribution than the α-effect. The β-effect may be interpreted in terms of the change in the mean excitation energy, ΔE, or the change of the effective nuclear charge, Z^*, due to the influence of the β-methyl group on the radial part of the 2p atomic orbital.[8] In

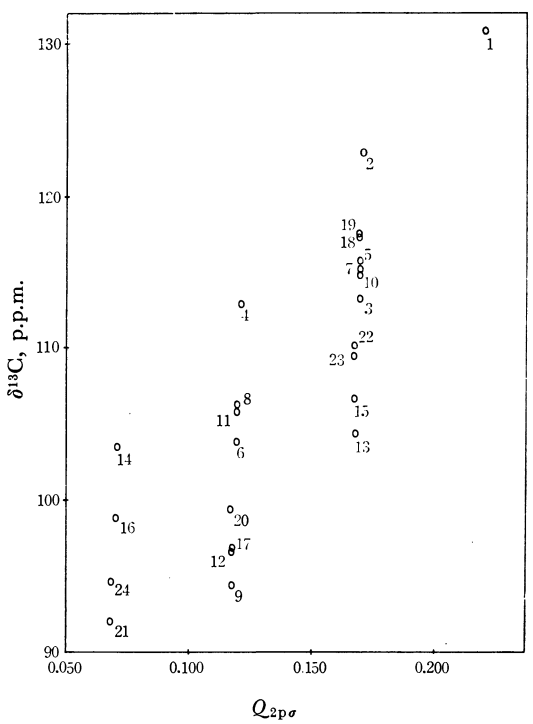

Fig. 3. A plot of the excess charge density of 2P electron ($Q_{2p\sigma}$) versus observed ^{13}C chemical shift ($\delta^{13}C$). The values of $Q_{2p\sigma}$ are summarized in Fig. 2 and the values of ^{13}C chemical shift ($\delta^{13}C$) are given in p.p.m. from CS_2 (Ref. 4).

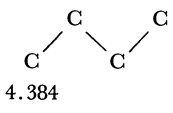
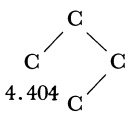
8) This was suggested by D. M. Grant at the International Symposium on NMR, Tokyo (1965).

fact, the diminution of ΔE may be expected in a branched alkane with reference to the value of the ionization potential.[9] The increase in Z^* and the decrease in ΔE may be considered to cause the paramagnetic shift. Another anomalous γ-effect which makes a positive contribution to the carbon-13 chemical shifts can be partly interpreted in terms the electronic effects. The γ-carbon relative to the carbon atom can occupy both a gauche and a trans position relative to the carbon atom under study. For example, consider a trans butane (I) and a gauche butane (II):



trans
(I)



gauche
(II)

We calculated the atom population of the terminal carbon atom by an extended Hückel molecular orbital theory,[10] which is useful in discussing the conformational change of the electronic sturcture by taking account of the resonance integral between non-bonded atoms. The terminal carbon for the gauche form with a larger charge density is more shielded than that for the trans form. Using Eq. 12 this effect was evaluated to be about 1.5 p. p. m. Hence the contribution of the gauche form causes a diamagnetic shift to the terminal carbon of normal butane. Recently, Grant presented[8] a theoretical interpretation of this effect by the valence bond method and also showed experimentally that *trans*-1, 4-carbon-carbon interactions should have a negative effect, while *cis*-1, 4-carbon-carbon interactions has a positive effect. Table I and Fig. 3 also show that the calculated values of $\delta^{13}C$ are fairly small, this may be attributed to a small difference in the calculated excess charge densities. This difficulty may be overcome by the improvement of the parametrization of the coulomb and resonance integrals. However, it may be stressed that the general trends of the carbon-13 chemical shifts of saturated compounds, with the exception of a large βth carbon effect, can be qualitatively interpreted by simple molecular orbital calculations. Our treatment is also applicable to other saturated systems, haloalkanes, for example, but the anomalous upfield tendency of the ^{13}C chemical shifts of the multisubstituted bromo and iodo methane cannot be interpreted by the electronic effect only.

The calculations were carried out partly on the digital compouter KDC-I of Kyoto University and partly on the IBM 7090 at the Japan IBM CO. with the permission of the UNICON Committee, whose help we hereby acknowledge.

9) The ionization potential (Ip) might be a measure of the mean excitation energy, ΔE. The Ip values of ethane, propane, *n*-butane and isobutane are 11.76, 11.21, 10.86 and 10.40 eV. respectively.

A Thermodynamic Approach to Thixotropy

By Manabu SENŌ

The Institute of Industrial Science, The University of Tokyo, Azabu, Tokyo

(Received October 29, 1965)

The thixotropic behavior is discussed on the basis of the thermodynamics of irreversible processes. The fundamental equations are given for the thixotropic fluids by accepting the concept that the internal structure of the system is destroyed by the applied forces, and the general phenomenological equations are written for all the processes occurring in this system. The process by which the thixotropic recovery takes place is non-stationary. A method of specifying this process is proposed by introducing the concept of a fictitious pressure tensor; the data on a rubber latex suspension given by Mooney is analyzed by this method.

The isothermal process by which a system is softened by the disturbance of external forces and is hardened to the original state on settling is called thixotropy. This process is observed under appropriate conditions in the mechanical behavior of bodies showing the so-called structural viscosity. The thixotropy and the structural viscosity have been treated by many researchers since Freundlich[1]; it has been revealed that they are caused as a result of the breakdown and recovery of the internal structure of the system.

1) H. Freundlich and H. L. Löder, *Trans. Faraday Soc.*, **34**, 308 (1938).

In special cases, such as a suspension of rod-like particles, a detailed mechanism has been proposed for the behavior of anomalous viscosity under advanced treatment.[2] However, no general theoretical work is yet available, probably because the varieties and complexity are involved in terms of the internal structure.

Recently, a fundamental approach to the rheological behavior has been undertaken by Meixner[3] and by Kluitenberg[4] on the basis of the thermodynamics of irreversible processes. This treatment is phenomenological; for this reason, it is excellent, for it does not require detailed information on the internal structure. The latter author considered the thixotropic behavior to be a higher-order effect, introducing an internal degree of freedom, in his general theory of rheological processes. The purpose of this paper is to extend this approach and to interpret the thixotropy in terms of the general principles of thermodynamics.

General Equations of Thixotropic Fluids.— The viscous processes of isotropic fluids are described, on the basis of the thermodynamics of irreversible processes,[6] as follows. The Gibbs' equation reads;

$$T\frac{ds}{dt}=\frac{du}{dt}+v\sum_{\alpha,\beta=1}^{3}P_{\alpha\beta}^{eq}\frac{d\varepsilon_{\alpha\beta}}{dt} \tag{1}$$

where s is the specific entropy; u, the specific internal energy; v, the specific volume; T, the absolute temperature; t, the time; $P_{\alpha\beta}^{eq}$, the equilibrium stress tensor, and $\varepsilon_{\alpha\beta}$, the total strain tensor. This is the equation that is applied to the Voigt model, i. e., the bodies having a parallel viscoelasticity; the fluid is one of special cases, as Kluitenberg has pointed out.[4]

It is assumed that the total pressure causes both the flow of the fluids and the destruction of the internal structure; that is,

$$P_{\alpha\beta}=P_{\alpha\beta}^{def}+P_{\alpha\beta}^{des} \tag{2}$$

Then, the balance equation for the total energy reads;

$$\rho\frac{du}{dt}= -\mathrm{div}\boldsymbol{J}^{q}-\sum_{\alpha,\beta=1}^{3}P_{\alpha\beta}^{def}\frac{d\varepsilon_{\alpha\beta}}{dt}-\sum_{\alpha,\beta=1}^{3}P_{\alpha\beta}^{des}\frac{d\xi}{dt} \tag{3}$$

where ρ is the density (the reciprocal of the specific volume); $\boldsymbol{J}^{q}$, the heat flow, and ξ, the degree of internal structure (a measure of the internal structure). The last term on the right-hand side of the equation represents the change in the internal structure of the fluid caused by the forces; it may be omitted in the case of the simple fluid with no structural viscosity, as Kluitenberg did.

The stress tensor for deformation, $P_{\alpha\beta}^{def}$, is divided into two parts, the equilibrium stress tensor and the viscous stress tensor,

$$P_{\alpha\beta}^{def}=P_{\alpha\beta}^{eq}+P_{\alpha\beta}^{v} \tag{4}$$

The equation for the entropy balance is derived from Eqs. 1, 3 and 4 as follows:

$$\rho\frac{ds}{dt}=-\mathrm{div}J^{s}+\sigma^{s} \tag{5}$$

where:

$$J^{s}=J^{q}/T \tag{6}$$

$$\sigma^{s}=\frac{1}{T}\left(-\frac{J^{q}}{T}\cdot\mathrm{grad}\,T-\sum P_{\alpha\beta}^{v}\frac{d\varepsilon_{\alpha\beta}}{dt}-\sum P_{\alpha\beta}^{des}\frac{d\xi}{dt}\right) \tag{7}$$

The former is the entropy flow, and the latter is the irreversible production of entropy, which consists of three terms, the heat flow, the viscous flow and the rate of the breakdown of the internal structure.

The stress and the strain tensors are divided into a tangential part and a normal part as:

$$P_{\alpha\beta}=\tilde{P}_{\alpha\beta}+P\delta_{\alpha\beta} \tag{8}$$

$$P_{\alpha\beta}^{v}=\tilde{P}_{\alpha\beta}^{v}+P^{v}\delta_{\alpha\beta} \tag{9}$$

$$\varepsilon_{\alpha\beta}=\tilde{\varepsilon}_{\alpha\beta}+\varepsilon\delta_{\alpha\beta} \tag{10}$$

where $\delta_{\alpha\beta}$ is Kronecker's symbol and P, P^{v} and ε are traces of the corresponding tensors. It must be noticed that the tensors, $P_{\alpha\beta}$, $P_{\alpha\beta}^{v}$ and $\varepsilon_{\alpha\beta}$, and also $\tilde{P}_{\alpha\beta}$, $\tilde{P}_{\alpha\beta}^{v}$ and $\tilde{\varepsilon}_{\alpha\beta}$ are all symmetrical. The same division is applied to the stress tensor for destruction. We set the trace of this tensor, P^{des}, as equal to zero. This implies that only the tangential force breaks down the internal structure of the system.

Under these procedures, Eq. 7 is rewritten as:

$$\sigma^{s}=\frac{1}{T}\left(-\frac{J^{q}}{T}\cdot\mathrm{grad}\,T-\sum\tilde{P}_{\alpha\beta}^{v}\frac{d\tilde{\varepsilon}_{\alpha\beta}}{dt}-3P^{v}\frac{d\varepsilon}{dt}-\sum\tilde{P}_{\alpha\beta}^{des}\frac{d\xi}{dt}\right) \tag{11}$$

In this equation, the viscous flow term of Eq. 7 is separated into the shearing viscous and the volumetric viscous term. From this formulation of the entropy production, the following phenomenological equations are derived:

$$J^{q}=-\lambda\,\mathrm{grad}\,T \tag{12}$$

$$\tilde{P}_{\alpha\beta}^{v}=-\eta\,d\tilde{\varepsilon}_{\alpha\beta}/dt \tag{13}$$

2) N. A. Scheraga, *J. Chem. Phys.*, **23**, 1526 (1955).
3) J. Meixner, *Z. Naturforschg.*, **4a**, 594 (1949); **9a**, 654 (1954).
4) G. A. Kluitenberg, *Physica*, **28**, 217, 561, 1173 (1962); **29**, 633 (1963).
5) S. R. de Groot and P. Mazur, "Non-equilibrium Thermodynamics," North-Holland Publ. Co., Amsterdam (1962).

$$P^{v} = -\eta^{v}\mathrm{d}\varepsilon/\mathrm{d}t \tag{14}$$

$$\tilde{P}_{\alpha\beta}^{\mathrm{des}} = -\zeta\,\mathrm{d}\xi/\mathrm{d}t \tag{15}$$

The first is the equation of the heat conduction, and the last, that of the breakdown and recovery of the internal structure.

When the fluid is not elastic on the shearing deformation, the equilibrium pressure tensor does not have non-diagonal components and the trace of this tensor, P^{eq}, is dependent on the volume (therefore, the trace of the total strain tensor, ε) and the temperature. Therefore, the linearized equation is assumed:

$$P^{\mathrm{eq}} = b\varepsilon + c(T-T_0) \tag{16}$$

where b and c are phenomenological constants and T_0 is the reference temperature. Using these relations, the phenomenological equations, 13 and 14, may be rewritten as:

$$\tilde{P}_{\alpha\beta} = -\eta\,\mathrm{d}\tilde{\varepsilon}_{\alpha\beta}/\mathrm{d}t \tag{17}$$

$$P = b\varepsilon - \eta^{v}\frac{\mathrm{d}\varepsilon}{\mathrm{d}t} + c(T-T_0) \tag{18}$$

The equation of entropy production is, by the use of these linearized phenomenological equations:

$$\sigma^{s} = \frac{1}{T}\left\{\frac{\lambda}{T}(\mathrm{grad}\ T)^2 + \eta\sum\left(\frac{\mathrm{d}\tilde{\varepsilon}_{\alpha\beta}}{\mathrm{d}t}\right)^2 + 3\eta^{v}\left(\frac{\mathrm{d}\varepsilon}{\mathrm{d}t}\right)^2 + \zeta\sum\left(\frac{\mathrm{d}\xi}{\mathrm{d}t}\right)^2\right\} \tag{19}$$

The phenomenological coefficients defined in the phenomenological equations are positive, as the second principle of thermodynamics requires. λ is the coefficient of thermal conduction, η is the shearing viscosity, b is the volumetric elasticity and η^{v} is the volumetric viscosity; all are conventional terms. These coefficients depend on the state variables, $\tilde{P}_{\alpha\beta}$, T and ξ.

The structural viscosity and the thixotropy may be understood on the basis of the above formulation. In the first place, the apparent viscosity, η', which is measured experimentally, is defined as:

$$\tilde{P}_{\alpha\beta} = \tilde{P}_{\alpha\beta}^{\mathrm{def}} + \tilde{P}_{\alpha\beta}^{\mathrm{des}} = -\eta'\frac{\mathrm{d}\tilde{\varepsilon}_{\alpha\beta}}{\mathrm{d}t} \tag{20}$$

This quantity is expressed from Eqs. 15, 17 and 20 as:

$$\eta' = \eta + \zeta\left(\frac{\mathrm{d}\xi}{\mathrm{d}t}\right)\Big/\left(\frac{\mathrm{d}\tilde{\varepsilon}_{\alpha\beta}}{\mathrm{d}t}\right) \tag{21}$$

It should be noted that the ordinary viscosity, η, is not dependent on the rate of shear, $\mathrm{d}\tilde{\varepsilon}_{\alpha\beta}/\mathrm{d}t$, but is dependent on T and ξ. These formulations explain most of the viscous behavior of the fluids with internal structures.

When the internal structure is built up by deformation, i. e., $(\mathrm{d}\xi/\mathrm{d}\tilde{\varepsilon}_{\alpha\beta})>0$, the fluid exhibits the non-Newtonian viscosity of shear-rate hardening, i. e., $\eta'>\eta$. On the contrary, when the internal structure is broken down by deformation, i. e., $(\mathrm{d}\xi/\mathrm{d}\tilde{\varepsilon}_{\alpha\beta})<0$, the fluid exhibits the non-Newtonian viscosity of shear-rate softening, i. e., $\eta'<\eta$. When $\tilde{P}_{\alpha\beta}$, therefore $\tilde{\varepsilon}_{\alpha\beta}$, is very high, the internal structure of the fluids is broken down completely; then

$$(\mathrm{d}\xi/\mathrm{d}\tilde{\varepsilon}_{\alpha\beta})\tilde{P}_{\alpha\beta}\to\infty \to 0, \quad \eta'=\eta \tag{22}$$

and the apparent viscosity becomes identical with the ordinary viscosity.

It should be noted that we have been considering the case in which the time-scale of the rate of change in the internal structure is sufficiently small compared to that of observation.

When the rate of change in the internal structure is comparable to or higher than the time-scale of observation, we observe a time-dependent behavior. This is the case when the thixotropic behavior takes place.

The Characterization of Thixotropic Fluids. —The simplest behavior of thixotropy is observed when the internal structure is destroyed instantaneously when force is applied, followed by stationary deformation and recovery, but the recovery of the structure into the stationary state is so slow sufficiently as not to be detected experimentally. This behavior is represented schematically in Fig. 1.

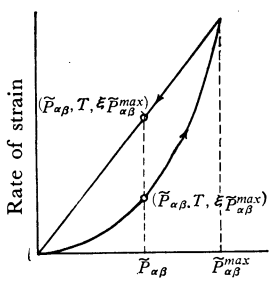

Fig. 1. A schematic plot of a simplest thixotropic behavior.

The up-curve of this figure is in the stationary state. The state variables of this fluid are $\tilde{P}_{\alpha\beta}$, T and ξ, and the following condition is required for the affinity of the change in the internal structure in the stationary thixotropic state from the theorem of minimum entropy production;[6]

$$\frac{\mathrm{d}}{\mathrm{d}t}\tilde{P}_{\alpha\beta}^{\mathrm{des}}(\tilde{P}_{\alpha\beta}, T, \xi) = 0 \tag{23}$$

By this equation the degree of internal freedom, ξ, is determined uniquely by $\tilde{P}_{\alpha\beta}$ and T.

From this consideration, it is clear that the state

6) I. Prigogine, "Introduction to Thermodynamics of Irreversible Processes," 2nd. Ed., Interscience Publishers, New York (1961).

of the up-curve in Fig. 1 is stationary and that it is specified with the two variables of the three state variables, $\tilde{P}_{\alpha\beta}$, T and ξ. On the other hand, the state of the down-curve of Fig. 1 is not stationary. Since Eq. 23 does not hold in a non-stationary state, this state is specified by all three variables. That is, in the above case, the up-curve state is in $(P_{\alpha\beta}, T, \xi_{\tilde{P}_{\alpha\beta}})$ and the down-curve state is in $(\tilde{P}_{\alpha\beta}, T, \xi_{\tilde{P}_{\alpha\beta}^{max}})$, where $\tilde{P}_{\alpha\beta}^{max}$ is the maximum stress applied to the system.

However, no information is available on the degree of internal freedom in general. In order to overcome this difficulties, let us introduce the fictitious pressure tensor, $\tilde{P}_{\alpha\beta}^{f}$; the fictitious pressure tensor is defined as the pressure tensor at which the non-stationary state of interest becomes the corresponding stationary one; i. e.,

$$\frac{d}{dt}\tilde{P}_{\alpha\beta}^{des}(\tilde{P}_{\alpha\beta}^{f}, T, \xi_{\tilde{P}_{\alpha\beta}^{f}}) = 0 \tag{24}$$

By this relation the fictitious pressure is a function of T and ξ, and the non-stationary state is specified by the two variables, $\tilde{P}_{\alpha\beta}$ and $\tilde{P}_{\alpha\beta}^{f}$. In the above case, the fictitious pressure is $\tilde{P}_{\alpha\beta}^{max}$.

The non-stationary state approaches the stationary one with the lapse of time. At the stationary state, only the flow conjugated with the forces fixed externally remains at a constant value; the other flows vanish, resulting their conjugated forces attaining constant values.[6] If the total force is fixed and the stationary viscous flow is established instantaneously, the system is non-stationary, as with the change in the internal structure. The entropy production of this non-stationary irreversible process is expressed as;

$$\sigma_{\xi}^{s} = \tilde{P}_{\alpha\beta}^{des}\frac{d\xi}{dt} \tag{25}$$

When the system is near to the stationary state, the following linear equation is assumed;

$$\tilde{P}_{\alpha\beta}^{des}(\tilde{P}_{\alpha\beta}, T, \xi) = (\xi - \xi^{f})\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \xi}\right)_{P_{\alpha\beta}, T}$$

$$= (\tilde{P}_{\alpha\beta} - \tilde{P}_{\alpha\beta}^{f})\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \tilde{P}_{\alpha\beta}}\right)_{T,\xi} \tag{26}$$

where ξ^{f} is the fictitious degree of internal structure, which is defined by the same consideration as the fictitious pressure tensor. Moreover, the signs of the quantities, $(\partial \tilde{P}_{\alpha\beta}^{des}/\partial\xi)_{\tilde{P}_{\alpha\beta}, T}$ and $(\partial \tilde{P}_{\alpha\beta}^{des}/\partial \tilde{P}_{\alpha\beta})_{T,\xi}$, may be determined by simple consideration as follows:

$$\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \xi}\right)_{\tilde{P}_{\alpha\beta}, T} < 0, \quad \left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \tilde{P}_{\alpha\beta}}\right)_{T,\xi} < 0 \tag{27}$$

From Eqs. 25 and 26;

$$(\tilde{P}_{\alpha\beta} - \tilde{P}_{\alpha\beta}^{f})\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \tilde{P}_{\alpha\beta}}\right)_{T,\xi} = \zeta\left(\frac{d\xi}{dt}\right) \tag{28}$$

and, using the equation of total differential;

$$\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial t} =$$

$$\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \tilde{P}_{\alpha\beta}}\right)_{T,\xi}\frac{d\tilde{P}_{\alpha\beta}^{f}}{dt} + \left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \xi}\right)_{\tilde{P}_{\alpha\beta}, T}\frac{d\xi}{dt} = 0 \tag{29}$$

the equation

$$\frac{d\xi}{dt} = -\left\{\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \tilde{P}_{\alpha\beta}}\right)_{T,\xi}\Big/\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \xi}\right)_{\tilde{P}_{\alpha\beta}, T}\right\}\frac{d\tilde{P}_{\alpha\beta}^{f}}{dt} \tag{30}$$

is derived. Equation 28 then becomes

$$\tilde{P}_{\alpha\beta} - \tilde{P}_{\alpha\beta}^{f} = -\left\{\zeta\Big/\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \xi}\right)_{\tilde{P}_{\alpha\beta}, T}\right\}\frac{d\tilde{P}_{\alpha\beta}^{f}}{dt} \tag{31}$$

By the integration of this equation, the final expression is obtained; that is;

$$\tilde{P}_{\alpha\beta} - \tilde{P}_{\alpha\beta}^{f} = (\tilde{P}_{\alpha\beta} - \tilde{P}_{\alpha\beta}^{fo})\exp(-t/\tau) \tag{32}$$

where the positive coefficient, τ, is defined as;

$$\tau = -\zeta\Big/\left(\frac{\partial \tilde{P}_{\alpha\beta}^{des}}{\partial \xi}\right)_{\tilde{P}_{\alpha\beta}, T} \tag{33}$$

and $\tilde{P}_{\alpha\beta}^{fo}$ is the initial value of the fictitious pressure tensor. As Eq. 32 predicts, the fictitious pressure, $\tilde{P}_{\alpha\beta}^{f}$, approaches the real pressure, $\tilde{P}_{\alpha\beta}$, with the lapse of time. This is a process of the thixotropic recovery.

When the thixotropic recovery takes place and its relaxation time is larger than the time-scale of observation, a complicated behavior is observed, as we see in most of the colloidal suspensions. The above-described treatment can be applied to the interpretation of this behavior. For instance, if the stationary up-curve is obtained with the slow observation and if the measurement at the point A of Fig. 2 is made over the time-interval, Δt, in order to obtain the down-curve, the fictitious pressure changes from the initial value, $\tilde{P}_{\alpha\beta}^{max}$, to:

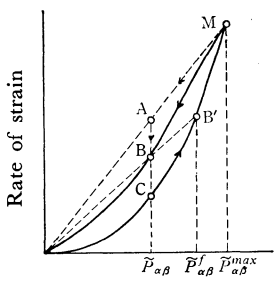

Fig. 2. Analysis of a flow curve of the thixotropic fluid.

$$\tilde{P}^{f}_{\alpha\beta}=\tilde{P}_{\alpha\beta}-(\tilde{P}_{\alpha\beta}-\tilde{P}^{max}_{\alpha\beta})\exp(-\Delta t/\tau) \quad (34)$$

after the lapse of time Δt. Points A, B, B' and C of this figure are specified by:

Point A, $\frac{d}{dt}\tilde{P}^{des}_{\alpha\beta}(\tilde{P}_{\alpha\beta}, T, \xi_{\tilde{P}^{max}_{\alpha\beta}})\neq 0$,

Point B, $\frac{d}{dt}\tilde{P}^{des}_{\alpha\beta}(\tilde{P}_{\alpha\beta}, T, \xi_{\tilde{P}^{f}_{\alpha\beta}})\neq 0$,

Point B', $\frac{d}{dt}\tilde{P}^{des}_{\alpha\beta}(\tilde{P}^{f}_{\alpha\beta}, T, \xi_{\tilde{P}^{f}_{\alpha\beta}})=0$, and

Point C, $\frac{d}{dt}\tilde{P}^{des}_{\alpha\beta}(\tilde{P}_{\alpha\beta}, T, \xi_{\tilde{P}_{\alpha\beta}})=0$

That is to say, Point B, which is measured by the experimental procedure, can be predicted by the fact that Point B' is at the fictitious pressure, $\tilde{P}^{f}_{\alpha\beta}$, on the stationary up-curve and that Point B is at the pressure, $\tilde{P}_{\alpha\beta}$, on the straight line, OB'.

If the recovery of the thixotropic structure is very fast and if the pressure is lower than $\tilde{P}_{\alpha\beta}$ before the measurement at $\tilde{P}_{\alpha\beta}$, the apparent negative thixotropy may be observed. The real negative thixotropy can, however, be observed only when $(\partial\xi/\partial\tilde{P}^{des}_{\alpha\beta})_T>0$. To this case the above treatment can be applied also. More generally, there may happen this behavior in case where the rate process occurs by the procedure of the up-curve measurement. The above treatment may easily be extended for such a case.

An Analysis of the Experimental Results and Discussion—Many efforts have been made by many researchers to elucidate thixotropic behavior. Although concrete discussions have been given for the mechanism of the thixotropic breakdown and recovery in some cases, a full quantitative description has not yet been successful. Of the researchers, Green and Weltmann made the most extensive study.[7,8] They proposed the hysteresis curve method for the characterization of thixotropic behaviors. However their experimental parameter is selected arbitrarily, and the comparison of the thixotropic behaviors of various samples is possible only under limited conditions; that is, their work is principally practical. In order to get a better description, Mooney,[9] Alfrey and Rodewald,[10] and Rehbinder[11] undertook to record the time-dependent shear-rate at a fixed shearing stress in order to characterize the thixotropic behaviors. By these studies, the thixotropic behavior is described by well-defined parameters, but their work has not had a general basis for the refined treatment.

The theoretical work described above provides a plausible basis for these studies. For example,

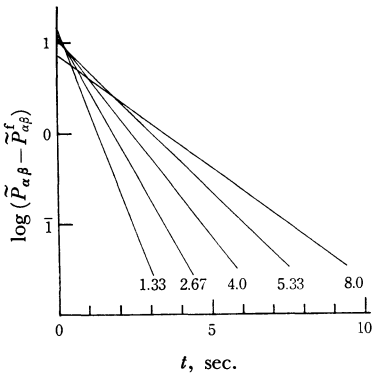

Fig. 6. Verification of the prediction of Eq. 32 using Mooney's data.

Mooney's work may be analyzed by this treatment as follows. Mooney measured the apparent viscosity of a suspension of a compounded rubber latex, the internal structure of which had been broken down completely beforehand, as a function of settling time at fixed shearing stresses; he thus obtained the results reproduced in Fig. 3. From this data the stationary shearing stress is drawn against the rate of shear in Fig. 4, while the apparent viscosity is replotted in Fig. 5.

When the fluid, the internal structure of which has been broken down completely, is fixed at a fixed shearing stress lower than that necessary for the complete destruction, the system is initially in the non-stationary state and approaches the stationary state. This non-stationary state is specified by the real and the fictitious shearing stress described in the preceding sections. The fictitious shearing stress is a function of the time at a constant shearing stress and becomes the real shearing stress as the time becomes infinite. The fictitious shearing stress is determined from the stationary stress vs. rate of shear curve as a value of the shearing stress at the corresponding value of the apparent viscosity or the rate of shear. The values calculated by this procedure are shown on the logarithmic scale against the time. This curve obeys to the prediction of Eq. 32, with the parameter, τ, varying with the stress; this is reasonable considering its definition given by Eq. 33.

From this treatment, all the stress vs. rate of shear curves may be constructed from the stationary curve and the parameter of the rate process of the thixotropic recovery. Green and Weltmann's hysteresis curve is also included in these curves.

In this treatment the fluids are assumed to be ideally viscous. Actually, the thixotropic fluids have yield values in most cases, as Freundlich first noted. This fluid may be treated by introducing the principle of relaxability in small proposed by Eckart[12] and by Kluitenberg[4]. However, this treatment is omitted here, for the extension of the present treatment to such a substances results in complicated expressions.

Lastly, it should be noted that the effect of the temperature on the thixotropic behavior is significant in most cases, as Lower, Walker and Zettlemoyer have already pointed out.[13] This effect is considered precisely in such fundamental equations as Eq. 19. However, no detailed discussions can be made here because of the lack of experimental data.

The Application of the Molecular Orbital Theory to the Bond Scission of Aliphatic Amines*

By Kozo HIROTA

and Michiyasu ITOH

Institute for Protein Research, Osaka University, Joan-cho, Kitaku, Osaka

(Received November 8, 1965)

The relative scission-probabilities of C–C bonds of *n*-propyl, *n*-butyl and isobutyl amines being formed by electron impact (90 V.) were determined by the use of mass spectrometers of the usual type and of the high-resolution type. They were in good accordance with the theoretical values calculated by the LCBO-MO theory which had been proposed and found successful in explaining the mass spectra of *n*-paraffins and methyl alkyl ketones.

It was proposed by Thompson,[1] with regard to the mass spectrum of normal octane, that the relative amount of the abundant ions could be given theoretically if the "scission probability" of each C–C bond in the parent ion were assumed to be proportional to the electron density at the bond on the highest occupied molecular orbital (MO) of a starting molecule, and if the MO were expressed by the linear combination of the bond-orbitals (LCBO). Such a molecular orbital theory could be applied successfully to the relative abundance of the ions produced by several normal paraffins[2] (C_4H_{10}—$C_{10}H_{22}$) and by several methyl alkyl ketones[3]. Nevertheless, the application of this LCBO theory to the other paraffins higher than decane has not proved satisfactorily. This is the reason why there are some objections[4] to this theory, though its application to the evaluation of ionization potentials is generally admitted. The above discordance can, however, be explained by introducing the multiple scission of bonds in the parent ions of large carbon numbers.

The point of criticism on the theory may lie, rather, in a new assumption, one which is quite different from that of the statistical theory of Rosenstock et al.[5] According to this assumption, even the good coincidence may seem to be fortuitous, especially in the cases of ketones which contain lone-pair and π-bonding electrons as well as σ-bonding electrons in the molecules. On the other hand, the scission of the bonds determined by comparing the spectra of ketones labeled with deuterium may arouse some doubt about using them as the experimental data to be compared, because the transposition of deuterium is possible during the process of fragmentation. If it occured markedly, the above comparison would be of little meaning.

It is the object of the present paper to extend the applicability of the theory to the calculation of the relative abundance of ions produced from *n*-propyl (*n*-PA), *n*-butyl (*n*-BA) and isobutyl amines (*i*-BA), using mass spectrometers of the high-resolution type as well as of the usual type, in order to clarify the ambiguity of the assignment of the ion produced.

Experimental

Mass spectra with usual resolutions were obtained with a Hitachi RMU-5B apparatus (magnetic scanning type), with a bombarding electron beam of 90 V. These data, shown in Table I, indicate that the peaks resulting from the scission of the C–N bond are negligible. However, some of the peaks (indicated by asterisks in Table I) (m/e=15, 27, 28, 29, 41, 42, 43) could not be assigned in the cases of *n*-BA and *i*-BA by these spectra alone; e. g., each of the seven peaks corresponding to different fragmentations is described in the third and the fourth columns of Table II. Therefore, for the sake of determining the probability of bond-scission, their ratios (A/B) were determined by their relative peak height in the spectra of the high-resolution type. They were obtained with a Hitachi PMU-7Hr apparatus. Its resolution is at least 5000 at m/e=28. However, it was found unnecessary to make such an allocation in the case of propylamine, so the spectrum of this amine was not measured. The results for the two butylamines are shown in Table II; they were obtained also with a bombarding electron beam of 90 V. The ratio was determined by opening the collector slit so that both tops of the peak to be compared become flat; the mean value for three runs was used.

Assuming the peak-ratio thus obtained to be the same as that in the usual spectra (shown in Table I),

the percentages of all the ions concerned are allotted in Table II.

It is noteworthy that the ions produced by the scission of the C–N bond could not be found in both butyl amines; e. g., the ions containing nitrogen (N, NH, NH_2) and those corresponding to C_4H_9, C_4H_8 and C_4H_7 were not observed actually in the case of *n*-butylamine. This is the reason why propyl amine was not subjected to mass spectrometry of the high-resolution type. By combining the other data in Table I with Table II, the relative abundance of all the ions can be obtained to be as shown in Table III.

The relative probabilities of the scission of bonds can be determined from the data in Tables I and III, so a comparison of the theoretical values with the experimental ones becomes possible.

Table III. Relative intensities of ions produced from the amines

m/e	Ions	*n*-$C_3H_7NH_2$	*n*-$C_4H_9NH_2$	*i*-$C_4H_9NH_2$

	C_2NH_5	2.8	1.4	1.3

a) The sums of both ions are listed, but they can be estimated to belong mainly to hydrocarbon ions, as is explained in the text.

LCBO-MO Theory

In the case of ethyl alkyl ketone,[3] the bond orbitals of C–C and C=O bonds were calculated under the assumption that CH_2 and CH_3 were united atoms, because the electron density of the C–C bond was practically the same in the case of paraffins whether it was calculated with the united atom approximation[6] or with a more rigorous treatment[7]. Besides, a mutual interaction between only the neighboring bond-orbitals was taken into consideration in both the above papers, as is usually done generally in simple LCAO-MO theory.

These approximations were also adopted in the present paper, regarding NH_2 as a united atom as well as CH, CH_2, and CH_3; e. g.,

n-Propyl amine (*n*-PA): $CH_3\overset{2}{-}CH_2\overset{1}{-}CH_2\overset{0}{-}NH_2$

n-Butyl amine (*n*-BA): $CH_3\overset{3}{-}CH_2\overset{2}{-}CH_2\overset{1}{-}CH_2\overset{0}{-}NH_2$

Isobutyl amine (*i*-BA): $\begin{matrix}CH_3\overset{3}{}\\ CH_3\overset{3}{}\end{matrix}\!\!>\!\overset{2}{CH}\overset{1}{-}CH_2\overset{0}{-}NH_2$

The numbering of each bond-orbital, i, will be indicated by the numerals attached to the bond shown above.

Table IV shows the Coulomb (α) and exchange (β) integrals necessary to solve the secular equation for each molecule: $[e_{ij}-\delta_{ij}E]=0$, where e_{ij} equals α or β, according as $i=j$ or $i\neq j$, the suffix N denotes the integrals concerning the nitrogen atom.

Table IV. Explanation of integrals.

	$\overset{i}{C-C}$	$\overset{i+1}{C-C}$	$\overset{0}{C-N}$
$\overset{i}{C-C}$	α	β	β_N
$\overset{i+1}{C-C}$	β	α	0
C—N	β_N	0	α_N

Among these integrals, α and β were taken to be -13.75 V., and -1.80 V. respectively from Fueki's values,[8] which were determined in the evaluation of the ionization potential of saturated hydrocarbons. The values of α_N and β_N were determined by solving the secular equations for *n*-ethylamine and *n*-butylamine, so that they satisfy their observed ionization potentials, 9.26 and 9.19 V. respectively. The values thus obtained were $\alpha_N=-9.60$ V. and $\beta_N=-1.24$ V.

The necessary electron density can be calculated by the squares of the coefficient, C_i, in the wave function of the highest-occupied orbital, $\Psi=\sum_i c_i\phi_i$.

Results

For the sake of comparison, the calculated ionization potentials for *n*-PA and *i*-BA are shown in Table V, along with the observed values. Though the accuracy of the observed values is not very good, the tendency for the ionization potential to decrease with a decrease in the carbon number is shown by the calculated values in Table V.

Table V. Calculated and observed I.P. values of the amines

	Observed		Calculated
$C_2H_5NH_2$	9.32[9]	9.19[10]	(9.26)
n-$C_3H_7NH_2$	9.17[9]		9.20
n-C_4H_9NH	9.19[9]		(9.19)
i-$C_4H_9NH_2$	9.00[9]		9.17

N.B. The values in parentheses are used for the calculation.

The squares of the coefficient, C_i, of the *i*th bond orbital in the highest occupied MO concerned are shown in Table VI. In Table VI, case I or II

represents, respectively when the coefficient of the C–N bond is taken into calculation or when it is not. The values are normalized, in both cases. Since the scission of the C–N bond can be neglected because of the small peaks resulting from its scission, as has been mentioned already, it is unnecessary to consider the electron density at the C–N bond; however, some discussion is desirable and will, therefore, be given. Thus, the case II was used in the comparison of the observed probability with the calculated probability.

Table VI. Square of the C_i's

	II	—	86.5	6.75	6.75

a) The contributions of peaks produced by two bond-scissions are not included.

In previous papers[3] the experimental probability of each bond-scission was discussed by comparing the spectrum of ketones with that of the corresponding deuterated species. Similarly, three amines were compared, as is shown in Fig. 1; the degree of coincidence is the same as that in the case of ketones. This result supports the method of research adopted for ketones.

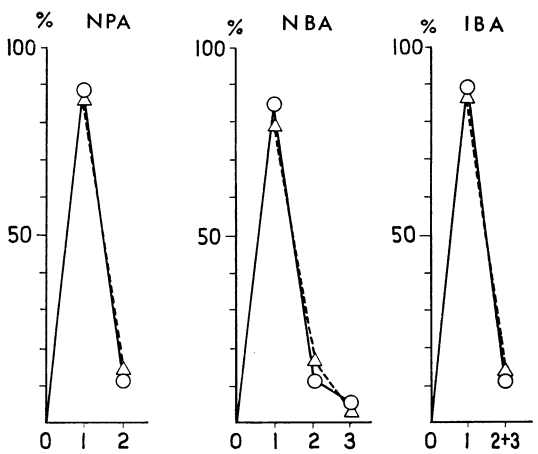

Fig. 1. Bond-scission probability and positive charge distribution.
○——○ : Experimental
△----△ : Theoretical

Discussion

We may now discuss why the adoption of the case II is more justified than that of the case I; i. e., this choice means that only the scission probability of the C–C bond can be considered, with no regard to that of the C–N bond. The same criticism may be given concerning the stability of the C=O bond in the case of alkyl-methyl ketones.

From the standpoint of the rate theory, the scission probability would be proportional to the specific rate, k, which is expressed by the Arrhenius formula:

$$k = X\exp(-E_a/\boldsymbol{R}T) \qquad (2)$$

In the cases of comparisons between the same bonds, e. g., C–C, the activation energy, E_a, will be the same. The difference in the scission probability in the case of paraffins is, therefore, determined only by the pre-exponential factor, X. On the other hand, the difference may depend also on E_a in the comparison of scission probabilities between different bonds. This is the reason why fragment ions produced by the scission of C–H and C–N bonds are, respectively smaller and very much smaller, than those produced by the scission of the C–C bond.

Now, as has often been done, the bond energy may be assumed to be proportional to the E_a value, if the potential curves of the bonds have the same shape. This first approximation seems successful as far as C–C (ca. 80 kcal.), C–H (ca. 100 kcal.) and C=O (>127 kcal.) are concerned, because the scission probability decreases in this order: C–C>C–H>C=O.

However, this approximation does not hold well if the C–N bond is considered, because its bond energy is nearly equal to or even smaller than that of the C–C bond. Considering this, the shape of the potential curve of the C–N bond may be quite different from that of the other bonds.

In conclusion, it seems promising to apply the present LCBO-MO theory on mass spectra to substances of kinds other than paraffins, though the theory is completely different in standpoint from the usual statistical theory of Rosenstock et al.[5] However, some assumptions will be necessary in using the theory so as to be able to predict which fragment will be charged after the scission of a bond.

We wish to express our deep thanks to Dr. M. Hatada for his help in this research.

This paper is dedicated to Professor Masao Kotani, the University of Tokyo, in celebration of his 60th birthday.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1410—1414 (1966)

Vibrational Frequencies and Normal Coordinates: Their Relationship to Force Constants and Inertial Coefficients

By Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

and John OVEREND

Molecular Spectroscopy Laboratory, Department of Chemistry, University of Minnesota, Minneapolis, Minnesota 55455, U. S. A.

(Received November 11, 1965)

Small variations in the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices can be related linearly to variations in the calculated frequencies and normal coordinates through a transformation matrix, $\boldsymbol{J}$. Explicit expressions are given for the elements of $\boldsymbol{J}$ and $\boldsymbol{J}^{-1}$. Isotope effects on normal-coordinate coefficients are also treated.

In the harmonic-oscillator theory of molecular vibrations, the molecular variables (the frequency parameters, $\lambda_a = 4\pi^2c^2\nu_a^2$, and the normal-coordinate coefficients, L_{ia}) are determined completely by the parameters of the model (the elements of the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices in Wilson's notation[1]) and vice versa, through the equations:

$$\boldsymbol{G} = \boldsymbol{L}\tilde{\boldsymbol{L}} \tag{1}$$

and

$$\boldsymbol{\Lambda} = \tilde{\boldsymbol{L}}\boldsymbol{F}\boldsymbol{L} \tag{2a}$$

or

$$\boldsymbol{F} = \tilde{\boldsymbol{L}}^{-1}\boldsymbol{\Lambda}\boldsymbol{L}^{-1} \tag{2b}$$

In the general case, in which the molecule has n vibrational degrees of freedom, there are n frequency parameters and n^2 normal-coordinate coefficients, making a total of $n(n+1)$. Since $\boldsymbol{G}$ and $\boldsymbol{F}$ are symmetric, each has $n(n+1)/2$ independent elements— a total of $n(n+1)$. Thus there should be, in general, $n(n+1)$ relationships between the $[\boldsymbol{G}, \boldsymbol{F}]$ and $[\boldsymbol{\Lambda}, \boldsymbol{L}]$ elements present in Eqs. 1 and 2. Although these relationships are nonlinear, small variations in $\boldsymbol{\Lambda}$ and $\boldsymbol{L}$ can be interpreted in terms of small changes in $\boldsymbol{G}$ and $\boldsymbol{F}$ through a linear transformation:

$$[\Delta\boldsymbol{\Lambda}, \Delta\boldsymbol{L}] = \boldsymbol{J}[\Delta\boldsymbol{G}, \Delta\boldsymbol{F}]$$

Similarly, small changes in $\boldsymbol{G}$ and $\boldsymbol{F}$ can be related to small changes in $\boldsymbol{\Lambda}$ and $\boldsymbol{L}$ through the reverse transformation:

$$[\Delta\boldsymbol{G}, \Delta\boldsymbol{F}] = \boldsymbol{J}^{-1}[\Delta\boldsymbol{\Lambda}, \Delta\boldsymbol{L}]$$

These transformations, $\boldsymbol{J}$ and $\boldsymbol{J}^{-1}$, can be written as square matrices, the elements of which are the partial derivatives $\partial[\boldsymbol{\Lambda}, \boldsymbol{L}]/\partial[\boldsymbol{G}, \boldsymbol{F}]$ and $\partial[\boldsymbol{G}, \boldsymbol{F}]/\partial[\boldsymbol{\Lambda}, \boldsymbol{L}]$ respectively. The purpose of this paper is to present the algebraic form of these two transformations and to show that each is, in fact, the inverse of the other.

Parts of the $\boldsymbol{J}$ matrix are well known, and their utility has been well established.[2,3] However, the $\boldsymbol{J}$ transformation from $\Delta\boldsymbol{G}$ to $\Delta\boldsymbol{L}$ or the $\boldsymbol{J}^{-1}$ transformation have not previously been described and, as far as we know, the existence of the inverse relationship has not been pointed out.

We will follow current practice and cast the problem in the form of the first-order perturbation theory. Consider the small perturbations $\boldsymbol{G}_1$ and $\boldsymbol{F}_1$ such that:

$$\boldsymbol{G} = \boldsymbol{G}_0 + \boldsymbol{G}_1 \tag{3}$$

and

$$\boldsymbol{F} = \boldsymbol{F}_0 + \boldsymbol{F}_1 \tag{4}$$

These will result in corresponding perturbations in $\boldsymbol{\Lambda}$ and $\boldsymbol{L}$:

$$\boldsymbol{\Lambda} = \boldsymbol{\Lambda}_0 + \boldsymbol{\Lambda}_1 \tag{5}$$

$$\boldsymbol{L} = \boldsymbol{L}_0 + \boldsymbol{L}_1 = \boldsymbol{L}_0(\boldsymbol{E} - \boldsymbol{P}) \tag{6}$$

where $\boldsymbol{E}$ is the unit matrix.[3] It then follows that

$$\boldsymbol{L}^{-1} = \boldsymbol{L}_0^{-1} + \boldsymbol{L}_1^{-1} = (\boldsymbol{E} + \boldsymbol{P})\boldsymbol{L}_0^{-1} \tag{7}$$

From Eqs. 1 and 6, neglecting higher order terms;

$$\boldsymbol{G}_0 + \boldsymbol{G}_1 = \boldsymbol{L}_0(\boldsymbol{E} - \boldsymbol{P})(\boldsymbol{E} - \tilde{\boldsymbol{P}})\tilde{\boldsymbol{L}}_0 \tag{8}$$

whence:

$$\boldsymbol{G}_1 = -\boldsymbol{L}_0(\boldsymbol{P} + \tilde{\boldsymbol{P}})\tilde{\boldsymbol{L}}_0 \tag{9}$$

1) E. B. Wilson, Jr., J. C. Decius and P. C. Cross, "Molecular Vibrations," McGraw Hill Book Company, New York (1955).

2) T. Miyazawa, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **76**, 1132 (1955); W. T. King, I. M. Mills and B. L. Crawford, Jr., *J. Chem. Phys.*, **27**, 455 (1957).

3) I. Nakagawa and T. Shimanouchi, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **80**, 128 (1959). The notation in Eqs. 6 and 7 follows theirs.

or, by rearranging:

$$\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1} = -(\boldsymbol{P}+\tilde{\boldsymbol{P}}) \tag{10}$$

Similarly, from Eqs. 2a and 6:

$$\boldsymbol{\Lambda}_0 + \boldsymbol{\Lambda}_1 = (\tilde{\boldsymbol{L}}_0 - \tilde{\boldsymbol{P}}\tilde{\boldsymbol{L}}_0)(\boldsymbol{F}_0+\boldsymbol{F}_1)(\boldsymbol{L}_0 - \boldsymbol{L}_0\boldsymbol{P}) \tag{11}$$

whence:

$$\boldsymbol{\Lambda}_1 = \tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0 - (\tilde{\boldsymbol{P}}\boldsymbol{\Lambda}_0 + \boldsymbol{\Lambda}_0\boldsymbol{P}) \tag{12}$$

or

$$\boldsymbol{F}_1 = \tilde{\boldsymbol{L}}_0^{-1}\boldsymbol{\Lambda}_1\boldsymbol{L}_0^{-1} + \tilde{\boldsymbol{L}}_0^{-1}(\tilde{\boldsymbol{P}}\boldsymbol{\Lambda}_0 + \boldsymbol{\Lambda}_0\boldsymbol{P})\boldsymbol{L}_0^{-1} \tag{13}$$

As has been suggested by Nakagawa and Shimanouchi,[3] the transformation is more usefully expressed with respect to $\boldsymbol{P}$ rather than to $\boldsymbol{L}$; therefore, the transformations have been redefined accordingly:

$$[\Delta\boldsymbol{\Lambda},\ \boldsymbol{P}] = \boldsymbol{J}[\Delta\boldsymbol{G},\ \Delta\boldsymbol{F}]$$

and

$$[\Delta\boldsymbol{G},\ \Delta\boldsymbol{F}] = \boldsymbol{J}^{-1}[\Delta\boldsymbol{\Lambda},\ \boldsymbol{P}]$$

The elements of $\boldsymbol{J}^{-1}$ are then obtained from Eqs. 9 and 13. In designating matrix elements by a double subscript, we follow convention and write the row index first and the column index second. The $i, j, k, \cdots$ indices refer to internal coordinates, while the $a, b, c, \cdots$ indices refer to normal coordinates.

$$\partial G_{ij}/\partial\lambda_a = 0 \tag{14}$$

$$\partial G_{ij}/\partial P_{ab} = \partial G_{ij}/\partial P_{ba} = -(L_{ia}L_{jb} + L_{ib}L_{ja}) \tag{15}$$

$$\partial F_{ij}/\partial\lambda_a = L_{ai}^{-1}L_{aj}^{-1} \tag{16}$$

$$\partial F_{ij}/\partial P_{ab} = \lambda_a(L_{ai}^{-1}L_{bj}^{-1} + L_{bi}^{-1}L_{aj}^{-1}) \tag{17}$$

$$(\partial F_{ij}/\partial P_{ba})/\lambda_b = (\partial F_{ij}/\partial P_{ab})/\lambda_a \tag{18}$$

Equations 14—18 complete the elements of $\boldsymbol{J}^{-1}$.

To determine the elements of $\boldsymbol{J}$, we require $\boldsymbol{\Lambda}$ and $\boldsymbol{P}$ to be explicit functions of $\boldsymbol{G}$ and $\boldsymbol{F}$. It is important to recognize that $\boldsymbol{P}$ is, through Eqs. 10 and 12, a function of $\boldsymbol{G}_1$ and $\boldsymbol{F}_1$. From the diagonal elements of Eq. 12:

$$(\boldsymbol{\Lambda}_1)_{aa} = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{aa} - (P_{aa}\Lambda_{aa} + \Lambda_{aa}P_{aa}) \tag{19}$$

From Eq. 10:

$$(\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1})_{aa} = -2\boldsymbol{P}_{aa} \tag{20}$$

and, by combining Eqs. 19 and 20:

$$(\boldsymbol{\Lambda}_1)_{aa} = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{aa} + \lambda_a(\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1})_{aa} \tag{21}$$

from which:

$$\partial\lambda_a/\partial G_{ij} = 2\lambda_a L_{ai}^{-1}L_{aj}^{-1} \tag{22}$$

$$\partial\lambda_a/\partial G_{ii} = \lambda_a(L_{ai}^{-1})^2 \tag{23}$$

$$\partial\lambda_a/\partial F_{ij} = 2L_{ia}L_{ja} \tag{24}$$

and

$$\partial\lambda_a/\partial F_{ii} = (L_{ia})^2 \tag{25}$$

The expression for P_{ab} as an explicit function of $\boldsymbol{G}$ and $\boldsymbol{F}$ follows from the off-diagonal elements of Eqs. 10 and 12:

$$-(P_{ab} + P_{ba}) = (\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1})_{ab} \tag{26}$$

and

$$P_{ba}\lambda_b + \lambda_a P_{ab} = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{ab} \tag{27}$$

By multiplying Eq. 26 by λ_b and by adding Eq. 27:

$$P_{ab}(\lambda_a - \lambda_b) = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{ab} + \lambda_b(\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1})_{ab} \tag{28}$$

Similarly:

$$P_{ba}(\lambda_b - \lambda_a) = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{ab} + \lambda_a(\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1})_{ab} \tag{29}$$

From Eqs. 28 and 29:

$$\partial P_{ab}/\partial F_{ij} = -\partial P_{ba}/\partial F_{ij} = (\lambda_a - \lambda_b)^{-1}(L_{ia}L_{jb} + L_{ib}L_{ja}) \tag{30}$$

$$\partial P_{ab}/\partial F_{ii} = -\partial P_{ba}/\partial F_{ii} = (\lambda_a - \lambda_b)^{-1}L_{ia}L_{ib} \tag{31}$$

$$\partial P_{ab}/\partial G_{ij} = [\lambda_b/(\lambda_a - \lambda_b)](L_{ai}^{-1}L_{bj}^{-1} + L_{aj}^{-1}L_{bi}^{-1}) \tag{32}$$

$$\partial P_{ab}/\partial G_{ii} = [\lambda_b/(\lambda_a - \lambda_b)]L_{ai}^{-1}L_{bi}^{-1} \tag{33}$$

$$(\partial P_{ba}/\partial G_{ij})/\lambda_a = -(\partial P_{ab}/\partial G_{ij})/\lambda_b \tag{34}$$

$$(\partial P_{ba}/\partial G_{ii})/\lambda_a = -(\partial P_{ab}/\partial G_{ii})/\lambda_b \tag{35}$$

Finally, from the diagonal elements of Eq. 9:

$$\partial P_{aa}/\partial G_{ij} = -L_{ai}^{-1}L_{aj}^{-1} \tag{36}$$

and

$$\partial P_{aa}/\partial G_{ii} = -\frac{1}{2}(L_{ai}^{-1})^2 \tag{37}$$

and from Eq. 20:

$$\partial P_{aa}/\partial F_{ii} = \partial P_{aa}/\partial F_{ij} = 0 \tag{38}$$

Eqs. 22—25, 30—33, and 36—38 complete the elements of $\boldsymbol{J}$.

The complete transformations, $\boldsymbol{J}$ and $\boldsymbol{J}^{-1}$, for the particular case of $n=2$ are given in Tables I and II. The product matrices, $\boldsymbol{J}\boldsymbol{J}^{-1}$ and $\boldsymbol{J}^{-1}\boldsymbol{J}$, for the general case have also been constructed. As is shown in Tables III and IV, these matrices are indeed equal to the unit matrix [order of $n(n+1)$]. Accordingly, $\boldsymbol{J}^{-1}$ is now confirmed to be both the left and the right inverse of $\boldsymbol{J}$.

Similar transformations relate $[\Delta\boldsymbol{\Lambda},\ \Delta\boldsymbol{L}]$ and also $[\Delta\boldsymbol{\Lambda},\ \Delta\boldsymbol{L}^{-1}]$ to $[\Delta\boldsymbol{G},\ \Delta\boldsymbol{F}]$. From Eqs. 6 and 7.

$$\boldsymbol{P} = \boldsymbol{L}_1^{-1}\boldsymbol{L}_0 = -\boldsymbol{L}_0^{-1}\boldsymbol{L}_1 \tag{39}$$

whence:

$$\partial P_{ab}/\partial L_{ai}^{-1} = L_{ib} \tag{40}$$

and

$$\partial P_{ba}/\partial L_{ia} = -L_{bi}^{-1} \tag{41}$$

* The unit matrix $\boldsymbol{E}$ was derived from the product of $\boldsymbol{L}^{-1}\cdot\boldsymbol{L}$.

Table IV. The elements of the $J^{-1}J$ matrix

Row $(i\leq j)$	Column $(k\leq l)$	Elements*
ΔG_{ij}	ΔG_{kk}	$E_{ik}E_{jk}\begin{cases}=1 \text{ only if } i=j=k\\=0 \text{ otherwise}\end{cases}$
ΔG_{ij}	ΔG_{kl} $(k\neq 1)$	$E_{ik}E_{jl}+E_{il}E_{jk}\begin{cases}=1 \text{ only if } i=k \text{ and } j=l\\=0 \text{ otherwise}\end{cases}$
ΔG_{ij}	ΔF_{kl}	0
ΔF_{ij}	ΔG_{kl}	0
ΔF_{ij}	ΔF_{kk}	$E_{ki}E_{kj}\begin{cases}=1 \text{ only if } i=j=k\\=0 \text{ otherwise}\end{cases}$
ΔF_{ij}	ΔF_{kl} $(k\neq l)$	$E_{ki}E_{lj}+E_{kj}E_{li}\begin{cases}=1 \text{ only if } i=k \text{ and } j=l\\=0 \text{ otherwise}\end{cases}$

* The unit matrix $\boldsymbol{E}$ was derived from the product of $\boldsymbol{L}\cdot\boldsymbol{L}^{-1}$.

Then:

$$\frac{\partial}{\partial L_{ia}}=\sum_b\frac{\partial P_{ba}}{\partial L_{ia}}\cdot\frac{\partial}{\partial P_{ba}}=\sum_b(-L_b^{-1}{}_i)\frac{\partial}{\partial P_{ba}} \tag{42}$$

and

$$\frac{\partial}{\partial L_a^{-1}{}_i}=\sum_b\frac{\partial P_{ab}}{\partial L_a^{-1}{}_i}\cdot\frac{\partial}{\partial P_{ab}}=\sum_b L_{ib}\frac{\partial}{\partial P_{ab}} \tag{43}$$

Simple expressions may be derived for example, by substituting Eq. 39 into Eq. 9:

$$\boldsymbol{G}_1=\boldsymbol{L}_0(\boldsymbol{L}_0^{-1}\boldsymbol{L}_1+\tilde{\boldsymbol{L}}_1\tilde{\boldsymbol{L}}_0^{-1})\tilde{\boldsymbol{L}}_0=\boldsymbol{L}_1\tilde{\boldsymbol{L}}_0+\boldsymbol{L}_0\tilde{\boldsymbol{L}}_1 \tag{44}$$

whence:

$$\partial G_{ii}/\partial L_{ia}=2L_{ia} \tag{45}$$

$$\partial G_{ij}/\partial L_{ja}=L_{ia} \tag{46}$$

$$\partial G_{ij}/\partial L_{ka}=0 \qquad (k\neq i,\ j) \tag{47}$$

Expressions for the $\boldsymbol{F}$ matrix may be derived by substituting Eq. 39 into Eq. 13:

$$\begin{aligned}\boldsymbol{F}_1=\tilde{\boldsymbol{L}}_0^{-1}\boldsymbol{\Lambda}_1\boldsymbol{L}_0^{-1}&-\tilde{\boldsymbol{L}}_0^{-1}(\boldsymbol{\Lambda}_0\boldsymbol{L}_0^{-1}\boldsymbol{L}_1\\&+\tilde{\boldsymbol{L}}_1\tilde{\boldsymbol{L}}_0^{-1}\boldsymbol{\Lambda}_0)\tilde{\boldsymbol{L}}_0^{-1}=\tilde{\boldsymbol{L}}_0^{-1}\boldsymbol{\Lambda}_1\boldsymbol{L}_0^{-1}\\&-(\boldsymbol{F}_0\boldsymbol{L}_1\boldsymbol{L}_0^{-1}+\tilde{\boldsymbol{L}}_0^{-1}\tilde{\boldsymbol{L}}_1\boldsymbol{F}_0)\end{aligned} \tag{48}$$

whence:

$$\partial F_{ij}/\partial L_{ka}=-(F_{ik}L_a^{-1}{}_j+F_{jk}L_a^{-1}{}_i) \tag{49}$$

We have found the $\boldsymbol{J}$ and $\boldsymbol{J}^{-1}$ transformations to be particularly useful in the propagation of uncertainties in the force constants and geometrical parameter to obtain estimates of the uncertainties in derived quantities; these derived quantities may include, for example, calculated frequencies, normal coordinate coefficients, Coriolis coefficients, and dipole-moment derivatives with respect to internal coordinates. They may also be useful in the more chemical group-frequency problems which are usually handled by perturbation formalism.

Appendix

Isotope Effects on Normal Coordinate Coefficients.—Small variations in atomic masses Δm_t have been previously[4] related with variations in frequency parameters λ_a. The present results may also be used to treat the isotope effects on normal-coordinate coefficients.

The $\boldsymbol{G}$ matrix is given by[1]

$$\boldsymbol{G}=\boldsymbol{B}\boldsymbol{M}^{-1}\tilde{\boldsymbol{B}} \tag{A-1}$$

where $\boldsymbol{M}^{-1}$ is the inverse mass matrix and the matrix $\boldsymbol{B}$ is the transformation from the Cartesian coordinates to the internal coordinates. Consider small variations[5] $\boldsymbol{M}_1$ such that

4) T. Miyazawa, *J. Mol. Spectry.*, **13**, 321 (1964).
5) The requirement is that the relative changes in masses, i. e. the elements of $\boldsymbol{M}_1\boldsymbol{M}_0^{-1}$, are small.

$$\boldsymbol{M} = \boldsymbol{M}_0 + \boldsymbol{M}_1 \tag{A-2}$$

The corresponding perturbation in $\boldsymbol{M}^{-1}$ is

$$\boldsymbol{M}^{-1} = \boldsymbol{M}_0^{-1} + \boldsymbol{M}_1^{-1} \tag{A-3}$$

where

$$\boldsymbol{M}_1^{-1} = -\boldsymbol{M}_0^{-1}\boldsymbol{M}_1\boldsymbol{M}_0^{-1} \tag{A-4}$$

This results in a small perturbation in $\boldsymbol{G}$, given by

$$\boldsymbol{G}_1 = \boldsymbol{B}\boldsymbol{M}_1^{-1}\tilde{\boldsymbol{B}} = -\boldsymbol{B}\boldsymbol{M}_0^{-1}\boldsymbol{M}_1\boldsymbol{M}_0^{-1}\tilde{\boldsymbol{B}} \tag{A-5}$$

whence

$$\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1} = -\boldsymbol{L}_0^{-1}\boldsymbol{B}\boldsymbol{M}_0^{-1}\boldsymbol{M}_1\boldsymbol{M}_0^{-1}\tilde{\boldsymbol{B}}\tilde{\boldsymbol{L}}_0^{-1} \tag{A-6}$$

Since the normal-coordinate coefficients $\boldsymbol{L}^{\mathrm{X}}$ for Cartesian displacement coordinates are given[6] as

$$\boldsymbol{L}^{\mathrm{X}} = \boldsymbol{M}^{-1}\tilde{\boldsymbol{B}}\tilde{\boldsymbol{L}}^{-1} \tag{A-7}$$

it follows that

$$\boldsymbol{L}_0^{-1}\boldsymbol{G}_1\tilde{\boldsymbol{L}}_0^{-1} = -\tilde{\boldsymbol{L}}_0^{\mathrm{X}}\boldsymbol{M}_1\boldsymbol{L}_0^{\mathrm{X}} \tag{A-8}$$

Small corresponding variations in the frequency parameters may be derived by substituting Eq. A-8 into Eq. 19,

$$\Delta\lambda_a = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{aa} - \lambda_a(\tilde{\boldsymbol{L}}_0^{\mathrm{X}}\boldsymbol{M}_1\boldsymbol{L}_0^{\mathrm{X}})_{aa} \tag{A-9}$$

giving, as derived previously,[4]

$$\partial\lambda_a/\partial m_t = -\lambda_a[(L_{t\,a}^x)^2 + (L_{t\,a}^y)^2 + (L_{t\,a}^z)^2] \tag{A-10}$$

where m_t is the mass of the t-th atom.

Similarly, by substituting Eq. A-8 into Eqs. 20 and 28,

$$P_{aa} = \frac{1}{2}(\tilde{\boldsymbol{L}}_0^{\mathrm{X}}\boldsymbol{M}_1\boldsymbol{L}_0^{\mathrm{X}})_{aa} \tag{A-11}$$

and

$$P_{ab}(\lambda_a - \lambda_b) = (\tilde{\boldsymbol{L}}_0\boldsymbol{F}_1\boldsymbol{L}_0)_{ab} - \lambda_b(\tilde{\boldsymbol{L}}_0^{\mathrm{X}}\boldsymbol{M}_1\boldsymbol{L}_0^{\mathrm{X}})_{ab} \tag{A-12}$$

Accordingly,

$$\partial P_{aa}/\partial m_t = \frac{1}{2}[(L_{t\,a}^x)^2 + (L_{t\,a}^y)^2 + (L_{t\,a}^z)^2] \tag{A-13}$$

and

$$\partial P_{ab}/\partial m_t = -[\lambda_b/(\lambda_a - \lambda_b)] \times [L_{t\,a}^x L_{t\,b}^x + L_{t\,a}^y L_{t\,b}^y + L_{t\,a}^z L_{t\,b}^z] \tag{A-14}$$

This $\boldsymbol{P}$ matrix may also be used in expressing small variations in the $\boldsymbol{L}^{\mathrm{X}}$ matrix as shown below,

$$\boldsymbol{L}^{\mathrm{X}} = \boldsymbol{L}_0^{\mathrm{X}} + \boldsymbol{L}_1^{\mathrm{X}} \tag{A-15}$$

where

$$\begin{aligned}\boldsymbol{L}_1^{\mathrm{X}} &= (\boldsymbol{M}_0^{-1} - \boldsymbol{M}_0^{-1}\boldsymbol{M}_1\boldsymbol{M}_0^{-1}) \\ &\quad \times \tilde{\boldsymbol{B}}\tilde{\boldsymbol{L}}_0^{-1}(\boldsymbol{E} + \tilde{\boldsymbol{P}}) - \boldsymbol{L}_0^{\mathrm{X}} \\ &= \boldsymbol{L}_0^{\mathrm{X}}\tilde{\boldsymbol{P}} - \boldsymbol{M}_0^{-1}\boldsymbol{M}_1\boldsymbol{L}_0^{\mathrm{X}}\end{aligned} \tag{A-16}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1414—1418 (1966)

The Basicities of Tropone and Tropolone

By Haruo Hosoya and Saburo Nagakura

The Institute for Solid State Physics, The University of Tokyo, Azabu, Minato-ku, Tokyo (S. N.)
The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo (H. H. & S. N.)

(Received November 19, 1965)

The ultraviolet absorption spectra of tropone (I) and tropolone (II) were measured with sulfuric acid solutions of various acidities. The accurate pK_a values, as determined by the proposed method, were -1.02 and -0.86 for I and II respectively. The Raman spectra of II were measured with sulfuric acid solutions of various acid concentrations. The bands in the 6 and 15 μ regions change sharply when the solvent acidity changes from 5 to 25%, corresponding well to the ultraviolet absorption change. The infrared absorption spectra of II were measured with the concentrated deuterosulfuric acid solution in the 6 μ region. The vibrationals mode of the protonated tropolone were discussed.

As evidenced by the facile production of their hydrochlorides, tropone and tropolone are known to be relatively stronger bases than most other unsaturated ketones.[1,2] We have shown theoretically in a previous paper[3] that this anomalously large basic character of tropone derivatives is attributable to the large (16%) contribution of the polar structure to the ground state. The

stabilities of tropone and tropolone hydrochlorides are also related to the stability of a unipositively charged seven-membered ring (the tropylium ion $C_7H_7^+$) system.

Recently Raman spectra have come to be used to study the structural change of organic bases in strong acidic media,[4,5] while ultraviolet absorption measurements have been shown to be suitable for the critical analyses of equilibria, even in strong acidic media.[4] Therefore, both methods were applied to the study of the protonations of tropone and tropolone.[6]

Experimental

Materials.—Tropone and tropolone were purified by the methods described in previous papers.[3,7] Concentrated sulfuric acid of a G. R. grade (95%) was used without further purification. Deuterosulfuric acid (97% acid concentration and 99% deuterium concentration) was purchased from the Showa Denko K. K.

Measurements.—A Cary recording spectrophotometer, model 14 M, was used for the ultraviolet absorption measurements. The ultraviolet absorption spectra of tropone and tropolone (ca. 10^{-4} M) were measured with sulfuric acid solutions of various acidities (H_0), fused quartz cells with a path length of 1 cm. being used. Because of its unstability, tropone was purified by distillation just before the solution was prepared. The numerical values for the acidity function (H_0) of the solvent sulfuric acid were taken from the table of Paul and Long (at 25°C).[8] The measurements were carried out in a temperature-controlled room adjusted at 20°C (±1°C). Since the temperature dependency of acidity functions is small, no temperature corrections to them were made.

The Raman spectra of tropolone (5—10 wt. %) in various acidities of sulfuric acid solutions were measured with the Cary model 81 recording Raman spectrophotometer located at the Government Chemical Industrial Research Institute, Tokyo.[9] The solution in the cell was warmed as high as about 40°C during the Raman spectral measurements.

The infrared absorption spectrum of tropolone in a concentrated deuterosulfuric acid solution was measured with a Hitachi EPI-2 infrared spectrophotometer, with a rock salt prism attached. Polyethylene bag cells were used for this purpose; the details have been described elsewhere.[10]

Results and Discussion

The Basicities of Tropone and Tropolone.—The ultraviolet absoprtion spectrum of tropolone consists of two parts. We have assigned that the longer wavelength bands (250—400 mμ, A and B bands in Ref. 3) are due to the tropone excitation (perpendicular to the C=O axis) perturbed by the hydroxyl group. The spectrum changes with the sulfuric acid concentration of the solvent, the change at about 360 mμ being the most prominent (Fig. 1). For solutions with sulfuric acid concentrations higher than 60% the absorption curve gradually shifts to shorter wavelengths, but its shape remains unchanged. The former change unequivocally corresponds to the following equilibrium (X=OH) between tropolone and its conjugated acid,[11] while the latter change is probably due to the solvent effects. We have shown that the latter effects can be eliminated from the pK determination by applying the least

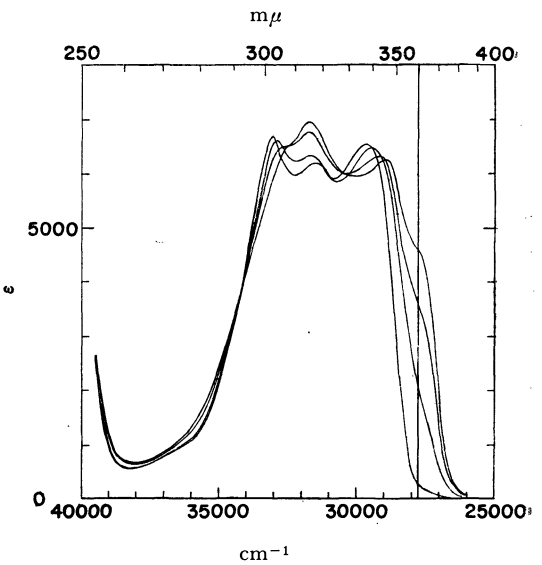

Fig. 1. Ultraviolet absorption spectra of tropolone in sulfuric acid of various concentrations.
The acidity constants H_0's of the solvents are −0.02, −0.48, −1.24, and −3.38 (from the top to the bottom at 360 mμ).

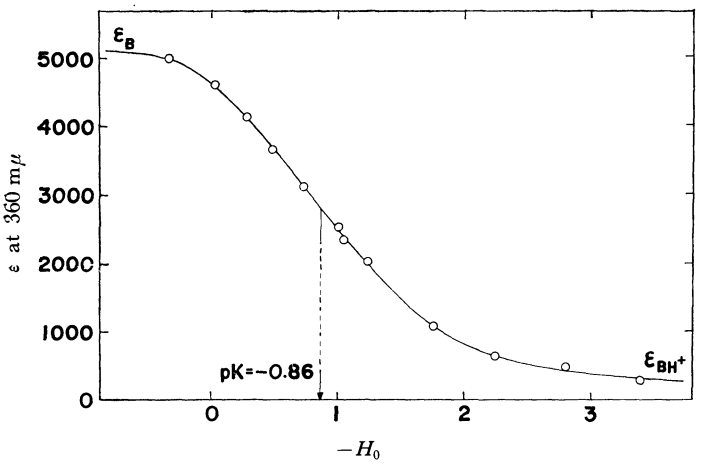

Fig. 2. Acidity dependency of the molar extinction coefficients at 360 mμ of tropolone in sulfuric acid. The vertical line and dots represent the inflection point of the sigmoid curve giving the pK_a value.

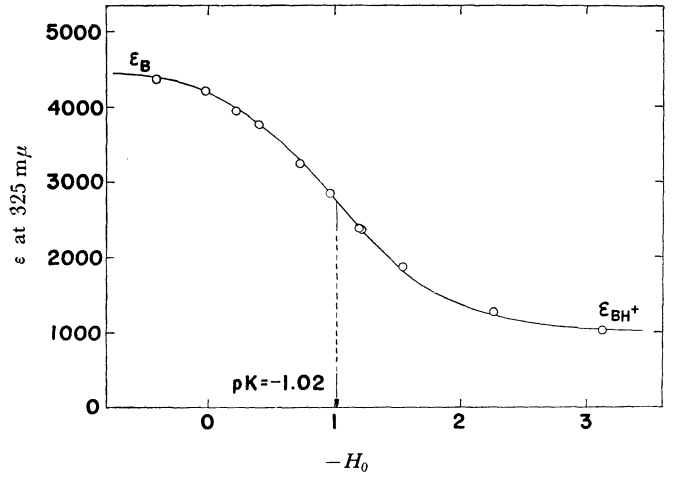

Fig. 3. Acidity dependency of the molar extinction coefficients at 325 mμ of tropone in sulfuric acid.

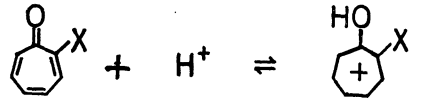

(1)

(X=H, OH)

squares calculation.[4,12] Namely, the H_0 value for the inflection point of the ε_λ—H_0 curve is just the pK value wanted, where ε_λ is the extinction coefficient subjected to the correction of solvent effects at the wavelentgh λ.

As is shown in Fig. 2, the observed ε values, at 360 mμ, for instance, change with the sulfuric acid concentration (H_0). The iterative calculation for determining simultaneously the pK_a, ε_B, and ε_{BH^+} values was executed following the method previously described.[4,12]

$$pK_a = -\log([B][H^+]/[BH^+]) \quad (2)$$

After repeating the least squares calculations for twelve pairs of data, we found the pK_a value of tropolone to be −0.86.

The same method was applied to the tropone-sulfuric acid system, ε's at 325 mμ being used. The pK_a value was thus found to be −1.20 (see Fig. 3); namely, tropone is less basic than tropolone. The existence of the equilibrium 1 was confirmed by the H_0—log $[(\varepsilon-\varepsilon_{BH^+})/(\varepsilon_B-\varepsilon)]$ plots, with slopes of 0.96 and 0.89 for tropolone and tropone respectively (Fig. 4).[4]

The pK_a value of −1 means that the concentrations of a base, B, and its conjugated acid, BH^+

12) The quantity in the summation of the last term in each of the three Eqs. 14 in Ref. 4 should be multiplied by ε.

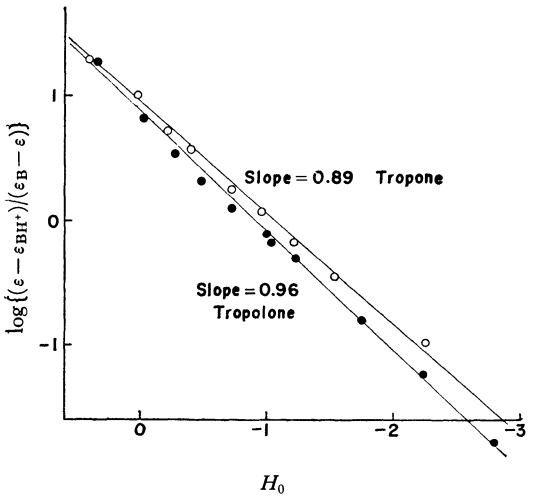

Fig. 4. Check of the existence of the equilibria 1. Open and filled circles stand, respectively, for tropone and tropolone.

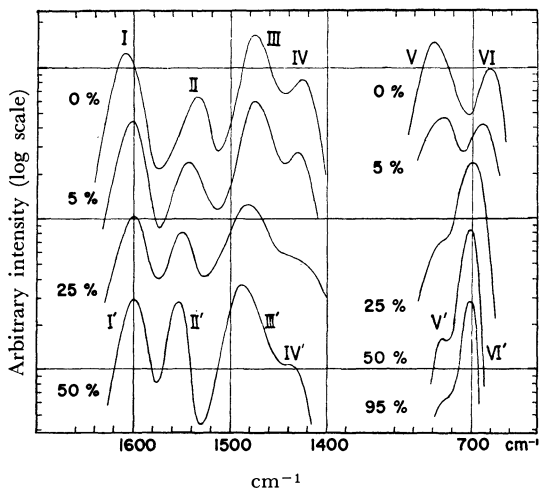

Fig. 5. Raman spectra of tropolone in sulfuric acid of various concentrations. The peak wave numbers of the characteristic bands of the neutral and protonated tropolone are, respectively, 1608 (I) and 1539 (II), and 1598 (I') and 1553 (II') cm^{-1}.

are almost equal in a 20% sulfuric acid solution (4.7 N), while the sigmoid ε - H_0 curve observed shows that in sulfuric acid solutions more concentrated than 40% (the same acid concentration as the concentrated hydrochloric acid), these compounds are completely protonated. However, a host of carbonyl compounds, such as aromatic and aliphatic ketones, aldehydes and carboxylic acids, have their pK_a values in the -6——7 range (in 70—80% sulfuric acid half-protonated).[13] This anomalously basic character of the carbonyl groups of troponoid compounds is due to the stability of the tropylium cation, as derivatives of which the protonated tropone or tropolone have been described. This is also the case for the anomalously basic cyclopropenone derivative.[6,14]

The dilution of the sulfuric acid solutions of these compounds with water gives almost the same spectra for their respective aqueous solutions, within an accuracy of about five per cent. This fact suggests the fair stabilities of these two compounds in concentrated sulfuric acid and the reversivility of the protonation processes.

Changes in Vibrational Spectra.—The infrared and Raman spectra of tropolone and its conjugated acid have characteristic but complicated features in the 1400—1650 cm^{-1} region, making a plausible assignment difficult.[15] Although the absolute intensities of the Raman spectra were not obtained accurately, therefore, a good reproducibility was obtained in each run. Thus, we have reproduced the spectra in various concentrations of sulfuric acid solutions on a logarithmic scale. Figure 5 shows the acicity dependency of the Raman spectra of this system in the 14 and 6—7 μ regions. It may be noticed that the relative intensities of several bands within each run greatly change in the concentration range of sulfuric acid between 5 and 25 per cent. Namely, the 1539 cm^{-1} band (II) has the weakest intensity in the 6—7 μ region spectra of tropolone in sulfuric acid with a concentration lower than 5 per cent, while the 1553 cm^{-1} band (II'), the shifted band of the 1539 cm^{-1} band, has an intensity comparable to the strongest 1490 cm^{-1} band (III') in the spectra of the solutions with concentrations of sulfuric acid higher than 25 per cent. The same tendency is also seen for the two bands in the 14 μ region. It should be remembered that the ultraviolet absorption data shows that the sharpest transference of the equlibrium 1 occurs at about a 20 per cent sulfuric acid solution. Thus, it may be concluded that the changes in the Raman spectra shown in Fig. 5, namely, the shifts of the bands to the respective bands, are caused by the protonation of tropolone.

The Assignments of the Vibrational Spectra of Tropolone and the Protonated Tropolone in the 6—7 μ Region.—As has been mentioned above, the vibrational spectrum of tropolone has several bands in the 6—7 μ region which have not yet been given conclusive assignments. Among these, the two bands near 1610 cm^{-1} (Band I) and 1540 cm^{-1} (Band II) have been recognized as having a mixed character C=C and C=O stretching vibrational modes. Recently Ikegami[16] showed

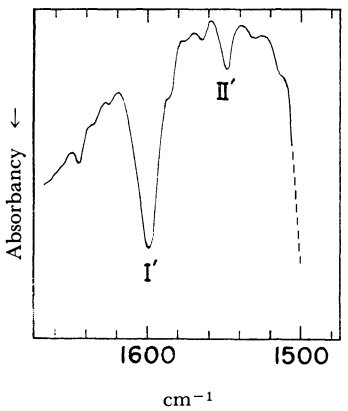

Fig. 6. Infrared absorption spectra of tropolone in a concentrated deuterosulfuric acid solution. The peak wave numbers are 1598 and 1547 cm^{-1} for I′ and II′, respectively.

that the infrared absorption band, II, is more liable to be influenced by the solvent change than Band I. As is evident in Fig. 5, the acidity dependency of the Raman Band II is the most prominent among the four in the 6—7 μ region. The intensity of the Raman Band II′ (1553 cm^{-1}) is increased to almost the same value as that of Band I′ (1598 cm^{-1}) for the protonated tropolone spectrum. Contrary to this, the infrared Band II′ (1547 cm^{-1}) of tropolone in a deuterosulfuric acid solution is much weaker than Band I′ (see Fig. 6). They have almost equal intensities in the spectrum of neutral tropolone.

Since the band pertinent to the C=O stretching vibration is expected to be sensitive to the protonation, Band II of tropolone may be assigned as largely due to the C=O stretching, and partly due also to the ring C=C stretching. The reverse is the case for Band I.

The protonated tropolone was shown by the X-ray crystal analysis technique to have two nearly equal C–OH bonds.[11] Therefore, it may be expected that absorption bands corresponding to the symmetrical and antisymmetric C–O stretching vibrations will appear. Band II′ may be assigned as due to symmetrical C–O stretching, because the intensity of Band II′ relative to that of Band I′ is stronger in the Raman spectrum than in the infrared spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1418—1422 (1966)

The Effect of Oxygen on the Semiconductivity of Quaterrylene

By Yusei MARUYAMA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received November 30, 1965)

The electrical conductivity of an evaporated film of quaterrylene varied with the pressure of the ambient oxygen. The resistivity was 1.1×10^{12} Ωcm. in a vacuum of 4×10^{-8} mmHg; this was very large compared with the previously-reported value, $\sim 10^{6}$ Ωcm., which was obtained after exposing the film to the air of an atmospheric pressure. The temperature dependence of the resistance of the film was also affected by the ambient oxygen. The intrinsic semiconductor model could be applied only in the case of a high vacuum ($\sim 10^{-8}$ mmHg); the band gap, $\Delta\varepsilon$, was 1.7 eV. in this case. From the resistance-temperature relations at the various oxygen pressures, it seems that two acceptor levels, 0.03 eV. and 0.6 eV. above the valence band respectively, exist.

The effect of an impurity on the semiconduction of organic molecular crystals is very important and has been studied by several workers. Adsorbed oxygen, as one kind of impurity, is known to modify the semiconductivity and the photoconductivity of organic semiconductors. Anthracene, one of the most frequently-investigated organic semiconductors, is also rather sensitive to oxygen[1]; this fact is partly responsible for the difficulty of interpreting experimental results reliably.

Recently, Heilmeier and Harrison observed the Hall effect in copper phthalocyanine single crystals and explained their results in terms of an extrinsic band model, in which the oxygen impurity formed a donor or an acceptor level.[2] Kuroda and Flood also reported on the effect of ambient oxygen on the semiconductivities of the evaporated films of mesonaphthodianthrene and mesonaphthodianthrone.[3]

1) H. Pick and W. Wissman, *Z. Physik*, **138**, 436 (1954); A. Bree and L. E. Lyons, *J. Chem. Soc.*, **1960**, 5179.

2) G. H. Heilmeier and S. E. Harrison, *Phys. Rev.*, **132**, 2010 (1963).

3) H. Kuroda and E. A. Flood, *Canad. J. Chem.*, **39**, 1475, 1981 (1961).

In this experiment, we will report how a high vacuum of the order of 10^{-8} mmHg has been employed to ascertain the dark conductivity of the evaporated films of quaterrylene; the conductivity and also the band gap, $\Delta\varepsilon$, have thus been found to be strongly sensitive to ambient oxygen.

The applied hydrocarbon, quaterrylene $C_{40}H_{20}$, is a very stable organic substance, unlike anthracene or mesonaphthodianthrene;* it is, therefore, hard to subject it to ordinary chemical oxidation. The electronic properties of quaterrylene were reported by the present authors some years ago.[4] As will be described below, the oxygen effect on the semiconduction of quaterrylene is so large and so decided that the interpretation in terms of the extrinsic band model is rather reasonable quantitatively.

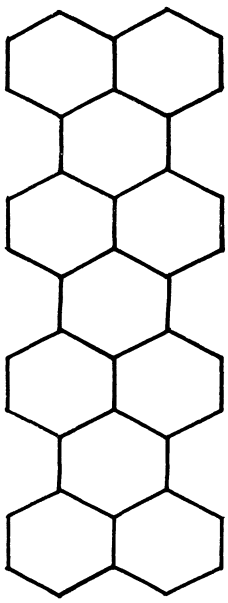

Fig. 1. The molecular structure of quaterrylene.

Only a little of the absorbed oxygen can be removed by evacuation without heating, and its adsorption energy may be expected to be fairly large compared with the usual van der Waals' energy. Therefore, careful treatment is needed in order to measure the intrinsic properties after the substance has been exposed to air.

Experimental Procedures

The high-vacuum evaporation apparatus was designed to obtain a clean vacuum of the order of 10^{-8} mmHg. As the main pumping system, a NEC 40 l./sec. ion pump (1) was employed, while a usual rotary pump was applied as the fore-line. An oil trap (2) containing a molecular sieve was used in the fore-line system. An ultra-high-vacuum cut-off valve (3) between the fore-line and the high-vacuum chamber separated the latter from the atmospheric pressure during the operation. A Bayard-Alpert gauge (5) on the top of the chamber recorded the degree of vacuum.

Figure 2 illustrates the whole system schematically.

The sample holder (10) was supported by the rotary axis in the center of the base plate. Four pairs of electrodes (13) were placed on the base plate; two of them

* A farily strong oxidation of these two aromatic hydrocarbons is found under atmospheric circumstances.

4) Y. Maruyama, H. Inokuchi and Y. Harada, This Bulletin, **36**, 1193 (1963).

served for the metal evaporation, and the other two, for the evaporation of organic substances. Above the electrodes the appropriate masks for evaporation (15) were applied. Metals for the cell electrodes and the samples of organic compounds were successively evaporated on the clean glass plate fitted on the sample holder by rotating it magnetically from the outside around the center axis (9).

The glass plate mentioned above had been thoroughly cleaned with a chromic acid mixture in advance. The surface conductivity of the plate was lower than 10^{-16} Ω^{-1}. No difference in electrical resistance between the two surface-type cells, arranged as glass plate - electordes - organic film and also as glass - organic film-electrodes, could be found.

The stainless-steel bell-jar (4) was heated to about 200°C under evacuation for a few days in order to remove the adsorbed gases, mainly water vapor; the inside of the jar also warmed to about 120°C. The evaporation sources (14), the gun and the sample, were also degassed by preheating in order to make them capable of maintaining a vacuum in the order of 10^{-8} mmHg during the evaporation.

In order to measure the conductivity of the cell which had been kept in a high-vacuum evaporation vessel, silver lead wires (12) were attached to the edges of the glass plate cell by silver paste before evacuation; these wires were connected at the other ends to a Cary-31 vibration-reed electrometer through a high-resistance glass seal (17). The evaporation velocity of the organic substances was about 10—50 Å in thickness per second; the value was calculated from the increase in the electrical conduction of the film specimen during evaporation.

Either side, the top or the bottom, of the cell could be irradiated by appropriate light sources through the two windows (7) and the mirrors (8).

It took five hours to evacuate the cell from an atmospheric pressure up to about 10^{-7} mmHg, and then a few days to obtain a high vacuum of 2×10^{-8} mmHg; during this time the vessel was kept at a fairly high temperature (120°C) to facilitate degassing.

After these treatments, the metal to be used for electrodes, aluminum or gold, was evaporated to bring it in contact with the silver paste which was stuck to the silver lead wire, and then an organic substance was evaporated to form a surface-type conductivity cell. The sample dimensions were 15 mm. $\times$ 3 mm. $\times$ a few microns (thickness). Dried oxygen passed through active charcoal, itself cooled by liquid nitrogen, was then introduced into the vessel, and its effect on the conductivity was examined.

Results

Some previous results of measurements of the resistivity of quaterrylene are listed in Table I.

TABLE I.

Sample	Resistivity, Ωcm.	$\Delta\varepsilon$, eV.
Powder	10^{10}	0.6
Single crystal	10^{6}	
Sandwich-type cell	10^{13}	0.6
Surface-type cell	10^{6}	0.6

The present results show a large discrepancy from the previous ones; particularly, the effect of oxygen is rather extraordinary. The resistivity, however, fluctuated according to the conditions of the preparation of the conductivity cell. One of the typical results for the quaterrylene films was as follows: The resistivity of the film, when it was kept in a high vacuum of 4×10^{-8} mmHg, reached 1.1×10^{12} Ωcm.; this was very large compared with the previously-obtained value, $\sim10^{6}$ Ωcm.

When the evaporated film was brought in contact with a trace of oxygen at room temperature, the resistance gradually decreased with the time. When the increase in oxygen pressure was large, the decrease in resistance was also large during a short initial period; after this period, however, the rate of decrease fell off, and the resistance approached a constant value. The resistance of the quaterrylene film varied with the pressure of the ambient oxygen, as is shown in Fig. 3.

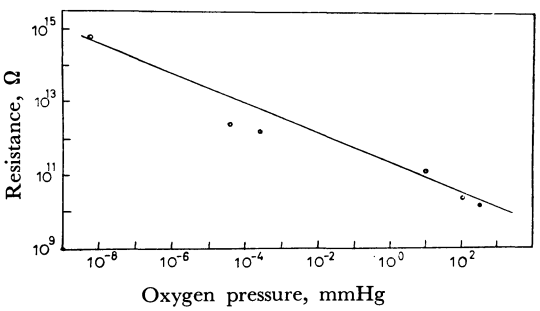

Fig. 3. The resistance of the quaterrylene film as a function of the pressure of the ambient oxygen.

When the pressure of the oxygen was lower than about 10^{-4} mmHg, the change in the resistance was reversible at room temperature. However, when the oxygen pressure increased to a point higher than this value, the process of recovering the sharply-decreased resistance was a very slow one at room temperature. Particularly when the film was exposed to oxygen in the air of an atmospheric pressure, the reduced resistance hardly increased at all after more than 1×10^{3} hrs' evacuation at room temperature; that is to say, the adsorption of oxygen on the organic crystal was practically irreversible. During this evacuation, however, when the cell was heated at about 100°C, the recovery of the resistivity was nearly attained after about 30 hr.

In Table II the resistivities of a quaterrylene surface-type film are summarized according to the ambient pressure of oxygen, P_{O_2}. No change in the resistance of the films was found when herium gas was introduced. Further, only a small effect of hydrogen gas in increasing the resistivity, or

Table II. The resistivity of the quaterrylene film as a function of the pressure of oxygen (P_{O_2})

Pressure, mmHg	Resistivity (15°C, Ωcm.)
$P_{O_2}=8\times10^{-9}$	1.1×10^{12}
$P_{O_2}\sim2\times10^{-5}$	3.5×10^{9}
$P_{O_2}\sim2\times10^{-4}$	2.7×10^{9}
$P_{O_2}=10$	2.1×10^{8}
$P_{O_2}=100$	5.0×10^{7}
$P_{O_2}=152$	3.3×10^{7}

the $\Delta\varepsilon$ value, of the oxygen-exposed film was observed.

Figure 4 shows the temperature dependence of the resistance of the quaterrylene film. The resistance was observed at temperatures from 23°C to about 120°C. With an film prepared under a vacuum of the order of 10^{-8} mmHg (Curve 1 of Fig. 4: $P_{O_2}=8\times10^{-9}$ mmHg), a linear relation was obtained between $\log R$ and $1/T$. The temperature dependence of Curve 1 can be expressed by an exponential function such as is usually found with intrinsic semiconductors:

$$R = R_0\exp(\Delta\varepsilon/2kT) \quad (1)$$

where $\Delta\varepsilon$ is the band gap for the semiconductivity. The value of $\Delta\varepsilon$ determined from the experimental results was 1.7 eV. After the ion pump had been switched off, the pressure in the vessel gradually increased to about 10^{-3} mmHg after five days. For this pressure ($P_O\sim2\times10^{-4}$ mmHg), the resistance-temperature relation curve, Curve 2, was obtained; it showed a large departure from Curve 1 in the low temperature region, which seemed to be the saturation region, but in the high temperature region it coincided exactly with Curve 1. When dried oxygen gas was introduced into the jar, linear relations, Curve 3 and Curve 4, were again obtained over the temperature range measured. However, their inclinations and resistance values were much smaller than those of Curve 1. Curve 3 was found to hold for $P_{O_2}=10$ mmHg, and Curve 4, for $P_O=100$ mmHg. Curve 5 was obtained in 10^{-3} mmHg after exposure to air under an atmospheric pressure; it corresponded to $P_{O_2}=152$ mmHg.

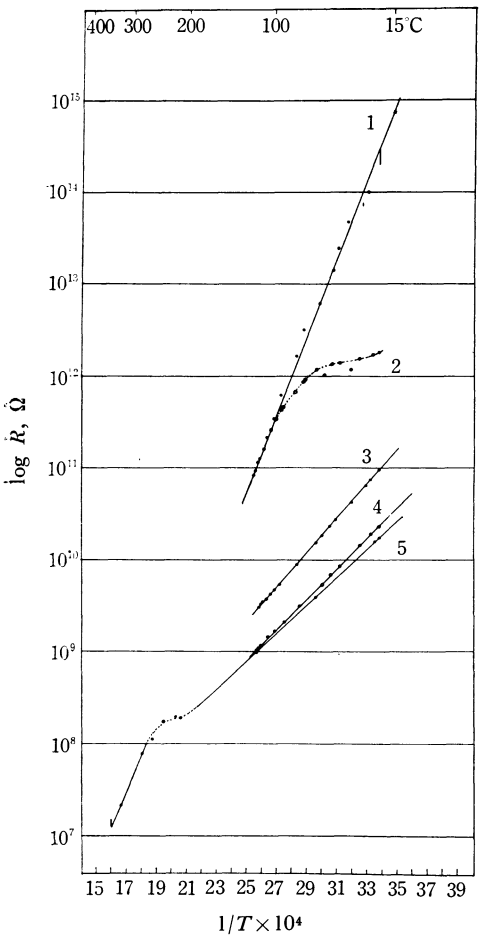

Fig. 4. The temperature dependence of the resistance of the quaterrylene film.
Curve 1 : $P_{O_2}=8\times10^{-9}$ mmHg, $\Delta\varepsilon=1.7$ eV.
Curve 2 : $P_{O_2}\sim2\times10^{-4}$ mmHg, $\varepsilon_A\sim0.03$ eV.
Curve 3 : $P_{O_2}=10$ mmHg, $\varepsilon_A=0.74$ eV.
Curve 4 : $P_{O_2}=100$ mmHg, $\varepsilon_A=0.66$ eV.
Curve 5 : $P_{O_2}=152$ mmHg, $\varepsilon_A=0.6$ eV.

This behaviour seems to be due to the adsorption of oxygen; it may be analysed by the method for extrinsic semiconductors:

$$R = R_0'\exp(\varepsilon_A/2kT) \quad (2)$$

where ε_A is the depth of the acceptor or donor levels from the valence or conduction band. The values of ε_A calculated from the slope for each curve (Curves 3, 4 and 5) are also shown in Fig. 4.
When we extended Curve 5 to the high temperature region (up to 350°C), a sharp kink in the curve was found at around 250°C; the curve at high temperatures lay exactly on the line extraporated from Curve 1.

Other organic compounds, circumanthracene,[5] tetrathiotetracene,[6] and violanthrene,[7] were also investigated briefly. The effects of oxygen were not as evident as for quaterrylene, but a decrease in the resistivities caused by the ambient oxygen was found in all compounds.

The time-response curves of the current when the electric field was applied to the specimen film were also affected by the ambient oxygen pressure. In a high-vacuum region the response curve was of a rather square type, but above 10^{-3} mmHg it was an exponential-decay curve which corresponded to the establishment of the polarization field by trapping the carriers. The photoconduction response curves against the time were also of the

7) N. Imatake, private communication.

decay type above 10^{-3} mmHg, in contrast to the clear-cut square-type response in a high vacuum.

Discussion

The experimental results described above suggest that the semiconduction of quaterrylene films may be identified as of the extrinsic type except for the case of a high vacuum. In this case it may be classified as an intrinsic type from the linear relation between log$R$ and $1/T$; its energy gap is about 1.7 eV.

As was described in presenting the results, at high temperatures the experimental points for different specimens lie on a single line, a line which coincides with Curve 1. This is a reason to assume that the energy gap, $\Delta\varepsilon = 1.7$ eV., is an intrinsic one. Further, in the optical absorption spectrum of quaterrylene film, Fig. 5, the long-wavelength-side shoulder at 710—760 mμ seems to correspond to this fundamental absorption threshold. These peaks may correspond to the 564—668 mμ peaks in the solution state spectrum of quaterrylene. The 668 mμ peaks (1.86 eV.) may be assigned to the lowest singlet excitation of the quaterrylene molecule. We obtained -0.3691 β (β: resonance integral) as this excitation energy by means of the Simple Molecular Orbital (SMO) calculation

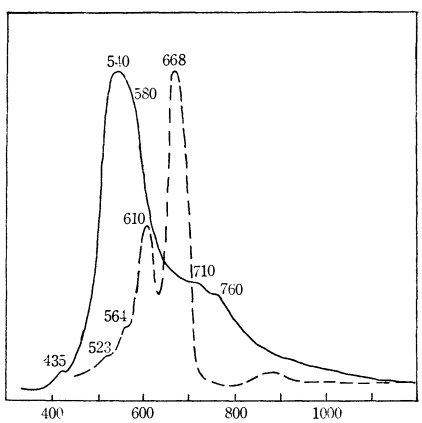

Fig. 5. The absorption spectra of the evaporated film (full line) and the solution (dashed line) of quaterrylene.

of the quaterrylene molecule. In order to fit this calculated value to the 668 mμ observed peaks, one must assume the value of -5.01 eV. for β. For the case of perylene, β is estimated as -4.11 eV. to obtain the agreement between the observed spectrum and the SMO calculation; therefore, this large value of β for quaterrylene is not unreasonable. Thus, the value of 1.7 eV., which corresponds to the lowest singlet excitation energy for the quaterrylene molecule in the solid state, can be considered to be the intrinsic band gap.

For the extrinsic semiconduction, it is not clear whether the oxygen impurity forms an acceptor or a donor level, but the former may be more likely in view of the fact that the electronegativity of oxygen is larger than that of the hydrocarbon. Therefore, as has been well established for the p-type semiconductor, the carrier density, n, may be given by the formula:

$$\frac{n(n+N_D)}{N_A-N_D-n} = \frac{N_C}{2}\exp(-\varepsilon_A/\boldsymbol{k}T) \qquad (3)$$

where N_A or N_D is the density of the acceptors or donors, ε_A is the energy depth of the acceptor level measured from the top of the valence band, and N_C is the effective state density. When $N_A \gg n \gg N_D$, Eq. 3 is reduced to the form:

$$n = \left(\frac{N_C N_A}{2}\right)^{1/2}\exp\left(-\frac{\varepsilon_A}{2\boldsymbol{k}T}\right) \qquad (4)$$

This corresponds to Eq. 2.

The adsorption of oxygen may occur not only on the surface of the film, but also in its bulk. This was verified by the measurement of the oxygen effect on a cell which had a guard ring electrode* applied to its surface.

The electrode effect is also important in this experiment.[8] The details of the study of this effect will be presented in due time.

One of the present authors, Y. M., would like to express his thanks to financial support of Sakkokai Fundation in performing study.

8) H. Inokuchi, Y. Maruyama and H. Akamatu, This Bulletin, **34**, 1093 (1961).

* The electrodes and guard ring were evaporated onto the organic film. The guard ring was located in the center line portion between two electrods; it was grounded to prevent any surface current.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1423—1426 (1966)

The Benzene-photosensitized Isomerization of Butene-2 and Pentene-2

By Masahiro TANAKA, Masaaki KATO and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Tokyo

(Received December 8, 1965)

The benzene-photosensitized *cis-trans* isomerization of butene-2 has been reinvestigated, using 2537 Å as the light source. A comparative study with pentene-2 has also been carried out. In all experiments, pentene-2 behaved very similarly to butene-2. The quantum yield of the isomerization was estimated to be 0.27 ± 0.03, irrespective of the olefin used. The following photostationary ratios of the *cis* to the *trans* isomer were obtained: $1.0_5\pm0.1$ for butene-2, and $0.9_9\pm0.1$ for pentene-2. The ratio of the initial rates of isomerization was, for both olefins, $1.1_5\pm0.1_5$, in favor of the isomerization from the *cis* to the *trans* isomer. Both ratios are very close to unity; this finding is in agreement with our previous results (M. Tanaka, T. Terao and S. Sato, *Bull. Chem. Soc. Japan*, **38**, 1645 (1965)).

The benzene-photosensitized *cis-trans* isomerization of butene-2, first observed by Cundall and Palmer,[1] provides one of the simplest examples of intermolecular energy transfer in the gas phase. Cundall et al. recently carried out[2] a more detailed study of this reaction, using pyridine as well as benzene as the sensitizer; they concluded that the isomerization takes place through a triplet-triplet interchange. We have also studied this reaction[3,4] and have obtained similar results except for the *cis-trans* photostationary ratio, ours is about unity, while Cundall et al. reported it to be 1.37 in favor of *trans*-butene-2.

Some complications may arise in this system because the fate of the photoexcited benzene[5,6] depends on the experimental conditions, such as the wavelength of the irradiating light, the pressure of the reactants, the temperature, and so on.

In the present work, we have re-examined the butene-2 reaction in order to confirm the data previously obtained; we also attempted to find the reason for the discrepancy with the results of Cundall et al. At the same time, we have also carried out a comparative study with pentene-2.

Experimental

Materials.—The benzene and *cis-* and *trans*-butene-2 used were the same as those previously reported.[4] *Cis-* and *trans-* pentene-2 supplied by the Takachiho Shoji Co., which contained 3% of various pentene isomers, were purified gas chromatographically on a 30 m. column of dimethylsulfolane on celite. After the separation on this column, no impurities could be detected.

Apparatus.—The apparatus[4] was freshly reconstructed, with special attention paid to avoiding contamination by mercury. Since neither isomerization nor decomposition could be detected on prolonged irradiation in the absence of benzene, it was evident that competitive mercury photosensitization did not occur.

The pressure was measured roughly with an oil manometer (Silicone DC 704) which absorbed the reactants to some extent. More accurate values were calculated indirectly from the chromatographic peak areas of samples of the reacting mixture. The gas chromatograph was composed of two columns; one, packed with 30 to 50 mesh celite with Silicone DC 550 as the liquid phase (3 m. long; 80°C), was used for the separation of benzene and olefins, while the other, packed with 30 to 50 mesh celite with dimethylsulfolane (20 m. long; room temperature), was used for the separation of the *cis* and *trans* isomers.

The vacuum was checked with a Pirani gauge (supplied by The Japan Vacuum Engineering Co.), its filament being always kept below 200°C in order to avoid thermal reactions. The cylindrical quartz reaction vessel was 5 cm. in diameter and of nearly the same length. Metal valves were used in a few required places to prevent the reactants from being absorbed in the stopcock grease. The vessel was illuminated with a low-pressure mercury arc through a UV 25 filter (supplied by the Toshiba Denki Co.) which cut off the light of wavelengths shorter than 2000 Å. In order to determine the incident light intensity (I_0), the previously-described mercury-photosensitized decomposition of ethylene was employed.[7,8] The fraction of the light transmitted (I_t/I_0) at various benzene pressures (p) was found to be given by the empirical expression:

$$\log_{10}(I_0/I_t) = 0.0245\,p - 0.00014\,p^2$$

where I_t is the intensity of the transmitted light. The incident intensity, I_0, was occasionally redetermined

in order to check the stability of the low-pressure mercury arc.

Results

As expected, the behavior of pentene-2 was found to be very similar to that of butene-2. Table I summarizes the initial rates of isomerization at a constant benzene pressure and at varying olefin pressures. The conversion was always kept below 5%. There is a tendency for the rate to increase slightly with an increase in the pressure. Another trend observed is that $R(cis\rightarrow trans)$, the rate of isomerization from *cis* to *trans*, seems to be slightly larger than $R(trans\rightarrow cis)$ in both olefins. The ratio is $1.1_5\pm0.1_5$.

* The values in parentheses are not used for averaging.

The effect of the variation in benzene pressure on the isomerization has also been examined, using the *cis* isomers of the two olefins as the starting compounds. The results are shown in Table II. Here I_a/I_0 is the ratio of the absorbed light intensity to the incident light intensity as calculated from the empirical relation quoted in the preceding section. The data are consistent with those of the previous paper.

Figure. 1 shows the time dependence of the *cis-trans* ratio, with olefin and benzene pressures of 3.9 and 39 mmHg respectively. It is evident that butene-2 and pentene-2 behave very similarly, except that the photostationary ratios differ. Table III summarizes the photostationary ratios.

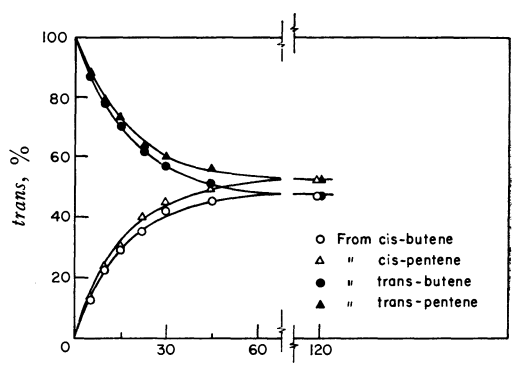

Fig. 1. The time dependence of the *cis-trans* ratio.
Olefin pressure: 3.9 mmHg, Benzene pressure: 39 mmHg.

Table III. Photostationary *cis-trans* ratios at various pressures

Benzene pressure mmHg	Olefin pressure mmHg	Stationary ratio (*trans* %)* Butene-2	Pentene-2
39.2	0.20	47	58
39.2	0.39	50	52
39.2	0.78	50	53 (53)
39.2	3.92	48 (48)	52 (53)
39.2	7.83	48	53 (52)
7.8	1.57	(48)	(53)

* The values were obtained with the *cis* isomer as the starting compound, except for the values in parentheses, which were obtained with the *trans* isomer as the starting compound.

thus obtained at various pressures of benzene and olefins. In the case of butene-2, the *cis* compound is favored, while in the case of pentene-2 the reverse is true, although the difference is not very pronounced.

Discussion

As may be seen in Table I, all the isomerization rates are nearly the same, irrespective of the pressure of the olefins, if the benzene pressure is kept constant. In other words, the fractions of the excited benzene molecules which sensitize the isomerization are almost constant over the pressure range investigated. At considerably lower pressures, however, the isomerization rate has been observed to decrease.[5]

As a basis for discussion, we will employ the same reaction mechanism as that assumed in a previous paper.[4]

$$B + h\nu \rightarrow {}^1B_n \quad (1)$$

$${}^1B_n + M \rightarrow {}^1B_0 \quad (2)$$

$${}^1B_0 \nearrow B + h\nu \quad (3)$$

$${}^1B_0 \searrow {}^3B_n \quad (4)$$

$${}^1B_0 + B \rightarrow B + B \quad (5)$$

$${}^3B_n + M \rightarrow {}^3B_0 + M \quad (6)$$

$${}^3B_0 \rightarrow B \quad (7)$$

$${}^3B_0 + B \rightarrow B + B \quad (8)$$

$${}^1B_0 + C \rightarrow B + {}^1A \quad (9)$$

$${}^3B_0 + C \rightarrow B + {}^3A \quad (10)$$

$${}^1A \xrightarrow{1-\alpha} C \quad (11)$$
$${}^1A \xrightarrow{\alpha} T$$

$${}^3A \xrightarrow{1-\beta} C \quad (12)$$
$${}^3A \xrightarrow{\beta} T$$

where B, C and T refer to benzene, *cis* and *trans*-olefins respectively, and where A refers to the excited olefin.

In this paper, we are concerned only with the *cis-trans* isomerizations. These reactions are believed to occur through the triplet-triplet[2,9] energy transfer, at least in the pressure range investigated.*1 Consequently, we will neglect reactions 9 and 11 in the following discussion.

A steady-state treatment gives the following relation:[4]

$$\frac{\beta I_a}{R_{\mathrm{isom}}} = \frac{k_3+k_4+k_5[B]}{k_4}\,\frac{k_7+k_8[B]+k_{10}[C]}{k_{10}[C]} \quad (I)$$

Equation I indicates that a plot of the reciprocal of the isomerization rate, R_{isom}, against that of the olefin pressure should give a straight line when the pressure of benzene is kept constant. These plots are shown in Fig. 2. The ratio of slope to intercept in Fig. 2 should give $(k_7+k_8[B])/k_{10}$, which is calculated to be 0.3 ± 0.1 mmHg^{-1} irrespective of the olefin used.*2 Therefore, with more than 3 mmHg of the olefin and at benzene pressures below 50 mmHg, more than 90% of the triplet-excited benzene is utilized for the *cis-trans* isomerization.

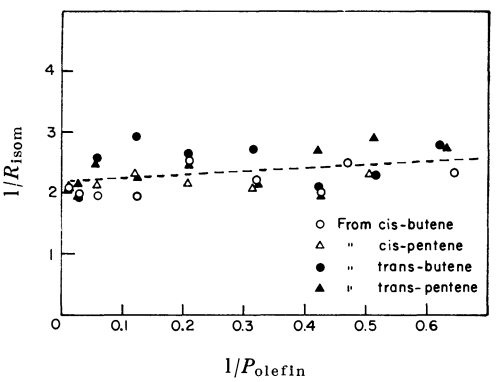

Fig. 2. The relationship between the reciprocals of the isomerization rate and of olefin pressure.

The quantum yields of isomerization are also shown in Table II. The values range from 0.25 to 0.30, again irrespective of the olefin used. Cundall et al. give 0.36 ± 0.02 for this value with butene-2.[2]

In order to discuss the photostationary ratio, it is necessary to consider also the reverse reactions:

$${}^1B_0 + T \rightarrow B + {}^1A \quad (13)$$

$${}^3B_0 + T \rightarrow B + {}^3A \quad (14)$$

9) H. Ishikawa and W. A. Noyes, Jr., *J. Chem. Phys.*, **37**, 583 (1962).

*1 The absence of products of decomposition and the pressure independence of the isomerization rates shown in Table I also support this assumption.

*2 If $k_7 \ll k_8[B]$, the value of k_{10}/k_8 can be calculated for the two olefins. The value thus calculated, $(1.5\pm0.2)\times10^2$, is about 10 times larger than that obtained in a previous paper.[4] The reason for this discrepancy is not certain, but it could be due to the very small magnitude of the slope of the plot in Fig. 2.

Here, however, reaction 13 can be disregarded for the same reason for which reactions 9 and 11 were previously neglected. From the proposed mechanism, the following relation is, then, readily obtained:

$$\frac{[C]_\infty}{[T]_\infty} = \frac{(1-\beta)k_{14}}{\beta k_{10}} \qquad \text{(II)}$$

where $[C]_\infty/[T]_\infty$ is the photostationary ratio of *cis* to *trans*. The observed values are $1.0_5\pm0.1$ for butene-2 and $0.9_5\pm0.1$ for pentene-2. On the other hand, in view of Eq. I, the ratio of the initial rates of isomerization at identical benzene pressures is:

$$\frac{R(trans\rightarrow cis)}{R(cis\rightarrow trans)} = \frac{(k_7+k_8[B])/k_{10}[C]+1}{(k_7+k_8[B])/k_{14}[T]+1}\frac{1-\beta}{\beta} \simeq \frac{1-\beta}{\beta} \qquad \text{(III)}$$

The experimental values are $1.1_5\pm0.1_5$, irrespective of the olefin used. Cundall et al. reported 1.37 ± 0.01 for both the photostationary ratio and the ratio of the initial rates of isomerization with butene-2. This would require that k_{10} be exactly equal to k_{14}. In the mercury photosensitization, quenching cross-sections of *cis*- and *trans*-butene-2 have indeed been found to be the same within the limits of experimental error.[10] Although the reason for the discrepancy in the value of the photostationary ratios as found by Cundall et al. and by us remains unknown, it seems worth mentioning that the photostationary ratio is not necessarily equal to the ratio of the initial rates of isomerization, since k_{10} need not necessarily be equal to k_{14}.

Recently, Noyes has pointed out[11] that the quantum yields of fluorescence and intersystem crossing from $^1B_{1u}$ to $^3B_{1u}$ in benzene strongly depend on the wavelength of the irradiating light in the region from 2400 to 2600 Å. This presents another potential complication in the investigated reaction.

Nuclear Magnetic Resonance Spectra of Polyethylene*

By Yoshinori KATO and Atsuo NISHIOKA

The Electrical Communication Laboratory, Musashino, Tokyo

(Received December 11, 1965)

A quantitative study of some structural irregularities of polyethylenes by an improved proton magnetic resonance method is reported. The background noise of a nuclear magnetic resonance spectrometer can be remarkably eliminated with the aid of the Mnemotron Computer of Average Transients. The total numbers of methyl groups in polyethylenes were estimated by this method using 5% solutions of the polymer in tetrachloroethylene. Spectra were obtained at about 110°C in order to suppress the thermal degradation of the polymer. The results agree well with those estimated by an infrared compensating method. Information about the species of branches and, in some cases, the number-average molecular weight of the polymer can be obtained by examining the resonance shape of methyl groups. The chemical shift difference between the triplet due to ethyl branches and that due to the other longer branches was found to be less than 0.05 p.p.m. This method can also be applied to the detection of unsaturations in polyethylene. In this case, however, the signal-to-noise ratio has to be increased to a factor of at least 20. Thus, the purification of the solvent is very important in the experiment.

It is well known that the various solid state properties of polyethylene (PE) are strongly affected by the degree of chain branching. Therefore, many papers[1-6] have been published on the determination of the number of methyl groups in PE. Most of them were based on the measurements of the infrared absorption (IR) at 1378 cm^{-1}. Of course, the lengths of the branches as well as

their numbers will be very important in characterizing this polymer.

Recently, an infrared absorption method, a double-beam compensation method,[6] has proved to be very effective in the quantitative analysis of chain branching in PE. However, in making an "absolute" measurement of the methyl group content, the IR method appears to present a serious complication because a series of samples containing known different numbers of branches are necessary for the calibration work.

On the contrary, the "absolute" concentration of methyl groups can be directly determined by the nuclear magnetic resonance (NMR) technique. We have already briefly reported that the degree of chain branching in a commercial low-density PE can be estimated by measuring the relative area of the methyl proton signal.[7] Though our results are in fairly good agreement with those obtained by the conventional IR method, the accuracy of the ordinary NMR method is not satisfactory because of some difficulties in applying it to commercial PE. Since the methyl proton signal is very weak and appears at 9.1 τ, near the strong methylene peak at 8.7 τ, an overlap occurs between them. Moreover, there is considerable background noise in some cases. Thus, an accurate evaluation of the methyl concentration is difficult. Fortunately, however, if we use a new accessory like the Mnemotron Computer of Average Transients (CAT), we can obtain an improved signal. By repetitively adding the signal under investigation, the signal-to-noise ratio (S/N) can usually be increased by a factor of the square root of the number of scans. With this technique, the exact evaluation of the methyl concentration will be possible by the NMR method.

The work to be described in the present paper was undertaken in an effort to study some structural irregularities of polyethylenes quantitatively. A preliminary experiment of the same kind was first reported by Porter et al.,[8] with respect to low-molecular-weight PE.

Experimental

Most of our works were carried out with an NMR spectrometer, Mullard SL44 Mk. II, at 40 Mc./s., together with a variable temperature probe and the CAT 400B. Each spectrum was obtained at about 110°C in order to suppress the thermal degradation of the polymer.

The samples examined were commercially-available polyethylenes, manufactured by E. I. du Pont de Nemours & Co. (Alathon 5BNC-10), the Allied Chemical Corporation (AC-617), and the Phillips Chemical Company (Marlex 6009), and some laboratory grades made by the Furukawa Chemical Ind. Co. (Staflen E570L) and the Mitsui Petrochemical Ind. Co. (Hizex E, I and K).

All the samples were reprecipitated from a xylene solution into a large amount of methanol; they were then dried in vacuo at about 60°C. Each sample was put into a specimen tube, together with tetrachloroethylene containing 2% tetramethylsilane (TMS). Then the tube was sealed and heated at 130°C for a few minutes in order to dissolve the PE completely. The concentration of the polymer solution suitable for our experiment was found to be 5% (w/w).

The CAT-averaging technique in the methyl resonance region was accomplished by using the TMS peak itself as a reference point from which a sweep of the decreasing magnetic field started. In the other cases, a sideband technique was employed to place the TMS sideband just before the region of interest in the spectrum, and an increasing magnetic field sweep was adopted. In order to complete each analysis as quickly as possible, a sweep rate of about 1.7 milligauss/sec. was chosen. A little slower sweep rate is needed, however, to avoid the relaxation wiggles which distort the line shape. The averaged spectra were read out in analog form onto an ordinary stripchart recorder. In our experiment, each division of 0.25 c. p. s. or less was stored in each memory address of the CAT.

Results and Discussion

Linearity.—The accuracy of the CAT-averaging technique depends upon the linearity of the modulator incorporated in it. This is shown in Fig. 1.

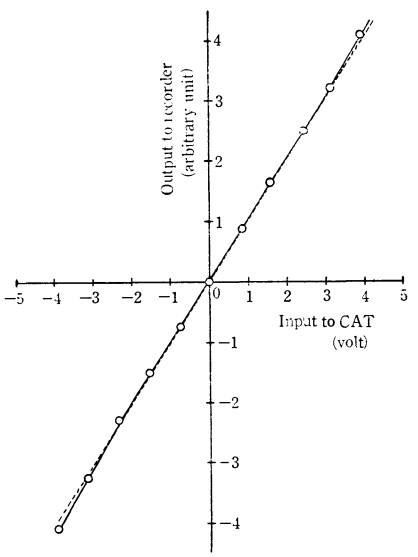

Fig. 1. Modulator linearity.

The linear relationship between the area under the averaged resonance curve and the number of runs is also shown in Fig. 2. If the magnitude of the input signal to the CAT is chosen to be less than ± 3 V., and if we take care to avoid the saturation phenomenon, the area under the resultant

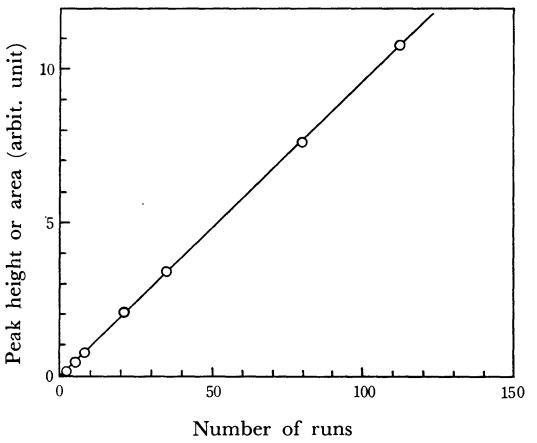

Fig. 2. Linearity check of CAT averaging technique.

peaks can be expected to be closely proportional to the number of protons involved.

Total Number of Branches.—A typical NMR spectrum of low-density PE, Alathon 5BNC-10, obtained in an ordinary way is illustrated in Fig. 3. A small signal of methyl protons can be seen

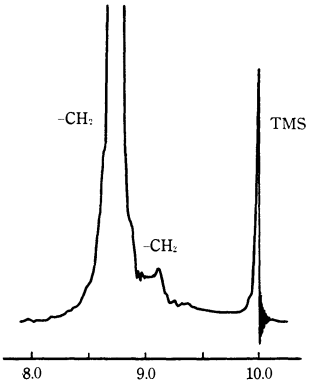

Fig. 3. NMR spectrum of polyethylene (Alathon 5BNC-10, Original pellet).

TABLE I. ESTIMATED NUMBER OF METHYL GROUPS PER 100 CARBON ATOMS IN LOW DENSITY POLYETHYLENE, ALATHON 5BNC-10

Sample	NMR	IR
Original pellet	3.0	—
Reprecipitated sample	2.3	2.8
Lower molecular weight fraction	2.2	—
Higher molecular weight fraction	1.7	—

near the very strong peak due to methylene protons. We measured the relative areas of these two peaks separately in order to estimate the number of methyl groups in the various states of this PE, which are treated differently. The results are shown in Table I. Since this sample is a low-density PE, it contains as many as 30 methyl branches for every thousand carbon atoms. As has been mentioned above, however, these results are not as accurate as those obtained by a conventional IR method.

Figure 4 illustrates the NMR spectrum of PE with CAT. In this case, a slow sweep rate of 25 milligauss per min. was adopted in order to get rid of the relaxation wiggles completely. The lower spectrum b was recorded after 19 runs, while the upper spectrum a was obtained after 30 runs. In practice the a spectrum is equivalent to that recorded after 300 runs except for the S/N, because the magnification of the ordinate is exactly ten times as large as that of the spectrum b.

Two examples of the methyl resonance patterns obtained at 40 Mc./s. are shown in Fig. 5. The methylene peak is not shown in these spectra. The methyl resonance at about 9.1 τ is located in the tail of the methylene peak. With a spectrometer operating at 100 Mc./s., this trouble can be eliminated to a great extent. In this case, however, it should be noticed that a spinning sideband of the TMS signal may appear in this region frequently. Therefore, we have to examine the spectrum very carefully. In the case of a spectrometer operating at 40 Mc./s., we can easily remove the spinning sideband, even to the low field side of the methylene signal, by increasing the rate of spinning. Shoolery[9] obtained the spectra of some *n*-hydrocarbons by a spectrometer operating at 200 Mc./s. with a superconducting electromagnet; they observed a clear-cut separation between the methyl and the methylene resonances.

The total number of runs necessary for the averaging-out of noises depends on the intensity of the signal under investigation. The spectra shown in

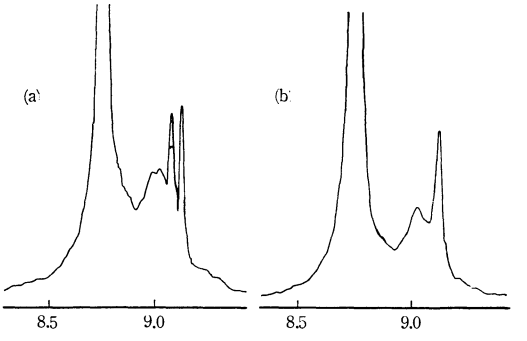
t: triplet, d: doublet

Fig. 5 were obtained after 30 and 180 runs. For a linear PE, such as Marlex 6009, it was necessary to scan more than four hundred times; this corresponds to an increase in the S/N by a factor of more than 20. Since exactly the same resonance pattern as that shown in Fig. 5 can easily be obtained by the normal NMR method without CAT when the sample of AC-617 is melted at 130°C, we are confident that this new method can be safely used in estimating the minute concentrations of several types of double bonds, such as terminal vinyl, internal vinylene and vinylidene, in PE.

On the basis of the above-mentioned linearity, we compared the intensities of the two signals including the methyl resonance in a spectrum by taking account of the number of runs. All the results are summarized in Table II. The determination of the total number of branches, i. e. CH_3/1000C, by the double-beam infrared compensating method was carried out by Mr. Kobayashi of our laboratory.

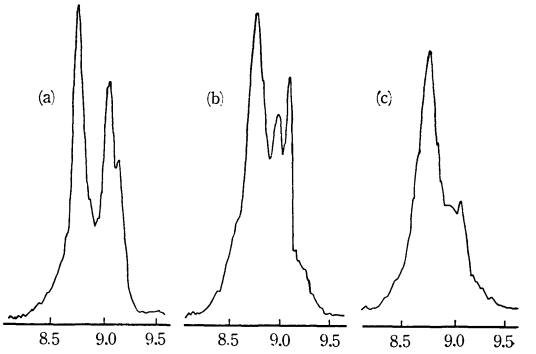
Although the results shown in the second and the fourth columns of Table II agree with each other fairly well, a small discrepancy can still be found between them, mainly in low-density PE. This is perhaps due to a distribution of methyl groups among different species of branches; that is, an ethyl branch may have quite a different absorption coefficient from that of a butyl branch. From this point of view, we would suggest that the total number of branches evaluated by the NMR-CAT method might be the most reliable one at present.

Resonance Patterns of the Methyl Groups.— The methyl proton resonance would be expected to show either a doublet or a triplet, because methyl groups in PE can form either methyl branches, or ends of the main chain and of such branches as ethyl, propyl, butyl and other long-chain branches. This consideration can be easily substantiated by an examination of some model compounds and polymers containing methyl groups such as is shown in



τ, p.p.m. τ, p.p.m.

Fig. 6. NMR spectra of (a) 5, 8-diethyl-*n*-dodecane and (b) *n*-hexadecane.



τ, p.p.m. τ, p.p.m. τ, p.p.m.

Fig. 7. NMR spectra of (a) ethylene-propylene copolymer, (b) polybutene-1 and (c) polyhexene-1.

Fig. 6. The chemical shifts of methyl protons in these compounds are summarized in Table III. The chemical shift difference between the triplets due to the ethyl branch and those due to other, longer branches is found to be less than 2 c. p. s. at 40 Mc./s. Some kinds of polymers with methyl, ethyl and butyl branches were also examined (see Fig. 7). These results concerning the chemical shifts of the triplets in ethyl, butyl and other longer branches are in accordance with the suggestion that the shape of the triplet seems to be almost independent of the length of chain branches, except for a slight shift.[10] Therefore, it is difficult to discriminate between ethyl and butyl branches by examining the resonance shapes.

TABLE III. CHEMICAL SHIFT (τ) OF METHYL PROTONS IN SOME MODEL COMPOUNDS AND POLYMERS

Compounds and polymers	Types of branches			
	Methyl	Ethyl	Butyl	Longer chain
5, 8-Diethyl-*n*-dodecane	—	9.09	9.13	—
n-Hexadecane	—	—	—	9.12
Ethylene-propylene copolymer	d {9.07, 9.17}	—	—	—
Poly-butene-1	—	t {9.00, 9.12, 9.24?}	—	—
Poly-hexene-1	—	—	9.11	—

The methyl signal of the AC-617 sample can be recognized as a distorted triplet. However, the intensity ratios of the three peaks are remarkably different from those of a typical triplet, i. e., 1 : 2 : 1. A simple illustration of the theoretical spectrum for the A_3 part of the A_3B_2 spin system is given in Fig. 8, where J and δ represent, respectively, the spin coupling constant and the chemical shift difference between the A and B nuclei. The characteristic feature is that the two outer peaks are much broader than the central one. By assuming a Lorentzian line shape with the half-height line-width of 2 c. p. s., the discrete spectrum can be synthesized into a continuous spectrum, as is shown in the middle pattern. However, the observed spectrum cannot be fully explained by the A_3B_2 spin system. For instance, the downfield peak of the theoretical spectrum seems a little higher than that of the one observed for AC-617. A part of this discrepancy can probably be removed by analyzing a more complicated spin system. The observed patterns of the methyl resonance of various kinds of polyethylenes were identified as being given in the 6th column of Table II.

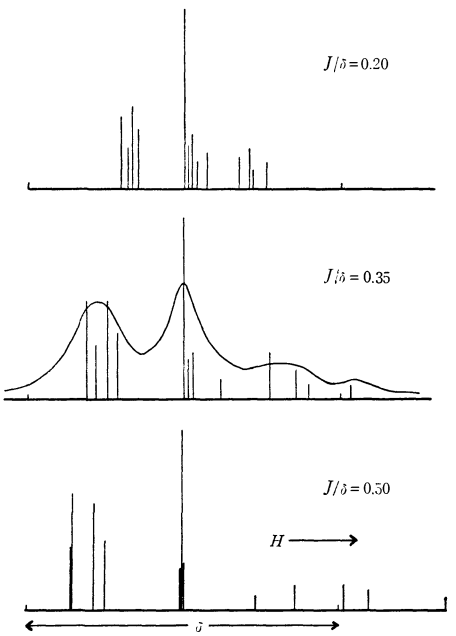


Fig. 8. Theoretical spectra for A_3 part of A_3B_2 spin system.

Figure 9 shows an example of the analysis. The

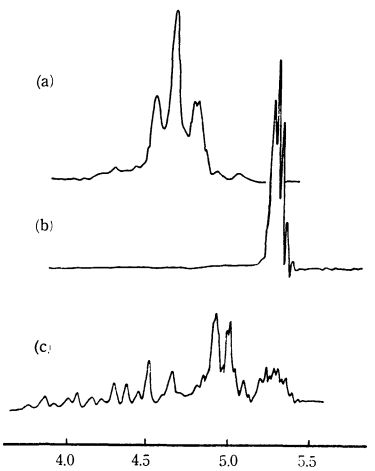
methyl resonance pattern obtained by the NMR-CAT method will give us fruitful information as to the structure of PE. For instance, the spectral pattern of the methyl groups in Staflen E570L, which is a ethylene-propylene copolymer containing a small amount of propylene, appears to be a doublet mixed with a small triplet. This finding is in good accordance with the suggested molecular structure of this copolymer. From the simple graphical treatment illustrated at the bottom right, we find that their areas are in the ratio of about ten to one, where it is assumed that the methyl NMR patterns of AC-617 and Hizex K give a typical triplet and a doublet respectively. If only the terminal methyl groups give rise to the triplet, the number-average molecular weight (M_n) of this polymer is

10) K. W. Bartz and N. F. Chamberlain, *Anal. Chem.*, **36**, 2151 (1964).

about 22000. On the other hand, an osmotic measurement of the M_n for the polymer gave a higher value of 36000. The difference may be explained by the permeation of low-molecular-weight polymers through the osmotic membrane, because it is estimated that the limit of permeation of the membrane is about 11000.

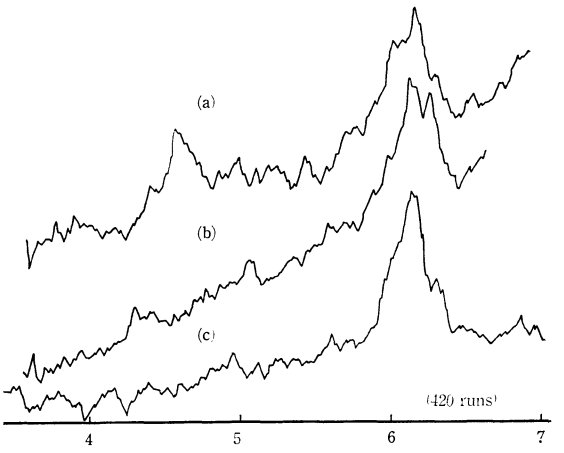
The Determination of Unsaturation.—The problem of determining the degree of bond unsaturation in PE has also been discussed mainly in the field of IR.[3,11-14] We have now also applied the NMR-CAT method to this problem. There are three types of unsaturations in PE, i. e., vinyl, vinylidene, and vinylene. Typical NMR spectra of these groups are shown in Fig. 10, using three kinds of model compounds, that is, hexadecene-1, 2-ethyl-hexene-1 and methyl linolenate, which correspond respectively to the above unsaturation groups.



τ, p.p.m.

Fig. 10. NMR patterns of unsaturations in (a) methyl linolenate, (b) 2 ethyl-hexene-1 and (c) hexadecene-1.

In Fig. 11 several results obtained by the NMR-CAT method are shown. These three spectra were recorded after 420 runs. The characteristic signals appear between 4.5 and 5.2 in the τ-scale. For instance, the NMR resonance due to vinylene unsaturation can be found at about 4.7 τ; this seems quite reasonable when compared with the chemical shift of vinylene protons in the model compounds. In these experiments the S/N has to be increased to a factor of at least 20. Having done so, the spectrum must be examined vey carefully because a small quantity of impurities in the solvent, or even in TMS, may disturb it. Thus most of the peaks at about 6.5 τ are perhaps due to the impurity in the solvent itself.



τ, p.p.m.

Summary

In the past decade the number and the length of branches in PE have been estimated mainly by IR methods. We have realized that, with the aid of the CAT, the NMR method is also very useful in studying them. In order to suppress the thermal degradation of the polymer, we obtained the NMR spectrum of PE in solution at about 110°C. In spite of a little uncertainty in our case in separating the NMR signal of methyl protons from that of methylene protons, the total numbers of methyl groups obtained by our NMR-CAT method agree well with those estimated by an infrared compensating method. The small discrepancy between them may be attributed to the IR method's ambiguous treatment of the absorption coefficient for the branch of each length.

From the resonance shape we can obtain information about the species of branches and, in some cases, the molecular weight of PE. With the NMR spectrometer operating at 40 Mc./s., however, the chemical shift difference between the triplet due to ethyl branches and that due to the other longer branches is so small that we cannot discriminate between them.

We have also applied the NMR-CAT method to the detection of the unsaturations in PE.

The authors are indebted to Mr. Kamiya of the Furukawa Chemical Industrial Co., Ltd., for his courtesy in supplying us with the sample of Staflen, to Mr. Kobayashi of our laboratory for his kind permission to quote his results using the IR method, and to Mr. Sekikawa for the osmometry.

The Electron Spin Resonance of γ-Irradiated Sodium Polyphosphate. I. The Glass and the Single Crystal

By Masaji MIURA and Akinori HASEGAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

and Tokinori FUKUI*

Research Reactor Institute, Kyoto University, Kumatori, Osaka

(Received December 13, 1965)

Under irradiation with γ-rays at room temperature, the glass of sodium polyphosphate or its single crystal doped with sodium sulfate becomes red, whereas the pure single crystal remains colorless. The glass and the doped single crystal exhibit ESR spectra which can be attributed to the hole trapped in the non-bonding orbital on the oxygen atom. The pure single crystal, of course, exhibits no ESR spectra. The determination of the degree of polymerization in the aqueous solution of the glass showed a decrease in the length of the main chain caused by the γ-ray irradiation. It may be concluded from these facts that the P–O–P bond is ruptured under the irradiation and that the effect of γ-rays on sodium polyphosphate is closely correlated with the local strain of the P–O–P bond.

A number of works have shown that a glass develops a color under exposure to ionizing radiation. The electron spin resonance (ESR), which has been remarkably developed, has become a most important means for the study of the coloration induced by such irradiation. ESR studies have already been made of irradiated silicate,[1] borate,[2] and phosphate glasses.[3] As to the γ-irradiated phosphate glass, Krapetyan and Yudin,[3a] observing the ESR spectrum consisting of a two-line hyperfine structure, have concluded that the spectrum is caused by an electron trapped on the phosphorus atom. By taking g values and coupling constants into account, however, it has recently been pointed out that the spectrum is to be attributed to the hole trapped by the oxygen atom rather than to the electron trapped by the phosphorus atom.[3b,c]

In ESR investigations, powder and glassy samples have hitherto been used. It is, however, more valuable to deal with a single crystal, since the data from the single crystal give directly not only three g values and coupling constants, but also the orientation of the radical. Therefore, the present investigation has been undertaken in order to obtain the ESR signals from the γ-irradiated single crystal of sodium polyphosphate, to analyze them, and then to compare them with those from the γ-irradiated glass. A mechanism for the coloration caused by the irradiation will also be discussed in this paper.

Experimental

The melt of sodium polyphosphate $(NaPO_3)_n$ was prepared by heating sodium dihydrogen phosphate dihydrate ($NaH_2PO_4 \cdot 2H_2O$) at 800°C for 6 hr. The glass of sodium polyphosphate was obtained by quenching the melt rapidly on dry ice; the single crystal was grown in the melt by slowly cooling and seeding it.[4] The single crystal of sodium polyphosphate doped with a small amount of sodium sulfate (the atomic ratio of sulfur to phosphorus: 1/100) was prepared by the same procedure as was used in the case of the pure single crystal. By X-ray diffractions, both of these crystals were identified as Type A of Kurrol's sodium salt,[5] which is a monoclinic crystal with the space group of $P2_1/n$ and the following crystallographic constants:

$a=12.12$ Å; $b=6.20$ Å; $c=6.99$ Å; $\beta=92°$.

These crystals have definite faces of cleavage (101) and plane ($\bar{3}01$).

These samples were exposed to γ-rays of 5×10^6 r. from a ^{60}Co source at room temperature. The ESR measurements were carried out at room temperature.

In an irradiated single crystal doped with sulfate, a rectangular co-ordination system, a'b'c', was selected for convenience; the a' axis is perpendicular to the plane of ($\bar{3}01$), the b' axis is identical with the crystallographic b axis, and c' axis is perpendicular to a' and b' axes. The crystal was rotated upon each of these axes in turn, and the ESR spectra were recorded at intervals of 15°.

The ESR spectra were obtained by using a T.D.S. (Tokyo Denki Seiki) Model T-5000 ESR spectrometer at a microwave frequency of 9225 Mc./sec. for the X-band and at one of 23000 Mc./sec. for the K-band

operating with a 100 kc./sec. field modulation. The g values were determined by comparing them with the value for DPPH, by using DPPH and a gaussmeter by means of nuclear magnetic resonance.

The viscosities of aqueous solutions of non-irradiated and γ-irradiated (7.8×10^7 r.) glasses were measured[6] at the concentration of 0.80 g./100 ml. and at 25°C (Fig. 2). The degrees of the polymerization of non-irradiated and irradiated glasses were determined by the pH titration of end groups[7] after the hydrolysis at the branching points had been completed (Fig. 3).

Results and Discussion

Sodium Polyphosphate Glass.—When sodium polyphosphate glass was irradiated with γ-rays, it turned dark red and exhibited two asymmetric ESR absorption lines (Fig. 1). The width of these

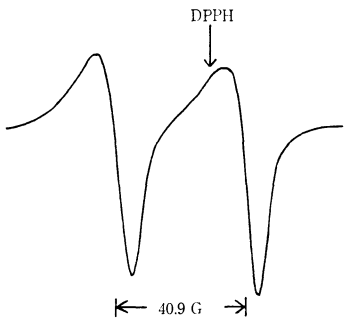

Fig. 1. The ESR spectrum of the γ-irradiated sodium polyphosphate glass at room temperature.

absorption lines at the temperature of liquid nitrogen is a little narrower than that at room temperature. These ESR spectra, as reported by some authors,[3] seem to be a doublet arising from the hyperfine structure due to the ^{31}P nucleus. The following facts are also known: they are not affected by the kind of cation and they are closely correlated with the visible absorption band with a maximum absorption at ca. 500 mμ. By taking account of the ESR spectrum consisting of the repetition of an asymmetric absorption line, this doublet is expected to have a practically isotropic coupling constant and three different g values; two of them resemble each other, and the other is the largest.

Sodium polyphosphate glass has branching points which are unstable and are easily hydrolyzed in the aqueous solution. The degradation at branching points can be detected by the decrease in the viscosity of the aqueous solution;[6] it is completed after about 8 hr. at 25°C, as may be seen in Fig. 2. This figure also shows that the γ-irradiation reduces the viscosity of the aqueous

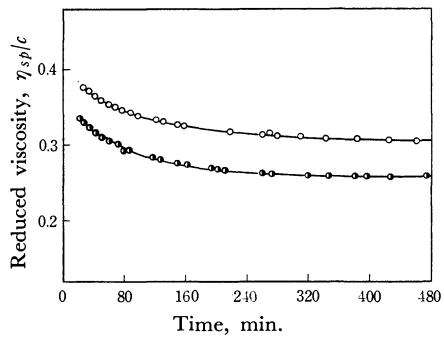

Fig. 2. Time dependence of the viscosity of the aqueous solutions of non-irradiated (○) and γ-irradiated (◑) glasses. $c=0.80$ g./100 ml. 25°C

solution of the glass without having an appreciable effect on the degradation at branching points. Further, the degree of polymerization, $\bar{n}$, decrease with the increase in irradiation dose, as is shown in Fig. 3, where $\bar{n}$ of non-irradiated glass is also

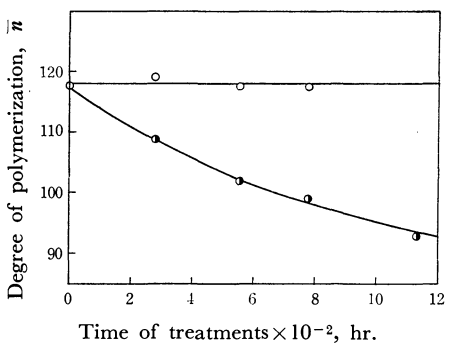

Fig. 3. The decrease in the degree of polymerization of polyphosphate glass with the irradiation dose.
○ stored in the room
◑ irradiated with γ-rays at 1×10^5 r/hr.

plotted against its storage period. These results show that the main chain of polyphosphate is ruptured by γ-irradiation.

The Pure Single Crystal of Type A of Kurrol's Sodium Salt.—The single crystsl of Type A of Kurrol's sodium salt irradiated with γ-rays at room temperature gave neither color nor any ESR absorption, even at the temperature of liquid nitrogen. When the single crystal, a part of which was covered with the glass, was irradiated, the glassy part turned dark red, but the part of the single crystal underneath acquired no color. Irradiation with γ-rays at room temperature seems to have no lasting effect on the pure single crystal of Kurrol's sodium salt.

The Single Crystal of Type A of Kurrol's Sodium Salt Doped with a Small Amount of Sodium Sulfate.—According to the facts described above, the effect of γ-rays on sodium polyphosphate seems to depend remarkably on its state, whether

6) U. P. Strauss, E. H. Smith and P. L. Wineman, *J. Am. Chem. Soc.*, **75**, 3935 (1953).
7) J. R. van Wazer, ibid., **72**, 647 (1950).

it is glassy or crystalline. In order to investigate the primary factor for this phenomenon and to speculate on the mechanism of the coloration, we attempted to inquire into the single crystal incorporating an impurity. Sodium sulfate was selected as the impurity because its structure is similar to PO_4. The single crystal of Kurrol's sodium salt doped with sodium sulfate was colorless and gave no ESR absorption before exposure to γ-rays, but it turned red and gave five ESR absorption lines after such exposure. Four of these lines show almost the same intensity, while the fifth one, which will be discussed below, shows a very weak intensity. The g values of these ESR absorption lines depend upon the orientation of the single crystal with relation to the direction of the magnetic field. The ESR spectra obtained when c' axis of the single crystal is parallel to the direction of the magnetic field are illustrated in Fig. 4, where

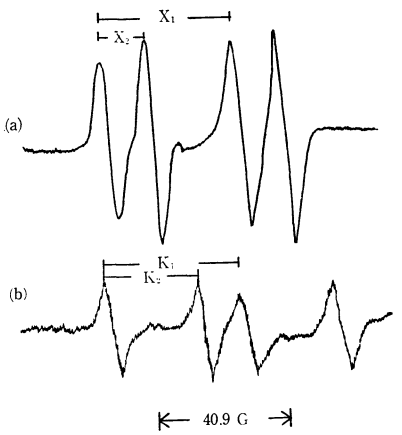

Fig. 4. The ESR spectra for the single crystal doped with sodium sulfate with (a) X-band and (b) K-band.

Fig. 4(a) shows the result with an X-band and Fig. 4(b) that with a K-band. The X_1 spacing shown in Fig. 4(a) is equal to the K_1 spacing in Fig. 4(b), and X_2 is about 1/2.5 times K_2; the frequency of the microwave has an influence not on the spacings X_1 and K_1, but on X_2 and K_2. These four absorption lines, therefore, are due to two doublets originating from two magnetically nonequivalent sites in the single crystal. These doublets are hyperfine structures arising from the interaction between an unpaired electron and a ^{31}P nucleus. The values of their coupling constants are equal to each other and are the same as that from the irradiated glass.

Figure 5 shows the variation in the four ESR absorption lines with the orientation of the single crystal in relation to the magnetic field. From these calculated components, the principal values of g and the direction cosines of the principal axes were evaluated as is shown in Table I. These principal values are different from one another;

TABLE I. PRINCIPAL VALUES AND THEIR DIRECTIONS.

Principal values	Direction cosines in a'b'c' axis system			
$g_1=2.006_4$	−0.496	−0.024	0.868	(I)
	0.995	−0.078	0.045	(II)
$g_2=2.008_2$	−0.123	0.314	0.945	(I)
	0.983	−0.157	0.024	(II)
$g_3=2.016_1$	0.912	0.111	0.395	(I)
	−0.330	0.009	−0.944	(II)

* (I) and (II) arise from two different nonequivalent sites.

g_1 is close to g_2, g_3, is largest, and all of them are larger than the value of the free spin, $g=2.0023$.

The isotropic coupling constant, A_{iso}, was determined from the spacing of the hyperfine structure, while the anisotropic coupling constant, B_{aniso}, was estimated from the anisotropic coupling components (<1 Gauss) in each plane.

$$A_{iso} = 50.9 \text{ Gauss}$$

$$B_{aniso} = 3—5 \text{ Gauss}$$

Here, this hyperfine structure is due to the interaction of an unpaired electron with a ^{31}P nucleus; the contributions to the hyperfine coupling constant from 3s and 3p electrons of the ^{31}P atom have already been calculated:[8]

$$A_{3s} = 3630 \text{ Gauss}$$

$$B_{3p} = 204.8 \text{ Gauss}$$

From the values of A_{iso}, B_{aniso}, A_{3s} and B_{3p}, the spin densities on the ^{31}P atom were calculated to be as follows:

$$\rho_{3s} = 1.1\%$$

$$\rho_{3p} \simeq 2\%$$

where ρ_{3s} and ρ_{3p} are the spin densities in the 3s and 3p orbitals of the phosphorus atom respectively. The phosphorus atom of polyphosphate, however, seems to combine with the oxygen atom by using its sp^3 hybridization.[9] Accordingly, the estimated spin density for the 3p orbital is smaller than the value expected from the 3s spin density.

The rest of the spin density, ca. 97%, may exist in the non-bonding orbital of the oxygen atom. Since the ESR spectrum of this single crystal, as will be described below, is equivalent to that of the glass which is independent of the kind of cation, the color in this single crystal seems to be due to the hole trapped in the non-bonding orbital of an oxygen atom shared by two phosphorus atoms before irradiation.

These spectra are also equivalent to that observed by Nakai.[3b] He has attributed the spectrum to

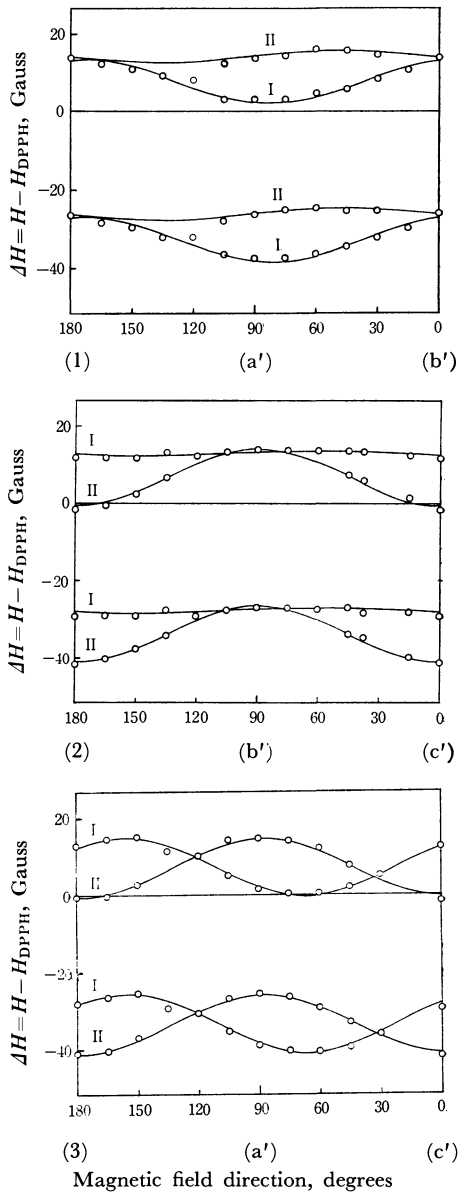

Fig. 5. Observed values and calculated curves for the hyperfine structure in the single crystal doped with sodium sulfate relative to the resonance of DPPH; the magnetic field being parallel to (1) a′b′, (2) b′c′ and (3) c′a′ planes. I and II are resonance lines arising from two nonequivalent sites respectively.

the hole trapped on the oxygen atom of the polyphosphate chain (P–O–P). Lee and Bray,[2a] from their study of the borate glass, have suggested that the hole giving rise to the ESR spectrum is trapped on an oxygen atom shared by two boron atoms, one three-coordinated and the other four-coordinated, and that it diffuses one-sidely to the latter atom. In polyphosphate glass, two phosphorus atoms at the branching point probably have somewhat different electronic configurations; therefore, it may be supposed that the hole is trapped on the oxygen shared by these two phosphorus atoms, as in the case of borate glass. However, as may be seen in Fig. 2, the branching point has an unappreciable effect upon γ-ray irradiation, though the degree of polymerization is reduced. Therefore, such a supposition as that described above seems to be unreasonable for the present case.

The crystal structure of Kurrol's sodium salt,[5] with its principal axes, is shown in Fig. 6. There

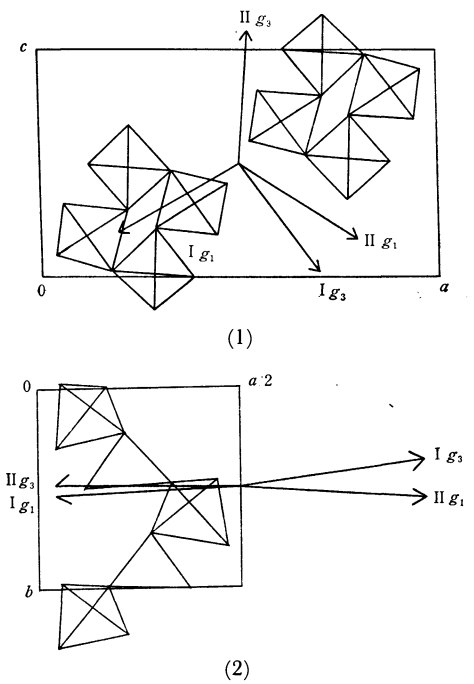

Fig. 6. The orientation of the principal axes against the crystal structure of type A of Kurrol's sodium salt; (1) and (2) are projections to ca and ab planes, where phosphorus atoms exist at the centers and oxygen atoms at the corners of these tetrahedrons.

is a considerable discrepancy between the principal axes and the non-bonding orbitals of oxygen in the main chain to be expected from the crystal structure. The following two explanations for this discrepancy are possible. One is that the center giving rise to the ESR spectrum is near the SO_4^{2-} group, which may exist at the interstice between polyphosphate chains where the chain may experience a local strain. The other is that the P–O–P bond strained by the SO_4^{2-} group is ruptured under the irradiation and that the resultant polyphosphate radicals occupy the stable orientation in the crystal. The latter interpretation is supported by the following facts: the absorption lines of the quartet, which must be expected from two equivalent phosphorus

atoms if the P–Ô–P bond is not ruptured, are not found, and the calculated principal values of g, which are different from one another and are larger than the value of the free spin, suggest that the two bonds in P–Ô–P are not equivalent to each other, but that one of these two bonds is rather ruptured.[10]

The principal values obtained from the irradiated single crystal doped with the sulfate are compared with the ESR spectrum from the irradiated glass in Fig. 7. This comparison obviously shows that

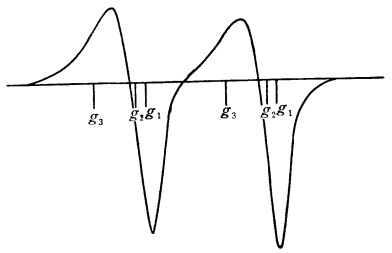

Fig. 7. The comparison between the principal values of g for the doped single crystal and the ESR spectrum of the glass.
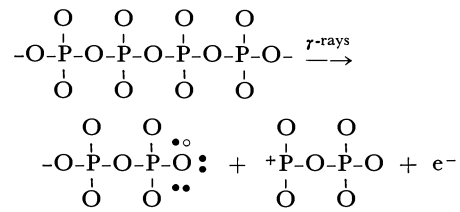
$g_1=2.006_4$ $g_2=2.008_2$ $g_3=2.016_1$

the center produced in this single crystal is just the same as that produced in the glass.

On the other hand, the degrees of the polymerization of non-irradiated and irradiated glasses were measured after thermal treatment at 250°C for 6 min. The red color of the irradiated glass was bleached by this treatment. Although the $\bar{n}$ values of both glasses decreased upon this treatment, the value of irradiated glass was distinctly smaller than that of non-irradiated glass (Fig. 8). This indicates that the degree of polymerization, which is reduced by irradiation with γ-rays, is not restored by thermal treatment, though the color is bleached.

In addition to these results, account must be taken of the facts that the ESR absorption lines with a large coupling constant expected from ·P–O–P do not appear, while an additional absorption band, probably due to the scattered electrons, appears in the ultraviolet region. Therefore, the following speculation may be given regarding the mechanism of the coloration by γ-ray irradiation. The P–O–P bond in the glass or the single crystal doped with the sulfate is ruptured under the irradiation, resulting in the production of a radical, a positive ion, and a scattered electron:



The radical thus produced gives rise to the red color.

A weak ESR absorption line in the irradiated single crystal doped with the sulfate was found at $g=2.007$; this absorption line is different from that due to a radical of the sulfate, for the latter was found at $g=2.003$ when the content of the sulfate in the glass increased. The ESR spectrum of irradiated glass has a weak shoulder at $g=2.007$ which becomes more noticeable as the degree of the polymerization of the glass decreases. These observations lead us to the conclusion that the center producing the weak absorption line at $g=2.007$ arises from the hole trapped by oxygen atoms of the end group.[11]

Thus, under irradiation with γ-rays, the single crystal doped with the sulfate acquires the same color center as in the case of the glass, whereas the pure single crystal shows no effect. These phenomena may be interpreted in the following way. The P-O-P bond in the pure single crystal is too stable to be ruptured under the irradiation with γ-rays, whereas the bond near the sulfate in the single crystal is weakened by the local strain caused by the foreign element. The bond in the glass may also be strained, as the glass was prepared by quenching the melt. Such strained bonds are easily ruptured, and the red color results from irradiation with γ-rays.

In conclusion, the effect of γ-rays on sodium polyphosphate seems to be closely correlated with the local strain of the P–O–P bond.

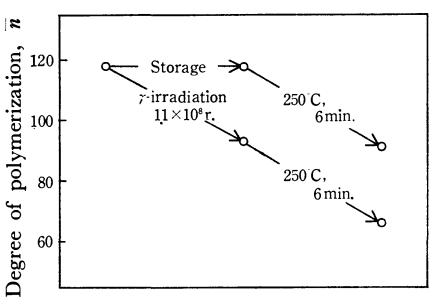


Fig. 8. The variation in the degree of polymerization of the glass with several treatments.

The authors wish to express their hearty thanks to Assistant Professor Takenobu Higashimura of Kyoto University and Assistant Professor Keiji Kuwata of Osaka University for their valuable discussions. Special thanks are also extended to Professor Satoru Tsuda and Mr. Akira Yokohata of Hiroshima University for kindly offering facilities for the γ-irradiation.

A Study of the Pyrolysis of Toluene Using ^{14}C as a Tracer

By Toyosaburo TAKEUCHI, Masakazu SAKAGUCHI* and Yoshio TOGASHI

Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received December 13, 1965)

The pyrolysis of toluene-1-^{14}C was carried out by means of the semi-flow method at 800 and at 1000°C in the presence of the registers of porcelain, and the distributions of the radioactive carbon in gaseous products and that of the deposited carbon were determined. The molar c.p.m. of methane and that of a mixture of C_2-compounds were about 1/20 of and twice the molar c.p.m. of the original toluene respectively, while the c.p.m. per gram-atom of the deposited carbon was about twice that of toluene, when the temperature of reaction was 800°C. In the case of the reaction at 1000°C, the c.p.m. per gram-atom of carbon of each product was found to be practically equal to that of the original toluene. It was proposed that methane is formed by the removal of the methyl group of toluene, and that the main source of the carbon of C_2-compounds and the deposited carbon is the 1-carbon of toluene. The equalization of the radioactive carbon in every product at a high temperature was interpreted by assuming that the tropyl radical is formed as an intermediate after the formation of the phenyl radical in the initial stage of the reaction.

The decomposition of toluene by heat, γ-ray irradiation or electron impact has been studied by many investigators.[1-8] These studies have concentrated on measurements of the reaction products, the reaction velocity and the behavior of hydrogen atoms using deuterium as a tracer; the behavior of carbon atoms in the reaction and the influence of the reaction temperature upon the mechanism remain unexplored. It is evident, however, that tracer study using ^{14}C would make the mechanism clearer. This paper is concerned with the pyrolysis of toluene by using toluene-1-^{14}C. The change in the distribution of ^{14}C in the reaction products by the change in reaction temperature from 800 to 1000°C was investigated in order to clarify the mechanism.

Experimental

The toluene-1-^{14}C used was provided by the New England Nuclear Co. Its specific activity was 1.23 mc./mmol. It was diluted to 2.63 mc./mol. with extra pure toluene before use. No impurity was detected in the sample by gas chromatography. The apparatus for the reaction is shown in Fig. 1, where A is a sample reservoir and B is the reaction tube of quartz, whose diameter and length were 2.0 cm. and 50cm. respectively. The tube was fixed in the furnace together with a thermo-junction of Pt-Pt·Rh. The registers of porcelain were packed in the tube in order to decompose the reactant readily. U_1 and U_2 are traps for the gaseous products, such as acetylene, ethylene and benzene, and U_3 is for carbon dioxide converted by the combustion of the deposited carbon to assay the ^{14}C. These traps were cooled by liquid nitrogen baths. C is a combustion tube filled with copper oxide. N and M_1 are a McLeod gauge and the manometers respectively. G is a gas-counting tube (about 50cc.), which is connected with an amplifier and a scaler. D is a safety bottle which contains mercury and is used for the admission of oxygen.

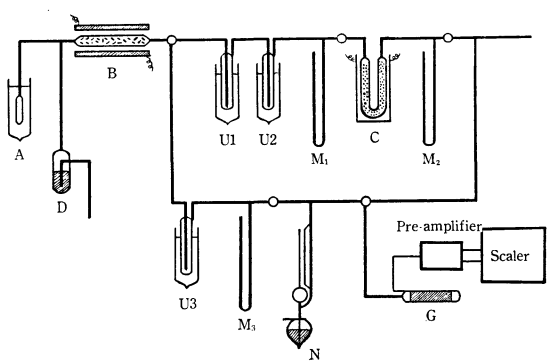

Fig. 1. Apparatus for reaction and assay of ^{14}C.

For each run of experiments, 0.2 cc. of toluene was taken in the sample reservoir. After the air dissolved in the sample had been removed by repeatedly freezing and evacuating the sample, the reaction tube was evacuated up to the pressure of 10^{-3} mmHg, keeping the reservoir at the temperature of liquid nitrogen; then the temperature of the reaction tube was raised to

1000°C. The reaction was started by replacing the bath of the sample reservoir with a water bath kept at 45°C. The vapor pressure of toluene at this temperature is 75 mmHg. When the sample in the reservoir had run out, the uncondensable gas produced, a mixture of hydrogen and methane, was passed over copper oxide in order to convert the hydrogen into water; then this water was condensed in trap U_3. The amounts of hydrogen and methane were determined by the measurement of pressures before and after the combustion by oxygen. Acetylene and ethylene were separated from benzene and toluene by replacing the liquid nitrogen baths of traps U_1 and U_2 with dry ice baths; they were collected in U_3 by cooling the trap with liquid nitrogen. The combined amount of ethylene and acetylene was determined from the pressure difference produced when the liquid nitrogen baths were replaced with the dry ice baths. The gas was then drawn off until the pressure in the reaction tube showed less than 1 mmHg; the dry ice baths were then replaced by ice baths in order to measure the amount of the mixture of benzene and toluene remaining in the traps. The deposited carbon on porcelain was oxidized to carbon dioxide by passing oxygen through the reaction tube at the temperature of 800°C.

The applied potential of the cathode of the counting tube was 2200V. PR gas, a mixture of argon and methane, was used for a filling gas. The details of the procedure of the assay of ^{14}C were the same as that adopted for tritium, which has been described elsewhere.[9]

Results and Discussion

A large amount of nonvolatile tar was found at the outlet of the reaction tube. The assay of ^{14}C in the substances was not attempted, however, because of the difficulty of collecting them completely. The amounts of gaseous products and the respective counting values are summarized in Tables I and II. The 4th column in each table indicates the molar c. p. m. of the products, while the 5th column indicates the c. p. m. per gram-atom of carbon in each molecule. In order to confirm the reliability of the results of analysis by the method mentioned above, the results were compared with those obtained by a mass spectrometer on the same sample. Nonradioactive toluene was used for this purpose. It was found that the results agree approximately with each other.

The molar c. p. m. of C_2-compounds was about twice, while that of methane was only 1/20 of, the molar c. p. m. of the original toluene in the reaction at 800°C. The small counting value of methane suggests that the carbon comes mainly from the methyl group of toluene. The conspicuously great counting value of C_2-compounds can not be explained in terms of reaction kinetics or mass effect. This point must be left for future investigation. The fact, however, would suggest that the carbon atoms of the C_2-compound come mainly from the 1-carbon atom of toluene. A similar result was reported recently by White et al.[10] Their study of the oxidation of propylene-1-^{14}C indicated that some of the reaction products must be formed from the combination of two or more radioactive fragments.

The c. p. m. per gram-atom of carbon of graphite was about twice that of toluene. This suggests that the graphite might be produced mainly from the carbon atoms of C_2-compounds.

In the case of 1000°C, the c. p. m. per gram-atom of carbon in each product was practically equal to that of toluene. This fact would suggest that each carbon atom of toluene, including that of methyl group, became equivalene in relation to each hydrogen atom at the elevated temperature. Consequently, the seven-membered ring structure of the tropyl radical can be considered, at a high temperature, as an intermediate which is produced by the rearrangement of the benzyl radical first formed. A plausible mechanism of the reaction in the initial stage may be represented as follows:

TABLE I. RESULT OF THE REACTION AT 800°C

Exp. No.	Product	Amount mol.	c.p.m./mol $\times 10^{-7}$	c.p.m./g. atom of C $\times 10^{-7}$
1	Hydrogen	0.486

where X and X′ denote the products produced successively from the benzyl radical and the tropyl radical respectively. If the velocity of step 2 is greater than that of step 3, it will be difficult for the redistribution of ^{14}C to occur. If step 2′ is included in the reaction paths of the decomposition, it seems, from a study of the configuration of carbon atoms, that benzene is not formed as the product. The experimental results suggests that the velocity of step 2 would be greater than that of step 3 at 800°C, but would be smaller at 1000°C, as is diagrammatically represented in Fig. 2. The velocity of the reverse reaction of step 3 would predominate if the reaction temperature were raised to 1000°C. If the velocity of the reverse reaction of step 3 is fairly great even at 800°C, ^{14}C should be detected more or less in methane. In addition to this, the c. p. m. per mol. of benzene would be smaller than that of the original toluene. The results of the reaction at 800°C (Table I) can be interpreted in such a way.

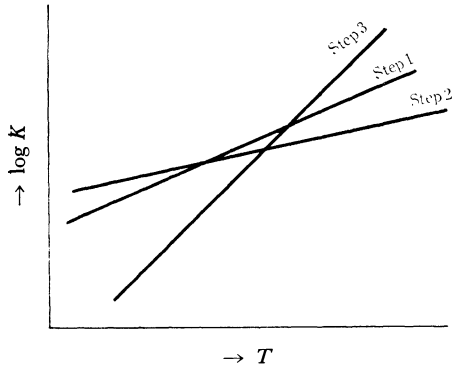

Fig. 2. Approximate representation of dependency of rate constant K in each reaction path on temperature.

Rylander et al.[6], who had found the mass number corresponding to C_7H_7 in the decomposition reaction of deuterated toluene by electron impact, proposed that the principal intermediate of the reaction is the tropylium ion. Recently, however, Gale et al.[7] have proposed, from a study by electron impact using toluene-α-^{14}C, that the tropylium ion should be excluded from the paths of the reaction. Our results would indicate that the reaction mechanisms in electron impact and thermal decomposition are substantially different from one another.

Summary

The pyrolysis of toluene at 800 and 1000°C has been made using toluene-1-^{14}C, and the ^{14}C in the reaction products of the gaseous state, such as methane, acetylene, ethylene and benzene, and the deposited carbon has been assayed.

The molar c. p. m. of methane and that of the mixture of C_2-compounds were about 1/20 of and twice that of the original toluene respectively, when the reaction was carried out at 800°C. The c. p. m. per gram-atom of the carbon in each product was practically equal to that of the original toluene when the reaction was carried out at 1000°C. It has been proposed that methane is formed by the removal of the methyl group and that the deposited carbon is formed mainly by the decomposition of C_2-compounds produced by the reaction. The formation of the tropyl radical has also been proposed as an intermediate in the reaction at a high temperature, through the formation of the benzyl radical.

The authors are grateful to Mr. Yoshisato Tezuka and Mr. Senji Watanabe for their assistance with much of the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1440—1442 (1966)

On the Asymmetric Interaction of the Optical Antipodes with Amylose

By Masaaki OHARA, Chau-Yang CHEN and Takao KWAN

Division of Physicochemical Technology, Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Tokyo

(Received December 20, 1965)

The asymmetric adsorption of D, L-mandelic acid and its homologues has been demonstrated on amylose by means of the column chromatographic and static techniques. The D-(−)-isomer of mandelic acid has been found to be adsorbed more weakly than the L-(+)-isomer; the separation factor of the two antipodes has been estimated to be 1.09 at 0°C. This value is greater than that on starch, suggesting that amylose may have a somewhat higher selectivity for the asymmetric adsorption of the optical antipodes than amylopectin. The anomalous interaction of D, L-atrolactic acid has been observed on the amylose much as in the case with starch reported previously.

It has been demonstrated,[1,2] that the optical antipodes of mandelic acid and its homologues are selectively adsorbed on starch. Since starch is composed of amylose and amylopectin, one question of interest would be which constituent is responsible for the asymmetric interaction. Another point of interest is what modes of selectivity are found in the interaction of the optical antipodes with these starch constituents.

In the present report, the authors will describe the asymmetric adsorption of D, L-mandelic acid and its homologues on amylose. The distinct difference in the adsorption affinity will be revealed between the two optical antipodes by means of the column chromatographic and static techniques. Some information concerning the asymmetric adsorption on starch will then be deduced from the results obtained.

Experimental

The Preparation of the Adsorbent.—The following route of pretreatment was taken in order to obtain the water-insoluble amylose. Commercially-available amylose was immersed in distilled water at room temperature for 24 hr. The precipitates were filtered and repeatedly washed with distilled water until the optical rotation due to water-soluble fractions of the adsorbent completely disappeared from the mother liquor. Water-insoluble precipitates were obtained and then dried in air at room temperature. The amylose sample thus obtained was 20.1% moisture. This sample was characterized in an anhydrous state by measuring the limiting viscosity number, $[\eta]$, in a dimethyl sulfoxide solution at 25°C using an Ubbelohde-type viscometer.[3] The $[\eta]=0.257\ \overline{P}_w^{0.82}$,[4] relation, was employed to calculate the mean degree of polymerization, $\overline{P}_w$, from which the viscosity-average molecular weight was estimated to be about 210000.

Chromatographic Procedure.—The compounds subjected to the chromatographic separation were as follows; DL-mandelic acid, DL-methyl mandelate, DL-ethyl mandelate and DL-atrolactic acid.

Each racemate (1—2 g.) in 50% aqueous methanol was put on an amylose column (1.6×42 cm.) at room temperature and then eluted with the same solvent. The flow rate was 4.0 ml./min. The optical rotation of each fraction (1.6 ml.) was determined by a Zeiss-Kreis polarimeter, and the concentration of mandelic acid was determined by the optical absorption at 257 mμ. In the case of DL-atrolactic acid, the optical rotation in each fraction was too small to affirm the asymmetric interaction. Therefore, some enriched L-(+)- or D-(−)-isomer samples were subjected separately to chromatographic separation.

The Determination of Adsorption Equilibrium.—3.5 g. of the pretreated amylose was immersed in 30 ml. of a DL-mandelic acid solution. The system was allowed to stand at 0°C for 48 hr., by which time equilibrium had been attained. The supernatant liquid drawn off was then analyzed. The optical rotation of the solution was measured by a Yanagimoto Model OR-20-type photomagnetic polarimeter, and the concentration of the acid was determined by the optical absorption, as has been mentioned already.

Results

The asymmetric adsorption on amylose has been distinctly revealed by the column chromatography. Figures 1 and 2 show the specific rotation, $[\alpha]_D$, of mandelic acid and its homologues with respect to each fraction of the effluent. The observed angle of rotation, α_D, and the concentration of the adsorbates, c, in g. per 100 ml. of an aqueous methanol solution are given for some of the fractions.

It is apparent that (−)-isomers of mandelic acid and its esters were eluted first, followed by (+)-isomers. On the other hand, the order of elution was reversed with DL-atrolactic acid. The same situation was observed when starch was used as

the adsorbent.[1] This behavior of the enantiomers on amylose indicates that there is a parallel relationship between adsorption affinity and configuration, since optical isomers with the same sign can be assigned the same configuration for mandelic acid and its esters.[1] The adsorption affinity of D, L-atrolactic acid may be considered to be reversed on the basis of the generally-established theory that optical isomers of mandelic acid and atrolactic acid with the same sign can be assigned to the same configuration.[5]

Table I lists typical adsorption equilibrium data obtained by a static method. The adsorption data on starch[2] are also shown for the sake of comparison.

Table I. Adsorption equilibrium data of D, L-mandelic acid on amylose and starch (T=0°C)

Absorbent	Amylose	Starch
Amount of adsorbent, g.	3.5	9.0
Initial concentration of D, L-mandelic acid, C_i, mg./ml.	100.0	100.3
Equilibrium concentration of D, L-mandelic acid, C_e, mg./ml.	95.9	91.8
Amount of D, L-mandelic acid adsorbed, W, mg./g.	64	57
Optical rotation of the solution α_D	−0.036	−0.060
Specific rotation of the solution $[\alpha]_D$	−0.375	−0.66
$\Delta W/W$ %	3.8	2.6
Separation factor f	1.09	1.06

The values of the optical rotation described here were ascribed to the net rotation values of mandelic acid in the solution, which were determined by using a glycolic acid solution (concentration: 143 mg./ml.), as has been reported previously.[2] From these negative values, it may be inferred that the D-(−)-isomer is less adsorbable than the L-(+)-isomer. This finding is consistent with those revealed by the column chromatography. The amount of D, L-mandelic acid adsorbed per gram of amylose, W, was calculated much as that absorbed on starch[2] by assuming that the amounts of water bound to the two adsorbents were of the same magnitude. ΔW is the excess amount of the (+)- over the (−)-isomer adsorbed, so that $\Delta W/W$ may indicate the degree of the asymmetric adsorption of the optical antipodes. The separation factor, f, is defined by the ratio of the adsorption equilibrium constants of the two enantiomers and is expressed as:

$$f = \frac{W_d/C_{ed}}{W_l/C_{el}}$$

where W_d and W_l are, respectively, the amounts of the L- or D-isomer adsorbed, while C_{ed} and C_{el} are the concentrations of the L- and D-isomers,

5) See Footnotes 3—6 in a previous article by Ohara et al.[1]

respectively, in the liquid phase at equilibrium. It was found to be greater on amylose than on starch.

Discussion

It is interesting to note that amylose possesses the same mode of selectivity as starch for the asymmetric adsorption of the optical antipodes.

Separate static experiments[6] similar to that on amylose have been made using potato amylopectin and starch as the adsorbents in the methanol phases. In these cases, the asymmetric adsorption of D, L-mandelic acid has also been revealed on both adsorbents, and the orders of the adsorption affinity for the enantiomers have been shown to be as follows:

$$\text{L-}(+)\text{-isomer} > \text{D-}(-)\text{-isomer}$$

Accordingly, for the enantiomers of mandelic acid, it can be concluded that the modes of selectivity on amylose and amylopectin are identical with that on starch.

Now, let us consider which constituent of the starch is more responsible for the asymmetric adsorption of D, L-mandelic acid. It is generally accepted that amylose and amylopectin constitute 20—25% and 75—80% portions of the starch granule respectively.[7] By considering that the degree of the asymmetric adsorption, $\Delta W/W$, on amylose and on starch are 3.8% and 2.6% respectively, and by assuming that the amylose portion in the granular starch possesses the same $\Delta W/W$ value as the amylose employed in this experiment, the $\Delta W/W$ value ascribed to the amylopectin portion may be estimated as 2.2—2.3%. It is suggested, therefore, that amylose may have a somewhat higher selectivity for the asymmetric adsorption of D, L-mandelic acid than amylopectin. However, no large difference in selectivity can be seen between that on amylose and that on amylopectin. These facts may be explained from the fact that there is not essentially a large difference in structure between amylose and amylopectin, although amylose (with a linear-chain structure) has a somewhat more regular structure than amylopectin (with a branched-chain structure).

Finally, we want to refer to the anomalous interaction of amylose with atrolactic acid. This phenomena cannot be found in β-cyclodextrin, which is known to be a cycloheptaose connected with α-1, 4 glucosidic linkage. It was found[8] that β-cyclodextrin builds inclusion compounds stereospecifically with a series of mandelic acid homologues. Both in the case of ethyl mandelate and in the cases of atrolactic acid and ethyl atrolactate, (−)-isomers were proved to be more strongly interacting than (+)-isomers. Cramer and Dietsche elucidated the parallelism between the affinities of the two enantiomers to β-cyclodextrin and their configurations in terms of the generally-established theory,[5] as has been mentioned already.

However, this is not the case with amylose. This may be explained from the fact that the structure of β-cyclodextrin is fixed, while that of amylose is flexible.[9]

Consequently, it may be inferred that, in the case of β-cyclodextrin, the normal interaction of D, L-mandelic acid homologues can be observed. On the other hand, in the case of amylose, the adsorption structures of the optical isomers of mandelic acid are probably different from those of atrolactic acid.

The authors wish to make a special acknowledgement of the gift of an amylose sample by the Chugai Pharm. Co. The authors also wish to express their thanks to Professor Shun-ichi Yamada of The University of Tokyo for allowing them to use the photomagnetic polarimeter. This research was supported in part by a grant-in-aid from the Ministry of Education, to which the authors' thanks are due.

Photoemission from Polycyclic Aromatic Crystals in the Vacuum Ultraviolet Region

By Yoshiya HARADA and Hiroo INOKUCHI

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received December 20, 1965)

The external photoelectric effect of thin films of tetracene, pentacene, violanthrene, quaterrylene and tetrathiotetracene was studied in the vacuum ultraviolet region. The contact potential differences between the emitters, organic crystals, and the collector (Aquadaq) were determined from the saturation points of the current-voltage characteristics. It was observed that the quantum yields of photoemission increase markedly with an increase in the photon energy, reaching the order of 10^{-2} electrons/quantum at $h\nu=10$ eV. The threshold energies were lower by 1—2 eV. than the molecular ionization potentials. An energy diagram for the external photoelectric process of organic molecular crystals was introduced on the basis of the intrinsic band model. With the aid of this diagram, the band gap energies, $\Delta\varepsilon$, were obtained from the observed values of photoemission. The values of $\Delta\varepsilon$ thus obtained were in fairly good agreement with those based on the results of the temperature dependence of semiconduction.

The external photoelectric effect is valuable in investigating the electrical properties of organic molecular crystals, because the current-voltage characteristics and the spectral distribution of the yield offer knowledge concerning the electronic structure of the crystal.

At the beginning of this century the external photoelectric effect of a polycyclic aromatic hydrocarbon, anthracene, was observed by Pochettino.[1] Subsequently Hughes[2] and Volmer[3] measured the threshold of photoemission from anthracene and reported the values of 5.6—6.2 eV. and 5.5 eV. respectively. After these works, there was no observation of photoemission from polycyclic aromatic hydrocarbons until the 1950's. In 1953, Carswell and Iredale[4] investigated the photoelectric emission from anthracene and phenanthrene. Later the external photoelectric effect of aromatic hydrocarbons was studied by Kearns and Calvin,[5] Lyons and Morris,[6] and Vilessov, Sagrubsky, and Grabusov.[7] In the latter two articles observations of the emission extending to the vacuum ultraviolet region were reported.

In this paper, we will present the external photoelectric effect of some polycyclic aromatic hydrocarbons and tetrathiotetracene in the vacuum ultraviolet region. Further, an energy diagram for the photoelectric process will be introduced in order to correlate the observed values of photoemission with the activation energy of the electrical conduction.

Experimental

The materials used in the present study are shown in Fig. 1. Violanthrene (III) and tetrathiotetracene (V) were kindly furnished by Junji Aoki and Yoshio Matsunaga respectively. The other compounds were

provided by the Rütgeswerke-Aktiengeselshaft A. G., Germany. All of the materials were carefully purified by the recrystallization and vacuum sublimation method.

The photoemission was measured with a 0.5 meter Seya-Namioka-type[8] vacuum ultraviolet monochromator.* The monochromator, with its associated equipment, is shown schematically in Fig. 2. The grating was made by Bausch and Lomb Optical Company and had 1200 lines per mm. The wavelength calibration was made using the central image of the grating (0 Å) and also the line spectra of mercury (3650.2, 3654.8 and 3663.3 Å). Further, in the vicinity of the 1800 Å peak the wavelengths of the Schumann-Runge absorption band system of oxygen were compared with those described in the literature.[9]

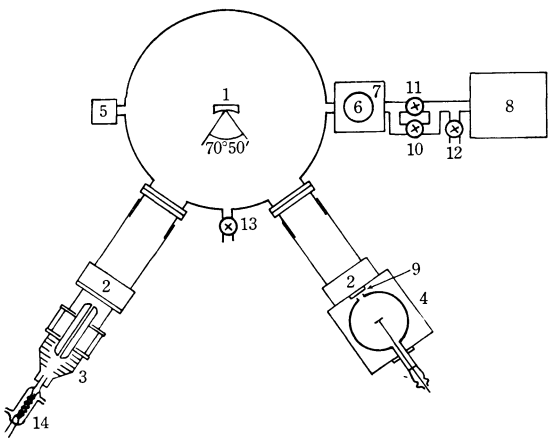

Fig. 2. Vacuum spectrometer.
1 Grating, 2 slit, 3 light source, 4 photoemission attachment, 5 Phillipps gauge, 6 oil diffusion pump, 7 cold trap, 8 rotary pump, 9 lithium fluoride window, 10 reducing valve, gate valve, 12 loak valve, 13 chamber leak valve and 14 palladium tube.

As a light source a Hinteregger-type hydrogen discharge lamp[10] was used. With the lamp turned on, pure hydrogen, prepared by passing commercial hydrogen from a cylinder through a palladium thimble (14 in Fig. 2), was introduced into the instrument. In order to control the velocity of the passage through the thimble, the Pd thimble was heated electrically by a coil wound on a Pyrex envelope. The temperature of the palladium tube and also of the opening of the reducing valve (10 in Fig. 2) were adjusted so that pure hydrogen flowed continuously through the monochromator chamber at an appropriate pressure. The normal operating pressure of hydrogen was around 4 mmHg.

In order to measure the photoemission the attachment illustrated in Fig. 3 was mounted onto the exit slit of the monochromator by iron fittings (6) and sealed vacuum-tight by means of an 0-ring (4). A photoemission cell (1) was mounted in a cylindrical chamber made of brass. A collector lead of the cell was taken out of the chamber through a glass-fused seal (3). When the vacuum spectrometer was used in the near-ultraviolet or visible region, the use of a set of filters became necessary in order to separate the higher-order spectra. From 2100 Å to 3500 Å, a potassium bromide plate was provided as a filter. Further, a glass filter was used in the wavelength region longer than 3500 Å. The filters (5) were mounted on a holder and were made exchangeable by sliding the holder shaft from the outside of the chamber.

In Fig. 4 the photocell is shown in detail. It is basically similar to that designed by Apker et al.[11] The collector is a glass sphere about 13 cm. in diameter. On the inside it is coated with a conducting layer of Aquadag (3), which was baked at 500°C in an electric furnace. After the heat treatment the work function

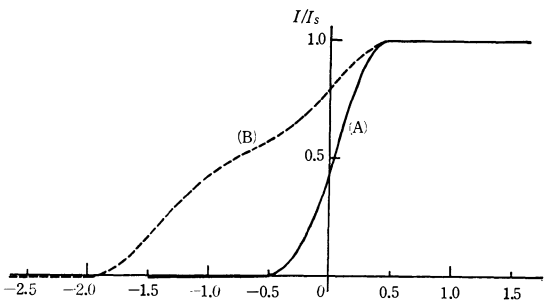
of the Aquadag layer was practically always 4.74± 0.05 eV.[11] A polycyclic organic compound (1) deposited onto a copper disk (2) (12 mm. in diameter) was fixed at the centre of the glass bulb as an emitter. The sublimation of the compound was carried out in vacuo (10^{-6} mmHg), the thickness of a film being several microns. Since the cell had no window, the pressure in it was equal to that in the attachment chamber (10^{-6} mmHg).

The absolute measurement of the light intensity was made by means of an Eppley circular thermopile, the sensitivity of which was 0.30 μV./μW. in vacuo. The output potential was amplified by a Keithley model 149 milli-micro voltmeter. The relative light intensity was obtained by measuring the fluorescence intensity from a coronene film evaporated onto a glass plate.[12] In this case the flange of the attachment chamber (7 in Fig. 3) is changed for another one which can be fitted with an end-on-type photomultiplier tube, RCA 5819. The intensity of the light source was examined in relative units after each series of photoemission measurements.

The emission current was amplified by a Cary 31 vibrating-reed electrometer.

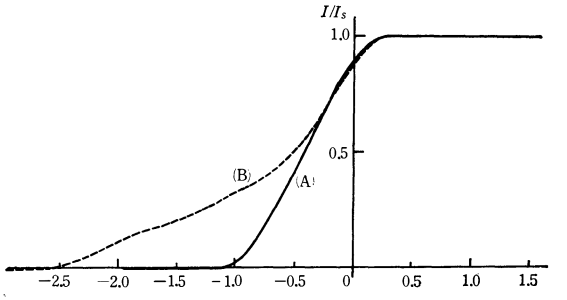
Results

Current - voltage Characteristics. — Monochromatic lights were used to observe the current-voltage characteristics of photoemission. The experimental results for tetracene and quaterrylene films are given in Figs. 5 and 6, where the ordinates



Applied potential, V.

Fig. 5. Current-voltage relation of tetracene.
hν: (A) 6.20, (B) 7.75 eV.



Applied potential, V.

Fig. 6. Current-voltage relation of quaterrylene.
hν: (A) 6.20, (B) 7.75 eV.

are normalized with the saturation current, I_s= 1.0. The values of the saturation voltage, V_s, of the current-voltage curves (the contact-potential differences between the emitters and the collector) are given in Table I for all of the compounds studied.*

Table I. Saturation voltages of the current-voltage characteristic

Compound	V_s, volt
Tetracene	0.44
Pentacene	0.41
Violanthrene	0.21
Quaterrylene	0.28
Tetrathiotetracene	0.42

In order to determine the saturation point, the data of the current-voltage relation are plotted in the form:

$$1 - (1 - I/I_s)^{1/2} \text{ vs. } V. \qquad (1)$$

The intersection of two straight lines, one in the retarding potential region, and the other in the saturation region, obtained by the plot gives the value V_s.[13]

In the case of tetracene, since the value of the electrical resistivity is high enough ($\rho_{15} = 10^{15}\Omega$cm.), the potential drop within a thick film becomes comparable to that between its surface and the collector. Hence, a thin film ($<1\ \mu$) should be examined if we are to observe the correct current-voltage characteristics. The current-voltage relations of the other compounds were successfully obtained for films with thicknesses of several microns.

Spectral Distributions of the Yield.—The spectral responses of photoemissive currents were

12) H. Inokuchi, Y. Harada and T. Kondow, *J. Opt. Soc. Am.*, **54**, 849 (1964).

* The V_s values obtained from I-V curves observed at different photon energies were in good agreement with each other.

13) L. Apker, E. Taft and J. Dickey, *Phys. Rev.*, **73**, 46 (1948).

observed under an applied potential of 10 V. In Figs. 7—9 the results for tetracene, pentacene and violanthrene are given. In each figure the ordinate shows the quantum yield, Y, derived from the ratio between the number of the incident photons and that of the emissive electrons.

The threshold values of the photon energies required for photoemission are compared in Table II with those obtained by other investigators. The table also includes the molecular ionization potentials. Since no appropriate extraporation formula has yet been found, the numerical value of the threshold was determined by extraporation to a quantum yield of 10^{-8} electrons per incident quantum.

Discussion

As may be seen from Table I, photocurrents saturate at low applied potentials (potentials of less than one volt). This phenomenon shows that the photocell used in the present study has a good

spherical geometry.

In the region of low applied potentials, the current-voltage curves are not parabolic (Figs. 5 and 6); especially, the curves for the incident light of 7.75 eV. have inflections. Hence, it can be pointed out that the kinetic energy distributions of the emitted electrons have several maxima. This behaviour of the emitted electrons will be discussed in a subsequent article.

Figures 7—9 show that the quantum yields of photoemission from tetracene, pentacene and violanthrene increase with an increase in the photon energy and reach the order of 10^{-2} electrons/quantum at $h\nu = 10$ eV. The other compounds give similar results. Thus, at large photon energies the yield of aromatic hydrocarbons is relatively large, comparable to those observed in such metals as palladium, tungsten and molybdenum.[14]

Table II shows that the threshold of photoemission (solid state ionization potential) occurs at an energy lower than by 1—2 eV. than the molecular ionization potential. As was suggested by Lyons,[15] this difference may be due to the polarization energy of the crystals by a positive centre.

14) W. C. Walker, N. Wainfan and G. L. Weisser, *J. Appl. Phys.*, **24**, 1318 (1953); **26**, 1366 (1955).

Finally, let us consider the external photoelectric process of the organic molecular crystal quantitatively using the observed threshold values of the photoemission and the saturation potential of the current-voltage curve. In the case of the intrinsic semiconductor, the energy difference, δ, between the top of the valence band and the Fermi level is a half of the band gap energy, $\Delta\varepsilon/2$, based on the results of the temperature dependence of the semiconduction. Generally, in the external photoelectric process, the Fermi level of the emitter coincides with that of the collector in thermal equilibrium. Thus, if we assume that the organic molecular crystals studied are intrinsic semiconductors, the schematic diagram in Fig. 10 can be introduced. In the diagram, the threshold energy, E_{th}, is determined by the energy difference between the

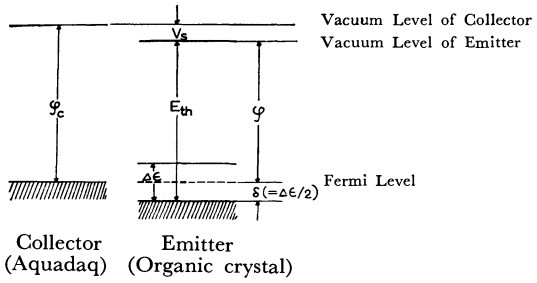

Fig. 10. Shematic diagram for the external photoelectric process of the organic molecular crystal.

vacuum level and the top of the valence band. On the other hand, the work function, φ, is the energy difference between the vacuum level and the Fermi level. Hence;

$$E_{th} = \varphi + \delta = \varphi_c - eV_s + \Delta\varepsilon/2 \qquad (2)$$

Table III. Comparison of band gap energies

Componud	$\Delta\varepsilon$, eV.[a]	$\Delta\varepsilon$, eV.[b]
Tetracene	1.88	1.70[c]
Pentacene	1.48	1.50[d]
Violanthrene	0.86	0.85[e]
Quaterrylene	0.60	0.60[f]
Tetrathiotetracene	0.48	0.41—0.57[g]

a) Present work; obtained from Eq. 3.
b) Obtained from the results of the temperature dependence of semiconduction.
c) D. C. Northrop and O. Simpson, *Proc. Roy. Soc.*, **A234**, 124 (1956). This value of $\Delta\varepsilon$ seems to be too low as compared with those of other hydrocarbons of polyacene series (anthracene, $\Delta\varepsilon = 2.7$ eV.; pentacene, $\Delta\varepsilon = 1.50$ eV.). The correct value may be near 2 eV.

where φ_c is the work function of a colloidal graphite, Aquadag. Setting $\varphi_c=4.74$ eV.,[11] we can obtain the band gap energy from the observed values of V_s and E_{th}:

$$\Delta\varepsilon = 2(E_{th} + eV_s) - 9.48\,\text{eV}. \qquad (3)$$

In Table III the $\Delta\varepsilon$ values obtained from Eq. 3 are compared with those found from the temperature dependence of the semiconduction. The table indicates that the two values of the band gap energy are in fairly good agreement. It has thus been established that the present diagram can explain the external photoelectric process of the organic molecular crystals studied.*

Future experiments on the photoemission of these crystals will be devoted to a study of the spectral dependence of the quantum yield at low temperatures and also to a detailed analysis of the current-voltage relation.

It is a great honour to dedicate this paper to Professor Masao Kotani in celebration of his sixtieth birthday.

* Recently, Maruyama and Inokuchi (This Bulletin, **39**, 1418 (1966)) studied the effect of oxygen on the semiconductivity of a quaterrylene film and found that the intrinsic semiconductor model is applicable only when there is a high vacuum ($\sim 10^{-8}$mmHg), the band gap being 1.7 eV. in this case. According to their results, the band gap of 0.6 eV. which is observed for a film exposed to air is due to an acceptor level formed by an oxygen impurity. Thus, the present results for quaterrylene should be interpreted in terms of the extrinsic band model. Since, in this case, the Fermi level is located halfway between the acceptor level and the top of the valence band, and since also, the emitted electrons from the acceptor level can be neglected, the energy diagram shown in Fig. A (instead of Fig. 10) may be considered to hold for photoemission from quaterrlene.

The Determination of Oxygen in Metals with High Melting Points by the Inert Gas Fusion Method: A Silicon Fusion Technique

By Jiro KASHIMA and Takuo YAMAZAKI

The Castings Research Laboratory, Waseda University, Shinjuku-ku, Tokyo

(Received April 12, 1965)

The determination of oxygen in metals with high melting points is important for the development of metallurgy. This paper will describe a very simplified apparatus and a procedure which gives precise results almost without a blank test. A silicon fusion technique developed by the present authors is used instead of the platinum bath method for the purpose of decomposing oxides in metals. It enables us to determine oxygen in a small quantity of a sample by the use of a highly-sensitive gas chromatograph. The amount of oxygen in the purified tantalum and niobium was determined within a standard deviation of 0.0038%. The precision established in tests of titanium samples containing 0.074% of oxygen was 0.0018%; this observed value is in good agreement with that obtained by the vacuum fusion method.

The precise determination of the oxygen content in metals with high melting points is important for the development of metallurgy. Many authors[1-5] have described complicated high-vacuum equipment and have obtained precise results by means of the platinum bath method, but for practical use some points may be improved at small expense.

Recently, various attempts, such as that using

the inert gas fusion method[9-12] without vacuum equipment and that using the neutron activation analysis method,[6-8] have been made to simplify the determination. Concerning the coulometric determination of oxygen in zirconium and zircaloy, Elbling and Goward[10] showed that Smiley's[9] platinum bath technique in a vacuum fusion method was applicable in the case of an inert gas fusion method. In other recent investigations, Holt and Goodspeed[12] have reported the simultaneous manometrical determination of oxygen and nitrogen in metals, while Evens and Fassel[13] have described a d.c. carbon-arc fusion method using gas chromatography for the determination of oxygen and nitrogen in steels.

This paper will describe a very simplified apparatus, a silicon fusion technique and a highly-sensitive method of gas chromatographic analysis. This method enables us to carry out the determination of oxygen in metals with high melting points almost entirely without a blank test; the agreement of this result with that obtained by the platinum bath method is satisfactory.

Experimental

Apparatus.—The apparatus was similar in principle to that already described[14] by the present authors. It consisted of gas extraction, collection, and measurement apparatus. The fusion products were transferred from the extraction system by means of an argon stream, and the concentration of this carbon monoxide was measured by the gas chromatograph.

A schematic diagram of the apparatus is given in Fig. 1. A high frequency induction furnace, Kokusai Denki combustion unit, Model HFT-7a, was used for the analyses of carbon and sulfur. The furnace assembly is shown in Fig. 2. A graphite crucible in the thimble was placed in a transparent silica tube, A, by controling the screw, G, attached to the pedestal, E. As the furnace was small, a special thimble was used instead of the silica thimble and graphite powder conventionally used; this new method has been found to be convenient and practical. The tube, D, was connected with a ground joint (a ball-shaped joint; 18 mm. in spherical diameter and with a 9 mm. bore) to the upper side of the silica tube, A, using a little Daifloil 50 grease and a spring clamp, I. The lower side was sealed by a metal cup, H, and a ring packing of silicone rubber. Purified argon, containing 0.0001% oxygen, 0.0005% nitrogen and 0.01 ml./l. water, was fed from a gas cylinder through a reducing valve, a needle valve, and a reference tube of the thermal conductivity cell, N. The gas was dried by passing it through columns of activated alumina, I, and phosphorus pentoxide, J. The fusion products were then transferred through a hard vinylon tube (3 mm. in diameter) to the concentration column.

Gas Chromatography. — The chromatographic column was built in a copper tube 1.5 m. long and 4 mm. in diameter. It was packed with Molecular Sieve 5A of 30—60 mesh. The column was maintained at 75°C, and the argon flow rate was 50 ml./min. The recorder had a sensitivity of 1.5 mV. at the full scale, as was determined by using a pre-amplifier; for a thermal conductivity cell of the gas chromatograph, the bridge current was adjusted to 150 mamp.

The concentration column, F, was a copper tube 50 cm. long and 4 mm. in diameter; it was packed with activated charcoal of 30—60 mesh. This column was capable of concentrating carbon monoxide in about 7 min. under ordinary conditions, with a flow rate of the argon carrier gas of 50 ml./min. at about −10°C. The concentrated gas was eluted from this column within one minute by warming it to 130°C.

Fusion Technique.—In the silicon fusion technique developed by the present authors, the platinum bath was not used. This technique was, however, found

to give just as good results as those obtained with the platinum bath technique.

Procedure.—The concentration column was pretreated at about 130°C. by passing the argon carrier gas through it at a flow rate of 50 ml./min. for about 30 min.

The sample (approximately 20 mg.), after the surface contamination had been removed, was weighed into a capsule (10—20 mg.) made of tin foil. The capsule was then introduced into a degassed graphite crucible, together with a piece of silicon (100—150 mg.), via the entrance, D. After air had been expelled from the extraction system by an argon flow for 30 sec., the concentration column was connected to the silica tube. This concentration column was dipped into a Dewar flask filled with a saline-ice solution. The inert gas fusion was started, and the fusion products were transferred into the column. A fusion time of about 3 min. was needed in order to decompose the oxides in the sample perfectly. The flow was then continued for about 5 more min., when only a trace of the gas remained. After the column had been separated from the extraction system by turning the cocks, T_2, T_3 and T_4, the column was warmed by dipping it into the boiling bath, H. It was then connected to the chromatographic column, K, by turning the gas sampling cock, L, and the concentrated gas was measured chromatographically. Typical chromatograms are shown in Fig. 3.

The carbon monoxide content was obtained from a

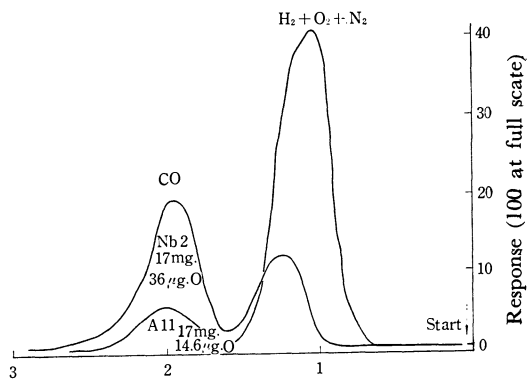

Fig. 3. Typical chromatograms of the gases collected.

peak area measured either by a planimeter or by the conventional approximate method. The oxygen content was obtained by means of the following equation;

$$\text{Oxygen, } \% = (a_t - a_b)/w \cdot K$$

where a_t: the area of the chromatogram of carbon monoxide (in sq. mm.) for the sample; a_b: the area of the chromatogram of carbon monoxide (in sq. mm.) for the blank test; w: the sample weight (in mg.); and K: the constant (0.014 μg. oxygen per sq. mm.). K was determined by using standard carbon monoxide. The standard gas is of a special grade (99.999%) which may be used for the calibration of gas chromatography or mass spectrometry. The calibration was carried out with gas samples containing 3.0—50.0 μg. of oxygen, which was introduced into the sampling cell (1.0 ml.) manometrically by the use of a silicone oil gauge (sp. gr. 0.987, at the temperature of 15°C). For simple calibration, it is also possible to use known steel samples as a secondary standard.

Results and Discussion

The accuracy of this method was tested with titanium samples. The results are compared with those obtained by other authors in Tables I and II. It was found that this method gives a good reproducibility. The determined values are in good agreement with the AED values of 0.085(A7) and of 0.103(B7) respectively for the samples of A11 and B21. The average value of the sample, B, which was obtained by ten co-operating laboratories using the vacuum fusion method was 0.098.

This method can be used for the determination of the amounts of oxygen in tantalum, niobium, molybdenum and tungsten. The results are summarized in Table III.

In order to degas the graphite crucible used in the experiment, it was necessary to heat it above 1800°C for about 10 min. In the case of the silicon fusion technique using 100—150 mg. of the metallic silicon, the time of heating was reduced (3—5 min.). The graphite-SiC crucible obtained by the above

treatment was heated at about 2000°C for 30 sec. before the experiment. If the fusion of the sample is completed within 3 min., the value obtained by the blank test is only about 0.3 μg. oxygen; this value is negligible.

molybdenum, tantalum, etc.) are very fusible at high temperatures in a large quantity of liquid silicon, because the Si-MSi_2 eutectics which are formed in the 78—95 wt.% range of silicon have melting points of 1300—1400°C (2) at very high temperatures (>1800°C), silicon and silicon-rich alloys penetrate into the crucible within one minute to form carbides. Six-hundred milligram of liquid silicon or 400 mg. of liquid silicon alloys (containing 50—100 mg. of metals) can be penetrate into a graphite crucible (about 2.5 g.) (3) semiconductor grade silicon or pure silicon (99.8—99.9 wt.% silicon containing 0.0005 wt.% of oxygen) can be used, because metals with high melting points contain large amounts of oxygen.

In the graphite-SiC crucible, the free silicon was found by a chemical method to be 1.24 wt.%. A fluorescent X-ray diffraction diagram of this crucible is given in Fig. 4. The metals contained in the crucible could be detected by studying the intensity of the sharp peak of the X-ray diagram; the intensity readings are summarized in Table IV. It was found that all of the metals combined to form carbides. By this fusion technique the oxide contained in the sample was almost decomposed when the sample was in the form of a filament, wire, powder, or a thin sheet.

The reactive metals, such as titanium, tantalum and niobium powders, fuse quickly and scatter from the crucible upon the addition of silicon; this produces erratic results. These metals must be treated with tin foil; when they are so treated, the duration of fusion increases from 20 sec. to about 50 sec. without scattering.

In the case of tantalum and niobium powder which contain more than 0.1 wt.% oxygen, the value of deviation increases slightly, as is shown in Table III. When the quantity of the sample is small, the analytical results will also be affected by the segregation of oxygen.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1453—1456 (1966)

The Routine Determination of Nitrogen in Cast Iron by the Chemical Distillation and Inert Gas Fusion Methods

By Jiro KASHIMA and Takuo YAMAZAKI

The Castings Research Laboratory, Waseda University, Shinjuku-ku, Tokyo

(Received July 3, 1965)

Although the chemical distillation method is generally employed for the determination of nitrogen in metals, it has been found that this method involves some difficulties in cast iron and pig iron samples. This paper will, therefore, describe new, repreoducible methods for the determination of nitrogen in chilled cast iron. They are the inert gas fusion and the chemical distillation methods. The most suitable sample for obtaining almost the same results with regard to ordinary cast iron by both methods was found to be a thin plate chilled by a copper mold. The accuracy of both methods was ±0.0004% when thin-plate samples containing from 0.0030 to 0.010% nitrogen were used.

The determination of nitrogen in cast iron and pig iron has acquired increasing importance in recent metallurgy. Nitrogen—one of the slightly-alloying elements in these metals—affects their mechanical properties. Therefore, it is necessary that the nitrogen contents of 0.001 to 0.01% in commercial cast irons be determined accurately by using the adequate analytical methods.

The standard method for the determination of nitrogen in metals is the chemical distillation method. This method is described in JIS G 1228 for the determination of nitrogen in steels and cast irons. The vacuum fusion method may also be used in the determination of hydrogen, oxygen and nitrogen in metals. However, in this method, the residual gas is assumed to be all the nitrogen contained in the metals, and it cannot be utilized as a standard method, for the nitrogen is not completely evolved. Therefore, the vacuum fusion and chemical distillation methods of obtaining the nitrogen contents have previously been described[1-2]; these methods involve the simultaneous determination of hydrogen, oxygen and nitrogen, as well as the determination of nitrogen alone.

Recently, in order to measure the evolved nitrogen in the vacuum fusion and the inert gas fusion methods, gas chromatography was attempted,[3-5] and some authors have described[6-8] how colorimetry can be used to find a trace of nitrogen in metals.

With regard to low carbon steels and alloy steels (with the exception of chromium and manganese steels), investigators have different opinions; one of them[9,10] considers that lower nitrogen value would be obtained in the vacuum fusion method, while others[1,2] consider that the same results would be obtained in both methods. In order to determine accurately the amount of nitrogen, the stable nitrides (e. g., CrN, Si_3N_4 and TiN) must be decomposed before analysis by suitable methods (for instance, solidifying the liquid metals quickly).

With regard to stainless steels, carbon steels and some cast irons, the results obtained by these methods have been discussed in a recent paper.[5] The nitrogen in cast iron is determined accurately in two ways. One of them is the use of a thin plate chilled from liquid metal by a copper mold in the inert gas fusion method; the other is the use of a powder prepared by crushing the chilled sample in the chemical distillation method.

Experimental

Materials.—All the cast iron samples, whose chemical compositions are shown in Table I, were prepared by means of several kinds of molds (shown in Table II). The samples were prepared as follows: (1) preparing a specimen 100 mm. in height from a chilled ingot 120 mm. in height, (2) abrasing its surface, (3) washing it in carbon tetrachloride, (4) crushing it in 9—64 mesh (until each sample is about 0.3—1.0 g.) for the inert gas fusion method, and crushing it in 100—200 mesh for the chemical distillation method, by using a mortar and a pestle of high-manganese cast steel.

hydroxide of analytical grade was dissolved in pure water obtained by passing water through an ion-exchange resin column; it was diluted to a concentration of 1/400 N. This solution was stored in a 1000-ml. polyethylene vessel connected to a Metrohm piston burette, Model E 274. The concentration of this solution was accurately determined by titrating it with benzoic acid. To reduce the nitrogen blank value, sulfuric acid and potassium sulfate of analytical grade were used; the other reagents, of the first grade, were used without purification.

Apparatus.—A Shimadzu high-frequency titrator, Model HF-1, was employed to determine the end-point. For the determination of the amount of nitrogen gas, a Yanagimoto Model GCG-100 gas chromatograph, an Ohkura Model AM 101 d. c. amplifier, and a Minneapolis-Honeywell (U. S. A.) Model SY-153 recorder were used. As the furnace used in the inert gas fusion, a Kokusai Denki Model HFT-7a high-frequency combustion furnace was adopted.

Procedure.—*The Chemical Distillation Method.*—The apparatus was that of JIS G 1228, the measurements were carried out conductometrically by means of a commercially-available H-F titrator.

The sample, approximately 5.0 g., was slowly dissolved in 100 ml. of dilute hydrochloric acid (1 : 1) in a 500 ml. round-bottom flask with a condenser, while the solution was being heated by an electric heater for at least 60 min. To determine the acid-soluble nitrogen, the solution was separated from the residue by means of a centrifuger (at 2500 r.p.m.).

The solution was then transferred to a distillating flask containing 75 ml. of a 12 N sodium hydroxide solution and 200 ml. of pure water; steam distillation was then carried out. The distillate was collected in a 100 ml. receiving flask containing 10 ml. of 1/10 N sulfuric acid. The distillation was continued until the distillate reached about 95 ml.; this process took about 20 min. The distillate was then transferred to a 100 ml. measuring flask and diluted to the mark with pure water. The amount of acid-soluble nitrogen was obtained by titrating the excess sulfuric acid with a 1/400 N standard sodium hydroxide solution; the total nitrogen content was also calculated. Actually, a 20 ml. portion of this solution was transferred to the cell of a commercially-available high-frequency titrator and was titrated with the standard sodium hydroxide solution. The residue separated by a centrifuger was treated with a mixture of 10 ml. of concentrated sulfuric acid and 5 g. of potassium sulfate at 350°C for about 2 hr., in order to decompose the acid-insoluble nitrides completely. In this way, the acid-soluble and the acid-insoluble nitrogen contents were determined.

The Inert Gas Fusion Method.—This method has been described in recent papers.[5,12] It is capable of measuring immediately the nitrogen content from the chromatogram obtained by the gas chromatographic separation in the gases evolved by the inert gas fusion. The experiments were carried out in the following ways: (1) the argon gas flow was at a rate of 50 ml./min.; (2) in the gas chromatograph experiment, the bridge current of the thermal conductivity cell was 150 mamp., the potential at the full scale of the recorder was 0.5 mV., and the temperature of the thermostat chamber was 115°C; (3) the gas chromatographic column was a copper tube (1.5 m. long and 4 mm. in dia) packed with Molecular Sieve 5A, and (4) the capacity of the gas sampling cell was 1.0 ml.

Many data concerning nitrogen were obtained from the observations based on the time-concentration curve described in a previous paper.[5] This curve was obtained by introducing 1.0 ml. portions of the argon stream into the gas chromatograph at intervals of 0.6 to 1.0 min.

Results and Discussion

The nitrogen contents of many chilled cast iron samples were determined. The plate samples prepared by the copper-chilled method, shown in Fig. 1, are suitable for the nitrogen analysis of ordinary cast iron; when they are used, the results obtained by the fusion method are almost exactly

* Application of this method does pricisely proved on the analytical method for oxygen in metals.

the same as those obtained by the solution method. The data are shown in Tables III and IV. The nitrogen contents obtained by the inert gas fusion method are somewhat lower, as is also shown in the tables. The plate samples, which show a deviation from the average value of below ±0.0004%, were preferable to the bar samples, which show a deviation from the average value of ±0.0004% in the chemical distillation method and a deviation from the average value of ±0.0006% in the inert gas fusion method. Therefore, the sample which can be used for both the methods is the plate form of the A08 sample, which is prepared by the split copper mold shown in Fig. 1.

The cast iron samples generally used for the chemical distillation method were of gray cast iron with a matrix of eutectic graphite cells growing about a cluster of kish graphite, for this sample can easily be treated by the machinery and dissolved in acid. The nitride contents in a sample are determined separately, an acid-soluble nitrogen and an acid-insoluble nitrogen. Some remarks on the determination of the acid-insoluble nitrogen demonstrated in a recent paper[5] are given below:

1) The blank value for nitrogen found in the decomposition of insoluble nitride is very high, about 50 μg., while the nitrogen contained in the sample is 50—200 μg.

2) The nitrogen contents of the sample containing insoluble nitrides show a deviation from the average value of ±0.0009%; this value is 2—9 times that found in the case of soluble nitrides obtained by the chemical distillation method.

3) It is necessary to separate graphite from the solution before steam distillation, because the graphite residue prevents the evolution of ammonia to some extent.

4) Some investigators[13,14] have had the opinion that the amount of acid-insoluble nitrogen is

13) Y. Ueda, *J. Japan Foundrymens Soc. (Imono)*, **33**, 776 (1961).

changed by the sampling methods or by the annealing treatment.

This must be taken into account before executing the conventional chemical distillation. However, if the total nitrogen content of the cast iron can be established by the simple chemical distillation procedure, without treating the acid-insoluble residue, this procedure may be most desirable. For this reason, the authors have studied this problem, particularly in connection with white cast irons.

The acid-soluble powdered samples were prepared by crushing solid white cast iron (acid-proof), but their acid-dissolution-time was not short, even though the nitrides included were almost acid-soluble compared with those of the gray cast iron. However, the deviation of the nitrogen content of each sample is small in white cast iron, as Table III shows.

In this experiment, the calibration for the nitrogen content was performed by the following procedure: the relation between the concentration and the chromatogram area was obtained by introducing into the 1.0-ml. samping cell of the gas chromatograph manometrically-measured standard nitrogen in liter glass container.

The sample chilled by the copper mold is suitable for nitrogen analysis or for spectroscopic analysis.[11] This may be due to the fact that nitrogen is dissolved in cast iron. If refractory nitrides are included in the sample, it seems impossible to decompose the nitrides perfectly by the inert gas fusion method, by which the sample is quickly heated to 2000°C. Although it may be difficult to decompose the refractory nitrides formed in some cast iron by ordinary methods, they may be decomposed by the inert gas fusion method using a platinum bath.

Hydrothermal Synthesis of Fluor-Hydroxyl Muscovite

By Tokiti Noda, Yasuhiko Endo and Masumi Ushio

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received September 8, 1965)

Fluor-hydroxyl muscovite was synthesized from a mixture of gels and chemicals of the $KAl_3Si_3O_{10}F_x(OH)_{2-x}$ composition, where $x=0$, 0.5, 1.0, 1.5 and 2.0, in the temperature range of 500—600°C under pressures ranging from 500 to 900 atm. The fluorine content of the synthetic muscovite increased with the increase in x, but the distribution coefficient of fluorine [(the fluorine content of the crystal)/(the fluorine concentration of the solution)] decreased with the increase in x, increased with the increase in the temperature of synthesis, and decreased with the increase in the pressure of synthesis. The synthetic fluor-hydroxyl muscovite crystallized mainly in 1M polymorph, and very little in 2M polymorph, at 500°C in 20 hr. The fraction of 2M muscovite increased with the increasing temperature of synthesis. The d_{005} and d_{060} lattice spacings of the mica were observed to decrease linearly with the increase in the fluorine content of the mica.

Noda and Roy[1] carried out the hydrothermal treatment of fluor-phlogopite with a dilute alkali solution, intending to replace F^- ions partially by $(OH)^-$ ions; they found that hydroxyl-phlogopite formed in a separated phase and that no appreciable ion exchange between $(OH)^-$ ions in the solution and F^- ions in the mica occurred. Noda and Ushio[2] reported the dependence of the fluorine content of fluor-hydroxyl phlogopite on the conditions of hydrothermal synthesis, such as the fluorine content of the starting material of phlogopite composition and the temperature and pressure of the synthesis. They also found a good linearity between c_0 spacing and the fluorine content of the mica.

In this paper, the results of similar experiments on fluor-hydroxyl muscovite will be reported. The syntheses of muscovite have been reported by various investigators and reviewed briefly by Yoder and Eugster.[3] Yoder and Eugster determined the pressure-temperature equilibrium in the decomposition of hydroxyl muscovite. They obtained 1 M and 2 M polymorphs of muscovite and reported that 1 M muscovite transformed to 2 M muscovite at higher temperatures, the transition temperature being in the 200—350°C range at 1000 kg./cm^2. Crowley and Roy[4] re-examined

1) T. Noda and R. Roy, *Am. Mineral.*, **41**, 929 (1956).
2) T. Noda and M. Ushio, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **67**, 292 (1964); *Geochem. Internatl.*, **1964** (1), 96.

the temperature-pressure equilibrium of hydroxyl-muscovite and determined the limits of the substitution of Mg^{2+} and Fe^{3+} ions in the muscovite structure. They also obtained muscovite by the hydrothermal treatment of a mixture of calcined gels and $KF \cdot 2H_2O$ with the requisite composition. Eitel[5] prepared fluor-muscovite from a mixture of calcined kaoline and K_2SiF_6 in a solid state reaction. According to Yoder and Eugster,[3] fluor-muscovite was obtained hydrothermally from a mixture of silica glass, γ-Al_2O_3 and K_2SiF_6 in only two runs, of one hour's duration, at 500 and 600°C. In longer runs and at higher temperatures, sanidine and topaz were usually obtained. They reported that the average fluorine content of some 60 specimens of natural muscovite was 0.58% (0.124 mol./2 mol. [F+(OH)]) and that the largest fluorine content of natural muscovite was 1.28%. The presence of fluorine ions in muscovite in place of hydroxyle ions may affect the stability range of the muscovite.

Experimental

Apparatus.—A cold-sealed test tube-type bomb[6] 12 mm. in inner diameter, 50 mm. in outer diameter and 280 mm. long and made of Stellite D6-K was used for the hydrothermal experiments. Mixtures of gels, potassium hydrogen fluoride and potassium carbonate with the requisite compositions were placed in sealed platinum tubes, 10 mm. in diameter, 90 mm. long and 0.03 mm. thick, and treated hydrothermally in the bomb. The bomb was pressurized by a pump. It was kept at a fixed temperature and pressure for 20-hr. After the treatment, the bomb was taken out of the furnace and cooled by a forced draft.

Materials.—$SiO_2 \cdot nH_2O$ gel was prepared by the hydrolysis of pure silicon tetrachloride and dried at 110°C. The dry gel was amorphous, and its water content was 5.0%. $Al_2O_3 \cdot nH_2O$ gel was precipitated by ammonia from a aluminum chloride solution which had been prepared by dissolving pure metallic aluminum (99.99%) in hydrochloric acid. The gel was washed with water and dried at 110°C. The dry gel was identified as gibbsite by the X-ray diffraction method. Its water content was 33.4%. The potassium hydrogen fluoride and potassium carbonate used were both pure chemicals. The calculated amounts of the gels and the chemicals were well mixed in an agate mortar. The water contents of the gels were determined before every mixing. The mixture contained about 18% water.

For experiments in which the fluorine distribution between crystal and solution was investigated, two parts of water was added to one part of the original mixture of the gels and the chemicals. The resulting mixture will be called the A-mix. Because the original mixture contained ca. 18% water, the ratio of solid substance to water in the A-mix was 0.38/1.00, or the ratio of the mica composition to water was 0.39/1.00, i. e., 0.97 mol./kg. water. In order to prepare specimens for the determination of lattice spacings, the original mixture moistened with a little water was used. This mix will becalled the B-mix. For both mixes, the chemical compositions given in Table I were used.

Table I. The chemical composition of the starting mixture in $KAl_2AlSi_3O_{10}(OH)_{2-x}F_x$

x	0,	0.5,	1.0,	1.5,	2.0
Abbreviations for the designation of the composition	F_0,	$F_{0.5}$,	$F_{1.0}$,	$F_{1.5}$,	$F_{2.0}$

After the hydrothermal treatment, the pH value of the coexisting solution was measured, and then the solution was separated from the solid substance. The solid substance was suspended in Thoule's solution (mercury(II) iodide - potassium iodide solution) with a density of ca. 3.0 in order to separate the heavier impurities by a centrifuge, and then the solution was diluted to a density of ca. 2.7 in order to separate the lighter impurities. For the determination of the fluorine content of the mica, the purified mica was fused with sodium carbonate and zinc oxide, the fused mass was dissolved in water, perchloric acid was added to the solution, the fluoride in the solution was distilled as fluosilicic acid, and the distillate was titrated with a thorium nitrate ($Th(NO_3)_4$) solution.[7] The fluorine in the coexisting solution was distilled from the solution and titrated with a thorium nitrate ($Th(NO_3)_4$) solution.

Results

The Distribution of Fluorine between Crystal and Solution.—The plot of the fluorine content of the muscovite crystal vs. the fluorine content of the starting mixture (dry basis) is give in Fig. 1. The fluorine content of the muscovite increases with the increase in the fluorine content of the starting mixture, x, with some variation with the temperature and pressure of syntheses.

The plot of the mean value of the fluorine content of muscovite, C_m, vs. the mean value of the fluorine concentration of the coexisting solution, C_s, is given in Fig. 2. In general, for the same starting mixture, F_x, C_m increases and C_s decreases with an increase in the temperature at a constant pressure, while C_m decreases and C_s increases with an increase in the pressure at a constant temperature. The dependences of C_m on the temperature at a constant pressure and of C_m on the pressure at a constant temperature are more clearly shown in Figs. 4a and 4b.

The plot of C_s vs. x in F_x is given in Fig. 3. The dependences of C_s on the temperature at a constant pressure and of C_s on the pressure at a constant temperature are given in Figs. 5a and 5b. C_s

× 550°C 700 atm.
△ 550°C 500 atm.

decreases with an increase in temperature and increases with an increase in pressure. The dependences of C_s on the temperature and pressure are thus just the reverse of those of C_m. Because a definite amount of the starting mixture was used in a sealed platinum tube, thus making a closed system, the increase in C_m results in the decrease in C_s. The amount of C_m relative to C_s is determined by the distribution coefficient of fluorine between crystal and solution.

The distribution coefficient (C_m/C_s) is given in Table II.

Table II. The distribution coefficient of fluorine between crystal and solution

Starting mixture	Pressure atm.	Temperature, °C 500	550	600	(B-mix)
$F_{2.0}$	500	—	2.0	—	
	700	1.0	1.2	1.6—1.9	(1.7)
	900	—	1.1	—	
$F_{1.5}$	700	1.2	—	2.2	(1.9)
$F_{1.0}$	700	6.5	—	6.1	(5.8)

The distribution coefficient increases with the increase in temperature for $F_{2.0}$ and $F_{1.5}$, but it does not change much for $F_{1.0}$. The coefficient decreases with the increase in pressure. It decreases with the increase in x.

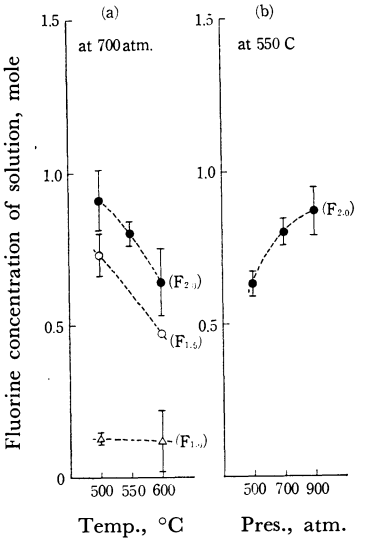

Fig. 5. Dependence of fluorine concentration of solution on (a) temperature and (b) pressure of synthesis.

Almost the same results were obtained in the experiments using the B-mix. The series experiments were carried out at 600°C under 700 atm. The dependence of C_m on x given in Fig. 6 is almost identical with that found in the A-series experiments carried out at 600°C under 700 atm. One could estimate the C_s values of B-series experiments from the C_s vs. x curve of the A-series experiments

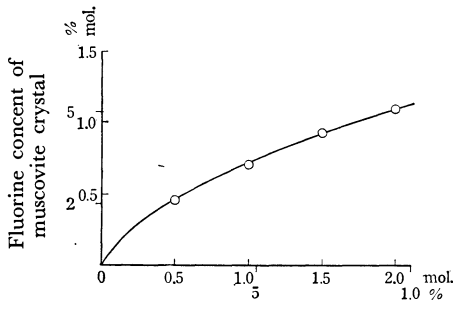

Fig. 6. Dependence of fluorine content of muscovite crystal on fluorine content of starting mixture (B-Series).

at the same temperature and pressure. The C_m/x vs. x ratio of the B-mix is shown in Fig. 7. One can see that the ratio decreases with the increase in x. Using the C_s values of Fig. 3 and the C_m values of Fig. 6, the distribution coefficients were obtained; they are given in parentheses in Table II.

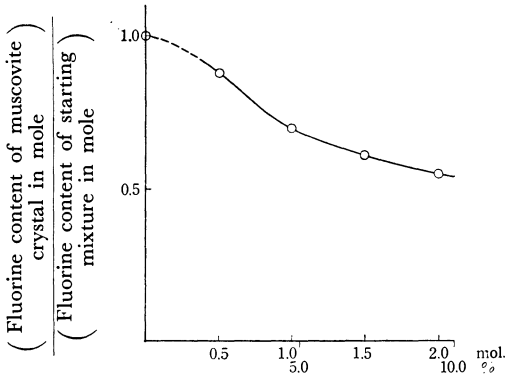

Fig. 7. Dependence of the ratio [(Fluorine content of muscovite crystal)/(Fluorine content of starting mixture)] on fluorine content of starting mixture.

The pH values of the coexisting solution increase with the increase in C_s, although there is a considerable scattering of points, as is shown in Fig. 8. There are approximate proportionalities of pH with C_s among the experiments made at 500, 550 and 600°C under 700 atm., and among the experiments made at 500, 700 and 900 atm. at 550°C for the F_2 composition. There is also an approximate proportionality of pH with x among the experiments using $F_{2.0}$, $F_{1.5}$, $F_{1.0}$ at 500°C under 700 atm. However, there are too few points to establish a definite relationship for each set of experimental conditions.

of gels of silica and alumina and potassium fluoride in muscovite composition were accompanied by small amounts of topaz and feldspar. Topaz was concentrated in the heavier fraction separated by centrifuging the mixture in Thoule's solution. Topaz crystals are seen as columnar crystals in the electron micrographs shown in Plates I and II.

Fluor-hydroxyl muscovite crystallized from fluorine-containing compositions mainly in 1 M or 1 Md polymorph, and very little in 2 M polymorph, at 500°C in 20 hr. (cf. the X-ray diffraction patterns shown in Fig. 9, Nos. 1, 4 and 7). The fraction of 2 M muscovite gradually increased with the increase in the temperature of synthesis (Fig.

9, Nos. 1, 2 and 3 for $F_{2.0}$, Nos. 4 and 5 for $F_{1.5}$, and Nos. 7 and 8 for $F_{0.5}$). The X-ray diffraction patterns of some of the muscovite specimens synthesized at 500°C from $F_{2.0}$ and $F_{1.5}$ compositions were found to be that of the 1 Md structure (Fig. 9, Nos. 1 and 4), while that of muscovite synthesized at 500°C from a $F_{0.5}$ composition was found to be of the 1 M structure (Fig. 9, No. 7). The muscovite synthesized at 600°C from $F_{2.0}$ and $F_{1.5}$ compositions was composed of almost equal amounts of 1 M and 2 M polymorphs (Fig. 9, Nos. 3 and 5), while

muscovite synthesized at 600°C from $F_{1.0}$ and $F_{0.5}$ compositions (Fig. 9, Nos. 6 and 8) contained a smaller fraction of 2 M polymorph than those obtained from $F_{2.0}$ and $F_{1.5}$ compositions. It seems that muscovite containing a larger amount of fluorine tends to crystallize more in 2 M polymorph than those containing a smaller amount of fluorine at higher temperatures. Hydroxyl-muscovite which had crystallized at 600°C in 20 hr., was 1 M polymorph. Well-developed hexagonal crystals with the prism faces on the basal plate were observed in muscovite specimens synthesized from $F_{2.0}$ and $F_{1.0}$ compositions by an electron microscope (Plates I and III). Hydroxyl-muscovite crystals had less well-developed plates (Plate IV). Also, in the case of synthetic fluor-hydroxyl phlogopite,[8] fluorine-containing mica crystallized in a better-developed form than did hydroxyl-phlogopite.

The lattice spacings of synthetic muscovite were determined by an X-ray diffractometer with copper radiation and a nickel filter, using extra pure silcon powder as an inner standard.

The plots of d_{005} and d_{060} vs. C_m are given in Figs. 10 and 11. The spacings change linearly with the change in the fluorine content of muscovite, and both plots have the same slope. The deviation of a point from the straight line may mostly be caused by an error in the determination of the fluorine content in the mica. The linear dependence of the spacings on the fluorine content in muscovite is very obvious, although Crowley and Roy[4] observed a very slight increase in the spacings of "F" mica as compared with those of "OH" mica.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1462—1468 (1966)

The Chlorine and Fluorine Contents of Tertiary Sediments on the Miura Peninsula

By Bunji IWASAKI, Kenzo KITAYAMA and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received September 15, 1965)

Tertiary sediments were collected from the Miura group on the Miura Peninsula, and the total chlorine and fluorine in these sediments were determined colorimetrically, together with the water-soluble chlorine and fluorine. There was little correlation of the contents of insoluble chlorine and fluorine in the sediments to their locations and ages. The insoluble chlorine contents of the psammitic rocks were higher than those of the pelitic rocks, whereas the insoluble fluorine contents of the former were lower than those of the latter. There seemed to be a moderately negative correlation between the contents of insoluble chlorine and fluorine in the sediments. All the sediments analyzed contained very small amounts of water-soluble fluorine (0.001 to 0.002% F). The frequency distributions of the insoluble chlorine contents in both the psammitic and pelitic rocks were lognormal.

Studies of the chlorine content of sedimentary rocks have been published by Behne,[1] Akaiwa and Nishimura,[2] and Gulyaeva.[3] On the other hand, the fluorine content of sedimentary rocks has been studied by Koritnig,[4] Kokubu,[5] and Itkina.[6] These studies have chiefly been made in order to see whether or not the two halogens are useful as geochemical indicators of marine and fresh water sediments, and to obtain the average contents of the two halogens in sediments in order to estimate their geochemical balance. For the most part, the data described above were obtained from a very few samples, without considering the distribution of the two halogens in sedimentary rocks throughout a member, a smaller unit of stratigraphy, of a region. Among these studies, however, Akaiwa

and Nishimura[2] have made clear the vertical distribution of chlorine in two regions, i. e., the Yubari district, Hokkaido, and the Niigata district.

In this paper, an attempt will be made to see how the two halogens, chlorine and fluorine, in sediments vary vertically and horizontally throughout a member of a region, and to gain some information on the behavior of the two halogens in the sedimentary and diagenetic processes.

The tertiary sediments of the Miura group on the Miura Peninsula have been well studied in detail by many geologists[7] from the geological standpoint, and it has been said that no metamorphic process has affected these sediments. This is the reason why we chose this area for determining the chlorine and fluroine contents in sediments. After having collected the samples from this area, we determined colorimetrically the content of total and two water-soluble halogens in these samples. From the basis of the results obtained, we will discuss the following: 1) the horizontal and vertical distributions of the two halogens throughout a member; 2) their distributions among the various members formed in different geological ages; 3) the effect of the particle size of the sediments on their distributions, and 4) the correlation between the chlorine and fluorine contents in these sediments.

Experimental

Sample.—The Miura group is usually divided into three formations consisting of fourteen members. All members except the Tomioka member are composed of marine sediments, e. g., siltstone, silt, sandstone, sand, pebble conglomerate, breccia, and pyroclastic sediment. The number of the samples collected from each member is shown in Table I.

Tomioka member	4
Total	91

The members are presented in the order of the stratigraphical sequence. Only a few specimens were collected from most of the members, while thirty-five samples were collected from the Zushi member in order to ascertain the horizontal and vertical distributions of its two elements. The locations of the samples are shown in Fig. 1.

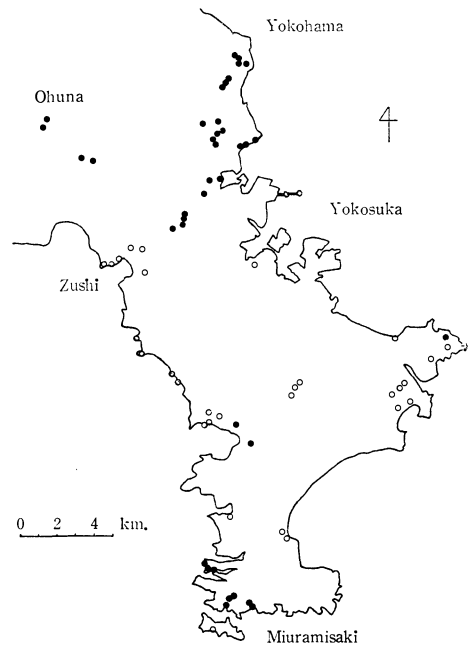

Fig. 1. The location of samples.
○ The samples from the Zushi member
● The samples from the other member

About 1 kg. of a sample was collected from each point and dried in the sunshine. Then about 100 g. of each 1 kg. was split away from the central part of the sample and crushed with a steel mortar. After about 100 g. of the sample had been quartered, about 25 g. of the sample was ground to fineness with an agate mortar in order to make a chemical analysis.

Analytical Methods.—The total chlorine was determined by the method of Iwasaki et al.[8] with some improvements. The water-soluble chlorine was determined by the thiocyanate method[9] after extraction as described in a previous paper.[10] The total fluorine was determined as follows: After about 1.00 g. of the sample had been fused with sodium peroxide in a nickel crucible, the melt was leached with a small amount of water and treated with an excess of sulfuric acid, and the fluorine was steam-distilled as fluosilicic acid. The total fluorine in distillate was colorimetrically determined by the method of Kamada et al.[11] The water-soluble

fluorine was determined by the same method after the same extraction and separation processes as were for water-soluble chlorine.

Duplicated analyses were made for all of the samples, and it may safely be said that the precision of the present determination of chlorine is within ±5%, while that of fluorine is within ±10%, over the whole range obtained here. The fluorine contents of the standard rock samples, W-1 and G-1, and the basaltic rock samples of O-sima Volcano, A-15 and H-13, were determined in order to confirm the accuracy of our present results. The results are shown in Table II, together with the results of other authors. As is shown in Table II, our values are fairly well consistent with the data of Yoshida.

Results

Tables III-a and III-b give the insoluble chlorine and fluorine contents of the tertiary sediments on the Miura Peninsula, together with the water-soluble chlorine and fluorine contents.

Table III-b shows the findings on pairs of the sediments, e. g., siltstone and sandstone, and silt and sand, which were contiguous to one another.

Abbreviation used in Tables III-a and III-b has the following meaning:
W-Cl, water-soluble chlorine content; I-Cl, insoluble chlorine content; W-F, water-soluble fluorine content. I-F; insoluble fluorine content.
B, breccia; P, pebble conglomerate; Py P, pyroclastic pebble conglomerate; Py Ss, pyroclastic sandstone; S, siltstone; Ss, sandstone.

Discussion

Water-soluble Chlorine. — As is shown in Tables III-a and III-b, the water-soluble chlorine contents range from 0.001 to 1.5%. The samples containing a large amount of water-soluble chlorine seem to be contaminated with sea-water; they were collected on or near the coast. Therefore, we will omit the data which can be suspected of being contaminated with sea-water.

The frequency diagrams of the water-soluble chlorine contents of psammitic and pelitic rocks are shown in Fig. 2.

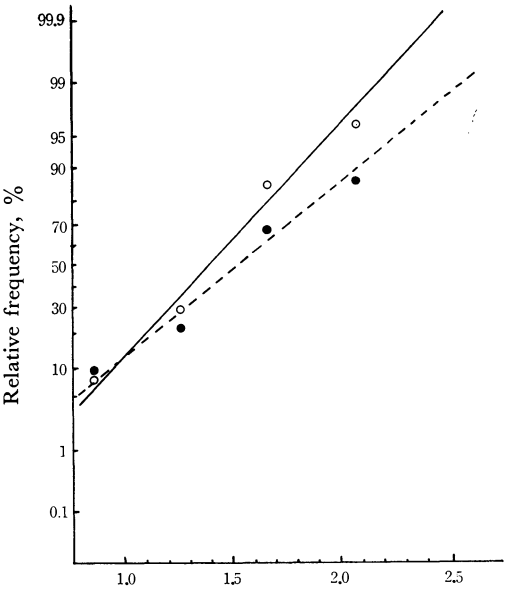

Fig. 2. Cumulative frequency distribution of water-soluble chlorine content of sediments.
○ Psammitic rocks
● Pelitic rocks

In this paper, we will divide all the sediments into two rock types. One is the psammitic rock type, in which sandstone, sand, pebble conglomerate, breccia, and pyroclastic sediment are included, and the other is the pelitic rock type, in which siltstone and silt are included. As is shown in Fig. 2, these two types of sediments show approximate lognormalities, rather than normalities. Provided that the frequency diagrams of the water-soluble chlorine contents of both psammitic and pelitic rocks obey the lognormal distribution, we obtain the geometrical means of the water-soluble chlorine contents of the two types of rock as 0.002 and 0.003 per cent respectively. From these values, it is clear that the samples which are not likely to be contaminated with sea-water contain very small amounts of water-soluble chlorine. Judging from their geometrical means, no significant effect caused by particle size was found on the distribution of water-soluble chlorine in these rock types. However, the water-soluble chlorine contents of the pelitic rocks are frequently higher than those of the psammitic rocks, as Table III-b shows. The tendency may be explained by saying that the

pelitic rocks are much more retentive of chlorine than the psammitic rocks because of the larger adsorption surface and the lower permeability of the pelitic rocks.

Insoluble Chlorine.—The insoluble chlorine contents range from 0.00 to 0.09%. Figure 3 gives the frequency diagrams of the insoluble chlorine contents of the psammitic and pelitic rocks.

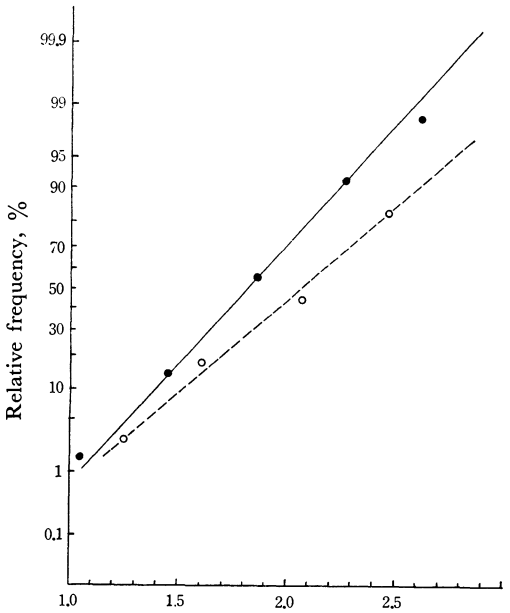

Fig. 3. Cumulative frequency distribution of insoluble chlorine content of sediments.
○ Psammitic rocks
● Pelitic rocks

They also show the lognormal distributions. We obtain the geometrical means of the insoluble chlorine contents of both psammitic and pelitic rocks as 0.011 and 0.006% respectively.

Figure 4 gives the horizontal and vertical distributions of the insoluble chlorine contents of the pelitic rocks in the Zushi member.

As Tables III-a and III-b show, the insoluble chlorine contents range from 0.00 to 0.070%. The terms "coast" and "deep sea" imply coastal and deep sea conditions during the age when the sediments were formed. The alphabetical letters on the right hand side of Fig. 4 indicate the names of the pyroclastic key beds. The thickness of the sediments among each key bed is arbitrarily drawn. We cannot find any regularity in the distribution of insoluble chlorine in the Zushi member from Fig. 4; this means that one specimen, or even a few specimens, collected from a member may not be truly indicative of the insoluble chlorine content. Also, it may be seen that the insoluble chlorine contents of the sediments can not be related to their sedimentary ages.

Water-soluble Fluorine.—As is shown in Tables III-a and III-b, the water-soluble fluorine contents range from 0.001 to 0.002%. Such small amounts of the water-soluble fluorine in the sediments are in striking contrast to the larger amounts of the water-soluble chlorine in the sediments previously shown. It is, however, clear that the water-soluble fluorine content may only slightly be influenced by the contamination of sea-water, because sea-water contains only 1.4 p.p.m. fluorine.

Assuming the extreme case that fluorite is a main carrier of fluorine in sediments and that the solution extracted is an aqueous solution saturated with

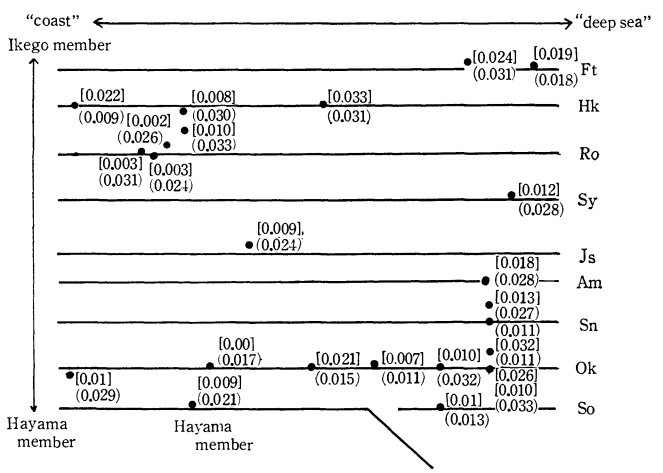

Fig. 4. Vertical and horizontal distributions of insoluble chlorine and fluorine in the Zushi member.
[ ] Insoluble chlorine content
( ) Insoluble fluorine content

Psammitic rocks
Pelitic rocks

fluorite (13.1 mg. fluorite per liter at 0°C[12]) in the case of water-soluble fluorine from 1 g. of a sample with 20 ml. of water, the fluorine content of the solution may be expected to become 0.013%. Actually, the water-soluble fluorine contents of samples were about ten times smaller than that calculated above. Therefore, it is thought that fluorine in these sediments does not exist as fluorite but as other forms.

Insoluble Fluorine.—As Tables III-a and III-b show, the insoluble fluorine contents of the sediments range from 0.001 to 0.042%. Figure 5 gives the frequency diagrams of the insoluble fluorine contents of both psammitic and pelitic rocks.

They seem to have neither normal nor lognormal distributions. Provided that they show normalities, we obtain the arithmetical means of psammitic and pelitic rocks as 0.025 and 0.014% respectively. The mean insoluble fluorine content of the former is twice as much as that of the latter. As may be seen in Fig. 5 and Table III-b, it is evident that the insoluble fluorine contents of the pelitic rocks are higher than those of the psammitic rocks, as has already been pointed out by Koritnig.[4] It is generally believed that the amounts of OH-bearing minerals in pelitic rocks are higher than those of psammitic rocks; thus, assuming that hydroxide ions in these minerals are replaced by fluoride ion in an aqueous solution, it may be reasonable to say that fluorine is concentrated in pelitic rocks.

Figure 4 gives the horizontal and vertical distributions of the insoluble fluorine in the Zushi member. As is shown in Tables III-a and III-b, the insoluble fluorine contents range from 0.009 to 0.033%. Figure 4 does not, however, show any trend in the distribution of insoluble fluorine in the Zushi member horizontally or vertically.

The Correlation between the Content of Insoluble Chlorine and of Fluorine in the Sediments.—Figure 6 shows the correlation between the contents of insoluble chlorine and fluorine in the sediments.

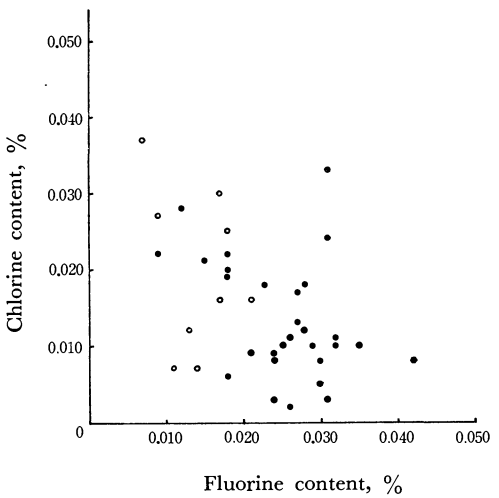

Fig. 6. Relationship between the contents of insoluble chlorine and fluorine of sediments.
○ Psammitic rocks
● Pelitic rocks

This shows a moderately negative correlation. Indeed, we have very little knowledge of the properties of OH-bearing minerals in sedimentary rocks, by which property some sort of replacement reaction might be expected to occur between halide and hydroxide ions. However, if we simply assume that the effective amount of hydroxide ions in the

12) F. Kohlrausch, *Z. physik. Chem.*, **50**, 355 (1904-5); **64**, 121 (1908).

sediments is constant and that the hydroxide ions are completely replaced by fluoride and chloride ions, there will be a negative correlation between the contents of fluorine and chlorine. As has been seen in Fig. 6, fluorine is more concentrated in pelitic rocks than in psammitic rocks, and concentrations above 0.02% fluorine are found exclusively in pelitic rocks. This may be attributed to the larger electronegativity and the smaller ionic radius of the fluoride ion than those of the chloride ion.

Conclusion

We may conclude from the above discussions that; 1) there is little correlation between the contents of insoluble chlorine and fluorine in the sediments and their sedimentary locations and ages; 2) it is almost impossible to estimate the contents of both insoluble chlorine and fluorine in a given member of sediments by using only one specimen geologically regarded as representative of the sediment in the member; 3) the insoluble chlorine contents of the psammitic rocks are higher than those of the pelitic rocks, whereas the insoluble fluorine contents of the former are lower than those of the latter; 4) there seems to be a moderately negaitve correlation between the contents of insoluble chlorine and fluorine; 5) all the sediments analyzed contain very small amounts of water-soluble fluorine (0.001 to 0.002% F), and 6) the frequency distributions of the insoluble chlorine contents in both psammitic and pelitic rocks are approximately lognormal.

The authors wish to express their thanks to Dr. Takashi Mitunashi, Geological Survey of Japan, for his valuable advice and criticism in the field observations. They are also much obliged to Dr. Sunao Ogose, the University of Tokyo, for his advice in the collection of the samples. They wish also to express their thanks to Professor Iwaji Iwasaki, Tokyo Institute of Technology, for his encouragement throughout this study. The expenses of this reseach were defrayed by a Scientific Reseach Encouragement Grant from the Ministry of Education, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1468—1471 (1966)

The Crystal Structure of Succinonitrilo-disilver Nitrate, $2AgNO_3 \cdot NC(CH_2)_2CN$

By Teruo NOMURA and Yoshihiko SAITO

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received December 2, 1965)

The structure of $2AgNO_3 \cdot NC(CH_2)_2CN$ has been determined by X-ray analysis. It is monoclinic; $a=5.87$, $b=17.79$, $c=4.61$ Å, $\beta=118.2°$, space group $P2_1/a$, two formula units in the cell. The structure is essentially ionic and consists of the complex cations, $[AgNC(CH_2)_2CNAg]^{2+}$ (Ag–N, 1.97 Å), and the nitrate anions. All the bond lengths are normal. The molecule of succinonitrile was found to take the trans configuration; this is in conformity with the conclusion drawn from the infrared study.

In a series of investigations of the structures of the complexes with the general formula $[Cu\{NC(CH_2)_nCN\}_2]NO_3$,[1-3] Kinoshita and one of the present authors have found that succinonitrile molecules coordinate to central metal atoms, taking a "gauche" configuration. In the case of succinonitrile silver nitrate complexes, however, Shimanouchi et al. concluded, by infrared study, that succinonitrile molecules take a trans configuration in the crystals of $2AgNO_3 \cdot NC(CH_2)_2CN$.[4] In cooperation with their study, this crystal has now been subjected to X-ray analysis in order to establish the coordination about the silver atoms and the configuration of the succinonitrile molecules.

Crystallographic Data

White needle-like crystals of $2AgNO_3 \cdot NC(CH_2)_2CN$ were kindly supplied by Prof. Shimanouchi. From oscillation and Weissenberg photographs taken using Cu$K\alpha$ radiation ($\lambda=1.542$ Å), the unit cell was found to be monoclinic and to have the

2) Y. Kinoshita, I. Matsubara and Y. Saito, ibid., **32**, 1216 (1959).
3) Y. Kinoshita, I. Matsubara, T. Higuchi and Y. Saito, ibid., **32**, 1221 (1959).
4) M. Ohara, T. Fujiyama and T. Shimanouchi, presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

following cell dimensions:

$$a = 5.87 \pm 0.04 \text{ Å}$$
$$b = 17.79 \pm 0.05 \text{ Å}$$
$$c = 4.61 \pm 0.03 \text{ Å}$$
and $$\beta = 118.2 \pm 0.2°.$$

On the basis of this unit cell, the needle axis of the crystals was determined to be [$\bar{2}$01]. The space group was found to be $P2_1/a$—C_{2h}^5 from systematic absences. The cell contains two formula units of $2AgNO_3 \cdot NC(CH_2)_2CN$ (density; calculated, 3.30 g./cm^3; found, 3.34 g./cm^3).

The crystals are fragile and decompose gradually on exposure to daylight as well as to X-rays. The intensity data for the *hk*0, 0*kl* and *h*0*l* reflections were recorded about each principal axis on zero-level Weissenberg films by the multiple film technique, in each case using 0.05 mm. × 0.05 mm. × 1mm. crystals. Since we are merely interested in the establishment of the coordination about the silver atom and the configuration of the ligand molecule, and not in attaining high precision in the structural parameters, no special pains have been taken with the intensity estimates; they were carried out visually and were uncorrected for absorption errors. The estimated intensities were corrected for Lorentz and polarization factors. The observed structure amplitudes were brought to an absolute scale by scaling them against the calculated values at a later stage.

The Determination of the Structure

Since there are two molecules of succinonitrile in the unit cell, their center of gravity must lie on a set of twofold special positions. Thus, the succinonitrile molecule must have a center of symmetry and must assume a trans configuration.

The structure determination is based mainly on the analysis of the *hk*0 and 0*kl* reflections, which can be carried out in quite a straightforward fashion. Because of the occurrence of the heavy silver atoms, the Patterson functions are extremely simple and can be solved without difficulty, thus yielding the approximate positions of silver atoms. The signs for all but weak reflections can be derived on the basis of the positions of the silver atoms. Fourier syntheses of the electron density projected along [001] and [100] were evaluated without the weak reflections of uncertain signs. On both projections, all the atoms appeared. The maxima of some light atoms deformed under the influence of heavy silver atoms. In the refined two-dimensional Fourier syntheses, including all the terms, all the peaks of the light atoms were found in the expected positions. The atomic parameters thus obtained were refined by performing cycles of least-squares refinement of the positional and isotropic thermal parameters of the atoms: the programme employed was devised by Iitaka. The value of the discrepancy factor was 0.15 for all *hk*0, 0*kl* and *h*0*l* reflections.

The final projection of the electron density, together with that of the structure, is shown in Fig. 1.

Table I contains the final parameters of all the atoms. The observed and calculated structure amplitudes are compared in Table II.

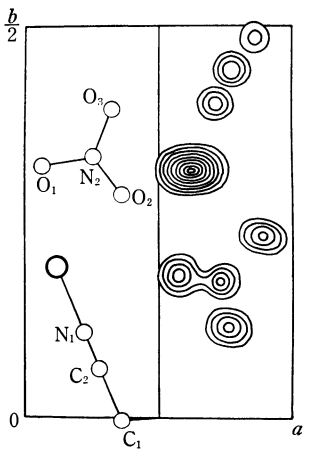

Fig. 1. The electron density and the structure projected along [001].

The calculations of the structure amplitudes, Fourier syntheses and least-squares refinement were carried out on the PC 2 computer of this Institute.

Description of the Structure and Discussion

The interatomic distances and bond angles are given in Table III.

The structure is essentially ionic and consists of the complex ion, $[AgNC(CH_2)_2CNAg]^{2+}$, and nitrate ions. The structure is most easily understood with the aid of Fig. 2, in which the arrangement of the complex ions and nitrate ions projected upon the crystallographic plane ($\bar{2}$01) is illustrated. The complex ion has a center of symmetry. A succinonitrile molecule takes a trans configuration; this is in conformity with the conclusion drawn from the infrared study. It is coordinated to two silver

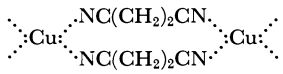
latter, however, there exist polymeric chains of the composition,



and a succinonitrile molecule in the complex takes a gauche configuration with respect to the central C–C bond.

As is shown in Fig. 2, the complex ions and the nitrate ions are arranged approximately in one layer parallel to the ($\bar{2}01$) plane. In each layer nitrate ions are arranged with their planes nearly perpendicular to it.

A silver atom at the end of the complex ion is surrounded by four oxygen atoms of the nitrate ions, with interatomic distances ranging from 2.49 Å to 3.36 Å. Two of them belong to the nitrate ions in the same layer as the silver atom, while the others belong to those in the adjacent layers. All the interatomic distances are in good agreement with those obtained for other crystals.

The Stability of Fused Rings in Metal Chelates. III. The Relative Stability of Copper(II) Complexes of Aldehyde- and Ketone-Schiff Bases[1]

By Yasuo NAKAO, Ken-ichi SAKURAI and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received December 4, 1965)

The relationship between the structure of fused-ring systems and the relative stability of copper(II) Schiff base chelates has been discussed, on the basis of the properties of six copper(II) complexes, in connection with the transamination reaction. As the conclusion it has been suggested that the transamination reaction in fused-ring systems containing copper(II)-glyoxylate- or -pyruvate-Schiff bases may be expected only in such appropriately unstable systems as have two five-membered rings and that it is generally accompanied by a stabilization of the system. The preparation and properties of the two new copper(II) chelates, glyoxylidene-β-alaninatoaquocopper(II) and pyruvidene-α-alaninatoaquocopper(II), have been described.

The previous effort in this laboratory has been directed toward the investigation of the properties of fused-ring systems in copper(II) complexes of Schiff bases derived from salicylaldehyde[2] or pyruvic acid[3] and amino acids or other amino compounds. In order to extend our previous interpretation concerning the relationship between the relative stability of metal chelates and the

structure of fused-ring systems, we have recently undertaken the syntheses of some copper(II) chelates of Schiff bases derived from glyoxylic acid and amino acids.

In the meantime we have found that there is a delicate correlation between the structure of fused-ring systems and the transamination reaction. For example, the complex isolated in the crystalline state from the copper(II)-glyoxylate-alaninate system has been proved to be pyruvideneglycinato-aquocopper(II) instead of glyoxylidenealaninato-aquocopper(II). This finding is apparently related to a transamination reaction occurring in the fused-ring system of the metal complex. It seems noteworthy that only a chelate of glycine with pyruvate and copper(II), not of one alanine with glyoxylate and copper(II), is isolated. In such a way we can describe the relative stability of fused ring systems containing aldehyde- or ketone-Schiff bases in connection with the transamination reaction.

The preparation and some properties of two new complexes, glyoxylidene-β-alaninatoaquocopper(II) and pyruvidene-α-alaninatoaquocopper(II), will also be described.

The Transamination Reaction of the Copper-(II)-glyoxylate-α-alaninate System.—We prepared a pair of copper(II) Schiff base complexes which could be discriminated from each other only through the relative location of the >C=N- double bond in the fused-ring system, as is indicated by the structures I and II. The two complexes isolated

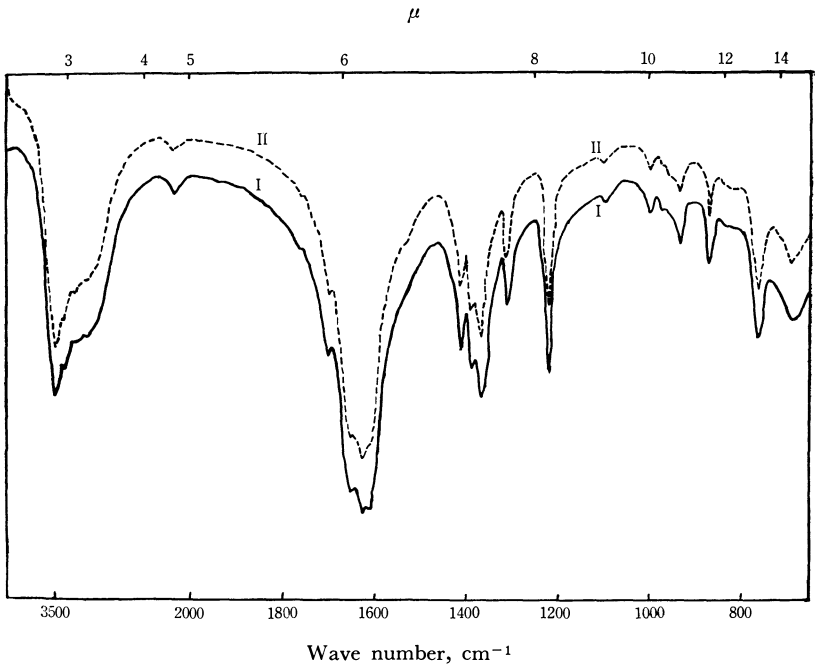

Fig. 1. Infrared spectra of [Cu pyv=gly(H_2O)]·$2H_2O$, I, and the complex derived from copper(II), α-alanine and glyoxylic acid, II.

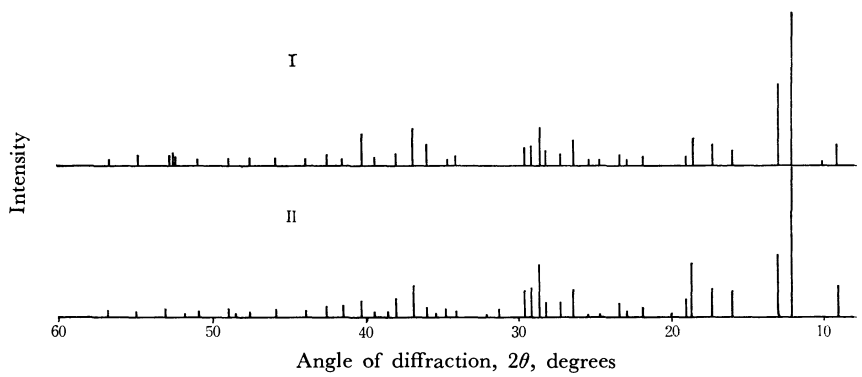

Fig. 2. X-Ray diffraction patterns of [Cu pyv=gly(H_2O)]·$2H_2O$, I, and the complex derived from copper(II), α-alanine and glyoxylic acid, II.

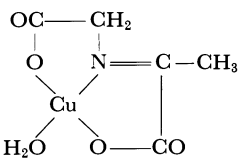
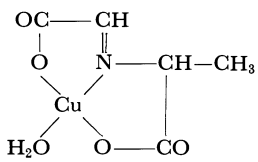
in the crystalline state, however, revealed that there was no difference in their colors, shapes and habits; both the compounds displayed the same decomposition temperature (192°C). No difference was observed either in their solubilities in water, ethanol and dimethylsulfoxide. The infrared study and the X-ray powder measurements of the two crystals also verified their identity, as is shown in Figs. 1 and 2 respectively, although there were some apparently meaningless small differences in relative intensity of the X-ray diffraction pattern. These differences can probably be supposed to be due to inevitable errors in the preparation of the powder. However, an additional decisive proof for the identity of the two compounds and the elimination of the possibility for the structure II was given by a cleavage reaction of the Schiff base >C=N- double bond of the respective complex. The two solutions obtained by precipitating copper(II) as cupric sulfide exhibited only one spot corresponding to glycine in the presence of pyruvic acid in their paper chromatographic examination. An amino acid analyzer was also employed to ascertain the above result. While the existence of glycine was confirmed for both the solutions, no sign for alanine was recorded in either case. If the real structure of the complex produced from the copper(II)-glyoxylate-alaninate system were II, α-alanine would have been detected instead of glycine.

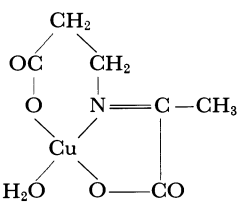
Although this kind transamination and of the glyoxylate-pyridoxamine system in the presence of metal ions have already been reported, the previous conclusions were drawn only from equilibrium studies of solutions[4]; the intermediate complexes were not isolated. Furthermore, it should be emphasized that the present transamination proceeds almost quantitatively. This may be one of the most clear-cut examples of an effective transamination catalyzed by a metal ion.



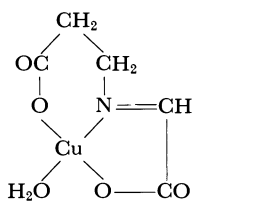
(I)
[Cu pyv=gly(H_2O)]



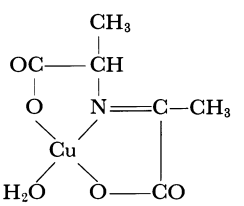
(II)
[Cu glyox=α-ala(H_2O)]



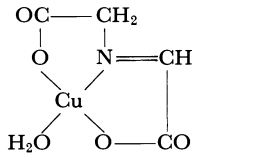
(III)
[Cu pyv=β-ala(H_2O)]



(IV)
[Cu glyox=β-ala(H_2O)]



(V)
[Cu pyv=α-ala(H_2O)]



(VI)
[Cu glyox=gly(H_2O)]

Thus it can be concluded that the complex I is more stable than the complex II (I>II).

Copper(II) Complexes of Schiff Bases with β-Alaninate.—The copper(II) complex of the Schiff base derived from β-alanine and pyruvic acid, III, was introduced in a previous paper.[3] In order to obtain knowledge concerning the delicate difference between aldehyde- and ketone-Schiff base complexes, the copper(II) complex of the Schiff base derived from glyoxylic acid and β-alanine, IV, has now been prepared.

First of all, no transamination reaction was observed in the cases of III and IV. This was recognized by means of the paper chromatographic examination of the solutions obtained from III and IV using the same procedure as was used for I and II. The decisive factor was the failure to find the spot for α-alanine or for glycine; only β-alanine was detected for both the solutions. It seems, however, rather reasonable that the transamination reaction in the β-alaninate-Schiff base complexes does not occur, since the electronic arrangement in the transaminated structure is supposed to be quite unfavorable for the stabilization of the fused-ring system. Apart from the transamination reaction, one may conclude, on the basis of the experimental data indicated in Table I, that the complex III is probably more stable than the complex IV. An inspection of Table I reveals that the decomposition temperature of the complex III is distinctly higher than that of IV, and that the polarographic half-wave potential for the reduction of copper(II) is more negative in III than in IV. In addition to those numerical data, their behavior in an aqueous solution shows that the complex III is more stable than IV. For instance, it is considerably difficult to recover the complex IV from its aqueous solution without decompsotion, while it is not so difficult to recover the complex III.

Although it is not the authentic way of discussing the stability of complexes, the above described view may aid in the consideration of the qualitative relative stabilities of the two compounds. Hence, we may conclude that pyruvidene-β-alaninato-aquocopper(II), III, is more stable than glyoxylidene-β-alaninatoaquocopper(II), IV (III>IV).

Copper(II) Complexes of Schiff Bases with α-Alaninate.—The complex produced from copper(II), α-alanine and glyoxylic acid has already

TABLE I. PROPERTIES OF COPPER(II) SCHIFF BASE COMPLEXES

	Schiff base (ligand)	Decomp. temp. °C	Absorp. max. (ν_{max} in 10^{13} sec^{-1} and log ε_{max})	Half-wave potential vs. SCE at 25°C	Transamination reaction
I	Pyruvic acid and glycine	192—206	ν, 40.5 log ε, 1.85	$E_{1/2}^{(1)}$ −0.09 V. $E_{1/2}^{(2)}$ −0.42 V.	No
II	Glyoxylic acid and α-alanine	—	—	—	↑ Yes
III	Pyruvic acid and β-alanine	205—215	ν, 42.9 log ε, 1.82	$E_{1/2}^{(1)}$ −0.15 V. $E_{1/2}^{(2)}$ −0.28 V.	No
IV	Glyoxylic acid and β-alanine	188—193	ν, 42.9 log ε, 1.84	$E_{1/2}^{(1)}$ −0.05 V. $E_{1/2}^{(2)}$ −0.28 V.	No
V	Pyruvic acid and α-alanine	181—190	ν, 42.9* log ε, 1.62*	$E_{1/2}^{(1)}$ −0.09 V. $E_{1/2}^{(2)}$ −0.27 V.	No
VI	Glyoxylic acid and glycine	—	—	—	Probably yes

* These values for ν_{max} and log ε_{max} are considered as inappropriate to be the data for a fused ring system having two five-membered rings compared with those of other same type chelates.[3] This is perhaps because of a coexistence of a small amount of bis(alaninato)-copper(II) on which we described in the section of the Experimental.

TABLE II. SPECIFIC ROTATION OF A STANDARD AND THE RECOVERED L-α-ALANINE
Solvent: 1 N HCl, Cell: 5 cm.

Sample	$[\alpha]_D^{15}$	$[\alpha]_{500}^{15}$	$[\alpha]_{450}^{15}$	$[\alpha]_{460}^{15}$
L-α-Alanine (standard)	+14.3°	+20.9°	+27.8°	+40.4°
α-Alanine (recovered from the complex V)	+13.0°	+19.5°	+26.2°	+37.6°

been described above. The complex II is not isolated as crystals since it spontaneously transforms itself into the I structure. On the other hand, the complex derived from copper(II), α-alanine and pyruvic acid, V, is comparatively easy to prepare. In this particular case, however, the paper chromatographic test is not suitable for investigating the transamination reaction in the fused-ring system, since the solution obtained from V is always expected to give the spot for α-alanine, regardless of the transamination reaction, as may be understood from the V structure. We have, therefore, measured the loss of the optical rotatory power of the L-α-alanine recovered from the complex V. If the transamination reaction occurs freely in the fused-ring system, the alaninate moiety will transform into pyruvate, and, conversely, the original pyruvate moiety will transform into alaninate. In the course of that intramolecular rearrangement, L-α-alanine will entirely be racemized. However, we have observed just a slight loss of the rotatory power for the recovered alanine, even after the complex had been allowed to stand in water for more than three days at 30 to 40°C. It may, therefore, be concluded that no remarkable transamination reaction proceeds in the copper(II)-α-alaninate-pyruvate system. However, this finding doees not eliminate all possibility of transamination in the complex V, since our experiment has been confined to the neutral region.

As a matter of course, it can be asserted that the complex V is more stable than the complex II (V>II). This is because the complex II undergoes the transamination, while the complex V does not.

Attempts to Isolate the Copper(II) Complex of the Schiff Base Derived from Glyoxylic Acid and Glycine.—It has been disclosed above that the copper(II) complexes of glyoxylate-Schiff bases are always less stable than the corresponding complexes of pyruvate-Schiff bases. If this conclusion is valid, the fused-ring in the copper(II)-glyoxylate-glycinate system may be expected to be quite unstable, since the complex is obliged to have a glyoxylate moiety regardless of the transamination reaction, as may be understood from the VI structure. Indeed, all our efforts to isolate the complex VI have been in vain, though we could observe, for several minutes, a bluish green color which was probably due to the formation of the complex VI. It may be speculated that the instability of this particular complex originates from the violent transamination reaction occurring to-and-fro in the fused-ring system. Though we do not have a proper way of verifying this, an investigation using ^{18}O is now under way.

At all events, the complex VI is apparently less stable than the complex I or V (I>VI; V>VI).

The Structure of Fused-rings and the Transamination Reaction.—On the basis of the properties of the six copper(II) complexes, we have discussed the relationship between the structure of fused-rings and the relative stability of copper(II) Schiff base chelates in connection

with the transamination reaction. All the findings concerning the relative stability of copper(II) complexes of aldehyde- and ketone-Schiff bases may be summarized as follows:

$$I>II;\ III>IV;\ V>II;\ V>VI;\ I>IV.$$

All these relations indicate that the fused-rings of aldehyde-Schiff bases are generally less stable than those of ketone-Schiff bases. Therefore, the transamination from the aldehyde- to the ketone-type structure corresponding to a stabilization of the fused-ring system in the metal chelate. On the other hand, it has already been pointed out that the copper(II) complexes of Schiff bases with β-alaninate do not undergo transamination, even in the case of the less stable aldehyde-type structure. This was elucidated in terms of the unfavorable electronic arrangement of the fused-ring system in the transaminated structure. However, it may also be supposed to be important to take into account that the β-alaninate Schiff base chelates are too stable to undergo transamination.

This is because of the previous conclusion that the fused-ring system with one five- and one six-membered ring is more stable than that with two five-membered rings.

By combining all this knowledge, we may suggest that *the non-enzymatic transamination reaction of the present kind can be expected only in such appropriately unstable fused-ring system as one with two five-membered rings and that it is generally accompanied by a stabilization of the system.* A different catalytic effect may be expected for a different metal ion; investigations of this are now in progress in this laboratory.

Experimental

Pyruvideneglycinatoaquocopper(II), I, [Cu pyv=gly(H_2O)].—The compound was prepared by the reaction of cupric acetate with a mixture of pyruvic acid and glycine according to the directions presented in a previous paper.[3]

The Copper(II) Complex of the Schiff Base Derived from Glyoxylic Acid and α-Alanine.—To a mixture of 7.1 g. of D, L-α-alanine and 9.1 g. of sodium glyoxylate monohydrate in 25 ml. of aqueous ethanol (two-to-one by volume mixture) was added 4.8 g. of glacial acetic acid. Into this was added 16 g. of copper(II) acetate monohydrate with constant stirring at room temperature. The reaction was completed within one hour to give a dark blue solution, with the precipitation of pale blue microscopic crystals. After it had been filtered, the solution yielded more of the same product. The precipitate was recrystallized from a small amount of water. The final pure product appears as thin pale blue plates which begin to decompose at 192°C. The compound is soluble in water and dimethylsulfoxide and slightly soluble in ethanol, but it is insoluble in acetone and chloroform.

Found: C, 23.03; H, 4.27; N, 5.29; H_2O, 20.31. Calcd. for dihydrate of I or II: C, 23.00; H. 4.27; N, 5.36; H_2O, 20.65%.

All the experiment to discriminate the present complex from I were in vain. In other words, the complex was proved to be pyruvideneglycinatoaquocopper(II), I, and not glyoxylidene-α-alaninatoaquocopper(II), II.

Pyruvidene-β-alaninatoaquocopper(II), III, [Cu pyv=β-ala(H_2O)].—Although the method of preparing this compound has already been reported in a previous paper,[3] the procedure used here was a little simplified by using cupric acetate and aqueous ethanol instead of freshly preciptated cupric oxide and water respectively.

Glyoxylidene-β-alaninatoaquocopper(II), IV, [Cu glyox=β-ala(H_2O)].—To a mixture of 5.1 g. of β-alanine and 6.5 g. of sodium glyoxylate monohydrate in 20 ml. of aqueous ethanol (two-to-one by volume mixture) 3.4 g. of glacial acetic acid was added. Into this 11.4 g. of copper(II) acetate monohydrate was added with constant stirring at room temperature. The reaction was completed within one hour, giving a dark blue solution. After it had been fiiltered, the solution was cooled at about 5°C. To this ethanol was added until the solution became turbid.

The reaction mixture was then allowed to stand for a few hours in a refrigerator. Hereupon a sky blue crystalline product was deposited.

The product was filtered and recrystallized from a small amount of water. M. p. 188—193°C(decomp.).

Found: C, 23.09; H, 4.20; N, 5.35. Calcd. for dihydrate of IV: C, 23.00; H, 4.21; N, 5.36%.

Pyruvidene-α-alaninatoaquocopper(II), V, [Cu pyv=α-ala(H_2O)].—Into a solution of 8.9 g. of D, L-α-alanine and 9 g. of pyruvic acid in 30 ml. of water 20 g. of copper(II) acetate monohydrate was added at 40°C with constant by stirring. The reaction was completed within one hour to give a dark blue solution. After it had been filtered, the solution was cooled at about 5°C. To this a large amount of ethanol was then added. Hereupon a large amount of a precipitate was obtained. This was recrystallized repeatedly from water by adding a large amount of ethanol. Finally the crystalline powder was washed by acetone and dried over silica gel. M. p. 181—189°C (decomp.). Found: C, 29.00; H, 4.55; N, 6.37; Cu, 25.5; H_2O, 10.2. Calcd. for hemihydrate of V: C, 29.03; H, 4.03; N, 5.65; Cu, 25.6; H_2O, 10.9%. As is clear from these values, the experimental values for nitrogen and hydrogen did not agree well with the corresponding calculated values on account of the difficulty in purifying the complex. However, this was not so serious as to negate the proposed structure, V, since there had to be taken into consideration the possibility of the co-precipitation of bis(alaninato)-copper(II) in such a recrystallization process as has been described above. The properties of the complex V are listed in Table I.

The Copper(II) Complex of the Schiff Base Derived from Glyoxylic Acid and Glycine.—Although the same method of preparation as was used for V was employed, only a dark brown solid, which was believed to be a decomposition product, was obtained. By the use of a nitrogen atmosphere, the reaction was improved to some extent, but no complex was isolated. In the midst of the reaction, however, a greenish blue solution, probably based on the formation of the complex VI, could be observed for a few minutes.

Other Chemicals Used.—Sodium glyoxylate was

prepared from tartaric acid according to the method in the literature.[5] Unless otherwise specified, all the chemicals used in the measurements were of analytical reagent grade.

Transamination Study.—The following procedure was employed to estimate the transamination reactions in the fused-ring systems of chelates.

Through an aqueous solution of the chelate concerned, the hydrogen sulfide was bubbled until the bluish color characteristic of copper(II) complexes vanished. To this an appropriate amount of charcoal was added for the convenience of rapid filtration. After it had been filtered, the brown solution was concentrated to a small volume in vacuo at 30 to 40°C. The intact solution was used as a sample solution for the paper chromatographic test, which employed the solvent system of *n*-butanol : acetic acid : water (4 : 2 : 1) and Toyo filter paper No. 50. The same solution had to be appropriately diluted as a sample solution for an amino-acid analyzer. A Hitachi Amino-Acid Analyzer Model KLA-3 was used.

Optical Rotation Study.—The purpose of the experiment was to determine the loss of the optical rotatory power of L-α-alanine by the formation of the Schiff base chelate. Therefore, the specific rotation of a standard L-α-alanine was compared with that of a recovered α-alanine using several wave-lengths. The results are tabulated in Table II. In order to recover α-alanine from the pyruvidene-α-alaninatoaquo-copper(II), V, principally the same procedure as that described above (Transamination Study) was employed. In this particular case, however, the complex solution had been allowed to stand at 30 to 40°C for about 75 hr. before the hydrogen sulfide was bubbled in; the solution which had been separated from cupric sulfide was evaporated to dryness in vacuo at about 50°C in order to remove the pyruvic acid. The white crystalline residue was dissolved in water and freed centrifugally from the insoluble residue. The solution was then concentrated again to a small volume. To this an appropriate amount of ethanol was added until the solution became turbid. When the solution was allowed to stand in a refrigerator, white crystals of α-alanine were deposited. These were used for the optical rotation study. The measurements were made by the use of a Yanagimoto Spectropolarimeter OR-100 at 15°C. The concentrations of α-alanine used were 4.77 and 4.79% in 1 N hydrochloric acid for the standard L-α-alanine and the recovered α-alanine respectively. The details are shown in Table II.

X-Ray Powder Measurements.—The X-ray powder patterns were recorded by the use of a Toshiba ADX-103 X-ray diffractometer at room temperature, with the Cu-$K\alpha$ line filtered through nickel. The diffraction patterns are depicted diagrammatically in Fig. 2.

Spectroscopic Measurements.—The visible and ultraviolet absorption spectra were determined with a Shimadzu Spectrophotometer QR-50 at room temperature. The solvent used in this work was water in all cases, while the concentration of the solutions varied from 10^{-2} to 10^{-3} M. Only the numerical data for the absorption band in the visible region are listed in Table I. The infrared spectra were recorded by the use of a Hitachi EPI-2 Infrared spectrophotometer. The measurements were made at room temperature using the pressed potassium bromide disk technique in the wave number range from 700 to 4000 cm^{-1} and using a rock salt prism.

The spectra obtained are shown in Fig. 1.

Polarographic Measurements.—The measurements were made with a Yanagimoto Recording Polarograph PA-102. An "H" cell was used, the reference electrode being a saturated calomel electrode and the whole cell being thermostated at 25±0.5°C. Pure distilled mercury was used throughout. Tank nitrogen was, without any further purification, bubbled through the sample to remove the dissolved oxygen. The concentration of the copper(II) chelates varied from 10^{-4} to 10^{-3} M. The supporting electrolyte used was 0.1 M potassium nitrate in all cases. The plot of log $i/(i_d-i)$ against the voltage revealed that the reduction wave for copper(II) was irreversible in all cases except in the complex I and the complex III. In addition, the half-wave potentials determined in this work for the complex I and the complex III did not agree well with the corresponding values reported previously.[3] This was, however, clarified as being due to the different concentration of the maximum suppressor, methyl red. As far as the present work was concerned, a constant concentration of methyl red was used throughout (0.03%).

The authors hereby gratefully acknowledge the helpful assistance in this study of Mr. Hisao Imayasu. Grateful acknowledgment is also made to Professor Tokunosuke Watanabe of this College of General Education for many valuable suggestions and discussions, particularly concerning the interpretation of the results of the X-ray powder measurements.

A part of the expenses for this work was defrayed by a grant from the Ministry of Education, to which the authors' thanks are due.

The Effect of Acetates on the Synthesis of Acetic Acid from Methanol and Carbon Monoxide in the Presence of Cobalt(II) Iodide as a Catalyst

By Tsutomu MIZOROKI and Mikitake NAKAYAMA

Government Chemical Industrial Research Institute, Tokyo, Meguro-ku, Tokyo

(Recived July 23, 1965)

In the synthesis of acetic acid from methanol and carbon monoxide in the presence of cobalt(II) iodide as a catalyst, the addition of an acetate has been shown to have a great influence upon the methanol conversion into total acetic acid. When the added amounts of potassium acetate are from one to two times as much as that of cobalt(II) ion, both methanol conversion and its reaction rate reach a maximum, and methanol is prevented from forming dimethyl ether. On the other hand, the reaction nearly stops when the amount of potassium acetate becomes more than four times as large. The variation in the absorption spectrum of cobalt(II) ion in course of the reaction shows that the increase in the added amount of an acetate is favorable for the formation of cobalt carbonyls and that most cobalt(II) ions are tetrahedral species of the $[Co(AcO)_{4-n}I_n]^{2-}$ type so long as the reaction is promoted with the catalyst. From these experimental results, the course of the reaction has been discussed.

The reaction rate of the synthesis of acetic acid from methanol and carbon monoxide is promoted by the use of cobalt(II) iodide as a catalyst, a method which originated in Reppe's work.[1] The present authors have previously reported that, when a mixture of cobalt(II) acetate and an iodide*1 was used as the catalyst, both the conversion of methanol into acetic acid and the absorption rate of carbon monoxide were always larger than in the case where only cobalt(II) iodide was used as the catalyst.[2] There is no difference in their components between cobalt(II) iodide and a mixture of cobalt(II) acetate and an iodide except that the latter contains acetates. In our last paper,[3] dealing with the variation in the absorption spectrum of cobalt(II) ion catalysts during the course of the reaction of methanol with carbon monoxide-hydrogen mixtures, it was shown that, when iodide ions were also present, most of the cobalt(II) ions did not form cobalt carbonyls, but tetrahedral species of the $[Co(AcO^{*2})_{4-n}I_n]^{2-}$ type. These facts suggest that an acetate should have some influence upon the methanol conversions into C_2-oxygenated organic compounds as well as on the absorption spectrum of cobalt(II) during the course of the reaction.

This work was undertaken in order to make clear the effect of an acetate, especially on the acetic acid synthesis reaction, and in order to study the behavior of cobalt(II) ion through recording its absorption spectrum.

Experiments

Apparatus for Carrying Out the Reaction.—The apparatus for carrying out the reaction was nearly the same as that described in previous papers.[2] The reaction vessels used were 180 ml. and 230 ml. vessels lined with a titanium manganese alloy. After a mixture of methanol, acetic acid and water containing a given amount*3 of the catalyst had been placed in the vessel, carbon monoxide was introduced up to 50 kg./cm^2 at room temperautre. The mixture was then heated up to 210—215°C (the pressure became about 120 kg./cm^2) by a shaking type of electric furnace (60 r.p.m.) within 2 hr. After the temperature had been kept constant for about one hour., carbon monoxide of a higher pressure was introduced up to a definite reaction pressure (200—400 kg./cm^2) from a pressure accumulator. During the reaction, the pressure was kept constant by supplying carbon monoxide; the amount of it was measured in order to ascertain its absorption rate. The heating and additiob of gas were stopped after a predetermined time of the reaction, and then the vessel was allowed to cool to room temperature.

Apparatus for Taking the Absorption Spectra in the Course of the Reaction.—The special autoclave used for taking the absorption spectrum of the cobalt(II) ion catalyst during the course of the reaction was essentially the same as that described in the last paper, except that it was improved so as to endure pressures of 250—350 kg./cm^2 at 210°C. A solution of 2.5 ml. was placed in the special autoclave (6.0 ml. in vol.) with a couple of thick quartz windows, and then carbon

monoxide was introduced up to the pressure of 70—80 kg./cm^2 at room temperature. The autoclave was heated up to 21°C within one hour. After the temperature had been kept constant (±0.5°C) for about 20 min. by an electronic thermo-controller, carbon monoxide was introduced up to 300 kg./cm^2 and the absorption spectra were recorded by an automatic spectrophotometer from 340 mμ to 1000 mμ.

Materials.—The carbon monoxide and hydrogen were obtained from the decomposition of formic acid and the electrolysis of water respectively; they were compressed into the pressure accumulator. All of the other materials used were obtained from commercial sources.

Analytical Procedures.—The main components in the liquid products were determined by a gas chromatographic procedure. A 4.0 meter glass column or a 6.0 meter copper one with PEG-400 on a Diabase-A*4 was used at the temperature of 80°C, with the hydrogen carrier at the gas flow rate of 50 ml. per min. In this way, the amounts of methanol, methyl acetate and water in the liquid products obtained from the acetic acid synthesis were determined quantitatively,*5 using diethyl ketone as an internal standard substance. On the other hand, the amounts of dimethyl ether, acetaldehyde, methyl acetate, ethyl acetate, methanol, ethanol and water in the liquid products, obtained from the reaction of methanol with carbon monoxide and hydrogen mixtures, were determined by using pyridine as an internal standard, because it was difficult to separate diethyl ketone from ethanol by this gas chromatography. The amount of free acetic acid was determined by titration with an aqueous potassium hydroxide solution. The other analytical procedures were exactly the same as those used in previous papers.

Results and Discussion

The Effect of Acetates on the Methanol Conversion.—When a mixture of cobalt(II) acetate and an iodide is used as the catalyst in the reaction of methanol with carbon monoxide to form acetic acid, the presence of a relatively large amount of an iodide favors an increase in its rate.[2] When cobalt(II) iodide is used, however, neither the methanol conversion into total acetic acid (free acid and its ester) nor its rate increases, even if an iodide is added in considerable amounts. It was very difficult, therefore, to obtaine the most favorable mole ratio of iodide ions to cobalt(II) ions for this reaction. In all experiments, the I^-/Co^{2+} ratios present in the solutions used were always adjusted to be four by using proper amounts of cobalt(II) iodide and sodium iodide. Lithium acetate, sodium acetate, magnesium acetate or manganese(II) acetate was added as an acetate*6 to the solutions, although there were no differences in their effects. The effects of potassium propionate, sodium benzoate, sodium succinate, potassium isobutyrate and borax were examined at the same time in order to compare them with that of potassium acetate. The results are summarized in Fig. 1 and Table I. Both the absorption rate*7 of carbon monoxide and the methanol conversion into acetic

acid reach a maximum when the amount of potassium acetate added is from 1.0 to 2.0 times as much as that of cobalt(II) ions. However, the reaction nearly stops when it becomes more than four times as large. Nearly the same results are obtained by using other salts of carboxylic acid or borax in place of the acetates. The curve 4 in Fig. 1 is the result obtained from the reaction of methyl acetate with carbon monoxide, in which case methyl acetate was placed into the autoclave instead of methanol. It is different from the curves 1 and 2 in that the conversion of methyl acetate into acetic acid ($AcOCH_3 + CO + H_2O \rightarrow 2AcOH$) does not decrease with an increase in the amount of potassium acetate added. These salts also have a great influence on the reaction of methanol with

The solution used are mixtures of CH_3OH (54 mol.%), AcOH (6.0 mol.%) and wates (40 mol.%) containing CoI_2 (0.10 mol.%), NaI (0.20 mol.%) and potassium acetate (0.0—0.30 mol.%). The added amounts of potassium acetate are (1) 0 mol.%, (2) 0.05 mol.%, (3) 0.10 mol.%, (4) 0.20 mol.%, (5) 0.30 mol.%

carbon monoxide - hydrogen*8 to form acetaldehyde, ethanol and acetic esters. As is shown in Table II, the addition of potassium acetate surely increase the methanol conversions into C_2-oxygenated compounds, especially into ethanol, but the reaction nearly stops when the amount of potassium acetate added becomes about three times as much as that of cobalt(II) ions.

These salts of carboxylic acids dissolve well in aqueous solutions and dissociate nearly completely, although the dissociation constants of their acid forms are small.*9 It is to be expected, therefore, that the addition of these salts results in a decrease in the concentration of hydrogen ions in the solutions, especially in the early period of the reactions mentioned above. This expectation is supported by the results obtained using borax, which is well known to make a good buffer solution. Hydrogen ions are considered to increase the reaction rates of dimethyl ether formation and the polymerizations of the acetaldehyde produced. The addition of suitable amounts of these salts, therefore, results in a decrease in the amount of dimethyl ether formed and an increase in the methanol conversions into C_2-oxygenated compounds, as is shown in Table I and II. However, it was very difficult to obtain more direct information regarding the behavior of hydrogen ions during the course of the reactions.*10

The Absorption Spectrum of Cobalt(II) Ions.—The cobalt(II) ion species is octahedral in aqueous solutions, while at an elevated temperature it is tetrahedral. The tetrahedral species of the $[CoX_4]^{2-}$ type, where X represents Cl^-, Br^-, I^-, AcO^-, NCS^-, etc., shows only one main absorption band in the visible region of the spectrum due to d'd electronic transitions. In glacial acetic acid, $[Co(AcO)_4]^{2-}$ has an absorption from 450 to 650 mμ, the maximum wavelength of which is 565 mμ, and the extinction coefficient of which is 1700 mol^{-1}. cm^{-1}; $[CoI_4]^{2-}$ has an absorption from 620 to 810 mμ, the maximum wavelength of which is 755 mμ, and the extinction coefficient of which is 1050 $mol.^{-1}$ cm^{-1}. When the temperature of the solution containing cobalt(II) ions, acetate ions and iodide ions is raised to 210°C, cobalt(II) ions form tetrahedral species of the $[Co(AcO)_{4-n}I_n]^{2-}$ (n= 0—4) type and the addition of acetate shifts the visible absorption to shorter wavelength. Figure 2 shows the effect of potassium acetate on the absorption of cobalt(II) ions at 210°C in the absence of the reaction of methanol with carbon monoxide. On the other hand, cobalt carbonyls as $Co_2(CO)_8$ and $HCo(CO)_4$ have no absorption in the visible region because of their electronic configurations of

*8 In this reaction, it is unnecessary to add water to methanol (See This Bulletin, **37**, 236 (1964)).

*9 10^{-4}—10^{-5} at 25°C. For example, the dissociation constants of acetic acid are 1.75×10^{-5} (25°C) and 1.54×10^{-5} (60°C); these constants are nearly independent of the concentrations.

*10 A preliminary experiment indicated that the amount of dimethyl ether formed increased upon an increase in the amount of sodium iodide added, while it decreased upon an increase in the amount of potassium acetate.

d^{10}, although they have very strong absorptions in the near ultraviolet region. Therefore, the visible absorption of cobalt(II) ions would disappear if most of cobalt(II) ions formed cobalt carbonyls in the course of the reaction. Figure 3 shows the absorption spectra in the course of the reaction of the acetic acid synthesis under the same conditions as those used in the experimental run of the curve 3 in Fig. 1, except that the special autoclave for taking absorption spectra could not be shaken so much. When small amounts of potassium acetate are present in the solution, the absorption from 500 to 650 mμ decreases and that in the longer wavelengths increases as soon as carbon monoxide has been introduced up to 300 kg./cm^2 at 210°C. However, the absorption from 500 to 600 mμ gradually increases as the reaction time goes on. This shows that the reaction is accompanied by an increase in the amount of tetrahedral iodo-cobalt(II) complex ions. However, all the absorptions from 500 to 700 mμ decrease when the amount of acetate added becomes large until they disappear nearly completely when 0.30 mol.% is added. In the near ultraviolet region, the strong absorptions always take place. These are considered to be partly due to the charge transfer from iodide ions to cobalt(II) ions and partly due to cobalt carbonyls, although it was very difficult to distinguish them from each other. The variation in the absorption spectra of Fig. 3 and the curve 3 in Fig. 1 shows that the amount of cobalt(II) ions present in the solution during the course of the reaction of methanol with carbon monoxide decreases with an increase in the amount of acetate added and that, when the reaction rate is promoted with this catalyst, most of the cobalt(II) ions do not form cobalt carbonyls, but tetrahedral complex ions of the $[Co(AcO)_{4-n}I_n]^{2-}$ type.

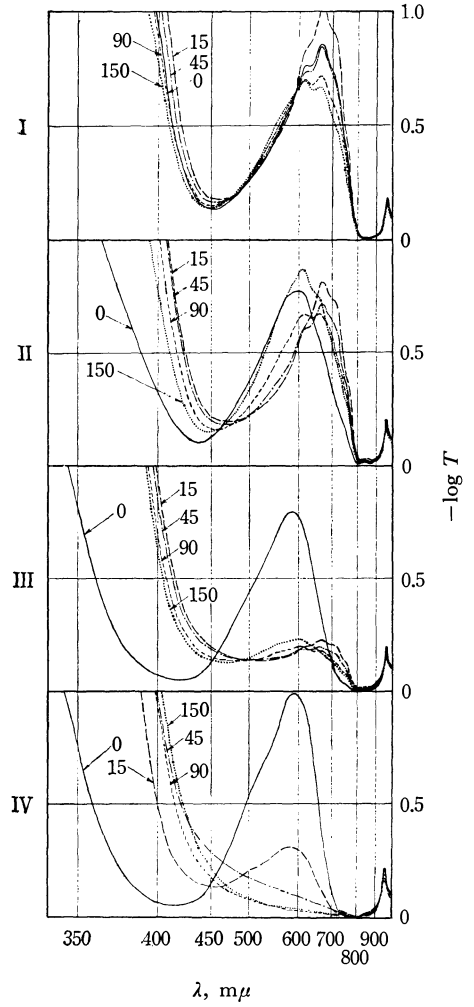

Fig. 3. The variation in the absorption spectrum of cobalt(II) ion in course of the reaction of the acetic acid synthesis under the constant pressure of 300 kg./cm^2 at 210°C.

The solution used are the same as these used in Fig. 2. and the added amounts of potassium acetate are I 0 mol.%, II 0.10 mol.%, III 0.20 mol.% and IV 0.30 mol.%. Numbers in the figure are the times (min.) since carbon monoxide has been introduced up to 300 kg./cm^2 at 210°C.

On the Reaction Mechanism.—Reppe estimated the course of the reaction to be as follows[1,5]:

$$3\,CoI_2 + 2\,H_2O + 10\,CO \rightarrow Co_2(CO)_8 + 4HI + 2\,CO_2$$

$$Co_2(CO)_8 + H_2O + CO \rightarrow 2\,HCo(CO)_4 + CO_2$$

$$CH_3OH + HI \rightarrow CH_3I + H_2O$$

$$CH_3I + HCo(CO)_4 \rightarrow CH_3Co(CO)_4 + HI$$

$$CH_3Co(CO)_4 \rightleftarrows CH_3COCo(CO)_3$$

$$CH_3COCo(CO)_3 + CO \rightarrow CH_3COCo(CO)_4$$

$$CH_3COCo(CO)_4 + H_2O \rightarrow HCo(CO)_4 + AcOH$$

The effect of acetate on methanol conversion into C_2-oxygenated compounds may be correlated with the concentration of hydrogen ions in the solution. The following explanation on the basis of Reppe's mechanism seems possible. The increase in the amount of acetate added will be favorable to the formation of cobalt carbonyls and will prevent the formation of dimethyl ether from methanol, however, it will be unfavorable to the formation of methyl iodide from methanol and hydroionic acid because of the decrease in the concentration of hydrogen ions in the solution. The reaction rate, therefore, reaches its maximum only when a suitable amount of acetate is added to the solution. However, his mechanism is obviously inconsistent

5) The abstract of Reppe's lecture given in Japan, April, 1965, or N. von Kutepow, W. Himmele and H. Hohenschutz, *Chem. Ingr.-Tech.*, **37**, 383 (1965).

with the fact that most of the cobalt(II) ions are tetrahedral species during the course of the reaction so long as the reaction rate is promoted by this catalyst. From the experimental results, it may be postulated that both the conversion of methanol into acetic acid and its rate decrease with the increase in the amount of cobalt carbonyls formed in the early period of the reaction. This suggests that the main course of the reaction may be represented as follows:

$$I^- + H^+ \rightleftarrows HI, \quad AcOH \rightleftarrows AcO^- + H^+$$

$$CH_3OH + HI \rightleftarrows CH_3I + H_2O$$

$$[Co(AcO)_{4-n}I_n]^{2-} + CO \rightarrow [(OC)Co(AcO)_{4-n}I_n]^{2-}$$

$$[(OC)Co(AcO)_{4-n}I_n]^{2-} + CH_3I \rightarrow [CH_3COCo(AcO)_{4-n}I_{n+1}]^{2-}$$

$$[CH_3COCo(AcO)_{4-n}I_{n+1}]^{2-} + HR \rightarrow [Co(AcO)_{3-n}I_{n+1}]^{2-} + CH_3COR + AcOH$$

(R: OCH_3, OH or H)

$$[Co(AcO)_{3-n}I_{n+1}]^{2-} + AcO^- \rightarrow [Co(AcO)_{4-n}I_n]^{2-} + I^-$$

Summary

We have examined the effects of the salts of carboxylic acids, especially acetates, on the reaction of methanol with carbon monoxide in the presence of a mixture of cobalt(II) ion and iodide ion ($I^-/Co^{2+}=4$) as a catalyst, and on the visible absorption spectra of cobalt(II) ions during the course of the reaction. Both the methanol conversions into C_2-oxygenated compounds and their reaction rates reach a maximum when the amounts of potassium acetate added are from one to two times as much as that of cobalt(II) ions. However, these reactions stop nearly completely when they become more than four times. The variation in the absorption spectrum of cobalt(II) ion in the course of the reaction shows that most of the cobalt(II) ions are tetrahedral species of the $[Co(AcO)_{4-n}I_n]^{2-}$ type so long as the reaction is promoted by the catalyst. From the experimental results and our discussion, it has been postulated that the increase in the amount of an acetate added is favorable to the formation of cobalt carbonyls and helps prevent methanol from forming dimethyl ether, while the reaction rate of methanol with carbon monoxide to form C^2-oxygenated compounds decreases with an increase in the amount of carbonyls formed in the early period of the reaction.

The Preparation of Ethylenes with Polyfluorocyclobutenyl and Polyfluorocyclopentenyl Groups

By Hiroshige MURAMATSU,† Soyao MORIGUCHI†† and Kan INUKAI†

† *Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya*

†† *Central Research Laboratory, Showa Denko Co., Ota-ku, Tokyo*

(Received August 30, 1965)

The new ethylenes, with a 2-hydroperfluorocyclobutyl, 2-chlorotetrafluoro-1-cyclobutenyl or 2-chlorohexafluoro-1-cyclopentenyl group, were synthesized in good yields by the dehydration of the 1 : 1 adducts prepared by the addition of the alcohols to perfluorocyclobutene, 1, 2-dichlorotetrafluorocyclobutene or 1, 2-dichlorohexafluorocyclopentene respectively. The dehydrofluorination of 2-hydroperfluorocyclobutylalkylethylenes gave a mixture of perfluoro-1-cyclobutenyl- and perfluoro-2-cyclobutenylethylene. In the mixture, the former was predominant over the latter. Some polyfluorocycloalkenylethylenes prepared polymerized in the presence of peroxide to yield transparent polymers.

Several ethylenes containing polyfluorocyclobutenyl groups have been synthesized, mainly by the cycloaddition of fluoroolefin with conjugated enyne[1] or diene[2], followed by dehydrohalogenation. No papers have, however, been published on the syntheses of polyfluorocyclopentenyl ethylenes.

In a previous report,[3] the radiation-induced addition reactions of alcohols to perfluorocyclobutene were found to produce the corresponding

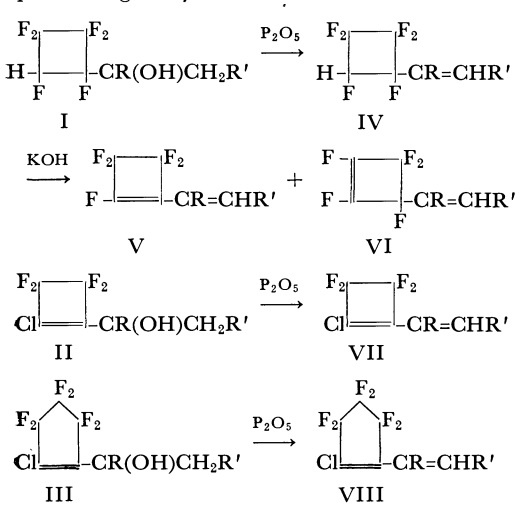
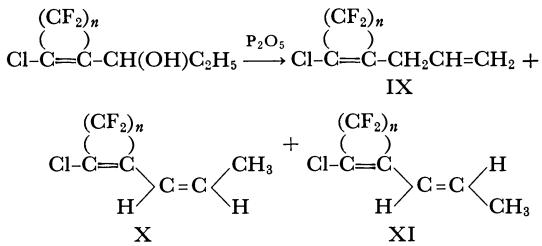
a) The first absorption bands are due to the C=C of the cyclobutenyl groups and the second bands due to the C=C of the ethylenes.

1 : 1 adducts, the carbinols with a 2-hydroperfluorocyclobutyl group (I). Similar additions of alcohols to 1, 2-dichlorotetrafluorocyclobutene or 1, 2-dichlorohexafluorocyclopentene[4] gave mainly the dehydrochlorinated 1 : 1 adducts, 2-chloro-3,3,4,4-tetrafluoro-1-cyclobutenylcarbinol (II) and 2-chloro-3,3,4,4,5,5-hexafluoro-1-cyclopentenylcarbinol (III) respectively.

By the dehydration of these 1 : 1 adducts with phosphorus pentoxide, new ethylenes, with polyfluorocyclobutyl (IV), polyfluorocyclobutenyl (VII), or polyfluorocyclopentenyl (VIII) groups, were prepared in good yields.



Since the (2-hydroperfluorocyclobutyl)alkylcarbinol (I) two stereoisomers[5] (the *trans* and *cis* forms in the halocyclobutyl group), the product, (2-hydroperfluorocyclobutyl)ethylene (IV), was a mixture of the *trans* and *cis* forms. In the dehydration of the *cis* or *trans* form of (2-hydroperfluorocyclobutyl)ethylcarbinol, the proton rearrangement was observed, yielding a mixture of three isomers in each case. The proton rearrangement occured also in the dehydration of (2-chlorotetrafluoro-1-cyclobutenyl)- or (2-chlorohexafluoro-1-cyclopentenyl)ethylcarbinol.



The compositions of the isomers, IX, X, and XI, were calculated from the areas under each peak of the gas chromatograms of the products; they

4) H. Muramatsu, K. Inukai and T. Ueda, ibid., **30**, 2546 (1965).

5) The stereoisomers were assigned to the *trans* and *cis* form from the dipole moment of the isomers of 2-hydroperfluorocyclobutylethylene, which were derived from 2-hydroperfluorocyclobutylmethylcarbinol. See Ref. 3.

were found to be 6%, 5%, and 89% in the case of the chlorotetrafluorocyclobutenylcarbinol and 9%, 13%, and 78% in the case of the chlorohexafluorocyclopentenylcarbinol respectively. The structures of the isomers were determined from their infrared spectra.

The conditions and yields for the dehydration of I are summarized in Table I. Each stereoisomer was isolated by a Shimadzu 10A preparative gas chromatograph. The physical properties of the (2-hydroperfluorocyclobutyl)ethylene (IV), (2-chlorotetrafluoro-1-cyclobutenyl)ethylene (VII), and (2-chlorohexafluoro-1-cyclopentenyl)ethylene (VIII) are shown in Tables II, III, and IV respectively. The *cis* form of 2-hydroperfluorocyclobutylethylene has a boiling point higher by about 20°C than the *trans* form.

The dehydrofluorination of (2-hydroperfluorocyclobutyl)ethylenes was accomplished using powdered potassium hydroxide; this gave two isomers, (perfluoro-1-cyclobutenyl)ethylene (V) and (perfluoro-2-cyclobutenyl)ethylene (VI). The isomer V, which has the conjugated double bonds, was predominant over the isomer VI. The conditions for dehydrofluorination and the physical properties of the (perfluorocyclobutenyl)ethylenes prepared are summarized in Tables V and VI respectively.

The peroxide-induced polymerization was attempted on these ethylenes. Only the ethylenes which have a $-CH=CH_2$ group conjugated with the double bond in the halocycloalkenyl group were found to be polymerized to give the transparent polymers.

Experimental[6]

The Dehydration of the (2-Hydroperfluorocyclobutyl)alkylcarbinols. — To 312 g. (2.18 mol.) of phosphorus pentoxide in a flask with a reflux condenser there was added, drop by drop, 315 g. (1.42 mol.) of (2-hydroperfluorocyclobutyl)ethylcarbinol (a mixture of the *trans* and *cis* in a molar ratio of 1.6 : 1.0) over a 2 hr. period. The reaction mixture was then heated to reflux for 3 hr. and distilled. Since a gas chromatogram[7] of the distillate has six peaks, the compounds of each peak were isolated using preparative gas chromatography. The stereoisomer was assigned on the basis of the products obtained in the dehydration of the clean *trans* or *cis* form of the carbinol. During dehydration, no conversion between the *trans* and *cis* forms was observed. The structures of the isomers were determined from elemental analyses and from a study of their infrared spectra. Thus, the products were 35.5 g. of the *trans* form of 3-(2-hydroperfluorocyclobutyl)-1-propene (retention time, 3.0 min.), 83.7 g. of the *trans* form of 1-(2-hydroperfluorocyclobutyl)-1-propene (a mixture of the *trans* and *cis* forms in a double bond; retention times, 3.6 and 3.8 min. respectively), 19.4 g. of the *cis* form of 3-(2-hydroperfluorocyclobutyl)-1-propene (retention time, 5.3 min.), and 45.5 g. of the *cis* form of 1-(2-hydroperfluorocyclobutyl)-1-propene (a mixture of the *trans* and *cis* forms in a double bond; retention times, 6.8 and 8.1 min. respectively). Upon standing at room temperature, the isolated *cis* forms (in a double bond) gradually changed to the *trans* forms.

Other (2-hydroperfluorocyclobutyl)alkylcarbinols were dehydrated under similar conditions; they are shown in Table I.

The Dehydration of the (2-Chloro-3, 3, 4, 4-tetrafluoro-1-cyclobutenyl)carbinols. — To 24.7 g. (0.17 mol.) of phosphorus pentoxide there was added, drop by drop, 23.1 g. (0.11 mol.) of the halocyclobutenylmethylcarbinol. A reaction mixture was then heated in an oil bath at about 130°C for 20 min. and distilled. The distillation of the product gave 13.8 g. (0.074 mol., 65% yield) of 2-chloro-3, 3, 4, 4-tetrafluoro-1-cyclobutenylethylene, b. p. 103—104°C.

Under similar conditions, the reaction of 29.2 g. (0.21 mol.) of phosphorus pentoxide and 30.0 g. (0.14 mol.) of the halocyclobutenyldimethylcarbinol yielded 16.6 g. (0.083 mol., 60% yield) of 2-(2-chloro-3, 3, 4, 4-tetrafluoro-1-cyclobutenyl)-1-propene. In the dehydration of the halocyclobutenylethylcarbinol (12.8 g., 0.059 mol.) with phosphorus pentoxide (12.5 g., 0.088 mol.), 8.9 g. (0.048 mol.; 82% yield) of the products were obtained. The products were found from gas chromatogram[8] to be a mixture of three isomers, 3-(2-chloro-3, 3, 4, 4-tetrafluoro-1-cyclobutenyl)-1-propene (retention time, 3.5 min.), the *cis* form (4.3 min.), and the *trans* form (6.3 min.) of 1-(2-chloro-3, 3, 4, 4-tetrafluoro-1-cyclobutenyl)-1-propene. The products were fractionated in order to separate a mixture of the *cis* and *trans* isomers. Though not each isomer was isolated, their structures were determined from the infrared spectra.

The physical properties and analyses of the ethylenes containing 2-chlorotetrafluoro-1-cyclobutenyl group are listed in Table III.

The Dehydration of the (2-Chloro-3, 3, 4, 4, 5, 5-hexafluoro-1-cyclopentenyl)carbinols.—A mixture of 52 g. (0.20 mol.) of the halocyclopentenylmethylcarbinol and 43.5 g. (0.31 mol.) of phosphorus pentoxide was heated at about 135°C for 35 min. and then distilled to give 42.5 g. (0.18 mol.; 88% yield) of 2-chloro-3, 3, 4, 4, 5, 5-hexafluoro-1-cyclopentenylethylene, b. p. 119—121°C. Using the same procedure, 32.5 g. (0.12 mol.) of the halocyclopentenyldimethylcarbinol was reacted with 25.8 g. (0.18 mol.) of phosphorus pentoxide to yield 26.6 g. (0.11 mol.; 88% yield) of 2-(2-chloro-3, 3, 4, 4, 5, 5-hexafluoro-1-cyclopentenyl)-1-propene.

The dehydration of 31.0 g. (0.12 mol.) of the halocyclopentenylethylcarbinol with 24.6 g. (0.17 mol.) of phosphorus pentoxide gave 25.5 g. (0.10 mol.; 83% yield) of the products, which were found to consist of three isomers, 3-(2-chloro-3, 3, 4, 4, 5, 5-hexafluoro-1-cyclopentenyl)-1-propene (retention time,[9] 3.0 min.),

6) All temperature readings are uncorrected.

7) A Hitachi-KGL-2 was employed using helium carrier gas at flow rate of 60 ml./min. and column temperature of 64°C; 2 m. of column packed with 25% Silicone DC-550 was used.

8) The same conditions as Ref. 7 except a helium flow rate 55 ml./min.; column temperature, 93°C.

9) A helium flow rate 50 ml./min.; column temperature 98°C.

the *cis* form (3.9 min.), and the *trans* form (5.9 min.) of 1-(2-chloro-3, 3, 4, 4, 5, 5-hexafluoro-1-cyclopentenyl)-1-propene. The isomers were separated by preparative gas chromatography, and their structures were determined from their infrared spectra.

The physical properties and analyses of the ethylenes containing 2 - chloro-3, 3, 4, 4, 5, 5-hexafluoro-1-cyclopentenyl group are shown in Table IV.

The Dehydrofluorination of (2-Hydroperfluorocyclobutyl)ethylenes.—To 87 g. (1.55 mol.) of powdered potassium hydroxide there was added 90 g. (0.47 mol.) of (2-hydroperfluorocyclobutyl)ethylene. The reaction mixture was then heated under reflux for 1 hr. and distilled. The gas chromatogram of the distillate (23.6 g., 0.14 mol., 29% yield) had two peaks, showing the existence of two isomers. They were isolated by preparative gas chromatography and found to be perfluoro-1-cyclobutenylethylene and perfluoro-2-cyclobutenylethylene from their elemental analyses and from a study of their infrared spectra. The perfluoro-1-cyclobutenylethylene was readily polymerized upon standing in the air.

Other (2-hydroperfluorocyclobutyl)ethylenes, dehydrofluorinated under similar conditions, are summarized in Table V.

The Peroxide-Induced Polymerization of the Halocyclobutenylethylene and Halocyclopentenylethylene.—2-Chloro-3,3,4,4-tetrafluoro-1-cyclobutenylethylene (2 g.) and benzoyl peroxide (0.1 g.) were placed in a glass tube. The tube was then sealed and kept at 100°C for 3 hr. The ethylene polymerized to give a transparent solid. Upon heating, the polymer (0.8 g.) was dissolved in *o*-chlorobenzotrifluoride (7 ml.), and the solution was poured into methanol (80 ml.). The polymer thus precipitated (0.6 g.) was washed with methanol and dried. In its infrared spectrum, the absorption bands of 3.23 ($=CH_2$), 3.30 (=CH–), and 6.19 μ (C=C) in the ethylene disappeared, and a band due to the C=C stretching in the halocyclobutenyl group shifted from 6.03 μ to 6.07 μ.

In a similar procedure, 2-chloro-3, 3, 4, 4, 5, 5-hexafluorocyclopentenylethylene was polymerized in the presence of benzoyl peroxide to give a transparent solid. The polymer was dissolved in trifluorotrichloroethane and precipitated in methanol. The absorption bands of 3.205 ($=CH_2$), 3.29 (=CH–), and 6.26 μ (C=C) in the ethylene disappeared, and a band due to C=C stretching in the halocyclopentenyl group shifted from 6.09 μ to 6.11 μ.

In a similar way, (perfluoro-1-cyclopentenyl)ethylene was polymerized to give a pale brown solid. The polymer was dissolved in acetone and precipitated in methanol. The absorption bands of 3.205 ($=CH_2$) and 6.20 μ (C=C) in the ethylene disappeared, and a band due to C=C stretching in the perfluorocyclobutenyl group shifted from 5.84 μ to 5.81 μ.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1486—1490 (1966)

The Reaction of Amino Alcohols with Acrylates

By Naoya OGATA* and Tomohiko ASAHARA

Basic Research Laboratories, Toyo Rayon Co., Ltd., Tebiro, Kamakura

(Received August 31, 1965)

The addition reaction of amino alcohols with acrylates were studied. The addition takes place at the amino group of amino alcohol, producing *N*-(hydroxyalkyl)-β-alanine in a good yield. The reaction rate becomes slower as the ester group of acrylate becomes larger, and phenyl acrylate gives a polymer as soon as it is mixed with ethanolamine. The rates of the addition reaction with acrylate are in the following order: $NH_2CH_2CH_2OH > CH_3NHCH_2CH_2OH \gg RNH_2 > NH(CH_2CH_2OH)_2$.

It is well known (the Michael reaction) that a conjugated system of the C=C–C=O type, such as an α, β-unsaturated carbonyl compound, adds a compound with an active hydrogen group in the presence of the base.

When a compound with two active hydrogen groups reacts with acrylates, the product could be a new monomer for polymer materials, since a further polycondensation between the remaining group and carboxylate group is possible:

$$H\text{-}X\text{-}H + CH_2{=}CHCOOR \rightarrow H\text{-}X\text{-}CH_2CH_2COOR \rightarrow -(X\text{-}CH_2CH_2CO)- + ROH$$

It is reported[1] that β-aminoethyl mercaptane reacts with acrylates as is shown bleow to give a thialactam:

$$H_2NCH_2CH_2SH + CH_2{=}CHCOOR \rightarrow \begin{array}{c} CONH \\ | \quad | \\ S \end{array} + ROH$$

If an amino alcohol is used in place of β-aminoethyl mercaptane, the following products would be formed in the system:

* Present address: Dept. of Chem., Sophia Univ., Chiyoda-ku, Tokyo.

1) F. Jacob and P. Schlack, *Chem. Ber.*, **96**, 88 (1963).

$$HOCH_2CH_2NH_2 + CH_2{=}CHCOOR \rightarrow \begin{array}{c} CONH \\ | \quad | \\ O \end{array}$$

$$H_2NCH_2CH_2OCH_2CH_2COOR$$

$$HOCH_2CH_2NHCH_2CH_2COOR$$

Therefore, kinetic studies on the Michael-type reaction between amino alcohols and acrylates have been carried out. They will be described below.

Experimental

Reagents.—Commercial amino alcohols and acrylates were dried in the presence of calcium hydride and distilled by means of a Shibata fractional distillation column.

Reaction.—Amino alcohols and acrylates were dissolved in solvents at given concentrations, and the solutions were mixed at a given temperature, with or without an alkali alkoxide. The reaction rates were followed by the gas chromatographic method, using a polyethyleneglycol 6000 column. After the evaporation of the solvents, the products were distilled under a high vacuum and the products were characterized by an elementary analysis and by a study of their infrared and 100 Mc. NMR spectra.

Results and Discussion

Reaction with Amino Alcohols.—The reaction rates of amino alcohols with acrylates were measured in tetrahydrofuran in the absence of an alkali alkoxide at 0, 20 and 50°C. In each case, the reactions were completed within 10 hr. at 20°C and unchanged acrylates were found in the system only in amounts of 1 to 2% .

The rates apparently followed a second-order reaction; the rate constants are summarized in Table I. In the case of methyl acrylate, the rate constant decreased at the initial stage of the reaction and an auto-catalytic effect was apparently observed. The rate constants in Table I for methyl acrylate are extrapolated values at $t=0$ for the linear part.

It may be seen from Table I that the rate constants decreased with the size of ester groups in the following order: $-CH_3 > -C_2H_5 > nC_4H_9$. The effect of alkyl groups on the addition reaction may be ascribed to the increasing –I effect, which may reduce the carbonium ion character of the β-carbon atom and, hence, may prevent a neucleophilic attack of the amino group.

$$CH_2{=}CH{-}\overset{\overset{O}{\|}}{C}{-}O{-}R \rightleftarrows C^+H_2{-}CH{=}\overset{\overset{|}{O^-}}{C}{-}O{-}R$$

When phenyl acrylate and ethanolamine were mixed in tetrahydrofuran at a concentration of 0.1 mol./l., the reaction rate was too rapid to measure and a polymer was precipitated as soon as they were mixed. A theoretical amount of phenol was found, and neither phenyl acrylate nor ethanolamine remained in the system. The

Table I. Rate constants* of the reaction of amino alcohols and acrylates

Amino alcohol	Acrylate	0°C	20°C	50°C
Ethanolamine	$-CH_3$	3.9×10^{-2}	9.0×10^{-2}	4.7×10^{-2}

* Concentration is 1 mol./l. of tetrahydrofuran, unit; min^{-1}

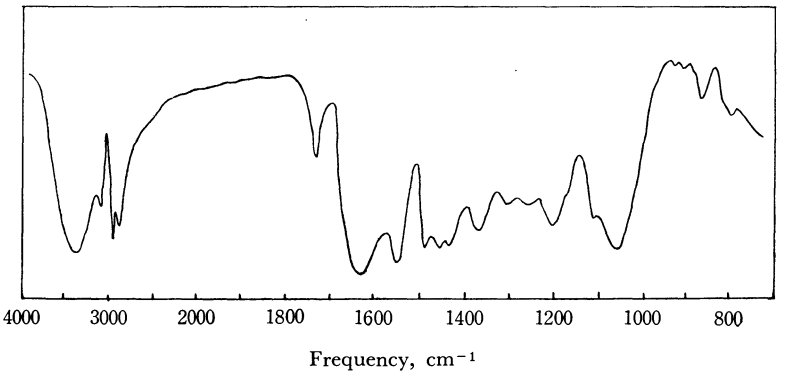

Fig. 1. Infrared spectrum of the polymer from phenyl acrylate and ethanolamine.

analytical data of this polymer were as follows: C=49.0%, H=8.5%, N=7.9%, M. W.=500. The infrared spectrum of the polymer, shown in Fig. 1, suggests a polyamide structure.

When an amine hydrogen of ethanolamine is replaced by an alkyl group, the rate becomes slower, especially for diethanolamine, the rate constant being one-thousandth that of ethanolamine.

The solvent effect on the addition reaction of ethanolamine and methyl acrylate was measured to be as shown in Table II. Generally speaking, the reaction is faster in a solvent with a higher dielectric constant. This finding suggests that the reaction might proceed through an ionic mechanism.

TABLE II. RATE CONSTANTS* OF THE REACTION OF ETHANOLAMINE AND METHYL ACRYLATE IN VARIOUS SOLVENTS AT 20°C

Solvent	Dielectric constant (20°C)	k_1, min^{-1}
Methanol	3.26	9×10^{-2}
Tetrahydrofurane	—	7×10^{-2}

Dimethylformamide	36.6	4×10^{-2}
Pyridine	12.3	3×10^{-2}
Dioxane	2.2	2×10^{-2}

* Concentration is 1 mol./l.

Reactions with Amines or Alcohol.—When an amino alcohol is added to an acrylate, there are two reaction sites, namely, an amino and a hydroxy group. Therefore, the rates of the addition reaction of simple amine or alcohol to ethyl acrylate were compared; they are summarized in Table III.

TABLE III. RATE CONSTANTS* OF THE REACTION OF AMINE OR ALCOHOL WITH ETHYL ACRYLATE IN TETRAHYDROFURANE AT 20°C

Reactant	pK_a	k_1, min^{-1}
Aniline	4.62	0
Benzylamine	9.34	5.0×10^{-5}
Diethanolamine	8.80	9.0×10^{-5}
Allylamine	9.49	1.6×10^{-4}
n-Buthylamine	10.59	2.1×10^{-3}
Ethanolamine	9.50	2.4×10^{-2}
Ethanol**	—	1.2×10^{-1}

* Concentration is 1 mol./l.

** In the presence of 5 mol.% of potassium metal.

Aniline does not react at all, even in the presence of 5 mol.% CH_3OK, and, generally, amines with higher pK values react faster. However, ethanolamine, which has almost the same pK value as allylamine, reacts about 150 times as fast as allylamine. The greatac cerelating effect of the hydroxyethyl group on the reactivity of the amino group is very interesting; it needs a further investigation. On the other hand, when an amine hydrogen of ethanolamine is further replaced by the hydroxyethyl group, the rate of the addition reaction decreases:

$$NH_2CH_2CH_2OH > CH_3NHCH_2OH \gg RNH_2 > NH(CH_2CH_2OH)_2$$

This peculiar behavior of ethanolamine suggests that the reaction involves not only a simple nucleophilic mechanism, but also a more complicated mechanism.

Alcohol does not react at all with ethyl acrylate, while in the presence of 5 mol.% of potassium ethoxide it reacts 5 times as fast as ethanolamine.

The Structure and Properties of the Reaction Products.—*Amine or Alcohol.*—The analytical results of the reaction product on *n*-butyl amine or ethanol with ethyl acrylate are as follows:

	B. p.	M.W.	C,%	H,%	N,%	Yield
n-Butyl amine						
Obs.	70/3 mmHg	173	62.3	6.9	8.1	87
Calcd.	—	173	62.4	7.5	8.1	—
Ethanol						
Obs.	54/8 mmHg	146	58.3	9.59	—	60
Calcd.	—	146	58.1	9.62	—	—

The analytical data and infrared spectra of the products support the following reactions:

$$C_2H_5OH + CH_2{=}CHCOOC_2H_5 \rightarrow C_2H_5OCH_2CH_2COOC_2H_5$$

$$n\text{-}C_4H_9NH_2 + CH_2{=}CHCOOC_2H_5 \rightarrow n\text{-}C_4H_9NHCH_2CH_2COOC_2H_5$$

Amino Alcohol.—The reaction products were polymerized into a sticky polymer by letting them stand at room temperature for several days, though it was necessary to keep them below 0°C. Their analytical results are shown in Table IV.

The infrared spectra of the products showed strong absorptions at 1720, 1200 and 1100 cm^{-1}; these absorptions were easily assigned to an ester group, as can be seen in Fig. 2. The absorption peak at 3400 cm^{-1} is assigned to a hydroxy group, since no absorption at 1600 cm^{-1} resulting from an amine deformation was found; the strong absorption observed at 1050 cm^{-1} was assigned to a hydroxy deformation band. The infrared spectrum of the reaction product of *N*-methyl ethanolamine also showed the existence of a hydroxy group.

The qualitative analysis of the reaction products gave strong support for the existence of a secondary amine. The NMR spectra of the products are shown in Fig. 3. In the case of the methyl ester, a sharp peak at 6.2 τ and a broad peak at 6.53 τ can be assigned to $-OCH_3$ and OH or $-NH_2$ respectively. As the absorption strengths of 6.31, 7.03, 7.24 and 7.43 τ are almost identical, there

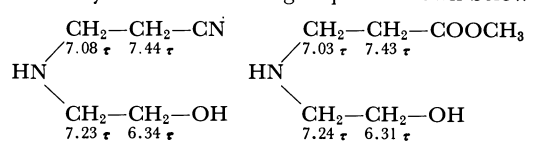
	$-C_2H_5$	135/3	28	161	165	6.2×10^{-3}	6.0×10^{-3}	8.7	8.9
	$-nC_4H_9$	116/1	—	189	188	5.3×10^{-3}	5.1×10^{-3}	7.4	7.6
N-Methyl ethanolamine	$-CH_5$	95/4	—	161	162	6.2×10^{-3}	6.2×10^{-3}	8.7	8.8
Propanolamine	$-CH_3$	102/2	—	161	227	—	—	8.7	9.8
	$-C_2H_5$	137/3	—	175	180	—	—	8.0	8.5

are four methylene groups. The chemical shift of $-OCH_2$ is generally in the range from 5.5 to 6.7 τ,[2] and the peak at 6.31 τ may be assigned to $-OCH_2-$. The peak at 7.43 τ is assigned to $-N-CH_2$, which was split into two peaks by the influence of a functional group at the β-position.

It is known[3] that ethanolamine adds to acrylonitrile and the structure of the product is *N*-(β-cyanoethyl)-ethanolamine. The NMR spectrum of this product reconfirms that ethanolamine adds to an acrylate at the amino group as is shown below:



2) K. Nukada, O. Yamamoto, T. Suzuki, M. Takeuchi and M. Ohnishi, *Anal. Chem.*, **35**, 1892 (1963).
3) Y. Ogata, *J. Am. Chem. Soc.*, **78**, 5426 (1956).

Hydroxylamine reacts with acryamide[4] at the amino group;

$$HONH_2 + CH_2{=}CHCONH_2 \rightarrow HONHCH_2CH_2CONH_2$$

From these results, it may be said that the reaction of amino alcohols with acrylates in the absence of a basic catalyst takes place at the amino group, yielding *N*-(hydroxyalkyl)-β-alanine:

$$NH_2{-}R{-}OH + CH_2{=}CHCOOR' \rightarrow HO{-}R{-}NHCH_2CH_2COOR'$$

(Yield=95—99%)

As has been stated above, the reaction rate of alcohol with ethyl acrylate in the presence of a potassium catalyst is about 600 times as fast as that of amine itself, and it is much faster than ethanolamine. The reaction of ethanolamine in the presence of an alkali alkoxide is expected to take place at the hydroxy group of ethanolamine. However, the reaction in the presence of an alkali alkoxide caused a polymerization, yielding a theoretical amount of alcohol; a low-molecular-weight polymer was also precipitated, the analytical data of which showed the same results as in the case of phenyl acrylate, and the polymer was not a homo-polyacrylate. This peculiar reaction, as well as the reaction of phenyl acrylate, will be elucidated in the near future.

The authors wish to express their thanks to Dr. Toshio Hoshino for permission to publish this paper and also to Dr. Kenkichi Nukada for his helpful discussion of the NMR spectra.

Intramolecular Hydrogen Bonds. VII.[1] Methyl Mandelates and Related Compounds

By Nobuo MORI, Yoshiteru TANAKA and Yojiro TSUZUKI

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received September 21, 1965)

The infrared OH spectra of an $ArCH(OH)(CH_2)_nCOOMe$ series ($n=0$ and 1) in dilute carbon tetrachloride solutions have been measured at 25°C with a Perkin-Elmer 21 spectrometer. A comparison of the data with those of other related compounds shows that the OH group forms a hydrogen bond predominantly with the carbonyl-oxygen atom and also with the ether-oxygen atom and/or the π-electrons of the phenyl group, while, practically speaking, no free OH group is present. Further, the NMR chemical shifts of the methine- and the methyl-protons when $n=0$, as measured with a Varian A-60 spectrometer, have been correlated with the Hammett substituent constants; the shift of the methine-proton, when the ring-substituent is a halogen, does not fall on the correlation line, but falls on a separate line.

The infrared spectrum of ethyl mandelate in a dilute carbon tetrachloride solution exhibits, in the OH-stretching region, a very strong band at 3534 cm^{-1} and a weak shoulder at 3602 cm^{-1}.[2] Flett[2] assigned the former to the OH group bonded to the carbonyl-oxygen atom of the ester group and the latter to the free OH group, mainly on the basis of a comparison of the frequencies and the half-band widths; he also suggested that the lowering of the free OH frequency from that of ca. 3625 cm^{-1} characteristic of secondary alcohols is to be attributed to the electrostatic influence of the adjacent ester group. However, the assignment of the shoulder seems doubtful because the frequency is very close to that of the OH group internally bonded to the ether-oxygen atom of an alkoxycarbonyl group in aliphatic α-hydroxycarboxylates[3] and to that of the OH group bonded to the π-electrons of a phenyl group in α-phenylalkanols.[4]

This paper will report on an investigation which has solved this problem by measuring the infrared spectra of a variety of methyl mandelates in dilute carbon tetrachloride solutions. Further, this paper will deal with their characteristics in nuclear magnetic resonance, and also with the intramolecular hydrogen bonding in two methyl β-phenyl-β-hydroxypropionates.

Experimental

Samples.—All the esters investigated, some of which have hitherto been unknown, are listed in Table I. The mandelates, except for Nos. 4 and 6, were prepared in the usual way[5-7] by the conversion of the corresponding benzaldehyde-cyanohydrins into the iminomethylether hydrochlorides, followed by hydrolysis. The cyanohydrins were synthesized by treating a suspension of the corresponding substituted benzaldehyde in glacial acetic acid with potassium cyanide[5,6] (in the case of Nos. 1 and 2) or by treating a mixture of the corresponding benzaldehyde and potassium cyanide with concentrated hydrochloric acid[7] (in the case of Nos. 3, 5, 7 and 8); they were used without further purification for the preparation of the esters. The ester of No. 4 was derived from *p*-bromoacetophenone by way of *p*-bromomandelic acid,[8] while the ester of No. 6 was prepared by the conversion of the benzaldehyde into mandelic acid,[9] followed by esterification. Methyl β-phenyl-β-hydroxypropionates 9 and 10 were prepared by the Reformatsky reaction[10] from benzaldehydes and methyl bromoacetate. All the esters were purified by recrystallization from a mixture of benzene and ligroin or by fractional distillation; their physical constants and the data of analysis are summarized in the table. The constants of the known esters agree closely with those reported in the literature.

Infrared and NMR Measurements.—The infrared measurements in the OH-stretching region were carried out, by the method previously described,[3] at 25°C with a Perkin-Elmer 21 spectrometer equipped with a lithium fluoride prism and a cell 3 cm. long. The concentrations were about 0.004 mol./l. in carbon tetrachloride, at which concentration no intermolecularly hydrogen-bonded OH band was observed; however, a very weak absorption, due to the overtone of a carbonyl-stretching vibration, appeared at ca. 3460 cm^{-1}.

The NMR spectra were measured at ca. 25°C using a Varian A-60 spectrometer on pre-calibrated chart paper, in which TMS was used as the internal standard. The concentration was 5 w./v. % in carbon tetrachloride and in chloroform. Preliminary measurements with solutions from 0.5 to 40% in both solvents showed that the resonance positions of the methine- and the methyl-protons were constant*1 within the limits of experimental accuracy (±0.5 c. p. s.). The NMR data listed in Table III are the average of two measurements.

Results and Discussion

The infrared OH spectra of the mandelates apparently consist of two resolved bands, whose frequencies are in the range from 3601 to 3611 cm^{-1} and from 3526 to 3536 cm^{-1} respectively; the higher frequency band is much weaker than the lower frequency band, as Fig. 1 shows, and the separation between the two peaks is constant to 77 cm^{-1}. It should be noted that the stronger band is located at ca. 3526 cm^{-1} and that it is somewhat broadened

* Bands I, II and III denote those due to the OH groups bonded to the proton-acceptors, =O, -O- and π-electrons, respectively, and band IV means the free OH band.

** $D=\log I_0/I$, for the apparent OH band in the case of Nos. 1—8 and for the separated OH band-component in the case of Nos. 9—14.

on the higher frequency side (the most broadened position being at ca. 3535 cm^{-1}) when the ring-substituent is of an electron-attracting nature (Nos. 1—4), while it appears at ca. 3534 cm^{-1} and is substantially symmetric in respect to the ordinate at the maximum when the substituent is a *p*-chlorine or hydrogen atom or an electron-repelling group (Nos. 5—8). The reason for this is not clear at the present time. The β-hydroxy-esters 9 and 10 show a strong, broad band around 3540 cm^{-1} and a sharp band at 3618 cm^{-1}, the former being highly broadened on the higher frequency side; each of the observed spectra can be graphically separated into three symmetric components,*2 as is shown in Fig. 2.

*2 Although it is not clear whether or not the individual band-components are intrinsically symmetric, their symmetry is, at any rate, assumed to simplify the graphical separation. This separation was thus made by reflecting the major component about the ordinate at the apparent maximum and by subtracting the mirror image from the observed spectrum. The residual minor part, which had a shoulder at ca. 3590 cm^{-1}, was then similarly separated into two. Alternatively, by reflecting the minor component and subtracting the mirror image, the major part remained; this was highly broadened around 3590 cm^{-1}. It is unlikely that either the major or the minor component is intrinsically unsymmetric with the broadening or the shoulder at 3590 cm^{-1}. Rather, the part at 3590 cm^{-1} may reasonably be attributed to an absorption of another bonded OH group, as will be discussed in detail later.

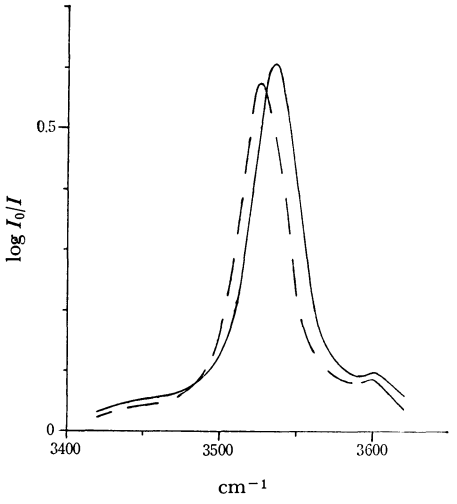

Fig. 1. IR spectra of methyl *p*-nitromandelate (— —) and *p*-methoxymandelate (——).

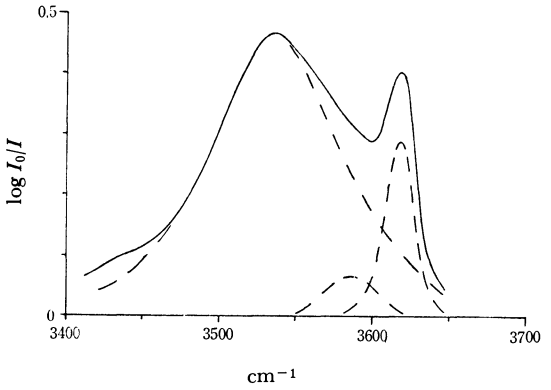

Fig. 2. IR spectrum of methyl β-phenyl-β-hydroxypropionate.

Table II includes the IR data of the apparent OH bands of the mandelates and the OH band-components separated from the observed spectra of the β-phenyl-β-hydroxypropionates, together with those of some related compounds for the purpose of comparison.

In order to assign the bands, it is convenient to take account of the six hydrogen-bonded conformations possible by rotation around the C–O axis; these conformations are shown in Fig. 3. Further, there must be considered the electrostatic and the steric influence on the OH frequency of the phenyl group and the methoxycarbonyl group, both skew

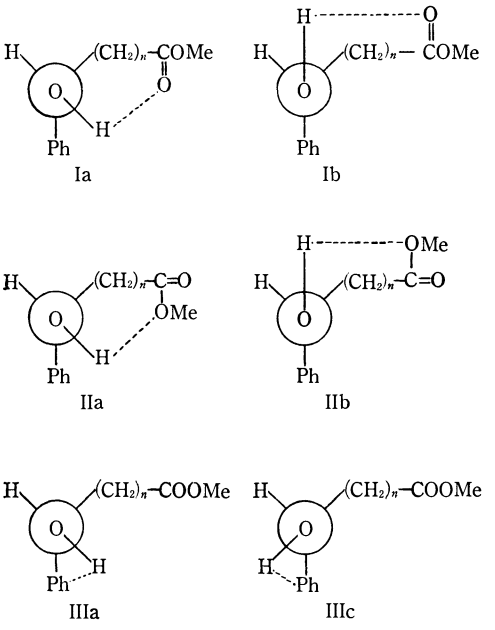

Fig. 3. Hydrogen-bonded conformations possible around the C–O axis.

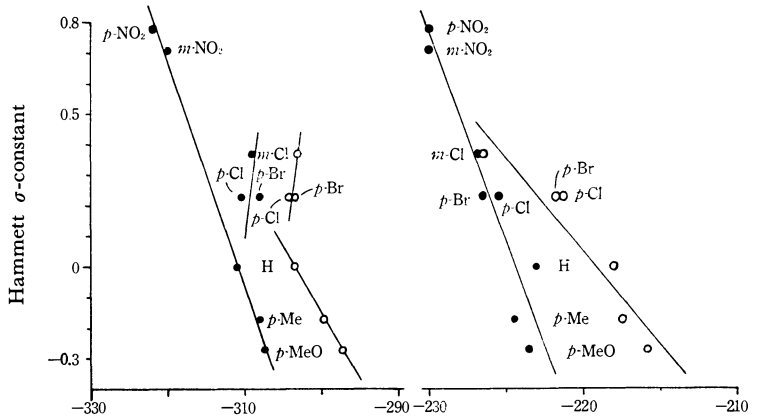

Fig. 4. Chemical shifts vs. Hammett σ-constants for: (left) the methine- and (right) the methyl-protons in chloroform (-●-) and carbon tetrachloride (-○-).

to the OH group. Fortunately, it is known that the influences both of an unsubstituted and a substituted phenyl group are substantially of the same degree as those of a methyl group,[4,17] while the electron-attracting nature of the methoxycarbonyl group lessens the OH frequency by 10 cm^{-1} at most.[3]

In the mandelates ($n=0$ in Fig. 3), the lower frequency band is undoubtedly due to the OH group bonded to the carbonyl-oxygen atom in form Ia and to the bonded OH group in form Ib, since its frequency agrees with that of band I of the comparative α-hydroxycarboxylates. The higher frequency band should not be attributed to a free OH group, since it is considerably lower than the frequency of 3620 cm^{-1} or more which is to be expected for the OH group in form Ib, IIb or IIIc, if it is not hydrogen-bonded. The frequency is also lower than the 3618 cm^{-1} of band II of ethyl glycolate 11 in a form corresponding to form IIb, but it is rather close to the 3606 cm^{-1} of band II of ethyl α-hydroxyisobutyrate 12 in a form corresponding to form IIa. On the other hand, the bonded OH frequencies of forms IIIa and IIIc may fall within the frequency range from 3601 to 3611 cm^{-1}, if the lowering of frequency due to the electron-attracting nature of the methoxycarbonyl group is 7 cm^{-1} and this is then subtracted from the bonded OH frequencies of 3607 and 3617 cm^{-1} of phenyldimethylcarbinol 16 and benzylalcohol 15. Consequently, the band is due to the bonded OH group in at least one of the forms, IIa, IIb, IIIa and IIIc. For a more detailed discussion, it is necessary to investigate the electronic effect of a ring-substituent influencing on the band-intensity. Unfortunately, however, the observed absorbance is too low and inexact to make such an investigation possible.

In the β-phenyl-β-hydroxypropionates ($n=1$ in Fig. 3), the three bands can easily be assigned by comparing their frequencies with those of aliphatic β-hydroxycarboxylates and α-phenylalkanols, as, practically speaking, it is not necessary to take account of the frequency-lowering effect of the methoxycarbonyl group.[3] The band at around 3540 cm^{-1} can undoubtedly be assigned to the OH group bonded to the carbonyl-oxygen atom in form Ia and the bonded OH group in form Ib, while the band at ca. 3590 cm^{-1} may be assigned to the OH group bonded to the ether-oxygen atom in forms IIa and IIb for two reasons: (1) such forms should be present to some extent, though less stable than forms Ia and Ib, and (2) the frequency closely agrees with the ν_{OH} of 3590—3600 cm^{-1} of some 1, 3-diol monoacetates[18] in a similar six-membered ring formed through the intramolecular hydrogen bonding. On the other hand, the highest frequency band may be due to the OH group bonded to the π-electrons of the phenyl group in forms IIIa and IIIc, rather than due to a free OH group. This assignment may be further supported by the fact that the relative intensity of band III to II is higher than those of the free OH band, IV, to band II in β-hydroxycarboxylates 13 and 14; this heightening may result from the hydrogen bonding of the OH group with the π-electrons. As can be seen from a comparison of the data of esters 9 and 10, the p-methoxy substituent appears to raise the relative intensity of band III to II; this is in agreement with the effect of an electron-repelling substituent in strengthening the bonded OH band in series of α- and β-phenylalkanols.[17,19] Thus, no free OH group is present in these esters, since there is no absorption in the frequency region around 3627 cm^{-1} characteristic of the free secondary OH group of α-phenylalkanols.[4]

The above assignments are reasonable also in view of the half-band widths. Thus, the $\Delta\nu_{1/2}$ values of bands I and II (or III) of the mandelates are essentially equal to those of the α-hydroxycarboxylates 11 and 12. The same relationship can be found between the two series of β-hydroxycarboxylates (9 and 10) and (13 and 14).

The Correlation of the Chemical Shift with the Hammett σ-Constant.—Table III includes the NMR data of the methine- and the methyl-protons of the mandelates.

The chemical shifts of protons not directly bonded to the aromatic ring in some aryl compounds have recently been correlated with the Hammett σ-constants.[20] In Fig. 4 the chemical shifts of the methine- and methyl-protons in the mandelates are plotted vs. the Hammett σ-constants.*3 When the substituent is a halogen, the methine-proton point in both solvents does not fall on the correlation line, but falls on a separate line. A similar deviation of the halogens from the correlation line has been obtained when they are plotted vs. the σ^0-values reported by Taft.[21] This at present admits of no explanation. However, it is noteworthy that the falling of the halogens on a separate line is

Studies of the Organic Reaction of Metal Carbonyl. VIII.* The Isomerization of Aliphatic C_5- and C_6-Acylcobalt Carbonyls

By Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Hiromitsu MASADA
Yasukazu OKUDA, Keiji KUBO and Chikao YOKOKAWA

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 24, 1965)

The isomerization of C_5-acyl(*n*-valeryl- and α-methylbutyryl-) and C_6-acyl(*n*-caproyl-, α-methylvaleryl- and α-ethylbutyryl-)cobalt carbonyls has been studied and compared with that of C_4- acyl(*n*- and isobutyryl-)cobalt carbonyls previously reported. It has been observed that solvents have great effects on the isomerization (the rate and equilibrium) of the C_5-acylcobalt carbonyls. The equilibrium proportion of the isomers (iso/normal) is almost 1 in diethyl ether and tetrahydrofuran. In solvents such as dioxane, ethyl acetate and benzene it seems difficult for this isomerization to occur. α-Ethylbutyrylcobalt carbonyl appears to isomerize directly to *n*-caproylcobalt carbonyl. However, *n*-caproylcobalt carbonyl isomerizes only to α-methylvaleryl-cobalt carbonyl; the reverse isomerization also occurs, but it seems very difficult for any other isomerization between the two of them to occur.

The previous studies of this series have shown that acylcobalt carbonyls readily isomerize and that this isomerization is remarkably affected by the various reaction conditions; with the isomerization of *n*- and isobutyrylcobalt carbonyl (C_4-acylcobalt carbonyls), such solvents as diethyl ether and ethyl acetate have a great effect on the rate and the equilibrium.[1-3]

In the present investigation, the isomerization of C_5- and C_6-acylcobalt carbonyls has been studied in detail by examining the effects of solvents on this reaction. In addition, the possible course of the isomerization of α-ethylbutyrylcobalt carbonyl to *n*-caproylcobalt carbonyl has been investigated.

Experimental

The General Procedures.—The reactions were carried out in the way described in previous papers.[1,2]

The Analytical Procedures.—The reaction products were analyzed by means of a study of their infrared spectra, which were measured on a Shimadzu model IR-27 spectrophotometer, and by gas chromatography; a column 4.5 m. long and 3 mm. in diameter, filled with dilauryl phthalate or silicon DC 550 on cerite, was used. The column temperature was 80 to 110°C, and the flow rate was 50 to 75 ml. per minute.

Materials.—Cobalt hydrocarbonyl was prepared

according to the method described in a previous paper.[2] Valeryl chloride, α-methylbutyryl chloride, and *n*-caproyl chloride were commercial products. α-Ethylbutyryl chloride and α-methylvaleryl chloride were prepared by the chlorination of α-ethylbutyric acid and α-methylvaleric acid respectively with thionyl chloride. As the authentic samples, methyl, ethyl, and propyl esters of these acids, prepared by the alcoholysis of the acid halides, were used. The solvents used were dried by the usual methods.

Results and Discussion

The Reaction of *n*-Valeryl and α-Methylbutyryl Chloride with Potassium Cobalt Carbonylate.—The results of the reactions of *n*-valeryl chloride and α-methylbutyryl chloride are summarized in Tables I and II.

In the isomerization of *n*- and isobutyrylcobalt carbonyls, equilibrium between the two isomers has been observed to exist and to be remarkably affected by the solvents; the equilibrium proportion of the isomers (iso/normal) is almost zero in dioxane and tetrahydrofuran, 1/3 in ethyl acetate, and about 1 in diethyl ether, but in a nonpolar solvent such as benzene this isomerization does not occur at all.[1,2]

In this program, the isomerization of C_5-acylcobalt carbonyls was carried out in various solvents in order to study the effect of solvents in detail. The percentages in the last columns of the tables indicate the degree of the isomerization, the proportion of isomerized *n*-valeryl- or α-methylbutyrylcobalt carbonyls. As the reaction products, about 0.7 to 0.3 mol. of valerate and methylbutyrate per mole of potassium cobalt carbonylate was obtained. The yield of the esters decreased with an increase in the reaction time. This may be partly attributed to a thermal instability of the acylcobalt carbonyls.

In diethyl ether under carbon monoxide or nitrogen, *n*-valerylcobalt carbonyl isomerized readily to α-methylbutyrylcobalt carbonyl (Exps. 1—3). The degree of the isomerization amounted to 43% after 9 hr. On the other hand, α-methylbutyrylcobalt carbonyl also isomerized, to give 30% of *n*-valerate, after 9 hr. (Exp. 13). In these

two cases, the degree of isomerization seemed to increase with an increase in the reaction time. These facts seem to suggest that there is an isomerization equilibrium between the isomers:

$$\text{C-C-C-C-COCo(CO)}_{3\text{ or }4} \rightleftharpoons \begin{array}{c} \text{C} \\ | \\ \text{C-C-C-COCo(CO)}_{3\text{ or }4} \end{array}$$

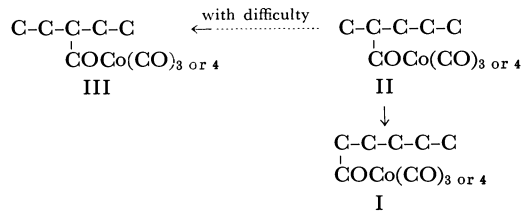
The equilibrium proportion (iso/normal) may be about 1 under the conditions used. Similarly, in tetrahydrofuran the equilibrium proportion (iso/normal) of the same reaction seemed to be about 1. However, with butyrylcobalt carbonyls the equilibrium is almost completely favorable to *n*-butyrylcobalt carbonyl in tetrahydrofuran.[1] Therefore, the behavior of tetrahydrofuran in the isomerization of the C_5-acylcobalt carbonyls appears to be different from that in the isomerization of the C_4-acylcobalt carbonyls.

In dioxane, ethyl acetate and benzene *n*-valerylcobalt carbonyl isomerized, but they gave only about 2% of α-methylbutyrate after 4 hr. (Exps. 9—11), while α-methylbutyrylcobalt carbonyl gave 2 to 7% of *n*-valerate after 4 hr. (Exps. 20—22), suggesting that the C_5-acylcobalt carbonyls isomerize with much difficulty in these solvents. On the other hand, it has been observed that, in dioxane, isobutyrylcobalt carbonyl readily isomerized to give almost 100% of *n*-butyrylcobalt carbonyl after 2.5 hr. at 25°C, whereas the C_4-acylcobalt carbonyls seem very difficult to isomerize in benzene.[1] Thus, dioxane and benzene also seem to have effects on the isomerization of the C_5-acylcobalt carbonyls apparently different from those

on the isomerization of the C_4-acylcobalt carbonyls.

The Reaction of α-Ethylbutyryl Chloride, α-Methylvaleryl Chloride, and n-Caproyl Chloride with Potassium Cobalt Carbonylate. —The isomerization of C_6-acylcobalt carbonyls was also investigated. The results of these reactions are summarized in Tables III and IV.

As is shown in Table III, α-methylvalerylcobalt carbonyl (II) isomerized to give some *n*-caproate, but only a trace of α-ethylbutyrate (Exps. 33, 35).



The reverse isomerization of I to II was also observed (Exps. 36—41); in diethyl ether, 23, 26 and 28% of α-methylvalerate was obtained after 4, 9, and 14 hr. respectively, and in ethyl acetate 17% of α-methylvalerate was formed after 23 hr., these facts suggest that the proportion of the isomerized product increases with an increase in the reaction time. However, in ether or ethyl acetate I gave only a trace of α-ethylbutyrate, even after 14 to 23 hr. From this fact, I appears to isomerize to II rather easily, but only with much difficulty to III:

$$\text{II} \longleftarrow \text{I} \dashrightarrow \text{III}$$

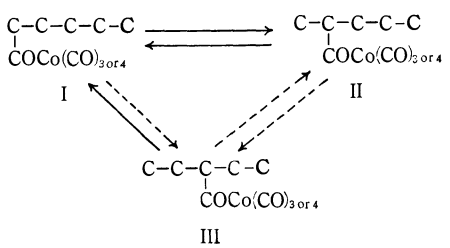
On the other hand, III isomerized to give I in a relatively good yield (Exps. 23—30); in diethyl ether, III gave 6, 10, and 25% of I after 4, 9, and 22 hr. respectively; similarly, in ethyl acetate, benzene or toluene, *n*-caproate was also obtained as the isomerization product. However, α-methylvalerate, which was expected to be one of the isomerization products, was obtained in only a low yield in all of these cases; in these solvents, only a trace or less than 2% of α-methylvalerate was obtained after 4 to 22 hr. These facts seem to indicate that III isomerizes relatively readily to I but only with difficulty to II:

$$\text{III} \begin{cases} \longrightarrow \text{I} \\ \dashrightarrow \text{II} \end{cases}$$

As the course of this isomerization (III to I), two ways are possible: in the first course, III directly isomerizes to I, while in the second course III isomerizes to I via II.

In the present case, the isomerization of III to I seems to proceed through the first course, This conclusion is drawn from the following facts: a) The isomerization of II to I occurred relatively slowly; in diethyl ether, II gave 10% of *n*-caproate, even after 14 hr. but III gave 10% of *n*-caproate after 9 hr. These facts have a strong suggest that the isomerization of II to I occurs more slowly than that of III to I. It is, however, reasonable to consider that the isomerization of III to I via II can not proceed more rapidly than that of II to I. Thus, the isomerization of III to I seems not to take the second course. b) In the isomerization of III, α-methylvalerate, i. e., II, was obtained in only a very low yield. This fact could be explained by the second course as follows: the isomerization of III to II was slower than that of II to I, the isomerization of III to II being the rate-determining step. However, the actual isomerization of III to I proceeds more readily than that of II to I, as has been described in a). Accordingly, in the isomerization of III, II seems to be formed by the successive isomerizations, III to I and then I to II.

On the base of facts mentioned above, the isomerization relation among the C_6-acylcobalt carbonyls (I, II and III) may be summarized as follows:



That is, such isomerizations as I to II, II to I and III to I occur relatively readily, but it appears difficult for the other isomerizations to occur.

The isomerization equilibrium among the three isomers could not be determined since the C_6-acylcobalt carbonyls generally isomerize more slowly than the C_5-acylcobalt carbonyls (for example, cf. Exps. 1 and 36).

As Exps. 32, 35, and 42 show, in dioxane it seems difficult for C_6-acylcobalt carbonyls to isomerize, suggesting that the behavior of a solvent may be different in the isomerization of the C_6-acylcobalt carbonyls and in that of the C_4-acylcobalt carbonyls.[10]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1499—1501 (1966)

Studies of the Organic Reaction of Metal Carbonyl. IX.*[1] The Formation of *o*-Toluylcobalt Carbonyl in the Reaction of Benzyl Chloride with Potassium Cobalt Carbonylate

By Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Hiromitsu MASADA and Chikao YOKOKAWA

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Kyoto

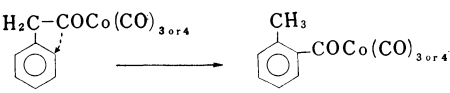
(Received October 1, 1965)

The reaction between benzyl halide and potassium cobalt carbonylate has been studied. *o*-Toluylcobalt carbonyl is found among the reaction products. This carbonyl seems to be formed by the isomerization of benzyl cobalt carbonyl via phenylacetylcobalt tricarbonyl or *o*-tolylcobalt carbonyl. This isomerization occurs only at relatively high temperatures (30—50°C). At 0°C, only phenylacetyl cobalt carbonyl is formed in a good yield. The isomerization is highly promoted by the addition of cobalt hydrocarbonyl. The reaction atmosphere (carbon monoxide and nitrogen) also has a great effect on the isomerization. Such additives as oxalic acid, *p*-toluenesulfonic acid, trichloroacetic acid, and ethyl alcohol-hydrogen chloride have no promoting effect on the isomerization.

The previous works of this series have shown that α-ethylbutyrylcobalt carbonyl directly isomerizes to *n*-caproylcobalt carbonyl as follows:[1,2]

Namely, the acylcobalt carbonyl group bonded to the middle carbon atom of the *n*-C_5 structure appears to rearrange to the terminal carbon atom by leaping one carbon atom at the 2-position.

In this connection, it seems of considerable interest to study whether phenylacetylcobalt carbonyl may analogously isomerize to *o*-toluylcobalt carbonyl:



In the present paper, the reaction between benzyl halide and potassium cobalt carbonylate has been investigated in order to examine the possibility of this isomerization.

Experimental

The Reaction Procedures.—A 100-ml. four-necked flask, equipped with a 50-ml. dropping funnel, a stirrer and a rubber stopple, was connected with a gas buret, and the air in the system was replaced with carbon monoxide or nitrogen. By the use of a syringe, 50-ml. of a 0.09 M cobalt hydrocarbonyl solution in *n*-hexane was put into the flask; then the solution was titrated with a 1/2 N ethyl alcohol solution of potassium hydroxide, using phenolphthalein as indicator. To the potassium cobalt carbonylate thus formed, 4.5 mmol. of benzyl halide and an appropriate amount of a cobalt hydrocarbonyl solution in *n*-hexane or various organic acids were introduced; then the mixture was stirred at various temperature for 2 to 15 hr.

Analytical Procedure.—After a certain reaction time, about 30 ml. of a saturated solution of iodine in toluene and about 4 ml. of alcohol (methyl, ethyl or propyl alcohol) were stirred into the reaction mixture. By this treatment acylcobalt carbonyl was converted into the corresponding ester of carboxylic acid. The solution of the ester was concentrated to about 5 ml. and then analyzed by means of a study of the infrared spectra, which were measured on a Shimadzu model IR-27 spectrophotometer, and by gas chromatography. A column (3 m. long and 3 mm. in diameter), filled with dilauryl phthalate on cerite, was used; the column temperature was 170°C, and the flow rate of the carrier gas (hydrogen) was 70 ml./min.

Materials.—Cobalt hydrocarbonyl was prepared according to the method described in a previous paper.[3] The benzyl chloride, the bromide and the various organic acid were commercial products.

Results and Discussion

The results of the reactions of benzyl halide with potassium cobalt carbonylate are summarized in Table I.

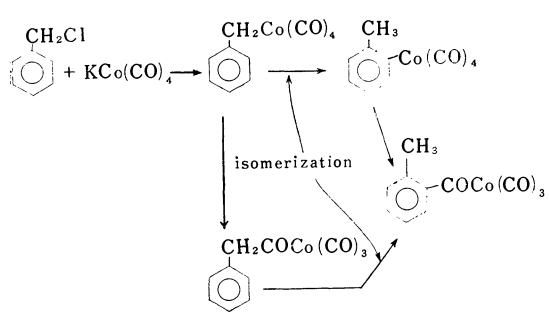
*1 Solution in *n*-hexane.
*2 The negative sign shows the gas evolution.
*3 The reaction products were identified as ethyl phenylacetate and ethyl *o*-toluate.
*4 (*o*-Toluate/(*o*-Toluate + Phenylacetate))×100
*5 Benzyl bromide was used. The reaction was carried out in two stages: at first at 0°C for 3 hr. (0.91 mol. of carbon monoxid was absorbed.) and then at 40°C for 4 hr. (2.03 mol. of gas was evolved.).

As Exp. 1 shows, without additives the reaction of benzyl chloride at 40°C under carbon monoxide proceeded with the evolution of gas*2 to give ethyl phenylacetate as the main product. Besides this ester, only a small amount of ethyl *o*-toluate was obtained as an isomerization product. Under nitrogen, a larger amount of gas was evolved, but *o*-toluate was also obtained in a low yield (Exps. 2 and 3):



The formation of *o*-toluylcobalt carbonyl seemed to proceed by the isomerization of benzylcobalt carbonyl and/or phenylacetylcobalt carbonyl, as has been shown above. However, it is considered difficult for such an isomerization to occur under these conditions. At a lower reaction temperature (20 to 0°C) under carbon monoxide, the reaction proceeded with the absorption of gas*3, to give ethyl phenylacetate in a relatively good yield, but no ethyl *o*-toluate, indicating that under milder conditions the isomerization occurs with much difficulty.

However, this type of isomerization was remarkably promoted by the addition of cobalt hydrocarbonyl. When 0.5 mol. of cobalt hydrocarbonyl per mole of potassium cobalt carbonylate was present, a tolerable amount of *o*-toluate*4 was

*2 The evolution of gas seemed to be partly attributable to the decomposition of the alkyl- and acylcobalt carbonyls formed.
*3 The gas absorption seemed to be attributable to the formation of phenylacetylcobalt tetracarbonyl.
*4 (*o*-Toluate/(*o*-Toluate+Phenylacetate))×100 Indentified by gas chromatography and by a study of the infrared spectrum of the solution of the products in toluene, which showed absorption bands at 1729 and 1740 cm^{-1}: The retention time of the esters in gas chromatography increased with the molecular weight of the alcohol used in the cleavage of the crude products;

$$RCOCo(CO)_{3\text{ or }4} \xrightarrow{I_2 + R'OH} RCOOR'$$

obtained (Exps. 4—14). Under carbon monoxide at 40°C, the percentage of *o*-toluate amounted to 55% after 11 hr. (Exp. 8). The total yield of esters, i. e., phenylacetate and *o*-toluate, decreased with an increase in the reaction time. Under these conditions, large gas evolution gradually occurred; this amounted to about 3 mole*[5] after 11 hr. On the other hand, at 20°C gas absorption occurred, but no isomerized product was obtained, even after 13 hr. (Exp. 4). These facts indicate that a relatively high temperature, which seems to cause the acyl- and alkylcobalt carbonyls to decompose, may be effective in the isomerization.

Under nitrogen, *o*-toluate was also formed in the presence of cobalt hydrocarbonyl. At 40°C about 7% of *o*-toluate was obtained after only 2 hr. (Exp. 10); this percentage became 36 and more than 95% after 5 and 7 hr. respectively. Thus, the isomerization, the formation of *o*-toluylcobalt carbonyl, occurred under nitrogen more readily than under carbon monoxide, as in the isomerization of aliphatic acylcobalt carbonyls.[1-4] At 50°C, 40% of *o*-toluate was formed after only 2 hr., but at 30°C only 10% of *o*-toluate was obtained, even after 8 hr. Therefore, higher temperatures seem to promote the isomerization. In these cases, a large gas evolution was also observed. The total yield of the esters appeared to decrease with an increase in the amount of gas evolved; when about 2 to 3 mol. of gas were evolved, the yield of the esters amounted to only 0.1—0.2 mol.

As for the course of the isomerization, two ways are possible; in the first course, benzylcobalt carbonyl, which is derived by the reaction of benzyl halide with potassium cobalt carbonylate, isomerizes to *o*-toluylcobalt carbonyl via phenylacetylcobalt carbonyl, while in the second course this isomerization occurs via *o*-tolylcobalt carbonyl. In the present study, it can not be decided which course should be chosen for this type of isomerization. From the fact that a nitrogen atmosphere remarkably promotes the isomerization, however, *o-tolylcobalt carbonyl and phenylacetylcobalt* tricarbonyl, i. e., carbon monoxide-lacking states, appear to be very important as isomerization species, as in the isomerization of aliphatic acylcobalt carbonyls.[1-4] This consideration is supported by the results of Exps. 15 and 16, in which the reaction was carried out in two stages under carbon monoxide, first at 0°C and then at 40°C. At 0°C, about 0.9 mol. of carbon monoxide was absorbed over 3 hr. period, indicating that benzylcobalt carbonyl might be converted into phenylacetylcobalt tetracarbonyl in a good yield; then the reaction temperature was changed to 40°C, which is effective for the isomerization, but only a small amount of the isomerized product was obtained after 6 hr., even in the presence of cobalt hydrocarbonyl. From this fact, it seems that phenylacetylcobalt tetracarbonyl is difficult to isomerize.

It has been known that cobalt hydrocarbonyl is a strong acid.[5] In relation to this character of cobalt hydrocarbonyl, the effects of the addition of various organic acids on the reaction have been examined. Oxalic acid, *p*-toluenesulfonic acid, trichloroacetic acid and ethyl alcohol - hydrogen chloride were used, 0.5 mol. portions of these acids were added to the reaction system instead of cobalt hydrocarbonyl. However, these acids seemed to have no promoting effect on the isomerization, even at 40°C, as Exps. 17—20 show. Thus, the promoting effect of cobalt hydrocarbonyl seems not to be attributable to only its acidic character. The reason why cobalt hydrocarbonyl has this effect could not be determined in the present investigation.

*5 "Mole" means mole per mole of potassium cobalt carbonylate in this description.

Ferrocene-containing Polymers. VIII. Polycondensation of *N*, *N*-Dimethylaminomethylferrocene with Ferrocene

By Eberhard W. NEUSE and Kazuko KODA

Polymer Laboratory, Missile & Space Systems Division, Douglas Aircraft Company, Inc. Santa Monica, California, 90406, U. S. A.

(Received September 25, 1965)

Based on previous investigations involving the self-condensation of the ferrocenyl Mannich base, *N*, *N*-dimethylaminomethylferrocene (I), the present paper describes the co-condensation of this Mannich base with ferrocene. The reactions are conducted in the melt phase in the presence of a $ZnCl_2$/HCl catalyst system. The resulting polymeric products are soluble and partially fusible and have number-average molecular weights in the 500—4000 range (unfractionated). The polymers, exhibiting the idealized structure III, are closely related to the products of self-condensation (II), with recurring units composed of ferrocenylene and methylene groups and homoannular substitution predominating along the chain. Due to the presence of ferrocene, however, an additional termination step is introduced into the overall reaction, leading to a reduced degree of polymerization. The considerable excess over the stoichiometric amount of ferrocene required to achieve this competitive termination and concomitant decrease in M_n suggests that pronounced inductive and hyperconjugative effects are operative in the ferrocenylene-methylene system, resulting in activation of the methylene-substituted ring. The isolation of the lowest homolog possible, diferrocenylmethane, lends further support to the proposed structure of the recurring unit. Spectroscopic evidence obtained on subfractionated material suggests the substitution pattern along the chain to be essentially the same as in the earlier described homocondensation polymers, which is consistent with the assumption of essentially like propagation mechanisms in both cases. A small degree of branching is also inferred from spectroscopic data.

In a previous publication,[1] the $ZnCl_2$/HCl-catalyzed formation of ferrocene-containing polymers from the ferrocenyl Mannich base, *N*, *N*-dimethylaminomethylferrocene (I), was described. The products of condensation were shown essentially to be composed of ferrocenylene-methylene recurring units, and the overall polymer structure was depicted, somewhat idealized, by the novolac-type formula II. Each polymer molecule was believed to contain a double-bridged segment resulting from termination steps through self-substitution on the penultimate ferrocenylene group of the growing chain, much as proposed[2] for the identical polycondensation product of hydroxymethylferrocene. In continuation of these earlier efforts, the present paper describes work on the polycondensation of the Mannich base in the presence of ferrocene, in which case essentially the same propagation sequence, but a different termination step, may be expected, leading to polymer III rather than II.

Results and Discussion

As in the case of homocondensation of I, the co-condensation of this Mannich base with ferrocene, summarized in Eq. 1, will proceed in several steps, the first of these[1] being the formation of adduct IV. By stepwise ionization, with V occurring as successor species,[3] complex IV will generate the metallocarbonium ion VIa (or VIb from polyhomologs of IV and V in an advanced stage of the condensation). For ions VI, the same three reaction steps can be visualized as in the homocondensation of I. These steps involve: (1) nuclear substitution of monomeric and polymeric complexes of the types IV and V (growth

step); (2) self-substitution on penultimate ferrocene nucleus with resulting formation of a double-bridged segment as part of a nitrogen-free polymer chain (termination step); (3) nuclear substitution of nitrogen-free polymer (growth step). In addition to these three reaction steps involved in the homocondensation of the Mannich base, nuclear substitution of ferrocene may now occur as an alternate termination step (4) competing with the self-substitution reaction (2). To what extent the self-substitution step in this largely diffusion-controlled process can be suppressed as a terminating reaction in favor of (4) will largely depend on both the ferrocene concentration in the melt and the difference in reactivity between the ferrocene molecule and the substituted ferrocenyl or ferrocenylene units. Prevalence of steps (1) through (3) over (4) may be predicted as a result of inductive and hyperconjugative[4-8] activation of the substituted ferrocene rings. Therefore, in order to enforce a reaction course according to Eq. 1 by suppressing the other three reaction steps in favor of (4), it would appear necessary to employ the ferrocene co-reactant in concentrations considerably higher than required by the stoichiometry of Eq. 1.

The experimental results of a series of co-condensations confirmed these expectations. When heated with various amounts of ferrocene in the presence of zinc chloride and hydrogen chloride (or zinc chloride and water, thus generating hydrogen chloride by hydrolysis) under conditions similar to those applied in homocondensations,[1] the Mannich base readily underwent condensation to give polymers in 75—85% yield. By combining extraction, precipitation and sublimation steps, the polymer was separated in each case from unreacted ferrocene, zinc salts and traces of crosslinked polymer, to be finally collected in two crude fractions of different average molecular weights. The first fraction consisted of polymeric material, whereas the second fraction, usually somewhat

smaller, contained essentially oligomeric constituents. The reactions are illustrated by 10 examples[9] summarized in Table I, and the pertaining analytical data are compiled in Table II.

The analytical results recorded confirm the anticipated structure III.[10] Furthermore, the effect of the ferrocene co-reactant on the average degree of polymerization is demonstrated by a

9) For comparison, several polycondensations were conducted with aluminum chloride as catalyst, applying experimental conditions similar to those summarized in Table I for zinc chloride. In a typical run employing Mannich base and $AlCl_3$ in a 2 : 1 molar ratio, polycondensation occurred even in the absence of additional catalyst components such as HCl or H_2O. However, due to unusually strong crosslinking and decomposition effects even at the comparatively low temperature applied (150°C), the reaction had to be terminated at an incomplete stage, and the yield in linear polymer barely approached 40%. These discouraging results prompted the abandonment of $AlCl_3$ as the Lewis acid component in these condensations.

10) Undoubtedly, the first fractions from experiments employing a high Mannich base/ferrocene ratio contain some polymer II formed via the self-substitution step (2). However, this cannot be borne out by chemical analysis since in the molecular weight ranges concerned the differences in elemental composition are too small to be analytically discernible, as becomes evident from a comparison of the calculated analytical data in Table II with those for the homocondensation product II recorded earlier[1] (Calcd. for II: C, 66.71; H, 5.09; Fe, 28.20%).

comparison of the M_n and yield values, lowest molecular weights being obtained at highest ferrocene concentrations. The data also show the enhanced susceptibility of the substituted, as compared to the unsubstituted, ferrocene moiety toward electrophilic attack. This can readily be seen in such experiments as Nos. 5, 6, 9 and 10, in which the yields in oligomeric III ($n \approx 2$) were markedly lower than would have been expected for comparable ring activation of substituted and unsubstituted ferrocene units.

Employing standard fractionation procedures, several typical polymer batches were separated into subfractions of enhanced monodispersity. These subfractions had molecular weights (M_n) ranging from about 400 to 11000 and showed elemental analyses in the same good agreement with structure III as noted above for the unsubfractionated products. An X-ray diffraction study revealed crystallinity only for fractions with $M_n <$ 700. This lack of crystallinity in fractions with constituents containing four or more ferrocene nuclei is not surprising in view of assumed branching (see below) and random distribution of the 1, 2-, 1, 3- and 1, 1'-disubstituted recurring units. The lowest subfraction isolated, after chromatographic purification, proved to be identical in m. p., M_n and elemental composition with the known[11,12] diferrocenylmethane (III, $n=1$), whose structure was confirmed by percent homoannularity value[2] (96.9) and NMR spectrum, the latter showing singlets due to ferrocene (18 protons) and methylene (two protons) resonances at τ 6.09 and 6.70, respectively.[13] This unambiguous identification of the lowest homolog as diferrocenylmethane is well in support of the structural assignment III to the presently discussed polymer.

The infrared spectra (KBr pellet) of polymer III showed the bands characteristic of the ferrocenylene-methylene unit as discussed elsewhere.[2] The spectra of high-molecular fractions were practically superimposable with those of polymer II prepared either from *N*, *N*-dimethylaminomethylferrocene[1] or from hydroxymethylferrocene.[2] This spectroscopic identity is predictable, since the effect, if any, of a double-bridged segment in homopolymer II on the absorption pattern of the ferrocenylene-methylene units is probably too small to be detectable, with interfering absorption of other origin appearing in all characteristic regions, notably in that at 10.6—11.0μ. The occurrence of the typical medium-intensity band near 7.8 μ not only in higher molecular fractions, but even in the lowest, solely monosubstituted member (diferrocenylmethane), prohibits utilization of this peak in distinguishing 1, 3- from 1, 2-disubstituted ferrocene derivatives as suggested by Nesmeyanov.[18] (Cf., in this connection, Rosenblum and Howells.[7]) By the same reasoning, the band in the 10.8—10.9μ range exhibited by diferrocenylmethane and all higher molecular fractions cannot be utilized for this distinction.[4,6,8,19] In going from low- to high-molecular fractions, the two bands near 9 and 10μ indicative of the presence of unsubstituted ferrocene rings[19] were attenuated in intensity. At the same time, an intensity decrease of the ring-breathing absorption near 7.1μ became apparent; while observed with other homoannularly substituted ferrocene derivatives made available for this comparison, this band failed to occur, or at best appeared very weakly, in a great number of heteroannular compounds investigated and may, therefore, be utilized in suitable cases as corroborative evidence for the presence of unsubstituted rings. The weak band at 10.60μ originally ascribed to a CH_2 rocking mode[2] was found to be exhibited in nearly unchanged intensity by all fractions except the lowest member, thus indicating a different origin; possibly, the band is associated with a 1, 3-disubstitution scheme[4,6] on ferrocene.

The majority of subfractions of III with $M_n <$ 5000 showed a defined melting behavior. This is in contrast to the predominantly infusible (when fractionated) polymer II; various degrees of monodispersity and branching possibly acount for this inconsistency. The m. p.-M_n relationship depicted in Fig. 1 may, within the molecular weight range from about 1000 to 4000, be employed for useful characterization purposes, as was done

12) P. L. Pauson and W. E. Watts, *J. Chem. Soc.*, **1962**, 3880.
13) The compound was converted by selenium dioxide treatment to the known[11,14-17] diferrocenylketone, for which additional structural proof resulted from its weak-coupling A_2X_2-type NMR spectrum exhibiting, in the expected area ratio, a singlet at τ 5.83 (unsubstituted ring protons) and two apparent triplet signals centered at 5.02 and 5.51 (strongly deshielded $\alpha-\beta$ protons) with practically identical "ortho" and cross-ring coupling constants ($J_{\alpha\beta} \approx J_{\alpha\beta'} \approx 2.0$ c.p.s.). These detailed analytical efforts on diferrocenylmethane appeared to be in order in view of some disagreement in the literature as to the identity of this compound. While both Schlögl's[11] and Pauson's[12] groups reported melting points in the 143—149°C range, Rinehart and co-workers, in an earlier communication,[14] assigned the diferrocenylmethane structure to a compound with m. p. 124—125°C. The analytical and spectroscopic data presented above, coupled with the oxidation to the ketone, substantiate the present assignment in accord with Schlögl's and Pauson's findings.

earlier in related cases.[2,20] For further characterization, again using subfractionated samples, the correlation

$$[\eta] = 1.1 \times 10^{-3} M^{0.38}$$

between intrinsic viscosity, $[\eta]$, and molecular weight was determined by standard procedures. The low value of the exponent points to more globular than rod-like shape of the polymer molecules, as was similarly inferred[1] for polymer II. This behavior suggests a slightly branched structure, for which corroborative spectroscopic evidence results from the downward trend[1] of the percent homoannularity-molecular weight curve plotted in Fig. 2 for 15 subfractions. This curve, furthermore, demonstrates a slight prevalence of homoannular over heteroannular bonding along the polymer backbone, as is predictable on electronic grounds.[1,2,4-8,21] It is of interest to note the complete coincidence of the curve in Fig. 2 with the corresponding plot[1] for polymer II reproduced here for comparison, supporting the earlier assumption in this paper of an identical propagation sequence (with resulting identical substitution orientation) for both polymers II and III.

In order to arrive at a quantitative value of the degree of intralinear homoannular bonding, i. e., that proportion of homoannular bonding which is restricted to links of the backbone, a monodisperse, trinuclear fraction composed of the isomeric bis(ferrocenylmethyl)ferrocenes (III, $n=2$) was isolated by chromatography from the hexane-soluble portions of the polymer, thus offering the possibility to study the substitution orientation in III unaffected by the occurrence of side-chains. Monodispersity of this fraction and absence of components other than isomers III, $n=2$, was demonstrated[22] by molecular weight determinations, elemental analyses and NMR spectra (ferrocene/methylene proton signals in the expected 26 : 4 area ratio) on subfractions obtained by repeated crystallization.[23] Determination of the percent-homoannularity of this trinuclear fraction gave a value of 86.5 (average of results from three parallel chromatographic runs). From this figure, one may calculate a 59.6% content of homoannular compounds (combined 1, 2- and 1, 3-bis(ferrocenylmethyl)ferrocene) in the trinuclear isomer mixture and, hence, approximately so, of ferrocenylene units bonded homoannularly into the polymer backbone.

Work on the separation of the trinuclear mixture into its components (the heteroannular compound was recently described[12]) is in progress and will be reported elsewhere.[24]

Polymer II (filled-in circles)

Experimental

Materials and Analytical Procedures. — Solvents were reagent grade; for chromatographic purposes, they were fractionated on a spinning-band column. Starting materials and other chemicals were obtained commercially or prepared and purified as described.[1,2] Elemental and instrumental analyses were performed as in the earlier work.[1] The solvents used for NMR and M_n determinations were, respectively, carbon

20) E. W. Neuse and D. S. Trifan, Abstr. Papers presented at 148th National Meeting, Am. Chem. Soc., September, 1964, p. 5S.

21) R. A. Benkeser, Y. Nagai and J. Hooz, *J. Am. Chem. Soc.*, **86**, 3742 (1964). Among the two possible homoannular dispositions, steric effects are likely to lead predominantly to 1,3-substituted units.

22) In addition, similar analyses of the preceding and subsequent chromatographic bands showed these to be devoid of isomers III, $n=2$, thus attesting to the quantitative collection of these isomers in the trinuclear fraction under consideration.

23) The conventional process of fractional precipitation and crystallization, resting on the different solubility behavior of the components, could obviously not be utilized for this separation of a monodisperse fraction, since strict dependence of the solubility on the chain-length would be expected only for those polyhomologous series in which all members are composed of identical recurring units. In contrast, with polymers composed, as in the present case, of isomeric recurring units differing in the relative position of the two substituting methylene groups, a different fractionation behavior is predictable in the low-molecular range insofar as the different solubility of isomeric oligomers possessing equal molecular weight would invariably result in the distribution of such isomers over several fractions, which hence would no longer be strictly monodisperse.

24) This effort has since been reported: E. W. Neuse, E. Quo, and W. G. Howells, *J. Org. Chem.*, **30**, 4071 (1965).

tetrachloride (deuteriochloroform for diferrocenylketone) and benzene; viscosities were measured in benzene.

Polycondensation Reactions: Formation of III.—Employing the equipment and general technique described in an earlier paper,[2] the mixtures of Mannich base I and ferrocene with the catalyst system were heated in the molar ratios and under the experimental conditions summarized in Table I. While the catalyst system in runs No. 1—3, 5 and 6 was anhydrous zinc chloride and concentrated aqueous hydrochloric acid, zinc chloride and water were used in Nos. 7—10, thus generating hydrochloric acid by hydrolysis.[1] In run No. 4, hydrochloric acid was introduced as the hydrochloride of I, with no water added to the system. From the reaction products, extraction with warm water removed catalyst residues and dimethylammonium tetrachlorozincate, as well as unreacted complexes IV and V. The crude polymer III was then reprecipitated from benzene[25] solution by excess 2-propanol. The solid precipitate, designated as first fraction, was washed with methanol and was dried for 10 days at 50°C in vacuo. The mother-liquor, combined with the alcoholic washings, was concentrated on a rotating evaporator to remove the major portion of benzene and was poured into excess water. The resinous precipitate was taken up in benzene, filtered and the solution evaporated to dryness. The orange-brown solid remaining after removal of admixed ferrocene by vacuum sublimation, composed of oligomeric material, was designated as second fraction. The analytical data for both fractions are collected in Table II. The first (higher-molecular) fractions dissolved readily in benzene, dioxane and chloroform; the second (oligomeric) fractions, in addition, showed enhanced solubility in aliphatic alcohols, ketones and hydrocarbons.

Subfractionation of polydisperse polymer (combined first and second fractions) by conventional precipitation procedures at 25±1°C, using benzene as solvent, resulted in separation of fractions possessing enhanced monodispersity. The precipitant was 2-propanol which was diluted increasingly with water as the fractionation proceeded. The total number of subfractions obtained in each series was 15—20; the last 8 of these, with molecular weights below 1000, were collected by stepwise concentrating the mother-liquor at 30°C in a rotating evaporator for benzene removal and allowing the solution to stand for 12 hr. at 25±1°C. The products gave analytical results comparable to those for the unsubfractionated polymers. For example, the highest subfraction isolated analyzed as follows: C, 66.83; H, 5.17; Fe, 27.49%; M_n, 11200 (Calcd. for III: C, 66.68; H, 5.09; Fe, 28.23%), while for a typical oligomeric subfraction the findings were: C, 65.77; H, 5.20; Fe, 29.02%; M_n, 690 (Calcd. for III: C, 66.12; H, 5.18; Fe, 28.70%).

Chromatographic Oligomer Separation.—For the chromatographic separation of dinuclear and trinuclear III, low-molecular fractions were extracted with cyclohexane, thus taking up only compounds with M_n essentially below 1000—1100. In a typical run, employing 2.0 g. of the second fraction from experiment No. 5 (Table II), a cyclohexane solution (20 ml.) was prepared, from which 0.19 g. of higher-molecular III (Found: C, 66.70; H, 5.23; Fe, 28.10%; M_n, 1840) was separated by filtration. The filtrate was chromatographed under light protection on Alcoa grade F-20 alumina partially deactivated by 12 hr. exposure to air of 40% r.h., using hexane as eluent. After elution of traces of ferrocene not previously removed by sublimation, there was eluted a second band containing 0.63 g. of diferrocenylmethane, m. p. 147—149°C (from 2-propanol). X-Ray diffractogram, Å: 5.05, 5.69, 4.88, 6.13, 4.21, 4.27. Upon fusing at 160°C and re-cooling, the compound crystallized in a different system (X-ray diffractogram, Å: 5.18, 5.88, 5.66, 4.81, 4.58, 4.45); this modification was occasionally found intermixed with the stable form crystallizing from 2-propanol. A third modification crystallized from hexane (X-ray diffractogram, Å: 4.80, 5.09, 9.60, 4.20). All modifications showed the same melting point and analytical data (Found: C, 65.67; H, 5.27; Fe, 28.86%; mol. wt. 370. Calcd. for $C_{21}H_{20}Fe_2$: C, 65.67; H, 5.25; Fe, 29.08%; mol. wt. 384). By treatment with selenium(IV) oxide in refluxing benzene (10 hr.), the compound was oxidized in 48% yield to diferrocenylketone, reddish needles, m. p. 206—210°C (sealed; lit.[16,17]: 204°C, 210—211°C).

Elution of a third orange band gave 0.53 g. of the crude trinuclear isomer mixture (III, $n=2$), melting range 100—145°C. Found: C, 66.20; H, 5.08; Fe, 28.66%; mol. wt. 550. Calcd. for $C_{32}H_{30}Fe_3$: C, 66.02; H, 5.19; Fe, 28.78%; mol. wt. 582; percent-homoannularity, 88.1 (the average of three values on fractions obtained in parallel chromatographic runs was 86.5). All subfractions obtained from this fraction by extended fractional crystallization, while varying in melting points, showed analytical and molecular weight data in the same ranges.

Two higher bands of the chromatogram gave only brittle, X-ray amorphous resins, from which no subfractions with $M_n<750$ were isolable by reprecipitation or crystallization.

25) In several parallel runs, peroxide-free dioxane was employed in lieu of benzene as solvent in the precipitation operation. Owing to the excellent water compatibility of this solvent, the second fractions could in these cases be isolated as tack-free solids, thus facilitating their work-up. This modification offered advantages in those reactions that gave predominantly oligomeric compounds and was, therefore, employed in condensations Nos. 6 and 10 (Table I). In general, however, use of benzene was preferred because of enhanced purity of the polymer fractions collected.

This investigation was conducted by the Douglas Aircraft Company under company-sponsored research and development funds. The authors gratefully acknowledge the assistance of Mr. E. Quo in the experimental work, and of Messrs. H. N. Holland and C. F. Wissman in conducting some of the elemental and instrumental analyses.

Ferrocene-containing Polymers. IX. Polycondensation of Ferrocene with Formaldehyde[1]

By Eberhard W. NEUSE and Edward QUO

Polymer Laboratory, Missile & Space Systems Division, Douglas Aircraft Company, Inc. Santa Monica, California, 90406, U. S. A.

(Received December 15, 1965)

The Lewis acid-catalyzed polycondensation of ferrocene with formaldehyde or its dimethylacetal gives rise to the formation of soluble, novolac-type polymers comprising ferrocenylene units interlinked by methylene bridges. In contrast to earlier work performed by other investigators in liquid hydrogen fluoride or sulfuric acid media, where only non-polymeric products were described, propagation is accomplished in the present case by condensing the reactants in a closed system in bulk at temperatures up to 170°C. The resulting polymers, with M_n values up to 4000 (unfractionated), are shown by elemental and spectroscopic analyses and viscometric data to be essentially identical with the previously reported polycondensation products of *N*, *N*-dimethylaminomethylferrocene with ferrocene. Infrared spectroscopy shows the intralinear substitution to be predominantly homoannular, which is expected as a result of the electronic effects exercised by the methylene substituent. Under appropriate conditions, additional methylene groups can be incorporated into the polymer, giving rise to double-bridged segments and inter-chain bridging. Strongly crosslinked polymers are obtained if excess aldehydic reactant is employed at temperatures in the 170—185°C range.

It has been shown in a recent paper[2] that ferrocene can be polycondensed with benzaldehyde in the melt phase to give polymers essentially conforming to structure I. This smooth generation of I from ferrocene and benzaldehyde suggested utilization of the same synthetic procedure for the preparation of the analogous, novolac-type polymer II obtained earlier[3] by polycondensation of *N*, *N*-dimethylaminomethylferrocene with ferrocene. However, all attempts in the previous work[2] to prepare this polymer by the direct condensation of ferrocene with formaldehyde (*s*-trioxane, paraformaldehyde, dimethoxymethane) failed. Neither in bulk nor in solution, employing various aliphatic or aromatic hydrocarbon solvents, could defined polymeric products be isolated.

It has now been found that under appropriate conditions, using a closed system, polycondensation of ferrocene with formaldehyde in its various forms can be enforced. This reaction, which is described in the present paper, leads to polymeric reaction products and is, thus, in contrast to ferrocene-formaldehyde condensations performed by other workers[4-8] in liquid hydrogen fluoride or sulfuric acid media, where only monomeric reaction products were reported.[8a]

Results

The polycondensation of ferrocene with formaldehyde leading to polymer II may be expressed by the summarizing Eq. 1.

When ferrocene was heated in sealed tubes with *s*-trioxane or paraformaldehyde in the presence of Lewis acids, polycondensation according to Eq. 1 was indeed observed. However, under all conditions of temperature, time, and catalyst type and concentration employed, polymer yields were generally low (25—50%) owing to side-reactions involving self-polymerization of the aldehyde and crosslinking. In contrast, good results were obtained by using the dimethyl acetal of formaldehyde, dimethoxymethane (formal). This

1) The work presented herein, briefly summarized in a recent note (*Nature*, **204**, 179 (1964)), was conducted by the Douglas Aircraft Company under company-sponsored research and development funds. The assistance of Messrs. R. C. Baird and R. J. Dimarzo in performing the iron analyses and scanning the infrared spectra is gratefully acknowledged. The authors are also indebted to Mr. C. A. Seil for many stimulating discussions on this subject.

compound was therefore employed as the aldehyde-furnishing reactant throughout the present work, and the summarized polycondensation course may accordingly be depicted by Eq. 2.

The reactions (8—12 hr., 150—170°C) were carried out in sealed tubes or high-pressure autoclaves, using zinc chloride as catalyst in concentrations ranging from 3 to 20% by wt. of ferrocene. Under such conditions, and at equimolar or near-equimolar ratios of the reactants, overall conversions were generally in the 55—70% range. At temperatures substantially lower than 150°C, only oligomers were isolable in low yields, whereas temperatures markedly higher than 170°C led to

polymers with compositions deviating from the desired structure II.

Table I summarizes the reaction conditions and resulting polymer yields for a number of typical experiments. The reactions listed were performed in an autoclave to establish conditions more suitable for large-scale preparations. For small-scale condensations conducted in ampoules, correspondingly shortened reaction times sufficed. The reaction products were worked up by earlier described procedures[3] and were collected as two fractions: a first fraction composed of higher-molecular polymer and a second fraction containing oligomeric condensation products. All pertinent analytical data for the two fractions are compiled in Table II.

An inspection of the first three experiments listed, in which no excess aldehyde was employed, clearly shows the agreement in elemental composition of

the condensation products with the anticipated structure II. Due to the presence of unreacted starting materials in the equilibrium ultimately attained, this agreement is evident even for the reaction products of such condensations (Nos. 4, 5, and especially 6) in which the acetal was employed in excess over the equimolar amount at temperatures low enough to prevent entire utilization of this reactant.

With temperatures in these reactions further increased, however, the products of polycondensation showed changes in composition distinctly detectable by elemental analysis. This is demonstrated, for instance, in experiment No. 7, in which the temperature was raised to 180°C; after 12 hr. of total heating time, the resulting polymer was found to contain as many as four $-CH_2-$ bridges[9] per molecule (M_n 2370) in excess over the number required for structure II.

For comparison, a reaction employing aluminum chloride as catalyst is included in the tables as No. 8; again, the ratio of the reactants was equimolar. The drastic increase in insoluble matter at the expense of soluble polymer resulting from crosslinking and partial destruction of the ferrocene molecule is clearly demonstrated by the analytical and yield data presented. In view of earlier communications[10-15] describing the reaction of ferrocene with aluminum chloride in chlorohydrocarbon solution, the observed effects of this Lewis acid under the presently applied conditions are not unexpected. Both Rosenberg[10,11] and Nesmeyanov[12-14] with their co-workers have shown such ferrocene derivatives to contain cyclopentyl and cyclopentenyl groups stemming from partial ferrocene cleavage. If a similar cleavage and ensuing cyclopentenyl substitution is assumed in the present case,[16] the observed crosslinking reactions might in part be explicable in terms of a polymerization mechanism involving double bonds of the cyclopentenyl rings. The major portion of crosslinks, however, was probably formed by inter-chain bridging through methylene groups as will be discussed below in detail.

On a combined polymer batch composed of fractions consistent in elemental composition with structure II, a subfractionation by precipitation and crystallization was performed as described loc. cit.[3] for the Mannich base-ferrocene polycondensation product. The 16 subfractions collected showed M_n values up to 10000 and corresponded in composition to II much as did the parent material. Chromatography of the final, lowest-molecular subfraction gave a compound shown to be identical in melting point and X-ray diffractogram with diferrocenylmethane (II, $n=1$).[3,8,17] These findings confirm the compositional identity of the present polymer with the earlier product[3] derived from *N*, *N*-dimethylaminomethylferrocene. Corroborative evidence for this identity arose from spectroscopic data, the infrared spectra recorded on comparable subfractions of both products being strictly superimposable. In addition, the viscosity-molecular weight correlation[3,18] for both products was found to be the same within experimental error, as was the relationship between intensity of the 9 μ infrared band (in terms of percent-homoannularity[2,3,19]) and number-average molecular weight depicted by the curve in Fig. 1. The coincidence of the plots in the latter case attests to the essentially identical branching pattern and substitution orientation along the polymer backbone. The trend of the graph in Fig. 1, predominantly homoannular in the oligomeric range and gradually approaching a minimum value of the percent-homoannularity, suggests[2,19] an increase in the degree of branching with rising molecular weight, this branching preferentially occurring on those ferrocene rings that are not part of the chain proper.

Figure 2 represents a plot of melting point (upper limit of melting range) against M_n, determined again

9) Incorporation of additional methylene bridges was accompanied by competing crosslink formation if, under heating conditions similar to those above, acetal concentrations substantially higher than equimolar were applied. Thus, at an acetal/ferrocene molar ratio of 1.4 and a heating time of 14 hr. at 185°C, crosslinked polymer amounted to a total of 53.7% (by wt. of ferrocene), with soluble polymer simultaneously collected in 33.2% yield. With 100% molar excess of the acetal (acetal/ferrocene ratio=2), even at only three hours heating time at 170°C, the yield in soluble polymer decreased to 17%, while the major portion of condensation product was isolated as crosslinked matter. In each of these cases, both the crosslinked product and the corresponding soluble polymer portion were of practically the same elemental composition. Also their infrared spectra were practically identical except that slightly enhanced methylene bands were exhibited by the crosslinked compound. From this observation, a close structural relationship between the soluble polymers and their crosslinked counterparts must be inferred, with the latter types differing in their structural build-up from the former merely by the existence of inter-chain methylene bridges.

on subfractionated samples. As expected, the curve passes through a minimum in the oligomer range. In the M_n range above ~1500, it ascends more steeply than does the corresponding curve replotted for the Mannich base-ferrocene polycondensation product,[3] pointing to some structural differences to be discussed below.

Discussion

If, in the reaction of ferrocene with formaldehyde or its dimethyl acetal, one assumes the intermediary occurrence of hydroxymethylferrocene or its methyl ether, methoxymethylferrocene, much as in the analogous case of ferrocene-benzaldehyde condensation,[2] the various propagation and termination steps comprised by the summarizing Eqs. 1 and 2 may be visualized as follows:

The primary step is the Lewis acid-catalyzed generation of ferrocenylcarbinyl cations from hydroxymethyl- or methoxymethylferrocene. For these cations, in principle, the same four reaction steps are available as in the self-condensation of ferrocenyl carbinols discussed at greater length elsewhere.[19] However, because of the low instantaneous concentrations of the hydroxymethyl- or methoxymethylferrocene intermediate expected under the experimental conditions (their further reaction proceeding at a rate considerably higher than their rate of formation[2]), the first two of these reaction steps, interaction with oxygen-containing species, will be irrelevant as compared to the third step, nuclear substitution of oxygen-free species. The latter step comprises the primary

reaction of the cation with free ferrocene present initially in large excess over carbinol, ether or polynuclear species. The arising dinuclear derivative, diferrocenylmethane (II, $n=1$), will now compete with ferrocene for further nuclear attack by the carbinyl cation, thus resulting in trinuclear and, as propagation proceeds, in polynuclear II. In this propagation step, the effects of the methylene group on the position of the entering ferrocenylmethyl substituent will be much the same as those operative in the analogous Mannich base - ferrocene polycondensation,[3] an assumption which is borne out by the coinciding percent-homoannularity - M_n plots for the two polymer series (Fig. 1). In addition to the prevalent propagation step involving electrophilic attack by the ferrocenylcarbinyl cation on ferrocene and the oligomeric and polymeric homologs of II, primary reaction of aldehyde or acetal with ferrocene units of II to give methylol- or methoxymethyl-substituted II must be expected in an advanced stage of the condensation. The cations generated therefrom may react intramolecularly, i. e., in a terminating self-substitution reaction (step 4 in the earlier quoted paper[19]; cf. restrictions discussed therein), resulting in double-bridged segments.[18] Competing with this self-substitution, they may also react intermolecularly, i. e., by attack on a different polymer molecule. If both the cationic site and the ferrocene unit attacked are in terminal position, as expected to be the predominant case during an early stage of the reaction, the result will be linear chain extension. In an advanced stage, with increasing probability of cationic site and/or attacked ferrocene unit being in an internal position, side-chain or crosslink formation will result. The occurrence of side-chain and inter-chain methylene bridging as a result of the latter reaction course must be expected accordingly in all higher-molecular fractions and is manifested experimentally in both the aforementioned trend of the curve in Fig. 1 and the higher ordinate values (in the M_n range beyond $\sim$1500) of the curve in Fig. 2 (filled-in circles) as compared to the corresponding plot (open circles) for the Mannich base-derived polymer. Such side-chain and inter-chain methylene bridge formation will become progressively important as excess aldehydic reactant is employed at elevated temperatures. The increased amounts of crosslinked polymer isolated in such typical experiments mentioned initially in which molar acetal/ferrocene ratios of 1.4—2.0 were employed at temperatures ranging from 170 to 180°C bear out this expectation.[20]

Considering the low average molecular weight range, notably of the second fractions, attained under the conditions of our closed-system experiments, it was of interest to investigate the possibility of post-condensing these low-molecular-weight products with aldehydic reactant. Such post-condensation would be expected to proceed as pointed out above, viz. through formation of methylol- or methoxymethyl-substituted II, followed by nuclear attack of the cations arising therefrom on a different polymer chain, thus resulting in distinctly increased molecular weights. In a series of experiments employing fractions of polymer II with M_n in the low 300—800 range the feasibility of such post-condensation could indeed be demonstrated. Again, the zinc chloride-catalyzed reactions were conducted in a closed-system under conditions similar to those applied in the primary condensations, formaldehyde being employed as its dimethyl acetal in concentrations ranging from 0.5 to 2 mol. per mol. of oligomer employed. A typical experiment is summarized as No. 9 in Table I. The analytical data collected for the reaction product in Table II show that the starting material, a fairly monodisperse fraction with M_n 780, was largely converted to higher-molecular polymer still exhibiting the elemental composition of II. These results suggested the direct utilization, without prior removal of the unreacted ferrocene, of the very low-molecular, crude second fractions obtained in experiments of the types listed as Nos. 1 through 7 in Table I. The post-condensation of such fractions, with concomitant partial consumption of the admixed ferrocene, is demonstrated by experiment No. 10. By circumventing the time-consuming removal of ferrocene by sublimation from the remainder of oligomers in the second fractions, the possibility of such post-condensations of ferrocene-containing oligomer batches may add to the economy of the closed-system condensations here described.

Experimental

Materials and Analytical Procedures.—*s*-Trioxane, paraformaldehyde and formal (dimethoxymethane) were used as received from commercial sources. Zinc chloride, ferrocene and solvents, all commercial products, were purified as described.[18,19] Procedures for elemental and instrumental analyses have also been presented earlier.[3,18]

Polycondensation Reactions.—The experiment described below, summarized as No. 4 in Tables I and II, exemplifies the conventional syntheses in which

20) While the products arising from branching and single-bridge crosslinking reactions cannot be distinguished by elemental analysis from linear II, the self-substitution products (and also those structures arising from multiple inter-chain bridging), possessing additional methylene groups, deviate in composition from II and thus lend themselves to analytical characterization, provided the number of such methylene groups additionally incorporated is large enough to exceed the experimental error limits of analysis. As a typical example of products which elemental analyses show to contain double-bridged segments, i. e., CH_2 bridges in excess over the number required for structure II, the experiment listed as No. 7 in Table I was mentioned above.

the aldehydic component was employed as the acetal.[21] The reactor was a stainless steel-lined, high-pressure autoclave of 1 l. capacity, equipped with mechanical stirrer, thermometer well and thermocouple, bleeding valve, and a special safety head (rupture disc tested to 3500 psi). The vessel was flushed with dry nitrogen and was charged with the mixture of 372.1g. (2.0 mol.) of ferrocene and 18.6 g. of anhydrous zinc chloride previously ground together in a dry-box. Upon the addition of 183.0 g. (2.4 mol.) of dimethoxymethane pre-cooled to 0°C, the sealed autoclave was heated with stirring for 9 hr. at 170±2°C. The reaction product was thoroughly digested and washed with water and, after drying, was reprecipitated from benzene solution (280 ml.) by 2-propanol (4 l.). Reprecipitation in the same manner gave a yellow solid which was washed with 2-propanol and vacuum-dried for 10 days at 60°C. This portion of polymer II, 159.6 g. (40.5% yield), is listed as lst fraction in Table II. From the combined and concentrated mother-liquors and washings, a mixture of oligomeric II and ferrocene was precipitated by excess water. From the dried product, ferrocene was removed by vacuum sublimation (81.7 g. recovered). The orange-yellow residual solid, 79.0 g. (20.4% yield), is listed in Table II as 2nd fraction. In a parallel experiment, 65.0 g. of the crude second precipitate still containing the admixed ferrocene was chromatographed in the manner described in detail loc. cit.[3] to give 32.40 g. of ferrocene, m. p. 173—176°C; 14.65 g. of diferrocenylmethane, m. p. 143—146°C; and 5.86 g. of crude trinuclear isomer mixture, melting range 95—145°C.

Subfractionation of II was accomplished by fractional precipitation and crystallization as discussed previously,[3] employing a polymer batch containing portions of the first and second fractions stemming from runs No. 4 and 5. The 16 subfractions collected, with M_n values ranging from 410 to 9850, gave elemental analyses consistent with II and showed the same infrared spectroscopic and solubility behavior as did the analogous fractions of the Mannich base - ferrocene polymer.[3] Some of these fractions were used for the viscometric measurements and the plots in Figs. 1 and 2.

For analytical rather than preparative purposes, several condensations were conducted using glass ampoules or stainless steel tubes in lieu of the high-capacity autoclave. Batch sizes for glass-tube reactions ranged from 5 to 30 g., whereas the steel tubes allowed for 50—200 g. batches. The solid components were well ground together in a dry-box and were placed in the tubes inserted into a dry ice - acetone bath. Upon addition of the liquid acetal (when using the solid paraformaldehyde or trioxane, all components were directly mixed and charged into the tube), the tube contents were frozen and degassed in the conventional manner. The re-cooled tubes were then flushed with dry nitrogen, sealed and heated in a thermo-regulated aluminum block, and the reaction products were worked up as described. These products showed no essential deviations in elemental composition from the corresponding polymers prepared in autoclave reactions.

Post-condensation of Oligomeric II with Formaldehyde.—The experiment described here, listed as No. 10 in Table I, may illustrate the post-condensations of low-molecular II. The well-ground mixture of 40.0 g. of anhydrous zinc chloride and 400.0 g. (1.563 mol.) of oligomeric II still containing ferrocene (M_n 260) was placed in the nitrogen-flushed autoclave. Upon the addition of 76.09 g. (1.0 mol.). of pre-cooled dimethoxymethane, the vessel was closed and heated at 170±2°C for 10 hr. with stirring as described. The reaction product was worked up in the conventional manner. The first and second fractions obtained in yields of 240.6 g. (58.1%) and 109.3 g. (26.7%) respectively, showed the melting point and analytical data collected in Table II.

21) Experiments employing formaldehyde in its solid, polymeric form (paraformaldehyde, *s*-trioxane) rather than as its acetal were conducted in the same manner as described above, except that the pulverized aldehyde was immediately ground together with ferrocene and catalyst. In these reactions, large amounts of insolubles were formed, and the polymers, obtained in yields up to 50%, showed elemental compositions less satisfactory than in the ferrocene-formal condensations tabulated. A typical reaction product (6 hr., 170°C, 10% $ZnCl_2$, equimolar ratio ferrocene/trioxane) analyzed as follows: C, 67.50; H, 5.23, Fe, 25.99%; M_n, 1960 (calcd. for II: C, 66.51; H, 5.12; Fe, 28.37%).

Specific Effects in Acid Catalysis by Polymeric Sulfonic Acids in the Hydrolysis of Some Carboxylic Esters[1)]

By Sadao YOSHIKAWA and Oh-Kil KIM

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received October 5, 1965)

The catalytic effects of polymeric sulfonic acids in ester hydrolysis in aqueous acetone were inferior to that of hydrochloric acid. However, the hydrolysis rate was accelerated by increasing the water content of acetone-water mixtures, and, in a water solution, polymeric sulfonic acids were much more effective catalysts. Furthermore, the catalytic efficiency of polymeric sulfonic acid in ester hydrolysis in water increased with the length of the ester molecule. The polymeric sulfonic acid with a strong hydrophobic character was more effective; 69% sulfonated polystyrenesulfonic acid, for example, hydrolyzed methyl hydrogen azelate in water over five times more rapidly than hydrochloric acid. The specificity thus obtained suggests that, in the hydrolysis of electrically-neutral esters in water, ester molecules are concentrated in the neighborhood of the polymer by the hydrophobic interaction between catalyst and substrate. Besides, in the hydrolysis of aliphatic esters catalyzed by polyvinylsulfonic acid in 50% aqueous acetone, there was a linear relationship between the reciprocal of the rate constant and the intrinsic viscosity of the polymer, while in the case of polystyrenesulfonic acid hardly such any relationship was found. These remarkably different behaviors of the two kinds of polymer catalysts should be attributed to the difference in the expansion of the polymer chain in solutions.

The acid-catalyzed hydrolysis of esters by polymeric sulfonic acids, as previously reported by others,[2)] has been carried out mostly in heterogeneous systems with cross-linked sulfonated polystyrene resins. Therefore, there is some difficulty in estimating and discussing precisely the catalytic activity relating to the molecular structure of the polymer in solutions.

It is the aim of the present paper to report on the specific behavior of water-soluble polymeric sulfonic acids in the hydrolysis of esters in various medium compositions of the homogeneous solution. The sulfonic acids were prepared by different polymerizing processes from their respective monomers, except sulfonated polystyrene sulfonic acid. Polymeric sulfonic acid is a strong polybasic acid comparable to sulfuric acid and protons are considered to be localized along the polymer chain. Hence, the proton density in solutions may be locally concentrated, unlike as in mineral acid. It may, therefore, be expected that if an interaction between the polymer catalyst and a substrate occurs, this interaction can be specifically changed according to the characteristics of the substrate and the outer solution used.

Experimental

Monomers.—Sodium vinylsulfonate was prepared from sodium β-bromoethanesulfonate and sodium hydroxide by modifying the patent directions.[3)] To 60 g. of sodium β-bromoethanesulfonate 29 g. of 40% sodium hydroxide was vigorously stirred drop by drop. During the addition the temperature was kept below 50°C. Further stirring was continued until the temperature fell to room temperature, and then the reaction mixture was neutralized with concentrated hydrochloric acid at 0—5°C. After large portions of sodium bromide had been filtered, an equal volume of alcohol was added to the filtrate at 0°C. Sodium vinylsulfonate was thus precipitated and filtered off. The yield was 24 g. (65% of the theoretical amount).

Potassium *p*-styrenesulfonate was prepared by the method of Wiley and Reed.[4)] To 65 ml. of chlorosulfonic acid at 0—5°C, there was added, drop by drop, 27.5 ml. (0.2 mol.) of β-bromoethylbenzene, which had been prepared according to the directions of Whitmore.[5)] After 30 min. the reaction mixture was poured onto ice with stirring in order to precipitate the sulfonyl chloride, which was then washed with ice water and taken up in ether. The ether solution was washed with dilute sodium bicarbonate and dried. The residue remaining on the evaporation of the ether was dissolved in 70 ml. of cold 95% ethanol. To this solution there

was slowly added a solution of 45 g. of potassium hydroxide in 200 ml. of 95% ethanol. This reaction mixture was refluxed for one hour and filtered. The solid thus collected was washed with an additional 100 ml. of hot ethanol and filtered. The combined filtrates were cooled to −20°C to precipitate the crude product. This crude product was dissolved in a minimum quantity of hot water and filtered. The filtrate was extracted with benzene and cooled to precipitate the product. A final recrystallization from 95% ethanol gave 13 g. (30% yield) of potassium *p*-styrenesulfonate.

The polymerizations of sodium vinylsulfonate and potassium *p*-styrenesulfonate were carried out with three different methods.

Poly(sodium vinylsulfonate) was obtained as follows:

a) PVSH(A): Five grams of sodium vinylsulfonate in 4.9 ml. of water was poured into an ampoule, chilled in ice, and evacuated to about 2 mmHg; the evacuation and pressuring with nitrogen were repeated, and then the ampoule was sealed. The polymerization was carried out by exposing the mixture to a ^{60}Co source yielding about 2×10^5 r./hr. for 72 hr. at 0°C. The resulting stickey solid was dissolved in 30 ml. of water and precipitated by adding 45 ml. of methanol. Treating the gummy precipitate with methanol yielded 3.5 g. (70% conversion) of a straw-colored polymer after it had been dried in vacuo over phosphorus pentoxide. The intrinsic viscosity*1 of the polymer was 12.8, and the molecular weight*1 was 20000.

b) PVSH(R)[6]: Twelve grams of a 50% sodium vinylsulfonate solution (6 g. of sodium vinylsulfonate) containing 0.075 g. of potassium persulfate and 0.023 g. of sodium bisulfite was poured into an ampoule; the ampoule was evacuated and pressured repeatedly with nitrogen, and then sealed. The ampoule was tumbled in a bath at 18°C for 72 hr. The resulting viscous oil was dissolved in 30 ml. of water and precipitated with 45 ml. of methanol; 4.08 g. of a polymer was obtained after drying in vacuo over phosphorus pentoxide. The intrinsic viscosity was 7.20, and molecular weight was 12000.

c) PVSH(S): Five grams of the finely-powdered and dried crystalline sodium vinylsulfonate was sealed in an ampoule and exposed to a ^{60}Co source yielding about 2.5×10^5 r./hr. for 72 hr. at room temperature. The irradiated crystals, after precipitation with 70% aqueous methanol in the usual fashion to remove the monomer, gave 2.5 g. of a polymer. The intrinsic viscosity and the molecular weight of the polymer were 1.70 and 3000 respectively.

Poly(potassium *p*-styrenesulfonate) was obtained as follows:

a) PSSH(A): Four grams of potassium *p*-styrenesulfonate in 16 ml. of water was poured into an ampoule. Polymerization was carried out in the same manner as in PVSH(A). After exposure to γ-radiation for 72 hr. at room temperature, the polymer formed was precipitated from 70% aqueous dioxane. Drying the precipitates in vacuo over phosphorus pentoxide, yielded 2.5 g. of a polymer. The intrinsic viscosity*2 of the polymer was 42.0.

b) PSSH(R)[7]: Five grams of potassium *p*-styrenesulfonate in 15 ml. of water was taken into an ampoule, and then a solution of 1.35 g. of potassium persulfate (2.66% based on the monomer) and 0.66 g. of sodium bisufite (1.34% on the monomer) in 2 ml. of water was added as an initiator. The ampoule was then evacuated and sealed in the usual fashion. The polymerization was carried out under tumbling in a bath at 18°C for 72 hr. The resulting viscous oil was precipitated from 70% aqueous dioxane; 3.2 g. of polymer was obtained after drying in vacuo over phosphorus pentoxide. The intrinsic viscosity was 30.7.

c) PSSH(S): Five grams of finely-powdered and dried crystalline potassium *p*-styrenesulfonate was sealed in an ampoule and exposed to a ^{60}Co source yielding about 2.5×10^5 r./hr. for 72 hr. at room temperature. The irradiated crystals yielded 2.3 g. of polymer after it had been precipitated with 75% aqueous methanol and dried according to the usual manner. The intrinsic viscosity was 18.09. All the sodium and potassium polymer sulfonates were completely converted into free acids by passing them through a column of cation exchange resin in hydrogen form, such as Amberlite IR-120.

The sulfonation of polystyrene was carried out using the addition-compound of sulfur trioxide and dioxane by the method described by Signer and his co-workers.[8] The addition-compound was easily formed by the addition of one mole of sulfur trioxide to one mole of dry dioxane. To the finely-divided suspension of the adduct, consisting of 20 g. of sulfur trioxide and 26 ml. of dioxane in 140 ml. of dichloroethane, a solution of polystyrene ($\overline{M}_w=15\times10^4$) in 140 ml. of dichloroethane was added in one portion; then the mixture was agitated for several minutes. The sulfonation proceeded to 69% after the mixture had stood at 20°C for 24 hr. The reaction was stopped by the addition of water. The polymer was dissolved easily in water and neutralized with sodium hydroxide. The sulfonated polymer salt was dialysed to remove sulfuric acid through a semipermeable membrane by keeping it in distilled water. The specific conductivity of the outer solution dropped below $3\times10^{-5}\cdot ohm^{-1}\cdot cm^{-1}$ after a period of one month. The dialysed sulfonated polymer salt was converted into free acid through the ion exchange resin in hydrogen form in the usual method. The degree of the sulfonation of polystyrene was determined by both gravimetric and elementary analyses of the sulfur atom. The two results corresponded satisfactorily.

Other Reagents.—The esters and acetone were obtained commercially (except methyl hydrogen succinate, methyl hydrogen glutarate and ethyl hydrogen adipate) and were further fractionated in a thirty-inch column of glass helices. Methyl hydrogen succinate was prepared according to the procedure of Cason,[9] by

*1 The value of intrinsic viscosity of poly(sodium vinylsulfonate) was determined in 0.5 N sodium chloride solution at 20°C and the molecular weight was calculated by K. Dialer and R. Kerber, *Makromol. Chem.*, **17**, 56 (1956).

*2 The value of intrinsic viscosity of poly (potassium *p*-styrenesulfonate) was determined in 2 N sodium hydroxide solution at 20°C.

the reaction of succinic anhydride and methanol (m. p. 57—58°C). Methyl hydrogen glutarate was prepared by the reaction of glutaric anhydride and methanol using the method described by Harris[10] (b. p. 158—165°C/23 mmHg). Methyl hydrogen adipate was prepared from adipic acid and methanol according to the procedure of Morgan and Walton[11] (b. p. 128°C/30 mmHg). The methyl hydrogen azelate was a gift of the Soda-Perfumery Co., Ltd.

Procedures.—The initial concentrations of esters and acid catalysts were adjusted to 0.2 mol./l. in acetone (or 0.05 mol./l. in water) and 0.08 N in water respectively. Three or four samples were used in each run, and each reaction mixture was made up of 4 ml. of the initially-adjusted ester in acetone (or water) and an equal volume of aqueous acid. The reaction mixtures were placed in 10 ml. glass-stoppered bottles suspended in a thermostat controlled to 45±0.01°C. The reaction was followed by withdrawing samples from the bath at suitable intervals, and by titrating the acid present with 0.05 N standard sodium hydroxide, using a phenolphthalein indicator. The first-order rate constants were calculated using the expression:

$$k=\frac{2.303\log a/(a-x)}{(\text{Catalyst})\,t}$$

where a is the initial ester concentration; x is the concentration of acid formed after time t, and (Catalyst) is the concentration of added polymeric sulfonic acid or hydrochloric acid. The catalytic efficiency, q, was defined as the ratio of the specific rate of hydrolysis catalyzed by polymeric sulfonic acid to that catalyzed by hydrochloric acid.

Results and Discussion

The catalytic effects of cross-linked sulfonated polystyrene resins are supposed to be appreciably different from those of water-soluble polymeric sulfonic acids because of cross-linking and particle size. The effects of particle size and cross-linking reported by Haskell and Hammett[2a] and Davies and Thomas[2b] suggested that the outer layers of the resin particles are responsible for much of the catalytic effect, the diffusion of non-electrolytes towards or away from the center of the particles being a slow process.

The results obtained in the present hydrolysis showed several new aspects by eliminating the complicating factors. The catalytic effects of polyvinylsulfonic acid (PVSH) and polystyrenesulfonic acid (PSSH) (polymerized by different methods) on the hydrolysis in 50% (v./v.) aqueous acetone were inferior to that of hydrochloric acid, especially PVSH, as is illustrated in Table I. The hydrolysis rate was, however, found to be accelerated by the increasing of volume % water in acetone-water mixtures. The hydrolysis rates

measured in the presence of varying acetone concentrations are plotted in Fig. 1. In a water solution polymeric sulfonic acids were much more efficient than hydrochloric acid. This tendency is apparent in polystyrenesulfonic acid. The catalytic efficiency, q, of polymeric sulfonic acids, especially partially-sulfonated polystyrene ((PS)SH), in ester hydrolysis in water increased with the

number of carbon atoms in the ester, as is shown in Fig. 2. The catalytic efficiency, q, of PVSH is closest to unity for every ester, while that of (PS)SH (69%), for example, is more than five for methyl hydrogen azelate. This contrasts remarkably with the reaction in aqueous acetone. The specificity thus obtained suggests that in aqueous acetone, because of the preferential solvation of the organic solvent with the polymer, hardly any interaction between the polymer and the ester occurs, while in water the hydrophobic interaction between the polymer catalyst and the substrate may become predominant and increase apparently with an increase in the hydrophobic character of the ester and the polymer molecule, such as (PS)SH (69%). Accordingly, it may result in an increase of the ester concentration in the neighborhood of the polymer chain by the hydrophobic interaction. Thus, the rate difference in PVSH and PSSH under these conditions should be attributed mainly to the hydrophobic character of the molecule.

The above interpretation is supported by the facts that cross-linked sulfonated polystyrene resin absorb organic solvents preferentially rather than esters in the mixed solvents, while esters or organic acids in a water solution are positively adsorbed on the resin in proportion to the length of the carbon atoms.[12]

Furthermore, the catalytic activity of PVSH in the hydrolysis of several aliphatic esters depends on the molecular weight of the polymer catalyst in 50% aqueous acetone more distinctly than it does in water. There was a linear relationship between the reciprocal of the rate constant and the intrinsic viscosity of the polymer, while hardly any such relationship was detectable in the presence of PSSH and (PS)SH (69%). A plot of $1/k$ against $[\eta]$ is shown in Fig. 3.

It is believed that the remarkably different catalytic behaviors of these two kinds of polymers are due to the difference in the expansion of polymer chains in solutions and to the hydrophobic interaction between catalyst and substrate. The molecules of PVSH in solutions, especially in aqueous acetone, are not appreciably expanded as compared to those of PSSH. Since the expansion is subject to steric

12) C. W. Davies and G. G. Thomas, *J. Chem. Soc.*, **1951**, 2624.

restraints as the molecular weight of PVSH increases, the localized protons along the polymer chain result in confinement within an extremely limited region in the reaction system, thereby making the molecular weight of PVSH responsible for the reduction of the catalytic activity. This interpretation is supported by the observation that the catalytic effects of PVSH, in cases where the molecular weight was below 2000, were much the same as those of hydrochloric acid.

Although there is another view that the distance between sulfonic acid groups on the polymer chain may also be responsible for the catalytic activity, this is contradicted by the fact that the catalytic behavior of sulfonated isotactic polystyrene sulfonic acid (70% sulfonation) was nearly the same as that of the atactic one ((PS)SH (69%)). The hydrolysis rate constants with the former under the conditions shown in Table I were 17.12×10^{-3} for ethyl acetate and 6.08×10^{-3} for ethyl *n*-caproate. Moreover, the hydrolysis rates of esters with polymeric sulfonic acid in water were affected, to some extent, by the ester concentration. The results of some experiments are shown in Table II. The decrease in catalytic activity occurring when the concentration ratio of the ester to the polymer catalyst increased may be related to the reduction of the overall hydrolysis of esters as a result of a lack of an active site on the polymer. The above results suggest the presence of hydrophobic interaction between the polymer catalyst and the ester.

Synthetic Studies starting from β-Cyanopropionaldehyde. III.* The Synthesis of β-Cyanoacrolein

By Shinichi MOTOKI, Sadayoshi SATSUMABAYASHI and Takashi MASUDA

Department of Chemistry, Faculty of Science, Tokyo College of Science, Shinjuku-ku, Tokyo

(Received October 19, 1965)

β-Cyanopropionaldehyde dimethyl acetal was brominated in the presence of calcium carbonate to give α-bromo-β-cyanopropionaldehyde dimethyl acetal. This was then dehydrobrominated with 10% alcoholic potash at −5 to 0°C, β-cyanoacrolein dimethyl acetal was thus obtained in a high yield. Free aldehyde of a light green liquid was given by the hydrolysis of the acetal. A similar procedure using α-chloro-β-cyanopropionaldehyde dimethyl acetal was also examined. On the other hand, β-cyanoacrolein was prepared by the direct dehydrogenation of β-cyanopropionaldehyde with selenium dioxide.

In the present paper, we wish to report the synthesis of β-cyanoacrolein (VI) starting from β-cyanopropionaldehyde (β-CPA) (I) through the process illustrated in Fig. 1.

The synthesis of VI by the oxidation of β-methyl acrylonitrile with selenium dioxide has been reported by Rambaud and others.[1] However, β-cyanoacrolein was not isolated by them, and the 2, 4-dinitrophenylhydrazone and semicarbazone of VI gave low *N*-analytical values.

In the present study, two methods of the synthesis of VI will be described. First, β-cyanopropionaldehyde dimethyl acetal (II) was brominated in carbon tetrachloride. Calcium carbonate had previously been added to the solution in order to remove any hydrogen bromide produced in this

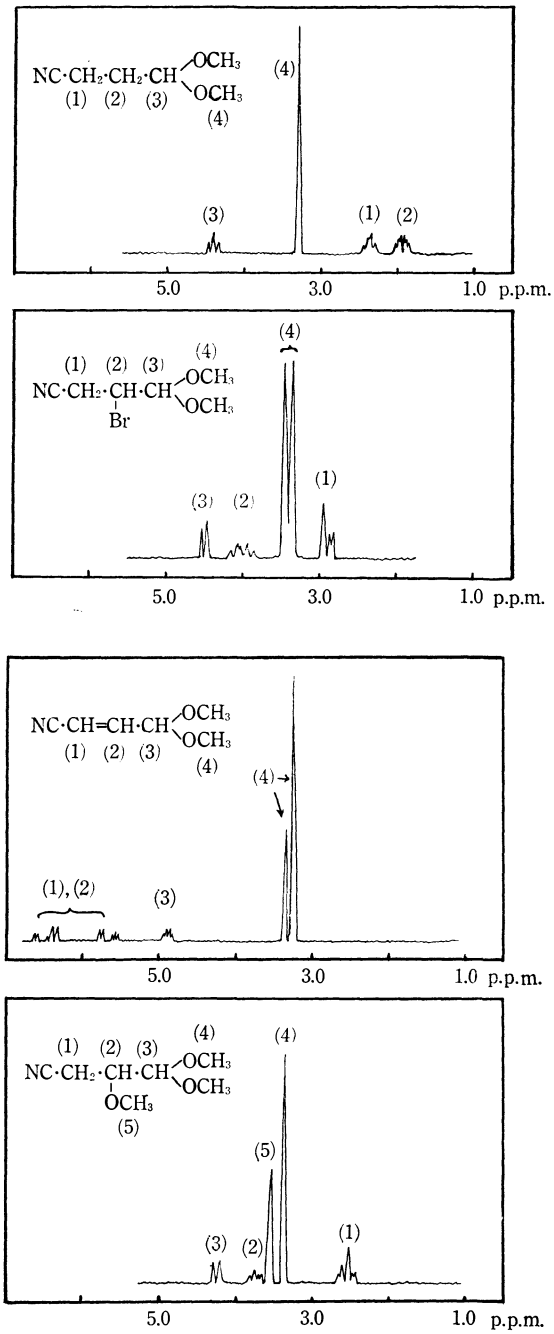

Fig. 2. A varian A-60 NMR spectrometer operating at 60 Mc./sec. was employed for all measurements.

reaction.[2] It was found, by means of a study of the NMR spectra (Fig. 2), that the bromine was introduced into the α-position of the aldehyde group; that is, the absorption of the protons of α-methylene group disappeared and the triplet of the aldehyde group changed to a doublet. Thus, the product was presumed to be α-bromo-β-cyanopropionaldehyde dimethyl acetal (IIIa). When IIIa was dehydrobrominated with 10% methanolic potash at -5 to 0°C, β-cyanoacrolein dimethyl acetal (IV) was obtained in high yield. The analytical values of the product were in accord with the calculated values of IV, and the infrared spectra showed the characteristic absorptions of methine at 3070 cm^{-1} and 3000 cm^{-1} and of carbon-carbon double bond at 1639 cm^{-1}. Moreover, in the NMR spectrum, all the absorptions of methylene groups disappeared, while new absorptions of methine groups appeared.

In the dehydrobromination, the main product was α-methoxy-β-cyanopropionaldehyde dimethyl acetal (Va in Table I) when the temperature was elevated or when the concentration of alkali was increased. Under the same reaction conditions, the corresponding ethoxy derivative (Vb in Table I) was obtained in an ethanol solvent.

The dimethyl acetal (IV) was easily hydrolyzed by dilute hydrochloric acid to β-cyanoacrolein (VI) in a nearly quantitative yield. Though VI is a light green liquid which is a comparatively stable compound, it gradually becomes brown upon standing at room temperature for several days.

Halogenation was also carried out with chlorine instead of bromine. Chlorine gas was blown into the chloroform solution of β-cyanopropionaldehyde dimethyl acetal (II) in the presence of calcium carbonate. However, in this case, the chlorinated product did not show a definite boiling point. Therefore, the fraction (which had a b. p. of 88—93°C/5 mmHg) was collected; dehydrochlorination by alcoholic potash carried out in a similar manner gave a product, boiling at 65—66°C/6 mmHg, which was identified as IV. However, the yield was much less than with bromine.

Chlorination by sulfuryl chloride gave nearly the same results as when chlorine was used, and no single product could be obtained.

In the second method of the synthesis of VI, the direct dehydrogenation of β-CPA was examined. When β-CPA was allowed to react with selenium dioxide in a mixed solvent of water and dioxane, β-cyanoacrolein (VI) was obtained

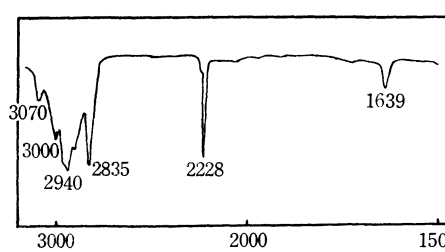

Fig. 3. The IR spectrum of β-cyanoacrolein dimethyl acetal.

in a relatively good yield. As may be seen in Table II, the yield was highest when the proportion of dioxane to water was 100 : 20; the yield decreased as the amount of dioxane or of water increased.

Table I

Experimental

α-Bromo-β-cyanopropionaldehyde Dimethyl Acetal (IIIa). — In a three-necked 1000 ml. flask, 65.5 g. (0.5 mol.) of II was dissolved in 300 g. of carbon tetrachloride, and then 30 g. (0.3 mol.) of powdered calcium carbonate was added. After the solution had been heated to boiling, vigorous stirring was started and 80 g. of bromine in 100 g. of carbon tetrachloride was added drop by drop, to the refluxing solution over approximately a two-hour period. After another one hour's stirring, the mixture was filtered and the filtrate was washed with water several times. The fractional distillation of the carbon tetrachloride solution gave 52.5 g. of pure IIIa; b. p. 87°C/2 mmHg; yield, 50.5%.

Found: C, 34.44; H, 4.97; N, 6.70; Br, 38.90. Calcd. for $C_6H_{10}O_2NBr$: C, 34.63; H, 4.87; N, 6.73; Br, 38.40%.

Care must be taken to stop the distillation when the contents of the flask become viscous and the temperature of the distillate begins to rise; otherwise, a vigorous decomposition of the contents will occur. The bromo-acetal thus obtained turned yellow or dark brown after standing at room temperature for several days.

β-Cyanoacrolein Dimethyl Acetal (IV).—The dehydrobromination of α-bromo-β-cyanopropionaldehyde dimethyl acetal was carried out with alcoholic potash in the usual manner. β-Cyanoacrolein dimethyl acetal, b. p. 62°C/4 mmHg.

Found: C, 56.40; H, 7.28; N, 11.14. Calcd. for $C_6H_9O_2N$: C, 56.68; H, 7.14; N, 11.02%.

α-Alkoxy-β-cyanopropionaldehyde dimethyl acetal was formed as a by-product. α-Methoxy-β-cyanopropionaldehyde dimethyl acetal (Va), b. p. 92°C/5 mmHg.

Found: C, 52.57; H, 8.37; N, 8.94. Calcd. for $C_7H_{13}O_3N$: C, 52.81; H, 8.23; N, 8.80%.

α-Ethoxy-β-cyanopropionaldehyde dimethyl acetal (Vb), b. p. 98°C/5 mmHg.

Found: C, 55.25; H, 8.89; N, 8.21. Calcd. for $C_8H_{15}O_3N$: C, 55.47; H, 8.73; N, 8.09%.

The results are summarized in Table I.

The hydrolysis of the acetal (IV) with dilute hydrochloric acid gave β-cyanoacrolein (VI), b. p. 52°C/5 mmHg; yiled ca. 90%.

Found: C, 58.99; H, 3.92; N, 17.50. Calcd. for C_4H_3ON: C, 59.26; H, 3.73; N, 17.28%.

2, 4-Dinitrophenylhydrazone: m. p. 176°C.

β-Cyanoacrolein (VI) (The Dehydrogenation of β-CPA).—Into a solution of 16.6 g. (0.2 mol.) of β-CPA in 30 ml. of dioxane there was stirred a solution of 11.1 g. (0.1 mol.) of selenium dioxide in 20 ml. of water and 70 ml. of dioxane over a two-hour period, with the temperature maintained at about 70°C. After the solution had been refluxed for another three hours, the reaction mixture was extracted with ether, washed with water, and dried over anhydrous sodium sulfate. By fractional distillation, 8.0 g. of VI was obtained, b. p. 52—53°C/5 mmHg; yield 29.1%.

Found: C, 59.17; H, 3.91; N, 17.21. Calcd. for C_4H_3ON: C, 59.26; H, 3.73; N, 17.28%.

The yield of VI was raised to 49.4% when an excess of selenium dioxide was used.

The authors wish the thank Professor Yojiro Tsuzuki for his helpful advice and encouragement. Acknowledgement is also made to the Ajinomoto Co., Ltd. for a grant and for a supply of raw materials.

The Catalytic Dehyrochlorination of 1, 2-Dichloroethane on Active Carbon in the Presence of Some Hydrocarbons

By Kunio OKAMOTO, Noboru TANAKA, Kiyoshi ADACHI and Haruo SHINGU

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 19, 1965)

The catalytic pyrolysis of 1, 2-dichloroethane on active carbon, carried out at 300 and 400°C in the presence of toluene, benzene and *n*-hexane, resulted predominantly in ethylene instead of vinyl chloride, which is known in the literature as the major pyrolysis product of the titled compound; the pyrolysis rates were suppressed by these hydrocarbons. These results have been explained by assuming a radical-chain mechanism similar to that suggested for the "homogeneous" pyrolysis of this compound. The chain length derived from the proposed mechanism has been estimated to be 20 to 50.

A number of studies concerned with the mechanism of the homogeneous pyrolysis of 1, 2-dichloroethane have been reported in recent years.[1] In contrast, little work has been done with the catalytic mechanism of the pyrolysis on active carbon, although the use of active carbon for the pyrolytic manufacture of vinyl chloride from 1, 2-dichloroethane has been extensively investigated.[2] During the course of our study of the active carbon catalyst for the preparation of vinyl chloride from 1, 2-dichloroethane,[2g,h] we felt it desirable to carry out several experiments in order to clarify the mechanistic nature of this catalytic reaction; in this paper we will report on some of the results, which support unambiguously the mechanism including radicals as the intermediates of the reaction on the surface of the active carbon catalyst.

The dehydrochlorination was carried out by means of a flow method at 300 and 400°C in the presence of hydrocarbons, such as *n*-hexane, toluene and benzene. 1, 2-Dichloroethane or a mixture of it with the hydrocarbons was fed to an integral reactor filled with the active carbon catalyst[2h] in a fixed bed. At the exit of the reactor the gaseous effluent entered a water-cooling condenser and ice-water trap; then hydrogen chloride was trapped by an absorption bottle containing aqueous sodium hydroxide, and finally the non-condensables were collected in a gas holder. The composition of the condensates and gases were analyzed by gas-liquid chromatography. The results are shown in Table I.

In the absence of hydrocarbons, 1, 2-dichloroethane decomposed almost completely under the reaction conditions employed. At the reaction temperatures of 300 and 400°C, the percentage conversion amounted, respectively, to 94.5 and 99% at the flow rate of 0.22 cc. of liquid 1, 2-dichloroethane per 1 cc. of active carbon per hour (Runs 1 and 2).

By the addition of hydrocarbons, the decomposition of 1, 2-dichloroethane was considerably inhibited. The addition of 4 mol. of toluene reduced the conversion percentage of 1, 2-dichloroethane from 94.5 to 8.5% at 300°C (Run 4). 1, 2-Dichloroethane mixed with 3 mol. of *n*-hexane gave a 50% conversion at 402°C (Run 7), whereas pure 1, 2-dichloroethane gave a 98% conversion at 380°C at a comparable flow rate (Run 3).

Furthermore, we found that the nature of the pyrolysis products was dramatically changed by the addition of these hydrocarbons. In the absence

a) Calculated from the amount of the recovered 1,2-dichloroethane.
b) Total rate constant, calculated from the conversion % of 1,2-dichloroethane and the composition of the products by using the equation similar to that cited by Barton.[1a]
c) For the other minor products see text.
d) Acetylene 0.05%; benzene, recovered, 98.5%.
e) Acetylene 0.3%; ethane, 0.8%; ethyl chloride, 0.1%; hexane, recovered, 94.0%.

of the hydrocarbons, pure 1, 2-dichloroethane gave vinyl chloride exclusively (more than 98% of the composition of the product); at most 2% of ethylene was found as a minor product (Runs 1, 2 and 3). A gas chromatographical examination of the other minor components reveales the presence of small amounts of ethyl chloride (about 0.1% in composition), *cis*-1, 2-dichloroethylene (0.05%), 1, 1-dichloroethane (0.02%), *trans*-1, 2-dichloroethylene (0.02%) and vinylidene chloride (0.01%). In the presence of the hydrocarbons, however, the major product was not vinyl chloride, but, rather, ethylene (more than 90% of the composition of the product). For instance, in the decomposition of 1, 2-dichloroethane mixed with 4 mol. of toluene, a mixture consisting of 94.8% ethylene, 4.7% vinyl chloride, and a small amount of other, minor products, such as ethyl chloride (about 0.04%) and acetylene (at most 0.01%), was obtained at 300°C (Run 4). More than 97.4% of the toluene was recovered; about 0.2% of it was then converted to *trans*-stilbene. In another example at 400°C (Run 7), a mixture of *n*-hexane and 1, 2-dichloroethane (3 : 1 by mole) gave a gaseous product containing 90% ethylene as a major product, 6% vinyl chloride, 0.04% acetylene, 0.54% ethane, and, at most, 0.01% ethyl chloride; more than 90% of the added *n*-hexane was recovered.

On the basis of the above results, we may suggest that the pyrolysis of 1, 2-dichloroethane on the active carbon catalyst proceeds by a radical chain mechanism similar to that suggested for the "homogeneous" dehydrochlorination.[1a,b] Namely, the homogeneous pyrolysis is also inhibited in the presence of these hydrocarbons,[1a] and the chain propagation can be initiated mainly at the treated, i. e., carbon-coated, walls.[1f,g]

Thus, for this catalytic dehydrochlorination, the initiation step may be formulated as:

$$ClCH_2CH_2Cl + \text{Active carbon} \xrightarrow{k_1} Cl + \cdot CH_2CH_2Cl$$

or $$\cdot CH_2CH_2Cl + \text{Active carbon} \xrightarrow{k_2} Cl + CH_2{=}CH_2$$

In the absence of the hydrocarbons, the chain propagation would proceed in the same manner as in the homogeneous pyrolysis, as is indicated below:

$$Cl + ClCH_2CH_2Cl \xrightarrow{k_3} HCl + Cl\dot{C}HCH_2Cl$$
$$Cl\dot{C}HCH_2Cl \xrightarrow{k_4} Cl + ClCH{=}CH_2 \quad \text{Chain}$$
$$Cl + Cl\dot{C}HCH_2Cl \xrightarrow{k_5} ClCH_2CHCl_2 \quad \text{Termination}$$

The further pyrolytic decomposition of 1, 1, 2-trichloroethane would form 1, 1-dichloroethane, *cis*- and *trans*-1, 2-dichloroethylene; these compounds have been identified in the minor reaction products.

In the presence of the hydrocarbons, the chain-carrying chlorine atom would be destroyed by the hydrogen donation from these hydrocarbons. As a result, the formation of vinyl chloride would be suppressed; accordingly, the decomposition of a 2-chloroethyl radical to ethylene would become preponderant:

$$Cl + RH \xrightarrow{k_6} HCl + \cdot R\downarrow \quad \text{Termination}$$

This termination of the radical-chain by the

hydrocarbons cansequently causes a decrease in the total rate of the conversion of 1, 2-dichloroethane. This is illustrated by a comparison of the following total rate expressions for 1, 2-dichloroethane alone and for its mixture with the hydrocarbons.

In the absence of the hydrocarbons:

$$-\frac{d(EDC)}{dt}=\left(\frac{2k_1k_3k_4}{k_5}\right)^{1/2}(EDC)+k_1(EDC) \quad (1)$$

In the presence of the hydrocarbons:

$$-\frac{d(EDC)}{dt}=\left\{\left(\frac{k_6k_4}{2k_5}\right)^2(RH)^2+\frac{2k_1k_3k_4}{k_5}(EDC)^2\right\}^{1/2}-\frac{k_4k_6}{2k_5}(RH)+k_1(EDC) \quad (2)$$

where (EDC) and (RH) are, respectively, the effective concentrations of 1, 2-dichloroethane and of the hydrocarbon on the surface of the active carbon; it is assumed that the reaction proceeds in the adsorbed layer and that the rate of adsorption and desorption are rapid as compared to the reaction rates.

If the above reaction sequence is accepted and the second term of Eq. 1 is neglected compared to the first, it is possible to compute the chain length in the propagation stage for this catalytic dehydrochlorination:

$$\text{Chain length}=\frac{k_3(EDC)}{k_5(ClCHCH_2Cl)}=\frac{1}{2}\cdot\left(\frac{2k_1k_3k_4}{k_5}\right)^{1/2}\cdot\frac{1}{k_1}=\frac{1}{2}\cdot\frac{d(\text{Vinyl Chloride})}{d(\text{Ethylene})}=\frac{1}{2}\cdot\frac{(\text{Vinyl Chloride }\%)}{(\text{Ethylene }\%)} \quad (3)$$

Therefore, the chain length at temperatures ranging from 300 to 400°C is estimated to be 20 to 50 from the data in Runs 1 and 2.

Experimental

Apparatus. — All the reactions were studied by streaming the vapor of 1, 2-dichloroethane* or its mixture with hydrocarbons at a constant rate through a catalyst bed in a hard-glass tube, 1.9 cm. in internal diameter. The tube was 70 cm. in length of which 50 cm. were heated in an electric furnace inclined at a slight angle to the horizon. An active carbon catalyst[2h] (manufactured by the Takeda Chemical Ind. Co., Ltd., Osaka; 15 g.; 40 cc. bulk volume; 8 to 12 mesh) was supported by a plug of glass wool. A glass thermocouple well (7 mm. o. d.) ran through the center of the catalyst bed, which was 20 cm. long for 40 cc. of the catalyst, and was situated in the center portion of the furnace. The bed temperature was uniform along its length to ±2°C (300 to 400°C). The 10 cm. portion of the tube immediately in front of the catalyst served as an evaporator and a preheater. 1, 2-Dichloroethane, placed in a graduated liquid feed tube with a capillary outlet tubing fitted at the top, was forced into a reaction vessel by feeding mercury from a dropping funnel into the tube at a constant rate. The delivery rates (liquid space velocity) of 1, 2-dichloroethane were 0.22 and 1.25 (cc. per cc. of the catalyst per hr.). In the case of the latter liquid space velocity, the bed temperature and the temperature at the preheater portion were kept about 10°C higher than the reaction temperature just before the feeding in of 1, 2-dichloroethane, because the endothermicity of this pyrolysis causes a temperature depression at such a high feeding rate. The temperature of the inlet of the bed was 5 to 10°C lower than that of the outlet. Thus, the reaction temperature was measured at the midpoint of the bed. At the exit of the reactor the gas flow entered a series of tared product traps, i. e., a water-cooling condenser fitted with a graduated cylinder, a graduated trap at 0°C (ice water), and a graduated gas-holder filled with saturated aqueous sodium chloride. In the case of the run for analysis of the minor reaction products, the gas-holder was replaced with another trap at −70°C (solid carbon dioxide - methanol). Except in this analysis run, hydrogen chloride was caught by means of an absorption bottle filled with 2—5 N sodium hydroxide provided between the gas-holder and the other traps. Before each run, the air in the free space was replaced by nitrogen, and after the run the gaseous products in the free space were transfered to the condensers or traps by a nitrogen stream.

Product Analysis.—The reaction products were analyzed gas chromatographically with a Perkin-Elmer model 154B Vapor Fractometer. The column for chlorine compounds was a Perkin-Elmer column A (2 m. long with diisodecyl phthalate as the liquid). The retention times for ethyl chloride, 1, 1-dichloroethane, 1, 2-dichloroethane, 1, 1, 1-trichloroethane, 1, 1, 2-trichloroethane, 1, 1, 2, 2-tetrachloroethane, vinyl chloride, vinylidene chloride, *trans*-1, 2-dichloroethylene, *cis*-1, 2-dichloroethylene and 1, 2-dichloropropane were, respectively, 1.7, 6.1, 13.0, 9.4, 54, 217, 1.2, 3.0, 4.7, 8.8, and 18.5 min., as determined at 64°C with hydrogen as a carrier gas and at a flow rate of 55 cc. per min. The column for hydrocarbon gases was a Perkin-Elmer column J (2 m. long, with silica gel as the solid). The retention times for ethane, ethylene, acetylene and vinyl chloride were, respectively, 3.6, 5.5, 13.6, and 51 min., as determined at 84°C with helium as the carrier gas and at a flow rate of 50 cc. per min.

After the run the aqueous sodium hydroxide in the absorption bottle was neutralized with nitric acid and the chlorine content was determined by the Mohr method. The condensates in the water-cooling condenser were distilled, and most of the hydrocarbons were recovered (Runs 4—7). In the run with toluene (Run 4), a small amount of the distillation residue (a solid) gave 0.20 g. of *trans*-stilbene, m. p. 120—122°C, after the recrystallization from ethanol. The identity of this with authentic *trans*-stilbene was established by comparing the infrared spectra taken with a Shimadzu model IR-27.

* The material contained as impurities 0.029% 1, 1-dichloroethane, 0.023% 1, 2-dichloropropane, and 0.058% 1, 1, 2-trichloroethane (analysis by gas chromatography).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1525—1529 (1966)

Sophorol[1]

By Hiroshi SUGINOME

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 20, 1965)

The structure of sophorol was confirmed to be 2′: 7-dihydroxy-4′: 5′-methylenedioxyisoflavanone by the synthesis of dehydro-*O*-dimethylsophorol, 2′: 7-dimethoxy-4′: 5′-methylenedioxyisoflavone.

This paper will describe the synthesis of 2′:7-dimethoxy-4′: 5′-methylenedioxyisoflavone (VII), which is one of the possible formulas of the dehydro-*O*-dimethylsophorol derived from *O*-dimethylsophorol[2] by palladium dehydrogenation. The paper will, therefore, complete the elucidation of the structure of sophorol (VIII).

The starting material, 2-hydroxy-4:5-methylenedioxybenzaldehyde (III) (R=H), was synthesized by Campbell et al.[3] through nitration and amination, followed by hydroxylation from piperonal. The repetition of this procedure did not, however, lead to satisfactory results; the reduction of 6-nitropiperonal with ferrous sulfate does not give good yields and leads to unreproducible results because of the quality of the ferrous sulfate, as the previous workers found. As the compound is a useful building stone for the syntheses of some naturally occurring oxygen heterocyclics with a 2-hydroxy-4:5-methylenedioxy oxygenation pattern, ayapin,[4] pachyrrhizon,[5] pachyrrhizin,[6] and jamaicin,[7] a new method of preparation was developed. Piperonal, a readily-available natural product, was submitted to Baeyer and Villiger's oxidation in order to form sesamol,[8] using performic acid. In the present experiments it was observed that the use of diluted peracids gave rather poor yields. However, for the preparation of sesamol in quantity, Beroza's modified procedure[8] was useful. The application of Gattermann aldehyde synthesis to sesamol,[9] in the presence of anhydrous zinc chloride as a catalyst, yielded almost quantitatively 2-hydroxy-4:5-methylenedioxybenzaldehyde (III) (R=H). No isomeric 6-hydroxyaldehyde was obtained.

9) Sesamol used in the present experiments was provided by custom synthesis of Aldrich Chemical Company, Inc., Milwaukee, Wis., U. S. A.

The condensation of methylated aldehyde with hippuric acid in the presence of acetic anhydride readily afforded the corresponding azlactone, which was then hydrolysed to the corresponding phenylpyruvic acid by the usual method. 2-Methoxy-4 : 5-methylenedioxyphenylpyruvic acid was converted into the corresponding oxime. The treatment of the oxime with acetic anhydride yielded 2 - methoxy - 4 : 5 - methylenedioxyphenylacetonitrile (IV) (R=CN), which exhibited a weak characteristic band at 2241 cm^{-1} attributable to C≡N.[10]

This nitrile was condensed with resorcinol to give a desoxybenzoin derivative in a poor yield; the condensation was effected by Hoesch procedure, using a mixed solvent of chloroform and ether. Hoesch condensation in ether did not proceed smoothly, and when the reaction mixture was saturated with hydrogen chloride, a crystalline precipitation which was different from ketimine hydrochloride was obtained. This compound was found to be the corresponding amide (IV) (R=$CONH_2$) by a study of its infrared and ultraviolet spectra.

Attempts to synthesize the desoxybenzoin by the condensation of phenylacetic acid (IV) (R=COOH) with resorcinol in the presence of BF_3[11] failed.

This desoxybenzoin, on partial methylation with ethereal diazomethane, gave 2-hydroxy-4:2'-dimethoxy-4':5'-methylenedioxydesoxybenzoin, (V) (R=CH_3), m. p. 131—132°C, which was identical with the ketone, $C_{17}H_{16}O_6$,[2] obtained by the mild alkaline hydrolysis of *O*-dimethyl ether of sophorol.

The cyclization of 2-hydroxy-4:2'-dimethoxy-4':5'-methylenedioxydesoxybenzoin with sodium and ethyl formate[12] furnished a product, $C_{18}H_{16}O_7$, which melted at 185°C, in a good yield. The presence of an alcoholic hydroxyl band in its infrared spectrum and its ultraviolet spectrum indicated that this compound was a 2-hydroxyisoflavanone derivative (VIb).

The cyclization of *O* - hydroxyphenylbenzyl ketones to isoflavones with sodium and alkyl formates has frequently been postulated as proceeding through intermediates of the VIb type or through the direct dehydration of an intermediate (VIa).[13a] In only a very small number of instances, however, namely, the conversions of 2-methoxydesoxybenzoins into the corresponding isoflavones, have crystalline products of 2-hydroxyisoflavanone been isolated and characterized.[13b] Whalley[13a] has postulated that the stability of the products may be attributed, in part at least, to the possibility of hydrogen bonding between 2-hydroxyl and 2'-methoxyl groups of the type shown in VIb. The infrared spectrum of 2-hydroxy-2' : 7-dimethoxy-4' : 5'-methylenedioxyisoflavanone in a dilute chloroform solution shows two hydroxyl bands, at 3413 and 3563 cm^{-1}. The former (broad) is attributable to an internal hydrogen bonding between 2-hydroxyl and 2'-methoxyl groups.

When boiled in acetic acid, this intermediary isoflavanone was readily dehydrated to 2':7-dimethoxy-4':5'-methylenedioxyisoflavone, which melted at 209—210°C. The selenium dioxide oxidation product (m. p. 203—205°C)[2] derived from the natural substance was identical with this synthetic isoflavone.

Thus, the correctness of the assumed structure (VIII)[2] for sophorol was fully proved.

On the basis of this formula, some comments on the compound derived from sophorol should be added.

When sophorol was methylated with dimethyl sulfate containing a trace of acid, a new compound, $C_{17}H_{12}O_5$, was obtained in a poor yield. The absence of carbonyl and hydroxyl bands in the infrared spectrum of this substance, as well as the close similarity of its ultraviolet spectrum (Fig. 1) to that of anhydrosophorol (IX) (R=H), confirmed the formula IX (R=CH_3) as holding for this compound. Attention should also be directed to the structural similarity of anhydrosophorol and erosnin (X).[14]

The possible half-chair conformation of chromanone and chroman has been discussed, notably by Whalley.[15] Philbin and Wheeler[16] pointed out that the chromanone system may occupy a plane, except for carbon 2, which can be the only cyclic atom out of that plane because the infrared spectra of a series of flavanones show the carbonyl frequency to be in the range of 1695—1661 cm^{-1}, showing the conjugation of the carbonyl group

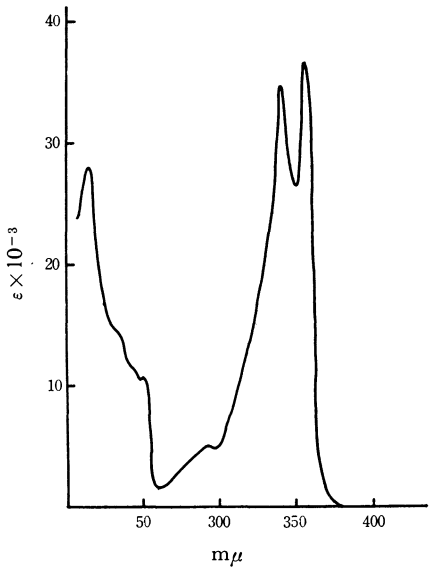

Fig. 1. UV spectrum.

with the fused benzene ring. Furthermore, a substituted phenyl group on the number 3 carbon of isoflavanone can occupy either an equatorial or an axial position, because the isoflavanone system would have a tendency toward conformational inversion by diminishing the repulsion of nonbonded atoms through the lack of hydrogen atoms at positions 1 and α.

An examination of the model of sophorol showed that when the phenyl group was in the 3-equatorial position, the 2'-phenolic hydroxyl group on the phenyl group was located near enough to the dihydropyrone carbonyl group to form an intramolecular hydrogen bond, but when it was in the 3-axial position, the distances were too great to allow the formation of this bond.

Table I shows the carbonyl and hydroxyl frequencies in the infrared spectra of sophorol and *O*-dimethylsophorol, together with those of the model compounds.

From Table I it can be seen that isoflavanones with 2'-methoxyl groupings have a carbonyl band in the 1677—1681 cm^{-1} range, almost identical with the location of the parent flavanone (1680 cm^{-1}). However, this band, is shifted to 1658 cm^{-1} in compounds with 2'-hydroxyl groupings, giving evidence of an intramolecular hydrogen bond. It is also clear that a dilute solution of isoflavone or isoflavanone with 2'-hydroxyl groupings exhibits a broad hydrogen-bonded hydroxyl band in the hydroxyl stretching region, showing intramolecular hydrogen bonding. The above observation indicates that the 3-phenyl group of sophorol is in an energetically favorable equatorial orientation, and it shows the presence of a hydrogen bond between the dihydropyrone carbonyl and the 2'-hydroxyl groups.

Table I

Compound	OH(cm^{-1})	C=O(cm^{-1})	
2'-Hydroxyisoflavone[17]	3187[a]	1621[a]	Δ21 cm^{-1}

Experimental[20]

2 - Hydroxy - 4 : 5 - methylenedioxybenzaldehyde (III) (R=H).—Dry hydrogen chloride was bubbled through a solution of 713 mg. of sesamol and 1.5 ml. of hydrogen cyanide in absolute ether (5 ml.) containing anhydrous zinc chloride (300 mg.) under ice cooling. After 30 min., the solution showed a blue color, and violet precipitates of ketimine hydrochloride were deposited. The product was then separated and washed with ether (3 ml.). This ketimine hydrochloride was recrystallized from water (4 ml.), forming fine green-colored crystals (825 mg.). The product was stable in air and was not hygroscopic. When this ketimine hydrochloride was boiled with water (7 ml.) for 1 min., crude 2-hydroxy-4 : 5-methylenedioxybenzaldehyde (620 mg.) separated from the solution. After purification, this was found to be identical with an authentic specimen.

The Azlactone of 2-Methoxy-4 : 5-methylenedioxybenzaldehyde. — 2-Methoxy-4 : 5-methylenedioxybenzaldehyde (15.7 g.), hippuric acid (15.7 g.), and fused sodium acetate (7.9 g.) were powdered to an intimate mixture and heated with 30 ml. of acetic anhydride for 2 hr. on a bath to give an orange crystalline mass. After evaporation and washing with small volumes of alcohol and water successively, crude azlactone (20.6 g.) was obtained. This porduct was recrystallized from alcohol, forming fine orange-colored

20) Melting points are uncorrected. The ultraviolet absorption spectra were measured on a Beckman Model D. U. spectrophotometer in ethanol. The infrared spectra were measured in Nujol, unless otherwise stated. NMR spectra were taken in deuteriochloroform by Japan Electron Optics 3H 60 high resolution spectrometer (60 Mc.). Tetramethylsilane was used as an internal standard.

crystals, m. p. 266—267°C.[21]

Found: C, 66.95; H, 4.27. Calcd. for $C_{18}H_{13}O_5N$: C, 66.87; H, 4.05%.

2-Methoxy-4 : 5-methylenedioxyphenylpyruvic Acid.—The azlactone (5.0 g.) obtained above was suspended in 25 ml. of a 10% sodium hydroxide solution and then refluxed for 2 hr. on an oil bath in a nitrogen stream. The dark brown solution, after cooling, was extracted with ether and then saturated with sulfur dioxide. After the evaporation of the solvent from the ethereal solution, crude 2-methoxy-4 : 5-methylenedioxybenzaldehyde (0.28 g.) was obtained. After the benzoic acid had been removed by filtration, the filtrate was extracted with ether. The ethereal solution contained 0.7 g. of benzoic acid. The aqueous solution was then concentrated under reduced pressure to about 7 ml. and set aside overnight under ice cooling. The bisulfite-addition compound of 2-methoxy-4 : 5-methylenedioxyphenylpyruvic acid (6.0 g.) which separated was collected by filtration. When this bisulfite-addition compound (1.0 g.) was heated with 6 ml. of 2 N hydrochloric acid for a few min., colorless 2-methoxy-4 : 5-methylenedioxyphenylpyruvic acid (0.3 g.) separated. This was recrystallized from water, m. p. 220—221°C.

Found: C, 55.77; H, 4.36. Calcd. for $C_{11}H_{10}O_6$: C, 55.46; H, 4.23%.

The bisulfite-addition compound was used conveniently in the next oxime formation.

The Oxime. — The bisulfite-addition compound obtained above (20 g.), hydroxylamine hydrochloride (7.8 g.), and an 8% caustic soda solution (95 ml.) were warmed for a few minutes at 50°C and then set aside overnight. On acidification with hydrochloric acid, the crude oxime (9.6 g.) separated. This was recrystallized from water, m. p. 162—163°C (decomp.).

Found: C, 52.32; N, 4.50. Calcd. for $C_{11}H_{11}O_6N$: C, 52.17; H, 4.38%.

2-Methoxy-4 : 5-methylenedioxyphenylacetonitrile (IV) (R=CN).—The oxime (5.0 g.) was heated with acetic anhydride (3 ml.) on a water bath and, after the vigorous reaction had subsided (after 2—3 min.), a large volume of water added. The nitrile (3.3 g.) then separated and solidified. On repeated washings with water and recrystallization from alcohol, the nitrile was obtained as needles, m. p. 123—124°C. The crystals dissolved with difficulty in ether, but they were readily soluble in chloroform and acetone.

Found: C, 63.10; H, 5.00; N, 7.18; OCH_3, 16.5. Calcd. for $C_{10}H_9O_3N$: C, 62.82; H, 4.75; N, 7.33; OCH_3, 16.2%.

UV λ_{max} (ε_{max}): 213 (4741), 239 (5540) and 301 (6945) IR: 2241 cm^{-1} (w) (C≡N).

2'-Methoxy-2 : 4-dihydroxy-4' : 5'-methylenedioxydesoxybenzoin (V) (R=H).—a) For 2 hr. at room temperature, dry hydrogen chloride was passed through a solution of resorcinol (0.8 g.) and 2-methoxy-4 : 5-methylenedioxyphenylacetonitrile (0.5 g.) in a mixture of dry ether (6 ml.) and chloroform (10 ml.) containing fused anhydrous zinc chloride (0.5 g.). After this mixture had been kept overnight, orange ketimine hydrochloride separated; this was washed with ether and heated for about 40 min. with 5 ml. of water. On cooling, the crystalline solid separated; after it had been washed with 5% aqueous sodium hydrogen carbonate and water successively, it was crystallized from aqueous alcohol (0.28 g.), m. p. 160—162°C. After recrystallization, it formed needles, melting at 164—165°C.

Found: C, 63.29; H, 4.50. Calcd. for $C_{16}H_{14}O_6$: C, 63.57; H, 4.67%.

IR: 3537—3747 cm^{-1} (m), (OH) 1618 cm^{-1} (s) (chelated conjugated C=O).

b) A solution of resorcinol (0.63 g.) and 2-methoxy-4 : 5-methylenedioxyphenylacetonitrile (0.5 g.) in dry ether (80 ml.) containing zinc chloride (0.3 g.) was saturated with dry hydrogen chloride for 2 hr. under ice-cooling. After a few days, feeble brown crystals separated from the solution. This material was very hygroscopic and dissolved readily in water. When the aqueous solution was heated for a few min. on a bath, colorless 2-methoxy-4 : 5-methylenedioxyphenyl acetamide (IV) ($R=CONH_2$) separated in a poor yield. After recrystallization from water, it had a m. p. of 156—157°C.

Found: C, 57.29; H, 5.54. Calcd. for $C_{10}H_{11}O_4N$: C, 57.41; H, 5.30%.

IR: 3396, 3221 cm^{-1} (NH_2), 1654 cm^{-1} (s), (amide 1) 1621 cm^{-1} (m), (amide 2) 1501 cm^{-1} (m) (aromatic C=C).

2-Methoxy-4 : 5-methylenedioxyphenylacetic Acid (IV) (R=COOH).—2-Methoxy-4 : 5-methylenedioxyphenyl acetonitrile (0.5 g.), a 4 N potassium hydroxide solution (10 ml.), and methanol (10 ml.) were refluxed for 12.5 hr. After the evaporation of the methanol under reduced pressure and the acidification of the aqueous solution, colorless crystals separated, they were collected by filtration (0.5 g.). These crystals were then recrystallized from water, forming 0.45 g. of 2-methoxy-4 : 5-methylenedioxyphenylacetic acid (IV) (R=COOH). This solid acid melted at 155—157°C.[6,22] IR: 1690 cm^{-1} (s) (C=O).

Found: C, 57.38; H, 4.92. Calcd. for $C_{10}H_{10}O_5$: C, 57.14; H, 4.80%.

Methyl Ester (IV) (R=COOMe).—The above acid (0.1 g.) in acetone (2 ml.) was treated with ethereal diazomethane obtained from nitrosomethylurea (0.2 g.). After the evaporation of the solvent, the residual crude ester (IV) ($R=COOCH_3$) was recrystallized from aqueous acetone. Plates, m. p. 69—70°C.

Found: C, 59.02; H, 5.60. Calcd. for $C_{11}H_{12}O_5$: C, 58.92; H, 5.40%.

2-Hydroxy-4 : 2'-dimethoxy-4' : 5'-methylenedioxydesoxybenzoin (V) (R=Me).—The above ketone (0.23 g.) in acetone (3 ml.) was treated with an ethereal solution of diazomethane and then set aside overnight. The evaporation of the solvent under diminished pressure and the recrystallization of the residue from aqueous alcohol yielded 2-hydroxy-4:2'-dimethoxy-4':5'-methylenedioxydesoxybenzoin. Needles, m. p. 131—132°C.

Found: C, 64.50; H, 5.07. Calcd. for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10%.

IR: 1632 cm^{-1} (s) (chelated conjugated C=O) 1616 (s), 1590 (m) and 1506 cm^{-1} (m) (aromatic C=C) 1039, 931 cm^{-1} (m) (-C-O-C-O-C-). A mixed melting point determination with a specimen of the hydrolysed product (m. p. 120—123°C)[2] of *O*-dimethylsophorol was undepressed.

21) Reported m. p. 273—274°C.

22) Reported m. p. 97—98°C.[6]

2-Hydroxy-7 : 2′-dimethoxy-4′ : 5′-methylenedioxyisoflavanone (VIb).—A solution of 2-hydroxy-4 : 2′-dimethoxy-4′ : 5′-methylenedioxydesoxybenzoin (100 mg.) in ethylformate (4 ml.) was added to powdered sodium (200 mg.) at 0°C. After it had been kept for 66 hr. at −5°C, the reaction mixture was decomposed by the addition of ice water. The aqueous solution was then acidified and freed from ethylformate under reduced pressure. The separated solid was extracted with ether (30 ml.×2). The evaporation of the solvent left a brown crystalline residue, m. p. 181—183°C. This residue was washed with a small amount of alcohol, resulting in the formation of 2-hydroxy-7 : 2′-dimethoxy-4′ : 5′-methylenedioxyisoflavanone (85 mg.). The material purified from aqueous alcohol formed colorless crystals (m. p. 185°C).

Found: C, 62.60; H, 4.80. Calcd. for $C_{18}H_{16}O_7$: C, 62.79; H, 4.68%.

IR spectrum (chloroform) 1677 cm^{-1} (s) (C=O) 3413, 3563 cm^{-1} (m) (OH) UV λ_{max} (ε_{max}) 230 (19200), 274 (17700) and 303 (16400).

7 : 2′-Dimethoxy-4′ : 5′-methylenedioxyisoflavone (VII). — When a solution of the above 2-hydroxyisoflavanone (50 mg.) in acetic acid (0.5 ml.) was boiled for 30 min. and was then diluted with water, a pale pink-colored material separated. Purification from aqueous ethanol gave rise to 2′ : 7-dimethoxy-4′ : 5′-methylenedioxyisoflavone in fine, colorless needles, m. p. 208—209°C.

Found: C, 65.98; H, 4.20. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

IR 1642 cm^{-1} (s) (γ-pyrone C=O) 1028 and 940 cm^{-1} (m) (methylenedioxyl). UV λ_{max} (ε_{max}): 247 (22200), 264 (13460), 304 (19570). $\lambda_{min}(\varepsilon)$: 245 (21650), 260 (13400) 280 (11020). A mixed melting point determination with dehydro-*O*-dimethylsophorol derived from a natural substance (m. p. 203—205°C)[2] showed no depression.

***O*-Methylanhydrosophorol (IX) (R=H).**—A mixture of sophorol (20 g.) and dimethylsulfate (20 ml.) containing a trace of acid in methanol (40 ml.) was set aside overnight. The next day, 30% aqueous sodium hydroxide was added, drop by drop, to this solution. After the reaction had subsided, the solution was diluted with water.

The resultant precipitation was washed and then recrystallized five times from aqueous acetone, thus forming silky needles (m. p. 187—188°C) of *O*-methylanhydrosophorol (ca. 80 mg.). The material recovered from the filtrate had a wide range of melting points (ca. 120—180°C), but it was not examined in detail.

Found: C, 68.96; H, 4.12; OCH_3, 10.48. Calcd. for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08; OCH_3, 10.5%.

The author is grateful to Professors Tōshi Irie, Takeshi Matsumoto and Tadashi Masamune for their kind interest in this work and to Mr. Mitsuru Kusama for assistance in the preparation of starting materials and to Mr. Hanzo Shimokawa for the measurements of the NMR spectra. The author thanks Mrs. Noriko Etoh for the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1529—1534 (1966)

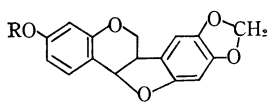
Maackiain[1),*]

By Hiroshi SUGINOME

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 20, 1965)

This isolation and determination of the structure of a new, naturally-occurring chromanocoumaran, maackiain (I) R=H, are described. On the basis of these results, the structure of pterocarpin is revised to (I) R=CH_3.



(I)

In preceding papers[2,3)] the isolation and the structure of a new isoflavanone, sophorol $C_{16}H_{12}O_6$, were discussed. Biogenetical considerations[2)] suggest the probable coexistence of pterocarpinoids

1) Oxygen Heterocycles. VII. Read before the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961. A brief account of this work has been published. H. Suginome, *Experientia,* **18**, 161 (1962).

* It was suggested to call this class of naturally occurring substances pterocarpinoids.

2) H. Suginome, *Tetrahedron Letters,* **1960**, 16; and preceding paper.

3) H. Suginome, *J. Org. Chem.,* **24**, 1655 (1959).

or rotenoids in the same plant. Therefore, we decided to examine this problem. A previous paper[3] described the isolation of an unknown phenolic substance, which was accompanied by sophorol and which had the molecular formula $C_{16}H_{12}O_5$. In reference to the source of this new compound, the name "maackiain" is suggested. The following proof of the structure of the compound as a chromanocoumaran gives support to the earlier biogenetical suggestions.[2]

Maackiain formed leaflets containing a half-equivalent molecule of water from aqueous methanol. The analytical data of dried maackiain crystals (m. p. 180—181°C) are in excellent agreement with the molecular formula of $C_{16}H_{12}O_5$ as has already been reported.[3] The compound is optically active, giving a value of $[\alpha]_D^{20}$ 251.7° in a chloroform solution. The optical rotatory dispersion curve of maackiain exhibits a negative Cotton effect curve. This was phenolic. A Zeizel determination showed no methoxyl group to be present. The presence of a methylenedioxyl group in the maackiain molecule was, however, suggested by the positive color tests. Maackiain showed the following maxima in infrared absorption, confirming all of the chemical evidence for the functional groups in the maackiain molecule: (3472: phenolic hydroxyl) (1617, 1600, 1507: aromatic C=C) (1496, 1379, 1347, 1315, 1292, 1267, 1234, 1204, 1180) (1161: C–O in dihydropyran) (1150, 1125, 1112, 1078, 1064, 1016, 978). (1035, 929: –C–O–CH_2–O–C–) (888, 861, 844, 813, 781, 758, 740 cm^{-1}).

On the basis of the above evidence, the functional groups of maackiain may be summarized as follows:

$$C_{15}H_9 \begin{cases} -O- \\ -O- \\ -O-CH_2-O- \\ -OH \text{ (phenolic)} \end{cases}$$

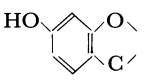
In accordance with the above results, maackiain readily formed mono-*O*-methyl ether, $C_{17}H_{14}O_5$, with ethereal diazomethane or with methyliodide and potassium carbonate in dry acetone. The *O*-methyl ether showed no band attributable to a hydroxyl stretching frequency in the infrared region.

In connection with a possible biogenetic linking of pterocarpin and homopterocarpin to naturally-occurring 2'-hydroxyisoflavonoids, the reduction of a carbonyl in the functional pattern (I) of sophorol, followed by dehydration to ether linkage, should give rise to a functional pattern (II) of maackiain.

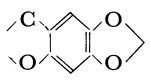
$$C_{14}H_8 \begin{cases} C=O \\ OH \text{ phenolic} \\ OH \text{ phenolic} \\ -O-CH_2-O- \\ -O- \end{cases} \xrightarrow[-H_2O]{+H_2} C_{15}H_9 \begin{cases} -O- \\ \text{——} \\ OH \text{ phenolic} \\ -O-CH_2-O- \\ -O- \end{cases}$$

(I) (II)

Furthermore, *O*-methylmaackiain has the same functional groups as pterocarpin. These considerations lead to the assumption that the two arylic systems in the maackiain molecule may be the A and B groupings, which are chromophores of sophorol:[2]



(A)



(B)

The ultraviolet spectra of maackiain and *O*-methylmaackiain in alcohol gave valuable information on the structure. Maackiain exhibits characteristic absorption peaks in two main regions, one of high intensity at 311 mμ (ε, 8510), and the other of a lower intensity at 286 mμ (ε, 5120). The medium intensities of these absorption maxima showed that the aromatic nucleus is in no conjugation with any other chromophore, e. g., ethylenic linkage.

Curves a, b, c, and d, in Fig. 1 show the ultraviolet absorption curves of 2:4-dimethoxyphenylacetonitrile, 2-methyl-4:5-methylenedioxyphenol, *O*-methylmaackiain and the summation of curves a and b respectively. As may be expected from the above discussion, curves c and d are very similar in shape.

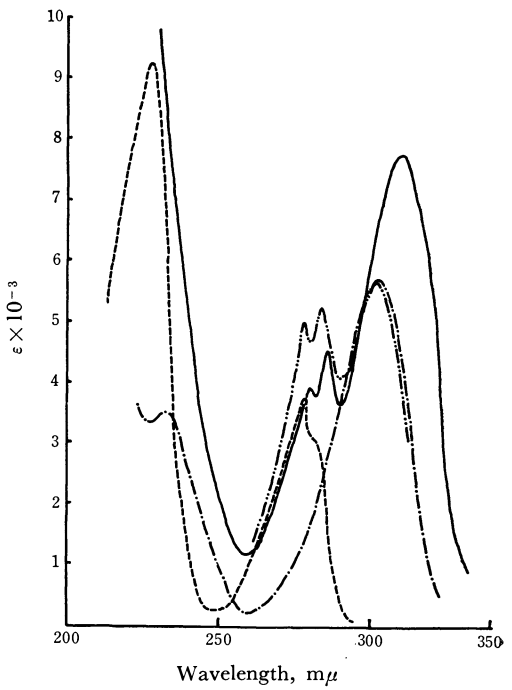


Fig. 1. UV spectra.
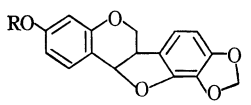
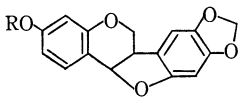
------ 2, 4-Dimethoxyphenylacetonitrile (curve a)
—·—· 2-Methyl-4: 5-methylenedioxyphenol (curve b)
——— *O*-Methylmaackiain (curve c)
—··— Curve a + b (curve d)

On the other hand, the ultraviolet absorption spectrum of *O*-methylmaackiain and that of pterocarpin** were also superimposable, and a mixed melting point determination of the two substances showed no depression.

Therefore, the structure of *O*-methylmaackiain was thought to be either III ($R=CH_3$) or IV ($R=CH_3$).



(III)



(IV)

Formula IV ($R=H$) for maackiain was proved as follows: the catalytic reduction of *O*-methylmaackiain gives rise to a new phenolic substance, $C_{17}H_{14}O_5$, melting at 146—148°C. The same substance was also produced in a good yield by the Birch reduction[4] of *O*-methylmaackiain. This phenol gave mono-*O*-methyl ether.

On the basis of formula IV, the structure of this phenolic compound should be explained by the isoflavan structure (V) formed by the hydrogenolysis of the benzilic-type ether linkage.

The structure of the *O*-methyl ether of dihydro-*O*-methylmaackiain was confirmed by the synthesis

4) A. J. Birch, *Quart. Rev.*, **4**, 69 (1950).

of racemic 2': 7-dimethoxy-4': 5'-methylenedioxy-isoflavan (V, R=CH_3). The catalytic reduction of 2' :7-dimethoxy 4': 5'-methylene-dioxyisoflavone (VI)[3] gave an oily mixture of the corresponding isoflavan-4-ol (VII) and isoflavanone (VIII). The Clemmensen reduction of this gave racemic 2':7-dimethoxy - 4':5' - methylenedioxy - isoflavan (V), which had a m. p. of 111—113°C (V, R=CH_3).*** The latter and *O*-methyldihydro-*O*-methylmaackiain gave identical infrared-spectra in a chloroform solution, thus establishing the structure IV (R=H) for maackiain.[5] Since a comparison of the infrared spectra of *O*-methylmaackiain and pterocarpin in a chloroform solution disclosed that the two substances are identical, the structure of pterocarpin should be corrected to IV (R=CH_3). This finding is complementary to the conclusion, from the NMR spectrum, on the structure of pterocarpin.[6] Moreover, this conclusive evidence for the structure of pterocarpin and biogenetical considerations suggest that the structure of pisatin,[7] for which the structure IX has been given, should be X.

On the basis of a direct comparison with *O*-methylanhydrosophorol[3] and some spectral properties, the structure of pisatin was recently revised[8] to X. The NMR spectrum of *O*-acetylmaackiain (Fig. 2) further confirms the above conclusion.

The sharp single peak at $\tau=7.72$ which has the relative area of three hydrogens is due to the acetoxy group at the position 7. The value is in good agreement with the value of the acetoxy group attached to the aromatic ring. The peaks between $\tau=2.0$ and $\tau=3.6$ are attributed to aromatic protons. Ring A in *O*-acetylmaackiain has a pair of hydrogen atoms at the positions 5 and 6 and a hydrogen atom at the position 8. As expected, a hydrogen at the position 5 which is coupled with only one hydrogen on C6 appeared as a doublet centered at $\tau=2.44$. The coupling constant ($J=8.9$ c. p. s.) is an expected value for the ortho coupling of hydrogens on a benzene ring. Of the rest of the signals of this ABX system of the ring A, only one doublet, at $\tau=3.13$ and $\tau=3.16$, was observable. This doublet is considered to be a part of the quartet arising from a hydrogen on the position 6 which is coupled with a proton on the position 8 (meta coupling) and with a proton on the position 5 (ortho coupling). Other protons on the benzene ring B, will give two singlet peaks attributable to a proton on the position 3' and to a proton on the position 6' (para coupling). The lines at $\tau=3.56$ (1 proton) and $\tau=3.29$ (2.5 protons) are assigned to these protons. The observed broadening and the area of the former suggested that this had to include another proton. A proton on the position 8 will give rise to a doublet by meta coupling with a proton on the position 6. However, no isolated doublet was observed in the expected position. The peaks which are due to a hydrogen on the position 8 apparently formed a broad single peak at $\tau=3.29$, together with the signal of a hydrogen of the position 6'. It should be noted that, due to the *O*-acetyl substituent on the position 7, the position of the signal of a proton on the position 8 is shifted to a lower magnetic field than that to be expected for a proton adjacent to two oxygens. The peak at $\tau=3.29$ also includes the rest of the quartet of a proton on the position 6. The methylenedioxy peak appeared at 4.09 τ as a singlet. The triplets with center of 4.51 τ are assigned to a hydrogen on the position 4, which is coupled with only a proton of the position 3.

Since the interaction with a proton on the position 3 should give rise to doublets with the lines of a proton on the position 4, the following can explain the situation. The shape of the peaks indicates that they may be an unresolved quartet. *O*-Acetylmaackiain in deuteriochloroform could exist in an equilibrium of the two possible cis conformations, which will have somewhat different coupling constants for a proton on the position 4. The molecular model of the strainless configuration of *O*-acetylmaackiain, in which the two hydrogens on carbons 3 and 4 are cis, suggests that two conformations are possible. The conformational inversion between these two forms could be favorable in a chromanocoumaran system due to the lack of some 1, 3-hydrogen interaction. The two hydrogens on the position 2 which consititute the AB part of the ABX system and a hydrogen on the position 3 appeared in the range from $\tau=5.5$ to $\tau=6.6$. The two hydrogens on the position 2 should give rise to eight lines; these hydrogens appeared as a triplet centered at $\tau=6.42$. The rest of this ABX system, i. e., a hydrogen at the position 3, formed the multiplets $\tau=5.69$ to $\tau=6.17$.

*** A communication from the University of Manchester recorded m. p. 110—111°C for the same compound which was derived from pterocarpin.

In view of the observed antifungicidal activity of this group of compounds, it is of interest to compare the variation in biological activity with the variation in structure. The results of tests on the antimicrobial activity[7] of maackiain and related compounds, kindly performed by Professor Yuji Sasaki and his colleagues, are recorded in the Experimental section.

Experimental[9]

The isolation and purification were described, with the isolation of sophorol, in the Experimental section of the previous paper.[3] Maackiain formed leaflets from aqueous methanol. After it had been dried under a vacuum, the melting point of this compound (178.5—179°C) rose to 180—181°C.

Found: C, 65.68; H. 4.69; 1/2H_2O, 3.7, 3.6. Calcd. for $C_{16}H_{12}O_5 \cdot 1/2H_2O$: C, 65.53; H, 4.46; 1/2$H_2O$; 3.6%. Found: (in a sample dried at 100—110°C in vacuo) C, 67.67; 67.33; H, 4.41; 4.58. Calcd. for $C_{16}H_{12}O_5$: C, 67.60; H, 4.26%.

$[\alpha]_D^{22}$ −251.7° (*c* 0.46, chloroform). RD[10] (*c* 0.074, methanol). 26°: [α]700 −175.8, [α]589 −227.0, [α]400 −559.0, [α]360 −684.0.

Maackiain was soluble in aqueous 2 N sodium hydroxide but insoluble in aqueous sodium hydrogen carbonate. Maackiain dissolved readily in acetone, ethylacetate, dioxane, chloroform and benzene. It gave no ferric reaction. The solution of maackiain in concentrated sulfuric acid became green when a drop of a 5% alcoholic gallic acid solution was added.

Maackiain-*O*-methyl Ether (Pterocarpin).—*a*) *With Diazomethane.*—Maackiain (150 mg.) in acetone (6 ml.) was treated with an ethereal solution of diazomethane (from nitrosomethylurea. 1.5 g.) and then set aside overnight. Evaporation under diminished pressure and the recrystallization of the crystalline residue from absolute ethanol yielded *O*-methylmaackiain, m. p. 168—169°C.

Found: C, 67.92; H. 4.74; OCH_3, 10.35. Calcd. for $C_{17}H_{14}O_5$: C, 68.45; H, 4.37; OCH_3, 10.40%. RD[6] (*c* 0.077, chloroform), 16°:[α] 700 −119.4, [α]589 −223.5, [α]400 −530.1, [α]340 −481.0.

UV *max.*: 310 mμ (ε, 10156), 386 mμ (ε 5687), 280 mμ (ε, 4813).

This was insoluble in a 2 N sodium hydroxide solution. The solution of the compound in concentrated sulfuric acid became green when one drop of a 5% alcoholic gallic acid solution was added.

b) *With Methyl iodide.*—A mixture of maackiain (670-mg.), potassium carbonate (2 g.), methyl iodide (15-ml.), and acetone (14 ml.) was heated under reflux for 4 hr. The filtered solution was then evaporated, and the residue was washed with water and recrystallized from alcohol.

Colorless leaflets; m. p. 168—169°C (560 mg.).

Dihydro-*O*-methylmaackiain Obtained by the Hydrogenolysis of *O*-Methylmaackiain.—*a*) *By Catalytic Hydrogenation.*—*O*-Methylmaackiain (200 mg.), dissolved in glacial acetic acid (24 ml.) containing a pre-reduced platinum catalyst (platinum oxide, 40 mg.), was hydrogenated for 2 hr. at room temperature. After the catalyst had then been removed, the filtrate was evaporated to dryness. The residue was treated with aqueous 2 N sodium hydroxide. Upon the acidification of the sodium hydroxide solution, crude dihydro-*O*-methylmaackiain separated. This was recrystallized from aqueous ethanol, forming colorless leaflets (m. p. 146—148°C) (8 mg.). Crude *O*-methylmaackiain (158 mg.) was recovered unchanged.

Found: C, 68.10; H, 5.12. Calcd. for $C_{17}H_{16}O_5$: C, 67.99; H, 5.37%.

IR spectrum: 3285 cm^{-1} (phenolic OH); 1618, 1591 and 1499 cm^{1-} (aromatic C=C).

UV max.: 290 and 302 mμ (ε, 6729 and 6467).

b) *With Sodium and Liquid Ammonia.*—Sodium (50 mg.) in small pieces was stirred into *O*-methylmaackiain (150 mg.) in toluene (8 ml.) and liquid ammonia (28 ml.) within a five-minute period. After the reaction mixture had been set aside overnight, 10 ml. of water was added. After the extraction of the mixture with ether (40 ml.), the ethereal solution was extracted with 4 N aqueous sodium hydroxide (20 ml.×2). The alkaline layer was acidified with 6 N hydrochloric acid and extracted with ether (40 ml.+20 ml.+20 ml.), washed with water, and dried. The solution was evaporated to dryness to yield an intractable residue (120 mg.). The neutral fraction, after it had been washed and dried, yielded a crystalline residue of 155 mg. This was recrystallized from dilute ethanol, yielding dihydro-*O*-methylmaackiain (m. p. 146—148°C, 67 mg.) which was identical with the specimen obtained from procedure a) above.

***O*-Methyl Ether of Dihydro-*O*-methylmaackiain.**—Dihydro-*O*-methylmaackiain (20 mg.), methyliodide (0.02 ml.), anhydrous potassium carbonate (60 mg.), and dry acetone (1 ml.) were refluxed for 4 hr. After the potassium carbonate had been removed, the filtrate was evaporated to dryness and the residue was washed with a small volume of water and then recrystallized from aqueous ethanol, yielding *O*-methyl ether as short needles, m. p. 109—110°C.

Found: C, 68.66; H, 5.70. Calcd. for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77%.

***O*-Acetylmaackiain.**—Maackiain (85 mg.) was dissolved in 0.5 ml. of pyridine and 0.5 ml. of acetic anhydride and then set aside. A work-up by the standard procedure gave crude *O*-acetylmaackiain (93 mg.). This was recrystallized from aqueous ethanol. M. p. 177—178°C; leaflets; 60 mg.

Found: C, 66.37; H, 4.29. Calcd. for $C_{18}H_{14}O_6$: C, 66.25; H, 4.32%.

The Hydrogenation of 2′ : 7-Dimethoxy-4′ : 5′-methylenedioxyisoflavone.—When isoflavone (84 mg.) in acetic acid (20 ml.) was hydrogenated in the presence of a pre-reduced platinum catalyst (PtO_2, 20 mg.) for 26 min., it absorbed 1.1 mol. of hydrogen. The solvent was then removed under reduced pressure to yield 77 mg. of a residue, which showed hydroxyl and γ-pyranone carbonyl in its infrared spectrum and

9) Melting points are uncorrected. Ultraviolet spectra were taken in ethanol unless otherwise stated. Analyses were made by Mrs. Noriko Etoh in this laboratory and Mr. Kusuo Narita, Department of Pharmacy, Faculty of Medicine, Hokkaido University. The NMR spectrum was taken by Japan electron optics 3H 60 high resolution NMR spectrometer (60 Mc.). Tetramethylsilane was used as internal standard.

10) Measurements by Dr. Masao Maruyama of Tohoku University.

which was immediately submitted to the next reduction.

The Clemmensen Reduction of the Mixture of 7 : 2'-Dimethoxy 4' : 5'-methylenedioxyisoflavan-4-ol and 7 : 2'-Dimethoxy-4' : 5'-methylenedioxyisoflavanone.—The mixture (77 mg.) of isoflavan-4-ol and isoflavanone obtained above was dissolved in 2 ml. of toluene. To this solution was then added mercury amalgam, which had been prepared from zinc (0.79 g.), mercuric chloride (0.087 g.), concentrated hydrochloric acid (3 ml.), and water (1.5 ml.). The solution was refluxed for 14 hr. and 20 min. To the solution further amounts of hydrochloric acid (0.12 ml. × 3) were then added after 2 hr. 40 min., 6 hr. 5 min., and 9 hr. 15 min. The zinc amalgam was filtered and washed with toluene-ether. To the combined filtrate and washings, there was added a further volume of ether. The ethereal solution was washed with water, a 2 N sodium hydroxide solution (5 ml.) and twice again with water (5 ml. × 2) successively. The solution was then dried over sodium sulfate. On evaporation, the residual yellow oil crystallized. M. p. 96—107°C; 50 mg. This was recrystallized from ethanol to yield d, *l*-7: 2'-dimethoxy-4': 5'-methylenedioxyisoflavan, m. p. 111—113°C.

Found: C, 68.66; H, 5.86. Calcd. for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77%.

2-Methyl-4 : 5-methylenedioxyphenol.—A mixture of zinc dust (5 g.), 0.5 g. of mercuric chloride, 0.25 ml. of concentrated hydrochloric acid, and 7.5 ml. of water was stirred for 15 min. The aqueous solution was decanted, and the zinc amalgam was covered with 5 ml. of water and 5 ml. of concentrated hydrochloric acid. To this refluxed solution, there was then added 0.5 g. of sesamol in 2.5 ml. of concentrated hydrochloric acid and 2.5 ml. of water over the course of 1 hr. and twenty minutes. After a further 2 ml. of concentrated hydrochloric acid had been added, the solution was refluxed for 2 hr. The solution was then cooled to room temperature. The aqueous layer was separated from the zinc amalgam, and sodium chloride was added to the solution. This was extracted with ether. The ethereal solution was combined with the ethereal washings of the zinc amalgam and washed with an aqueous sodium chloride solution, decolorized with activated charcoal, and dried. After the ether had been removed, the residue (0.36 g.) was distilled under reduced pressure (2.5 mmHg) (bath temp. 132—142°C) (0.172 g.). This distillate was recrystallized from petroleum benzine. 96 mg. M. p. 58—59°C. IR: 3573 cm^{-1} (OH) (chloroform) UV λ_{max} (ε_{max}): 232 (3525) 302 (5720).

Antimicrobial Tests (Performed by Professor Yuji Sasaki and his colleagues, Laboratory of Applied Microbiology, Department of Agricultural Chemistry, Faculty of Agriculture, by courtesy of Professor Tōshi Irie).—The inhibition of the growth of bacteria, fungi or yeast was assayed according to the agar-plate method. The compounds were introduced in the form of acetone dilutions or in the form of crystals on agar. The strains of bacteria, fungi or yeasts used are described in Table I. These were incubated on the agar medium at the optimum temperature.

When the compounds were introduced in the form of crystals, no antimicrobial activity was observed in any of the specimens. However, in an acetone solution, maackiain exhibited antimicrobial action in reaction to yeast and fungi.

The author is grateful to Professors Tōshi Irie, Takeshi Matsumoto and Tadashi Masamune for their kind interest in this work, and Drs. F. E. King and J. W. W. Morgan, for providing the sample of pterocarpin. The author wishes to thank Mr. Toshiro Kio for help in experiment and Mr. Hanzo Shimokawa for the measurements of NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1535—1541 (1966)

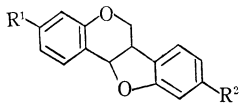
The Synthesis of *d, l*-Homopterocarpin[1]

By Hiroshi SUGINOME and Tsukasa IWADARE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 20, 1965)

The synthesis of chromanocoumaran (I) ($R^1=R^2=H$), the skeleton of pterocarpinoids, is described. This method, which follows a plausible biogenetic pathway, is then extended to the synthesis of *d, l*-homopterocarpin (I) ($R^1=R^2=OMe$). The synthesis and NMR studies allow us to assign a cis B/C ring junction to the compounds of this class.

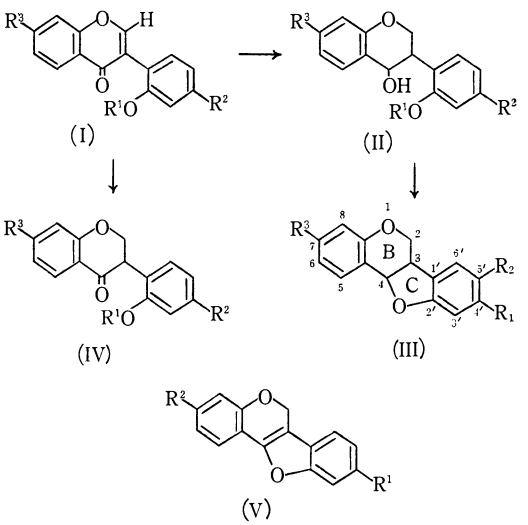


(I)

Pterocarpin and homopterocarpin were first isolated by Cazeneuve in 1874.[2] The structure of homopterocarpin was elucidated in 1940 by Späth and Schläger[3] and by Robertson et al.[4] as III ($R^1=R^3=OMe$, $R^2=H$). The structure of pterocarpin was also elucidated by Robertson et al.[4] and, more recently, by Bredenberg and Shoolery[5] spectroscopically, and also by one of the present authors synthetically,[6] as III ($R^3=OMe$, R^1, $R^2=-O-CH_2-O-$). However, the syntheses of these natural products, even their simple cores, have not been completed. This paper is an account of the syntheses of their skeleton and the racemic homopterocarpin.

In view of an apparent biogenetic link of these naturally-occurring chromanocoumarans to 2'-hydroxyisoflavonoids,[7] the synthetic sequence was chosen in order to trace a plausible biogenetic path.

In explorative studies, the skeleton III ($R^1=R^2=R^3=H$) of pterocarpin was synthesized for the first time.



(I) (II) (IV) (III) (V)

It was found that the mild acid hydrolysis of liquid 2 : 2'-bismethoxymethoxybenzoin[8] which had been purified by distillation yielded 2 : 2'-dihydroxybenzoin, together with a second product. This was identified as the corresponding benzil. It showed a doublet carbonyl absorption in its infrared spectrum (1614 cm^{-1} and 1631 cm^{-1}) and an absorption maxima at 256 mμ (ε, 14930) and 330 mμ (ε, 6300) in its ultraviolet spectrum. It was apparent that the original, protected benzoin was contaminated by the corresponding benzil, which could be isolated as crystals from liquid 2 : 2'-bismethoxymethoxybenzoin. This benzil may be produced by autooxidation during distillation, and La Forge's liquid bismethoxymethoxybenzoin could be a mixture of benzoin and the

corresponding benzil. The mixture of 2 : 2'-dihydroxybenzoin and benzil thus obtained was reduced with zinc and sodium hydroxide to yield 2 : 2'-dihydroxydesoxybenzoin (m. p. 102—103°C), together with a small amount of 2'-(*O*-hydroxyphenyl)-coumarone. This desoxybenzoin was then transformed to the corresponding 2'-hydroxyisoflavone with sodium and ethyl formate.[9] No isomeric 3-benzoylcoumarone and intermediary 2-hydroxyisoflavanone could be isolated. It has already been suggested by Whalley[10] that a 2'-methoxy subsituent is necessary to isolate an intermediary 2-hydroxyisoflavanone in the reaction of desoxybenzoin with sodium and alkyl formates, since a weak hydrogen bonding between the 2-hydroxyl group and the 2'-methoxy group will be a major contributing factor to the stability of the 2-hydroxyisoflavanone system. In the present investigation, obviously the hydrogen bond between the 2'-hydroxyl group and the carbonyl group is stronger than that between the 2' and 2-hydroxyl functions. This must be the reason for the failure to isolate an intermediate 2-hydroxyisoflavanone. The 2'-hydroxyisoflavone thus obtained was reduced to the corresponding isoflavanone in the presence of Adams' platinum catalyst. This isoflavanone was very easily converted to chromenocoumarone (V) ($R^1=R^2=H$) (m. p. 87—89°C) with 50% acetic acid, thus confirming the conversion of sophorol to anhydrosophorol.[7] The ultraviolet spectrum of chromenocumarone is shown in Fig. 1. The tetrasubstituted double bond in chromenocoumarone (V) ($R^1=R^2=H$) resists catalytic hydrogenation in the presence of the platinum catalyst. 2'-Hydroxyisoflavone was reduced to a liquid stereoisomeric mixture of 2'-hydroxyisoflavan-4-ol with either sodium borohydride[11] or lithium aluminum hydride. In the case of dehydrorotenone, reduction with lithium aluminum hydride leads to the corresponding isoflavan-4-ol, whereas reduction with sodium borohydride results in the formation of the corresponding isoflav-2-en-4-ol.[11] It is of interest to note that, in the present case, reduction with both these metal hydrides resulted in the isolation of the same product, which is probably due to the 1, 4-addition of hydride reagents to the γ-pyrone system followed by further reduction. This crude isoflavan-4-ol was successfully converted into the pterocarpin ring system. III ($R^1=R^2=R^3=H$) in a 70% yield by mild treatment with 50% acetic acid. No appreciable formation of isoflav-(3)-ene was observed.

The NMR spectrum (Fig. 2) in deuteriochloroform of the synthetic chromanocoumaran shows 8 aromatic protons as the multiplet ranging $\tau=2.34$ to $\tau=3.18$. The doublet centering at $\tau=4.47$, $J=5.7$ c. p. s. (1 proton) is assigned to a proton on position 4, which is coupled only to a proton on the position 3. The Karplus equation[12] has

been shown experimentally to apply to a wide variety of compounds.

The equation gives $\phi = 33°$ for the dihedral angle $-HC^3-C^4H-$. The model inspection obviously favored a B/C ring junction of cis for chromanocoumaran. Although the calculated angle seems to give a higher value than that to be expected from the model, the deviation is perhaps attributable to the electronegativity[13] of the substituent adjacent to the coupling protons. The two hydrogens on the position 2 which constitute the AB part of the ABX system appeared as the triplet centered at $\tau = 6.28$. A proton on the position 3 gives rise to the multiplet ranging from $\tau = 5.65$ to $\tau = 5.92$.

In view of the above described results, the same sequence of reaction was applied to the 2′: 4′: 7-trihydroxyisoflavone (I) ($R^1=H$, $R^2=R^3=OH$) series. The starting material, 2′: 4′: 7-trimethoxyisoflavone, had been synthesized by Späth and Schläger[3] by the reaction of 2-hydroxy-2′ : 4′-trimethoxydesoxybenzoin with methylformate in the presence of sodium. Although they did not isolate any intermediary 2-hydroxyisoflavanone from this reaction, one repetition of this work by using ethylformate led to the isolation of 2-hydroxy-7 : 2′ : 4′-trimethoxyisoflavanone in a 94% yield. The result is in accord with the experienced facts and the previous assumption.[10] The isoflavanone obtained above was dehydrated with acetic acid to yield 2′: 4′: 7-trimethoxyisoflavone in a 69% yield. The demethylation of 2′: 4′: 7-trimethoxyisoflavone[3,7] to 2′: 4′: 7-trihydroxyisoflavone was achieved in a 98% yield by using anhydrous aluminum chloride.[14] Since it was found that the relatively strong acidic character of the 7′-hydroxyl group prevented the use of complex metal hydride, the 7′-phenolic function of 2′: 4′: 7-trihydroxyisoflavone had to be methylated before reduction. This selective methylation of the 7′-phenolic function was accomplished in a 73% yield at 30 to 40°C using methyl iodide and potassium carbonate in acetone. The same substance was also obtained by partial methylation with diazomethane. The structure of monomethoxyisoflavone was confirmed by studying its ultraviolet spectra in neutral and alkaline solutions. Thus, as expected, the ultraviolet spectrum of 7-methoxy-2′: 4′-dihydroxyisoflavone does not reveal any appreciable bathochromic shift in an alkaline solution (Fig. 3). However, the ultraviolet spectrum of the corresponding 7-hydroxyisoflavone in an alkaline solution exhibits batho- and hypochromic shifts when compared with that in a neutral solution (Fig. 4). When the 7-methoxy-2′: 4′-dihydroxyisoflavone thus obtained was submitted to sodium borohydride reduction, it gave rise to an oily stereoisomeric mixture of 7-methoxy-2′: 4′-dihydroxyisoflavan-(4)-ols. The final step of the synthesis was accomplished as follows. The oil obtained above was refluxed with 50% acetic acid for one hour.

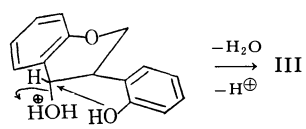
The product was then treated with methyl iodide and potassium carbonate in acetone for 3 hr. When the product was treated with aqueous ethanol, short needles of *d, l*-homopterocarpin, m. p. 123—125°C, was obtained in a rather poor yield. When compared with the natural specimen, m. p. 87—88°C, synthetic *d, l*-homopterocarpin showed NMR, infrared and ultraviolet spectra identical with those of natural homopterocarpin.

The aryl group in the carbon 3 of isoflavan-4-ol obtained from the reduction of the isoflavone with sodium borohydride should be almost entirely in an equatorial position. However, the hydroxyl group in the carbon 4 of diol II can be either in the quasi equatorial or quasi axial position,[15] because of the easy conformational inversion of intermediary isoflavanone during metal hydride reduction. That is, the isoflavan-4-ol obtained is a mixture of cis 3(eq.): 4(ax.) and trans 3(eq.): 4(eq.) with respect to 3 and 4-substituents. Although the SN2 mechanism of the ring formation can not be entirely excluded, the smooth formation of chromanocoumaran (III) ($R^1=R^2=R^3=H$) from isoflavan-4-ol (II) ($R^1=R^2=R^3=H$) in a high yield (70%) can perhaps be better explained by assuming the SNl character of the reaction in which the common carbonium ion is produced from the protonated form VI of cis and trans isomers, and by also assuming a simultaneous attack by the phenolic hydroxyl.



(VI)

From these considerations, it may be concluded that the reaction should produce a stable cis B/C ring junction and that, therefore, the B/C ring junction of natural homopterocarpin and the related compounds are cis.

The NMR spectrum of the synthetic *d, l*-homopterocarpin in deuteriochloroform showed a proton on position 4 as a doublet centered at $\tau=4.54$ ($J=6.0$ c. p. s.). The Karplus equation gives $\phi=55°$ for the dihedral angle HC^3–C^4H–. Assignment of other protons: $\tau=6.27$ and 6.30 (4′ and 7 methoxyls), the multiplet, $\tau=5.75$ to $\tau=6.54$ (two hydrogens on position 2 and one hydrogen on position 3), a doublet centered at $\tau=2.91$ ($J=8.6$) (a hydrogen on the position 6′) and the multiplet $\tau=3.32$—3.66 (protons on the positions 3′, 5′, 6′ and 8).

Experimental[16]

2 : 2′-Bismethoxymethoxybenzoin and 2 : 2′-Bismethoxymethoxybenzil.—Potassium cyanide (1 g.) and 2-methoxymethoxybenzaldehyde[8,17] (b. p. 112.5—115.5°C/5 mmHg, 6 g.) in 7.2 ml. of ethanol were refluxed on a water bath for 2 hr. The solvent was then removed under reduced pressure, and the oily residue was extracted with ether. The ethereal solution was washed with water and dried. After the ether had been removed, and the starting material (b. p. 103°C/3 mmHg) had been distilled, the viscous, reddish residue yielded 2 g. of a viscous, pale yellow oil boiling at 176—186°C/0.05 mmHg.[18] On standing, this oil partially crystallized. It was recrystallized from 80% ethanol, giving 2 : 2′-bismethoxybenzil; m. p. 107—107.5°C. IR: 1665 cm^{-1} and 1675 cm^{-1} (–CO-CO–).

Found: C, 64.79; H, 5.59. Calcd. for $C_{18}H_{18}O_6$: C, 65.4; H, 5.5%.

2 : 2′-Dihydroxybenzoin and 2 : 2′-Dihydroxybenzil.—The oily mixture of benzoin and benzil (1.7 g.) obtained above, in 50% acetic acid (12 ml.) containing 0.05 g. of sulfuric acid, was refluxed for 15 min. The solution was then cooled and poured into ice water containing 6 g. of sodium carbonate. The solid which separated was extracted with ether. The ethereal extract was washed with water and dried over sodium sulfate. After the solvent had been removed, the residual yellowish brown substance was recrystallized from benzene to yield 0.6 g. (m. p. 161—163°C) of benzoin.[19] IR: 1643 cm^{-1} (C=O) 3305 and 3507 cm^{-1} (OH). The filtrate from the isolation of benzoin was concentrated to yield crude benzil, which was then recrystallized from 80% ethanol. Yellow needles, m. p. 156—157°C.[20] IR: 1631 and 1614 cm^{-1} (COCO) 1635 cm^{-1} (–CO–CO–, chloroform) 3180 cm^{-1} broad, (OH). UV λ_{max} (ε_{max}): 256 (14930), 330 (6300); λ_{min} (ε_{min}): 292 (1850). This benzil (0.5 g.) in acetone (20 ml.) was refluxed with dimethylsulfate (0.5 g.) and sodium carbonate (1.5 g.) for 20 hr. After the solvent had been removed, the residue was extracted with ether, washed with water, 2 N sodium hydroxide, and water successively, and dried. The residue was then recrystallized from 80% ethanol to yield 2 : 2′-dimethoxybenzil. Colorless needles, m. p. 127—128°C.[21] IR: 1653 and 1673 cm^{-1} (–CO–CO–) 1663 cm^{-1} (–CO–CO–, chloroform). This benzil formed a quinoxaline derivative; m. p. 181.5—182.0°C.

2 : 2′-Dihydroxydesoxybenzoin and 2-(*O*-Hydroxyphenyl)-coumarone. — 2 : 2′-Dihydroxybenzoin (14 g.) in 50% ethanol (90 ml.) and 15% aqueous potassium hydroxide (150 ml.) were refluxed with powdered zinc (40 g.) for 8 hr. After the zinc had been removed and the solution had been neutralized with 2 N

hydrochloric acid, ethanol was evaporated under reduced pressure. The solution was extracted with ether, washed with water, and dried. The residue was then recrystallized from benzene to yield desoxybenzoin. Colorless needles; m. p. 102—103°C.[22] Yield 9.3 g. (71%). IR (KBr): 1629 cm^{-1} (–CO–CO–) 3465 cm^{-1} (OH). UV λ_{max} (ε_{max}): 327 (3060), 253 (8310); λ_{min} 293 (1360).

The filtrate was concentrated to yield crude 2-(*O*-hydroxyphenyl)-coumarone, which was then recrystallized from 80% ethanol. Feeble pink colored needles; m. p. 95—95.5°C.[23] A ferric chloride color reaction was negative. IR (KBr): 3213 cm^{-1} (broad, OH). UV λ_{max} (ε_{max}): 328 (16750), 314 (17650), 289 (12410); λ_{min} (ε_{min}): 323 (14880), 293 (10740), 249 (2320).

2' - Hydroxyisoflavone (I) ($R^1=R^2=R^3=H$).—2 : 2'-Dihydroxydesoxybenzoin (8 g.) in ethylformate (280 ml.) was added, dropwise to powdered sodium (11 g.) under ice-cooled conditions. After the solution had been set aside for three days at −5°C, the reaction mixture was slowly poured into 100 g. of ice water. The aqueous solution was neutralized with 2 N hydrochloric acid and freed from ethylformate under reduced pressure, and the solution was extracted with chloroform. The chloroform solution was washed with water and dried. After the solvent had been removed, the residue was recrystallized from methanol. Yield 6.3 g. (75.5%). Colorless plates; m. p. 153—154°C.

Found: C, 75.67; H, 4.45. Calcd. for $C_{15}H_{10}O_3$: C, 75.62; H, 4.23%. UV λ_{max} (ε_{max}): 285 (10100), 240 (24320); λ_{min} (ε_{min}): 271 (7720). IR: 1633 cm^{-1} (–CO–), 3185 cm^{-1} (OH) (broad).

2'-Hydroxyisoflavanone (IV) ($R^1=R^2=R^3=H$).—2'-Hydroxyisoflavone (2 g.) in acetic acid (110 ml.) was hydrogenated in the presence of a platinum catalyst. 220 ml. of hydrogen was thus absorbed. After the catalyst had been removed, the solvent was evaporated to dryness. The residue was thus extracted with chloroform, washed with water, and dried. After the solvent had been removed, the residue was recrystallized from 80% ethanol; m. p. 118—122°C.

Found: N, 13.27. Calcd. for $C_{21}H_{16}O_6N_4$: N, 13.33%. UV λ_{max} (ε_{max}): 318 (3400), 276 (3310), 250 (9700). IR: 1660 cm^{-1} (–CO–) 3297 cm^{-1} (broad, OH).

2, 4-Dinitrophenylhydrazone was prepared in the usual way; m. p. 223°C (decomp.); red needles.

2'-Methoxyisoflavone[24] (I) ($R^1=CH_3$, $R^2=R^3=$ OMe).—2'-Hydroxyisoflavone (0.2 g.) in a mixed solvent of ether and acetone (20.3 g.) was treated with ethereal diazomethane (from nitrosomethylurea, 1.5 g.) and then set aside for 24 hr. The solution was washed with 2 N sodium hydroxide solution, and with water, and dried. After the solvent had been removed, the residue was recrystallized from methanol; m. p. 174—178°C. Yield 0.05 g. (23.6%). IR (KBr): 1642 cm^{-1} (CO). UV λ_{max} (ε_{max}): 299 (6440), 282 (6560), 240 (18850, inflection); λ_{min} (ε_{min}): 290 (5980), 270 (5280). (Found: C, 16.53; H, 5.14%.)

Chromenocoumarone (V) ($R^1=R^2=H$).—2'-Hydroxyisoflavanone (1 g.) and sulfuric acid (0.5 g.) in 50% acetic acid (100 ml.) were refluxed for 1 hr. on a heating mantle. The solvent was then removed under reduced pressure, and the residue was extracted with ether. The ethereal solution was washed with a 2 N sodium hydroxide solution, and with water, and dried over sodium sulfate. After the solvent had been removed, the residue was recrystallized from ethanol (2 ml.). Colorless needles, m. p. 87—89°C. Yield (0.55 g.) (59.4%).

Found: C, 81.21; H, 4.73. Calcd. for $C_{15}H_{10}O_2$: C, 81.06; H, 4.54%.

2'-Hydroxyisoflavan-(4)-ol (II) ($R^1=R^2=R^3=H$).—Into 2'-hydroxyisoflavone (1 g.) in dry dioxane (100 ml.), there was stirred sodium borohydride (200 mg.) in 95% ethanol (7.5 ml.) at 60 to 65°C. The solution was kept at 60 to 65°C for 1 hr. and then it was set aside overnight. After acetone (75 ml.) had been added, the solution was stirred for 15 ml. in order to destroy any excess sodium borohydride. The precipitation yielded was removed by filtration. After the solvent had been removed, the residue was extracted with chloroform, washed with water, and dried. After the chloroform had been removed, a light brown oil (0.8 g). was obtained. This oil was used for the next step without further purification.

IR (liquid film). No carbonyl absorption; a broad band around 3327 cm^{-1} (OH). UV λ_{max} (ε_{max}): 275 (3110); λ_{min} (ε_{min}) 252 (1390).

Chromanocoumaran (III) ($R^1=R^2=R^3=H$).—2'-Hydroxyisoflavan-(4)-ol (0.2 g.) in 50% acetic acid (20 ml.) was refluxed for 1 hr. After the solvent had been removed, the residue was extracted with ether (15 ml.). The ethereal solution was then washed with water (5 ml.), and dried. After the solvent had been removed, the residue was recrystallized from ethanol. Colorless needles; m. p. 126—127°C (125 mg.).

Found: C, 79.83; H, 5.49. Calcd. for $C_{15}H_{12}O_2$: C, 80.33; H, 5.39%. UV λ_{max} (ε_{max}): 278 (3260); λ_{min} (ε_{min}): 247 (590).

2 : 4-Dihydroxy-2' : 4'-dimethoxydesoxybenzoin.[25]—This was prepared by the Hoesch reaction in the usual manner. 25 g. of 2 : 4-dimethoxyphenylacetonitrile[26] (by the procedure of Mitter and Mitra[27]) and resorcinol (35.5 g.) in the presence of zinc chloride (249 g.) in dry ether (630 ml.) yielded 25.2 g. of the desired desoxybenzoin, m. p. 152—153°C.[25]

2 - Hydroxy-2' : 4 : 4'-trimethoxydesoxybenzoin.[3]—2 : 4-Dihydroxy-2' : 4'-dimethoxydesoxybenzoin (23.8 g.) and methyliodide (7.7 ml.) in acetone (450 ml.) were refluxed for 70 min. in the presence of potassium carbonate (30 g.) After the acetone and potassium carbonate had then been removed, the residue was recrystallized from 70% ethanol to yield 12.7 g. (51%) of the desired material, m. p. 109—113°C. The residue from the filtrates yield the corresponding tetramethoxydesoxybenzoin as colorless needles, m. p. 73.5—74.0°C (0.9 g.). A ferric chloride color reaction was negative.

2-Hydroxy-7 : 2' : 4'-trimethoxyisoflavanone.—2-Hydroxy-7 : 2' : 4'-trimethoxydesoxybenzoin (6.6 g.) in 178 ml. of ethylformate was added, dropwise to

powdered sodium (6 g.), which had been cooled to −5°C, in the course of 30 min. After the reaction mixture had been set aside at 0°C for 55 hr., the deep reddish solution was poured onto ice (100 g.) and the solution was acidified with 30 ml. of 2 N hydrochloric acid. The ethyl formate layer was separated, washed with 50 ml. of water, and concentrated under reduced pressure. The crystals which separated were collected by filtration to yield 12.8 g. of nearly pure isoflavanone (m. p. 130—141°C). The concentration of the filtrate yielded a further 0.88 g. of the isoflavanone. Recrystallization from aqueous ethanol; m. p. 149—150°C.

Found: C, 65.40; H, 5.48. Calcd. for $C_{18}H_{18}O_6$: C, 65.44; H, 5.49%. IR: 1665 cm^{-1} (pyranone C=O) 3392 cm^{-1} (OH).

2′: 4′: 7-Trimethoxyisoflavone (I) (R^1=CH_3, R^2=R^3=OMe). — 2 - Hydroxy - 2′ : 4′ : 7 - trimethoxyisoflavone (11.8 g.) in acetic acid (100 ml.) was refluxed for half an hour. To the filtered solution there was then added water (170 ml.). The crystals which separated were collected by filtration; m. p. 138—142°C, 9.9 g. They were then recrystallized from 70% ethanol to yield a pure material (7.8 g.), m. p. 146—148°C.[28] IR: 1635 cm^{-1} (C=O).

2′: 4′: 7-Trihydroxyisoflavone (I) (R^1=H, R^2=R^3=OH).—2′: 4′: 7-Trimethoxyisoflavone (0.5 g.) dissolved in benzene (60 ml.) was refluxed with anhydrous aluminum chloride (5.5 g.) for two hours on a water bath. The supernatant benzene was removed by decantation and then under reduced pressure. The residual benzene-free complex was decomposed with ice-cooled water. The precipitation was collected by filtration and dissolved in methanol (40 ml.). Upon the concentration of the above solution to approximately 5 ml., 2′: 4′: 7-trihydroxyisoflavone (0.42 g.) was separated; m. p. 272°C (decomp.). IR: 1617 cm^{-1} (C=O), associated OH 3400 cm^{-1}. UV λ_{max} (ε_{max}): 248 (15600), 262 (14500), 292 (11110). UV 0.1 N sodium hydroxide solution λ_{max} (ε_{max}): 254 (27400), 325 (15390).

UV λ_{max} (ε_{max}): 260 (19800), 290 (15650).

UV 0.1 N sodium hydroxide λ_{max} (ε_{max}) solution: 250 (25400), 297 (17400).

28) Reported m. p. 148—149°C.[8]

b) To 2′ : 4′ : 7-Trihydroxyisoflavone (49 mg.) in acetone (10 ml.) there was added ethereal diazomethane (from 80 mg. of nitrosomethylurea) (15 ml.). The solution was then set aside for 24 hr. and 40 min. After the solvent and diazomethane, had been removed, the residue (46 mg.) was recrystallized from 80% ethanol (1 ml.), thus yielding 27 mg. of yellow needles, m. p. 206—207°C. This material was identical with the 7-methoxy-2′: 4′-dihydroxyisoflavone obtained by procedure a).

7-Methoxy-2′: 4′-dihydroxyisoflavan-(4)-ol, (II) (R^1=H, R^2=OH, R^3=OCH_3).—Sodium borohydride (200 mg.) in 95% alcohol (25 ml.) was added, dropwise to a solution of 7-methoxy-2′: 4′-dihydroxyisoflavone (680 mg.) in dioxane (45 ml.) at 60—65°C. The reaction mixture was kept for 1 hr. at 60—65°C and then set aside overnight at room temperature. After acetone (5 ml.) had been added to decompose the excess reducing reagent, the solvents were removed under reduced pressure, and the residue was extracted with ether (25 ml.) and water (20 ml.). The ethereal layer was washed with water and dried. After the solvent had been removed, the light-brown, oily isoflavan-4-ol (457 mg., 67%) was obtained.

UV λ_{max} (ε_{max}): 280 (5500); λ_{min} (ε_{min}): 248 (248).

IR (liquid film), no carbonyl absorption. Broad band around 3300 cm^{-1} (OH).

***d, l*-Homopterocarpin (III) (R^1=R^3=OCH_3, R^2=H).**—The oil obtained above was refluxed with 50% acetic acid (11 ml.) for one hour, and then the solvents were removed under reduced pressure. The ultraviolet spectrum (Fig. 5) of the residue (438 mg.) exhibited two maxima, at 286 mμ (ε, 6900) and at 325 mμ (ε, 3130). The latter is due to the presence of isoflav-3-ene in the product. The residue was refluxed with

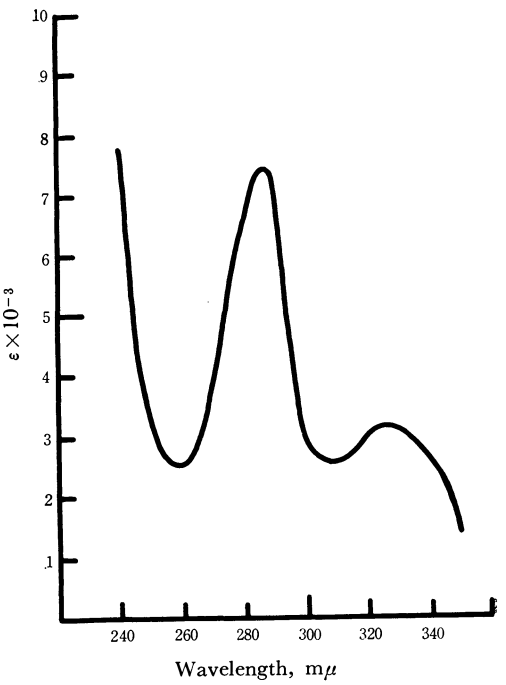

Fig. 5.

methyl iodide (4 g.) and potassium carbonate (2 g.) in acetone (20 ml.) for three hours. After the potassium carbonate and acetone had been removed, the residue was extracted with ether (25 ml.) and with water (20 ml.); after extraction with a 2 N aqueous sodium hydroxide solution (10 ml.), the dried ethereal solution yielded a light yellow oil (219 mg.). This oil in acetone (50 ml.) was refluxed with Norit (100 mg.) for 1 hr. The removal of Norit and acetone left the residue (84 mg.). This was chromatographed on Merck acid-washed alumina (5 g.). The first elution (27 mg.), with benzene (20 ml.), yielded 27 mg. of *d, l*-homopterocarpin (121—124.5°C). A further 9 mg. of the substance was obtained by the elution of Norit with acetone (30 ml.). On recrystallization from ethanol, colorless short needles of *d, l*-homopterocarpin (m. p. 123—125°C) were obtained. Its infrared spectrum in chloroform and its ultraviolet spectrum were superimposable upon those of a natural specimen. UV λ_{max} (ε_{max}): 286 (9200).

Found: C, 71.72; H, 5.59. Calcd. for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

The authors are grateful to Professors Tōshi Irie, Takeshi Matsumoto and Tadashi Masamune for their kind interest in this work, and to Drs. F. E. King and J. W. W. Morgan for providing the sample of homopterocarpin. The authors thank Mr. Hanzo Shimokawa for the measurements of NMR spectra. The work was supported in part by a Grant in Aid of Scientific Research from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1541—1543 (1966)

The Co-occurrence of Isoflavonoids at Different Oxidation Levels[1]

By Hiroshi SUGINOME and Toshiro KIO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received October 20, 1965)

Some biogenetic aspects of the co-occurrence of pseudobaptigenin, maackiain and sophorol are discussed.

In previous papers[2] the isolation from the same plant of two new oxygen heterocycles, which are designated sophorol (V) and maackiain (VI), has been described, and their structures have been elucidated.

Biogenetical interests led the author to examine the other components in this plant. Ethanol extracts contained considerable amounts of a product which was relatively insoluble to polar solvents and exhibited strong infrared absorption bands at 935 cm^{-1} and 1630 cm^{-1}, attributable to aromatic methylenedioxyl and γ-pyrone carbonyl groups respectively. The purification of this fraction afforded the colorless component, $C_{16}H_{10}O_5$.

Ultraviolet, infrared, NMR spectra and some chemical evidences proved that this compound is identical with ψ-baptigenin (III). This was confirmed by a direct comparison of it with synthetic ψ-baptigenin *O*-acetate.

Although ψ-baptigenin is known to occur at the 7-*O*-rhamnoglucoside,[3,4] pseudobaptisin, in *Baptisia tinctoria,* and as 7-*O*-3-methylbut-2-enylyl ether, Maxima substance B, in *Tephrosia maxima,*[5] the present finding is the first example of the occurrence of its aglycone in nature.

In view of the wide problem of aromatic biogenesis, the co-occurrence of ψ-baptigenin, sophorol and maackiain is of interest; it may have some implication regarding the biogenesis of this class of natural products.

It was in 1921 that Robinson first put forward his ideas on the phytosynthetic process of flavonoids[6] (the condensation of the C_6–C_3 unit with the C_6 of ring A).

The biogenesis of isoflavones has recently been investigated with the aid of ^{14}C tracer techniques, by Grisebach,[7] and it has been the subject of an

extensive review article.[8] It has been shown that ring B of formononetin in *Triforlium pratense* can be derived from phenylalanine,[8a] while ring A is derived from acetate.[9] This pathway of the formation of isoflavones seems to be generally acceptable. Although the formation of an intermediary chalcone also seems generally accepted, however, the mechanism of the formation of the isoflavones from intermediary chalcones (accompanied by aryl rearrangement) is still ambiguous.[10]

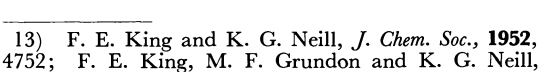
In the present investigation, the common oxygenation pattern in ring A of the three compounds involves the reductive loss of the 5-oxygen function (perhaps in an open-chain forerunner[9]).

As has previously been emphasized,[11] 2'-oxygenation in ring B of sophorol raises an interesting problem. Regarding the introduction of the 2'-oxygen function for isoflavonoids, a process involving the participation of an intermediary coumarin has been suggested by Ollis and Grisebach.[8] However, a recent investigation has shown that the ortho-hydroxylation of *trans-p*-methoxy cinnamic acid could occur; this may be generally true for the *ortho*-oxidation of cinnamic acids.[12]

Considering these speculations and experimental facts, the following tentative scheme of biogenesis to account for the co-occurrence of ψ-baptigenin, sophorol and maackiain can be drawn.

In the chart, the formation of an ether ring by an attack of the benzylic hydroxyl group on the 2' position (e. g., IV)[12a] would be improbable, because of the possibility of the easy formation of the benzylic cation.

2-Oxygenated isoflavanone and simple isoflavone may be derived from the common intermediate, either cinnamic acid (I) or chalcone (II). In this connection, it is noteworthy that in *Ferreirea spectabilis* a relationship parallel to the present example, i. e., the co-occurrence of isoflavone, biochanin-A and a 2'-oxygenated isoflavanone, ferreirin, has been reported.[13]



A possible interrelationship between 2'-oxygenated isoflavanones and coumaranochromans was originally suggested by King.[14] Although the possibility of maackiain being a forerunner of sophorol

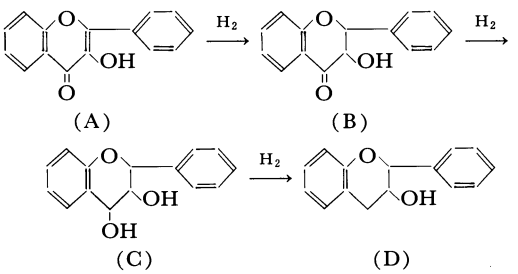
can not be entirely excluded, the co-occurrence of maackiain and sophorol can perhaps be better understood by assuming the presence of a reductive process (isoflavanone → chromanocoumaran) in nature. Furthermore, a close laboratory analogy to this process involving mild experimental procedures has recently been achieved by the authors.[15]

The corresponding reduction sequence was already noted by King[14] in the flavonol→catechin series, as is illustrated by structures A→D, beginning with flavonol and ending with catechins.



It has previously been noted[11] that sophorol has the essential core and the oxygenation pattern of rotenoids. Speculative pathways on the biogenesis of rotenoids have been proposed by Robinson,[16] by Schmid et al.,[17] and by Grisebach and Ollis.[8] The problem has also recently been reviewed.[18]

Experimental[19]

The Isolation and Purification of ϕ-Baptigenin. —A light brown solid obtained from the ethanol extracts of *Maackia amurensis Rupr. et Maxim. var. Buergeri (Maxim). C. K. Schneid* (3 kg.) was digested with boiling dilute methanol. (Methanol/water 1 : 1). An insoluble material (0.9 g.) was thus collected. Four grams of this material were dissolved in aqueous 2 N sodium hydroxide (20 ml.), and the solution was filtered from a small amount of an insoluble material. After acidification, the material was collected by filtration and then recrystallized from a large volume of ethanol, yielding crystals of ϕ-baptigenin. (M. p. 294°C (decomp.)),[20] 200 mg. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1544—1547 (1966)

The Absolute and Relative Stereochemical Correlation of Isoflavanone, Sophorol and Naturally-occurring Isoflavan Derivatives[1]

By Hiroshi SUGINOME

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 9, 1965)

By rotatory-dispersion studies, it was confirmed that sophorol, (−) maackiain, pterocarpin, equol and homopterocarpin have the same absolute configuration at position 3. The results of the O. R. D. examination of (−) halostachine and pterocarpinoids allow us to assign the 3R, 4R configuration to pterocarpin and to the related compounds.

A number of natural isoflavanones have been discovered,[2] although sophorol[2a] is the only member of the group which has been isolated in an optically active state. In recent years, the existence of various chromanocoumarans*, which are closely related biogenetically to isoflavanones, has been disclosed. It is of interest to determine the stereochemical relationship between these compounds and their absolute configurations.

At present, nine chromanocoumarans, their glycosides (I—VIII)[3] and isoflavan equol (IX) are known; they have all been isolated in an optically active form.

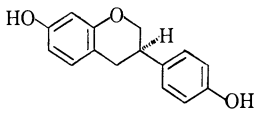
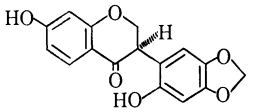
IX (−) Equol[12]



X (+) Sophorol



The absolute and relative stereochemical correlations between corresponding asymmetric centers of sophorol and those chromanocoumarans have not yet been defined, however. Therefore, the relative stereochemistry of these compounds has now been examined by rotatory-dispersion studies. The rotatory dispersion curves are recorded in Figs. 1 and 2.

Figure 1 shows the rotatory-dispersion curves of sophorol,[2a] the oxidation product of *O*-methyldihydropterocarpin obtained from pterocarpin by hydrogenolysis, followed by methylation and oxidation with potassium permanganate,[5] and *O*-dimethylsophorol.[2a] These three substances

a Dihydro-*O*-methylmaackiain-*O*-methylether
b Equol diacetate
c Homopterocarpin
d Pterocarpin
e Maackiain

exhibit virtually identical plain positive dispersion curves throughout the spectral range under examination. This result can be taken as conclusive evidence of an identical absolute configuration at C^3 in sophorol and the corresponding asymmetric center of pterocarpin and related compounds; it confirms previous assumptions.[13]

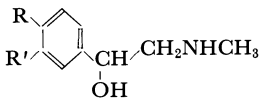
In Fig. 2 are collected the rotatory-dispersion curves of homopterocarpin, pterocarpin, maackiain, equol diacetate and dihydro-*O*-methylmaackiain-*O*-methylether. Homopterocarpin, pterocarpin and maackiain all exhibit negative Cotton-effect curves. It is apparent from the figure that in these cases C^3 asymmetric carbon in the chromanocoumaran molecule makes a very weak negative contribution,[14] as is shown in the dispersion curves of dihydro-*O*-methylmaackiain-*O*-methylether. Therefore, the relatively strong negative rotation accompanying the Cotton effects in these compounds is probably produced by the C^4 asymmetric center with an aromatic ring and an ether linkage.

12) G. F. Marrian and D. Beall, *Biochem. J.*, **29**, 1586 (1935); R. Suemitsu, M. Hiura and M. Nakajima, *J. Agr. Chem. Soc. Japan*, **29**, 591 (1955).

13) W. B. Whalley, "The Chemistry of Flavonoid Compounds," T. A. Geissman ed., Pergamon Press, London, (1962), p. 441.

14) The formation of ring compounds from open chains is accompanied by an increase in optical rotation.[16] Needless to say, no Cotton effect will be produced by C3 center after ring formation to chromanocoumaran.

Lyle reported that the compounds of the XI, XII, XIII, (−) ephedrine and (−)-ψ-ephedrine types showed negative Cotton effects of a similar



(XI) R=R′=H
(XII) R=H, R′=OH
(XIII) R=R′=OH

shape; he also identified the absolute configuration of (−) halostachine (XI) as R on the basis of an unequivocal chemical correlation.[15]

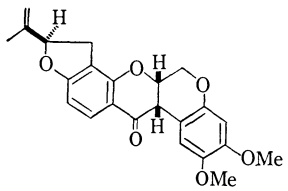
Attention must be paid to the structural similarity between the asymmetric center of halostachine (XI) and the environment of the corresponding asymmetric center of pterocarpin.

Although in the present series of compounds, the aromatic ring is not free to rotate, and the enhancement of optical activity can be observed,[16] the negative Cotton effects of the asymmetric center of the R configuration in halostachine (XI) and the C^4 environment of pterocarpin are strong evidence for assuming that the asymmetric centers of these compounds have the same absolute configuration R.

Since the B/C ring junction in pterocarpin is cis,[17] pterocarpin is represented as having the C^4R, C^3R, configuration IIA. Consequently, all the other chromanocoumarans which have been reported to exhibit a negative rotation can be identified as having the C^4R, C^3R configuration, IA, IIA, IVA, VIA, VIIA. Since it is apparent from Fig. 2 that C^3 in equol and the corresponding asymmetric center of dihydro-*O*-methylmaackiain-*O*-methylether have the same absolute configuration, the R configuration is assigned to be the C^3 center of equol. Then sophojaponicin[8] must have the C^4S, C^3S configuration (VB). Pisatin is of particular interest in that there is an extra hydroxyl function in the angular position.

This situation leads to two benzyl alcoholic functions in a molecule which would cause a stronger rotation than in pterocarpin. The reported $[\alpha]_D$ of pisatin is +280° (pterocarpin, −230°). It is considered that an asymmetric center with an angular hydroxyl group is much less effective in causing a negative rotation because of the free rotation of the hydroxyl group. Since C^3 hydroxyl and C^4 hydrogen have cis interrelationship,[17a] the C^4S, C^3S configuration (VIII) is also assigned to pisatin.

Furthermore, it follows that the absolute configuration of C^3 of sophorol is (R) (X). It is perhaps surprising that sophorol has an opposite absolute configuration in the corresponding asymmetric center of rotenone and the rotenoids, which was assigned the 4b(s) 9b(s) configuration (XIV).[18]



(XIV)

Although no isoflavanone of the s-configuration has yet been found in nature, apparently two enzymatic reactions which lead to a pair of enantiomers of the isoflavanone, as shown by the coexistence of *d*-maackiain and *l*-maackiain,[6] operate in plants.

The present assignment of the absolute configuration should be examined further by unequivocal chemical correlation.*

Experimental

All measurements of rotation were made on a Rudolph Model 200S, 80, photoelectricspectropolarimeter with an oscillating polarizer prism, using zirconium arc.

Plastic Scintillators. II. The Synthesis of Some Distyrylbenzene Derivatives as Wavelength Shifters in Plastic Scintillators

By Tadao NAKAYA and Minoru IMOTO

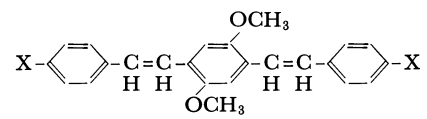
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received October 25, 1965)

The synthesis and the absorption and fluorescence spectra of 2, 5-dimethoxy-1, 4-distyrylbenzene derivatives and the related compounds are reported on. Their absorption and their fluorescence spectra, are then discussed. According to the spectra, some of the compounds synthesized here are better wavelength shifters in plastic scintillators that the compounds described in the literature.

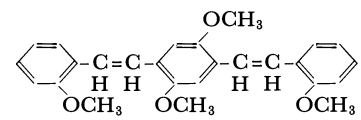
The use of some anthracene derivatives as efficient wavelength shifters in plastic scintillators were described in our previous paper.[1] In 1954, Pichat and Pesteil[2] showed that distyrylbenzene acts as a scintillation solute in plastic scintillators. Recently, Heller[3] suggested that substituted distyrylbenzenes would be highly efficient wavelength shifters in organic liquid scintillators. In the present paper, in order to increase the fluorescent intensity, the solubility in alkylbenzene solution, and the separation of the nearest maxima of the absorption and fluorescence spectra, two methoxy groups were introduced into the central benzene nucleus of the substituted distrylbenzenes. Ten derivatives of 2, 5-dimethoxy-1, 4-distyrylbenzene were synthesized by Wittig reaction.[4]

In order to ascertain the effect of substituents in the *meta* position on the absorption and fluorescence spectra, we also prepared some derivatives of *meta*-distyrylbenzene. The compounds synthesized here may be summarized as follows:



(I)

X=H(1), CH_3(2), OCH_3(3), NO_2(4), $N(CH_3)_2$(5), Cl(6), $CH(CH_3)_2$(7)



(II)

(VII)

These compounds all have *trans*-forms with the exception of 1, 4-bis(*p*-dimethylaminostyryl)-2, 5-dimethoxybenzene; they have been little described in the literature, as far as we have been able to determine. Some of the compounds synthesized here have been proved by Osio and his co-workers[5] to be equal to the wavelength shifters reported in the literature.[6-7]

Experimental

1, 4-Dichloromethyl - 2, 5 - dimethoxybenzene. — Thirty-five grams of *p*-dimethoxybenzene was added at 0°C to a mixture of 230 ml. of a 37% formaldehyde solution and 600 ml. of concentrated hydrochloric acid. The temperature was kept below 35°C while the mixture was stirred for 4 hr. The solid was then collected, washed twice with water, and dried in vacuo. It was recrystallized from carbon tetrachloride to give 23 g. of 1, 4 - dichloromethyl - 2, 5 - dimethoxybenzene (43% yield), melting at 164—165°C.[8]

Found: C, 51.20; H, 5.36; Cl, 30.0. Calcd. for $C_8H_{10}Cl_2O_2$: C, 51.06; H, 5.11; Cl, 30.2%.

2, 5 - Dimethoxy - *p* - xylylene-bis(triphenylphosphonium chloride).—A solution of 2.3 g. of 1, 4-dichloromethyl-2, 5-dimethoxybenzene and 7.4 g. of triphenylphosphine in 350 ml. of dry xylene was refluxed at the boiling point of the solvent while being stirred for 11 hr. A crystalline solid began to separate after 10 min. The reaction products were collected, washed with dry xylene, and then dried in a vacuum desiccator at 10—20 mmHg and 60—70°C. Yield, 6.5 g. (85%); m. p. 271—275°C.

Found: Cl, 9.1. Calcd. for $C_{46}H_{42}O_2Cl_2P_2$: Cl, 9.4%.

The Derivatives of 2, 5-Dimethoxy-1, 4-distyrylbenzene (I_1—I_7).—To a solution of 0.01 mol. of the 2, 5 - dimethoxy - *p* - xylylene-bis(triphenylphosphonium chloride) and 0.028 mol. of the corresponding *p*-substituted benzaldehyde in 100 ml. of absolute ethanol, 150 ml. of a 0.3 M lithium ethoxide solution was added. After 10 hr., the excess ethanol was removed by distillation under reduced pressure. The crystalline solid which separated was collected and dried in vacuo. The solid was crystallized from cyclohexane. The *cis-trans*-mixture was changed to a *trans*-compound by refluxing it in cyclohexane which contained a trace of iodine. However, 1, 4-bis(*p*-dimethylaminostyryl)-2, 5-dimethoxybenzene (I_3) could not be isomerized, because of the formation of a complex between the compound and iodine in cyclohexane or benzene. The melting points, yields, and analysis of the compounds are shown in Table I.

1, 4 - Bis(*o* - methoxystyryl) - 2, 5 - dimethoxybenzene (II). — To a solution of 3.2 g. of 2, 5-dimethoxy-*p*-xylylene-bis(triphenylphosphonium chloride) and 2.0 g. of *o*-methoxybenzaldehyde in 100 ml. of absolute ethanol, 100 ml. of a 0.3 M lithium ethoxide solution was added. After a while, yellow crystals began to separate from the solution. After 15 hr., the yellow crystalline solid was collected and dried in vacuo. Recrystallization from cyclohexane containing a trace of iodine gave II with a m. p. of 178—179°C in a yield of 80%.

Found: C, 77.72; H, 6.82. Calcd. for $C_{26}H_{26}O_2$: C, 77.49; H, 6.44%.

1, 4 - Bis(4-phenylbutadienyl)-2, 5- dimethoxybenzene (III).—250 ml. of a 0.25 M lithium ethoxide solution was added to a solution of 5.5 g. of 2, 5-dimethoxy-*p*-xylylene-bis(triphenylphosphonium chloride) and 5 g. of cinnamaldehyde in 150 ml. of absolute ethanol. After a while, deep yellow crystals began to separate from the solution. The crystals were collected, washed with ethanol, and dried in vacuo. Recrystallization from benzene containing a trace of iodine gave III as a deep yellow powder with a m. p. of 229—231°C in a yield of 75%.

Found: C, 85.14; H, 6.68. Calcd. for $C_{28}H_{26}O_2$: C, 85.28; H, 6.60%.

1, 4-Bis (9-anthrylvinyl) - 2, 4 - dimethoxybenzene (IV).—To a solution of 6 g. of 2, 5-dimethoxy-*p*-xylylene-bis(triphenylphosphonium chloride) and 5.5 g. of 9-anthraldehyde in 380 ml. of absolute ethanol, 200 ml. of a 0.25 M lithium ethoxide solution was added. After a while, a deep yellow crystalline solid began to separate from the solution. After 10 hr., the mixture

was filtered, washed with ethanol, and dried in vacuo. The solid product was recrystallized several times from benzene in the presence of a trace of iodine to give IV as deep yellow prisms with a m. p. of 298—299°C in a yield of 78%.

Found: C, 88.11; H, 5.76. Calcd. for $C_{40}H_{30}O_2$: C, 88.56; H, 5.53%.

***m*-Xylylene-bis(triphenylphosphonium bromide).**—A solution of 25 g. of *m*-xylylene dibromide and 58 g. of triphenylphosphine in dry xylene was heated under reflux for 10 hr. After a while, white crystals began to separate from the solution. The solid product was collected, washed with dry xylene, and dried in a vacuum desiccator at 10 mmHg and 60°C for 15 hr. The white crystals, melting at 275—278°C were obtained The white crystals, melting at 275—278°C, were obtained in a yield of 83%.

Found: Br, 6.3. Calcd. for $C_{42}H_{34}Br_2P_2$: Br, 6.6%.

1, 3-Distyrylbenzene (V).—To a solution of 2.1 g. of *m*-xylylene-bis(triphenylphosphonium bromide) and 2.9 g. of benzaldehyde in 50 ml. of absolute ethanol, 50 ml. of a 0.2 M lithium ethoxide solution was added. After 15 hr., 110 ml. of water was added to the reaction mixture. The crystals then began to separate from the solution. The separated crystals were dried in vacuo and recrystallized from *n*-hexane in the presence of a trace of iodine to give V as white prisms, with a m. p. of 167—168°C and in a yield of 55%.

Found: C, 93.81; H, 6.18. Calcd. for $C_{22}H_{18}$: C, 93.62; H, 6.38%.

1, 3-Bis(4-phenylbutadienyl)benzene (VI).—To a solution of 2.0 g. of *m*-xylylene-bis(triphenylphosphonium bromide) and 2.9 g. of cinnamaldehyde in 50 ml. of absolute ethanol, 50 ml. of a 0.2 M lithium ethoxide solution was added. After 10 hr., a solid product was collected and recrystallized from benzene in the presence of a trace of iodine to give VI as white prisms, with a m. p. of 189—190°C and in a yield of 60%.

Found: C, 92.86; H, 6.73. Calcd. for $C_{26}H_{22}$: C, 93.41; H, 6.51%.

1, 3-Bis(9-anthrylvinyl)benzene (VII).—To a solution of 2.4 g. of *m*-xylylene-bis(triphenylphosphonium bromide) and 2.8 g. of anthraldehyde in 150 ml. of absolute ethanol, 100 ml. of a 0.2 M lithium ethoxide solution was added. After 8 hr., the yellow crystals were collected and recrystallized from benzene containing a trace of iodine to give VII, melting at 229—231°C, in a yield of 40%.

Found: C, 94.17; H, 5.59. Calcd. for $C_{38}H_{26}$: C, 94.60; H, 5.40%.

Spectra and Discussion

Absorption Spectra.—The absorption spectrum of 2, 5-dimethoxy-1, 4-distyrylbenzene (I_1) is given in Fig. 1. This compound exhibits, in the ultraviolet and visible region, three absorption maxima, at 233 mμ ($\varepsilon=27900$), 324 mμ ($\varepsilon=33100$) and 390 mμ ($\varepsilon=48600$).

The absorption spectra of the derivatives of 2, 5-dimethoxy-1, 4-distyrylbenzene (I_2—I_7), are similar in shape to that of I_1.

The wavelengths and molar extinction coefficients of the longest-wavelength absorption maxima of compounds I_1—IV and 1, 4-distyrylbenzene are summarized in Table II.

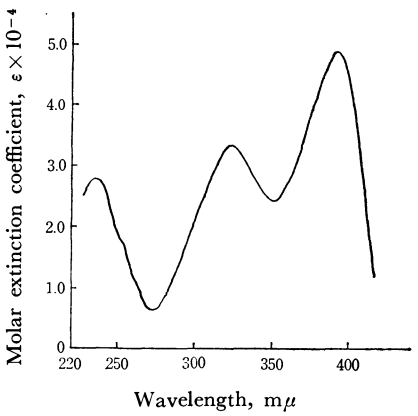

Fig. 1. The absorption spectrum of 2, 5-dimethoxy-1, 4-distyrylbenzene (I_1). (in dioxane)

Table II. The wavelengths and molar extinction coefficients of the longest-wavelength absorption maxima of 2, 5-dimethoxy-1, 4-distyrylbenzene and the related compounds (I_1—IV) (in dioxane)

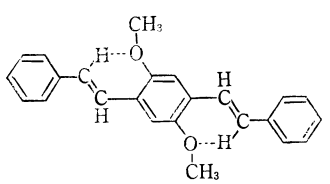
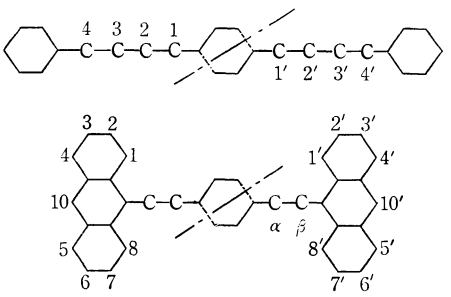
IV	deep yellow	413	4.36
1, 4-Distyryl-benzene[3]	colorless	357	5.70

The absorption maximum of 2, 5-dimethoxy-1, 4-distyrylbenzene shifts toward a longer wavelength than that of 1, 4-distyrylbenzene, as is shown in Table II. As the cause of this red shift, the full participation of lone pair electrons on the oxygen atoms of the methoxy groups in the π electron system of the benzene rings may be considered. Furthermore, this red shift may be due to the effect of hydrogen bonds between the oxygen atoms of the methoxy groups and the hydrogen atoms on the near β-carbon atoms:



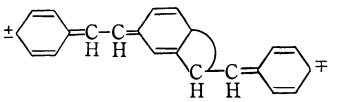
The maximum wavelength of compound III shifted to a wavelength longer than that of compound IV. The longest-wavelength bands of III and IV may be both associated with the *p*-band.

According to a method developed by Dewar,[9] if the methoxy groups are disregarded, the π electron systems of III and IV can be considered to be formed by joining up two odd-AH radicals as follows:



The magnitude of the splitting of the NBMO's of the two odd-AH radicals corresponds to the energy of the *p*-band. The splitting values for III and IV were 16/19 and 16/22, in units of β-(resonance integral), respectively. From the results of the calculation, the longest-wavelength band of III is expected to be at a shorter wavelength than that of IV.

However, the calculated values seem to be inconsistent with the experimental finding that the longest-wavelength band of III is observed in a longer-wavelength region than that of IV. Regarding the cause of this phenomenon, it may be considered that IV has a less planar structure than III, because of the repulsive forces of steric hindrance between the hydrogen atoms on the β-carbon atoms and the hydrogen atoms at the 1, 1′, 8 and 8′ positions of the terminal anthracene rings. The longest-wavelength absorption maxima and the molar extinction coefficients of compounds V—VII and *trans*- and *cis*-stilbene are shown in Table III. In the case of *meta*-substituted compounds, the conjugation between two terminal substituents is unimportant because it involves a structure with long, or ineffective, bonds, as in the following figure:



For example, 1, 3-distyrylbenzene and *trans*-stilbene absorbed at nearly the same wavelength, as is shown in Table III.

Fluorescence Spectra. — The fluorescence spectra of compounds I_1 and I_7 are shown in Figs. 2 and 3. The fluorescence spectra of the other compounds of the I series are similar in shape to those of I_1 and I_7. The shortest-wavelength fluorescence maxima and the difference in wavelength between the nearest maxima of fluorescence

and the absorption of the compounds synthesized here are tabulated in Table IV.

The separation of the maxima of absorption and fluorescence spectra for I_1 is larger than that of 1, 4-distyrylbenzene. Since it is desirable that there be little probability of the reabsorption of the photons emitted, the separation of the maxima of absorption and fluorescence is required. This requirement is fully satisfied in I_1 and in the other compounds synthesized here, as is seen in Table IV. The compounds are of practical use because of their high solubilities. Furthermore, the derivatives of 2, 5-dimethoxy-*p*-distyrylbenzene are better wavelength shifters in plastic scintillators, because the strongest-fluorescence maxima of these compounds match the most sensitive region of a phototube. Except for VII, the difference in wavelength between the nearest maxima of fluorescence and the absorption of the derivatives of *meta*-distyrylbenzene is nearly equal to those in *para*-distyrylbenzene derivatives.[3)]

The authors wish to express their hearty thanks to Professor Takahumi Osio and his co-workers for their helpful advice.

Plastic Scintillators. III. The Synthesis of Some Anthracene Derivatives as Wavelength Shifters in Plastic Scintillators

By Tadao NAKAYA, Takanori TOMOMOTO and Minoru IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received October 25, 1965)

Fifteen anthracene derivatives have been synthesized, and their absorption and fluorescence spectra have been measured. The spectra will be discussed in this paper. According to the spectra, some of anthracene derivatives synthesized here are better wavelength shifters than the compounds previously described in the literature.

In the first paper of this series,[1] we described the synthesis of some anthracene derivatives and their absorption and fluorescence spectra.

We have now synthesized fifteen more derivatives of anthracene; they are listed below.

9, 10-Bis(4-methoxybenzyl)anthracene (I) was obtained by the reaction of anthracene with 4-methoxybenzylalcohol. 9, 10-Bis(α-bromobenzyl)-anthracene (II_1), 9, 10-bis(α-*o*-toluidinobenzyl)-anthracene (II_2) and 9, 10-bis(α-acetoxybenzyl)-anthracene (II_3) were, respectively, obtained with the successive bromination, amination and acetoxylation of 9, 10-dibenzylanthracene. The derivatives of 9, 10-*trans*, *trans*-distyrylanthracene (III_1—III_2) were synthesized by the Wittig reaction of 9, 10-anthracenedimethyl-bis(triphenylphosphonium chloride) with the corresponding aldehydes. 9, 10-Anthracene-dimethanol diacetate (IV_1) and 9, 10-anthracene-dimethanol (IV_2) were prepared by the procedure described by Miller and his co-workers.[2]

9-Anthraldehyde tosylhydrazone (V) was synthesized by the reaction of 9-anthraldehyde with tosylhydrazine. The derivatives of 9, 10-dihydro-9, 10-*cis*-di(phenylcarbamoyl)anthracene (VI_1—VI_7) were obtained by the treatment of

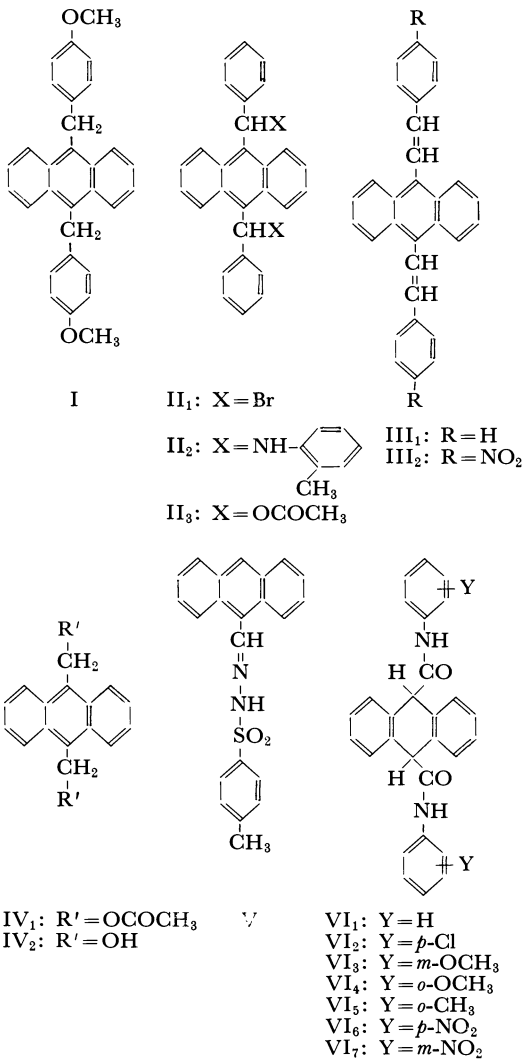
2) M. W. Miller, R. W. Amison and P. O. Tawney, *J. Am. Chem. Soc.*, **77**, 2845 (1955).



9, 10-dihydro-9, 10-*cis*-dicaroxylic chloride with substituted anilines.

This paper is concerned also with the absorption and fluorescence spectra of the compounds synthesized here. Some of them have been proved by Osio and his co-workers[3] to be superior to the wavelength shifters described in the literature.[4-6]

Experimental

9, 10-Bis(4-methoxybenzyl)anthracene (I).—1.7 g. of anthracene and 2.5 g. of 4-methoxybenzylalcohol were added to 50 ml. of acetic acid, and then the mixture was heated under reflux with a current of nitrogen gas for 4.5 hr. After the reaction mixture had been concentrated to removed the excess acetic acid, pale yellow crystals began to separate from the solution. The crystals were recrystallized several times from benzene to give I, with a m. p. of 223—224.5°C, in a 65% yield.

Found: C, 86.28; H, 6.33. Calcd. for $C_{30}H_{26}O_2$: C, 86.12; H, 6.22%.

9, 10-Bis(α-bromobenzyl)anthracene (II_1).—9, 10-Dibenzylanthracene was obtained by a method similar to that described in the previous paper.[1] A mixture of 9, 10-dibenzylanthracene (3.8 g.) and *N*-bromosuccinimide (4.0 g.) was heated in 250 ml. of oxygen-free carbon tetrachloride. To take off the *N*-bromosuccinimide, the mixture was filtered. The mixture was then concentrated by distillation under reduced pressure to give yellow crystals. The separated crystals were washed twice with diethylether, dried in vacuo, and crystallized from carbon tetrachloride to give II_1, melting at 193—195°C, in a 60% yield.

Found: Br, 30.8. Calcd. for $C_{28}H_{20}Br_2$: Br, 31.0%.

9, 10-Bis(α-*o*-toluidinobenzyl)anthracene (II_2).—Three grams of 9, 10-bis(bromobenzyl)anthracene and 3 g. of *o*-toluidine were added to 80 ml. of benzene, and then the mixture was heated for 9 hr. at the boiling point of the solvent. The reaction mixture was then chilled. The crystals which separated were collected and washed with cold benzene. The pale yellow crystalline solid was recrystallized from benzene to give II_2, with a m. p. of 261—262°C, in a 39% yield.

Found: C, 89.08; H, 6.01; N, 4.91. Calcd. for $C_{42}H_{36}N_2$: C, 88.93; H, 6.34; N, 4.93%.

9, 10-Bis(α-acetoxybenzyl)anthracene (II_3).—Two grams of 9, 10-bis(bromobenzyl)anthracene and 1.5 g. of silver acetate were added to 30 ml. of benzene, and then the mixture was heated under reflux for 1.5 hr. The reaction mixture was filtered at about 50°C. The mother liquor was concentrated to separate white crystals. The separated crystals were recrystallized several times from benzene to give II_3, with a m. p. of 227—229°C, a 52% yield. This compound showed the infrared absorption of the carbonyl group at 1735 cm^{-1}.

Found: C, 80.74; H, 5.94. Calcd. for $C_{32}H_{26}O_4$: C, 81.01; H, 5.48%.

9, 10-Anthracenedimethyl-bis(triphenylphosphonium chloride).—A solution of 2.7 g. of 9, 10-dichloromethylanthracene and 7.0 g. of triphenylphosphine in 350 ml. of dry xylene was heated at the boiling point of the solvent with stirring for 9 hr. The yellow crystals began to separate after 15 min. The mixture was then cooled to room temperature. The crystals were filtered, washed several times with excess dry xylene, and then dried in a vacuum desiccator at 10 mmHg and 60°C. The solid product, melting at 298—300°C, was obtained in a yield of 85%.

Found: Cl, 9.1. Calcd. for $C_{52}H_{42}Cl_2P_2$: Cl, 8.9%.

9, 10-*trans*, *trans*-Distyrylanthracene (III_1).—To a solution of 2.0 g. of 9, 10-anthracenedimethyl-bis(triphenylphosphonium chloride) and 0.8 g. of benzaldehyde in 30 ml. of absolute ethanol, 70 ml. of a 0.2 M lithium ethoxide solution was added. A yellow crystalline solid began to separate from the solution after 7 hr. After the solution had stood for 15 hr., the solid was collected on a filter glass and dried in vacuo. The

solid product was crystallized from benzene. The solid, which was a mixture of cis and trans isomers, was recrystallized several times from boiling benzene containing a trace of iodine to give III_1 as yellow crystals, m. p.>310°C in a 24% yield.

Found: C, 93.19; H, 6.81. Calcd. for $C_{30}H_{22}$: C, 92.79; H, 7.21%.

9, 10-*trans*, *trans* - Bis(*p*-nitrostyryl)anthracene (III_2).—To a solution of 4.4 g. of 9, 10-anthracenedimethyl-bis(triphenylphosphonium chloride) and 2.0 g. of 4-nitrobenzaldehyde in 80 ml. of absolute ethanol, 110 ml. of a 0.2 M lithium ethoxide solution was added. A yellow red crystalline solid began to separate from the solution after a while. After the solution had stood for 10 hr, the solid was collected on a filter glass and dried in vacuo. The solid was then treated as above. The solid product was recrystallized several times from benzene in the presence of a trace of iodine to give III_2 as yellow red crystals, with a m. p. of >320°C, in a 28% yield.

Found: N, 5.90. Calcd. for $C_{30}H_{20}N_2O_4$: N, 5.93%.

9, 10-Anthracene-dimethanol Diacetate (IV_1).—This compound was prepared by the procedure reported by Miller and his co-workers.[2] A solution of 20 g. of 9, 10-dichloromethylanthracene and 25 g. of anhydrous sodium acetate in 400 ml. of glacial acetic acid was heated at reflux for 5 hr. The mixture was then allowed to cool to room temperature; yellow crystals were filtered out and dried in vacuo. The solid product was recrystallized from benzene to give IV_1 as yellow needles, melting at 220—222°C, in a 70% yield.

Found: C, 74.75; H, 6.07. Calcd. for $C_{20}H_{18}O_4$: C, 74.31; H, 5.66%.

9, 10-Anthracene-dimethanol (IV_2).—This compound was also prepared by the procedure reported by Miller and his co-workers.[2] To 4.9 g. of IV_1 in 400 ml. of methanol, 15 g. of 85% potassium hydroxide was added. After the mixture had been stirred under reflux for 2 hr., it was poured into 500 ml. of cold water. The solid products were collected, dried in vacuo, and recrystallized from benzene to give IV_2 as yellow prisms, melting at 280—282°C, in a 75% yield.

Found: C, 80.23; H, 6.10. Calcd. for $C_{16}H_{14}O_2$: C, 80.07; H, 5.88%.

9-Anthraldehyde Tosylhydrazone (V).—Anthraldehyde (2 g.) was added to a solution of 2g. of *p*-toluenesulfonylhydrazine in ethanol by an adaptation of the method described by Depuy and Froemsdolf.[7] The reaction mixture was kept at 70—80°C for 3 hr. and then chilled to room temperature. The solid product was collected and crystallized from ethanol. Recrystallization from ethanol gave V as yellowish prisms, melting at 183—184°C, in a 75% yield.

Found: C, 70.59; H, 5.13; N, 7.55. Calcd. for $C_{22}H_{18}N_2O_2S$: C, 70.67; H, 4.81; N, 7.49%.

9, 10-Dihydroanthracene-9, 10-*cis*-dicarboxylic Chloride.[8]—Two grams of 9, 10-dihydroanthracene-9, 10-*cis*-dicarboxylic acid[9] in thionyl chloride was heated under a nitrogen atmosphere for 2 hr. The reaction mixture was concentrated to remove the thionyl chloride. The yellow crystals, with a melting point of 169—170°C, were obtained in a 80% yield.

Found: Cl, 23.2. Calcd. for $C_{16}H_{10}O_2Cl_2$: Cl, 22.9%.

Derivatives of 9, 10-Dihydro-9, 10-*cis*-di(phenylcarbamoyl)anthracene (VI_1—VI_7).—To a solution of 0.01 mol. (3.1 g.) of the dicarboxylic chloride in benzene was 0.05 mol. of the corresponding substituted aniline at room temperature. An immediate precipitate formed. The mixture was then stirred at room temperature. The crystalline solid was collected, washed with benzene and water, and dried in vacuo. The solid was recrystallized from ethanol. The melting points and analysis of the compounds VI_1—VI_7 are tabulated in Table I. The yields of the compounds were quantitative.

Spectra and Discussion

Absorption Spectra.—The absorption spectrum of compound I closely resembles that of 9, 10-dibenzylanthracene, as is shown in Fig. 1. The shapes of the absorption spectra of II_1, II_2 and II_3, in which the hydrogen atoms of the methylene

groups of 9, 10-dibenzylanthracene are replaced by bromine, *o*-toluidino and acetoxy groups respectively, are also similar to that of 9, 10-dibenzylanthracene. The wavelengths and molar extinction coefficients of the longest-wavelength absorption maxima of II_1, II_2 and II_3 are shown in Table II. The spectra of III_1 and III_2 indicate some resemblance to that of the parent anthracene, except for the considerable red shift, although the molar extinction coefficients could not be determined because of the low solubilities in organic solvents. The spectra of IV_1 and IV_2 are very similar to that of 9, 10-dimethylanthracene.[10] The wavelengths and molar extinction coefficients of the longest-wavelength absorption maxima of IV_1 and IV_2 are shown in Table II. When the longest-wavelength absorption maximum of II_3 are compared with those of II_1, II_2 and 9, 10-dibenzylanthracene, it is obvious that the introduction of acetoxy groups shifts the absorption band toward a shorter wavelength. As the reason for this blue shift, two interpretations are possible. One is that the acetoxy groups withdraw the π electron in the anthracene ring, since we would expect that the introduction of an electron-attracting group such as an acetoxy group increases the energy difference between the highest occupied and lowest vacant orbitals of the molecule; the other is the deformation of conjugation by the steric hindrance between the acetoxy groups and the hydrogen atoms at the 1, 4, 5 and 8 positions of the anthracene nucleus. Probably, both the effects play important roles. The spectrum of V is given in Fig. 2. The spectra of VI_2 and VI_5 are shown in Fig. 3. The wavelengths and molar extinction coefficients of the longest-wavelength absorption maxima of compounds V—VI_7 are tabulated in Table III.

that the methoxy or methyl groups increase the intensities of those compounds, because the methoxy or methyl groups exert electron-donating and conjugative effects on the anthracene nucleus.

Fluorescence Spectra. — The fluorescence spectrum of I are shown in Fig. 4. The shortest-wavelength fluorescence maxima and the difference in wavelength between the nearest maxima of the absorption and the fluorescence are given in Table IV.

The differences are 8—12 mμ, as is shown in Table IV. This may be ascribed to the fact that the conjugation of the molecules occurs more easily in the excited state than in the ground state, because the molecules are somewhat less strained in the excited state.

The fluorescence intensity of II_1 was very weak. This may be due to the effect of the heavy atoms of bromine in the molecule.[11] The fluorescence intensity of II_2 was also weak, as the substituents of the bulky *o*-toluidino groups prevent the conjugation between anthracene and benzene rings. The intensity of the fluorescence spectrum of II_3 was strong, because the acetoxy groups in the molecule should increase the intensity of the fluorescence in spite of the introduction of the bulky acetoxy groups.

The fluorescence intensities of III_1, III_2 and VI_1—VI_7 were also too weak to be observed.

The fluorescence spectrum of IV_2 is given in Fig. 5. The fluorescence spectrum of IV_1 closely resembles that of IV_2. The strongest fluorescence maximum of I is near the maximum sensitivity region of the widely-used photoelectron amplifier. In addition, the separation of the nearest maxima of the spectra of absorption and of fluorescence is sufficient. Therefore, there is a small probability of the reabsorption of photons, and a good scintillation property is predicted for it. This compound attains practical importance because of its high solubility in an alkylbenzene solution.

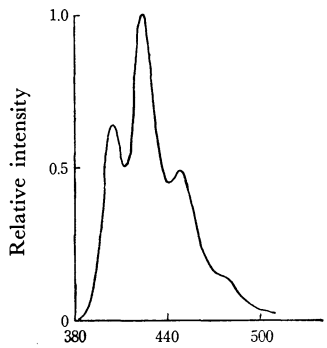

Fig. 5. Fluorescence spectrum of 9,10-anthracenedimethanol (IV_2). (2.3×10^{-5} mol./l. in dioxane)

The scintillation properties of II_3, IV_1 and IV_2 are also good in undergoing conformational changes in the excited states and in high solubilities in an alkylbenzene solution. In the case of V, the broad peak of fluorescence covers the maximum

11) J. Ferguson, *J. Mol. Spectroscopy*, **3**, 177 (1959).

sensitivity region of the phototube. The compound shows a greenish fluorescence in the crystals. Furthermore, it has a very good solubility in an alkylbenzene solution.

The authors are indebted to Professor Takahumi Osio and his coworkers for measuring the absorption and fluorescence spectra and the helpful discussion.

The Synthesis of Bicyclic Lactam Ether

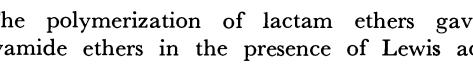
By Naoya OGATA* and Shyunroku TOHOYAMA

Basic Research Laboratories, Toyo Rayon Co. Ltd. Tebiro, Kamakura

(Received October 28, 1965)

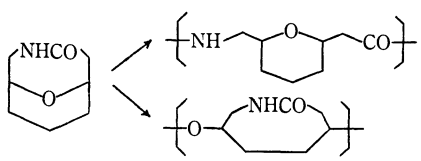
The bicyclic lactam ether, 3-aza-10-oxabicyclic[4.3.1]decane-4-one has been attempted to synthesize by the Beckmann rearrangement of the oxime of 9-oxabicyclo[3.3.1]nonane-3-one; this rearrangement caused polymerization through the cleavage of the ether group in acidic media. Therefore, it may be presumed that the cationic polymerization of lactam ethers in the presence of Lewis acid proceeds through the opening of the ether linkage.

The polymerization of lactam ethers gave[1] polyamide ethers in the presence of Lewis acid catalysts at relatively low temperatures. It was assumed that the polymerization proceeds through the coordination of Lewis acid to the ether group, followed by the cleavage at the ether group, since lactams do not polymerize under the same reaction conditions. However, lactam ethers give the same kind of polyamide ethers by means of the cleavage of either ether or amide linkages, and the reaction scheme is not clear.



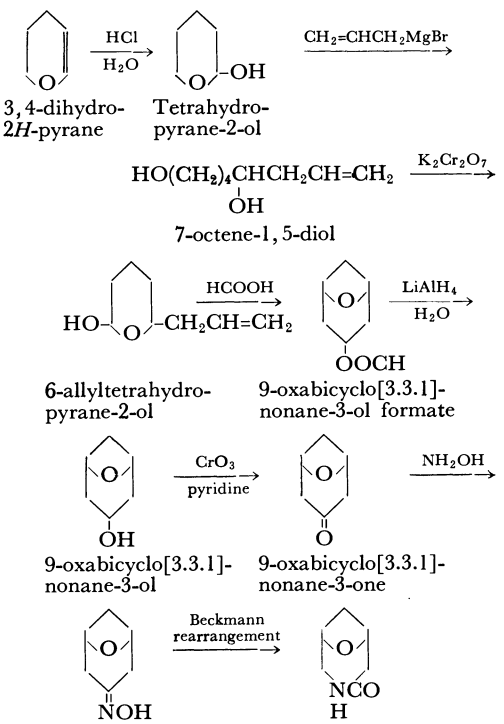
The ring-opening polymerization of the following bicyclic lactam ether gives different kinds of polymers according to whether the ring-cleavage occurs at the amide or ether linkages: hence, the structural analysis of the resultant polymer should show where the ring-opening occurs.

Therefore, the synthesis of 3-aza-10-oxabicyclo-[4.3.1]decane-4-one has been attempted for the first time.



Experimental

The synthetic route of 3-aza-10-oxabicyclo[4. 3. 1]-decane-4-one is shown as follows:



Tetrahydropyrane-2-ol.—A solution of 94 g. of purified dihydropyrane in 400 ml. of 0.2 N hydrochloric acid was heated under reflux for 1 hr. After the solution had been neutralyzed by sodium hydroxide, the product was extracted with ether and distilled. B. p. 60.7—65.0°C/9 mmHg; yield, 88.3 g. (74%).

Found: C, 58.65 (58.80); H, 9.83% (9.87).

7-Octene-1, 5-diol.—A solution of 61 g. (0.5 mol.) of allylbromide in 200 ml. of ether was dropped, with stirring, into 300 ml. of ether in the presence of 72 g.

* Present address: Chemistry Department, Sophia University, Tokyo.

1) N. Ogata, T. Asahara and S. Tohoyama, *J. Polymer Sci.*, to be published.

(3.2 mol.) of magnesium. The mixture was heated for a period of 4 hr. at such a rate that the ether refluxed gently; then the solution was heated at a gentle reflux for an additional 30 min. The Grignard solution was transferred into a 1l. three-necked flask, and then a solution of 15 g. of tetrahydropyrane-2-ol in 150 ml. of ether was added, drop by drop. The solution was heated under reflux for an additional 40 min. and then decomposed with a saturated aqueous solution of ammonium chloride. The product was extracted with ether and distilled. B. p. 114—127°C/5 mmHg; yield, 11.4 g. (53%).

Found: C, 66.42 (66.43): H, 11.18 (11.24); mol. wt., 148 (144).

6-Allyltetrahydropyrane-2-ol.—A portion of 15 g. (0.1 mol.) of 7-octene-1, 5-diol was dissolved in 30 ml. of benzene, and then 65 ml. of a Beckmann solution (12 g. $K_2Cr_2O_7$, 10 g. H_2SO_4 and 120 ml. of water) was

—— 9-Oxabicyclo[3.3.1]nonane-3-one oxime

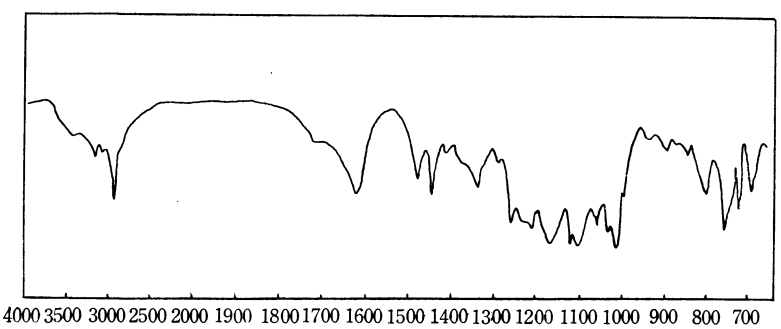

Fig. 3. Infrared spectrum of polymer (Film).

dropped, with stirring, into the solution over a period of 2 hr., with the temperature maintained at 35°C. The stirring was then continued for an additional hour at 35°C. The benzene layer was separated, and the aqueous solution was extracted twice with 100 ml. of dichloroethane. Benzene and dichloroethane solutions were combined, washed with water, and dried in the presence of magnesium sulphate. The distillation of the solution gave a fraction (7.2 g. (48%)) of 120—128°C/0.5 mmHg. The infrared spectrum of the product is shown in Fig. 1.

Found: C, 66.57 (66.77); H, 9.93% (9.78).

9-Oxabicyclio[3. 3. 1]nonane-3-ol formate. — A solution of 7.45 g. (0.05 mol.) of 6-allyltetrahydropyrane-2-ol in 50 ml. of 92% formic acid was heated while being stirred for 1 hr. at 40°C and then distilled. The gaschromatographic analysis of the distillate showed two peaks in almost equivalent amounts; separation could not be effected either by distillation or by column chromatography. The analytical data as well as the infrared spectrum showed that the distillate was the aimed-for product and it might include stereoisomers. B. p. 96—102°C/3 mmHg; yield, 4.83 g.

Found: C, 62.97 (63.51); H, 8.25 (8.29); mol. wt., 170 (170).

9-Oxabicyclo[3. 3. 1]nonane-3-ol.—A solution of 4.8 g. of 9-oxabicyclo[3. 3. 1]nonane-3-ol formate in 50 ml. of ether was added, drop by drop, into a solution of 4.8 g. of lithium aluminum hydride in 200 ml. of ether, with the temperature maintained at 0°C. The solution was allowed to stand, while being stirred for an additional 2 hr. at 0°C, then it was decomposed with a saturated aqueous solution of ammonium chloride. A continuous extraction with ether, followed by distillation, yielded 8 g. (80%) of the product. B. p. 132—134°C/0.5 mmHg.

Found: C, 66.90 (67.6); H, 9.00 (9.20).

9-Oxabicyclo[3. 3. 1]nonane-3-one.—A solution of 1.5 g. (0.01 mol.) of 9-oxabicyclo[3. 3. 1]nonane-3-one in 20 ml. of pyridine was added, drop by drop, into a solution of 4.2 g. (0.042 mol.) of chromic acid in 42 ml. of pyridine, with the reaction temperature at 0°C. kept by the use of an ice bath. Stirring was then concontinued at room temperature for an additional 4 hr., after which the solution was neutralized by the addition of concentrated hydrochloric acid. Continuous extraction, followed by the removal of the ether, yielded 0.78 g. of the product.

Oximation. — 9-Oxabicyclo[3. 3. 1]nonane-3-one (2 g.(0.014 mol.)), hydroxylamine hydrochloride (2 g.) and sodium carbonate (2 g.) were dissolved in a mixture of 20 ml. of ethanol and ether; the solution was then heated under reflux for 20 hr. After the solution had been extracted with ether and the ether removed, white crystals were obtained. The recrystallization of these from ethanol yielded 1.2 g. (56%) of needle crystals, m. p. 124—125°C.

Found: C, 60.40 (61.9); H, 8.30 (8.4); N, 8.5% (9.0) mol. wt., 160 (155).

Beckmann Rearrangement.—A strong reagent for the Beckmann rearrangement, such as sulfuric acid, decomposed oximes with an ether group, and mild reaction conditions, using thionyl chloride at a low temperature, have been recommended[1] for the synthesis of lactam ethers.

In this case, however, not even thionyl chloride could give the aimed-for product; only a sticky polymer was obtained. Neither phosphorus pentachloride nor benzene sulfonyl chloride could give the aimed-for bicyclic lactam ether, even at such a low temperature as below 0°C., and the product was a polymer with molecular weight of about 580 to 650. The polymer was a soft solid, and its melting point was not clear. The infrared spectrum of the polymer is shown in Fig. 3.

Found: C, 61.5 (61.9); H, 8.5 (8.4); N, 8.6% (9.0).

Discussion

Bohlmann[2] synthesized 9-oxabicyclo[3.3.1]-nonane-3-ol through the alkaline hydrolysis of the formate of the alcohol. However, the yield was poor by this method; the reduction of the formate, followed by hydrolysis, gave a better yield of the alcohol. The oxidation of the alcohol into ketone in the presence of the chromic acid-pyridine complex gave a better yield than in the Beckmann solution ($K_2Cr_2O_7/H_2SO_4$) since a ring cleavage was observed in an acidic medium. Pure bicyclic lactam ether was not able to isolate by means of the Beckmann rearrangement of the oxime, but a polymer was easily obtained. The infrared spectrum of the polymer showed absorption resulting from the amide group at 3250, 3100 and 1625 cm^{-1}. The strong absorption at 1625 cm^{-1} is supposed to be due to an amide carbony group; no absorption was observed in the range from 1550 to 1600 cm^{-1}.

The chain trans amide group shows a strong absorption, the so-called amide II band, in the region from 1550 to 1600 cm^{-1}. Therefore, the ring cleavage may be presumed to have occured at the ether linkage, because no absorption resulting from a chain trans amide group was observed, as would be expected if the amide group was cleaved.

The derivatives of bicyclic ether show an absorption band resulting from the ether group in the region from 1030 to 1020 cm^{-1}, while the cleaved product of the bicyclic lactam ether shows an ether band at 1010 cm^{-1}. A monocyclic oxime ether, tetrahydro-γ-pyrone oxime and its isoxime, gave an absorption band resulting from the ether group at 1100 cm^{-1}, a band which was shifted to 1070 cm^{-1} in the polymer from a monocyclic lactam ether, tetrahydro-1, 4-oxazepine-5(4*H*)-one. The tetrahydropyrane derivatives show an ether band around 1100 cm^{-1}. Therefore, the shift of the ether band toward a lower frequency also support the above presumption.

The protonation of the ether group, followed by the cleavage, caused the polymerization of bicyclic lactam ether at a low temperature. Therefore, the cationic polymerization of lactam ethers proceeds

2) F. Bohlmann, H. T. Schulz and J. Poamann, *Tetrahedron Letters*, **1964**, 1705.

through the opening of the ether group. Further evidence on the structure of the polymer will provide for the elucidation of the reaction scheme.

The authors wish to thank Dr. Toshio Hoshino for his permission to publish this paper. Thanks are also due to Dr. Bohlmann, who sent us detailed informations on the synthesis of the bicyclic ketone ether.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1559—1562 (1966)

Methylene-hydantoin and Related Compounds. I. On the Reaction of Pyruvic Acid and Urea: The Synthesis of 5-Methylene-hydantoin

By Shunsuke MURAHASHI,† Heimei YUKI,†† Koichi KOSAI†† and Fumihiro DOURA†

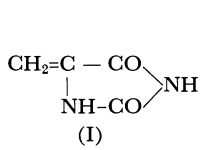
† *Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka*

†† *Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka*

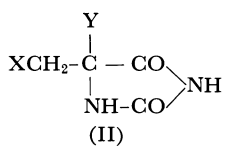
(Received November 10, 1965)

Various condensation products were obtained by the reaction between pyruvic acid and urea. They are 5-hydroxy-5-methyl-hydantoin, homoallantoin, homoallantoic acid, and dipyruvic triureide. 5-Methylene-hydantoin was prepared from some of these compounds, or directly from pyruvic acid and urea, by reactions in organic acid. The most convenient method was the dehydration of 5-hydroxy-5-methyl-hydantoin, which is a new compound melting at 166°C. 5-Methylene-hydantoin, m. p. 214°C, is a new monomer of the vinylidene type which polymerizes easily by means of a free radical mechanism. 3-Methyl-5-methylene-hydantoin was also prepared from 5-hydroxy-5-methyl-hydantoin through its 3-methyl derivative.

The derivatives of 5-methylene-hydantoin may be vinylidene-type monomers of some interest because they give polymers containing hydantoin groups along the hydrocarbon main chains. However, 5-methylene-hydantoin (I) itself has not been prepared, although the preparation of substituted 5-methylene-hydantoins, such as 1-phenyl-5-methylene-hydantoin[1] and 3-phenyl-5-methylene-hydantoin,[2] has been reported in the literature.



(I)



(II)

Various attempts to derive I from the compounds represented by formula II, such as 5-bromo-5-methyl-hydantoin (X=H, Y=Br),[3] 5-bromomethyl-hydantoin (X=Br, Y=H),[4] 5-hydroxymethyl-hydantoin (X=OH, Y=H),[5] and 5-carboxymethylene-hydantoin,[6] by the elimination of XY or by decarboxylation in the case of 5-carboxymethylene-hydantoin were not successful because of the difficulty of the elimination reaction and/or the polymerization of the product during the reaction.

5-Methylene-hydantoin is considered to be the condensation product of equimolar amounts of pyruvic acid and urea; this suggests the possibility of its formation from these compounds. It was found that 5-methylene-hydantoin could be prepared from pyruvic acid and urea directly or through their reaction products as intermediates. In this paper, the synthesis of 5-methylene-hydantoin and, in connection with this, the results of the investigation of the reaction of pyruvic acid and urea will be described.

Results and Discussion

The prolonged reaction of equimolar amounts of pyruvic acid and urea in water at room temperature gave 5-hydroxy-5-methyl-hydantoin (III) in a fairly good yield. If the reaction was carried out with higher concentrations of the reagents, homoallantoic acid (α, α-diureidopropionic acid) (IV) was produced predominantly, and at higher temperatures mainly homoallantoin (5-methyl-5-ureido-hydantoin) (V) and dipyruvic triureide (VI) were obtained. The reaction probably proceeded by the course shown in Fig. 1. The condensation product (VII) of pyruvic acid and urea is converted into 5-hydroxy-5-methyl-hydantoin by cyclization in a dilute solution, but at

higher concentrations of the reagents urea may attack VII and give homoallantoic acid. This acid is slightly soluble in water and is precipitated from a cold solution. At higher temperatures, homoallantoic acid is converted into homoallantoin by dehydration or into dipyruvic triureide through condensation with VII.

5-Hydroxy-5-methyl-hydantoin is a new compound whose melting point is 166°C. The reduction of 5-hydroxy-5-methyl-hydantoin with hydroiodic acid gave 5-methyl-hydantoin. It has been known that homoallantoic acid itself can be prepared from one mole of pyruvic acid and two of urea.[7] When heated at 100°C in 80% formic

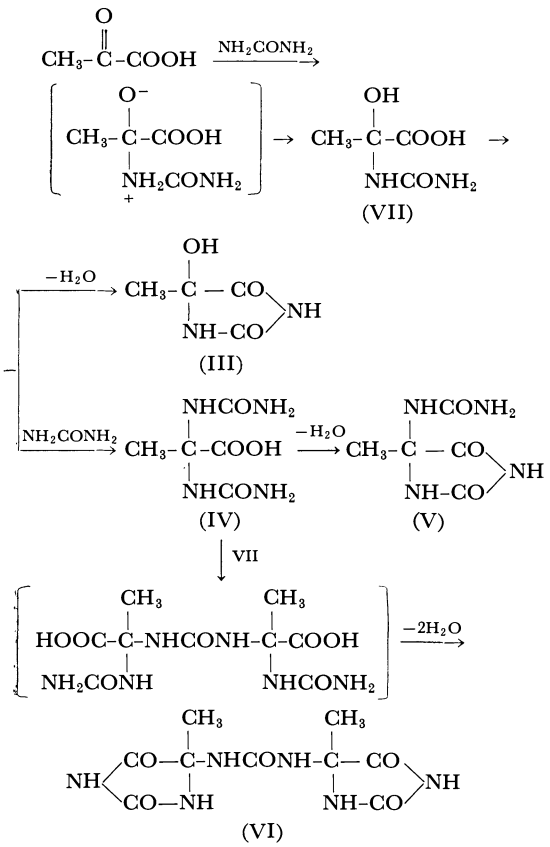

Fig. 1. Reaction of pyruvic acid and urea.

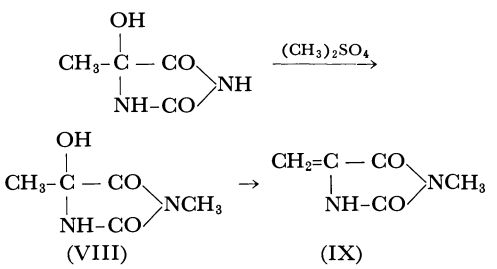
acid, 5-hydroxy-5-methyl-hydantoin easily gave 5-methylene-hydantoin in a 60% yield. The prolonged reaction did not improve the yield, but by the addition of acetic anhydride to the reaction mixture as a dehydrating agent, 5-methylene-hydantoin was obtained almost quantitatively, even in several minutes. The reaction carried out in acetic acid or in 1 N hydrochloric acid gave 5-methylene-hydantoin in only low yield. However, 5-methylene-hydantoin was obtained in a high yield when a mixture of glacial acetic acid and a small amount of concentrated hydrochloric acid was used as the solvent. 5-Methylene-hydantoin gave 5-methyl-hydantoin by reduction with hydroiodic acid.

3, 5-Dimethyl-5-hydroxy-hydantoin (VIII) was prepared by the methylation of 5-hydroxy-5-methyl-hydantoin with dimethyl sulfate. The dehydration of this compound gave 3-methyl-5-methylene-hydantoin (IX) under the same conditions as produced 5-hydroxy-5-methyl-hydantoin.



Dipyruvic triureide has been known to be easily obtainable by a reaction of 2 moles of pyruvic acid and 3 of urea in concentrated hydrochloric acid.[8] Dipyruvic triureide was hydrolyzed to give 5-hydroxy-5-methyl-hydantoin and homoallantoin almost quantitatively by boiling it in water for several hours. By a prolonged reaction at a much slower rate, homoallantoin could be hydrolyzed to 5-hydroxy-5-methyl-hydantoin and urea.

5-Methylene-hydantoin could also be obtained from dipyruvic triureide and from homoallantoin by hydrolysis in organic acid under conditions similar as those in the dehydration of 5-hydroxy-5-methyl-hydantoin. In these cases, however, some difficulties were encountered in isolating 5-methylene-hydantoin from the other hydrolysis products, urea and homoallantoin, while 5-methylene-hydantoin might polymerize during the isolation if it requires too long a time.

Davidson[8] has reported that dipyruvic triureide was converted by concentrated sulfuric acid into dipyruvic ureide (X), the dimer of 5-methylene-hydantoin, which is stable and almost insoluble in cold water. In this reaction the initial product must be 5-methylene-hydantoin, which dimerizes in sulfuric acid by the cationic mechanism.

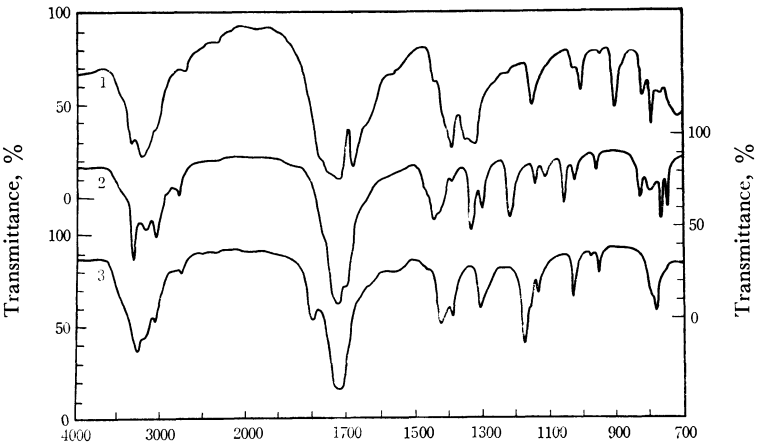

Fig. 2. Absorption spectra of: 1, 5-methylene-hydantoin; 2, 5-methyl-hydantoin; 3, 5-hydroxy-5-methyl-hydantoin (in KBr disks).

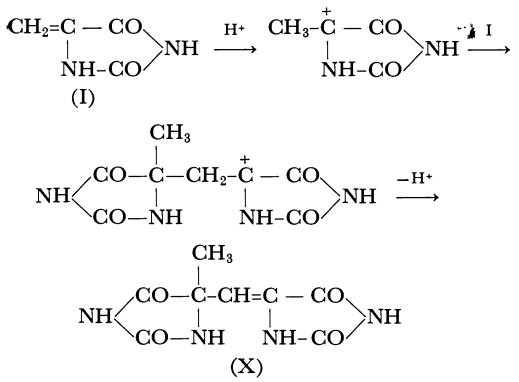

Directly from pyruvic acid and urea, 5-methylene-hydantoin could be prepared in a low yield by heating it in acetic acid containing a small amount of hydrochloric acid. However, the slow rate of reaction left the reagents unreacted, or resulted in the polymerization of the hydantoin produced during the long period of reaction.

As has been described above, there are various routes possible in the synthesis of 5-methylene-hydantoin from pyruvic acid and urea as starting materials. However, the most convenient route among these is that via 5-hydroxy-5-methyl-hydantoin because of its high yield and the simple procedure.

The infrared spectra of 5-methylene-hydantoin, 5-methyl-hydantoin and 5-hydroxy-5-methyl-hydantoin are shown in Fig. 2.

Experimental

5-Hydroxy-5-methyl-hydantoin.—A solution of pyruvic acid (50 g., 0.57 mol.) and urea (34 g., 0.57 mol.) in water (250 ml.) was allowed to stand at room temperature for 14 days and then evaporated under reduced pressure. Methanol (350 ml.) was added to the residue, and the insoluble materials were filtered off. Then the unreacted urea was removed by precipitation by adding dry ether to the filtrate. When the solution was evaporated, crude crystals of 5-hydroxy-5-methyl-hydantoin were obtained. Recrystallization from acetic acid gave colorless crystals; yield, 51 g. (69%); m. p. 166°C. This compound was soluble in water, alcohol, acetone, and tetrahydrofuran, sparingly soluble in ethyl ether, and insoluble in petroleum ether.

Found: C, 36.82; H, 4.61; N, 21.62. Calcd. for $C_4H_6N_2O_3$: C, 36.93; H, 4.65; N, 21.53%.

The reaction carried out at a higher concentration of the reagents, at a higher temperature or in the presence of an acid or a base did not improve the yield of 5-hydroxy-5-methyl-hydantoin. The results of the reaction under varying conditions are shown in Table I.

Homoallantoic Acid.—This compound was prepared according to Simon.[7] It was converted into homoallantoin in hot water in a 50% yield.

5-Methylene-hydantoin from 5-Hydroxy-5-methyl-hydantoin.—5-Hydroxy-5-methyl-hydantoin (10 g., 0.077 mol.) was dissolved in a mixture of 80% formic acid (100 ml.) and acetic anhydride (120 ml.), and then heated at 100°C for 5 min. in the presence of a small amount of hydroquinone. The solution was then cooled and evaporated under reduced nitrogen pressure. The residue was recrystallized from acetic acid. 5-Methylene-hydantoin (8 g.) was thus obtained almost quantitatively; m. p. 214°C.

Found: C, 42.80; H, 3.62; N, 25.13. Calcd. for $C_4H_4N_2O_2$: C, 42.86; H, 3.60; N, 25.00%.

5-Methylene-hydantoin was soluble in water, alcohol, and acetone, sparingly soluble in ethyl ether, and insoluble in hexane and benzene. It polymerized easily when heated in the presence of a radical initiator. The polymerization and the properties of the polymer will be described in a following paper.[9]

To a solution of 5-methylene-hydantoin (0.05 g.) in acetic acid (2 ml.), hydroiodic acid (2 ml., d=1.6)

9) S. Murahashi, H. Yuki, K. Kosai and F. Doura, This Bulletin, **39**, 1563 (1966).

was added. Immediately the brown color of iodine appeared. The solution was heated at 100°C for 10 min. and then concentrated under reduced pressure. Water was added to the residue, and the solution was evaporated. This procedure was repeated five times in order to remove the iodine. Colorless crystals of 5-methyl-hydantoin were thus obtained; m. p. 142°C. They showed the same infrared spectrum as an authentic sample, and their melting points were undepressed on admixture.

The reaction of 5-hydroxy-5-methyl-hydantoin and hydroiodic acid gave the same product as that described above.

3, 5-Dimethyl-5-hydroxy-hydantoin. — 5-Hydroxy-5-methyl-hydantoin (20 g., 0.15 mol.) was dissolved in 1 N sodium hydroxide, after which dimethyl sulfate (21 g., 0.17 mol.) was stirred in drop by drop. The temperature was then kept at 35°C for about one hour. The evaporation of the solvent left a syrupy residue, which was extracted with absolute alcohol. Dry ether was added to the solution, and the precipitates produced were filtered off. When the filtrate was evaporated, a white solid (18 g.) was obtained. Recrystallization from acetone-petroleum ether gave pure 3, 5-dimethyl-5-hydroxy-hydantoin; yield, 17 g. (77%); m. p. 104°C. The compound was soluble in water, alcohol and acetone, slightly soluble in ether, and insoluble in petroleum ether.

Found: C, 44.66; H, 5.66; N, 19.27. Calcd. for $C_5H_8N_2O_3$: C, 44.66; H, 5.59; N, 19.44%.

3-Methyl-5-methylene-hydantoin. — This compound was obtained quantitatively from 3, 5-dimethyl-5-hydroxy-hydantoin by the same procedure as that described in the synthesis of 5-methylene-hydantoin from 5-hydroxy-5-methyl-hydantoin. 3-Methyl-5-methylene-hydantoin, m. p. 142°C, was soluble in water, alcohol and acetone, slightly soluble in ether, and insoluble in petroleum ether.

Found: C, 47.52; H, 4.89; N, 22.33. Calcd. for $C_5H_6N_2O_2$: C, 47.62; H, 4.80; N, 22.22%.

Dipyruvic Triureide.—Dipyruvic triureide was prepared according to Davidson[8] as follows. To a solution of urea (75 g., 1.3 mol.) in concentrated hydrochloric acid (85 ml.), pyruvic acid (50 g., 0.57 mol.) was added. After the solution had been allowed to stand for 3 days, it solidified completely. Recrystallization from dilute aqueous ammonia and acetic acid gave long needles; yield, 73 g. (72%); m. p. above 300°C (decomp.).

Found: C, 33.88; H, 5.13; N, 26.41. Calcd. for $C_9H_{12}N_6O_5 \cdot 2H_2O$: C, 33.74; H, 5.04; N, 26.25%.

The Hydrolysis of Dipyruvic Triureide.—A suspension of dipyruvic triureide (50 g., 0.15 mol.) in water (1.2 l.) was refluxed for 5 hr. The resultant solution was evaporated to dryness. The residue was then triturated with dry methanol (130 ml.) and filtered. Homoallantoin was thus obtained as colorless crystals; yield, 24 g. (91%); m. p. 260°C (decomp.) (lit.,[7] m. p. 260°C (decomp.)).

Found: C, 34.79; H, 4.78; N, 32.69. Calcd. for $C_5H_8N_4O_4$: C, 34.88; H, 4.88; N, 32.55%.

The filtrate was concentrated after urea had been removed by adding dry ether. The crude crystals of 5-hydroxy-5-methyl-hydantoin were recrystallized from acetic acid; yield, 19 g. (91%).

The Hydrolysis of Homoallantoin.—Homoallantoin (10 g., 0.058 mol.) was dissolved in hot water (100 ml.), and the solution was refluxed for 10 hr. By the same procedure as has been described above, unreacted homoallantoin (5.5 g.) was recovered and 5-hydroxy-5-methyl-hydantoin (3.2 g.) was obtained from the mother liquor in a 94% yield (based on the consumed homoallantoin).

5-Methylene-hydantoin from Dipyruvic Triureide.—A suspension of dipyruvic triureide (5 g., 0.016 mol.) in 80% formic acid (100 ml.) or in a mixture of acetic acid (100 ml.) and concentrated hydrochloric acid (1 ml.) was heated at 100°C for 20 min. in the presence of hydroquinone. The concentration of the resultant solution under a reduced nitrogen pressure left a syrupy residue, which was dissolved in water (80 ml.) and filtered to remove homoallantoin and the polymer produced during the reaction. After the filtrate had been freeze-dried, the residual crystals were extracted with tetrahydrofuran (100 ml.) to remove the urea. When the extracted solution was evaporated, crude crystals of 5-methylene-hydantoin were obtained. Recrystallization from acetonitrile yielded 2.1 g. (60%). From the water-insoluble fraction, homoallantoin (0.5 g.) was obtained.

5-Methylene-hydantoin from Homoallantoin.—By a procedure similar to that described above, 5-methylene-hydantoin was obtained from homoallantoin in a 60% yield.

5-Methylene-hydantoin from Pyruvic Acid and Urea.—A solution of pyruvic acid (5.0 g., 0.06 mol.) and urea (3.4 g., 0.06 mol.) in acetic acid (20 mol.) containing a small amount of hydrochloric acid was heated at 100°C for 2 hr. 5-Methylene-hydantoin (1.5 g.) was thus obtained in a 24% yield.

Methylene-hydantoin and Related Compounds. II. Poly-5-methylene-hydantoin and Poly-α-aminoacrylic Acid

By Shunsuke MURAHASHI,† Heimei YUKI,†† Koichi KOSAI†† and Fumihiro DOURA†

† *Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka*

†† *Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka*

(Received November 10, 1965)

5-Methylene-hydantoin was polymerized easily by free radical initiators, and showed a higher reactivity in copolymerization with styrene. From the copolymerization of styrene (M_1) and 5-methylene-hydantoin (M_2), the monomer reactivity ratios, r_1 and r_2, were found to be 0.03 and 24, while the Q and e values in Alfrey-Price's Q-e scheme were found to be 21 and -0.23, respectively. As is shown by the large Q value, the high reactivity of 5-methylene-hydantoin is based on the high resonance stabilization of its radical, a stabilization which results from the conjugation system. This was also confirmed by a study of the ultraviolet spectrum. Poly-5-methylene-hydantoin showed electrolytic behavior in its solubility and solution viscosity. This property is due to the dissociation of NH at the 3 position of the hydantoin group. The polymers of 3-methyl-5-methylene-hydantoin and 3-phenyl-5-methylene-hydantoin were observed to show very weak acidities, resulting from the NH at the 1 position. Poly-α-aminoacrylic acid was obtained by the alkaline hydrolysis of poly-5-methylene-hydantoin. This polymer was soluble in water, and showed an unusual amphoteric behavior in solution viscosity.

In a previous paper,[1] the synthesis of 5-methylene-hydantoin (I) from pyruvic acid and urea was reported. This material is an exo-methylene compound, one which polymerizes easily in spite of having a bulky group at the double bond. In this paper, the investigations of the polymerization of 5-methylene-hydantoin, the properties of its polymer (II) and of a poly-ampholyte, poly-α-aminoacrylic acid (III), prepared by the hydrolysis of poly-5-methylene-hydantoin, will be reported on.

(III)

Results and Discussion

5-Methylene-hydantoin was polymerized in water and in acetic acid with free radical initiators. The polymerization was also carried out in situ with the monomer produced by the decomposition of dipyruvic triureide or by the reaction between pyruvic acid and urea without isolation. 3-Methyl- and 3-phenyl-5-methylene-hydantoin were polymerized in organic solvents with azobisisobutyronitrile. The results are shown in Table I.

The rate of the polymerization of 5-methylene-hydantoin was very fast. The precipitation of the polymer began immediately and was almost complete within one hour. The differences between the molecular weights of these polymers were shown by their solution viscosities. The smaller molecular weight of the polymer produced in water may be caused by the smaller solubility of the polymer in this solvent. It was found that the viscosities of polymers produced from the monomer in situ were almost the same as that obtained from the purified monomer.

The polymers were proved to be formed by the addition polymerization at the double bond in 5-methylene-hydantoin; there was a remarkable similarity between the infrared spectra of the polymer and of fused 5, 5-dimethyl-hydantoin, as is shown in Fig. 1.

It was found that 5-methylene-hydantoin did not copolymerize with vinyl acetate, but that it did copolymerize with styrene, methyl methacrylate and acrylonitrile when treated by a free radical initiator. Copoly-(acrylonitrile - 5 - methylene-hydantoin), containing a small amount of the latter monomer unit, showed good dyeing properties against a basic dyestuff such as Rhodamine 6G.

The copolymerization of styrene (M_1) and 5-methylene-hydantoin (M_2) was investigated in order

*2 m_2: Mole fraction of 5-methylene-hydantoin in copolymer.

to obtain the monomer reactivity ratios of these two monomers. The copolymerization reaction was carried out in methanol at 70°C using azobisisobutyronitrile as the initiator. The results are shown in Table II. It was found that 5-methylene-hydantoin was incorporated predominantly in all the copolymers. The composition curve derived from the results in Table II is shown in Fig. 2. The curve shows a higher reactivity of 5-methylene-hydantoin than that of styrene; the monomer reactivity ratios, r_1 and r_2, were calculated to be 0.03±0.02 and 24±1 respectively. The Q and e values calculated from these r_1 and r_2 were 21 and −0.23 respectively.

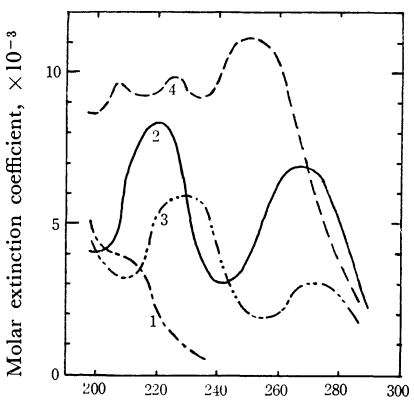

Fig. 3. Absorption spectra of: 1, 5-methyl-hydantoin in H_2O; 2, 5-methylene-hydantoin in H_2O; 3, 3-methyl-5-methylene-hydantoin in H_2O; 4, 3-phenly-5-methylene-hydantoin in EtOH.

The ultraviolet spectra of 5-methylene-hydantoin, 5-methyl-hydantoin, 3-methyl-5-methylene-hydantoin and 3-phenyl-5-methylene-hydantoin are shown in Fig. 3. 5-Methyl-hydantoin showed only an absorption band at 215 mμ, but the three methylene-hydantoins gave strong absorption bands at 240—280 mμ, resulting from the π—π* transition,

besides the bands in the 200—240 mμ region. The high reactivity of 5-methylene-hydantoin represented by the Q value is apparently correlated with this spectroscopic observation, which shows a strongly conjugated structure in this monomer.

Poly-5-methylene-hydantoin was a colorless solid which was insoluble in water and in common organic solvents, but soluble in dilute aqueous solutions of bases such as sodium hydroxide, ammonia, pyridine, triethylamine and ethanolamine. The dissolution of the polymer in a basic aqueous solution suggests the ionization of hydrogen at the 3 position of the hydantoin group. The hydrogen is made considerably acidic by the inductive effect of two neighboring carbonyl groups, contrary to the very weak acidity of the hydrogen at the 1 position. The mono-sodium salt of poly-5-methylene-hydantoin was obtained by pouring a solution of polymer and a large excess of sodium hydroxide into methanol. The polymers of 3-methyl- and 3-phenyl-5-methylene-hydantoin, which have no hydrogen at the 3 position, were also soluble in a basic aqueous solution, but higher concentrations of the base were required for their dissolution. Poly-5-methylene-hydantoin was soluble in a 0.02 N sodium hydroxide solution, and 0.5 N was needed to dissolve poly-3-phenyl-5-methylene-hydantoin with a bulky hydrophobic phenyl group.

The electrolytic properties of the polymers were observed by means of their viscosities. These are shown in Figs. 4 and 5. The reduced viscosities of a solution of poly-5-methylene-hydantoin in aqueous sodium hydroxide were measured at a constant concentration of the polymer but with varying concentrations of the base (Fig. 5), and vice versa (Fig. 4). Each viscosity curve showed a maximum at the equivalent concentrations of the polymer and the base. On the other hand, the reduced viscosity of the polymer in a 0.045 mol. aqueous triethylamine solution increased with a decrease in the concentration of the polymer (Fig. 4, Curve 2). The higher viscosity at a lower concentration of the polymer, even in the presence of an excess of triethylamine, is probably due to the small ionization of this weak base.

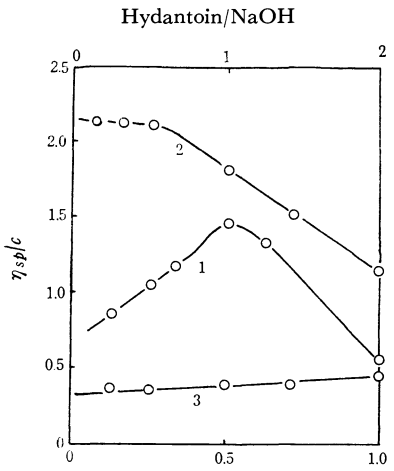

Fig. 4. Viscosities of poly-5-methylene-hydantoin and poly-3-methyl-5-methylene-hydantoin.
1 Poly-5-methylene-hydantoin in 0.179% aqueous NaOH solution
2 Poly-5-methylene-hydantoin in 0.460% aqueous Et_3N solution
3 Poly-3-methyl-5-methylene-hydantoin in 0.159 % aqueous NaOH solution
Temp., 30.0°C

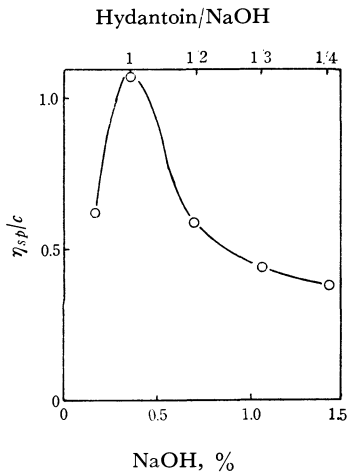

Fig. 5. Viscositiy of poly-5-methylene-hydantoin. Temp., 30.0°C; solvent, aq. NaOH; $c=1$ (g./100 ml.)

The solubility of poly-3-methyl-5-methylene-hydantoin in an alkaline solution suggests the electrolytic nature of this polymer. However, probably as a very weak poly-electrolyte, it gave only a linear relationship between the reduced viscosity and the polymer concentration in a 0.04 N aqueous sodium hydroxide solution.

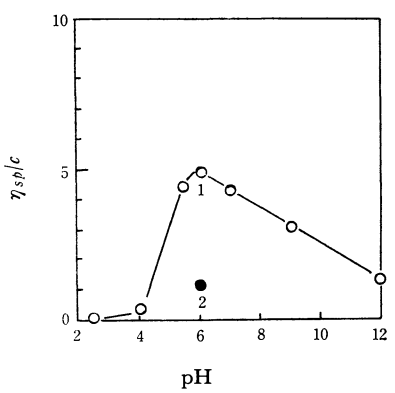

Fig. 6. Viscosity of poly-α-aminoacrylic acid.
1 Poly-α-aminoacrylic acid
2 Poly-5-methylene-hydantoin Na salt
Temp., 30.0°C; solvent, H_2O; $c=1$ (g./100 ml.)

Poly-5-methylene-hydantoin apparently behaved as a poly-acid upon the dissociation of the NH group at the 3 position. However, the changes in its viscosity with the variation in the circumstances were small in comparison with those of a typical poly-electrolyte, such as poly-acrylic acid or poly-methacrylic acid. This is probably due to the small degree of polymerization of the poly-5-methylene-hydantoin obtained. Furthermore, the bulky hydantoin group directly attached to the main chain may so largely prevent the internal rotation that the transformation of the polymer chain is restricted.

Poly-α-aminoacrylic acid is one of the most simple poly-ampholytes; several attempts to prepare it have been reported.[2-4] However, poly-α-aminoacrylic acid with quantitative amounts of free amino and acid groups has not been obtained. It has been found, though, that the neighboring amino and carboxyl groups easily reacted to form a lactam ring in strongly acidic media.

The hydrolysis of poly-5-methylene-hydantoin was carried out in aqueous sodium hydroxide at the boiling point. About fourteen days were necessary to complete the reaction. The careful neutralization of the reaction mixture gave a colorless polymer, which was soluble in water and dimethylformamide. The solubility in water was preserved not only in the alkaline region but also in the acidic region above pH 3. At pH 3 the polymer began to precipitate, but it was dissolved reversibly by the addition of aqueous alkali.

The elemental analysis showed the polymer to be poly-α-aminoacrylic acid and that it did not have a lactam ring in any appreciable amount. The number of free amino groups in the polymer was determined spectroscopically with the dinitrophenylated polymer. The amino-nitrogen content as calculated from the data was consistent with that of poly-α-aminoacrylic acid.

The amphoteric nature of the polymer was observed by means of a study of its solution viscosity. The effects of acid and base on the reduced viscosity are shown in Fig. 6. The viscosity of natural protein usually shows a minimum at the isoelectric point. Contrary to the usual poly-ampholyte, however, the viscosity of this polymer showed a maximum at pH 6, and decreased on both sides of that point almost symmetrically. This peculiar behavior of this polymer may be considered to be due to its intermolecular association in the neutral region and to its dissociation on the acidic and basic sides. The crowded amino and carboxyl groups along the main chain of this polymer seem to form zwitter-ions not only intramolecularly but also between the polymer molecules. This is also suggested by the viscosity of poly-α-aminoacrylic acid, which is very much higher than that of its parent polymer, poly-5-methylene-hydantoin.

Experimental

The Preparation of Poly-5-methylene-hydantoin.—a) The solution of 5-methylene-hydantoin (1.0 g.) and azobisisobutyronitrile (0.01 g.) in acetic acid (25 ml.) was sealed in an ampoule under nitrogen, and then left to stand at 60°C for 20 hr. The polymer thus precipitated was filtered, washed with methanol, and dried in vacuo at 100°C for one day. Poly-5-methylene-hydantoin (1.0 g.) was obtained. It was a colorless solid which decomposed above 300°C and was soluble in aqueous alkali, and was insoluble in water and in common organic solvents.

Found: C, 42.80; H, 3.74; N, 24.74. Calcd. for $C_4H_4N_2O_2$: C, 42.86; H, 3.60; N, 25.00%.

Its infrared spectrum is shown in Fig. 1.

b) Pyruvic acid (5.0 g.) and urea (3.4 g.) were dissolved in acetic acid (25 ml.) containing a small amount of hydrochloric acid, and the solution was heated at 100°C for 20 min. Then azobisisobutyronitrile (0.1 g.) was added to the cooled solution, and the solution was left to stand at 80°C for 20 hr. Poly-5-methylene-hydantoin (2.3 g., 37%) was obtained by the treatment described above.

c) A suspension of dipyruvic triureide (5.0 g.) in 80% formic acid (100 ml.) was heated at 100°C for 20 min.; after it had then cooled, the resultant clear solution was left to stand at 60°C for 20 hr. with azobisisobutyronitrile (0.05 g.). Poly-5-methylene-hydantoin (2.5 g., 72%) was obtained such as in the above-described treatment.

The Polymerization of 3-Phenyl-5-methylene-hydantoin.—The monomer was prepared according to Bergmann.[5] It melted at 200°C and polymerized immediately. (Lit.[5] 270°C (decomp.)).

A solution of 3-phenyl-5-methylene-hydantoin (2.0 g.) and azobisisobutyronitrile (0.06 g.) in acetone (35 ml.) was heated at 53°C for 20 hr. and then poured into methanol. The precipitates were washed with methanol and dried. The colorless polymer thus obtained (1.9 g.) was reprecipitated from tetrahydrofuran and methanol, and then dried. Poly-3-phenyl-5-methylene-hydantoin (1.7 g.) was thus obtained; yield, 85%. It was decomposed above 300°C; it was soluble in tetrahydrofuran, pyridine, dimethylformamide and dimethyl sulfoxide, and insoluble in water, alcohol, benzene and ether.

Found: C, 63.83; H, 4.54; N, 14.22. Calcd. for $C_{10}H_8N_2O_2$: C, 63.82; H, 4.29; N, 14.89%.

The Polymerization of 3-Methyl-5-methylene-hydantoin.—The monomer was prepared as has been described in the previous paper.[1] The polymerization was carried out in the same manner as that of 3-phenyl-5-methylene-hydantoin. Poly-3-methyl-5-methylene-hydantoin was thus obtained in a 78% yield. It was decomposed above 270°C; it was soluble in tetrahydrofuran, pyridine, dimethylformamide and

dimethyl sulfoxide, and insoluble in alcohol and benzene.

Found: C, 45.70; H, 5.07; N, 21.17. Calcd. for $C_5H_6N_2O_2$: C, 47.62; H, 4.80; N, 22.21%.

Sodium Salt of Poly-5-methylene-hydantoin.—A solution of poly-5-methylene-hydantoin (0.1 g., 0.89 mmol.) in 1 N sodium hydroxide (5 ml., 5.0 mmol.) was left to stand at room temperature for 30 min. Colorless precipitates were then produced by pouring the solution into methanol, filtering it, washing it with methanol, and drying it. Mono-sodium salt of poly-5-methylene-hydantoin (0.12 g.) was thus obtained. The salt was dissolved in water, and the original polymer was recovered by the addition of dilute hydrochloric acid.

Found: N, 20.2; Na, 16.0. Calcd. for $C_4H_3N_2O_2Na$: N, 20.9; Na 17.2%.

The Copolymerization of 5-Methylene-hydantoin with Styrene.—5-Methylene-hydantoin, freshly distilled styrene and azobisisobutyronitrile (about 5 mol% against the total of monomers) were dissolved in purified methanol (8 ml.). The copolymerization was carried out in a sealed glass tube under nitrogen at 70°C. The polymer composition was calculated from the results of a nitrogen analysis (Table II).

The Hydrolysis of Poly-5-methylene-hydantoin.—The solution of poly-5-methylene-hydantoin (1.5 g.) in 15% sodium hydroxide (100 ml.) was refluxed under a nitrogen stream. The evolution of ammonia ceased after 14 days. Hydrochloric acid was then added to the cold solution, and the pH was adjusted to about 6. The silicic acid produced from the glass vessel was precipitated, filtered off, and washed with water. The filtrate and washings were combined and concentrated in vacuo. To the residual solution (50 ml.), dilute hydrochloric acid was added, the pH of the solution was adjusted to 3, and the polymer was precipitated. The polymer was filtered, washed with 0.001 N hydrochloric acid and methanol, and dried in vacuo at 100°C for one day. A Beilstein test showed no chloride ion to be present. Poly-α-aminoacrylic acid (0.8 g.) was obtained; yield, 60%; colored above 250°C; soluble in water and dimethylformamide, and insoluble in common organic solvents.

Found: C, 40.7; H, 5.5; N, 16.0. Calcd. for $C_3H_5NO_2$: C, 41.4; H, 5.8; N, 16.1%.

The Determination of the Free Amino Group in Poly-α-aminoacrylic Acid.—The dinitrophenylation of the polymer was carried out according to Levy.[6] Poly-α-aminoacrylic acid (20.00 mg.) was dissolved in a solution of sodium carbonate (84.4 mg.) in water (30.0 ml.). 2, 4-Dinitrofluorobenzene (200 mg.) was then added to the solution, and it was stirred vigorously at 40°C for 2 hr. The excess reagent and the phenol thus produced were extracted off with ether from the acidified reaction mixture. The solution was neutralized with sodium bicarbonate. The ultraviolet spectrum of the solution of poly-α-(*N*-2, 4-dinitrophenyl)-aminoacrylic acid was measured with a Hitachi Perkin-Elmer type S 12-B spectrophotometer. The solution showed a λ_{max} at 360 mμ; the content of the dinitrophenyl group in the polymer was estimated using *N*-2, 4-dinitrophenyl glycine ($\lambda_{max}=360$ mμ, $\varepsilon_{max}=16.5\times10^3$; Lit.[7] $\lambda_{max}=360$ mμ, $\varepsilon_{max}=16.6\times10^3$) as the standard substance. The calculated amount of the free amino group for poly-α-aminoacrylic acid was 98 per cent of the theoretical amount.

We wish to express our deepest thanks to Mr. Heihachiro Kawaguchi for his active collaboration in the experiments.

The Trifluoroacetate Method of Peptide Synthesis. II. An Improved Synthesis of Bradykinin

By Shumpei SAKAKIBARA and Noriyoshi INUKAI*

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received November 11, 1965)

When *p*-nitrophenyl trifluoroacetate (I), 2, 4, 5-trichlorophenyl trifluoroacetate (II) and *N*-hydroxysuccinimide trifluoroacetate (III) were subjected to Anderson's racemization test, only reagent III showed resistance against racemization. However, reagents I and II were also found to be useful for fragment-condensation with acylpeptides possessing glycine or proline at the *C*-terminus. Bradykinin was prepared using these reagents. During the synthesis, a combination of the *t*-amyloxycarbonyl *N*-protecting group and the benzyl ester was mainly used, and the alkaline hydrolysis procedure of the ester group was eliminated. Thus, colorless bradykinin with full activity was obtained in a satisfactory yield without any purification procedure.

In the first paper of this series,[1] the syntheses of various esters of trifluoroacetic acid were presented, and it was confirmed that *p*-nitrophenyl

trifluoroacetate (I), 2, 4, 5-trichlorophenyl trifluoroacetate (II) and *N*-hydroxysuccinimide trifluoroacetate (III) are the best reagents for preparing the respective active esters of urethan-type acyl-L-amino acids by ester-exchange reactions in pyridine. Further, it was suggested that the method should be valuable for the stepwise elongation of peptides by the active ester method without the isolation of the intermediates.

The present paper is concerned with a study of the use of reagents I, II and III not only for the stepwise synthesis, but also for so called fragment-condensation of peptides. First, reagents I, II and III were subjected to Anderson's racemization test,[2] i. e., carbobenzoxyglycyl-L-phenylalanine was treated with each reagent in pyridine until the ester-exchange reaction was complete, and then, the mixture was directly subjected to the coupling reaction with glycine ethyl ester. It was found that the ester-exchange reaction of the acylpeptide with reagent I or II was comparatively slow at room temperature, and a completely racemized product was obtained. With reagent III, however, the ester-exchange reaction was completed smoothly within one hour at room temperature, and only about 2.5% of the entire product, which was obtained in a 80% yield, was found to be racemate. Therefore, the use of reagents I and II for the fragment-condensation of peptides must be limited to the condensation of acylpeptides with glycine at their *C*-terminus. As will be described later in this paper, the *C*-terminal L-proline residue in an acylpeptide was found to be stable against racemization with reagent I, II or III. Furthermore, it has been mentioned previously[1] that amino acid residues with active hydrogen (such as histidine, serine, threonine and tyrosine) and *C*-terminal glutamine or asparagine are susceptible to these trifluoroacetate reagents in pyridine. Therefore, unless they are protected with suitable groups, acylpeptides with amino acid residues such as these should not be treated by this method. However, when these amino acid residues are in the amine components (i. e., peptide esters), this method, of course, can be used freely.

Second, the synthesis of bradykinin was carried out as an example of the application of the trifluoroacetate method using reagents I, II and III. The *t*-amyloxycarbonyl (AOC) group was mainly used as an *N*-protecting group; it had already been confirmed in this laboratory that the AOC group is useful in peptide synthesis.[3,4] The use of a methyl or ethyl ester group for protecting the carboxylic acid, the method adopted by Nicolaides and De Wald[5,6] for bradykinin synthesis, was replaced by the use of a benzyl ester group in this study, except for the preparation of hydrazide, because the removal of benzyl group by catalytic hydrogenolysis is much safer than the saponification of alkyl esters at the end of the synthesis. It was also confirmed that the AOC-group can be removed safely using trifluoroacetic acid, without any effect on the benzyl ester.[4] Moreover, it may be recalled that, although the removal of the carbobenzoxy group with anhydrous hydrogen bromide in acetic acid is accompanied by the partial *O*-acetylation of the serine residue during the procedure,[6] treatment with trifluoroacetic acid does not result in any modification of the serine residue. Boissonnas et al.[7] first prepared bradykinin using a combination of carbobenzoxy and *p*-nitrobenzyl ester groups. However, the hydrogenolysis of the *p*-nitrobenzyl group yield *p*-toluidine, and the separation of *p*-toluidine from the main product was a problem. Then, Guttmann et al.[8] improved the synthetic method by using tosylarginine as a material. The tosyl group, however, can only be removed by sodium reduction in liquid ammonia, and, after the reduction, the product had to be purified by column chromatography and/or counter current distribution.

The best route of bradykinin synthesis found so far in this study is shown in Fig. 1. The nitro-L-arginine benzyl ester was prepared from nitro-L-arginine in a good yield, using two moles of *p*-toluenesulfonic acid and excess benzyl alcohol, by the azeotropic dehydration procedure with chloroform.[9] Compound VII, AOC-L-prolyl-L-phenylalanyl-nitro-L-arginine benzyl ester, was synthesized step by step from the nitroarginine benzyl ester by the trifluoroacetate method using reagent I. In this case, it should be considered that AOC-L-phenylalanine and the AOC-L-proline *p*-nitrophenyl ester are both oily materials, while the AOC-L-phenylalanine *p*-nitrophenyl ester (V) and AOC-L-proline are easily crystallizable substances.[3] Therefore, compound V was isolated as crystals and then subjected to the reaction with the nitroarginine benzyl ester, while AOC-L-proline was coupled directly to the dipeptide ester without isolating the *p*-nitrophenyl ester. The linking of serine to the tripeptide ester was a problem, as has been mentioned above. Since the

application of the trifluoroacetate method for *N*, *O*-protected serine was not practical, the azide method was adopted in this case. After various attempts, it was found that the coupling of AOC-L-phenylalanyl-L-serine azide to the *C*-terminal tripeptide ester gave a much better result than that of AOC-L-serine azide. Next, AOC-L-prolyl-L-prolylglycine (XII) was prepared by coupling AOC-L-prolyl-L-proline (XI) with the glycine benzyl ester, followed by catalytic hydrogenation. A comparison was made using the reagents I, II and III in this condensation reaction; also, the dicyclohexylcarbodiimide method for preparing the same compound XII was tested. It was found that there was no difference in the optical purity of the respective products with these reagents; this result shows that the prolyl residue at the *C*-terminus of an acylpeptide is stable against racemization with the trifluoroacetate reagents I, II and III. The AOC-L-prolyl-L-prolylglycine thus formed was then satisfactorily coupled with the previously-prepared pentapeptide benzyl ester by the direct condensation method using reagent I. Finally, the tricarbobenzoxy-L-arginine *p*-nitrophenyl ester, which had been prepared by the reported method,[10] was coupled with the octapeptide,[11] and then all the protecting groups were removed simultaneously from the final product (XIV) by a single catalytic hydrogenation. The bradykinin thus obtained was completely colorless, and its biological activity was found to be slightly greater than that of a bradykinin sample prepared in the laboratory according to the method described by Nicolaides et al.[5,6]

Thus, the method of the condensation of peptides with trifluoroacetate reagents was demonstrated to be useful for the synthesis of complicated peptides.

Experimental*

Anderson's Racemization Test with Reagent III. A solution of carbobenzoxyglycyl-L-phenylalanine (0.8 g., 0.0025 mol.) in pyridine (5 ml.) was cooled to 0°C; a solution of reagent III (0.7 g., 0.0033 mol.) in pyridine (2 ml.) was then slowly added to the above solution. After the mixture had been allowed to stand at room temperature for one hour, water (0.02 ml.) was added to the reaction mixture to destroy any excess reagent. A solution of glycine ethyl ester hydrochloride (0.47 g.,

10) E. D. Nicolaides, H. A. De Wald, P. G. Shorley and H. O. J. Collier, *Nature*, **187**, 773 (1960).

11) Since one carbobenzoxy group in tricarbobenzoxyarginine was found to be susceptible to reagent I in pyridine, the use of the trifluoroacetate method in this case was disadvantageous.

* All melting points given are uncorrected. Each reaction process was checked by thin-layer chromatography.[1]

0.0034 mol.) and triethylamine (0.47 ml., 0.0034 mol.) in chloroform (5 ml.) was then stirred into the reaction mixture, and the mixture was allowed to react for 3 hr. at room temperature. The solvent was removed in vacuo, and a small volume of water was added to the residue to obtain the product as crystals; wt. 0.775 g. (78.3%); m. p. 115—117°C. The whole product was dissolved in absolute ethanol (38 ml.), and the solution was seeded with a small amount of the carbobenzoxyglycyl-DL-phenylalanylglycine ethyl ester and stored in a refrigerator. The crystals which appeared in the solution were collected by filtration at intervals and weighed. The data obtained are given below:

	Time after seeding	Crystals obtained
1)	6.5 hr.	No crystal appeared
2)	25 hr.	0.01 g., m. p. 132—133°C (DL-form)
3)	49 hr.	0.005 g., m. p. 130—133°C (DL-form)

Then the solution was concentrated to 25 ml., and stored in a refrigerator after having been seeded with L-form crystals.

4)	4.5 hr	0.315 g., m. p. 118—121°C
5)	24 hr.	0.15 g., m. p. 118—119.5°C
6)	54 hr.	0.13 g., m. p. 118—119.5°C

The optical rotation of the last three portions was $[\alpha]_D^{22}$ −12.6° (*c* 2, ethanol); lit. m. p. 118—119°C, $[\alpha]_D^{24}$ −12.3° (*c* 2, ethanol).[2] The recovery of the recrystallized whole product was 0.61 g. (79%), which includes 0.015 g. of racemate. When reagent I or II was applied in the same test, three or more hours were necessary for the completion of the ester-exchange reaction in pyridine at room temperature, and the final product was found to be entirely in the DL-form; the yield with reagent I was 81%, while the yield with reagent II was 70%.

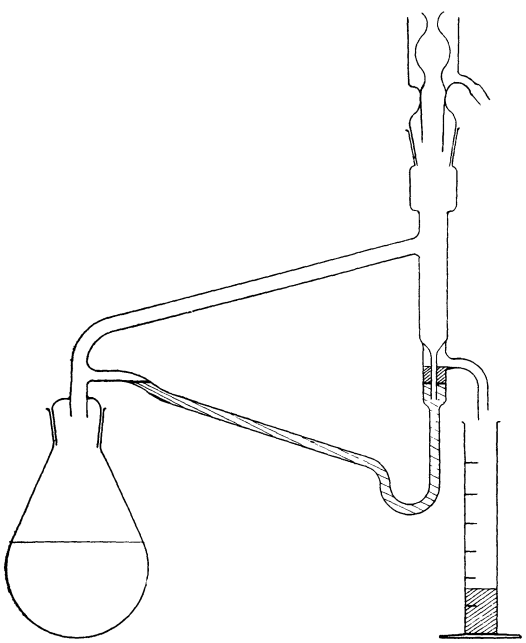

Fig. 2. An apparatus for the azeotropic dehydration with chloroform.

***g*-Nitro-L-arginine Benzyl Ester Ditosylate (IV).**—A mixture of *g*-nitro-L-arginine (11 g., 0.05 mol.), *p*-toluene sulfonic acid mono-hydrate (20 g., 0.1 mol.) and benzyl alcohol (40 ml.) in chloroform (100 ml.) was refluxed for 7—10 hr. in a dehydrating apparatus, as is illustrated in Fig. 2. After concentration to a small volume, the reaction mixture was extracted several times with petroleum ether, and the residue was crystallized by adding ether. The crude product was recrystallized from methanol-ether; wt. 29 g. (88.7%), m. p. 132—134°C, $[\alpha]_D^{24}$ +11.7° (*c* 3, pyridine).

Found: C, 49.40; H, 5.34; N, 10.61. Calcd. for $C_{27}H_{35}O_{10}N_5S_2$: C, 49.60; H, 5.41; N, 10.72%.

***t*-Amyloxycarboxyl-L-phenylalanine *p*-Nitrophenyl Ester (V).**—A solution of *t*-amyloxycarbonyl-L-phenylalanine (2.8 g., 0.01 mol.) in pyridine (5 ml.) was treated with *p*-nitrophenyl trifluoroacetate (2.7 g., 0.012 mol.) for about 2 hr. at room temperature; then water was added to the reaction mixture in order to precipitate the product as crude crystals (3.1 g., 77.5%). It was recrystallized from ethyl acetate and petroleum ether; wt. 2.6 g., yield 65%, m. p. 127—127.5°C, $[\alpha]_D^{24}$ −14.8° (*c* 1.4, ethanol); lit.[3] m. p. 128—129°C, $[\alpha]_D^{21}$ −14.4° (*c* 1.3, ethanol).

***t*-Amyloxycarbonyl-L-phenylalanyl-*g*-nitro-L-arginine Benzyl Ester (VI).**—Compound V (4 g., 0.01 mol.) was added to a solution of IV (6.5 g., 0.01 mol.) and triethylamine (2.8 ml., 0.02 mol.) in dimethylformamide (30 ml.), and the mixture was allowed to react for 60 hr. at room temperature. Then the mixture was diluted with ethyl acetate (about 200 ml.), and the solution was washed successively with water, N ammonia, 0.75 N hydrochloric acid and water, and dried over anhydrous sodium sulfate. The evaporation of the solvent left a crude product, which was recrystallized from ethyl acetate and petroleum ether; wt. 5.1 g. (ca. 90%), m. p. 120—124°C, $[\alpha]_D^{23}$ −15.8° (*c* 3, ethanol).

Found: C, 59.05; H, 6.44; N, 14.39. Calcd. for $C_{28}H_{38}O_7N_6$: C, 58.93; H, 6.71; N, 14.73%.

***t*-Amyloxycarbonyl-L-prolyl-L-phenylalanyl-*g*-nitro-L-arginine Benzyl Ester (VII).**—Compound VI (2.5 g., 0.0044 mol.) was treated with trifluoroacetic acid (5 ml.) for 30 min. at room temperature, and then the product was precipitated by adding dry ether. It was collected by filtration, washed with ether, and dried over sodium hydroxide in vacuo. *t*-Amyloxycarbonyl-L-proline (1.01 g., 0.0044 mol.) was treated with I (1.25 g., 0.0053 mol.) in pyridine (5 ml.) for about 2 hr. at room temperature, and then a solution of L-phenylalanyl-L-nitroarginine benzyl ester trifluoroacetate (2.5 g., 0.0044 mol.), prepared as described above, and triethylamine (1.36 ml., 0.0097 mol.) in dimethylformamide (55 ml.) was added to the reaction mixture. After it had stood for 2 days at room temperature, the reaction mixture was diluted with ethyl acetate. The diluted solution was washed successively with water, N ammonia, 0.75 N hydrochloric acid and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated to a syrup which was solidified by trituration with ether. The product was reprecipitated from ethyl acetate and ether; wt. 2.64 g. (90.5%), m. p. 80—86°C, $[\alpha]_D^{21}$ −39.6° (*c* 1, ethanol).

Found: C, 59.86; H, 6.79; N, 14.24. Calcd. for $C_{33}H_{45}O_8N_7$: C, 59.35; H, 6.79; N, 14.68%.

***t*-Amyloxycarbonyl-L-phenylalanyl-L-serine**

Methyl Ester (VIII).—Compound V (4 g., 0.01 mol.) and L-serine methyl ester hydrochloride (1.6 g., 0.01 mol.) were dissolved in dimethylformamide (35 ml.), and then triethylamine (1.4 ml., 0.01 mol.) was added to the mixture. After 20 hr. at room temperature, the reaction mixture was diluted with ethyl acetate (300 ml.), and the solution was washed successively with water, N ammonia, 0.75 N hydrochloric acid and water, and dried over sodium sulfate. The dried solution was concentrated to a syrup, which was then solidified with petroleum ether. The product was reprecipitated as an amorphous powder from ethyl acetate-petroleum ether; wt. 3.7 g., (97.5%), m. p. 60—90°C, $[\alpha]_D^{25}$ −3.2° (*c* 1, dimethylformamide).

Found: C, 59.82; H, 7.46; N, 7.34. Calcd. for $C_{19}H_{28}O_6N_2$: C, 59.98; H, 7.42; N, 7.36%.

***t*-Amyloxycarbonyl-L-phenylalanyl-L-serine Hydrazide (IX).**—Compound VIII (4.2 g., 0.011 mol.) was dissolved in ethanol (9 ml.), and then 90% hydrazine hydrate (1.7 ml.) was added to the solution. After about 2 hr. at room temperature, the crystals (needles) which appeared were collected by filtration and recrystallized from ethanol; wt. 3.35 g. (88%), m. p. 175—177°C, $[\alpha]_D^{25}$ −4.0° (*c* 1, dimethylformamide).

Found: C, 56.44; H, 7.27; N, 14.66. Calcd. for $C_{18}H_{28}O_5N_4$: C, 56.82; H, 7.42; N, 14.73%.

***t*-Amyloxycarbonyl-L-phenylalanyl-L-seryl-L-prolyl-L-phenylalanyl-*g*-nitro-L-arginine Benzyl Ester (X).**—Compound VII (2 g., 0.003 mol.) was treated with trifluoroacetic acid (4 ml.) for 30 min. at room temperature, and then the product was precipitated by adding dry ether. The precipitate was collected by filtration, washed well with ether, and dried over sodium hydroxide in vacuo; wt. 2.06 g. A solution of compound IX (1.03 g., 0.0027 mol.) in dimethylformamide (10 ml.) was cooled to −10°C; 2 N hydrochloric acid (2.73 ml., 0.0055 mol.) was stirred into the chilled solution and then a solution of sodium nitrite (0.207 g., 0.003 mol.) in water (1.5 ml.) was carefully added to the mixture at −10—−15°C. After about 15 min., a solution of previously-prepared tripeptide benzyl ester trifluoroacetate, dissolved in a mixture of dimethylformamide (3 ml.) and chloroform (8 ml.), was added to the reaction mixture, and then the pH was adjusted to 8 with triethylamine (about 0.84 ml.). Stirring was continued for 3 hr. at −10°C, and subsequently for 2 hr. at 0°C. During this period, the pH of the solution was maintained at 8 by adding triethylamine. The mixture was then stored in a refrigerator for 20 hr., after which the product was extracted thoroughly with ethyl acetate. The extracts were combined and washed well with N sodium bicarbonate, 0.75 N hydrochloric acid and water, and dried over sodium sulfate. The dried solution was concentrated to a syrup, and this was reprecipitated twice from methanol and ether as an amorphous powder; wt. 1.7 g. (70%), m. p. 100—115°C, $[\alpha]_D^{22}$ −38.2° (*c* 0.5, dimethylformamide).

Found: C, 59.85; H, 6.76; N, 14.17. Calcd. for $C_{45}H_{59}O_{11}N_9$: C, 59.92; H, 6.60; N, 13.98%.

***t*-Amyloxycarbonyl-L-prolyl-L-proline (XI).**—Reagent I (0.71 g., 0.003 mol.) was added to a solution of *t*-amyloxycarbonyl-L-proline (0.57 g., 0.0025 mol.) in dry pyridine (1.5 ml.) at room temperature. After about 2.5 hr., the excess reagent was destroyed with one small drop of water, and then a solution of L-proline benzyl ester hydrochloride (0.67 g., 0.0028 mol.) and triethylamine (0.385 ml., 0.0028 mol.) in chloroform (2.5 ml.) was added to the above reaction mixture. One more equivalent of triethylamine (0.4 ml.) was added to the mixture, which was then allowed to react for 3 days at room temperature. Then it was concentrated to a residue, which was dissolved in ethyl acetate (about 100 ml.); the solution was washed successively with N ammonia, 0.75 N hydrochloric acid and water, and dried over sodium sulfate. The dried solution was concentrated to a syrup, which was dissolved in methanol (20 ml.), and a small amount of palladium black was added to the solution. Hydrogen was bubbled through the solution for about 2 hr. with stirring, and then the catalyst was removed by filtration. The filtrate was concentrated to a syrup, and the material was crystallized by adding ether. The recrystallization of the product from ethyl acetate - petroleum ether gave prisms; wt. 0.66 g. (81%), m. p. 155—158°C, $[\alpha]_D^{21}$ −112.8° (*c* 1, ethanol).

Found: C, 58.97; H, 8.00; N, 8.53. Calcd. for $C_{16}H_{26}O_5N_2$: C, 58.88; H, 8.03; N, 8.58%.

***t*-Amyloxycarbonyl-L-prolyl-L-prolylglycine (XII).**—a) Compound XI (6.5 g., 0.02 mol.) and glycine benzyl ester tosylate (6.75 g., 0.02 mol.) were dissolved in chloroform (100 ml.), and triethylamine (2.8 ml., 0.02 mol.) was added to the mixture. After dicyclohexylcarbodiimide (4.12 g., 0.02 mol.) had been slowly added to the mixture, it was allowed to react for one day at room temperature. The urea formed was removed by filtration, and the filtrate was concentrated to a residue, which was then redissolved in ethyl acetate (about 100 ml.). This solution was washed successively with N sodium bicarbonate, N hydrochloric acid and water, and dried over anhydrous sodium sulfate. The dried solution was subjected to the hydrogenation procedure described above, and the final product was obtained as fine prisms which were dried over sulfuric acid in vacuo at room temperature; wt. 6.15 g. (80.5%), m. p. 109—112°C, $[\alpha]_D^{21}$ −132.8° (*c* 1, ethanol).[12]

Found: C, 53.70; H, 7.81; N, 10.49. Calcd. for $C_{18}H_{29}O_6N_3 \cdot H_2O$: C, 53.85; H, 7.78; N, 10.48%. The same sample was dried over phosphorous pentoxide in vacuo at 110°C for 3 hr. to remove the water of crystallization.

Found: C, 56.14; H, 7.56; N, 11.15. Calcd. for $C_{18}H_{29}O_6N_3$: C, 56.38; H, 7.62; N, 10.96%.

b) A solution of XI (0.815 g., 0.0025 mol.) in dry pyridine (1.8 ml.) was treated with reagent I, II or III at room temperature for 1—5 hr. until the ester-exchange reaction was complete; this was checked by thin-layer chromatography. Then a solution of glycine benzylester tosylate (0.93 g., 0.0028 mol.) and triethylamine (0.39 ml., 0.0028 mol.) in dimethylformamide (1.5 ml.) was added to the reaction mixture, and in the cases of reagents I and II, one more equivalent of triethylamine (0.4 ml.) was also added to the reaction mixture. After about 3 or 4 days, ethyl acetate (100 ml.) was added to the reaction mixture, and the solution was washed successively with N ammonia, 0.75 N hydrochloric acid and water, and dried over sodium sulfate. After the dried solution had been concentrated to a residue, it was dissolved in methanol (about 30 ml.), and then a small amount of palladium black was added to the

solution. Hydrogen was bubbled through the solution for about 3 hr., and then the catalyst was removed by filtration. The filtrate was concentrated to a syrup, and the material was crystallized from ethyl acetate and petroleum ether. The results are listed below.

Reagent	Weight	m. p.	$[\alpha]_D^{23}$ (c 1, ethanol)[12]
I	0.84 g. (88%)	110—113°C,	−132.8°
II	0.59 g. (62%)	109—112°C,	−132.5°
III	0.82 g. (86%)	110—112°C,	−132.2°

***t*-Amyloxycarbonyl-L-prolyl-L-prolylglycyl-L-phenylalanyl-L-seryl-L-prolyl-L-phenylalanyl-*g*-nitro-L-arginine Benzyl Ester (XIII).**—Compound X (0.72 g., 0.8 mmol.) was dissolved in trifluoroacetic acid (2 ml.), and after about 30 min. at room temperature, the product was precipitated by adding dry ether, collected by filtration, and dried over sodium hydroxide in vacuo; wt. 0.7 g. A solution of the dried compound, XII (0.33 g., 0.86 mmol.), in pyridine (0.8 ml.) was treated with reagent I (0.3 g., 1.3 mmol.) for 2—3 hr. at room temperature. Then one small drop of water was added to the reaction mixture in order to destroy any excess reagent, and a solution of the previously-prepared pentapeptide benzylester trifluoroacetate (0.7 g.) and triethylamine (0.33 ml., 2.36 mmol.) in dimethylformamide (6 ml.) was added to the mixture. After about 24 hr. at room temperature, the reaction mixture was diluted with ethyl acetate (about 200 ml.) and the solution was washed successively with N ammonia, 0.75 N hydrochloric acid and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated to a residue, which was triturated well with ether to obtain an amorphous powder. The product was reprecipitated from ethyl acetate and ether; wt. 0.69 g. (77%), m. p. 125—130°C, $[\alpha]_D^{22}$ −46.8° (c 0.5, dimethylformamide).

Found: C, 58.87; H, 6.61; N, 14.52. Calcd. for $C_{57}H_{76}O_{14}N_{12}$: C, 59.36; H, 6.64; N, 14.58%.

When reagent III was used instead of I, the yield of the product was 76%.

Tricarbobenzoxy-L-arginyl-L-prolyl-L-prolylglycyl-L-phenylalanyl-L-seryl-L-prolyl-L-phenylalanyl-*g*-nitro-L-arginine Benzyl Ester (XIV).—Compound XIII (0.2 g., 0.17 mmol.) was dissolved in trifluoroacetic acid (0.4 ml.), and after 40 min. the product was precipitated by adding dry ether. The precipitate was collected by filtration, washed well with ether, and dried over sodium hydroxide in vacuo; wt. 0.2 g. After the dried material had been dissolved in dimethylformamide (3.5 ml.), the tricarbobenzoxy-L-arginine *p*-nitrophenyl ester[10] (0.121 g., 0.175 mmol.) and triethylamine (0.0243 ml., 0.17 mmol.) were added to the solution. After one day at room temperature dry ether was added to the reaction mixture, and the precipitate which formed was washed well with ether by means of decantation. The residue was triturated with ethyl acetate, and then dissolved in chloroform. The solution was washed with water, N hydrochloric acid and water, and dried over anhydrous sodium sulfate. The dried solution was concentrated to a syrup under reduced pressure, and the remaining syrup was crystallized from ethyl acetate and ether. For purification the precipitation procedure from ethyl acetate and ether was repeated; wt. 0.17 g. (61%); m. p. 115—118°C, $[\alpha]_D^{22}$ −44.5° (c 0.5, dimethylformamide).

Found: C, 60.73; H, 6.23; N, 13.93. Calcd. for $C_{81}H_{96}O_{19}N_{16}$: C, 60.89; H, 6.06; N, 14.03%.

Bradykinin Triacetate.—Compound XIV (25 mg.) was dissolved in a mixture of acetic acid (3 ml.) and methanol (2 ml.), and a small amount of freshly-prepared palladium black was added to the solution. Hydrogen was bubbled through it for about 10 hr., until the absorption band of the solution at 267 mμ disappeared. This was measured at a concentration of 0.1 mg./5 ml. Then the catalyst was removed by filtration, and the filtrate was concentrated to a syrup under reduced pressure at room temperature. The residue was dissolved in water (15 ml.) and lyophilized. The product was completely colorless (wt. 16.7 mg.), and it was found to be homogeneous without any further purification. The homogeneity was tested by paper electrophoresis (pH 4.75, pH 3.5, pH 8.8) and by paper chromatography (BuOH : AcOH : H_2O=4 : 1 : 1, 80% pyridine, *t*-BuOH : AcOH : H_2O=2 : 1 : 1), using ninhydrin and Sakaguchi reagents respectively. The amino acid ratio in a hydrolyzate prepared with 6 N hydrochloric acid was as follows: Arg, 1.98; Pro, 2.89; Gly, 1.04; Phe, 1.96; Ser, 1.00. For analysis this material was dried at 110°C in vacuo over phosphorous pentoxide for 18 hr. About 13% of the weight was reduced during the procedure.

Found: C, 54.30; H, 7.01; N, 17.10. Calcd. for $C_{50}H_{73}O_{11}N_{15}\cdot 3CH_3COOH$: C, 54.22; H, 6.91; N, 16.94%.

The biological activity of this material was determined by the guinea-pig ileum contraction test;[13] it was thus found to be 1.4 times more than that of a sample prepared in this laboratory by the procedure of Nicolaides et al.[5,6]

The authors wish to express their thanks to Professor Tomoji Suzuki for determining the biological activity of the synthetic material.

12) The concentration was calculated in a dry base.

(Received December 4, 1965)

Alternaria Kikuchiana Tanaka is a fungus which produces a black spot disease in pears. The metabolite of this fungus contains a phytopathogenic substance for which the name "Altenin" has been proposed. A drop of an aqueous solution of altenin (2×10^{-5} mg./ml.) produces a black spot on pear leaves. The stability of altenin at 80, 60, and 40°C, and the behavior of altenin in relation to some adsorbents and solvents, were studied. Its isolation from the culture filtrate was found to be properly accomplished by adsorption with active charcoal, elution with acetone, and chromatography with silica gel and alumina columns. By these procedures, besides altenin, six metabolites, diheptyl phthalate, myristic acid, succinic acid, and the ester of C_{15}-carboxylic acid, C_{19}-steroid and trihydroxy anthraquinone, were obtained.

Alternaria Kikuchiana Tanaka is a fungus which is phytopathogenic to pears especially to the improved sort of *Pyrus Ussuriensis var. Aromatica* Rehder (Japanese name *Nijusseiki*).[1] On the leaves and fruits of the pears, it produces a black spot disease.[2] When the culture broth of this fungus, or ethyl ether or an ethyl acetate extract of the culture, is put on the plucked leaves of the pear, a similar black spot grows along the veins of the leaf. These phenomena suggest that there is some pathogenic substance in the metabolite of this fungus.[3] This substance was called "Altenin."[4] This paper will deal with the isolation of altenin and with some of its chemical properties.

Results and Discussion

As the first step, the stability of altenin was examined.[3] Its aqueous solution (pH 7.5) lost its pathogenic activity in 10 min. at 80°C, and in an hour at 60°C, but kept it for several hours at 40°C, as is shown in Table I. When the acetone solution with silica gel or alumina was left standing at room temperature, no change in activity was observed over a period of several hours. Further, the activities of the solutions in organic solvents, such as benzene, acetone, ethyl ether, methanol, ethanol or ethyl acetate, did not change at room temperature over a period of several hours.

TABLE I. THE STABILITY OF ALTENIN IN AQUEOUS SOLUTION (pH 7.5)

Time min.	40°C	60°C	80°C
0	18.6	18.6	7.4 (mm²)
5	17.8	19.8	2.3
10	19.2	21.2	0.5
20	9.1	11.0	0
40	12.7	4.8	0
80	17.9	3.2	0

The isolation and purification of altenin was attemped by two routes. In the first, it was extracted with ethyl acetate from the culture filtrate and then purified through silica gel-column chromatography. By this procedure, besides the active substance, five inactive metabolites, diheptyl phthalate, myristic acid, the ester of C_{15}-carboxylic acid, C_{19}-steroid and trihydroxy anthraquinone were obtained.

In the second route, the adsoption, extraction and chromatography were employed. Several adsorbents and eluting solvents were tested. The

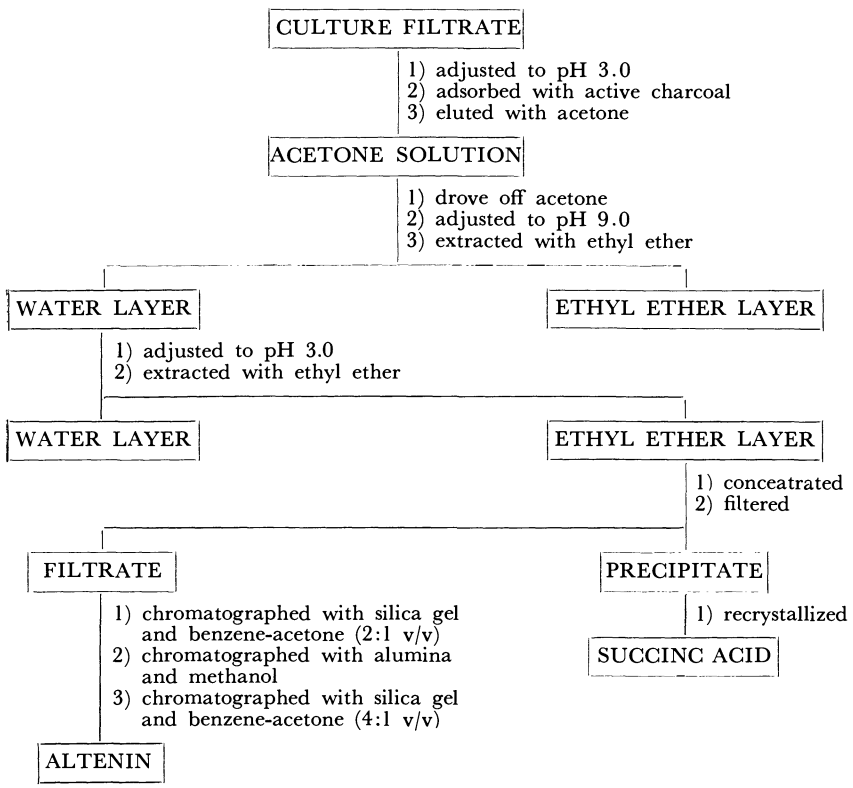

Fig. 1. Isolation of altenin.

results of these experiments are shown in Tables II and III. It was found that the most effective adsorbent was the active charcoal; from it acetone could elute altenin most effectively. By this procedure, besides altenin, succinic acid was obtained.

Altenin was also extracted with ethyl ether from the culture filtrate, which had been adjusted to pH 3 with hydrochloric acid. The distribution coefficients, K, of altenin at 20°C between ethyl ether and water were measured by the counter-current distribution method; they were found to be as follows: >10 (pH 3.5), 5 (pH 5.0), 2 (pH 5.5), 1 (pH 6.0) and <0.1 (pH 9.0).

By applying these results, altenin was isolated by the process illutsrated schematically in Fig. 1. One milligram of altenin was obtained from about 4 l. of the culture filtrate. One drop of an aquoeus solution of altenin (2×10^{-5} mg./ml.) exhibited a distinct phytopathogenic effect.

Altenin is a yellow liquid which gives only one spot on silica-gel thin-layer chromatography with a benzene-acetone (1 : 1 v/v) mixture; its R_f value was 0.76, while that of methyl red, a pilot dye, was 0.37. On alumina thin-layer chromatography with a methanol-water (5 : 1 v/v) mixture, its R_f value was 0.87, while that of methyl red was 0.41. The spot of the thin-layer chromatogram was developed by heating it after it had been

sprayed with concentrated sulfuric acid or with a *o*-dianisidine solution. By this method, it was demonstrated that altenin was the unique phytopathologically active substance in the metabolites of the fungus *Alternaria Kikuchiana* Tanaka.

The details of the cultivation of this fungus and the chemical studies of altenin will be reported on in the near future.

Experimental

The Cultivation of *Alternaria Kikuchiana* Tanaka (No. 5).—Though this fungus had previously been cultivated in stationary cultivation,[5] altenin enough for chemical study could not be obtained by this method. After many trial experiments, the following method was found to be effective.

A 200-l. tank fermenter was employed; it was charged with 120 l. of an aqueous solution of 4% sucrose, 0.2% dibasic ammonium phosphate, 1.1% monobasic potassium phosphate, 0.05% magnesium sulfate and 0.05% potassium chloride.

During cultivation, rotary stirring was effected, the temperature was maintained at 30°C, and air (20 l./min.) was bubbled in continuously. On the third day, a small quantity of silicon oil was added as an antifoam agent. On the ninth day, the culture broth exhibited a pH value of 3.0 and the maximum altenin activity. At this point the cultivation was stopped.

The Black-spots Test.—Fresh, young leaves of *Pyrus Ussuriensis var. Aromatica* Rehder (Japanes name *Nijusseiki*) were employed for this test. When an ethyl ether extract of the culture filtrate (270 ml.) was concentrated under a diminished pressure, a residue (85 mg.) was obtained. This residue was dissolved in an ammonium acetate-buffered (pH 8.0) solution, the concentrations of which were 85, 17, 3.4 and 0.7 mg./ml. A drop of each of these four solutions was put on the pear leaf. After 17 hr. at 23°C, the areas of the black spots were measured (Fig. 2).

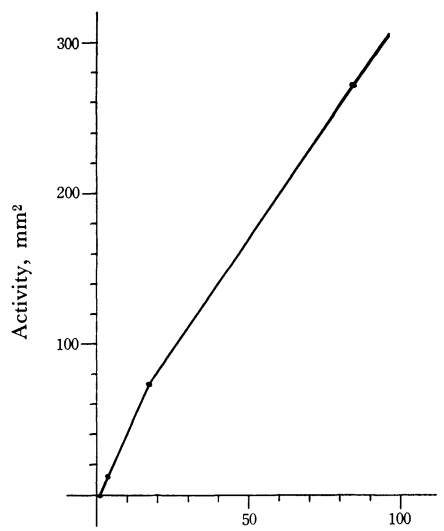

Fig. 2.

The Stability of Altenin.—The culture filtrate was heated to 40, 60, and 80°C for 80 min. and then the change in altenin activity was measured by the black spots test. At 40°C, the activity was observed for several hours. At 60°C, however the activity was lost in 40 min. and at 80°C in 10 min. The results are listed in Table I. However, altenin was stable for 2 days at room temperature, even when air was passed through the altenin aqueous solution.

The Isolation of Altenin (Route 1.)—The culture filtrate (130 l.) was extracted with ethyl acetate (13 l.). After the ethyl acetate had been removed under reduced pressure, the residue (40 g.) was passed through the silica gel (Wakogel C-2) column with benzene (fraction A) and with acetone (fraction B). After the evaporation of the benzene, the residue of fraction A (12.3 g.) was passed through the silica gel (Wakogel C-2) column with a benzene-acetone (20 : 1 v/v) mixture (fraction C) and with acetone (fraction D). The evaporation residue from the fraction C was chromatographed with silica gel (Merck 7729) and with a benzene-acetone (2 : 1 v/v) mixture; a yellow fluorescent elution contained 7 mg. of crude altenin, which showed spots with R_f values of 0.60, 0.70 and 0.78 on silica-gel (Wakogel B-5) thin-layer chromatography with a benzene-acetone (1 : 1 v/v) mixture.

During the above mentioned procedures, the following five metabolites were isolated.

Diheptyl Phthalate.—The residue from the fraction D was chromatographed with silica gel (Wakogel C-2) and with a benzene-acetone (1 : 1 v/v) mixture. A colorless liquid was thus obtained, b. p. 332—337°C.

Found: C, 72.89; H, 9.45; mol. wt. (Rast), 360. Calcd. for $C_{22}H_{34}O_4$: C, 73.23; H, 8.95%; mol. wt., 362.5.

From the infrared absorption spectrum, this substance was presumed to be an ester of some aromatic carboxylic acid. Liquid-gas chromatography suggested that the hydrolysate of this substance consisted of one alcohol and one aromatic acid. This acid was sublimed to a crystalline substance, m. p. 129°C, which was identified with phthalic anhydride. From these results alcohol was proved to be a heptanol. Therefore, the original substance was diheptyl phthalate.

Myristic Acid.—The fraction C was chromatographed through the silica gel (Merck 7729) column with a benzene-acetone (2 : 1 v/v) mixture. The solid substance which remained after the solvent had been removed from the first elution was recrystallized from aqueous acetone, m. p. 51.5°C; its infrared absorption spectrum showed absorptions at 1700 ($\nu_{C=O}$), 1290 (δ_{C-O}) and 940 cm^{-1} (δ_{C-O}). This substance with myristic acid.

An Ester of C_{15}-Carboxylic Acid.—By the chromatography of the fraction C with silica gel (Merck 7729) and chloroform, a liquid metabolite was isolated. Its infrared absorption spectrum showed the ester carbonyl group at 1740 cm^{-1}. By hydrolysis, a free carboxylic acid, m. p. 50.5°C, was obtained. The reaction of this substance with benzyl amine produced the *N*-benzyl amide, m. p. 88.5°C.

Found: C, 79.64; H, 11.17; N, 3.83; mol. wt.

5) R. Mohri and S. Ikeda, *The Liberal Arts Journal of Natural Science of Tottori University (Tottori Daigaku Gakugei Gakubu Kenkyu Hokoku)*, **10**, 38 (1960).

(Rast), 330. Calcd. for $C_{22}H_{37}NO$: C, 79.70; H, 11.25; N, 4.23%; mol. wt., 331.5.

It was suggested that this metabolite was an ester of C_{15}-saturated carboxylic acid.

C_{19}-Steroid.—After chromatography with silica gel (Wakogel C-2) and with a benzene-acetone (20 : 1 v/v) mixture, fraction A gave a solid material, which was then recrystallized from aqueous methanol. Colorless needles (11 mg.; m. p. 180°C) were obtained from 1.2 l. of the culture filtrate.

Found: C, 78.64; H, 10.35; mol. wt. (Rast), 301. Calcd. for $C_{19}H_{30}O_2$: C, 78.57; H, 10.41%; mol. wt., 290.4.

Its infrared absorption spectrum showed absorptions at 3450 (νOH), 1630 ($\nu_{C=C}$), 2950 and 2850 cm^{-1} (νCH), while the ultraviolet absorption spectrum showed a maximum at 230 mμ (ε 690) in ethanol, and at 257 (ε 20000), 253 (ε 18000), 262 (ε 14000), 375 (ε 2000) and 522 mμ (ε 9600) in concentrated sulfuric acid.[6] The color reactions of this substance were as follows: Liebermann-Burchard's reaction,[7] green; Salkowski's reaction,[8] red; Rosenheim's reaction,[9] green; Kägi-Miescher's reaction,[10] violet. These color reactions suggested the presence of an unsaturated steroid. By acetylation with acetic anhydride and pyridine, a mono acetate, m. p. 201°C, was obtained.

Found: C, 75.70; H, 9.66. Calcd. for $C_{21}H_{32}O_3$: C, 75.86; H, 9.70%.

2, 8-Dihydroxy-1-hydroxymethyl-9, 10-anthraquinone.—The solvent of the blue fluorescent elution from the silica gel (Wakogel C-2) chromatography of the fraction A with a benzene-acetone (20 : 1 v/v) mixture was removed. When the residue was then sublimed, pale yellow needles, m. p. 269°C (decomp.), were obtained.

Found: C, 64.78; H, 4.60; mol. wt. (Rast), 230. Calcd. for $C_{15}H_{10}O_5$: C, 66.67; H, 3.73%; mol. wt., 270.2.

The infrared absorption spectrum showed absorptions at 3420, 3350, 1665, 1620, 1590, 980, 850, 830 and 740 cm^{-1},[11] while the ultraviolet absorption spectrum showed its maxima at 257 (ε 49700), 289 (ε 10400), 300 (ε 10200) and 340 mμ (ε 11500) in ethanol,[3,12,13] these values shifted in an alkaline solution to 265 (ε 37600), 314 (ε 11300) and 370 mμ (ε 16600), and a pK_a value of 9.6 was obtained by a spectrometric method. This substance showed a negative color reaction with zirconium nitrate. This substance was methylated with diazomethane to a methylated substance, m. p. 177°C. These data suggested that this substance was possibly 2, 8-dihydroxy-1-hydroxymethyl-9, 10-anthraquinone.

The Test of an Adsorbent and an Eluting Solvent.—To each 1 l. of the culture filtrate, adsorbents, calcium carbonate, animal charcoal, hyflosupercel and active charcoal, in the amounts shown in Table II, were added; they were then stirred for one hour at room temperature. After the adsorbent had been filtered off with a suction pump, the altenin activity of the filtrate was examined. The activity was then compared with that of the original culture filtrate. The results are listed in Table II. Each filtered adsorbent in the preceding experiments was air dried and divided into ten equal parts. Each of these parts was added to a test solvent (10 ml.) and stirred for one hour at room temperature. After the adsorbent had been filtered off, the solvent was evaporated off under reduced pressure. To each residue there was added 100 ml. of a buffer solution of ammonium acetate adjusted to pH 7.8. The altenin activity of each solution was tested on the leaves of the pear, and it was compared with the altenin activity of the original culture filtrate. The results are expressed in percentages in Table III. Because of its greater volatility and greater eluting power, acetone was the most suitable eluting solvent.

The Distribution Coefficient of Altenin.—The ethyl ether extract of the culture filtrate was subjected to the counter-current distribution at 20°C with ethyl ether and aqueous solutions of various pH values. For the sake of simplicity, only ten tubes were used. From the altenin activity of each layer, the distribution coefficient, K, was calculated to be as shown in Table IV.

The Isolation of Altenin (Route 2).—A process for the isolation of altenin from the culture filtrate is schematically showed in Fig. 1. The culture filtate (101.) was adjusted to pH 3.0; then active charcoal (100 g.) was added, and the mixture was stirred for five hours. The active charcoal was filtered, and on it the pathogenic substance was adsorbed. After it had been dried in the air, the active charcoal was eluted with acetone (1 l.), and the acetone solution was concentrated to ca. 200 ml. under reduced pressure at 35—40°C in a nitrogen atomsphere. The residual solution was adjusted to pH 9.0 with aqueous ammonia, and the dusty substance was filtered off. This alkaline solution was extracted with ethyl ether (100 ml.). The aqueous layer was adjusted to pH 3.0 with dilute hydrochloric acid, and extracted with three 70 ml. portions of ethyl ether. The combined ethyl ether extracts were then dried over anhydrous sodium sulfate. On the removal of the solvent under reduced pressure at 35—40°C, the residue (170 mg.) was obtained. It was dissolved in a cold mixture of benzene and acetone (2 : 1 v/v) and filtered. The precipitate was recrystallized from ethyl ether, m. p. 183°C, which was identified with succinic acid. The filtrate was passed through a silica-gel (Merck 7729) column with a benzene-acetone (2 : 1 v/v) mixture. The blue fluorescent elution which was obtained was again passed through an alumina (Wako alumina) column with methanol. (The alumina had been deactivated with 6.7 per cent of water before use.) The methanol elution was then again passed through a silica-gel (Merck 7729) column with a benzene-actone (4 : 1 v/v) mixture. Altenin (2.5 mg.) was thus obtained as a yellow liquid.

14) R. Wasicky and O. Frehden, *Mikrochim. Acta*, **1**, 55 (1937).

Altenin showed a spot on silica-gel (Wakogel B-5) thin-layer chromatography with a benzene-acetone (1 : 1 v/v) mixture; the R_f value was 0.76, while that of methyl red, a pilot dye, was 0.37. On alumina (Merck 1090) thin-layer chromatography with a methanol-water (5 : 1 v/v) mixture, the R_f value was 0.87, while that of methyl red was 0.41. Altenin was developed on thin-layer chromatography by heating it over 80°C for one hour after it had been sprayed with concentrated sulfuric acid. Altenin was developed to yellow by heating it after it had been sprayed with an *o*-dianisidine solution.[14]

The Activity of Altenin.—The phytopathogenic activity of aqueous solutions of altenin with concentrations of 1×10^{-4}, 2×10^{-5}, 5×10^{-6} mg./ml. were examined by the black-spots test; it was found that the lower limit of the pathogenic activity was about 2×10^{-5} mg./ml.

The Test of the Pathogenic Activity of Other Metabolites.—The ethyl ether extract of the culture filtrate was developed by silica-gel (Wakogel B-5) thin-layer chromatography with a benzene-acetone (1 : 1 v/v) mixture; the chromatogram was divided into ten parts: R_f value, 0—0.1; 0.1—0.2; ··· ; 0.8—0.9; 0.9—1.0. Each part of the silica gel was eluted with acetone (5 ml.), and the elution was concentrated under reduced pressure. The residues obtained were each diluted to 0.1 ml. with an aqueous buffer solution of ammonium acetate (pH 7.4). The pathogenic activity of these solutions were then examined by the black-spots test. Only the solution from the R_f 0.5—0.6 division, which contained altenin, exhibited the black spot on a pear leaf.

The authors wish to express their thanks to Professor Tatsukichi Kobayashi and Dr. Isei Nakamura, Department of Agriculture, Tokyo Kyoiku University, for their kind advice and for their generous permission to use the 200 l. fermenter there. The authors also wish to thank Mr. Kazutoshi Koyama for a generous supply of the fresh young pear leaves.

The Photochemical Reactions of Ethylene Glycol and Its Ethers in the Presence of Ferric Chloride

By Hiroo INOUE, Kentaro TAMAKI, Nobuyuki KOMAKINE and Eiji IMOTO

Department of Applied Chemistry, College of Engineering, The University of Osaka Prefecture, Sakai, Osaka

(Received December 8, 1965)

The photochemical reactions of ethylene glycol, ethylene glycol monomethyl ether and ethylene glycol dimethyl ether with ferric chloride have been carried out under a nitrogen atmosphere and with irradiation by ultraviolet light. These reactions have involved the cleavage of the carbon-carbon bond to give formaldehyde and chloromethyl methyl ether; of the carbon($-CH_2-$)-oxygen bond to give acetaldehyde, methanol and water, or of the carbon(CH_3-)-oxygen and hydrogen-oxygen bonds to give methane, ethane, hydrogen chloride and methyl chloride. Furthermore, they have been accompanied by the photo-reduction of ferric chloride to ferrous chloride. From these results, it has been assumed that ferric chloride acts as an oxidizing reagent and Lewis acid in the photochemical reactions.

It has well been known that a transition metal ion can serve as an oxidation-reduction or Lewis acid reagent in some thermal reactions. Recently, an interest in the behavior of a transition metal ion in the photochemical reactions has been taken by several investigators. The catalysis of the photo-oxidation of ethanol by copper ions,[1] and the photochemical reactions of peresters in the presence of copper ions, have been reported on.[2] The properties of a transition metal ion in the excited state would be different from those in the normal state, and an excited transition metal ion may have a characteristic effect on a substrate through the formation of a transition metal ion-substrate complex. In this paper, we will describe our studies of the photochemical reactions of ethylene glycol and its ethers with ferric chloride under a nitrogen atomosphere. Ethylene glycol and its ethers were chosen in this study because their photo-oxidation by oxygen has well been studied in our previous paper.[3]

Experimental

Meterials.—Anhydrous ferric chloride, ethylene glycol and ethylene glycol monomethyl ether were of a commercial grade. Ethylene glycol dimethyl ether

1) H. R. Cooper and B. M. Talbot, *Trans. Faraday Soc.*, **61**, 506 (1965).
2) G. Sonsnovsky, *J. Org. Chem.*, **28**, 2934 (1963).
3) H. Inoue, K. Tamaki and E. Imoto, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **69**, 654 (1966).

was prepared according to the methods described in the literature.[4] These materials were purified by the manner described in a previous paper.[3]

The Procedure of the Photo-reaction.—A weighed amount of ferric chloride was dissolved into an appropriate amount of ethylene glycol or its ethers. This solution was then introduced into a cylindrical reaction vessel with a capacity of about 250 ml., and a 100 W. mercury lamp with a water-cooling jacket was placed in this vessel. After nitrogen gas had been bubbled in for about 5 min., the vessel was connected with a gas burette, the air space of which had previously been filled with nitrogen gas. The solution was then irradiated for 24 hr.

The Analysis of the Products.—The analysis of the products was mainly accomplished by means of gas chromatography (g. c.), using a Hitachi KGL-2 gas chromatograph. The irradiated solution was analyzed by immediately withdrawing 5 to 10 μl. of the solution into a syringe. A column containing polyethylene glycol-1600 and/or high vacuum silicon grease was used in the g. c. analyses. The major product peaks in the gas chromatogram were identified by a comparison of their retention times with those of authentic materials, if possible. Acetaldehyde, acetaldehyde ethylene acetal and methanol were identified by the methods described in the previous paper.[3] Chloromethyl methyl ether and ethylene glycol dimethyl ether were identified by trapping the materials from the column, and by then comparing the infrared spectra of the trapped materials with those of authentic materials. Besides the analyses by g. c., the total amounts of the compounds containing carbonyl groups were determined as their 2, 4-dinitrophenylhydrazones (2, 4-D.). The components of 2, 4-D.'s were identified by paper chromatography according to Horner's method.[5] Here, the 2, 4-D.'s of acetaldehyde and formaldehyde were confirmed to be the main components.

The Spectrophotometric Study of the Photo-reaction.—Solutions of 0.05 mol. of ferric chloride in 20 ml. of ethylene glycol, ethylene glycol monomethyl ether or ethylene glycol dimethyl ether were introduced into a spherical ampule (2 cm. radius). The sample solutions were cooled with a dry ice - acetone bath; the air was removed under the reduced pressure of 1—2 mmHg, and then the ampule was filled with nitrogen gas. After the procedure of the replacement by nitrogen gas had been repeated 4—5 times, the sample solution was poured into a reaction cell, which consisted of a spectrophotmeter cell (1 × 1 × 4 cm.) and the upper part of which was connected to the above ampule. The apparatus used is shown in Fig. 1. The cell was irradiated at a distance of 4 cm. from a light source, a 100 W. mercury lamp, at room temperature. At various time intervals, the sample cell was taken out and the absorption spectra were measured with a Hitachi spectrophotometer.

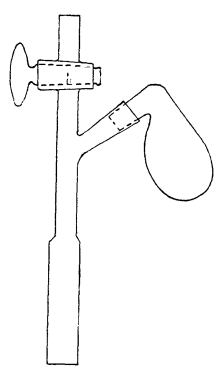

Fig. 1. Spectrophotometer cell.

Results and Discussion

Spectrophotometric Studies. — The visible absorption spectra of ferric chloride in ethylene glycol, ethylene glycol monomethyl ether and ethylene glycol dimethyl ether showed large absorption bands lower than 550 mμ and absorption peaks at 600, 620 and 685 mμ in all cases, as is shown in Figs. 2, 3 and 4. The visible spectra of these solutions varied with the irradiation of light.

In the case of ethylene glycol monomethyl ether and ethylene glycol dimethyl ether, the large band lower than 550 mμ and the peaks at 600, 620 and 685 mμ decreased with the irradiation time and two new peaks appeared, at 532 and 1000 mμ, as is shown in Figs. 3 and 4. The former new peak, at 532 mμ, corresponds to that of H^+FeCl_4 in diisopropyl ether reported by Metzler.[6] We also observed absorption peaks at 532, 600, 620 and 685 mμ in a ferric chloride - ethylene glycol monomethyl or ethylene glycol dimethyl ether - hydrochloric acid or methyl chloride system, as is shown in Fig. 5.

On the basis of these results, we are now able to suggest that in the course of the photo-reaction hydrochloric acid or methyl chloride is produced and that this forms a complex with ferric chloride according to the following scheme:

$$FeCl_3(\text{solvent}) \xrightarrow{RCl} RFeCl_4(\text{solvent})$$

This new peak, at 532 mμ, also decreased with the irradiation time. On the other hand, the latter new peak, at 1000 mμ, corresponded to the peak in a ferrous chloride - ethylene glycol system. This peak increased with the irradiation time. These results indicate that ferric chloride is photo-reduced by ether to ferrous chloride.

In the case of ethylene glycol, the peaks at 600, 620 and 685 mμ decreased with the irradiation. However, the decrease in the large band lower than 550 mμ could not be observed. This may result from the fact that the large band in the ferric chloride - ethylene glycol system does not vary even upon the addition of hydrochloric acid. A new peak appeared at 1000 mμ. The intensity

of this peak increased at an extremely slower rate than that in the case of ethers.

We may, therefore, assume that the photoreduction of ferric chloride by ethylene glycol proceeds very slowly.

A Comparison between the Photochemical and Thermal Reactions of Ethylene Glycol in the Presence of Ferric Chloride. — *Thermal Reaction.* — The thermal reaction of ethylene glycol in the presence of ferric chloride was investigated. A solution of 1.44 g. of anhydrous ferric chloride in 10 ml. of ethylene glycol was placed into a reaction vessel equipped with a condenser which had been connected to a trap cooled with a dry ice - acetone bath; the solution was then heated at 130°C for 5 hr. During this period no products were obtained in the trap. Although the reaction mixture was analyzed by g. c. and 2, 4-D. methods, no reaction products were observed. When 6.0 g. of the reaction mixture was distilled at 83—85°C/8 mmHg, most

TABLE I. THE AMOUNTS OF THE MAIN PRODUCTS IN THE PHOTOCHEMICAL REACTIONS*

* Reaction time: 24 hr.

of the ethylene glycol was recovered, and 1.2 g. of the polymeric material was obtained as the distilled residue.

Photochemical Reaction. — A solution of 28.8 g. of anhydrous ferric chloride in 200 ml. of ethylene glycol was irradiated with a 100 W. mercury lamp according to the method described above. In the course of the photo-reaction, the evolution of 0.4×10^{-2} mol. (at S. T. P.) of gas was observed. An analysis of the gas by g. c. showed that its gas mainly consisted of hydrogen, methane and carbon monoxide.

The reaction mixture was then fractionated through a Vigreux column to give (1) a fraction of b. p. 25—80°C/8 mmHg (trapped by a dry ice - acetone bath; approximately 26 g.), (2) a fraction containing mainly unchanged ethylene glycol (approximately 180 g.), and (3) a distilled residue (approximately 40 g.). From fraction 1, acetaldehyde ethylene acetal, acetaldehyde and water were confirmed and determined by g. c. The amounts of these products are shown in Table I. The distilled residue was a dark brown oily material; this material was not, however, analyzed in detai. Besides these products, a small amount of glyoxal was isolated as the 2, 4-D.

As has been described above, apparent differences between the photochemical and thermal reactions were observed. The photochemical reaction of ethylene glycol in the presence of ferric chloride proceeds via the dehydration of ethylene glycol to give acetaldehyde, followed by the reaction 1 with ethylene glycol to produce acetaldehyde ethylene acetal. The reaction mechanism will be discussed later.

$$\begin{array}{l} CH_2{-}CH_2 \\ | \quad | \\ OH \quad OH \end{array} \xrightarrow[FeCl_3]{h\nu} CH_3CHO + H_2O \xrightarrow{\begin{array}{l} CH_2{-}CH_2 \\ | \quad | \\ OH \quad OH \end{array}} CH_3CH\begin{array}{l} O{-}CH_2 \\ \quad | \\ O{-}CH_2 \end{array} + H_2O \qquad (1)$$

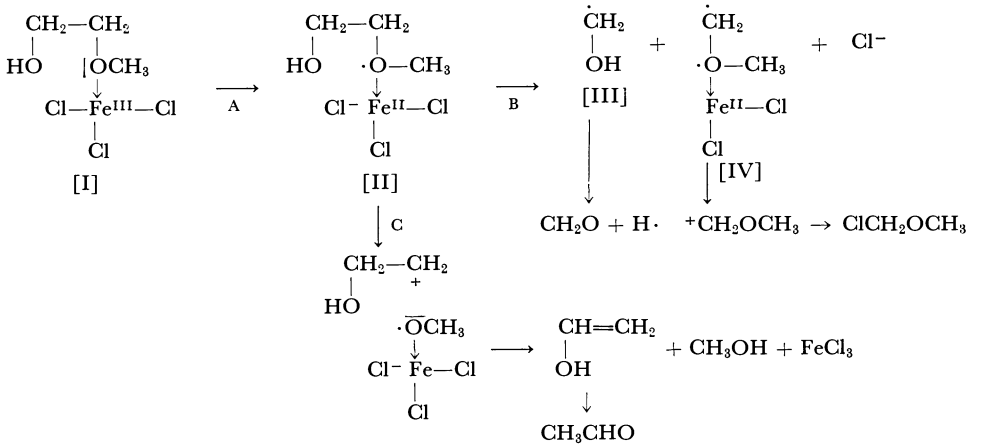
Photochemical and Thermal Reactions of Ethylene Glycol Monomethyl Ether with Ferric Chloride.—*Thermal Reaction.*—A solution of 2.08 g. of anhydrous ferric chloride in 20 ml. of ethylene glycol monomethyl ether was refluxed for 5 hr. The reaction mixture was then fractionated through a Vigreux column to give (1) a fraction of b. p. 80—90°C (approximately 3 g.), (2) a fraction containing mainly unchanged ethylene glycol monomethyl ether (approximately 15 g.), and (3) the distilled residue (approximately 3 g.). Ethylene glycol dimethyl ether was obtained from the fraction 1. The distilled residue was a black-brown clay-like solid containing ferric ions and chlorine ions.

As has been described above, the thermal reaction of ethylene glycol monomethyl ether with ferric chloride gave mainly ethylene glycol dimethyl ether. The reaction probably proceeds by a disproportionation 2. Although ethylene glycol was not confirmed in this investigation, it may be present in the distilled residue in the form of a complex with ferric chloride, or in the form of the polymeric material.

$$2\,CH_3OCH_2CH_2OH \xrightarrow{FeCl_3} CH_3OCH_2CH_2OCH_3 + HOCH_2CH_2OH \qquad (2)$$

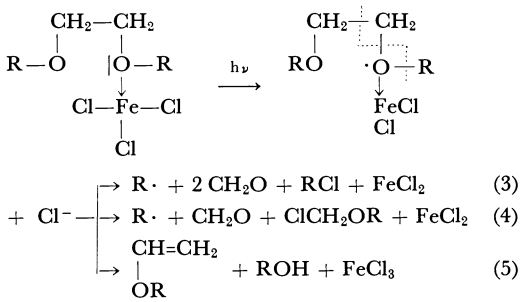
Photochemical Reaction. — The irradiation of ethylene glycol monomethyl ether with ferric chloride was made by the same procedure as in the case of ethylene glycol. In the course of irradiation, methane, ethane, hydrogen and carbon monoxide evolved. Among the products present in the reaction mixture, acetaldehyde, chloromethyl methyl ether, methanol, methoxymethyl methoxyethyl ether, methyl chloride and water were determined by g. c. In addition to these products, formaldehyde was determined by the 2, 4-D. method. The results are shown in Table I.

These results show that the mechanism of the photochemical reaction is different from that of the thermal reaction. Ferric chloride and ethylene glycol monomethyl ether form a complex, though the structure of the complex is not certain. (The formation of a complex was observed by spectrophotometric studies.) Ferric ions in a complex are reduced by ethylene glycol monomethyl ether to ferrous ions under ultraviolet irradiation. This means that the transfer of a lone-pair electron on an oxygen atom of a hydroxy or methoxy group to the excited ferric chloride occurs. This step is the primary process in the photochemical reaction. The formation and the amount of formaldehyde and chloromethyl methyl ether show the cleavage of the carbon-carbon bond (reaction 4), while those of acetaldehyde and methanol or water show the cleavage of the carbon-oxygen bond ($-CH_2-O-$) (reaction 5). From the results of the spectrophotometric studies, it may also be supposed that the



Scheme 1

reactions 4 and 5 are accompanied with the reaction 3, that is, the cleavage reaction of the R–O– bond to R^+ and ^-O–, because in the course of the reaction the formation of methyl chloride or hydrogen chloride was observed.



The cleavage of the carbon-carbon or carbon-oxygen bond is caused by the electron transfer in the primary process. It is not clear whether the cleavage of the carbon-carbon bond is ionic or homolytic. If the structure of a complex is I, and if the cleavage of the carbon-carbon bond is homolytic, the reaction proceeds via Paths A and B; that is, I is converted to II by the electron transfer, and then the cleavage reaction of II gives formaldehyde and chloromethyl methyl ether via the intermediate, III and IV. On the other hand, acetaldehyde and methanol are produced by the reaction paths A and C, in which the oxidative cleavage of the carbon-oxygen bond occurs, as is shown in Scheme 1. The fact that the amount of chloromethyl methyl ether is small (Table I) seems to show that chloromethyl methyl ether is converted into methanol, formaldehyde and methoxymethyl methoxyethyl ether by the following thermal reactions:

$$CH_3OCH_2Cl + H_2O \rightarrow CH_3OH + CH_2O + HCl$$

$$CH_3OCH_2Cl + CH_3OCH_2CH_2OH \rightarrow CH_3OCH_2OCH_2CH_2OCH_3 + HCl$$

Methyl vinyl ether, which can be produced by the dehydration of ethylene glycol monomethyl ether, and its polymer were not confirmed. The polymer may be present in the distilled residue.

Photochemical and Thermal Reactions of Ethylene Glycol Dimethyl Ether in the Presence of Ferric Chloride. — The photochemical and thermal reactions and the identification of the products were carried out by the same methods as in the cases of ethylene glycol and ethylene glycol monomethyl ether.

Thermal Reaction.—No reaction products were confirmed by g. c. and 2, 4-D. methods.

Photochemical Reaction. — In the course of irradiation, methane, ethane, hydrogen and carbon monoxide evolved, and crystals in the form of colorless prisms appeared on the walls of the lamp. These crystals were collected by filtration, washed with dry ether, and dried on phosphorus(V) oxide overnight. Attempts to measure the infrared spectrum and to make an elemental analysis of those crystals failed, since they were very unstable in relation to air or moisture. However, the results of the combustion test, Beilstein's test, and the other qualitative tests showed the presence of ferrous or ferric ions, chlorine ions and an organic compound in the crystals. When the crystals were allowed to stand under an air atmosphere they turned yellow, and the form of the crystals changed from colorless prisms to a semi-crystalline mush, the infrared spectrum of which showed large absorption bands at 3400, 1630 and 1600 cm^{-1} and other broad absorption bands at 1780, 1450, 1365, 1240, 1190, 1090 and 1045 cm^{-1}. The large absorption bands at 3400, 1630 and 1600 cm^{-1} corresponded to those of $FeCl_2 \cdot 4H_2O$.[7] Although the components of the colorless crystals are not clear, they seem to be a complex of ferrous chloride and an organic compound. The method of formation and the amounts of chloromethyl methyl ether and

7) I. Gamo, This Bulletin, **34**, 1495 (1961).

formaldehyde seem to support the assumption of the oxidative cleavage mechanism described above. However, an inbalance in the amounts of the products was observed, as is shown in Table I. This may be caused by the formation of colorless crystals under ultraviolet irradiation. A reaction would proceed by steps analogous to the steps of the reactions 3, 4 and 5, that is, an oxidative cleavage of a carbon-carbon bond to $\cdot CH_2OCH_3$ and $^+CH_2$-OCH_3.

Summary

The photochemical reactions of ethylene glycol, ethylene glycol monomethyl ether and ethylene glycol dimethyl ether in the presence of ferric chloride involve the cleavage process of the carbon-carbon bond to give formaldehyde and chloromethyl methyl ether; of the carbon($-CH_2-$)-oxygen bond to give acetaldehyde, methanol and water, or of the carbon(CH_3-), hydrogen-oxygen bond to give methane, ethane, hydrogen chloride and methyl chloride. These reactions are accompanied by the photoreduction of ferric chloride to ferrous chloride.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1582—1584 (1966)

Organoboron Compounds. X. On the Reaction of *o*-Hydroxybenzeneboronic Acid Anhydride with Some Sulfonamides

By Seiji KATO,* Keiko KIMURA, Katsuhisa NAGATA and Yojiro TSUZUKI

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received December 20, 1965)

Several new azo compounds containing boron atoms have been synthesized by the use of sulfonamides; these compounds have an excellent effect on bacilli. It was expected that the antibiotic effect would be very remarkable, since it had been reported that boron-containing azo dyes are useful for therapy on brain tumors. A mixed solvent of ethanol-water (1 : 1) and acetone was found useful for recrystallizing this class of compounds. The infrared spectra of these compounds show absorption bands at the 1090—1100 cm^{-1}, 1375—1380 cm^{-1} and 1600—1610 cm^{-1} regions these bands may be assigned to the carbon-boron, boron-oxygen and nitrogen-nitrogen bonds respectively.

Some azo compounds containing boron atoms were found to be effective in the medical treatment of brain tumors by Kruger[1] and by Zall et al.[2] It had been known that a number of azo compounds containing negative atoms or groups such as halogens, as well as hydroxyl, nitro and trifluoro groups, are also effective, if irradiated, even without boron atoms; however, the azo compounds containing boron atoms are more effective with respect to the absorption by tumors than the compounds without boron atoms. Gilman et al.[3] obtained a number of azo compounds containing boron atoms by coupling *o*-hydroxybenzeneboronic acid anhydride with the diazonium chlorides of benzene, *p*-bromobenzene and nitrobenzene. It was expected that if boron atoms were introduced into sulfonamides by coupling them with boronic acid, the antibiotic effect would be even more remarkable. This paper will deal with some studies of the reactions of *o*-hydroxybenzeneboronic acid anhydride with certain sulfonamides which contain at least one amino group capable of being diazotized, namely, sulfanilamide, N^1-2-thiazolylsulfanilamide, N^1-(2, 6-dimethoxy-4-pyrimidinyl)sulfanilamide and N^1-(6-methoxy-3-pyridazinyl)sulfanilamide. This coupling could occur at the position either ortho or para to the hydroxy group, but primarily at the para position.

Figure 1 illustrates the compounds of this class thus obtained.

The solubility of these products was tested with a solvent such as that used by Gilman[3] for the azo dyes from *o*-hydroxybenzeneboronic acid anhydride (Table I).

A solvent system including ethanol-water (1 : 1) was always found to be a better solvent for recrystallization than acetone.

Although melting point determination has been profitably employed as a criterion of purity for most organic compounds, it does not seem to hold generally true for azo boron compounds. The-

materials obtained also decomposed over 200°C before melting.

The infrared spectra of these azo boronic acids showed absorption bands at two regions, from 1090 to 1100 cm^{-1} and from 1375 to 1380 cm^{-1}, as have many of the boronic acids already reported; these bands may be assigned to the carbon-boron and the boron-oxygen bonds respectively. A band of a weak intensity appeared at 1600 to 1610 cm^{-1} in all the azo derivatives of boronic acid; this band may be due to the azo group.

Experimental

o-Hydroxybenzeneboronic Acid Anhydride.—*o*-Hydroxybenzeneboronic acid anhydride was prepared from 35.0 g. (0.2 mol.) of *o*-bromophenol and an equivalent quantity of tri-*n*-butyl borate (98.6 g.) in an atmosphere of nitrogen, almost exactly according to Gilman's method.[4] The ethereal solution of lithium *o*-lithiophenoxide was sucked up through a glass tube into a graduated dropping funnel which had previously been flushed with nitrogen. The crude material was then recrystallized three times from toluene using activated charcoal. This represents ca. a 44% yield of a nearly pure material with a melting point range of 176—179°C.

Diazotization and Coupling.—*With Sulfanilamide* (R=I).—The diazotization of sulfanilamide (1.7 g., 0.01 mol.) was carried out according to Datta's method.[5] The diazotized sulfanilamide solution was then slowly added to a stirred solution composed of 0.9 g. (0.0225 mol.) of sodium hydroxide, 1.4 g. (0.01 mol.) of *o*-hydroxybenzeneboronic acid anhydride, and 10 ml. of water, and cooled to 5°C by means of an ice-salt bath. Agitation was continued for two hours at 0—5°C following the completion of the addition. The reaction mass was then filtered, and the filter cake was suspended in 100 ml. of water at 40°C and acidified by adding 10% hydrochloric acid. After it had been cooled to room temperature, the precipitated solid was removed by filtration and dried in a vacuum oven; yield, 2.9 g. (96%). This solid does not change until 300°C. The crude product was recrystallized twice from an ethanol-water (1 : 1) mixture.

Found: C, 47.88; H, 3.79; B, 3.37; N, 13.90. Calcd. for $C_{12}H_{10}BN_3O_4S$: C, 47.52; H, 3.33; B, 3.58; N, 13.87%.

With N^1-2-Thiazolylsulfanilamide (R=II). — N^1-2-Thiazolylsulfanilamide (2.5 g., 0.01 ml.) was diazotized according to the method of Datta.[5] This diazonium chloride solution was then stirred over a 15-min. period into a solution composed of 1.1 g. (0.0275 mol.) of sodium hydroxide, 1.4 g. (0.01 mol.) of *o*-hydroxybenzeneboronic acid anhydride, and 10 ml. of water; then the solution was cooled in an ice-salt bath. Agitation was continued for 2 hr. following the completion of the addition, with the temperature maintained at 0—5°C. The reaction mixture was then filtered, and the filter cake was suspended in 100 ml. of water at 40°C and then acidified with 10% hydrochloric acid. The solid thus precipitated was removed by filtration after it had been cooled to room temperature;

4) H. Gilman, L. Santucci, D. R. Swayampati and R. O. Ranck, ibid., **79**, 3077 (1957).

5) S. K. Datta and S. N. Saha, *Z. anal. Chem.*, **174**, 38 (1960).

it was then dried in a vacuum oven. The brown crude material was recrystallized twice from an ethanol-water (1 : 1) mixture to give 2.5 g. of a pure, bitter, orange product decomposing at 220°C. Yield, 66%.

Found: C, 46.27; H, 2.62; B, 2.64; N, 14.77. Calcd. for $C_{15}H_{11}BN_4O_4S_2$: C, 46.62; H. 2.88; B, 2.80. N, 14.52%.

With N^1-(2, 6-Dimethoxy-4-pyrimidinyl)sulfanilamide (R =III). — N^1-(2, 6-Dimethoxy - 4 - pyrimidinyl)sulfanil - amide (4.3 g., 0.01 mol.) was dissolved in 3 ml. of 30% hydrochloric acid and diazotized with 0.7 g. of sodium nitrite and 25 ml. of water at −1 to −3°C. The diazonium chloride solution was added to a stirred solution composed of 1.4 g. of *o*-hydroxybenzeneboronic acid anhydride, 1.1 g. (0.01 mol.) of sodium hydroxide, and 10 ml. of water cooled to 0—5°C by means of an ice-salt bath. Agitation was continued for 2 hr. following the completion of the addition, with the temperature maintained below 5°C. The reaction mass was then filtered, and the residue was suspended in 100 ml. of water and acidified by adding 10% hydrochloric acid. The product was filtered, washed, and recrystallized from an ethanol-water (1 : 1) mixture. The yield was 3.8 g. (86%). This product decomposes at 210°C.

Found: C, 49.60; H, 3.69; B, 2.62; N, 16.09. Calcd. for $C_{18}H_{15}BN_5O_6S$: C, 49.08; H, 3.44; B, 2.46; N, 15.92%.

With N^1-(6-Methoxy-3-pyridazinyl)sulfanilamide (R=IV). —To a stirred solution of 1.4 g. (0.01 mol.) of *o*-hydroxybenzeneboronic acid anhydride and 1.2 g. (0.03 mol.) of sodium hydroxide in 10 ml. of water, cooled to 0—5°C in an ice-salt bath, there was slowly added a solution containing 2.8 g. of N^1-(6-methoxy-3-pyridazinyl)-sulfanilamide, 4.8 ml. of 30% hydrochloric acid, 0.7 g. sodium nitrite, and 25 ml. of water. The alkaline reaction mixture was stirred for 2 hr. at 0—5°C and was then filtered. The filter cake was suspended in 100 ml. of water and acidified with 10% hydrochloric acid. A product with a decomposition point of 210°C was thus obtained in a 70% yield. The crude product was recrystallized twice from an ethanol-water (1 : 1) mixture.

Found: C, 49.26; H, 3.12; B, 2.80; N, 16.93. Calcd. for $C_{17}H_{14}BN_5O_5S$: C, 49.62; H, 3.44; B, 2.63; N, 17.04%.

The Effects of Some Antioxidants on a Polyurethane Fuel Binder

By Kiroku YAMAZAKI

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo

and Harusuke TOKUI

Daicel Ltd., Yuraku-cho, Chiyoda-ku, Tokyo

(Received August 27, 1965)

The antioxidation effect of *N*, *N*'-diphenyl-*p*-phenylene diamine and *N*, *N*'-di-(2-naphthyl)-*p*-phenylene diamine was studied with polyol-cured polyurethane containing an organo-ferric compound as a curing catalyst. These antioxidants, after weathering for one year, were found to be very effective. The same polymer without the antioxidants was degraded and flowed after only three weeks exposure (during the month of May). Although most of the inhibited polymers showed no depression in tensile properties after being exposed for one year, it was noted that the reddish transparent polymers turned dark brown and became opaque. Polyurethane is, in general, strong and resistant to weathering and aging. The degradation mentioned in this study, however, should be attributed to the degradative action of sunlight and the atmospheric conditions. The characteristics of the specimens for tensile strength and elongation at the breaking point have generally been improved without any remarkable change in the tensile modulus, the effect of the "after cure" should be taken into account in addition to the degradative action of sunlight and air.

It is well known that elastomeric polyurethanes are quite resistant to the degradative action of oxygen, ozone and ultraviolet light and more durable in the face of aging and weathering than natural or synthetic diene-type rubbers. Generally, the products catalyzed or cured by amine display excellent resistance. This may be attributed to the fact that polyurethanes have no double bonds in their molecular structure although they are apt to hydrolyse. There are some cases in which a retarder of hydrolysis plays an effective role as a stabilizer.

It has been frequently observed, however, that the polyurethanes produced from toluene diisocyanate, trimethylol propane and diols (such as polyoxybutylene-polyoxypropylene glycol or polyoxypropylene glycol) containing a ferric compound as a catalyst deteriorate and gradually flow

from the edge of the surface when exposed to sunlight in a conventional atmosphere. This observation has been restricted only to the case of the polyurethane obtained by the catalytic action of the ferric compound. Direct exposure to sunlight seems to accelerate the deterioration process remarkably.

An amine-catalyzed polyurethane and those elastomers obtained from polyoxypropylene glycol, trimethylol propane and naphthylene diisocyanate using no catalyst are quite stable.

As the deterioration is due to the hydrolysis or to the depolymerization of urethane linkage, it should not be restricted to polymers produced by means of a ferric catalyst.

The following scheme is presumed for the deterioration of polymers[1]:

Activation

$$RH + h\nu \text{ (or thermal energy)} \rightarrow R\cdot + H\cdot$$

$$RH \xrightarrow{O_2} R\cdot + HOO\cdot$$

where RH : polymer molecule

Propagation

$$R\cdot + O_2 \rightarrow ROO\cdot$$

$$RH + ROO\cdot \rightarrow R\cdot + ROOH$$

$$ROOH \rightarrow RO\cdot + HO\cdot$$

$$2ROOH \rightarrow RO\cdot + ROO\cdot + H_2O$$

$$RH + RO\cdot \rightarrow R\cdot + ROH$$

$$RH + ROO\cdot \rightarrow R\cdot + ROOH$$

Termination

$$2R\cdot \rightarrow R\text{–}R$$

$$R\cdot + RO\cdot \rightarrow R\text{–}O\text{–}R$$

$$2RO\cdot \rightarrow R\text{–}O\text{–}O\text{–}R$$

$$2ROO\cdot \rightarrow R\text{–}O\text{–}O\text{–}R + O_2$$

Since ferric and ferrous ions would serve as catalysts to promote the decomposition reactions of the hydroperoxides, the weathering and aging of the polymer might then be accelerated:

$$Fe^{3+} + ROOH \rightarrow Fe^{2+} + H^+ + ROO\cdot$$

$$Fe^{2+} + ROOH \rightarrow Fe^{3+} + OH^- + RO\cdot$$

Tobolsky and his co-workers[2-4] pointed out that the weak bonds in polyurethane elastomers are those of the biuret, disubstituted urea, and allophanate linkages. The urethane linkage is relatively strong, although weaker than that of the polyesters or polyethers which constitute the main chains of the elastomer. Biuret and disubstituted urea are formed by means of the following reactions:

$$\sim NCO + H_2O + OCN\sim \rightarrow \sim N(H)\text{-}C(=O)\text{-}N(H)\sim + CO_2$$

$$\sim NCO + H_2N\sim \rightarrow \sim N(H)\text{-}C(=O)\text{-}N(H)\sim$$

$$\sim N(H)\text{-}C(=O)\text{-}N(H)\sim + \sim NCO \rightarrow \sim N(H)\text{-}C(=O)\text{-}N(\text{-}C(=O)\text{-}N(H)\sim)\sim$$

While aging, amine-catalyzed and cured polymers were quite stable. Deterioration, however, occurred with polyol-cured products. Accordingly, it may be reasonable to assume that the mechanism for aging (described above) in conjunction with the accelerating effect of ferric ions.

Schollenberger and his co-workers[5] studied the aging of the polyurethane, produced from the diphenylmethane diisocyanate and polyester derived from adipic acid and butanediol-1, 4. According to their theory, the incident radiant energy initiates free radical chains in the elastomer; the surface radicals in contact with air form hydroperoxides, which then decompose and produce an extensively cross-linked surface and cause hardened deterioration. This is in accordance with the mechanism mentioned above. Consequently, an ultraviolet light accepter and conventional antioxidants would be effective, since they improved the resistance against weathering of the polyurethane by the addition of carbon blacks, *N*, *N'*-diphenyl-*p*-phenylene diamine or *N*, *N'*-di-(2-naphthyl)-*p*-phenylene diamine.

The effect of the last two diamines as antioxidants was studied in order to improve the resistivity of the polyurethane against weathering or aging. In this work, however, the hardening as a result of cross-linking reaction did not occur, but the flowing due to the chain scission of the polymer was observed.

Polyoxybutylene-polyoxypropylene glycol was used as one of the starting materials for the polyurethane. Madorsky and Straus[6] reported, however, that introduction of oxygen in the skeleton of an aliphatic hydrocarbon lowered the stability of the chain, and that the C–C bond strength in the skeleton decreased with the substitution of alkyl groups for hydrogen atoms. Therefore, the polyurethanes employed in this work might be unstable against aging as compared with hydrocarbon polymers having C–C bond skeleton or polyethers containing no side alkyl groups (such as polyoxybutylene glycol or polyoxyethylene glycol).

Raw Materials

Polyoxybutylene-polyoxypropylene Glycol (*Sanyo Chem. Co.*).—A random copolymer of oxybutylene and oxypropylene units containing 25 mol. % of the latter. The hydroxyl number was 58.7.

Toluene Diisocyanate (*Mitsui Chem. Co.*).—A 80/20 mixture of 2, 4- and 2, 6- isomers.

Antioxidants (*Ouchi Shinko Co.*).—*N*, *N'*-Diphenyl-*p*-phenylene diamine and *N*, *N'*-di(2-naphthyl)-*p*-phenylene diamine sold under the trade names Nocrac DP and Nocrac White respectively.

Commercial materials were used without any further treatment.

Curing Catalyst.—An organo-ferric compound was synthesized.

Experimental

Polyurethane was synthesized by means of the one-shot method. A round flask is equipped with a gas outlet and a mechanical stirrer. Polyether, trimethylol propane, the curing catalyst and the antioxidant were mixed together in the flask; the mixture was heated to 80°C in an oil bath for one hour under a vacuum of 3—4 mmHg. In the course of the heating, the catalyst and trimethylol propane were dissolved, and the impregnated water was removed. After the mixture had then been cooled to 20°C, toluene diisocyanate

TABLE I. CHANGES IN PHYSICAL PROPERTIES OF POLYURETHANE ELASTOMERS ON WEATHERING

No.	Anti-oxidant added*	Before or after exposure	Tensile strength kg./cm²	Elongation at break point %	Stress at 100% elongation kg./cm²	Stress at 300% elongation kg./cm²	Hardness	Appearances after exposure

* Parts per hundred parts of polyether.

was added, and stirred again for 15 min. While the stirring, the pressure in the flask was held in vacuum. The reaction mixture was then poured into a cavity (2—3 mm. thick) formed by two parallel surface-lubricated glass plates, and cured at 50°C in an electric oven for 48 hr.

The ratio of the equivalents of isocyanates to hydroxyl groups, $R=1.10$, and the fraction of –OH from triol, $\rho_t=0.25$ were set as the composition of the polyurethane.[7] While R and ρ_t were kept constant, the amount of the antioxidants added were varied from 0 to 3%.

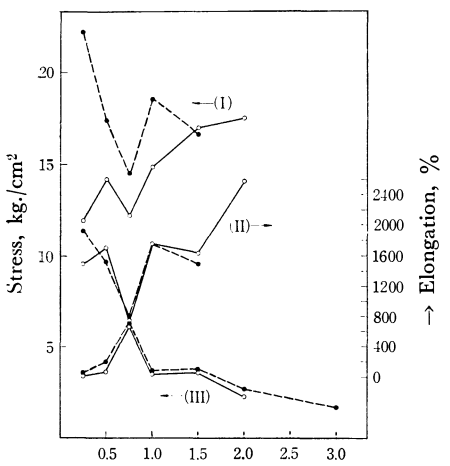
The tensile properties of the elastomers were determined on the basis of the JIS-K-6301 (Physical Testing Methods for Vulcanized Rubber); No. 3 dumbbell-shaped specimens were used, and the strain rate was 500 mm./min. The hardness was measured using an Asker Durometer J.

The weathering process was carried out as follows: Dumbbell-shaped specimens were fixed on the plates of the polyethylene-lined plywood and exposed on the roof of the Central Research Laboratory of the Daicel Ltd. (171 Ohi-mura Tsuruoka, Iruma-gun, Saitama Pref., Japan; longitude 139°30′ E; latitude 35°53′ N). The plates stood at a 30° angle to the floor and faced south. The exposure test was carried out from May 4, 1964 to May 6, 1965.

Results and Discussion

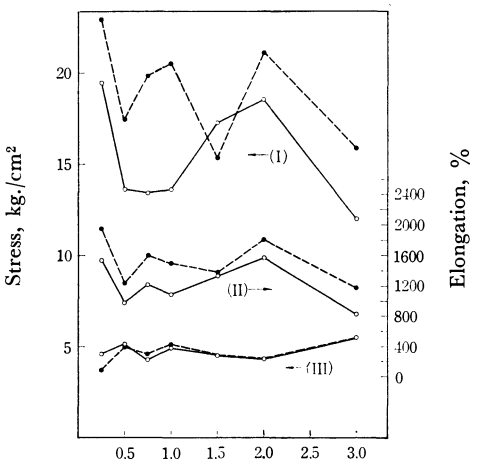
The results of the weathering test are tabulated in Table I.

Figures 1 and 2 show the changes in the tensile properties with the amounts of the antioxidants before and after exposure.



Nocrac DP added, (g./100 g. polyether)

Fig. 1. Tensile properties of polyurethane containing Nocrac DP.
(I) Tensile strength
(II) Elongation at break point
(III) Stress at 300% elongation
—— before exposure ---- after exposure



Nocrac White added, (g./100 g. polyether)

Fig. 2. Tensile properties of polyurethane containing Nocrac White.
(I) Tensile strength
(II) Elongation at break point
(III) Stress at 300% elongation
—— before exposure ---- after exposure

Since Nocrac DP was soluble to the reaction mixture, the produced elastomers were transparent, while Nocrac White was insoluble and the produced elastomers were less clear. After being exposed for one year, the reddish transparent elastomers turned dark brown and became opaque.

Die-cut specimens containing small amounts of the antioxidants (Nos. 1, 9 and 10) were attacked on exposure, and lozenge-patterned cracks developed on the surfaces from the edge. Figure 3 shows the appearance of the exposed surface of Specimen No. 9. (The back surface remained unchanged.)

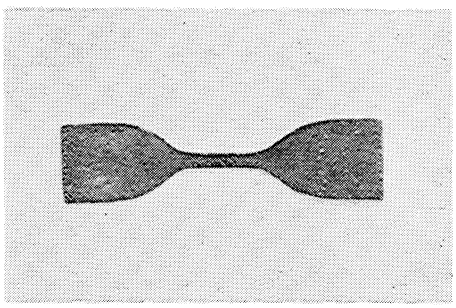


Fig. 3. View of the deteriorated surface of a specimen.
(No. 9, after exposure for one year)

Apparently, the tested antioxidants were very effective, for the uninhibited polymer deteriorated and showed a flow upon exposure for only three weeks in May. The quantities of the antioxidants, 0.5—1.0 parts per hundred parts of polyether, would be sufficient to inhibit the flow of the elastomer for at least one year.

7) H. E. Marsh, Jr., *Ind. Eng. Chem.*, **52**, 768 (1960).

Since amino groups would react faster than hydroxyl groups do with isocyanate, the R values and the degree of cross-linking changed from the predetermined values; then the physical properties of the elastomers changed irregularly with the amounts of the antioxidants. For this reason, the lines in Figs. 1 and 2 have little meaning; they make it easy, however, to look over the figures.

After being exposed, the stress at 300% elongation was slightly increased; the tensile strength, however, was increased remarkably. In the case of the specimens containing Nocrac White, moreover, the values of elongation at the breaking point also increased. Some polybutadiene rubbers were tested similarly. In this case, the tensile modulus was increased, while the tensile strength and elongation at the breaking point decreased and became very brittle. Since the polyurethanes did not show any decrease in tensile properties, these changes may be attributed to be the effect of the "after cure." The change in physical properties would be partly due to the aging by the mechanism mentioned above, and the slight increase in stress at 300% elongation might be the result of the cross-linking reaction caused by sunlight and air. The degrees of augmentation in tensile strength and elongation, however, were too large to attribute to the action of sunlight and air alone. In addition, the exposed specimens did not become brittle.

An effort was made to explain the effect of the "after cure" of polyurethane in connection with the residual quantity of isocyanate groups in the elastomer.[8] In the case of polyurethane containing Nocrac DP, the degree of augmentation in tensile strength after exposure decreased as the quantity of the antioxidant increased. Since, in all cases, toluene diisocyanate was used in excess; the more the quantity of the antioxidant, the less the quantity of unreacted isocyanate, and then the possibility of the succeeding reaction would be decreased. Nocrac White was insoluble to the reaction mixture; therefore, the reaction rate of isocyanate with an amino group could not be so fast as to influence the degree of the "after cure". Therefore, the amount of augmentation in tensile strength was almost the same as far as the data in Fig. 2 was concerned.

All of the specimens except Nos. 1, 8, 9 and 10 showed no depression in physical properties or any remarkable change in their appearance.

There still remain problems to solve for practical processing; for example, the unaimed side reactions as well as the reduction of pot life as a result of the catalytic effect of the antioxidants should be controlled, since these compounds may serve as a kind of amino compounds. The polyurethane used in this study was developed as a fuel binder for composite propellants; since ammonium perchlorate is widely used as an oxidizer for solid fuel, however, it may liberate ammonia and react with isocyanate.[9]

$$RNH_2 + NH_4^+ \rightarrow RNH_3^+ + NH_3$$

Phenolic antioxidants seems to be preferable to use in solving the problems cited above; it has been shown, however, that the propellant grain containing such a compound as an antioxidant is generally inferior to amino derivatives against aging.[10]

The authors wish to express their thanks to Mr. Toshimitsu Iwase for his assistance for the experiment.

NOTES

Formation Constants of Malonato- and Succinatochromium(III) Complexes*1

By Hiroko MURO (née ISEKI) and Ryokichi TSUCHIYA

Department of Chemistry, Faculty of Science, Kanazawa University, Marunouchi Kanazawa

(Received April 1, 1965)

In comparison with several reports[1,2] on formation constants in bivalent metal complexes with malonic and succinic acids, there have been no papers on those in tervalent metal complexes excepting for some rare earth metal complexes[3] with these ligands.

The formation constants of chromium(III) complexes with the oxalate ion have been reported in an earlier paper[4] by one of the present authors. In continuation of the above work, the formation constants of chromium(III) complexes containing the malonate and succinate anions as a ligand have been determined; the relationship between the stability and stereostructure among these complexes, including the oxalate complexes, will be discussed in the present work.

Experimental

In a manner similar to that described in a previous paper,[4] the formation constants were determined by means of pH measurements in solutions containing the hexaaquochromium(III) perchlorate and either malonic or succinic acid at the ionic strength, μ, of 0.1 at 25°C.

The preparation and analysis of the hexaaquochromium(III) perchlorate were also carried out according to procedures similar to those in the previous paper.[4] The malonic and succinic acids used were of an analytical reagent grade and were from Nakarai Chemicals, Ltd., and Wako Pure Chemical Industries, Ltd., respectively.

Results

The values of the acid dissociation constants of malonic and succinic acids required for the determination of formation constants of their complexes were taken from the literature.*2 The method of calculating the average number of corrdinated carboxylate anions as ligand per gram-ion of the chromium(III) ion, $\bar{n}$, and the method of calculating the concentration of non-coordinated one, $[A^{2-}]$, in solutions, are the same as those described in the previous paper.[4] The plots of $\bar{n}$ vs. $p[A^{2-}]$ for both malonato- and succinatochromium(III) systems are shown in Fig. 1.

By applying the successive approximation method to the tentative values of the formation constants obtained from the formation curve shown in Fig. 1, the stepwise formation constants of both

malonato- and succinatochromium(III) complexes were obtained; they are listed in Table I, together with those of the oxalatochromium(III) complexes reported previously[4] by one of the present authors.

Discussion

It may be seen from Table I that the stepwise formation constants, log k_1 and log k_1k_2, of the chromium(III) complexes decrease in the order: malonato<succinato<oxalato. This phenomenon will be discussed below.

First, one of the main factors controlling the difference in stability among these complexes may be a bond angle, like O–Cr–O, in its own chelate ring. The oxalate ion can usually form a five-membered chelate ring with a central chromium(III) ion, whereas the malonate and succinate ions can form six- and seven-membered rings with the same metal ion. Thus a O–Cr–O bond angle in a chelate ring may be expected to become larger as the size of the ring increases. Despite the above intuitive prediction, however, if the structure of the oxalatochromium(III) complex appearing in the literature[5] is compared with schematic structure of malonato- or succinatochromium(III) complex which is depicted by the aid of the bond angles and bond lengths reported for the former, it may be presumed that the bond angle, O–Cr–O, in these complexes does not deviate so greatly from rectangular as to have a vital effect on the difference in stability among these complexes.

Consequently, the most important factors determining the stability of these complexes seem to be the entropy and enthalpy changes brought about by the formation of these complexes.

The first factor is the entropy change in the complex formation. The degree of freedom of a molecule or ion becomes larger as the carbon chain in the acids becomes longer. Therefore, when the dicarboxylate anions coordinate to metal ions, the degree of the freedom of the anions decreases, depending upon the length of the carbon chain in the ligand. Thus, closely related to the above effect on the entropy change, the stability of complexes may be expected to decrease in the order: oxalato> malonato>succinato.

The results obtained in this study show that the stepwise formation, and also the overall formation constants of malonato complexes are larger than those of succinato complexes; such a stability sequence may, therefore, be reasonably explained in terms of the entropy change mentioned above. However, as this entropy factor alone may not give a complete answer to the stability order measured in the case of the oxalato complex, another factor must also be taken into account.

Since the overall acid dissociation constants of oxalic, malonic and succinic acids, pK_1+pK_2, are 4.98,[4] 8.05*[2] and 9.21*[2] respectively, the basicity of the oxygen atoms in carboxylate groups which can coordinate to a metal ion seems to be the smallest in oxalic acid, a little larger in malonic acid, and the largest in succinic acid. Although the basicity of the donor atoms is not the only factor in deciding the enthalpy change upon the coordination of these dicarboxylic acids with chromium(III) ion, it seems to be one of the most effective factors. Thus, the enthalpy change may be presumed to decrease in the order: succinato> malonato>oxalato. In the light of the enthappy change, only the stabilities of these complexes should range in the same order.

However, so far as log k_1 and log k_1k_2 are concerned, the stability order obtained here is: malonato>succinato>oxalato. This finding will be explained below.

Since the difference in the acid dissociation constants between the malonic and succinic acids is really smaller than that between the oxalic and malonic or succinic acid, the stability order in the malonato and succinato complexes seems to be not very much affected by the enthalpy change, but to depend mainly upon the entropy change, as has been assumed above, whereas the smaller stability of the oxalato complex than that of the malonato or the succinato complex is thought to be mainly due to the differences in the enthalpy effect among these complexes. In evaluating the above two main factors which may control the first and second stepwise stability constants of the complexes treated in this paper, it should perhaps be emphasized that an extra stability of the malonato complex over the succinato one is assumed to be responsible for the larger loss of entropy in the complex formation of the latter than in that of the former; the fact that the stability of the succinato complex is a little larger than that of the oxalato complex can be explained on the assumption that the enthalpy decrease accompanying the formation of the former is larger than that accompanying the latter's formation.

On the other hand, the third stepwise formation constant is largest in the oxalato complex and then descreases in the order: malonato>succinato complexes. This shows that the stepwise formation constants of the oxalato complex do not decrease so markedly as those of malonato or succinato complexes, as is shown in Table I. When the overall formation constants are arranged, the stability order is given as: malonato>oxalato> succinato. The trend in stepwise formation constants among the complexes involved in this work may be explained in terms of the concept of steric interaction existing among ligand molecules coordinated to a metal ion; the nearly planar structure of the oxalate ion is still held in the complex formation, whereas in the cases of both the malonate

5) J. N. Van Niekerk and F. R. L. Schoening, *Acta Cryst.*, **4**, 35 (1951).

and succinate anions it is possible for the mutual steric hindrance to occur among coordinated ligands as a result of their larger chelate rings.

The partial support received for this investigation from the Ministry of Education is gratefully acknowledged.

The Application of the Additivity Principle to the Ionization of 2, 3- and 2, 4-Dimethoxybenzoic Acids

By K. C. SRIVASTAVA

Department of Engineering Chemistry, Birla Institute of Technology & Science, Pilani (Rajasthan), India

(Received September 3, 1965)

The overall effect of multiple substitution in a molecule is generally the sum of the individual contributions of the substituents, and, according to Jaffé,[1] the Hammett equation can be applied to most of the cases. Exceptions to this rule have, however, been recorded,[2,3] especially when a methoxyl group is present in the system. Our findings on the ionization of 4-hydroxy 3, 5-dimethoxybenzoic acid,[4] however, strictly conform to the additivity principle. In view of the relatively few investigations reported on substituted benzoic acids, the author has determined the apparent dissociation constants of 2, 3- and 2, 4-dimethoxybenzoic acids at different temperatures. From the data obtained, it then appeared of interest to examine the applicability of the additivity principle to dimethoxybenzoic acids. The results of these investigations will be reported in the present communication.

Experimental

The 2, 3- and 2, 4-dimethoxybenzoic acids used were of E. Merck C. P. grade (m. p. 122°C and 110°C; lit.[5] 120—122°C and 109°C). The caustic soda used was of a B. D. H. AnalaR quality.

The pK values of the acid at different temperatures were determined pH-metrically with a Beckman pH meter (Model G), using an extension electrode assembly. The temperature of the titration cell was maintained at the desired value of ± 0.1°C by employing an oil thermostat operated by a micro relay.

Results and Discussion

In Table I are recorded the pK_a values of the acids at different temperatures as obtained from the pH-metric titration curves of the acid. These values were computed essentially by the method discussed by Britton[6]; the average values were obtained by the graphical procedure discussed earlier.[1] From these data the thermodynamic ionization constants of the acid corresponding to different temperatures were calculated; the data are given in column 3, Table I.

The values for methoxy-substituted benzoic acids, along with the contributions of the substituents to the pK_a of benzoic acid,[7] are recorded

Table I. The ionization constant of dimethoxybenzoic acids at different temperatures

Temp., °C	pK_a	pK_a (Thermodynamic)
2, 3-Dimethoxybenzoic acid:		
25	3.98	3.98
30	3.96	3.94
40	3.94	3.90
50	3.90	3.86
60	3.88	3.86
2, 4-Dimethoxybenzoic acid:		
25	4.36	4.36
30	4.34	4.32
40	4.30	4.28
50	4.28	4.26
60	4.25	4.24

Table II. pK_a Values of methoxy-substituted benzoic acids

Acid	pK	Contribution of substituents
Benzoic acid	4.21	—
2-Methoxy benzoic acid	4.09	−0.12
3-Methoxy benzoic acid	4.09	−0.12
4-Methoxy benzoic acid	4.47	+0.26
2, 3-Dimethoxy benzoic acid	3.98	−0.23
	(3.97)*	(−0.24)
2, 4-Dimethoxy benzoic acid	4.36	+0.15
	(4.35)*	(+0.14)

* The theoretical values are given in parentheses.

7) J. F. J. Dippy, *Chem. Revs.*, **25**, 151 (1939).

in Table II. These data indicate that the substitution of a methoxy group in the meta position lowers the pK_a value by 0.12 unit, while that in the para position enhances the same by 0.26 unit. These considerations lead, by the application of the additivity principle, to an unexpected contribution of −0.24 for methoxy substituents in 2 and 3 positions, and to a contribution of 0.14 for methoxy substituents in 2 and 4 positions, thus giving a value of 3.97 and 4.35 for pK of the acid (Table II).

This theoretical value is in close agreement with the values of 3.98 and 4.36 for the pK_a values of 2, 3- and 2, 4-dimethoxybenzoic acids obtained in the present investigation.

The author wishes to thank Professor V. Lakshmi Narayanan, Director, B. I. T. S., Pilani, for providing the facilities to carry out this work.

The Anodic Behavior of Lead-Platinum and Lead-Palladium Bielectrodes in Chloride and Sulfate Solutions

By Eiichi SATO

Industrial Research Institute of Kanagawa Prefecture, Tomioka-cho, Kanazawa-ku, Yokohama

(Received September 18, 1965)

In recent years the electrolytic anodes with platinum coating on the metallic bases, such as tantalum, titanium and tungsten, have attracted extensive attention in the fields of sodium chloride electrolysis and cathodic protection against corrosion.

Shreir[1] found that the lead anodes in chloride electrolytes were prevented from corroding when a platinum, indium or graphite microelectrode was introduced.

While tentative explanations have been made of the effects of platinum, it is considered, in view of the complications involved, that further experimental studies are necessary in order to get a clearer understanding of the reaction mechanisms.

Experimental

Lead anodes with an area of 1 cm^2 were prepared at a purity of 99.99%. Test specimens of platinum and palladium, as well as the lead anodes, were then immersed into the surfaces of resinous blocks.

The potential was determined by means of a saturated calomel electrode in a sodium chloride solution or in laboratory sea water and by means of a 1 N mercurous sulfate electrode in a sodium sulfate solution.

Results and Discussion

Lead Electrode in 0.5 N Sodium Chloride. —The anodic current of the lead electrode in the passive region was smaller than that in the active region, though the latter came below the anodic current of the other two electrodes. Figure 1 shows the anodic polarization curve for lead in 0.5 N sodium chloride.

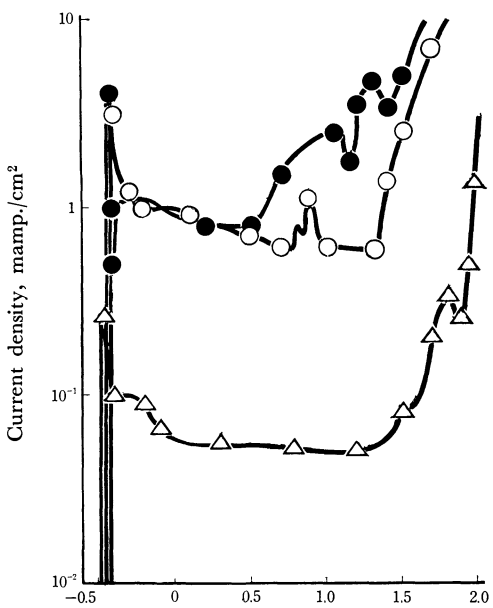

Fig. 1. Anodic polarization curve of lead electrode, lead-platinum bielectrode and lead-palladium.
△ Pb, ○ Pb-Pt bielectrode
● Pb-Pd bielectrode
Electrolyte: 0.5 N NaCl 100 cc.
Rate of potential change: 0.005 V./min.

This result suggests that lead chloride, formed and then dissolved in the active region, deposits on the electrode surface as illustrated in the following formulae:

$$Pb \rightarrow Pb^{2+} + 2e$$

$$E = -0.368 + 0.0295 \log A_{Pb^{2+}} \qquad (1)$$

1) L. L. Shreir, *Corrosion*, **17**, 118t (1961).

$$Pb^{2+} + 2Cl^- \rightarrow PbCl_2$$
$$E = -0.510 + 0.0295 \log A_{Cl^-} \quad (2)$$
$$K = 1.6 \times 10^{-5}$$

The palladium anode in a 0.5 N sodium chloride solution gave an incipient current in the potential region from 1.1 to 1.2 V., this was 500 mV. higher than the current for platinum. As has been decribed above, this means that the chloride ions are absorbed on the firmly-formed lead chloride layer, which is thus changed into lead dioxide. As the potential region from 1.4 to 1.9 V. is transpassive, the isolated lead present in the porous lead chloride layer will be dissolved as quadri-valent lead ions, according to the following reactions:

$$Pb \rightarrow Pb^{4+} + 4e$$
$$Pb^{4+} + 4OH^- \rightarrow PbO_2 + 2H_2O$$

The quadrivalent lead ions which are hydrated in the vicinity of the electrode are discharged and then deposited on it in this potential region. The lead dioxide formed still displays a fine appearance at first, but the film immediately decomposes as a result of the discharge of chloride ions.

It is considered that, in the passive region, the formation of metallic lead and chloride in the defective anode layer are involved in the absorption reaction of hydroxide ions. Fleischmann and Liler[2] established, using a lead acetate electrolyte, that lead dioxide easily neucleated and grew up on the platinum anode. They suggested the following reaction processes:

$$OH^- - e = OH_{ads} \quad (3)$$
$$Pb^{2+} + OH_{ads} + OH^- - e = Pb(OH)_2^{2+} \quad (4)$$
$$Pb(OH)_2^{2+} = PbO_2 + 2H^+ \quad (5)$$

Reaction 4 presumably controls the reaction rate. Feitknecht and Gäumann[3] proposed the following reactions:

$$OH^- = OH + e \quad (6)$$
$$PbO^+ + 2OH = Pb(OH)_2^{2+} + O^- \quad (7)$$
$$Pb(OH)_2^{2+} = PbO_2 + 2H^+ \quad (8)$$

For the anodic reaction of the Pb electrode in the presence of chloride ions, the authors inferred, instead of formulae 4 and 8, that:

$$Pb^{2+} \text{ (in layer)} + OH_{ads} + OH^- - e \rightarrow Pb(OH)_2^{2+},\ Pb(OH)_2^{2+} + 4Cl^- \rightarrow [PbCl_4(OH)_2]^{2-} \rightarrow PbO_2 + 4Cl^- + 2H^+ \quad (9)$$

and

$$PbCl_4 + 2OH^- - 2e \rightarrow [PbCl_4(OH_{ads})_2]^{2-} - 2e \rightarrow PbO_2 + 2Cl^- + 2H^+ + Cl_2 \quad (10)$$

Platinum and Palladium in Solutions of Sodium Chloride, Sodium Sulfate and Artificial Sea Water.—If palladium does not dissolve as well as platinum, the evolution potential of chlorine gas for palladium will be about 1.02 V., that is, 0.03 V. less than that for platinum. The evolution potential of oxygen on palladium is 0.075 V., and on platinum, 0.80 V. (referred to the mercurous sulfate electrode). It was found that the incipient anodic current for palladium appeared at 0.9 V., while that for platinum appeared at 0.9 V., too. Heumann and Schürmann[4] reported that the current-potential curves for the palladium anode in electrolytes containing chloride ions exhibited an active region, a primary passive region, and a secondary passive region; these correspond, respectively to the dissolution of palladium into the divalent state, the chlorine evolution from the passive electrode, and the oxygen evolution. They stated the experimental results as follows: For the palladium anode in 0.5 N hydrochloric acid, the anodic current begins at the potential of 0.62 V. and passes through a

Rate of potential change: 0.005 V./min.

2) M. Fleischmann and H. R. Liler, *Trans. Faraday Soc.*, **54**, 1370 (1958).
3) W. Feitknecht and A. Gäumann, *J. Chim. Physique, Physicochim. Biol.*, **49**, 135 (1956).
4) Th. Heumann and R. Schürmann, *Ber. Bensen Ges. Phys. Chem.*, **67**, 601 (1963).

maximum current density of about 0.04 amp./cm² at 1.4 V. in the active region; then it decreases towards the minimum value of 0.01 amp./cm² at 1.6 V. Another maximum in current density (0.06 amp./cm²) comes at the anodic potential of 1.75 V., after which the current again descends to 0.04 amp./cm². A further rise in the potential results in a monotonous increase in the anodic current.

Figure 2 depicts the anodic polarization curves for all the electrodes in aritificial sea water. On account of the dissolved oxygen, the current for the lead electrode becomes negative in the potential region from −0.8 to −0.55 V. The reaction mechanism was discussed in a previous report.[5] In our present experiments, the transpassivity region ranged between 0.6 and 0.9 V. when oxygen gas evolved on the electrode. The behavior of the lead platinum bielectrode is very like that of the lead electrode, but lead-palladium is so different that the anodic current begins to rapidly increase at −0.23 V. and the polarization curve is reflected at 0 V., above which point the transpassive region ranges from 0.8 to 1.1 V. Vetter[6] considered that the anodic current on the lead-palladium bielectrode indicated palladium dissolution but not lead dissolution in the potential region from −0.2 to 0 V., since the active region of palladium is in the potential region around −0.2 V.

The Influence of the Current Density on the Corrosion Rate of Palladium in Artificial Sea Water.—If palladium dissolves in the bivalent form, the dissolved ion amounts, according to Faraday's law, to 1.9903 g. at the current of 1 amp. for 1 hr. and 7.6416 g. at the current of 1 amp./dm² (32 mamp./3.2 cm²) for 5 days. The practical corrosion, however, weighed 0.00064 g., about 8/1000000 of the theoretical dissolved quantity. The difference in amount of electric charge between the calculation and the practical corrosion is caused by the gas evolution.

Summary

A potentiostatic method was used to investigate the behavior of lead electrodes and lead-platinum and lead-palladium bielectrodes in sodium chloride and sodium sulfate solutions and in sea water. The experimental results showed lead-palladium bielectrode to be of practical use in the electrolysis of sea water.

A Preliminary Study of the Determination of Hydrogen Content in Heavy Water by Means of Neutron Transmission

By Masayoshi ONO and Yoshiyuki KISO

Research Reactor Institute, Kyoto University, Kumatori-cho, Sennan-gun, Osaka

(Received September 22, 1965)

The aim of this work is to examine the applicability of a neutron transmission procedure to the determination of the hydrogen content in heavy water, although the mass spectrometric and infrared absorption spectrophotometric methods[1,2] are most commonly used for this purpose.

The principle suggested here is based on the difference in total cross sections of thermal neutrons between light and heavy water.[3]

1) I. Kirshenbaum, "Physical Properties and Analysis of Heavy Water," McGraw Hill, New York (1951), p. 201.
2) G. Gordon and H. Yamatera, *Anal. Chem.*, **36**, 1866 (1964).
3) ANL-5800, Reactor Physics Constants.

The following formula is derived to give the sensitivity as a function of the amount of light water in heavy water, while the relation is shown in Fig. 1.;

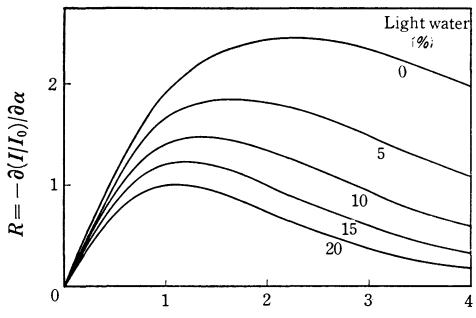

Fig. 1. Relation of R to thickness d of cell.

$$R = -\frac{\partial(I/I_0)}{\partial\alpha} = a.d.\exp\{-(a\alpha + b)d\} \quad (1)$$

where I_0 is the number of well-collimated incident neutrons falling on a small area; I, the number of neutrons which succeed in passing through the thickness, d, of the target over the same area; a, the difference between the macroscopic total cross sections for light and heavy waters; b, the macroscopic total cross section of heavy water, and α, the fractional molar concentration of light water.

From each maximum of the curves in Fig. 1 one can predict the optimum thickness, d, which will give the highest sensitivity of measurement for any arbitrary concentration of light water.

A preliminary experiment was performed by the arrangement shown in Fig. 2.

A series of samples were prepared by diluting pure heavy water (99.94 mol.%). The samples were poured into a dried cell by nitrogen-gas pressure. A cell 2 cm. thick was used, since this thickness, according to the curves in Fig. 1, seemed to give the maximum sensitivity for a 95—100 percent concentration of heavy water.

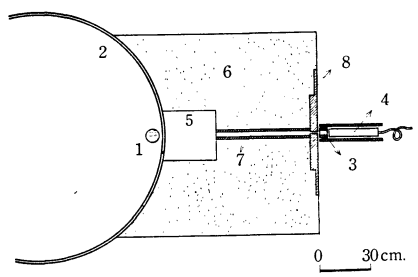

Fig. 2. Experimental arrangement.

(1): Neutron source (Am-Be, 6 curies)
(2): H_2O tank
(3): Cell (Al, 10×70 mm$^2\times20$ mm.)
(4): BF_3 counter (25 mm$\phi\times30$ cm.)
(5): Paraffin
(6): Boron paraffin
(7): Coarse collimeter
(8): Cadmium plate.

The counting rate of incident thermal neutrons through the cadmium slit (1.5×30 mm.) was 5.92 ± 0.01 c.p.m. during 12 hr. of measurement, and the background was 1.02 ± 0.025 c. p. m. during a 24 hr. period.

Figure 3 shows the curves obtained by the experiments and by calculations based on the neutron linear attenuation formula. This formula gives the highest sensitivity which can be expected by this method.

The fairly large disagreement between the two curves seems to be caused by more complicated phenomena than are taken into account by a simplified consideration like the linear attenuation formula. However, the results obtained experimentally show that this measurement procedure can be established as a method of chemical chemical analysis.

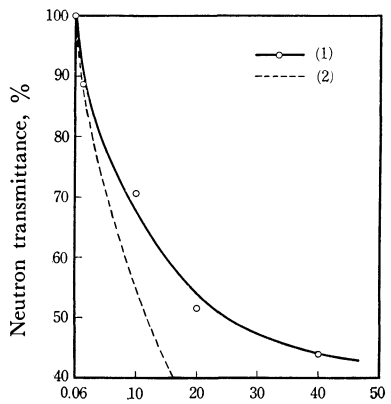

Fig. 3. Relation between neutron transmittance and concentration of light water (normalized to D_2O 99.94 mol. percent concentration).

(1): Experimental
(2): Calculated for linear attenuation formula $I/I_0 = \exp\{-(a\alpha+b)d\}$

The transmittance of the arbitrary sample to the standard (99.94 mol.%) at high concentrations of heavy water (98—100%) decreased to 11.1 percent for the concentration of light water shown in Fig. 3.

If a higher neutron flux, such as that from a nuclear reactor were used, this procedure could be established as a method for hydrogen determination of an even higher accuracy and an even greater rapidity.

The Japp-Klingemann Reaction of Diethyl Benzoylsuccinate

By Heinosuke YASUDA and Hiroshi MIDORIKAWA

The Institute of the Physical and Chemical Research, Bunkyo-ku, Tokyo

(Received September 28, 1965)

An extensive review of the Japp-Klingemann reaction has been made by Phillips.[1] It is well known that the coupling reaction of a diazotized aniline with a methinyl carbon gives an unstable azo compound, which then decomposes to give a hydrazone, whereas the coupling product between the same diazotized aniline and a methylene carbon is not an azo compound, but a hydrazone.

A previous paper[2] has presented a formation of 2-pyrazoline-5-one dye in an attempt to prepare the diethyl α-ketosuccinate phenylhydrazone by coupling diazotized aniline to diethyl acetylsuccinate in an alkaline medium.

This paper will describe the results obtained from the coupling reaction of diazotized anilines with diethyl benzoylsuccinate (I). The succinate I was prepared from ethyl sodiobenzoylacetate and ethyl monochloroacetate in boiling ethanol.

When benzenediazonium chloride reacted with I in ethanol containing sodium hydroxide, a product melting at 151—152°C was obtained; this product showed different behavior from expected diethyl α-ketosuccinate phenylhydrazone in melting point (76—78°C) or in debenzoylation. The analysis has suggested that this coupling product is 1-phenyl - 3 - ethoxycarbonyl - 4 - phenylhydrzaono-2-pyrazolin-5-one (IIa). The structure of the coupling product was further established by independent synthesis from the coupling reaction of benzenediazonium chloride with 1-phenyl-3-ethoxycarbonyl-2-pyrazolin-5-one.

Similarly, the reaction of I with two equivalents

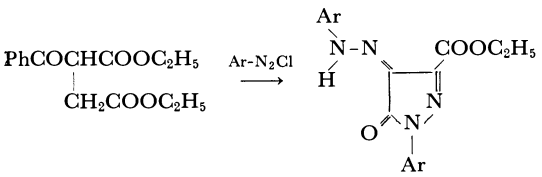
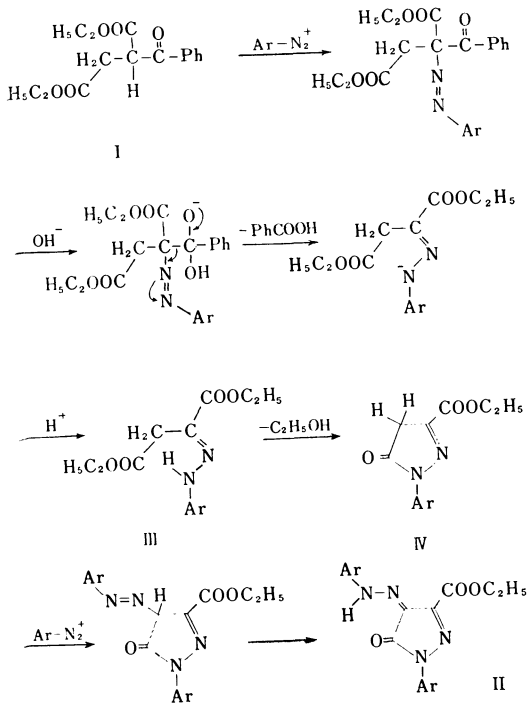
of the respective diazotized anilines gave the corresponding dyes (II) in varying yields, ranging from 25 and 46% respectively. In each case, the remainder of the reaction mixture was a non-distillable, resinous material which could not be identified further. The relatively low yields may be due to the formation of appreciable amounts of the resinous material during the coupling reaction. This reaction is illustrated in the following equations.



I II

Very recently,[3] the actual structures of 2-pyrazolin-5-one dyes, in which 4-positions are coupled with various diazotized anilines, have been shown to be the hydrazone-keto form and not an azo-keto or an azo-enol form. Table I summarizes the yield and other data obtained in the Japp-Klingemann reaction of I with eleven diazotized anilines.

The mechanism of the formation of the pyrazolinone dyes (II) from I and diazotized anilines apparently involves azo coupling on the α-methinyl carbon, thus forming an intermediate diethyl α-ketosuccinate arylhydrazones (III) via debenzoylation. This intermediate is expected to undergo an intramolecular cyclization by the elimination of one molecule of ethanol, thus giving 1-aryl-3-ethoxycarbonyl-2-pyrazoline-5-ones (IV). Compound IV, once formed, reacts with another molecule of diazotized aniline to give the pyrazolinone dyes (II). The probable scheme is illustrated as follows.



I

III IV II

Experimental

General Procedure for the Japp-Klingemann Reaction.—To a mechanically-stirred solution of 1 g. of sodium hydroxide in 50 ml. of 90% ethanol, 2 g. (0.00719 mol.) of diethyl benzoylsuccinate was added; the mixture was then cooled to 0°C. A diazonium solution (prepared by dissolving 0.0719 mol. of the appropriate aniline in 15 ml. of 2 N hydrochloric acid, cooling it to 0°C, and adding a saturated aqueous solution of 1.1 g. of sodium nitrite) was slowly stirred in mechanically. During the addition, a colored, oily, resinous matter separated. This matter was collected in a suitable manner and poured into a stirred mixture of 30 ml. of acetone and 30 ml. of ethanol. After the stirring had continued for 30 min., the mixture was diluted with water until clouding persisted. The colored solid which separated was collected, washed with methanol-water, and recrystallized from dioxane-water. The results are listed in Table I.

The authors wish to express their deep appreciation to Professor Taro Hayashi and Professor Tatsuo Takeshima for their invaluable discussions. All analyses were performed by Dr. Haruo Homma and the stuff of the Micro Analytical Laboratory in this Institute.

The Synthesis of 3, 6-Bis(α-hydroxyethyl)-2, 5-diketopiperazine

By Tadashiro FUJII and Kenji OKAWA

Department of Chemistry, Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Recieved October 6, 1965)

It is well known that diketopiperazine derivatives of the usual amino acids are readily obtained from the methyl or ethyl ester of the corresponding amino acid.[1] However, there has been no report concerning the synthesis of 3, 6-bis(α-hydroxyethyl)-2, 5-diketopiperazine, although other diketopiperazine derivatives of many hydroxy amino acids have already been synthesized.[2]

The authors obtained 3, 6-bis(α-hydroxyethyl)-2, 5-diketopiperazine from the product of the reaction, and then the catalytic hydrogenation, of carbobenzoxy-L-threonine and dicyclohexylcarbodiimide, it could also be obtained by the thermal condensation of the crystalline L-threonine methyl ester.* The infrared spectra of the products prepared by the two methods were identical, and both exhibited characteristic peaks at 3390 cm^{-1} (OH), 1680 cm^{-1} (amide I) and 1470 cm^{-1} (amide II).

The structure of the product was confirmed by the elemental analysis and molecular weight measurements by the cryosocopic method of Schwyzer.[3]

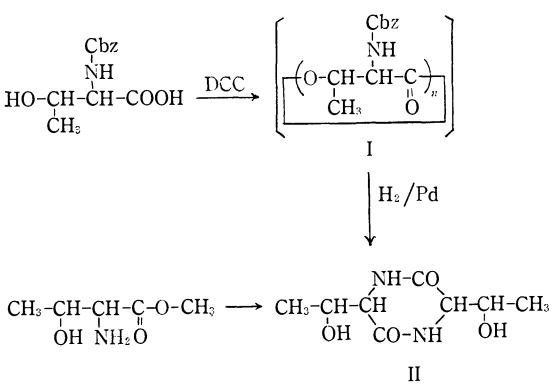

Fig. 1.

Experimental

The Synthesis of the Lacton Derivative (I).—A solution of 10.5 g. (0.054 mol.) of dicyclohexylcarbodiimide in 50 ml. of methylene chloride was added, drop by drop, into a solution of 13 g. of carbobenzoxy-L-threonine in 100 ml. of methylene chloride at room temperature.

After the addition had been completed, the stirring was continued for 1 hr. at room temperature. The reaction mixture was then allowed to stand overnight, the urea produced was filtered off (11.3 g., 100%), and the filtrate was washed with a N sodium bicarbonate solution and water and finally dried over anhydrous sodium sulfate. The filtrate was then concentrated in vacuo to give an oily product (12 g.) (I).

3, 6-Bis(α-hydroxyethyl)-2, 5-diketopiperazine (II).—To a 180 ml. methanol solution of 8 g. of I, 5 g. of palladium-charcoal was added, the mixture was then hydrogenated at room temperature for 5 hr. After the catalyst and the solvent had been removed, the product was dissolved in methanol.

Crystals were gradually separated. The yield was 625 mg. M. p. 254—256°C (decomp.). $[\alpha]_D^{23.5}$ −87.0° (*c* 1.01, water).

Found. C, 47.51; H, 7.09; N, 13.53; Mol. wt., 208.** Calcd. for $C_8H_{14}N_2O_4$: C, 47.56; H, 6.99; N, 13.87%; Mol. wt., 202.

The L-Threonine Methyl Ester.—Into a suspension of 5.95 g. (0.05 mol.) of L-threonine in 60 ml. of absolute methanol, 6.5 g. of thionyl chloride was added, drop by drop, under cooling at about −5°C, the stirring was then continued for 1.5 hr. at room temperature. After the reaction product had been allowed to stand at room temperature for 24 hr., the solvent was removed under reduced pressure at 30°C, an oily product (L-threonine methylester hydrochloride) was thus obtained (8.4 g. (99%)).

Three grams of triethylamine were added, drop by drop, into a solution of 5 g. of the above ester hydrochloride under cooling. After the addition was over, 150 ml. of ether was added to the resulting mixture, and it was stored in a refrigerator for 1 hr. The triethylamine hydrochloride was then filtered off, the solvent was removed, the resulting partly-crystallized oily material was dissolved in a small amount of ether, and the insoluble material was filtered off. The filtrate was then concentrated under reduced pressure until crystals appeared.

From the mother solution, other crops of crystals were obtained. The total yield was 2 g. (32%).

Recrystallization from ether gave 1 g. of fine crystals. M. p. 63—65°C $[\alpha]_D^{23.5}$ −21.0° (*c* 0.999, N HCl).

Found. C, 45.08; H, 8.22; N, 10.75. Calcd. for $C_5H_{11}NO_3$. C, 45.15; H, 8.34; N, 10.53%.

The Partial Specific Compressibility of Polyvinylpyrrolidone

By Hiroyasu NOMURA and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Recieved October 18, 1965)

In our previous papers[1-4] it has been shown that, in the study on the solution properties of high polymers, the compressibility of the solution can be used as a valuable parameter. In our treatment, the data of the compressibility of a dilute solution were extrapolated to an infinite dilution to give a quantity which limits the partial specific compressiblity (LC). So far the LC values of such polymers as polyvinyl acetate,[1,2] polystyrene,[3] and dextran[4] have been determined under various conditions. In the organic solvents, the LC was intimately related to the intrinsic viscosity. The LC of dextran in the aqueous solution was negative as a result of the hydration, and the amount of hydration water was estimated from the LC value.

In the present note, the LC of polyvinylpyrrolidone (PVP) was determined at various temperatures by ultrasonic velocity measurements. The details of the experimental procedure have been reported previously.[1,3] The PVP used was a commercial product, PVP K-30, supplied by the Tokyo Kasei (Chemical) Industrial Co., Ltd., the noted molecular weight was 40000. The sample was used without further purification.

TABLE I.

$t°$	$\kappa_1 \times 10^{12}$ cm²/dyn.	$\bar{v}_{20}$ cc./g.	$\bar{\kappa}_{20} \times 10^{12}$ cm²/dyne	ω cc./g.	$[\eta]$ cc./g.
5	49.14	0.783	−18.2	0.458	24.5
15	46.53	0.793	−8.2	0.230	24.5
25	44.84	0.794	−1.1	0.033	24.5
35	43.57	0.806	8.1		21.8
45	42.81	0.808	20.7		23.5
55	42.40	0.821	24.0		25.5

The experimental results are summarized in Table I, where κ_1 is the compressibility of the solvent; $\bar{v}_{20}$, the partial specific volume of the solute at infinite dilution; $\bar{\kappa}_{20}$, the LC; ω, the amount of hydration, and $[\eta]$, the intrinsic viscosity. The methods of the determination of these quantities were given in the previous papers. In the table, it should be noted that the LC increases from a negative value to a positive with the rise in temperature. As was discussed in the previous paper,[4] the negative value of LC can be ascribed to the hydration in the present case. The amount of hydration decreases with the increase in temperature, as in the cases of sucrose[5] and dextran,[4] as a result of the exothermic nature of the hydration process.

It is interesting to see that the value of LC becomes positive above 30°C. The temperature rise breaks the structure of water to some extent, and at the same time it reduces the amount of hydration. Then the behavior of dehydrated bare molecules of PVP becomes similar to that of a synthetic chain polymer, such as polystyrene in an organic solvent, and the LC becomes positive.

The intrinsic viscosities at various temperatures are also listed in the table. It may be seen that the variation in the intrinsic viscosity with the temperature is not so remarkable. This result is in contrast to the linear relationship between the intrinsic viscosity and the LC for the such synthetic chain polymers as polystyrene and polyvinyl acetate in the organic solvents.

The Calculation of the State Energies of *cis*- and *trans*-Terephthalaldehyde

By Kōzō Inuzuka

Department of Applied Science, Tokyo Electrical Engineering College, Chiyoda-ku, Tokyo

and Toshio Yokota

Tokyo University of Foreign Studies, Nishigahara, Kita-ku, Tokyo

(Received October 20, 1965)

Terephthalaldehyde is a carbonyl derivative of benzaldehyde and its *cis*- and *trans*-forms in solution have been found by Maki[1] by means of ESR experiments.

Since *cis*-terephthalaldehyde has the C_{2v} symmetry, its π-electronic state belongs to the A_1 or B_1 of the C_{2v} symmetry group. Electronic transitions of A_1 and B_1 types have transition moments parallel to the z and x axes respectively.

On the other, *trans*-terephthalaldehyde has the C_{2h} symmetry and its π-electronic state belongs to the irreducible representation, A_g or B_u, of the symmetry group. Electronic transitions from the A_g ground state to the A_g excited states are impossible, but transitions to the B_u excited state are possible. Their transition moments are localized in the molecular plane.

We calculated the state energies for the two isomers by the semiempirical SCF-MO-CI method. The calculated procedure was the same as that used in a previous paper,[2] in which the state energies of benzaldehyde were calculated. The molecular models of *cis*- and *trans*-terephthalaldehydes are shown in Fig. 1, in which the bond angle of C–C=O is assumed to be 120°.

Results and Discussion

The SCF-MOs and MO energies are listed in Table I. In large molecules multiply-excited configurations should make a negligibly small contribution to the lower excitation energies. Therefore, we take account of single excitations only in the present calculation. The configuration

We observed terephthalaldehyde to have three π-π^* absorption bands, at about 300, 260 and 200 mμ, in an *n*-hexane solution. The energy values corresponding to these absorption bands are also listed in Table II. The calculated values are in agreement with the observed values. From Table II we can not find any significant difference in state energies between the *cis*-isomer and the *trans*-isomer, but the 1st excited energy of the *trans*-isomer is lower than that of the *cis*-isomer. The values of the Coulomb integral are almost invariant over a great atomic distance. The change in the position of the carbonyl group from the *trans*-form to the *cis*-form does not have any appreciable effect on the molecular integral, because the distance between carbonyl groups is large. The similarity in electronic structure of *cis*- and *trans*-terephthalaldehydes is attributed to the above fact. The absorption spectrum of terephthalaldehyde resembles that of benzaldehyde. The spectrum of the former shifts to a longer wavelength side than that of the latter. The similarity in absorption spectra can be seen in the transition energies and oscillator strengths obtained for benzaldehyde[2,3] and for terephthalaldehyde. The charge densities and the free valences of both isomers for the ground and lower excited states are listed in Table III. These values of the excited states are calculated by assuming the same molecular structures as in the ground state. The charge densities of the position 4 of *cis*- and *trans*-terephthalaldehydes indicate a high reactivity to electrophilic reagents.

The present study was partially financed by the Scientific Research Fund of the Ministry of Education.

Some Rheological Properties of Sodium Polyacrylate Solutions

By Shiro KUROIWA and Matao NAKAMURA

Institute of Industrial Science, The University of Tokyo, Azabu, Tokyo

(Received October 20, 1965)

The viscoelastic properties of aqueous solutions of sodium polyacrylate (degree of polymerization= 45000) were studied. It seems that the results described below reveal some characteristics of the polyelectrolyte studied.

The dynamic rigidity and viscosity (G', η') and the steady flow viscosity (η_a) were measured by a coaxial double cylinder rheometer,*1 in which the outer cylinder was driven to oscillate or revolve. G' and η' were calculated by the method described by Markovitz.[1] η_a is the apparent viscosity, assuming the Newtonian flow.

For a comparison of G' with the rigidity G, calculated from the elastic recovery following a steady flow,*2 the data reported in a previous paper were used.[2]

The experimental results are illustrated in Figs. 1 and 2. In Fig. 1, the vertical shifts along the log G' axis for the superposition of log G' — log ω curves of varied concentrations were not proportional to (C_0/C), but to $(C_0/C)^{1.2}$, as may be seen in Fig. 3. C is the concentration, and the subscript refers to the reference concentration. Therefore, Ferry's reduced variables,[3] G_r', η_r'

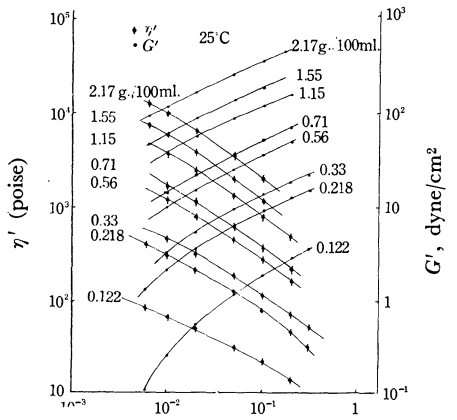

Fig. 1. Dependence of η' and G' on ω and concentration.

● $(C_0/C)^{1.2}$ (calc. value)

and ω_r, for the concentration were modified as follows at a costant temperature:

$$G'_r = G'(C_0/C)^{1.2} \quad (1)$$

$$\eta'_r = \eta'(\eta_0/\eta) \quad (2)$$

$$\omega_r = \omega(\eta/\eta_0)(C_0/C)^{1.2} \quad (3)$$

η indicates the zero shear viscosity. η/η_0 as a

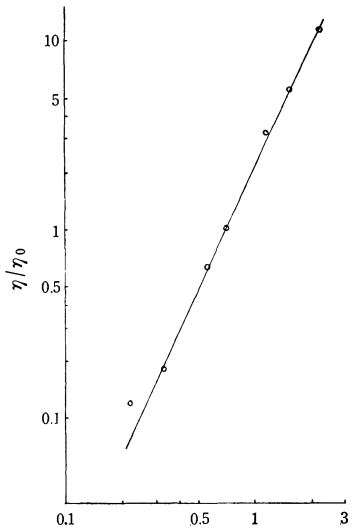

Fig. 4. Relation between η/η_0 and concentration.

function of C was determined from $(C_0/C)^{1.2}$ and the horizontal shifts along the log ω axis by means of Eq. 3. A linear relation between log η/η_0 and log C was obtained, as is illustrated in Fig. 4.

Reduced variables for η_a and $\dot{\gamma}_a$ (the average shearing rate) were defined as:

$$\eta_{ar} = \eta_a(\eta/\eta_0) \tag{4}$$

$$\dot{\gamma}_{ar} = \dot{\gamma}_a(\eta/\eta_0)(C_0/C)^{1.2} \tag{5}$$

Master curves reduced to 0.71 g./100 ml. are represented by Figs. 5 and 6. In Fig. 6, η_{ar} shows a small fluctuation, but it seems to be within the range of experimental error. It may be observed in Fig. 6 the difference between η_{ar} and η'_r becomes obvious with an increase in $\dot{\gamma}_{ar}$ or ω_r, as have been described by several authors for various polymer systems.[4-8] However, the concentration dependence of the zero shear viscosity seems to be very small compared with that of usual polymers, i e. $\eta/\eta_0 \propto C^2$. In the concentration range (0.25—1.5 g./100 ml.) studied, products of the chain length, Z, and the volume fraction of the solute, v, were calculated as 230—1400. The critical value of Zv, i. e., $Z_c v_c$, is known to be about 200—1400 in usual polymers.[9] The $Z_c v_c$ value for aqueous solutions of polyacrylic acid had been reported as 130.[10] Further, the η of the sample may be expected from Fig. 2 to be larger than 10^2 poise. Usually, under such conditions, the η values of many polymer solutions depend on C^{5-6}.[7,11-14] For example, Fukada reported that the η/η_0 values of aqueous collagen solutions in a concentration range similar to that of this study depend on C^6,

where a procedure analogous to that used in this study was employed for evaluating η/η_0.[14]

Accordingly, it may be said that the nature of the molecular interactions of the polyelectrolyte studied here is remarkably different from that of other polymers. In other words, some mechanisms other than the so-called Bueche entanglements[12,15] may dominate the viscosity of the solutions, in spite of their high Zv and η values. The extraordinarily anomalous non-linearity of flow and the very large recoverable strain of the sample[2] can probably be interpreted by means of this abnormal intermolecular mechanism.

When $\log G'$, $\log \eta'$, $\log \eta_a$ and $\log G$ were plotted against $\log C$ at fixed ω, $\dot{\gamma}_a$ and $\dot{\gamma}$ (true shearing rate) values respectively, straight lines were obtained. The slopes of these lines were estimated; they are plotted against ω, $\dot{\gamma}_a$ and $\dot{\gamma}$ respectively in Fig. 7. In this figure the concentration dependence of η_a seems to be extrapolated to about 2, whereupon $\dot{\gamma}_a$ becomes small. This is in agreement with the relation, $\eta/\eta_0 \propto C^2$, described above.

In Fig. 8, $\log G'$ is compared with $\log(\sigma^2/2G)$, where ω and $\dot{\gamma}$ are assumed to be equivalent. σ is the shearing stress. $\sigma^2/2G$ may be equal to $(P_{11}-P_{22})/2$, in which $P_{11}-P_{22}$ is the normal stress in rheogoniometry. According to the theory of Coleman et al.,[16] $(P_{11}-P_{22})/2$ as a function of the shearing rate must approach G' as a function of ω, when shearing rate of ω becomes small. This theory was confirmed by Kotaka et al. to hold for polystyrene solutions.[17] In Fig. 8, however, there

seems to be no tendency for G' and $\sigma^2/2G$ to approach each other when ω or $\dot{\gamma}$ becomes small. The reason for this is not clear. However, it is not inconceivable that the discrepancy between the theoretical and the experimental results comes from some thixotropic characteristic of the substance.

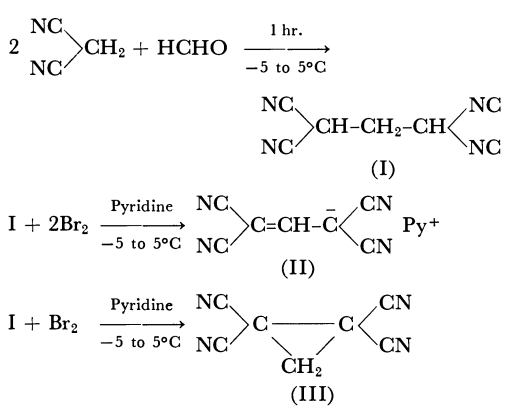
The Bromination of 1, 1, 3, 3-Tetracyanopropane*

By Akimasa TANIGUCHI, Kojiro SUZUKI and Hiroshi MIKAWA

Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received November 1, 1965)

Two compounds were obtained by the bromination of 1,1,3,3-tetracyanopropane[1] (I) in the presence of pyridine.

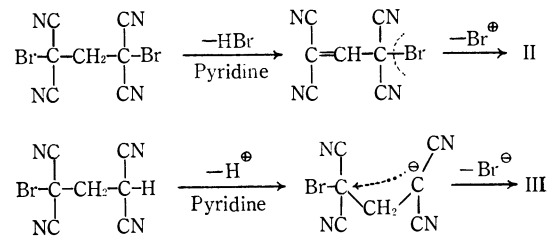


When I was brought into reaction with two moles of bromine, a white crystalline solid (II) melting at 157—159°C was obtained. II was pyridinium-1, 1, 3, 3-tetracyanopropenide. The sodium salt of the same compound has been reported by Urushibara.[2]

When I was brought into reaction with one mole of bromine, a white crystalline solid (III) was obtained, it melted at 224°C and sublimed at 150—180°C under diminished pressure. Its properties and melting point agree with those for 1, 1, 2, 2-tetracyanocyclopropane reported by Scribner et al.[3]

Thus, the reaction gave quite different products when the mole numbers of bromine were changed.

The mechanism of the reaction may be supposed to be as follows:



It is known that the active methylene is readily brominated by bromine in the presence of pyridine. In the case of the reaction using two moles of bromine, both active hydrogens are replaced by bromine and bromotetracyanopropene is formed by the elimination of hydrogen bromide. A cation of bromine is liberated from the propane to give tetracyanopropenide anion (II). It was recoginized by Trofimenko et al.[4] that the bromocation was produced from bromotricyanomethane.

On the other hand, when one mole of bromine is used, the first step is the replacement o one of the active hydrogens of I by bromine, and then the another active hydrogen is eliminated by pyridine. The cyclopropane ring is formed by an intramolecular condensation.

This reaction provides an excellent route for the preparation of III.

Experimental

Pyridinium-1, 1, 3, 3-tetracyanopropenide (II).— Four grams (0.028 mol.) of 1, 1, 3, 3-tetracyanopropane, 10 g. (0.0625 mol.) of bromine and 38 ml. of acetonitrile

* Presented at the 18 th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

were mixed at −5°C and then 9.0 g. (0.114 mol.) of pyridine was added over a period of 10 min. The mixture was stirred at 0°C for two hours until the red-orange solution became colorless; then the solution was poured into a mixture of 20 ml. of concentrated hydrochloric acid and 40 g. of crushed ice. The solution was concentrated at low temperature in vacuo and the white solid which was precipitated out from the solution was collected and washed with a mixture of cold water, alcohol and petroleum ether, and dried in a vacuum desiccator. It was then recrystallized from tetrahydrofurane to give 1.2 g. (34.3%) of white crystalls, m. p. 157—159°C.

Found: C, 64.98; H, 3.76; N, 31.76. Calcd. for $C_{11}H_7N_5$: C, 65.1; H, 5.78; N, 31.70%.

IR: 4.55 (CN), 6.14, 6.24, 6.38, 6.55, 6.75, 7.45, 8.10, 9.55, 10.6, 11.2, 12.3, 13.5 μ.

1,1,2,2-Tetracyanocyclopropane (III).—Ten grams (0.07 mol.) of 1, 1, 2, 2-tetracyanopropane, 12.5 g. (0.78 mol.) of bromine and 100 ml. of acetonitrile were mixed at 0.°C and then 11.3 g. (0.143 mol.) of pyridine was added over a period of 15 min. When the mixture was stirred at 0°C for an hour, it lost its red-orange color. The solution was then poured into a mixture of 30 ml. of concentrated hydrochloric acid and 60 g. of crushed ice. After an hour, a white solid separated from the solution. The product was collected and washed with a mixture of cold water, alcohol and petroleum ether, and dried in a vacuum desiccator. It was crystallized from ethyl acetate to give 7.5 g. (76.0%) of white crystals, m. p. 220—224°C. It sublimed at about 150°C (1 mmHg).

Found: C, 59.16; H, 1.42; N, 39.42. Calcd. for $C_7H_2N_4$: C, 58.62; H, 1.78; N, 39.42%.

IR: 3.23, 3.32, 4.43(CN), 6.90, 7.01, 8.25, 9.07, 9.88, 13.8 μ.

The authors wish to thank Mr. Takuzo Fujino and Mr. Tsuneyo Shishido for their elementary analyses.

Fluorescence Spectra of Acridine-Mercuric Halide Complexes

By Michio KONDO and Harumitsu KUWANO

Central Research Laboratories, Sankyo Co., Ltd, Shinagawa-ku, Tokyo

(Received November 13, 1965)

It has been reported that acridine is non-fluorescent in the solid state and in nonpolar solvents such as hexane and benzene.[1] In polar solvents such as alcohol and water capable of forming hydrogen bonds, acridine emits a blue fluorescence.[1,2] The radiationless deactivation of an excited molecule of acridine has been ascribed to interaction between n- and π-electrons.[2] In polar solvents, an excited molecule of acridine combines rapidly with the nearest OH group of a solvent molecule. Such a hydrogen-bonded molecule may be considered to be a fluorescent species, since the formation of hydrogen bonds in the excited state results in a decrease in the n—π interaction.[1,2] Acridinium ions emit a green fluorescence in various solvents[1] as well as in the solid state. This fact also supports the interpretation that the non-radiative degradation of acridine in the excited state is due to the n—π interaction.

Matsushita[3] examined the emission spectra of a number of benzylideneamine and salicylideneamine derivatives. He showed that the formation of intramolecular hydrogen bonds intensifies the emissivity of fluorescence because of the diminution of the n-electron contributions to the non-radiative degradation of the excited state.

Acridine forms crystalline molecular complexes with some inorganic compounds.[4] If the n-electrons at the nitrogen atom of acridine are involved in the formation of these molecular complexes, it is to be expected that the n—π interaction in the excited state will be reduced to a great extent and that the fluorescence emission will be enhanced.

Experimental

Materials.—Acridine and mercuric halides were purified by sublimation or recrystallization. An acetone solution of acridine was added to an acetone solution of an appropriate mercuric halide in order to prepare the molecular complexes.

Fluorescence Measurements.—The fluorescence spectra of the molecular complexes were recorded with a Shimadzu model SV-50 AL spectrophotometer equipped with an accessory for measuring the fluorescence spectra of solid samples.

Results and Discussion

Acridine-mercuric halide (1 : 1) complexes emit a green fluorescence in the solid state. Table I shows the results obtained under illumination with

a light of $\lambda=350$ mμ. It should be noted that the intensity of emission depends markedly on the kind of halogen ions, while fluorescence maxima are located at nearly the same wavelengths. The small variation in the peak position is probably due to a small change in the interaction between acridine and mercuric halides. The decrease in the fluorescence intensity of complexes with the increase in the atomic weight of the halogen ions may be attributed to the spin-orbit coupling which is generally considered to be a mechanism promoting the radiationless deactivation of excited molecules.

It is of interest, in this connection, to note that mercury atoms, in spite of their heavy atomic weight, do not strongly promote the spin-orbit coupling in diminishing the emission. This fact suggests that the mercury atoms may be located in the molecular plane of acridine, because the π-orbitals have their nodal planes on the molecular plane of acridine and, therefore, the spin-orbit interaction might be small. As judged from the efficiency of the spin-orbit coupling of the halogen ions, the mercuric halide molecules may be oriented perpendicular to the molecular plane of acridine, and the spin-orbit coupling between the nearest neighbor complex molecules may contribute to the diminution of emission. The square planar configuration about the metal atom was pointed out for NiI_2-(Acridine)$_2$ in the solid state.[4b]

The present authors examined the absorption spectra of two kinds of films of acridine-mercuric halides, one of which was prepared by the sublimation of an appropriate mercuric halide onto a presublimated film of acridine, while the other was prepared by the sublimation of acridine-mercuric halide complexes. The latter gave better results except for the case of acridine-mercuric iodide. Acridine hydrochloride yielded no good results, probably because it decomposes by losing hydrogen chloride. These complexes show broad absorption bands very similar to those of acridinium cations in solution with structures over the range of 350—440 mμ. From the similarity observed in the absorption and the fluorescence spectra, it may be considered that the electronic structure of the acridine part in the complexes is essentially the same as that of the acridinium cation. Thus, it may be concluded that the *n*-electrons at the nitrogen atom of acridine are partially transferred to the mercury atom, affording an intermolecular binding force.

Good photoconductive materials can be found among luminescent species.[5] In fact, anthracene is a representative photoconductive material in organic compounds, whereas acridine shows no good photoconductive property. From this point of view, the photoconductivity of these complexes was measured in a surface cell consisting of a polycrystalline pellet pressed under 1 kbar and two gold electrodes spattered onto the same surface of the pellet with a narrow gap of 1 mm. No positive results were obtained. In aromatic hydrocarbons, the photocarrier generation process in the crystal absorption region has been discussed in terms of the dissociation of singlet excitons on the crystal surface, but the idea that the photocarrier generation originates in exciton-exciton annihilation can not be eliminated.[6] In any case, the energy transfer of excitons produced by light absorption is essentially required for generating carriers. In the present case, acridine molecules seem to be separated from one another by intervening mercuric halide molecules. This weakens the overlap between the π-orbitals of the nearest neighbor acridine molecules to the extent that the exciton transfer is impossible. Therefore, no photocurrents were observed.

The Preparation and Properties of Dipotassium Bis(glycylglycinato)cuprate(II)

By Yasuo NAKAO, Ken-ichi SAKURAI and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received November 18, 1965)

In a previous communication[1] we reported the preparation of dipotassium bis(diketopiperazinato)-cuprate(II). The investigation was, there after, continued in an attempt to obtain more detailed information on the structure of that novel compound; contrary to our expectations, we reached the conclusion that the complex we had isolated before was bis(glycylglycinato)cuprate(II) instead of bis(diketopiperazinato)cuprate(II). Our results do, however, seem worth reporting because the isolation of dipotassium bis(glycylglycinato)cuprate(II) is still new, and it does contribute to the knowledge in this field. In fact, all the papers previously published dealing with the bis(glycylglycinato)cuprate(II) complex were concerned only with the complex formation in solution.[2] The purpose of the present paper is not only to rectify the erroneous conclusion in the previous communication, but also to describe the preparation and properties of the dipotassium bis(glycylglycinato)cuprate(II).

Experimental

Dipotassium Bis(glycylglycinato)cuprate(II).—A mixture of 11.4 g. (0.1 mol.) of diketopiperazine and 8.4 g. (0.15 mol.) of potassium hydroxide was dissolved in 150 ml. of water. To the solution there was added about 4 g. of freshly precipitated cupric oxide with a rapid agitation at about 25°C. Though the solution had been red-purple at the beginning of the reaction, it gradually became blue-purple. The reaction was completed within a few hours. After it had been filtered, the solution was evaporated to dryness in vacuo to give a red-purple, crystalline product. The product was repeatedly recrystallized from water by adding a large amount of acetone. The same compound was also prepared, employing the same procedure, from glycylglycine instead of diketopiperazine.

Although the thoroughly-purified crystal is fairly stable in a dry atmosphere, it is quite unstable to moisture; hence, it is impossible to obtain a red-purple aqueous solution without the coexistence of a large quantity of glycylglycinate ions. M. p. 113—120°C (decomp.). The results of the elemental analysis of the non-dehydrated crystal were as follows:

Found: K, 15.66; Cu, 12.75; C, 19.08; H, 5.00; N, 10.96; H_2O, 22.6. Calcd. for $K_2[Cu(C_4H_6N_2O_3)_2]\cdot 6H_2O$: K, 15.31; Cu, 12.43; C, 18.83; H, 4.71; N, 10.98; H_2O, 21.2%.

On the other hand, the results of the analysis of a completely dehydrated crystal were as follows:

Found: C, 24.12; H, 3.22; N, 13.15. Calcd. for $K_2[Cu(C_4H_6N_2O_3)_2]$: C, 23.88; H, 2.94; N, 13.90%.

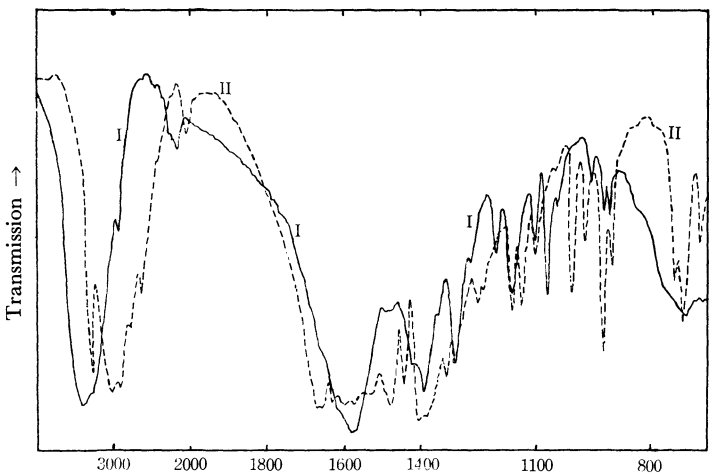

Fig. 1. Infrared absorption spectra of: I, dipotassium bis(glycylglycinato)cuprate(II); II, glycylglycine.

2) H. Dobbie and W. O. Kermack, *Biochem. J.*, **59**, 246 (1955); S. P. Datta and B. R. Rabin, *Trans. Faraday Soc.*, **52**, 1117 (1956); F. R. N. Gurd and P. E. Wilcox, "Advances in Protein Chemistry," Academic Press, New York (1956), p. 311; W. L. Koltun, R. H. Roth and F. R. N. Gurd, *J. Biol. Chem.*, **238**, 124 (1963).

Diketopiperazine (2, 5-Piperazinedione) was prepared according to the directions of Sannié,[3] while in preparing glycylglycine we applied the method of Fischer et al.[4]

Measurements.—The infrared spectra were obtained by a Hitachi EPI-2 Infrared Spectrophotometer. The measurements were made at room temperature using the pressed potassium bromide disk technique in the wave number range from 700 to 4000 cm^{-1} with a rock-salt prism. The spectra are shown in Fig. 1.

The visible and ultraviolet spectra were obtained with a Shimadzu Spectrophotometer, Type QB-50. Since the bis(glycylglycinato)cuprate(II) complex was readily dissociated in an aqueous solution, a solution containing 1F of potassium glycylglycinate was employed as the solvent.

The concentration of the complex used varied from 10^{-2} to 10^{-3}F. The spectra are shown in Fig. 2.

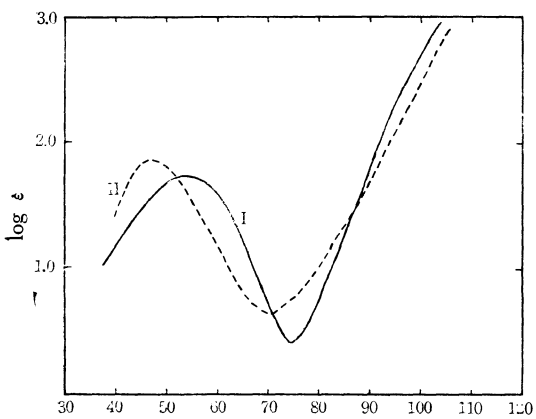

Fig. 2. Visible and ultraviolet absorption spectra of I, dipotassium bis-(glycylglycinato)cuprate(II) in water solution containing 1F of glycylglycine and 2F of potassium hydroxide; II, the same complex in water.

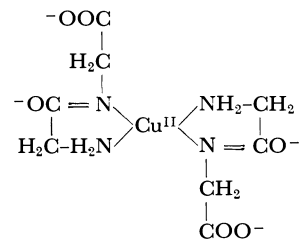
Results and Discussion

It will, first of all, be necessary to correct our previous communication, which reported the successful preparation of bis(diketopiperazinato)-cuprate(II). The diketopiperazinatocuprate(II) structure was finally negated by the following two facts. First, it has been disclosed that the complex derived from glycylglycine is identical with that derived from diketopiperazine. Second, it has also been found that the results of the elemental analysis of the perfectly dehydrated complex eliminate the possibility of diketopiperazinato-cuprate(II) structure. The second fact may be supposed to be particularly important because the analytical values of the constituent elements in the non-dehydrated complex are expected to be same (except for the value of the water of crystallization) in the case of either the octahydrate of diketopiperazinatocuprate(II) or the hexahydrate of bis(glycylglycinato)cuprate(II). Thus, we may conclude that the complex prepared from the reaction between a mixture of potassium hydroxide and diketopiperazine and cupric oxide is not diketopiperazinatocuprate(II) but the bis(glycylglycinato)cuprate(II) complex.

The formation of this complex in solution has been investigated by several chemists.[2] They have presented a structure in which copper(II) links to the glycylglycinate anion only through the terminal amino group and the nitrogen of the peptide linkage. In other words, the carboxylate group is not involved in the coordination. The present work strongly supports the above proposal, giving more evidence for the structure I.



Structure I. The Bis(glycylglycinato)cuprate(II) Ion.

For example, all the four donor atoms (apart from the further coordination sites of copper(II)) are apparently nitrogen, judging from the color of the crystal and the location of the ligand field absorption band of the complex in solution, as is clear from Fig. 2. Indeed, the absorption maximum of the complex in the presence of an excess of glycylglycinate ions, 54×10^{13} sec^{-1}, nearly coincides with that of bis(ethylenediamine)copper(II), suggesting its $Cu(N)_4$-type structure.

The proposal that the carboxylate group is not involved in the coordination can also reasonably be accepted, since there is estimated to be a considerable strain in the structure which contains the additional links of the carboxylate oxygens to the $Cu(N)_4$-type planar complex. As to the geometrical isomerism, the trans configuration, which has been suggested by Gurd and Wilcox,[2] is positively supported, because X-ray study* has recently shown that there is a center of symmetry in the complex.

The complex is readily dissociated in water, without the aid of a large quantity of glycylglycinate ions, to give a blue solution which may be considered to correspond to a $Cu(N)_3(O)_1$- or $Cu(N)_2(O)_2$-type structure.[5] This may be seen as the result of a displacement of peptide nitrogen in the coordination by water molecules. Indeed, the absorption

3) C. Sannié, *Bull. Soc. Chim. France*, **9**, 487 (1942).
4) E. Fischer and E. Fourneau, *Ber.*, **34**, 2868 (1901).

* Private communication from Dr. Yoshio Sasada of the Institute for Protein Research, Osaka University.
5) A. Nakahara, This Bulletin, **32**, 1195 (1959).

maximum of the complex alone in water appears in the region of considerably longer wavelengths, as is shown in Fig. 2, suggesting the validity of the above consideration.

Thus, the hygroscopic nature of this particular complex crystal does not imply the simple dissolution of the complex in the absorbed water, but it does imply the partial dissociation of the complex in the absorbed water. On the other hand, the water molecules which displaced the peptide nitrogen from the coordination sites can be expelled by a large amount of acetone to give the $Cu(N)_4$-type structure again. The recrystallization of the present complex using water and acetone may proceed by means of such a mechanism.

Summary

The previous conclusion has been corrected as follows. The complex prepared from the reaction of cupric oxide with a mixture of potassium hydroxide and diketopiperazine is not diketopiperazinatocuprate(II) but bis(glycylglycinato)-cuprate(II).

The preparation and some properties of dipotassium bis(glycylglycinato)cuprate(II) have been described. As to the structure of the complex, it has been concluded, from powerful evidence, that two glycylglycinate anions are coordinated around copper(II) in the trans configuration only through the terminal amino group and the nitrogen in the peptide linkage.

The authors wish to thank Dr. Shigeo Kida of Wakayama University for his analysis of potassium and the Ministry of Education for a grant-in-aid.

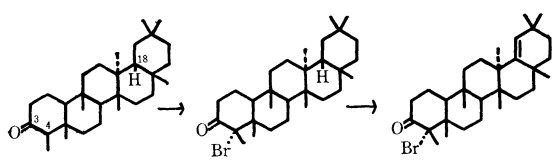
The Reaction of Friedelin with *N*-Bromosuccinimide

By Takahiko TSUYUKI, Yoshiaki TANAHASHI, Yoshiro SUDO
Sigeki NAKAMATA and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 19, 1965)

Kane and Stevenson[1,2] have reported the reactions of *N*-bromosuccinimide (NBS) with friedelin (I) and with friedelane (II). Friedelin is brominated with 1 mol. of NBS to give 4α-bromofriedelin (III), which in turn yields, after purification, 4α-bromofriedel-18-en-3-one (IV) upon further treatment with 1 mol. of NBS.



I III IV

Fig. 1

In the case of the hydrocarbon, friedelane, it is oxidized by NBS to the olefin, friedel-18-ene (V); furthermore, Stevenson et al. have more recently shown[3] that when a solution of bromine in carbon tetrachloride is added to friedelane, it is decolorized, and that the reaction mixture yields friedel-18-ene (V) in a yield comparable to that in the NBS reaction. This indicates that, in this highly selective oxidation, the intermediacy of the succinimidyl radical is not essential.[4-9]

They also isolated an unstable 18-bromofriedelane, which readily afforded friedel-18-ene (V), and they inferred that in the case of friedelin (I), particularly in the formation of di- and tri-bromo-derivatives at C-2 and/or C-4, a bromination at 18-position took place concurrently.

We first examined the bromination products of

9) G. A. Russell, C. DeBoer and K. M. Desmond, ibid., **85**, 365 (1963).

friedelin (I). According to the method of Kane and Stevenson,[2] friedelin was brominated with 1 mol. of NBS. The reaction mixture, showing two spots on the thin-layer chromatogram, was separated into bromo derivatives and bromine free derivatives. The latter was shown by gas chromatography to be a mixture of friedelin (I) and friedel-18-en-3-one (VI). The former was reduced with zinc in a boiling solution of benzene and ethanol, and examined by gas chromatography. Its retention time showed the presence of friedelin and friedel-18-en-3-one. It followed that the bromo-derivatives had contained 4α-bromofriedelin (III) and 4α-bromofriedel-18-en-3-one (IV).

It now appears likely that in the reaction of friedelin with 1 mol. of NBS, a competitive reaction occurs; namely, the bromine atoms independently attack the 4α- and 18-hydrogens of friedelin, giving rise to III and VI respectively, and then further attack the 18-position of III and /or the 4α-position of VI to afford 4α-bromofriedel-18-en-3-one (IV).

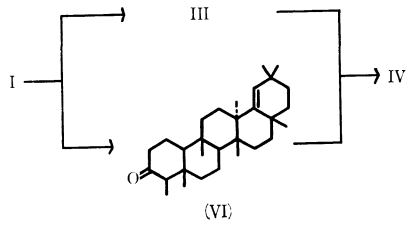

Fig. 3

The reaction products are shown in Table I, from which it is obvious that the main reaction pathway is I→III and that the I→VI pathway is minor.

In order to determine the catalytic action of 2, 2'-azo-bis-isobutyronitrile (AIBN) toward the reaction of friedelin with NBS, we treated friedelin in a carbon tetrachloride solution with 1 mol. of NBS and a catalytic amount of AIBN under irradiation with an infrared lamp. The reaction products were nearly the same as in the case without AIBN, as is shown in Table I.

Table I

Product (in mol.%)	III	IV	I	VI	Lost product
NBS(1.1 mol.), AIBN(0.01 mol.) in CCl_4	63	12	22	2	1
NBS(1.4 mol.) in CCl_4	61	13	10	0.4	16

Experimental

The Reaction of Friedelin with NBS (Method described by Kane and Stevenson[2]).—*N*-Bromosuccinimide (150 mg.) was added to a solution of friedelin (250 mg.) in carbon tetrachloride (70 ml.); the mixture was then heated under reflux for 37 min. by means of an infrared lamp. After 8 min. irradiation a yellow color appeared and the bromine color persisted for 3 min. The mixture was cooled and filtered, and the solvent was removed under reduced pressure. The yellow residue, which weighed 307 mg., was dissolved in petroleum ether - benzene (9 : 1, 70 ml.) and chromatographed on silica gel (Davison, 200 mesh, 7.5 g.). Elution with this solvent (ca. 1 l.) gave the bromofriedelin mixture (221 mg.). After elution with petroleum ether-benzene (4 : 1, 100 ml.), petroleum ether - benzene (1 : 1, 300 ml.) yielded 26 mg. of bromine-free materials, which were shown by gas chromatography* to be a mixture of friedelin (25.1 mg., retention time 8.0 min.) and friedel-18-en-3-one (0.9 mg., retention time 6.5 min.).

The Reduction of the Bromofriedelin Mixture.—Zinc dust (4.3 g.) was added, portion by portion and over 1-hr. period, to a boiling solution of the above bromofriedelin mixture (122 mg.) in benzene-ethanol (1 : 1, 150 ml.). After an additional 2 hrs.' boiling, the hot solution was filtered. The evaporation of the solvent under reduced pressure gave a solid. Gas chromatography showed that it was a mixture of friedelin and friedel-18-en-3-one in the ratio of 4.5 to 1, which indicated that the original bromofriedelin mixture (221 mg.) contained 181 mg. of 4α-bromofriedelin and 40 mg. of 4α-bromofriedel-18-en-3-one.

The Action of AIBN on the Reaction of Friedelin with NBS.—To a solution of friedelin (100 mg.) in carbon tetrachloride (28 ml.), NBS (49 mg.) and AIBN (0.4 mg.) were added. The solution was heated by means of an infrared lamp. After 13 min. a yellow color appeared, but it faded instantly. Heating at reflux was continued for 45 min. until the yellow color completely disappeared; the reaction mixture was then treated as before. The residue was chromatographed on silica gel (Davison, 200 mesh, 3.0 g.). Elution with petroleum ether - benzene (9 : 1) gave a solid (89.2mg.), and continued elution with petroleum ether - benzene (1 : 1) also afforded a solid (23.6 mg.). The former was reduced with zinc (3.2 g.), and the product was shown by gas chromatography to be a mixture of friedelin (67.2 mg.) and friedel-18-en-3-one (8.0 mg.), which corresponded to 79.7 mg. of 4α-bromofriedelin and 9.5 mg. of 4α-bromofriedel-18-en-3-one respectively. The latter was found by gas chromatography to be a mixture of friedelin (21.9 mg.) and friedel-18-en-3-one (1.7 mg.).

Analytical Approximations for Coherent and Incoherent Atomic Scattering Factors

By Shuzo SHIBATA

Department of Chemistry, Faculty of Science, Shizuoka University, Oiwa, Shizuoka

(Received November 29, 1965)

For the analysis of gas electron-diffraction data by the use of an electronic computer, analytical approximations[1] for coherent and incoherent atomic scattering factors are useful in order to decrease the amount of input data and to obtain their values for arbitrary scattering angles by smooth interpolation. A simple analytical function, $\exp(\sum a_n q^n)$, was found to be a good approximation for the coherent and incoherent atomic scattering factors. Here q is the scattering variable defined by $40\sin(\theta/2)/\lambda$, where θ is the scattering angle and λ is the wavelength of the incident X-rays or electrons. Such an expression was used by Silverman and Simonsen[2] for atomic scattering factors for an X-ray analysis. In their work, however, the values of the scattering variable, q, were limited to within 50. The q values usually convered by the experimental data of gas electron diffraction, however, range from 10 to 100. The present calculation of the analytical constants has, therefore, been carried out to cover this range of the scattering variable. The scattering factors given by Viervoll and Ögrim[3] were adopted in the present calculation, because no other scattering factors[4] calculated thus far extend to sufficiently large scattering angles.*1

The parameters of the polynomials were determined by a least-square method by minimizing $\sum_i(\ln f_{0i}-\ln f_i)^2$, where f_0 is the theoretical value and f is the calculated value. The evaluation was straightforward because the parameters were taken as linear. The function was tested mainly with polynomials of the fifth, sixth and seventh degrees. The standard deviation, σ, given by $[\sum_i(f_{0i}-f_i)^2/N]^{1/2}$, was calculated in each case. Here N is the number of the values fitted. The sixth-degree polynomial exponent gave a σ value smaller than that for the fifth-degree, whereas the polynomial exponent of a degree higher than the sixth did not give a much better fit. A typical case is presented in Table I. The parameters obtained are tabulated in Table II, with their standard deviations for twenty-three atoms from hydrogen to copper. Theoretical values below 9.55 in q were not used for the fitting, since the values in this range are not needed for usual analyses of gas electron diffraction.*2 Therefore, another set of parameters should be used if coherent scattering factors for smaller q values are required. This latter set was obtained by fitting thirty theoretical values of Viervoll and Ögrim*3, beginning with 3.18 in q, by a sixth-degree polynomial exponent. The standard deviation was somewhat larger. Table III shows several different sets of analytical constants for the coherent atomic scattering factor of carbon with varying minimum q values and varying numbers of the theoretical values fitted.

The incoherent scattering factor, $S(v)$, calculated by Bewilogua[7] was approximated by an analytical function, $1-\exp(\sum b_n v^n)$, where $v=0.0553\cdot Z^{-2/3}\cdot q$ and Z is the atomic number. The exponent of a fifth-degree polynomial was found to be sufficient to reproduce the theoretical values with a good accuracy over the entire range of v. The sets of parameters are tabulated in Table IV for various degrees of polynomial exponents. The incoherent scattering factors approximated by the fifth-degree polynomial exponent are compared in Table V with those calculated by Bewilogua.

*1 One exception is the atomic scattering factor calculated by Hanson et al.[5] from the Hartree-Fock-Slater wave function, but Viervoll and Ögrim's factors agree better with the absolute values of complex atomic scattering factors,[4] $|f|$, than Hanson's factors.

*2 Another reason for this was that the scattering factors in this region may be uncertain because of the exchange effect of electrons.

*3 It is desirable, however, to use other theoretical scattering factors obtained with reference to the exchange effect. For example, by the use of the scattering factor of carbon by Berghuis et al.,[6] the fit with a sixth-degree polynomial exponent resulted in the standard deviation of 0.013. Silverman and Simonsen, however, obtained 0.095 for the standard deviation from the same fit with a fixed coefficient, a_0.

The Crystal and Molecular Structure of 10-Halo-5, 10-dihydrophenarsazine*

By Makoto FUKUYO, Kazumi NAKATSU and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received January 5, 1966)

The 10-halo-5, 10-dihydrophenarsazine (phenarsazine halide) might be regarded as a tricyclic ring in which two benzene rings are connected by the arsenic and the nitrogen atoms. The present work was undertaken in order to elucidate the influence of the arsenic and the nitrogen atoms upon the configuration of this tricyclic ring. The disposition of halogen atoms around the arsenic atom would also be of interest in connection with the valence state of the arsenic atom. In the course of the present investigation, a paper on the structure of the chloride has already been published.[1] It would be interesting to compare this result with ours, although ours is still in the stage of refinement.

Preliminary powder photographs seem to indicate that the crystals of the chloride, the bromide, and the iodide belong to the same crystal system, while the fluoride crystal belongs to a different system. Among these halides, the chloride, the bromide and the iodide gave needle crystals suitable for X-ray work. These crystals were found to be elongated along the *c* axes. Oscillation and Weissenberg photographs were prepared with Cu$K\alpha$ radiation. The crystal data are listed in Table I. The intensities were estimated visually with a calibrated scale by making use of the multiple-film technique. The corrections for polarization and Lorentz factors were applied in the usual way, and that for absorption was neglected.

The chloride was first studied. Since the *c* axis is shorter, the Patterson projection onto the (001) plane was computed, and it clearly revealed the interatomic vectors between arsenic and chlorine atoms as well as between arsenic atoms.

TABLE I. CRYSTAL DATA

Phenarsazine chloride	Phenarsazine bromide
$C_{12}H_9AsClN$	$C_{12}H_9AsBrN$
Orthorhombic	Orthorhombic
$a=13.82$Å	$a=15.06$Å
$b=14.12$Å	$b=15.09$Å
$c=5.40$Å	$c=5.22$Å
$D_x=1.749$ g. cm^{-3} ($Z=4$)	$D_x=1.803$ g. cm^{-3} ($Z=4$)
$P2_12_12_1$	$P2_12_12_1$

The electron-density projection was then synthesized with the signs determined by the arsenic and chlorine atoms alone. Subsequent Fourier refinements made clear the positions of the lighter atoms. Electron-density projections along the other axes, obtained by means of the same procedure, gave the *z* coordinate of each atom. The reliability indices, *R*, were found to be 14.3, 17.7 and 22.4% for the *hk*0, *h*0*l* and 0*kl* spectra respectively. The isotropic temperature factors for all the atoms were estimated to be 3.2 Å^{-2} for the *hk*0 and 3.0 Å^{-2} for the *h*0*l* and 0*kl* spectra. Almost the same procedure of structure analysis was then applied to the bromide, the crystal structure of which was isomorphous with that of the chloride. The reliability index, *R*, was found to be 24.2, 22.1 and 36.3% for the *hk*0, *h*0*l* and 0*kl* spectra, the isotropic temperature factor being 5.0 Å^{-2} for the arsenic atom, 3.5 Å^{-2} for the bromine atom, and 5.0 Å^{-2} for the other atoms. The atomic coordinates in each crystal structure are listed in Table II.

Although the accuracy of analyses at this stage of refinement is not sufficient for us to discuss the results in detail, some interesting features of the molecular and crystal structure have been revealed. It may be remarked that the present results concerning the structure of the chloride agree approximately with those given by Camerman and Trotter,[1] although our work was done independently with two-dimensional data. The general scheme of the crystal structure may be seen in Fig. 1, which shows the crystal structure of the bromide isomorphous with the chloride. The interatomic distances within a molecule as well as between nearest molecules were found to be plausible in comparison with conventional values. A molecule consists of two nearly equivalent halves related by a plane of symmetry through nitrogen, arsenic and bromine atoms. The tricyclic ring can be regarded as a plane, from which only the halogen atom deviates significantly. Thus, the nitrogen atom may be in the sp^2 state of hybridization, while the arsenic atom may be in the p^3 state, probably with a slight *d* character. This situation indicates the delocalization of the lone-pair electrons in these two atoms to the benzene rings; this is in conformity with the ultraviolet spectra results shown in Fig. 2. There may be no intermolecular forces other than those of the van der Waals type, which are seen in all the intermolecular distances.

*) The major part of this paper was read at the symposium on Organometallic Compound, Nagoya, October, 1963, and also at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, March, 1964.

The Sintering of Colloidal Titanium

By Akira OKA

Department of Chemical Technology, Faculty of Engineering, Tokai University, Shibuya-ku, Tokyo

(Received March 24, 1966)

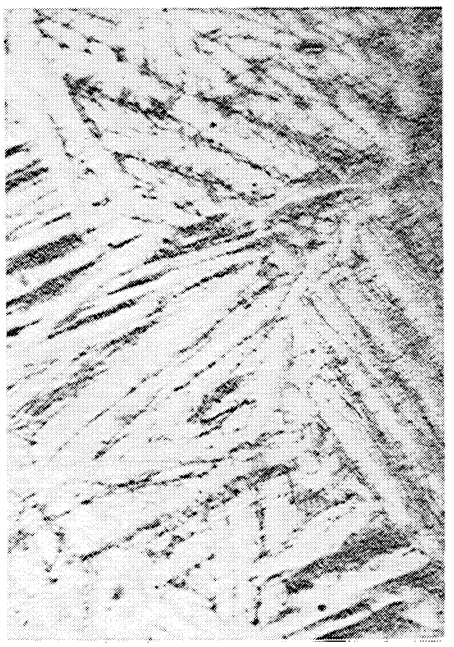
It is said that, in powder metallurgy, the finer the particle size of metallic powder, the more simplified conditions can be used in sintering it. So far as we can determine, however, nothing has been reported about the sintering of any metallic powder as colloidal as pyrophoric.

Recently, pure colloidal titanium was obtained through the dehydrogenation of titanium hydride, the composition of which was exactly stoichiometric ($TiH_{2.00}$). This dehydrogenated titanium was compacted at a pressure of 5 ton/cm^2, and then sintered for two hours at 1400°C. By this process a non-porous product was obtained; the density was found to be 4.54 g./cm^3, which corresponds to the full density of metallic titanium.

First of all, a mass of sponge titanium (purity 99.9% by ASTM standard) was subjected to reaction with pure hydrogen gas in a vessel at a red hot temperature; the hydrogen was carefully kept in the vessel, and prevented from being degraded lower than 99.999% in purity by passing it through a membrane of palladium alloy. A titanium hydride material with a composition exactly equal to $TiH_{2.00}$ was obtained by this process.

The titanium hydride obtained above was then milled for 40 hr. with a rotary mill made of sintered alumina. When the hydride powder thus pulverized was observed by electronmicroscopy, it was seen that the particles are of sizes between 60 Å and 300 Å, plus aggregated thereof. The hydride was then thremally dehydrogenated at 450°C in a tube furnace evacuated at 2×10^{-5} mmHg. A colloidal titanium was obtained, the specific surface of which was found to be 16 m^2/g. by the B.E.T. method; its mean particle size was therefrom calculated to be 0.08μ. The residual hydrogen of 27.7 p. p. m. was found by the fusion method. The colloidal titanium was kept in an air-tight jar filled with bomb nitrogen, as it is considerably pyrophoric in air.

The colloidal titanium obtained was then compacted in nitrogen atmosphere, by applying a pressure of 5 ton/cm^2, into a disk, with a diameter of 11.3 mm., a thickness of approximately 2 to 3 mm., and a green density of 3.1 g./cm^3. The disk thus obtained, after impregnation with liquid paraffin in order to protect it from air, was sintered at 1400°C for two hours in a vacuum furnace kept at 5×10^{-5} mmHg. The density of this product was 4.54 g./cm^3, as measured by a picnometer, while a nonporous structure was observed by means of microscopy (Mag. ×400).



Structure of non-porous titanium sintered at 1400°C for two hours. (Mag. ×400)

In contrast to the common idea that some porosity is unavoidable in a product obtained through the sintering of metallic powder, it may be seen that, if a colloidal particle of titanium is taken as the starting meterial, a substantially-full density of metallic titanium can be obtained by means of sintering alone, using a powder compacted at a sufficiently high pressure and kept away from air.

A Twinning Structure in Crystals of Potassium Terephthalate, p-$C_6H_4(COOK)_2$

By Shozo FURUYAMA and Nozomu EBARA

Department of Chemistry, College of General Education, The University of Tokyo, Meguro-ku, Tokyo

(Received April 14, 1966)

An unusual twinning structure of potassium terephthalate, p-$C_6H_4(COOK)_2$, has been found by means of an X-ray study using Cu$K\alpha$ radiation (λ=1.542 Å). The rotation, oscillation and the Weissenberg photographs on three principal axes displayed an orthorhombic symmetry, together with extinctions of $h0l$ when h=odd and $0k0$ when k=odd. No space group conformed to such diffraction patterns; it was, therefore, concluded that the crystal had the space group of $P2_1/a$ and that it twinned on the (100) plane by reflection. The crystal data are:

$a = 19.4$ Å

$b = 5.76$ Å

$c = 3.94$ Å

$\beta = 90°$

and $Z = 2$

β could not be measured directly, but it must be very near to 90°, so that the reciprocal lattice of one individual may fall by twinning on the lattice of the other individual, simulating a reciprocal lattice of an orthorhombic symmetry and preserving its original extinction.

The approximate positions of potassium cations, as projected on the (001) plane, were determined from the Patterson synthesis; a fairly good projection of the electron density (R=0.205), as is indicated in Fig. 1, was obtained after several trials. Figure 1 clearly demonstrates the very reasonable packing of molecules. Assuming a regular benzene ring with a C–C distance of 1.4 Å, the molecular axis tilts to the c-axis by about 70 −76°.

Further refinements are now being carried out.

Azetidine Enamines

By Teng-Yueh CHEN, Hiroshi KATO[1] and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 9, 1966)

The increasing interest in the chemistry of azetidines and recent reports[2a-d] on the addition reactions of aziridines to dimethyl acetylenedicarboxylate prompt us to report some similar results with azetidines.

Azetidine was added exothermally to dimethyl acetylenedicarboxylate and to methyl propiolate in ether to give dimethyl 1-azetidinylmaleate and methyl β-(1-azetidinyl)-*trans*-acrylate respectively. Similar enamine-type azetidinyl derivatives were readily prepared by the concondensation of azetidine with suitable ketones at room temperature; ethyl acetoacetate gave β-(1-azetidinyl)-crotonate, while cyclopentanone and cyclohexanone gave 1-(1-azetidinyl)cyclopentene and 1-(1-azetidinyl)cyclohexene respectively. With the more acidic ketones, such as ethyl benzoylacetate, dibenzoylmethane and acetylacetone, however, the rapid separation of a precipitate (presumably the azetidinium salts) was observed, while the expected condensation products could not be isolated. The results, as well as the characteristic spectral data, are summarized in Table I.

All the compounds show a strong infrared absorption of the enamine double bond in the 1500—1660 cm^{-1} region while a typical triplet-quintet NMR pattern of an azetidinyl group is present at 6.20—6.70 and 7.75—7.81 τ. An NMR peak of a vinylic hydrogen at quite a high resonance field is relevant to the cis addition of azetidine to the triple bond; this idea is further supported by the large coupling constant ($J=15$ c.p.s.) of the two trans vinylic protons of azetidinylacrylate. This is in contrast to the behavior of aziridine, where the trans addition competes to some degree with the cis addition.

The appearence of the vinylic proton chemical shifts in such a high field is remarkable. Indeed, it is probably the highest among all the chemical shifts of this type so far reported.

The exclusive formation of (*cis*)-crotonate by the reaction with acetoacetate may be explained by the initial attack of azetidine from the less crowded site.

Evidence for Nonplanarity in an Oxalamide*

By T. H. SIDDALL, III, and M. L. GOOD

Savannah River Laboratory, E. I. du Pont de Nemours and Co., Aiken, South Carolina

(Received May 13, 1966)

Mizushima[1] concluded that steric repulsion is the most important force determining the stable configuration of rotational isomers. We wish to report an interesting demonstration of the correctness of this conclusion.

Tetraisopropyl oxalamide (I) was obtained by the reaction of diisopropyl amine with oxalyl chloride, followed by repeated crystallization from a variety of solvents. Proton magnetic resonance (PMR) spectra were obtained with a Varian A-60 spectrometer equipped with a variable temperature insert.

The spectra of I in CD_3COCD_3 show two sets of methyl proton signals at 10°C and higher temperatures as would be expected from analogy with simple amides.[2] At −15°C these signals broaden and finally emerge as four sets at −40°C. The two isopropyl radicals on a nitrogen atom are nonequivalent as also are the two methyl groups within a radical. There can be nonequivalent methyl groups only if there is no molecular symmetry plane between the groups.[3] Since there must be such a plane if the whole molecule is planar, it must be that the halves of the molecule are not coplanar and, further, that rotation around the

rotation axis (–C—C–) is slow on the PMR time scale below about −15°C. Double bond character[1] in the rotation axis favors coplanarity. In spite of this, steric factors, that arise from the bulky amide groups, stabilize the nonplanar structure.

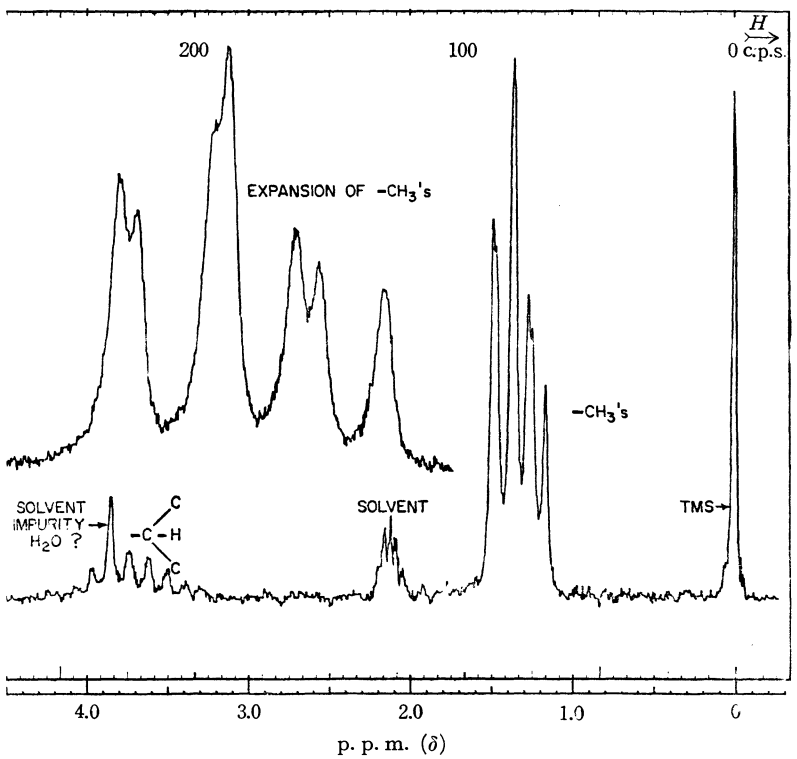

Fig. 1. PMR spectrum of I at −40°C 50 mg./ml.

Intramolecular Hydrogen Bonding Between the Carboxyl O-H Group and Nitrogen

By Michinori Ōki, Minoru Hirota and Yutaka Morimoto

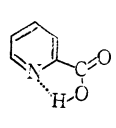
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo
Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minato-ku, Yokohama

(Received May 18, 1966)

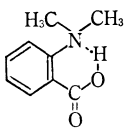
A series of previous investigations in the laboratories of the present authors[1] confirmed the existence of the intramolecular COOH···O hydrogen bond. The rather rare occurence of the hydrogen bond was explained in terms of the stability of the *cis* conformer.

The investigation is now extended to the hydrogen bond including nitrogen as a hydrogen acceptor. The infrared ν_{OH} and the $\nu_{C=O}$ absorptions of pyridine-2-carboxylic (I) and quinoline-2-carboxylic (II) acids were determined as examples of the five-membered hydrogen chelates, and the existence of the intramolecular hydrogen bond was indicated by the appearance of the ν_{OH} bands at lower frequencies (as are listed in the table). The higher $\nu_{C=O}$ frequencies of the acids, I and II, than the acids without intramolecular hydrogen bonds may be attributable to the trans conformation, which is a natural consequence of the formation of the hydrogen bonds, as has been discussed earlier in connection with the oxygen analogs.

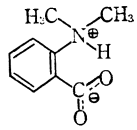
The enthalpies of hydrogen bond formation were obtained from the temperature dependence of the relative intensities of the two ν_{OH} absorptions. From a comparison of the data with those for α-alkoxy- and α-keto-carboxylic acids, it has been shown that the COOH···N hydrogen bonds in I and II are by far more favorable in spite of the smaller ΔH values. These results may be explained as follows. The hydrogen bonded conformer should have a planar *s-trans* conformation such as 1, which is one of the stable conformations from the viewpoint of the maximal conjugation between the aromatic heterocycles and the carboxyl group. In other words, the carboxyl groups of the molecules are so arranged as to be likely to form hydrogen bonds. Consequently, it is not the enthalpy but the entropy factor which controls the formation of the hydrogen bonds. The absence of the COOH···N hydrogen bond in *N*-methylanilinoacetic acid lends support to this conclusion; the COOH—N system is not planar in this molecule.



1



2



2_a

The hydrogen bond shifts of the ν_{OH} frequencies for *o*-dimethylaminobenzoic (III) and quinoline-8-carboxylic acids are extraordinarily large. The only ν_{OH} absorption observed is a broad band, distributed at from 2200 to 2750 cm^{-1}; it can be assigned to a hydrogen-bonded form such as 2. Intramolecular salt (2_a) formation seems to be improbable, since the carboxylic $\nu_{C=O}$ absorption appears at 1711 cm^{-1}* in both III and IV; this is too high for the antisymmetric stretching absorptions of the carboxylate anion. Ebullioscopic measurement also provides evidence for the strong hydrogen bond. Thus, no dimerization is observed over the concentration range in which benzoic acid dimerizes considerably; it can be explained that the strong intramolecular hydrogen bond prevents these acids from dimerization. Though no comparison of their thermodynamic quantities has been carried out, the larger $\Delta\nu$ value and the disappearance of the free ν_{OH} absoprtion in III and IV implies that a stronger hydrogen chelate is formed when a six-membered ring is to be made.

Table I. Infrared spectra and heat of hydrogen bond formationin dilute CCl_4 solution

Acid	ν_{OH} Absorption, cm^{-1} (Molar extinction coefficient)			$\nu_{C=O}$ Absorption, cm^{-1} (Molar extinction coefficient)	ΔH of H-bond formation (kcal./mol.)
	cis	trans	A_t/A_c

The Viscosity and Conductivity of Aqueous Solutions of Electrolytes Mixed with Glycine and Urea

By Tokuzo TONOMURA and Katsunobu OKAMOTO

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received July 2, 1965)

The viscosities, the densities, and the conductivities of aqueous solutions of electrolytes mixed with glycine or with urea have been measured at 15, 25 and 35°C. The relative viscosities and the relative conductivities of the mixed solutions have been expressed by the empirical formulae, $\eta=\eta'+\eta_0\beta C$ and $\Lambda=\Lambda_0(1-\gamma C)$, respectively. The retarding effect of glycine on the conductivity of the strong electrolytes has been found to be greater than that of urea in the mixed solutions. The states of the hydration of glycine, urea and the strong electrolytes have been discussed on the basis of the relations between B-values in the viscosity formula of Jones and Dole and the effective volumes in aqueous solutions.

Some studies of the electrochemical properties of aqueous solutions of strong electrolytes using several methods have been reported,[1-4] but only a few data are available in the literature[5-8] for aqueous solutions of mixed electrolytes. The purpose of the present study is to obtain some information concerning hydration and related problems, and to determine the behavior of weak electrolytes from measurements of the viscosity, density and conductivity of various electrolyte solutions in which weak electrolytes are mixed with strong electrolytes. In the present studies, glycine and urea[9] were used as weak electrolytes, and potassium chloride and lithium chloride, as strong ones. An aqueous solution of potassium chloride has a negative viscosity coefficient, while that of lithium chloride is well known to have an abnormal concentration dependence of the viscosity. The viscosity coefficients and densities of aqueous solutions of electrolytes were measured over and appropriate concentration range. Their conductivities were also measured in order to compare the retarding effects of glycine on the mobility of ions with those of urea. The viscosity formula of Jones and Dole is:

$$\eta = \eta_0(1 + AC^{1/2} + BC) \qquad (12)$$

where η is the viscosity of the solution; η_0, that of the medium, and C, the concentration of the solute, A and B being constants characteristic of the solute. The A coefficient in the above formula is considered to be chiefly due to the contribution of interionic forces, electrostatic in nature, and the B coefficient to the interaction between solute and solvent in the solution. As the second term, AC, in Eq. 1 is usually so small that it can be neglected,[10] Eq. 1 becomes:

$$\eta = \eta_0(1 + BC) \qquad (2)$$

According to Stokes and Mills,[11] the B coefficient in Eq. 2 may be expressed as follows:

$$\eta^E + \eta^A + \eta^D = \eta_0 BC \qquad (3)$$

where η^E is the viscosity increment arising from the size and shape of an ion; it normally increases with an increase in the ion size. η^A is the increment due to the alignment or orientation of polar molecules by the ionic field. η^D is the viscosity change associated with the distortion of the solvent structure; this effect can be interpreted as being due to competing forces from the solvent structure in the bulk and from the ionic field. It will cause the viscosity to decrease.

One gram of solution, whose specific volume is v at concentration of C mol./l., contains x g. of solute of the molecular weight M and $(1-x)$g. of solvent. Then,

$$x = MC/1000\rho \qquad (4)$$

where ρ is the density of the solution. We assume that the partial specific volume of the solute in

solution is v' at the concentration C; then:

$$v = (1 - x)v_0 + xv' \quad (5)$$

where $v_0(\fallingdotseq 1/\rho_0)$ is the partial specific volume of the solvent in a solution. From Eqs. 4 and 5,

$$\rho/\rho_0 = 1 + (M \cdot C \cdot 10^{-3})(v_0 - v') \quad (6)$$

The effective volume, V, of the ions in solution is equal to $M \cdot v' \cdot 10^{-3}$ l./mol.

Experimental

All of substances used here were of an analytical reagent grade. Glycine was purified by recrystallization from an ethanol-water solution, and potassium chloride and urea, by recrystallization from conductivity water, but lithium chloride was used without further purification. Solutions from 0.05 to 0.25 molality were prepared. The systems of aqueous solutions were as follows:

System 1. Strong electrolytes: KCl and LiCl.

System 2. Weak electrolytes: Glycine and Urea.

System 3. Mixed electrolytes:

KCl + Glycine, KCl + Urea,

LiCl + Glycine, LiCl + Urea,

The viscosities of the solutions were measured at 15, 25 and 35±0.05°C by an Ostwald viscometer with a flow time of about 260 sec. for water at 25°C. The reproducibility of the flow times was within ±0.2 sec. Two viscometers were always used for a given system, and each measurement was repeated six to ten times and then the average was taken to get the desired result. By the measurement of the viscosity of water, dioxane and benzene, the correction term for kinetic energy was found to be so small that it was ignored. The relative viscosity was calculated by the usual formula:

$$\eta/\eta_0 = \frac{t(\text{flow time of solns.})\rho(\text{density of solns.})}{t_0(\text{flow time of water})\rho_0(\text{density of water})} \quad (7)$$

The densities of the solutions were measured by an Ostwald pycnometer of about 4 ml. The resistance of the solutions was measured with a universal bridge, Yokogawa BV-Z-13A. Three cells with platinized electrodes were used, their cell constants being 7.379, 1.445 and 0.8541, respectively; the electrodes were checked frequently with the 0.01 N or 0.1 N potassium chloride solutions. The data were reproducible within ±0.5%.

Results and Discussion

The relative and absolute viscosities of aqueous solutions of glycine and urea are given in Table I. Also, the relative viscosities of the mixed solutions are given in Figs. 1, 2 and 3.

Plotting $(\eta/\eta_0 - 1)/C^{1/2}$ versus $C^{1/2}$, the A coefficient is the ordinate intercept, while the B coefficient is given by the slope. The A and B coefficients thus obtained are summarized in Table II. Figures 1, 2 and 3 show that the relationship between the relative viscosities of the solution of mixed electrolytes and the concentration of the weak electrolytes is linear. The empirical formula of the relative viscosities (System 3) was obtained by the method of least squares; namely:

$$\eta = \eta' + \eta_0 \beta C \quad (8)$$

where η' is the viscosity of the strong electrolyte at a given concentration, β is a constant characteristic of the weak electrolyte, and C is the molal concentration of the weak electrolyte. From the fact that the values of β thus found are nearly constant for a given weak electrolyte, as is shown in Figs. 1, and 2 and 3, the viscosity of weak electrolytes when mixed with strong electrolytes seems not to be influenced by the strong ones.

The specific gravities and the partial specific volumes of an aqueous solution of the weak electrolytes are given in Table III. In Fig. 4, a plot

of the ratio of the densities (ρ_3/ρ_1)* versus the concentration of the weak electrolyte gives a linear relation and is in accord with that of pure weak electrolyte solutions given in Table III. It is shown that the curves are independent of the temperature and species of the strong electrolyte used. From this fact, there seems to be little influence on the effective volume due to the electrostatic interaction between the ions and solutes of weak electrolytes, even though the solute is glycine, which has a comparatively large dipole moment,[5] in a polar solvent. Undoubtedly, the interaction between water molecules and all solutes in solution is more dominant than that between ions of the strong electrolyte and solutes of the weak one. It seems that the ions and the solutes in the mixed solution retain much the state of hydration they have in pure water, at least at the concentration considered.

The partial specific volumes of the electrolyte in solution are calculated from Eq. 5. The effective volumes(V) of ions in those solutions were estimated from the partial specific volume and are given in the third column of Table IV; other electrolytes quoted from the literature are given in the same column.

Let us assume that, for all the species thus obtained, the effective volume is a measure of the static volume occupied by the species in solution. Thus the B-values in the viscosity formula are considered to be the kinetic volumes of the solvated species in solution, and the values of the (B/V) ratio are considered to be closely related to the hydration. From Table IV it is apparent that the B/V values of alkaline halides, with the exception of lithium and sodium halides, are considerably different from

those of alkaline earth metal chlorides, glycine and urea. Potassium, rubidium and cesium halides have negative B/V values. This will be discussed below. It is generally believed that the degree of hydration in aqueous electrolyte solutions decreases with an increase in the radius of the univalent cation.[2] Moreover, anions have the effect of breaking the structure of water.[3,4] As has been described previously, the ions with large crystal radii, such as Cs^+ or I^-, have a weak orienting effect in the first layer because of their small surface charge densities. Thus η^A would be small. However,

a considerable distortion of the solvent structure may occur in the vicinity of the ion, and accordingly, η^D will become predominant. In this class of ions $\eta^A < \eta^D$ and the B/V value is negative. According to Samoilov,[15] the negative hydration was taken for the above case, and the molecules of water near the ion become more mobile than in pure water. On the other hand, as may be seen in Table IV, lithium chloride and alkaline earth metal chlorides produce a viscosity increment[16] greater than that corresponding to their effective volume in solution. The small size of cations with large surface charge densities, such as Li^+ and Mg^{2+}, cause a strong orientation of water molecules and they are believed to have a primary hydration. The η^E value will be large because of its primary sheath. The sum, $\eta^E + \eta^A$, will be larger than the decrement due to η^D. In this class, $\eta^A \gg \eta^D$ and the B/V value is fairly large and positive. Molecular ions such as glycine may be expected to have large η^E values because of their large size. As is shown in Table IV, the volume (V_c) of glycine in the crystal state is 0.0469 (l./mol.) and the effective volume (V) in solution is 0.0435 (l./mol.). This suggests that the behavior of glycine in hydration may resemble that of the strong electrolytes, such as lithium chloride, whose volume in a solution is apparently smaller than the volume in the crystal state due to the contraction of the solvent by electrostriction.[2] In addition, large η^A values may be expected from their large dipole moments, as has been pointed out already. However, the distortion effects would be the same as that of large ions mentioned above.

From the results obtained, it is evident that $\eta^A > \eta^D$ and that the B/V value for glycine is still positive. Isemura and Goto[17] have suggested, as a result of studies by the ultrasonic method, that glycine and strong electrolytes resemble each other in the mechanism of hydration; their suggestion is supported by the present results. The B/V values of urea is smaller than that of glycine, though the effective volume of urea, as may be seen in Table IV, is nearly equal to that of glycine. Again, we found that the V of urea in solution, as determined from the densities, is nearly equal to the volume(V_c) in the crystal state: V, 0.0457 (l./mol.); V_c, 0.0450 (l./mol.). It is well known that water molecules are attracted to the urea molecule, as urea has hydrophilic groups. From these findings, the hydration of urea can be interpreted as the result of competition between the breaking and the formation of the hydrogen bonding.

By means of measurements[13] of the NMR, the relative shifts of the proton resonances of aqueous solutions containing various electrolytes or organic compounds may be discussed with regard to their state of hydration. The results indicate that the degree of relative shifts of anions increase with an increase in the ionic radius. The differences in the B/V values in the lithium halides, therefore, seem to correspond with that of the relative shifts of anions, as they have a common cation in solution. Several methods,[8,12,13,16] from different standpoints and different assumptions, have been reported for determining the degree of hydration of electrolytes in an aqueous solution; these values are given in Table IV. The B/V values obtained may be compared with their hydration numbers, which are shown in the same table.

The relative conductivities of the mixed solutions are given in Figs. 5, 6 and 7. By plotting Λ/Λ_0 versus C, the γ coefficient is given by the slope. These figures show that the relative conductivities, Λ/Λ_0, are dependent on the concentration of the added weak electrolyte. Then, an empirical formula was obtained at each temperature, as follows:

$$\Lambda = \Lambda_0(1 - \gamma C) \qquad (9)$$

Table V. γ-Coefficient of the conductivity Eq. 9 at each temperature

	15°C	25°C	35°C

where Λ is the equivalent conductivity of the mixed solution; Λ_0 is that of a strong electrolyte in the pure solution, and γ is a constant characteristic of the added weak electrolyte. The γ coefficients thus obtained are summarized in Table V. From these results, it was found that the retarding effect of glycine on the ionic mobility of the strong electrolyte is greater than that of urea and that it is independent of the species of strong electrolyte used here. The ions of strong electrolytes, for example, are retarded to approximately the same extent when glycine is added to the solution at a given concentration. However, the viscosities of electrolytes are considerably different from each other. It seems that the retardation is independent of the frictional property of mixed solutions.

Monolayer Adsorption with Nearest Neighbor Interactions

By Ralph J. TYKODI

Department of Chemistry, Southeastern Massachusetts Technological Institute
North Dartmouth, Massachusetts 02747, U. S. A.

(Received July 23, 1965)

A sequence of approximate combinatorial treatments of the localized monolayer adsorption of a gas on a lattice of uniform sites with only nearest neighbor interactions allowed generates a one parameter family of isotherm equations. For each of those cases where the general lattice problem has been solved exactly, it is possible to find a value of the adjustable parameter such that critical behavior on the lattice in question is reproduced exactly.

In 1939 Fowler and Guggenheim[1] analyzed the treatment of localized monolayer adsorption of a gas on a lattice of uniform sites with only nearest neighbor (n. n.) interactions allowed in an elegant manner and discussed in detail two isotherm relations (*crude* and *refined*) showing first order phase change behavior under suitable conditions. Since the 1939 formulation of Fowler and Guggenheim, the parallel problem of the Ising model for ferromagnetism has received a great deal of attention.

1) R. H. Fowler and E. A. Guggenheim, "Statistical Thermodynamics," Ch. X, Cambridge University Press (1939).

The many advances made toward a complete solution of the general problem of nearest neighbor (n. n.) lattice statistics and the powerful and sophisticated mathematical methods employed by recent workers in the field have been reviewed by (e. g.) Temperley,[2] Hill,[3] and Domb.[4] The known exact solutions for two-dimensional lattices[4] show that it is not enough to consider only the coordination number of a lattice (as in the work of Fowler and Guggenheim[1])—more specific properties of the lattice must also be taken into account. In this paper, however, we shall consider a sequence of approximate combinatorial treatments of the adsorption problem based on coordination number arguments alone. Our results will generate a one parameter family of isotherm equations with the rather unexpected property of *exactly* reproducing critical behavior on the lattice in question for a suitable choice of the adjustable parameter. The effect of the more detailed features of the lattice that are neglected in the approximate treatments is merely to shift the value of the parameter in the basic family of equations. The combinatorial arguments, then, establish a set of "calibration points," with an easily comprehended physical basis, across the spectrum of possible values of the adjustable parameter.

In what follows we shall deal in a simple combinatorial manner with the problem of N identical gas molecules adsorbed on N_s identical sites, trying to take into account the n. n. (nearest neighbor) interactions among the adsorbed molecules.

The Combinatorial Problem

In many respects we shall follow the notation of Fowler and Guggenheim[1] closely; however, we shall feel free to vary that notation wherever it proves convenient to do so. We express the Helmholtz free energy for the macro state of a localized monolayer with N identical gas molecules adsorbed on N_s identical sites by

$$F^{ads}/\boldsymbol{k}T = -\ln \Omega\,(n_i) - N(n_i) \ln a^\circ(T) + \varepsilon(n_i)/\boldsymbol{k}T \quad (1)$$

where the n_i are parameters of a geometric nature (bonds, triangles, etc.) by means of which we shall take into account n. n. interactions among the adsorbed molecules, A is the *extra* potential energy (relative to the gas state at infinite separation) due to n. n. interactions, $a^\circ(T)$ is the partition function of an isolated adsorbed molecule,* and Ω is a combinatorial expression for the number of micro states corresponding to the set of parameters n_i.[5]

We shall minimize $F^{ads}/\boldsymbol{k}T$ with respect to the parameters n_i, subject to the restriction $N=N(n_i)$ = constant:

$$\delta\left(\frac{F^{ads}}{\boldsymbol{k}T}\right) = -\sum_i\left[\frac{\partial \ln \Omega}{\partial n_i} + \frac{\partial N}{\partial n_i}\ln a^\circ(T) - \frac{1}{\boldsymbol{k}T}\frac{\partial A}{\partial n_i}\right]\delta n_i = 0$$

$$\delta N = \sum_i (\partial N/\partial n_i)\delta n_i = 0 \quad (2)$$

Introducing the Lagrange multiplier α, we obtain i equations of the form

$$\frac{\partial \ln \Omega}{\partial n_i} + \frac{\partial N}{\partial n_i}(\ln a^\circ(T) - \alpha) - \frac{1}{\boldsymbol{k}T}\frac{\partial A}{\partial n_i} = 0 \qquad i=1,2,\cdots \quad (3)$$

Solution of the set of simultaneous equations given by Eq. 3 leads to the isotherm relation.

Our chief problem is the finding of adequate expressions for $\Omega=\Omega(n_i)$. We shall examine special cases, starting with simple ones and gradually proceeding to those more complex. Our ultimate goal is to find the appropriate form of the isotherm relation for the general case where adsorption takes place on a plane lattice for which each site is surrounded by z nearest neighbor (n. n.) sites.

Isolated Clusters

Turning now to the basic combinatorial problem, let us consider a set of N_s adsorption sites. If we were actually to draw in bonds between n. n. sites, we could divide those bonds into classes on the basis of the state—occupied (O) or unoccupied (U) by an adsorbed molecule—of the sites connected by a n. n. bond. Allowing the n. n. bonds to have a directional character (for proper multiplicity) we could distinguish four classes of bonds OO, OU, UO, and UU. We shall often find it convenient to discuss the combinatorial problem on a given lattice in terms of these classes of n. n. bonds.

Let us first turn to the case where the sites of a given set are treated as isolated clusters of sites. We consider the N_s sites as divided up into N_s/i clusters such that the clusters are relatively far apart but within any cluster each site has i-1 *equivalent* n. n. sites. If we denote a cluster containing i sites, everyone of which can be connected to each of the other i-1 sites by a n. n. bond, as an (i)-cluster, then in a (2)-cluster we have a pair of sites connected (connectable) by a n. n. bond,

2) H. V. N. Temperley, "Changes of State," Ch. VI, Cleaver-Hume Press Ltd., London (1956).

* See Ref. 1, p. 429.
5) J. Hijmans and J. de Boer, *Physica*, **21**, 471 (1955).

and in a (3)-cluster the triplet of sites may be regarded as forming an equilateral triangle with n. n. bonds for sides. For clusters of higher order it is not possible to arrange the sites in a plane configuration so that all the sites of a cluster are equivalent, i. e. each site of the cluster connected to the other i-1 sites of the cluster by n. n. bonds.

In distributing N molecules over the N_s sites grouped into isolated clusters we need a scheme for counting the number of n. n. bonds of the type OO and for keeping track of configurational permutations. We could set up a scheme in terms of the n. n. bond classes mentioned at the beginning of this section, but in this particular case we choose to proceed differently.

Let us first turn to the case of isolated (2)-clusters. Suppose we place our N molecules on the N_s sites in such a way that the number of clusters containing *at least* one molecule is n_1 and the number of clusters containing *at least* two molecules is n_2. The number of clusters containing *at least* zero molecules is equal to the total number of clusters, i. e. $n_0=N_s/2$, and (included for convenience in notation) the number of clusters containing *at least* three molecules (n_3) is zero. Similarly the number of clusters containing *exactly* i molecules ($i=0$, 1, 2) is just n_i-n_{i+1}; here, and in the remainder of the paper, the symbol n_i denotes the number of clusters (of a given type) containing *at least* i molecules.

With due allowance for the possible permutations within a cluster, the number of micro states corresponding to the above specification (in terms of the n_i) is

$$\Omega = \frac{2^{n_1-n_2}\, n_0!}{(n_0-n_1)!\,(n_1-n_2)!\,n_2!} \tag{4}$$

If $-\varepsilon$ is the interaction potential energy (relative to the gas state at infinite separation) of a pair of adsorbed molecules a n. n. distance apart, then the total extra potential energy due to n. n. interactions among the adsorbed molecules is just $-\varepsilon$ times the number of n. n. bonds of type OO. Thus, for isolated (2)-clusters

$$A = -\varepsilon n_2 \tag{5}$$

and

$$N = n_1 + n_2 \tag{6}$$

Setting $n_i/n_0=f_i$, where f_i is the fraction of the total number of clusters containing *at least* i molecules, and making use of Stirling's approximation for the logarithm of a factorial, we obtain from Eqs. 3, 4—6 the relations

$$\frac{f_1-f_2}{1-f_1} = 2x \qquad \frac{f_2}{f_1-f_2} = \frac{\zeta x}{2} \tag{7}$$

where $\zeta=\exp(\varepsilon/\boldsymbol{k}T)$ and $x=a^\circ(T)e^{-\alpha}=\lambda_g a^\circ(T)=p/p^\circ$ (λ_g being the absolute activity of the gas molecules*). Our ζ corresponds to the quantity $\exp(-2\omega/z\boldsymbol{k}T)$ in the notation of Fowler and Guggenheim.[1] Equation 7 yields the relation

$$4f_2(1-f_1)/(f_1-f_2)^2 = \zeta \tag{8}$$

Equation 8 is a slightly disguised version of the equation of quasichemical equilibrium discussed by Fowler and Guggenheim[1]; it is an exact equation for the case of isolated (2)-clusters and is often invoked as an approximation in the case of more complex lattice situations.

From Eq. 7 and the relation $f_1+f_2=2\theta$ we obtain

$$\frac{\theta}{1-\theta} = \frac{x(1+\zeta x)}{1+x} \tag{9}$$

Solving Eq. 9 for x we get

$$x = \frac{\theta}{1-\theta}\cdot\frac{1}{\zeta}\cdot\left[\frac{\beta-1+2\theta}{2\theta}\right] \tag{10}$$

where

$$\beta = [1-4\theta(1-\theta)(1-\zeta)]^{1/2}$$

If there are no interactions among the adsorbed molecules, then $\varepsilon=0$, $\zeta=1$, and Eqs. 9 and 10 reduce to the simple Langmuir equation $x=\theta/(1-\theta)$. If there are attractive interactions among the adsorbed molecules, then $\varepsilon>0$, $\zeta>0$, and the coverage θ is greater for a given temperature and pressure than that predicted by the Langmuir equation.

The treatment of isolated clusters is useful because it allows us to examine the effect of n. n. interactions on the adsorption isotherm for a simple case for which the combinatorial expression $\Omega(n_i)$ can be evaluated exactly. The formalism that we have set up for treating isolated clusters then serves as a starting point for the treatment of connected lattices where the exact evaluation of the combinatorial expression $\Omega(n_i)$ is an extremely difficult problem.

Rule of Thumb Approximation

We now wish to consider a plane connected lattice* for which each site has z n. n. sites and wish to treat the adsorption problem on such a lattice according to an approximate method which is modeled after the treatment of isolated clusters. The connectivity of the lattice is a great source of trouble in setting up an appropriate combinatorial expression. While in the isolated cluster treatment it was possible to change the parametric specification n_i in unitary steps by the addition of

* See Ref. 1, p. 431, for details.

* A lattice is called *connected* if the sites are all equivalent and it is possible to pass from an arbitrary site to any other site of the set by traveling along n. n. bonds only.

single molecules, on a connected lattice the parameters more often change by z units upon the addition of single molecules to the lattice; thus, if we place one molecule on an otherwise empty connected lattice we immediately form z n. n. bonds of type OU (or UO).

Now it is reasonably evident that to the first molecule placed on a uniform lattice (connected or otherwise) all the N_s sites are equivalent, and the connectivity of the lattice is a dormant feature which becomes important when more molecules are added. Thus there are just N_s ways of placing one molecule on N_s uniform sites, regardless of the connectivity of the lattice. We now adopt the following rule of thumb condition:

In any approximate treatment of adsorption on a connected lattice the combinatorial expression when evaluated for the case of one molecule on N_s sites must be at least approximately equal to N_s for all values of z.

If we let $\Omega(1)$ represent the value of the combinatorial expression Ω for the case of one molecule on the N_s sites of a plane connected lattice, then the mathematical form of the rule of thumb requirement is that

$$\lim_{N_s\to\infty} \{\ln \Omega(1)/\ln N_s\} = 1$$

for all values of z.

A plane connected lattice, each site having z n. n. sites, has $zN_s/2$ n. n. bonds between the sites. We should now like to treat these $zN_s/2$ n. n. bonds in a manner similar to the treatment of n. n. bonds in isolated (2)-clusters. In the case of isolated (2)-clusters we had a 1 - 1 correspondence between the number of clusters and the number of n. n. bonds, and we were at liberty to set up the combinatorial expression in terms of cluster parameters or bond parameters; in fact we chose cluster parameters. In this section we wish to deal with the n. n. bonds themselves, carrying the development through in terms of n. n. bond parameters.

In a familiar fashion we set m_i ($i=0, 1, 2$) equal to the number of n. n. bonds whose terminal sites are occupied by *at least* i adsorbed molecules. We shall assume that our directional convention for n. n. bonds is such that for any distribution of N molecules on the N_s sites the number of n. n. bonds of type OU is approximately equal to the number of type UO. Letting the symbol itself (OO e.g.) stand for the number of n. n. bonds of that type, we have, in terms of our more familiar parameters,

$$\left.\begin{aligned} zN_s/2 &= m_0 \\ \mathrm{UU} &= m_0 - m_1 \\ \mathrm{UO} = \mathrm{OU} &= (m_1 - m_2)/2 \\ \mathrm{OO} &= m_2 \end{aligned}\right\} \qquad (11)$$

If we were to treat the $zN_s/2$ n. n. bonds as *permutable things*, the number of distinguishable bond configurations corresponding to a definite set m_i would be

$$\Omega = \frac{m_0!}{(m_0-m_1)!\,[(1/2)(m_1-m_2)]!^2\,m_2!} \qquad (12)$$

Within the limits of Stirling's approximation for factorials Eq. 12 is the same as

$$\Omega = \frac{m_0!\,2^{m_1-m_2}}{(m_0-m_1)!\,(m_1-m_2)!\,m_2!} \qquad (13)$$

which bears out what we were saying previously about the treatment of isolated (2)-clusters.

In dealing with n. n. bond configurations (with $m_0=zN_s/2$) we are (for $z>1$) counting many more configurations than can be physically realized by distributing N molecules on N_s sites; we find, in fact, that

$$\lim_{N_s\to\infty} \{\ln \Omega(1)/\ln N_s\} = z$$

for Eq. 13. We note, however, that if we set

$$\Omega = \left\{\frac{m_0!}{(m_0-m_1)!\,[(1/2)(m_1-m_2)]!^2\,m_2!}\right\}^{1/z} \qquad (14)$$

the rule of thumb condition is satisfied.

Equations 3 and 14 together with the conditions

$$\left.\begin{aligned} A &= -\varepsilon m_2 \\ N &= (m_1 + m_2)/z \\ m_0 &= zN_s/2 \\ g_i &= m_i/m_0 \\ 2\theta &= g_1 + g_2 \end{aligned}\right\} \qquad (15)$$

lead to the isotherm equation

$$x = \frac{\theta}{1-\theta}\cdot\frac{1}{\zeta^z}\cdot\left[\frac{\beta^{(1)}-1+2\theta}{2\theta}\right] \qquad (16)$$

where $\beta^{(\nu)}=[1-4\theta(1-\theta)(1-\zeta^{z/\nu})]^{1/2}$. According to this convention our previous β (Eq. 10) is to be written as $\beta=\beta^{(z)}$.

In establishing Eq. 12 we assumed that all the n. n. bonds were freely permutable; for a connected lattice such is not the case, e. g. it is not physically meaningful to *singly* permute a bond of type OO with one of type UU. In the following we shall try to obtain a better treatment of the combinatorial problem.

For convenience we shall consider only connected lattices for which z is even. Let us adopt some convention whereby the z n. n. bonds connecting a given site with its z n. n. sites can be specified as pointing to the *left* or to the *right*, $z/2$ bonds belonging to each category. We now demand that all the n. n. bonds be considered as pointing to the *right*, say; this uniquely fixes the site of origin of each n. n. bond. We identify a given n. n. bond by giving the name of the site of origin and the name of the site of termination. There are

N_s sites which can serve as origin; and, for any of those sites, there are $z/2$ additional sites which can serve as terminus (lie to the *right*) for a n. n. bond—$zN_s/2$ possibilities in all, which is as it should be.

We now freely permute only n. n. bonds of similar origin; i. e. we permute bonds of type OV among themselves and those of type UV among themselves (V=O, U). The number of distinguishable n. n. bond configuarations corresponding to the above restriction is

$$\Omega = \frac{[(1/2)zN]!\,[(1/2)z(N_s-N)]!}{(m_0-m_1)!\,[(1/2)(m_1-m_2)]!\,[(1/2)(m_1-m_2)]!\,m_2!} \tag{17}$$

Within the limits of Stirling's approximation, Eq. 17 is the same as

$$\Omega = \frac{m_0!\,2^{m_1-m_2}}{(m_0-m_1)!\,(m_1-m_2)!\,m_2!} \times \frac{[(1/2)zN]!\,[(1/2)z(N_s-N)]!}{[(1/2)\,zN_s]!} \tag{18}$$

Once again we find that if we set

$$\Omega = \left\{\frac{[(1/2)zN]!\,[(1/2)z(N_s-N)]!}{(m_0-m_1)!\,[(1/2)(m_1-m_2)]!^2\,m_2!}\right\}^{2/z} \tag{19}$$

the rule of thumb condition is satisfied.

Equations 3, 15, and 19 lead to the isotherm equation

$$x = \frac{\theta}{1-\theta}\cdot\frac{1}{\zeta^z}\cdot\left[\frac{\beta^{(2)}-1+2\theta}{2\theta}\right]^2 \tag{20}$$

Finally, after a little casting about, we find that the expression

$$\Omega = \frac{m_0!\,2^{m_1-m_2}}{(m_0-m_1)!\,(m_1-m_2)!\,m_2!} \times \frac{[(z-1)N]!\,[(z-1)(N_s-N)]!}{[(z-1)N_s]!} \tag{21}$$

satisfies the rule of thumb condition and together with Eqs. 3 and 15 leads to the isotherm equation

$$x = \frac{\theta}{1-\theta}\cdot\frac{1}{\zeta^z}\cdot\left[\frac{\beta^{(z)}-1+2\theta}{2\theta}\right]^z \tag{22}$$

which (remembering that $\beta^{(z)}=\beta$) is just the *refined* isotherm relation of Fowler and Guggenheim.[1]

In order to solve the problem of adsorption with n. n. interactions by the methods of this section what is needed is a way of counting the number of *coherent* bond configurations corresponding to the set of parameters m_i. A bond configuration is called *coherent* if for each lattice site the bonds originating and terminating at that site are physically compatible; i. e., for a site occupied by an adsorbed molecule the bonds originating and terminating at that site must be of type O- and -O, respectively. In Eqs. 12 and 17 we counted the number of *incoherent* and *semi-coherent* bond configurations, respectively, corresponding to the set of parameters m_i; these numbers being considerably larger than the number sought, we reduced them to approximately the right order by raising them to fractional powers (Eqs. 14 and 19). In Eq. 21 we took the number of incoherent bond configurations and multiplied it by a (variable) reduction factor.

The sequence *incoherent, semicoherent, coherent* brings to mind a geometric progression, and we ask ourselves if perhaps it may not be the case (approximately) that

$$\Omega_{\text{coh}}/\Omega_{\text{semicoh}} = \Omega_{\text{semicoh}}/\Omega_{\text{incoh}}$$

Carrying out the implications of this assumption (Eqs. 14 and 19) we produce the isotherm equation

$$x = \frac{\theta}{1-\theta}\cdot\frac{1}{\zeta^z}\cdot\left[\frac{\beta^{(3)}-1+2\theta}{2\theta}\right]^3 \tag{23}$$

It is of interest to note that the various approximate isotherm relations of this section all have the common form

$$x = \frac{\theta}{1-\theta}\cdot\frac{1}{\zeta^z}\cdot\left[\frac{\beta^{(\nu)}-1+2\theta}{2\theta}\right]^\nu \qquad \nu = 1, 2, 3, z \tag{24}$$

The family of isotherms represented by Eq. 24 contains members that show first order phase change behavior. The critical condition is found by setting $\partial x/\partial\theta=0$ for $\theta=1/2$;* this operation leads to the relation

$$\zeta_c^{1/2} = [\nu/(\nu-2)]^{\nu/z} \tag{25}$$

We see that the class of isotherm equations with $\nu\leqq 2$ does not show first order phase change behavior, whereas the class of equations with $\nu>2$ does show such behavior. Now it is our conjecture that in deriving those equations with $\nu\leqq 2$ (in the context of the present series of approximations) we consistently *overcount* the number of distinguishable configurations Ω corresponding to a *given* amount of energy A and that in deriving the equation with $\nu=z$ we consistently *undercount* the requisite number of configurations. If our conjecture is valid, then Ω_{correct} should lie somewhere between the Ω values of Eqs. 19 and 21.

The foregoing considerations suggest that by suitable averaging of pairs of combinatorial expressions, one of which overcounts while the other undercounts, new approximations can be made to Ω_{correct}. By way of example, using the notation $\Omega_{(y)}$ to stand for the combinatorial expression stated in Eq. y, let us investigate the combinations

* See Ref. 1. All the members of the family of Eq. 24 have the same symmetry properties as the *refined* isotherm relation discussed by Fowler and Guggenheim.

$$\Omega_{\varphi} = \Omega_{(14)}{}^{1-\varphi}\Omega_{(21)}{}^{\varphi} \qquad (26\varphi)$$

$$\Omega_{\chi} = \Omega_{(19)}{}^{1-\chi}\Omega_{(21)}{}^{\chi} \qquad (26\chi)$$

$$\Omega_{\psi} = \left[\frac{N_s!}{N!\,(N_s-N)!}\right]^{1-\psi}\Omega_{(21)}{}^{\psi} \qquad (26\psi)$$

These combinatorial expressions together with Eqs. 3 and 15 lead to isotherm relations of the form 24 with $\nu=2+\varphi(z-2)$, $1+\chi(z-1)$, ψz respectively.

Conclusion

It is now clear that combinatorial arguments of the present type will preserve the form of Eq. 24 and will merely change the numerical value of the parameter ν. We have, then, as the end result of our combinatorial considerations the family of Eq. 24 containing the adjustable parameter ν. The individual values of ν thus far produced cannot be entirely satisfactory since the derivations took no explicit notice of lattice properties other than coordination number. The surprising thing about Eq. 24 is that it can reproduce *exactly* critical behavior on any given lattice by suitable adjustment of the parameter ν; this result should be of some importance in the general problem of lattice statistics.

In order to display the properties of Eq. 24 we have tabulated some exact results for two-dimensional lattices, as well as some "best" results for three-dimensional ones, as given in the article by Domb.[4] In Table I we display the quantity $(\ln \zeta_c{}^{z/4})^{-1}$, which corresponds to the quantity $\boldsymbol{k}T_c/qJ$ in Domb's notation,[4] together with the corresponding z and ν values for a number of lattice situations:

$$(\ln \zeta_c{}^{z/4})^{-1} = 2[\nu \ln (\nu/(\nu-2))]^{-1} \qquad (27)$$

TABLE I. EXACT OR "BEST" VALUES OF $(\ln \zeta_c{}^{z/4})^{-1}$ AND ν FOR VARIOUS LATTICE SITUATIONS

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1632—1635 (1966)

The Behavior of Free Radicals Produced by Ultraviolet Irradiation in the Frozen Propargyl Alcohol - Hydrogen Peroxide System

By Keiji TAKEDA, Hiroshi YOSHIDA,* Koichiro HAYASHI and Seizo OKAMURA

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 27, 1965)

In order to assertain the polymerization mechanism in the solid state, a solid mixture of propargyl alcohol (monomer), hydrogen peroxide and water was irradiated at −196°C by an ultraviolet light. The structure of the free radicals so formed in the solid medium was then studied by the electron-spin-resonance method. The trapped free radical was a monomer radical, $CH{\equiv}C{-}\dot{C}HOH$. This shows that the HO· radicals produced by the photolysis of hydrogen peroxide abstracted the methylenic hydrogen atoms from the alcohol. An examination of the kinetic behavior of free radicals revealed that HO· radicals migrated freely and reacted with monomers at −196°C. The reaction between the monomer radical and HO· radicals is more important than the recombination between monomer radicals.

Several studies have revealed that the radiation-induced solid state polymerization proceeds by means of a free radical mechanism.[1-7] In the solid state, the usual steady-state condition of the radical concentration does not hold because of a suppressed recombination between propagation

radicals. Therefore, the kinetic behavior of the polymerizations is more complex than that of usual liquid state polymerizations.

In order to assertain the mechanism of radiation-induced solid state polymerizations, it may be helpful to know the behavior of free radicals in the solid state, where they are formed by a simple photolysis. So far, several electron-spin-resonance (ESR) studies have been published on photo-irradiated frozen systems of hydrogen peroxide-alcohols or vinyl monomers.[8-11] In many of the saturated and unsaturated alcohols studied, HO· radicals formed by the photolysis of hydrogen peroxide abstract α-hydrogen atoms from the alcohols.[8,9] Alcohols with triple bonds have not yet been studied in the frozen state. The reactions of a few vinyl monomers with HO· have been studied kinetically by Kuwata et al.[11] And they also studied the polymerization kinetics in detail at a temperature at which the steady state was held for the concentration of propagating radicals. However, no kinetic study has yet been made of the radical behavior at such a low temperature that the ends of the propagating radical cannot move around. In the present work, the structure of free radicals formed in the solid state of propargyl alcohol-hydrogen peroxide by photolysis at −196°C was first assigned on the basis of its ESR spectra, and then the kinetic behavior of free radicals at −196°C was examined quantitatively by varying the concentration of the monomer or of the initiator.

Experimental

Materials.—Commercial propargyl alcohol was purified by vacuum distillation. A 30% aqueous solution of hydrogen peroxide was distilled in a vacuum, and the concentrated peroxide was used for the experiment. Purified water was used as the solvent.

The Ultraviolet Irradiation of Samples.—The monomer (propargyl alcohol), hydrogen peroxide, and water were pipetted into a qualtz tube, sealed in a vacuum, and irradiated with a high pressure mercury arc (Toshiba SHL-100UV, 75Watt) for a certain length of time in a liquid nitrogen bath. The distance between the sample and the arc was about 10 cm. The irradiation conditions were the same throughout this investigation. The emission spectra of the mercury arc spread widely from 3000 Å to the visible region. The solid mixture of propargyl alcohol and a concentrated aqueous solution of hydrogen peroxide formed a transparent glass at −196°C. It could be irradiated uniformly, except for a high concentration of water, when the sample is opaque.

ESR Measurements.—The microwave frequency was 9400Mc., and the field modulation frequency was 80C. After irradiation, the sample was quickly inserted into the cavity resonator and the ESR measurements were carried out at −196°C. The concentration of free radicals was determined in comparison with that of a standard sample of a DPPH (α, α'-diphenyl-β-picryl hydrazyl) solid solution in polystyrene, the radical concentration of which had already been determined.

Results and Discussion

ESR Spectra and Their Assignment.—The ESR spectra in Fig. 1(a) were obtained with samples immediately after irradiation at −196°C. The spectra were independent of the irradiation time and the concentration of the monomer or hydrogen peroxide. Since the free radical concentration was unchanged over a long period of time at −196°C, they were completely frozen and no recombination reaction could have occurred. No ESR signal was observed when the pure hydrogen peroxide was irradiated under the same conditions. Therefore, the spectra shown in Fig. 1(a) are due to monomer radicals formed from the reaction of the monomer with the HO· radical which was produced by the photolysis of hydrogen peroxide.

The observed spectrum is a poorly-resolved triplet. It is assigned to the structure of the free radical;

$$CH{\equiv}C\text{-}\dot{C}HOH \longleftrightarrow \dot{C}H{=}C{=}CHOH$$

formed by the abstraction of one of the methylenic hydrogen atoms of a monomer molecule by HO·

radicals. Dixon et al.[12] observed the ESR spectra of the above radicals formed in the reaction between propargyl alcohol and HO· using a flow method. They reported the coupling constants due to each proton as $a_H(CHOH)=18.5$ gauss and $a_H(CH)=10.2$ gauss. Fessenden et al.[13] also found similar radicals by the electron-irradiation of allene:

$$CH{\equiv}C\text{-}\dot{C}H_2 \longleftrightarrow \dot{C}H{=}C{=}CH_2$$

These authors reported the following coupling constants: $a_H(CH)=12.6$ gauss and $a_H(CH_2)=18.9$ gauss. These spectra of the free radicals in the liquid phase showed a well-resolved hyperfine structure. However, the same type of free radicals showed poorly-resolved triplet spectra, as is shown in Fig. 1(a), since they were trapped in a rigid medium. Other possible radicals which may be formed by the reaction between the monomer and HO· are addition-type radicals, i.e. $H(OH)C{=}\dot{C}\text{-}CH_2OH$ or $\dot{C}H{=}C(OH)CH_2OH$. These σ-type radicals, however, may show large coupling constants.[13] Therefore, the observed spectra cannot be attributed to them.

When the temperature of the irradiated sample was raised, the concentration of free radicals decreased and the spectrum changed to that shown in Fig. 1(b). This change is caused by a new overlapping spectrum with a different g-value. The new spectrum is probably due to the growing polymer radicals.

The Kinetics of Free Radical Reactions.—*Experimental Results.*—The kinetic behavior of free radical reactions was studied by examining the dependence of the monomer radical ($CH{\equiv}C\text{-}\dot{C}HOH$) formation rate on the monomer and hydrogen peroxide concentrations at −196°C. When the hydrogen peroxide concentration, $[H_2O_2]$, was varied (the maximum $[H_2O_2]$ value was about 6 mol./l.) and the monomer concentration, [M], was kept constant, the concentration of the trapped monomer radicals, [M·], increased with an increase in the irradiation time, as shown in Fig. 2. (The maximum [M·] value was about 10^{-3} mol./l.) Figure 3 shows the initial rate of monomer radical formation, $[d[M\cdot]/dt]_{t=0}$, against $[H_2O_2]$. Apparently the rate is proportional to $[H_2O_2]$. When, in turn, $[H_2O_2]$ was kept constant and [M] was varied, (the maximum [M] was about 14 mol./l.), the $[d[M\cdot]/dt]_{t=0}$ value remained the same for all [M] values. With an increase in the irradiation time, the $d[M\cdot]/dt$ value decreased. This phenomenon cannot be ascribed to a decrease of $[H_2O_2]$ because the concentration of the trapped radicals and, consequently, the consumption of hydrogen peroxide was smaller than the initial $[H_2O_2]$.

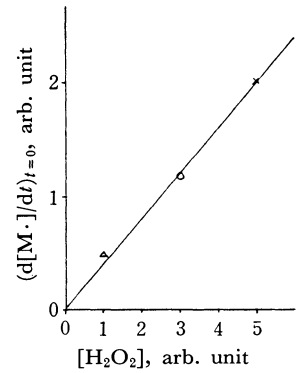

Fig. 3. The effect of hydrogen peroxide concentration on the initial rate of monomer radical formation in ultraviolet-irradiated propargyl alcohol-H_2O_2 glass at −196°C.

The Derivation of Kinetic Equations.—No ESR spectrum from HO· is observed after irradiation. Consequently, the HO· radicals formed from hydrogen peroxide during irradiation at −196°C are believed to migrate and to react readily, so that they disappear immediately after their formation. It is, therefore, reasonable to assume a steady-state HO· concentration in the solid state during irradiation. The experimental results indicate that monomer radicals are immobilized and that recombination between monomer radicals need not be considered. On the other hand, the concentration of monomer radicals increases to a considerable extent. This fact implies that recombination between trapped monomer radicals and the initiating HO· radicals should be considered as an elementary reaction, which is usually neglected in kinetic treatments of radical polymerizations in the liquid state. Consequently, the elementary reactions are as follows:

$$H_2O_2 \xrightarrow{k_1} 2HO\cdot \qquad (1)$$

12) W. T. Dixon and R. O. C. Norman, *J. Chem. Soc.*, **1963**, 3119.
13) R. W. Fessenden and R. Schuler, *J. Chem. Phys.*, **39**, 2147 (1963).

$$HO\cdot + HO\cdot \xrightarrow{k_2} H_2O_2 \quad (2)$$

$$HO\cdot + M \xrightarrow{k_3} M\cdot \quad (3)$$

$$HO\cdot + M\cdot \xrightarrow{k_4} \text{molecule} \quad (4)$$

From the assumption of a steady-state concentration of [HO·],

$$k_1[H_2O_2] - k_2[HO\cdot]^2 - k_3[HO\cdot][M] - k_4[HO\cdot][M\cdot] = 0$$

As [HO·] is small enough, one can neglect the second term. Thus, the following equation is obtained for the steady-state concentration of HO· radicals:

$$HO\cdot = \frac{k_1[H_2O_2]}{k_3[M]+k_4[M\cdot]} \quad (5)$$

From Eq. 5, the rate of monomer radical formation can be expressed as follows:

$$\frac{d[M\cdot]}{dt} = k_3[HO\cdot][M] - k_4[HO\cdot][M\cdot] = \frac{1 - k_4[M\cdot]/k_3[M]}{1 + k_4[M\cdot]/k_3[M]} k_1[H_2O_2] \quad (6)$$

Since $[M] \gg [M\cdot]$,

$$d[M\cdot]/dt \simeq \{1 - 2k_4[M\cdot]/k_3[M]\}k_1[H_2O_2] \quad (7)$$

By assuming that the consumption of monomer molecules and hydrogen peroxide is very small and that [M] and $[H_2O_2]$ are unchanged, the integration of Eq. 7 yields:

$$[M\cdot] = k_3[M]/2k_4\left\{1 - \exp\left[-\frac{2k_1k_4[H_2O_2]}{k_3[M]}t\right]\right\} \quad (8)$$

Comparison of Experimental Results with Kinetic Equations.—The experimental results shown in Figs. 3 and 4 indicate that $d[M\cdot]/dt \propto [H_2O_2]^1[M]^0$

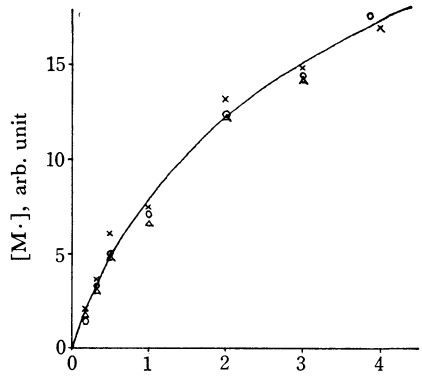

Fig. 4. The effect of irradiation time on the concentration of monomer radicals trapped in ultraviolet irradiated propargyl alcohol-H_2O_2 glass at −196°C.
$[H_2O_2]$ is kept constant.
[M]: the ratio of × : ○ : △ is 20 : 17 : 14.

for $t=0$. They are in good agreement with Eq.7, which shows that $d[M\cdot]/dt=k_1[H_2O_2]$ for $t=0$. From Eq. 8, [M·] is expected to show a saturating tendency with an increase in the irradiation time. In fact, this is obvious from the results shown in Figs. 2 and 4. Therefore, the two assumptions, i. e., the existence of a steady state of [HO·] and of recombination between HO· and M·, which have been made in deriving the kinetic equations, are found to be reasonable.

From the above discussion, it may be concluded that HO· radicals migrate in the irradiated solid mixture and react readily with monomers. The reaction between the monomer radical and HO· radical is much more important than the recombination reaction between monomer radicals. This is a significant feature of the behavior of free radicals in solid state polymerization.

Silent Discharge Reactions in Aqueous Solutions. III. Acidic Aqueous Solutions of Ferrous Sulfate and Ceric Sulfate in a Hydrogen Atmosphere*

By Akira YOKOHATA and Satoru TSUDA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received September 10, 1965)

A study has been made of silent discharge reactions in aqueous solutions of ferrous sulfate and ceric sulfate acidified with sulfuric acid in a hydrogen atmosphere. The present study has confirmed that silent discharge leads to the formation of hydrogen peroxide from water molecules in a dilute sulfuric acid solution, the oxidation of ferrous ions to ferric ions, and the reduction of ceric ions to cerous ions. The same reactions were previously studied in inert gases. A satisfactory interpretation can be made of their mechanisms by taking into consideration the action on the solvent of slow electrons produced in the gaseous phase. In a hydrogen atmosphere, the yields of the foregoing reactions were very small when compared with those in the case of inert gases; however, a good linear correlation was observed between the yield and the duration time of discharge. From these results it has been concluded that the yields can be well interpreted by taking into consideration the action of active species of hydrogen generated in the gaseous phase on the radicals formed from liquid water, besides the action of slow electrons; moreover, the action of active species on the solute cannot be serious. The absorbed dose in the solution was estimated to be approximately 1.9×10^7 r./hr. from the relation of the dissipated energy calculated electrically to the absorbed dose.

In previous reports[1] it has been pointed out that (1) in a helium or argon atmosphere the chemical reactions in an aqueous solution of ferrous sulfate or ceric sulfate by silient discharge can be well interpreted by taking into consideration the actions on the solvent of slow electrons produced in the gaseous phase, and that (2) neither the effect of the metastable excited state of helium and argon nor that of luminescence can be serious, while the silent discharge reaction apparently corresponds to the radiolysis caused by a particle of high LET (linear energy transfer).

The foregoing conclusions were drawn from a study of silent discharge in helium and argon atmospheres. However, in the case of gases other than inert gases, the reaction mechanisms may become complicated, for the effect of active species,[2-7] besides that of slow electrons, should also be taken into consideration.

In the current study, hydrogen gas was used as an atmosphere: the effect of active species of hydrogen generated in the gaseous phase was investigated, and the results were compared with those obtained with inert gases.

In acidic aqueous solutions, the experimental results showed the formation of hydrogen peroxide, the oxidation of ferrous ions to ferric ions, and the reduction of ceric ions to cerous ions. The reaction mechanisms were complicated by the formation of active species of hydrogen in the gaseous phase. However, the results could be well interpreted in terms of the radiolysis of an aqueous solution under the active species of hydrogen.

Experimental

The discharge tube and the electrical circuit were identical to those previously reported. All the experiments were performed at a constant solution volume of 10 ml. The surface of the solution vibrated gently during the discharge. This may be useful in renewing the surface of the solution. All the experiments were conducted at about 20°C after the oxygen dissolved in the solution had been completely removed by bubbling hydrogen gas into the solution. A constant discharge current of 1 mamp. was employed in most of the experiments, letting hydrogen gas flow at a velocity of about 120 ml./min. through the gas space of the discharge tube. The water used was purified by the multiple distillation procedure described by Johnson and Allen.[8] The Merck guaranteed reagents ferrous sulfate and ceric sulfate were used without further treatment. As pure hydrogen gas (99.95%) provided the same results

as purified hydrogen gas, it was used without further purification in later experiments. The concentrations of sulfuric acid, ferrous sulfate and ceric sulfate solutions varied from 1.5 to 0.1 N, from 1×10^{-2} to 1×10^{-3} M and from 2×10^{-3} to 5×10^{-4} M respectively.

Results

In the gaseous phases, hardly any ozone or hydrogen peroxide was formed. Moreover, hardly any hydrogen sulfide was formed from the dilute aqueous solution of sulfuric acid.

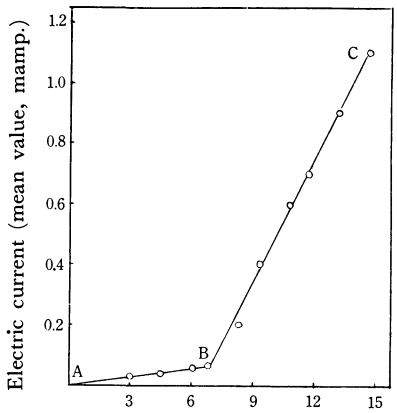

Fig. 1. Relation between applied voltage and electric current.

Figure 1 shows the relationship between the applied voltage and the electric current as measured by the method described in the previous report, where B is the firing voltage.

H_2SO_4: 0.8 N

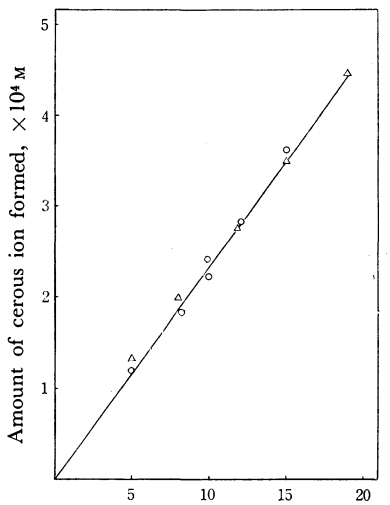

Fig. 4. Relationship between amount of cerous ion formed and duration time of discharge.
Initial concentration of ceric ion;
○ 5×10^{-4} M △ 2×10^{-3} M
0.8 N H_2SO_4

In a dilute aqueous solution of sulfuric acid, hydrogen peroxide appeared following the discharge. Also, in acidic solutions of ferrous sulfate and ceric sulfate, the oxidation of ferrous ions to ferric ions and the reduction of ceric ions to cerous ions were noted respectively. Figures 2, 3 and 4 show, respectively, the relationship between the amounts of hydrogen peroxide, ferric ion and cerous ion formed and the duration of the discharge. The results produced a good linear curve.

In the range from 0.1 N to 1.5 N of sulfuric acid, the yield of hydrogen peroxide was independent of the concentration of sulfuric acid. An independence of the solute concentration with relation to the yield was also found when the

ferrous ion concentration ranged from 1×10^{-2} M to 1×10^{-3} M, and when that of ceric ions ranged from 2×10^{-3} M to 5×10^{-4} M.

The yield of each product was obtained as follows:

$$Y(H_2O_2) = 8.3\times10^{-5}\text{ M},\ Y(Fe^{3+}) = 2.7\times10^{-4}\text{ M},$$
$$Y(Ce^{3+}) = 2.3\times10^{-4}\text{ M}$$

where Y shows the yield with the discharge current at 1 mamp. and with the duration of discharge at 10 min. These yields were very small when compared with those in helium and argon.

These points will be discussed in detail later.

Discussion

The Estimation of the Absorbed Dose in the Aqueous Solution.—It is very important to determine the absorbed dose in silent discharge chemistry. However, the estimation of the absorbed dose has been little studied. In our previous reports, we pointed out that, in an inert gas atmosphere, it is possible to estimate the absorbed dose in silent discharge by chemical dosimetry. Furthermore, it was shown that Eq. 1 holds good:

$$A(\text{He})/A(\text{Ar}) = E(\text{He})/E(\text{Ar}) \qquad (1)$$

where A is the value calculated by Eq. 3 from the standpoint of electrical engineering and gives the total energy dissipated per second by silent discharge. E gives the absorbed dose in the solution per second. Equation 1 shows that E is proportional to A and that the proportional constant is independent of the kind of gas, at least in the cases of helium and argon.

At the present stage, no adequate method is available to check experimentally whether Eq. 1 applies to other gases or not. However, in view of the fact that Eq. 1 holds good in helium and argon, despite the difference in such properties as the ionization potential, the mean free path, the firing voltage, and the absolute value of A, it may be said that Eq. 1 applies to other gases. If so, Eq. 2 can be obtained:

$$A(H_2)/A(X) \simeq E(H_2)/E(X) \qquad (2)$$

where X is helium or argon. Since $A(H_2)$ and $A(X)$ can be calculated by Eq. 3 and since $E(X)$ is known, $E(H_2)$ can be determined from 2. In Eq. 3,[9] C_{die} and C_a depend on the shape of the discharge tube, while V_i and V_d depend on the kind of gas used under given experimental conditions.

$$A=\frac{f(C_{die}+C_a)(V_i+V_d)\{2E_m-(V_i+V_d)(1+C_a/C_{die})\}}{1+C_a/C_{die}} \qquad (3)$$

where

f : the frequency of the electric source used
C_{die} : the total capacitance of the insulator
C_a : the capacitance due to the gap space in the tube
V_i : the voltage across the gap space at the firing voltage
V_d : the stopping voltage
E_m : the maximum value of the applied voltage

The relation between V_d and V_i is not well known, but the value of V_d/V_i is said to be approximately 0.4—0.2.[10]

Under our experimental conditions, $C_{die}=180$pF, $C_a=36$pF, $V_i=1.3$ kV. and $E_m=15.4$ kV. in helium, while $V_i=6.9$ kV. and $E_m=19$ kV. in hydrogen. By applying these values to Eq. 3, the ratio of the dissipated energy in helium and hydrogen may be estimated. Table I shows the

Table I. Calculated ratio of $A(H_2)$ to A(He)

V_d/V_i	$A(H_2)/A$(He)
0.2	5.2
0.4	4.9

calculated results when $V_d/V_i=0.2$ and 0.4. In this study the mean value for $A(H_2)/A$(He) was assumed to be 5. As E(He) is equal to 3.8×10^6 r./hr., $E(H_2)$ is estimated to be about 1.9×10^7 r./hr. This value, of course, varies with the value of the electric discharge current. Shown here are the values in the case of 1 mamp. This also gives the average integral dose absorbed by the aqueous solution in the apparatus used by the authors, where the volume of the solution is 10 ml.

An Estimation of the Apparent LET.—In order to estimate theoretically the radical or molecular yield from the absorbed dose, it is necessary to ascertain the LET values of electrons produced in a hydrogen atmosphere by silent discharge.[11]

Generally speaking, in silent discharge at one atmospheric pressure, electrons have an energy distribution from just above zero to somewhat above the ionization potential of the gas in which the discharge occurs.[12]

In view of the fact[13] that the ionization potential of the hydrogen molecule is equal to 15.4 eV., that of argon, to 15.7 eV., and that of helium, to 24.5 eV., the LET values of electrons in a hydrogen atmosphere may closely resemble that in argon. Therefore, a value of about 8(eV./Å) was

assumed for the LET value of electrons in hydrogen.[14]

The Formation of Hydrogen Peroxide.—The silent discharge reaction in a hydrogen atmosphere showed the formation of hydrogen peroxide from dilute aqueous solutions of sulfuric acid. As precursor of hydrogen peroxide, the hydroxyl radical has heretofore been proposed, but recent studies have also suggested contribution of the excited state of water.[15] Inasmuch as details of this new mechanism are yet to be elucidated, this remains a problem for future study. In this study an attempt will be made to explain the mechanism involved from the previously-proposed theory of the recombination reaction of hydroxyl radicals.

Two processes can be considered for the formation of hydroxyl radical, that is, the interaction of (a) water vapor and (b) liquid water, with slow electrons. As has been pointed out by Hart et al.,[3] however, the process a cannot be great in the presence of a large excess of molecular hydrogen. Therefore, the process b should be considered:

$$\text{lig.}H_2O \xrightarrow[\text{slow electron}]{\sim\!\!\wedge\!\!\vee\!\!\sim} OH,\ H \qquad (4)$$

$$OH + OH \rightarrow H_2O_2 \qquad (5)$$

The estimated yield of hydrogen peroxide calculated on the basis of the absorbed dose and the $G(H_2O_2)$ value, $Y_{cal}(H_2O_2)$, should be about 4.4×10^{-3} M. In the experiment, however, the value of $Y(H_2O_2)$ was only 8.3×10^{-5} M. This discrepancy might be ascribed to the radiolysis of an aqueous solution under the active species of hydrogen. In silent discharge, the radicals from liquid water are formed mainly just below the surface, because the energy of the electrons is very small. Therefore, a scavenging action of active species of hydrogen on these radicals may be expected:

$$H_{at} + OH \rightarrow R \qquad (6)$$

$$H_{at} + H \rightarrow S \qquad (7)$$

where H_{at} is the active species of hydrogen (H, H^+, etc.) generated in the atmosphere. R and S are the reaction products (H_2O or H_2 is mainly expected respectively). Therefore, this scavenging reaction 6 should lead to a decreased yield of hydrogen peroxide. In fact, as will be shown later, the estimated yield of hydroxyl radicals and hydrogen atoms were both very small. This is suggestive evidence that reactions 6 and 7 should be considered.

Other cases can also be mentioned. First, the action of the hydroxyl radical on hydrogen molecules dissolved in the solution-reaction 8; second, the action of hydrogen atoms on hydrogen peroxide in the solution-reaction 9, and third, the action of active species of hydrogen in the gaseous phase on hydrogen peroxide-reaction 10.[16]

$$OH + H_2 \rightarrow H + H_2O \qquad (8)$$

$$H + H_2O_2 \rightarrow H_2O + OH \qquad (9)$$

$$H_{at} + H_2O_2 \rightarrow H_2O + OH \qquad (10)$$

These reactions lead to the formation of another radical, in company with the disappearance of one radical. As will be shown later, however, the Y(H) and Y(OH) estimated from the experiments on ferrous sulfate and ceric sulfate being very small, reactions 8, 9 and 10 may not be serious.

The Formation of Ferric Ions.—The estimated yield of ferric ions, calculated on the basis of the absorbed dose and the $G(Fe^{3+})$ value, $Y_{cal}(Fe^{3+})$ should be about 1.3×10^{-2} M. However, the experiment gave the value of $Y(Fe^{3+})$ to be only 2.7×10^{-4} M, with the solute concentration ranging from 1×10^{-2} M to 1×10^{-3} M.

In silent discharge, the mechanism of oxidizing ferrous ions to ferric ions in an acidic solution might be shown as follows:

$$OH + Fe^{2+} \rightarrow Fe^{3+} + OH^- \qquad (11)$$

$$H + H^+ + Fe^{2+} \rightarrow Fe^{3+} + H_2 \qquad (12)$$

$$H_2O_2 + Fe^{2+} \rightarrow Fe^{3+} + OH + OH^- \qquad (13)$$

The yield of ferric ions, $Y(Fe^{3+})$, should, then, be expressed by Eq. 14:

$$Y(Fe^{3+}) = 2Y(H_2O_2) + Y(H) + Y(OH) \qquad (14)$$

Even if reaction 8 is caused by dissolved hydrogen molecules, the yield of ferric ions would be independent of 8, because one hydrogen atom and one hydroxyl radical oxidize one ferrous ion, and also one hydrogen atom obtained via 8 oxidizes one ferrous ion via 12. Therefore, with regard to the discrepancy between the observed yield and the calculated ferric ion yield, we must assign the reactions to reasons other than 8. Also, the value of Y(H+OH) estimated by 14, about 1×10^{-4} M, was very small when compared with the calculated value of about 4.4×10^{-3} M. This suggests that only a small part of the yield of hydrogen atoms and hydroxyl radicals expected theoretically from the radiolysis of water by slow electrons contributes to the oxidation of ferrous ions to ferric ions. The above facts are suggestive evidence which support reactions 6 and 7.

In addition, ferric ions produced via reactions 11—13 may be reduced by the active species generated in the gaseous phase:

$$H_{at} + Fe^{3+} \rightarrow Fe^{2+} + H^+ \qquad (15)$$

This reaction, however, may be not important in

14) Accordingly, the G value can be assigned as follows:
G(H)=0.7, G(OH)=0.7, $G(H_2O_2)$=1.4, $G(Fe^{3+})$=4.2, $G(Ce^{3+})$=2.8.

15) M. Anbar, S. Guttmann and G. Stein, *J. Chem. Phys.*, **34**, 703 (1961).

16) C. J. Hochanadel, *J. Phys. Chem.*, **56**, 587 (1952).

the range of a good linear correlation between the yield and the duration of discharge.

The Formation of Cerous Ions.—The estimated yield of cerous ions, calculated on the basis of the absorbed dose and the $G(Ce^{3+})$ value, should be about 8.9×10^{-3} M. However, the experiment gave a yield of only 2.3×10^{-4} M within the range from 2×10^{-3} M to 5×10^{-4} M in a solute concentration in a 0.8 N sulfuric acid solution. With regard to the discrepancy between the observed and calculated values, the following reasons might be mentioned.

In the case of gamma-ray irradiation and also silent discharge in an inert gas atmosphere, $Y(Ce^{3+})$ can be expressed by Eq. 16.[1b]

$$Y(Ce^{3+}) = 2Y(H_2O_2) + Y(H) - Y(OH) \qquad (16)$$

In a hydrogen atmosphere, if the active species of hydrogen act directly on the solute, a comparatively large increment in $Y(Ce^{3+})$ may be expected when compared with the case of inert gas. The experimental value of $Y(Ce^{3+})$, however, was very small, contrary to expectation. This suggests that the action of active species on the solute cannot be serious. Also, for the same reason, it might be said that the reaction of the hydrogen molecule on the hydroxyl radical (8) cannot be serious. Next, by combining Eq. 16 with 14, the values of $Y(H)$ and $Y(OH)$ can be separately estimated; that is, $Y(H)=8\times10^{-5}$ M and $Y(OH)=2\times10^{-5}$ M. Both values are very small when compared with the calculated values, $Y_{cal}(H)=2.2\times10^{-3}$ M and $Y_{cal}(OH)=2.2\times10^{-3}$ M. The above is also suggestive evidence for the adequacy of reactions 6 and 7.

It is our conclusion that the scavenging action of the active species of hydrogen on the hydroxyl radical and the hydrogen atom formed from liquid water by slow electrons plays an important role.

The Radiolysis of a Binary Mixture of Tetrahydrofuran with Furan

By Masao MATSUI

The Institute of Physical and Chemical Research, Bunkyo-ku, Tokyo

(Received September 27, 1965)

The radiolysis of a tetrahydrofuran(THF) and furan system was studied at a dose of about 2×10^{19} eV. ml^{-1} of ^{60}Co-γ-rays, and the hydrogen which may be formed by the no-ring opening and the carbon monoxide which should be formed by the ring scission were determined. The decrease in the hydrogen yield with an increase fraction of furan was found to be greater than had been expected, while $G(CO)$ fit the expected value. The charge transfer mechanism was presumed for the decrease in the hydrogen yield in the γ-radiolysis of this mixture. Suggestions were made on the probable mechanism of the ring opening of the excited molecule for the formation of carbon monoxide, and on the ionic reaction for hydrogen formation. Furthermore, the probability of the ring scission of the THF molecule was roughly estimated by using the assumed decomposition reaction and the determined G values.

We have as yet very little information on the γ-radiolysis of liquid cyclic ethers, such as dioxane, tetrahydrofuran(THF) and furan. Granzow et al[1] have discussed the relevancy between the stability for ionizing radiation and the aromaticity of the compound by comparing the radiolysis of furan, thiophen and benzene. Llabador et al.[2] have determined the G values of the gas and liquid products in the γ-radiolysis of cyclic ethers and have discussed the reaction mechanism, especially that of the radiolysis of dioxane.

The present work was carried out in order to examine the existence of the protection in the radiolysis of the binary system of THF and furan system which has the lowest aromaticity among the heterocyclic compounds, and, furthermore, to establish the mechanism of the radiolysis of THF which is a typical heterocyclic compound.

Experimental

Materials. — The G. R.-grade furan was further purified by bulb-to-bulb distillation, the middle fraction was used for the run. The impurities in the furan were found to be negligible by gas chromatography. The G. R.-grade THF, stored with sodium hydroxide, was distilled through an about 50 cm., glass-helix-packed column at a reflux ratio of 10 : 1 after it had been refluxed with metallic potassium for about 24 hr.

1) A. Granzow, J. Wedenburg and A. Henglein, *Z. Naturforsch.*, **19b**, 1015 (1964).
2) Y. Llabador and J. P. Adloff, *J. chim. phys.*, **61**, 681, 1467 (1964).

The fraction collected at 66.0—67.0°C was retained in storage vessel placed in the vaucum line in the dark. The remaining impurities were in the C_6 region and were found by gas chromatographic determination to total about 0.05%. These impurities were unchanged by γ-irradiation.

Sample Preparation, Irradiation and Analysis. —THF was distilled into a calibrated bulb from the storage vessel, and the middle fraction (about 10 ml.) was condensed into an irradiation cell. The furan for irradiation was prepared in a similar way.

These samples were subjected to ^{60}Co-γ-irradiation at 25.0±1.0°C and at a dose rate of $(1.22—1.30)\times10^{17}$ eV. ml^{-1} min^{-1}. The dose rate was determined by the Fricke method, assuming $G(Fe^{3+})=15.6$, and $\varepsilon_{Fe^{3+}}=2150$ at 20.0°C and 304 mμ.

The gas fraction volatile at −196°C was determined on a conventional calibrated gas burette and a Toepler pump. The hydrogen content of the −196°C fraction was determined by means of a heated palladium thimble, while carbon monoxide was analyzed by the method using copper(II) oxide containing 1.3% iron(III) oxide, prepared by the method of Brücker and Schick.[3]

The fraction volatile at −80°C, consisting of C_2–C_4 hydrocarbons, and liquid products such as furan and butanol, was analyzed gas-chromatographically by using a 6 m. column of squalane at 30°C, and a 2.25 m. column of P. E. G.-1000 at 100°C.

Result and Discussion

If the radiolysis products of THF in a binary solution are unaffected by the presence of furan, the expected G value, G_{ex}, for a product, P, from the solution should be given approximately by the expression:

$$G_{ex}(P) = G_T^0(P)\varepsilon_T + G_F^0(P)\varepsilon_F$$

where $G_T^0(P)$ and $G_F^0(P)$ refer to the yields of P from pure THF and furan respectively, and where ε_T and ε_F refer to the electron fraction in the solution radiolyzed. The G_{ex} values in Fig. 2 are represented by a linear dashed line.

The hydrogen which may be formed by the no-ring opening, and the carbon monoxide which should be formed by the ring opening were determined in this binary system. Llabador and Adloff have shown that $G(H_2)$ and $G(CO)$ are independent of the total dose up to about 10^{20} eV. ml^{-1} in the radiolysis of liquid furan. Since a similar result was also obtained for THF in the region of low dosage, as is shown in Fig. 1, the binary system was irradiated at a dose of about 2×10^{19} eV. ml^{-1}.

The G value of the hydrogen and carbon monoxide from the purified liquid sample were 2.95± 0.22 and 0.13±0.02 for THF, and 0.12 and 0.31 for furan. Those of the binary system of THF and furan are given in Table I and Fig. 2.

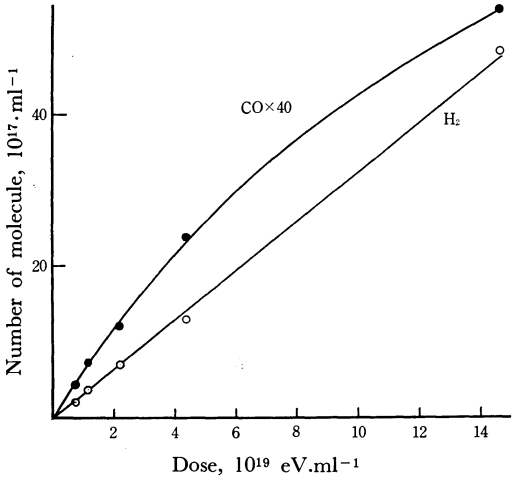

Fig. 1. The variation of $G(H_2)$ and $G(CO)$ with dose.

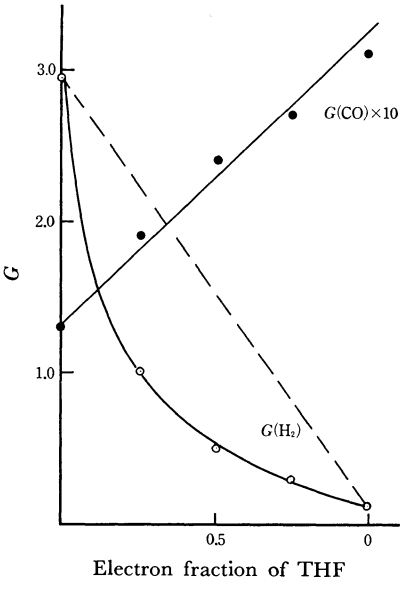

Fig. 2. Yields of H_2 and CO from the system THF-furan

Table I. Yields of hydrogen and carbon monoxide from mixture of THF and furan irradiated at ca. 25.0°C and 10^{19} eV. ml^{-1}

ε_T	$G(H_2)$ Obsvd.	$G(H_2)$ Calcd.	ΔG	$G(CO)$ Obsvd.	$G(CO)$ Calcd.	ΔG
1.00	2.95	2.95	0	0.13	0.13	0
0.74	1.01	2.21	−1.20	0.19	0.18	+0.01
0.49	0.50	1.51	−1.01	0.24	0.22	+0.02
0.25	0.29	0.83	−0.54	0.27	0.26	+0.01
0	0.12	0.12	0	0.31	0.31	0

The decrease in the hydrogen yield is shown to be greater than that to be expected from the above equation, whereas the yields of carbon monoxide fit the expected values. According to the current

3) H. Brückner and R. Schick, *Gas u. Wasserfach.*, **82**, 189 (1939).

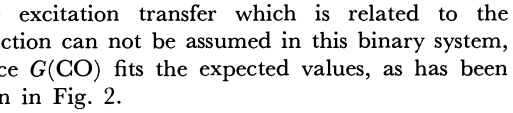
theories of radiation chemistry, radiolysis begins with the production of molecules of vibrationally- and electronically-excited state, in addition to that of ionic species. The different mechanisms may be possible for the formation of hydrogen and carbon monoxide in the radiolysis of liquid THF.

The decrease in hydrogen yield might be due to the protection of THF from reaction by an activation transfer mechanism which reduces the amount of the initial decomposition of the THF itself; it might be due to a scavenging process that removes precursors of hydrogen, or it might be due to a combination of the two.

The yields of hydrogen and carbon monoxide from neither THF nor furan are affected by adding I_2 and hydroquinone respectively as radical scavengers. Their constant G values were also observed by adding ethylene (0.56—3.55 mol.) in the γ-radiolysis of THF. Moreover, if furan acts as the scavenger for the H-atom, the amount of residual hydrogen should be constant at a high concentration of added furan. However, this is not the case, as is shown in Fig. 2. Consequently, there should be no hydrogen atoms scavenged by the added furan, and the decrease in $G(H_2)$ in the radiolysis of the THF-furan system might be due to the "sponge-type" protection[4] action of furan with relation to THF.

Since $G(CO)$ and the amount of constructional units containing oxygen atoms in the THF molecule are both half of those of dioxane, the mechanism of the formation of the carbon monoxide in the γ-radiolysis of THF may be similar to that of dioxane. Llabador and Adloff have suggested that the decomposition of the excited dioxane molecule gives rise to the formation of carbon monoxide. Furthermore, in the photolysis of ethyleneoxide, the ring opening was the main reaction, and in the mercury-sensitized photolysis of de-aerated THF, the ratio of carbon monoxide to hydrogen was about 10 times that in the γ-radiolysis. Therefore, it may be concluded that the excited molecule of THF is the most important precursor of the formation of carbon monoxide, though its energy state is not yet clear. However, the excitation transfer which is related to the reaction can not be assumed in this binary system, since $G(CO)$ fits the expected values, as has been seen in Fig. 2.

The mode of the ring opening in the THF molecule is supposed to be as follows:



The carbon monoxide should be formed by the decomposition of the active species, such as I, II and III, when those species have excess energy after the ring opening. If the C–O bond rupture also occurs preferentially in these active species, as has been suggested by Newton[5] and, Ng and Freeman[6] in the α-and γ-radiolysis of linear ethers respectively, the formation of carbon monoxide may be explained by the following scheme:

$$\mathrm{I} \longrightarrow (\mathrm{CH_2CH_2}\cdot)^* + (\mathrm{OCH_2CH_2}\cdot)^* \quad (1)$$

$$(\mathrm{CH_2CH_2}\cdot)^* \longrightarrow \mathrm{C_2H_4} \text{ or } \mathrm{C_2H_5}\cdot \quad (2)$$

$$(\mathrm{OCH_2CH_2}\cdot)^* \xrightarrow{\mathrm{C_4H_7O}\cdot} \mathrm{CO} + \mathrm{CH_3}\cdot + \mathrm{C_4H_8O} \quad (3)$$

$$\mathrm{CH_3}\cdot + \mathrm{C_4H_8O} \longrightarrow \mathrm{CH_4} + \mathrm{C_4H_7O}\cdot \quad (4)$$

According to Llabador's data, since the yields of ethylene and carbon monoxide indicate the "molecular" yield and since 90% methane was scavenged by the radical scavenger, the reactions 1, 2 and 3 may be taking place in the spur region. Carbon monoxide is considered to be formed also by the following scheme:

$$\mathrm{II} \longrightarrow (\mathrm{CH_2CH_2CH_2}\cdot)^* + (\mathrm{OCH_2}\cdot)^* \quad (5)$$

$$(\mathrm{OCH_2}\cdot)^* \longrightarrow \mathrm{CO} + \mathrm{H_2} \quad (6)$$

$$(\mathrm{CH_2CH_2CH_2}\cdot)^* \longrightarrow \mathrm{CH_3\text{-}CH{=}CH_2} \text{ or } (\mathrm{CH_2})_3 \text{ or } \mathrm{C_3H_7}\cdot \quad (7)$$

As the yields of propylene, cyclopropane, CO and H_2 indicate the "molecular" yield in Llabador's data at a high dosage, while no cyclopropane and only a trace of propylene were determined in the low-dosage experiment of this report, reactions 5, 6 and 7 may occur in spur region anyhow. A similar process may be presumed for the III species as follows:

$$\mathrm{III} \longrightarrow \mathrm{CH_3CH_2CH_2CH_2OH} \quad (8)$$

$$\mathrm{III} \xrightarrow{\mathrm{C_4H_7O}\cdot} \mathrm{CO} + \mathrm{C_3H_7}\cdot + \mathrm{C_4H_8O} \quad (9)$$

$$\mathrm{C_3H_7}\cdot + \mathrm{C_4H_8O} \longrightarrow \mathrm{C_3H_8} + \mathrm{C_4H_7O}\cdot \quad (10)$$

The decrease in $G(C_3H_8)$ caused by the added radical scavenger in Llabador's data at high dosage may be explained qualitatively by assuming the reactions 7 and 9 in the spur. Since $G(C_3H_8)$ is negligible in the low-dosage experiments of this report, reaction 8 may be more dominant than 9.

The probability of the formation of active species I, II and III by ring opening can roughly be estimated as I : II : III = 1.0 : ~0 : 1.3, by using the above scheme, and the results determined at a total does of 4.39×10^{19} eV. ml^{-1}. These results are $G(C_4H_9OH) = 0.40$, $G(CH_4) = 0.01$, $G(C_2H_4) = 0.30$, $G(C_2H_6) = 0$, $G(c\text{-}C_3H_6) = 0$, $G(C_3H_6) =$ trace and $G(C_3H_8) =$ trace. It may be presumed, by taking its estimated value, that the probability of the C–O bond rupture is a little greater than

the rupture of the C(β)–C(β') bond. The actual ratio of ring opening might be greater than these estimated values, depending upon the identity of the dimeric and polymeric products.

As for the formation of the hydrogen in this binary system, a charge transfer is probable. A positive ion of THF may easily be formed by ejecting, by means of ionizing radiation, one of the lone-pair electrons located at the oxygen atom. Since the ionization potentials of THF and furan are 10.3 and 9.06 eV. respectively, the charge transfer from the ground state of the THF ion to a furan molecule is probable, because the process is exothermic. Therefore, an ionic reaction, such as an ion-molecule reaction or an ion recombination reaction, is most probable for the formation of the hydrogen.

Dainton et al.[7] have suggested that the dominant primary species formed in the γ-radiolysis of methyltetrahydrofuran (MTHF) in the glassy state are an electron and a free radical (corresponding to the solvent molecule minus a hydrogen atom), followed by the ion-molecule reaction between MTHF and its ion. The experimental finding that the hydrogen yield was unaffected by an added radical scavenger could also be explained by the process of the ion-molecule reaction, because the "molecular" hydrogen is produced by this reaction. As the formation of "molecular" hydrogen may also be considered in the ion-recombination reaction, which is another process of the parent ion, it is convenient to conclude that the hydrogen is formed mainly by the ionic reaction, and that the precursor of the carbon monoxide is the directly-excited THF molecule.

7) F. S. Dainton, J. P. Keene, T. J. Kemp, G. A. Salmon and J. Teply, *Proc. Chem. Soc.*, **1964**, 265; F. S. Dainton, F. R. S., and G. A. Salmon, *Proc. Roy. Soc.*, **A285**, 319 (1965).

Summary

The charge transfer is presumed for the formation of hydrogen in the γ-radiolysis of liquid THF-furan mixtures. The ring opening of the excited molecule has been suggested to be the main process in the formation of carbon monoxide. It has also been suggested that hydrogen might be formed mainly by an ionic reaction including the parent positive ion of THF. The probability of the ring opening has been roughly estimated.

The author's thanks are due to Dr. Kenichi Shinohara, Masashi Imamura and Ko Taki for their stimulating discussions of the problems, and to Miss Noriko Tsunoo for her analysis by gas chromatography.

The Reaction of Oxygen Atoms with Dimethyl Ether*

By Yoshimasa TAKEZAKI, Sadayuki MORI and Hironobu KAWASAKI

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received November 6, 1965)

The gas-phase reaction of dimethyl ether with oxygen atoms produced by the mercury photosensitized decomposition of nitrous oxide has been studied by means of quantitative determinations of the reaction products. Characteristic products are water, methanol, formaldehyde, carbon monoxide, methoxy ethanol and methyl formate. The possible mechanisms of the oxygen attack on the substrate have been considered, and the following steps postulated on the basis of the relative importance of these products and their time variations:

$O + CH_3OCH_3 \xrightarrow{k_E} OH + CH_3OCH_2$, $OH + CH_3OCH_3 \longrightarrow H_2O + CH_3OCH_2$
and $CH_3OCH_2 + OH \longrightarrow CH_3O + CH_2OH$.

The rate constant, k_E, of the first step has been determined in the competitive reaction with *n*-butane as:

$$k_E = 6.3 \times 10^{10}\exp(-4700/\boldsymbol{R}T)\ 1.\ \mathrm{mol}^{-1}\,\mathrm{sec}^{-1}.$$

Rate data have been increasingly accumulated in recent years on the reactions of oxygen atoms with such saturated molecules as hydrogen and paraf-

* This paper was read at the International Conference on Photochemistry, Tokyo, 1965.

fins.[1-4] However, papers dealing with oxygen-containing compounds are still scant (Ref. 1f and Ref. 5), and the mode of the initial attack by oxygen seems still not to be conclusively known.

The mechanisms proposed hitherto may be classified into the following four types: hydrogen abstraction, a common type of reaction in atomic or monoradical reactions (ex., $CH_3CHO+O\rightarrow CH_3CO+OH$),[5] direct insertion into a C–H bond (ex., $CH_4+O\rightarrow CH_3OH$),[2] the displacement of one or two group(s) by O (ex., $n\text{-}C_4H_{10}+O\rightarrow CH_2O+H_2+:CHC_2H_5$ or $H_2+CH_3CHO+:CHCH_3$,[3] $(CH_3)_3CH+O\rightarrow(CH_3)_2CO+CH_4$ or $(CH_3)_2CO+H+CH_3$),[6] and the combination of an oxygen atom with two hydrogen atoms to form water (ex., $CH_4+O\rightarrow:CH_2+H_2O$).[7]

In all these instances, however, the methods of producing oxygen atoms vary; in the discharge in oxygen or water vapor, the formation of oxygen atoms of a single electronic energy state seems hardly to be expected, and the co-existence of oxygen molecules must obscure the proper reactions of oxygen atoms. Moreover, in high-temperature oxidation the features of the reaction may differ markedly from those prevailing in normal temperatures, further, in microwave discharge where the oxygen atom concentration is very high, the reactions of oxygen atoms with the produced radicals may complicate the discrimination of the primary action of oxygen atoms on the substrate.

In view of these facts, with the intention of determining the features of the oxygen attack on the oxygen-containing *saturated* compounds, dimethyl ether (referred to as DME hereafter) has been taken as an example, while as a source of oxygen atoms the mercury-photosensitized decomposition of nitrous oxide was used, since it has been established by Cvetanović[8] that the oxygen atoms in the ground ^3P state are produced in this reaction:

$$Hg(^1S_0)+h\nu(2537\ Å)\rightarrow Hg^*(^3P_1)$$
$$Hg^*+N_2O\rightarrow Hg(^1S_0)+N_2+O(^3P_2).$$

The qualitative aspects of this reaction have already been reported by the present authors,[9] but in this paper a more detailed discussion based on the quantitative results will be given.

Experimental

The reaction was carried out in a static system of the usual type. A Vycor glass reactor ($28\phi\times400$ mm.,

210 cc.) was placed parallel to a low-pressure mercury lamp (25ϕ × 436 mm., Toshiba Electric Co. germicidal lamp GL-15, dc-operated, 15 W.) in an air bath furnished with heating elements in the wall and a fan at the bottom. The Vycor glass cuts off the light wavelength shorter than 2200 Å; the temperature variation in the reactor was kept within 2°C during the reaction by means of forced air circulation. The reactant mixture was saturated with mercury vapor at room temperature prior to the reaction.

At the end of the irradiation, the reactor was warmed up to 70°C in order to vaporize the heavy liquid products; almost all the products, except for a trace of the heaviest ones, were then drawn out through a liquid nitrogen trap by means of a Töpler pump; then the permanent gases and vapors, and liquids condensing at room temperature were separately analyzed, mainly by gas chromatography, as is shown in Table I, where the products were identified with the authentic samples in 2 or 3 different coulmns (the methods of preparations of some of the samples have been given in the previous paper).[9]

The impurities of the reactants as measured by g.l.c. are: $O_2<0.00\%$, $N_2=0.15\%$, $CH_4=0.13\%$ in N_2O purified by the evacuation of the solid in a liquid nitrogen trap; $CH_3OH<0.01\%$, $H_2O<0.00\%$ in DME purified by repeated bulb-to-bulb distillation; the guaranteed purity of *n*-butane obtained from Takachiho Co.=99.8%.

Results

The Mercury-photosensitized Decomposition of DME.—In order to distinguish the reaction products of oxygen-atom reactions from those of the mercury-photosensitized decomposition of DME which takes place concomitantly, we have to know about the products of the latter reaction alone. This reaction has already been studied by Marcus et al.[11] in a flow system, but in order to make comparison easier, product analyses have now been performed in a static system under the conditions of the present investigation. Typical results are given in the columns 2 and 4 of Table II; the main products are H_2 and $(CH_3OCH_2)_2$ (ethylene glycol dimethyl ether; abbr. Dimer), together with small quantities of $CH_3OCH_2CH_2OCH_2CH_2OCH_3$ (bis-(β-methoxy ethyl) ether; abbr. BMEE or Trimer) and $CH_3OCH_2(OCH_3)CHCH_2OCH_3$ (glycerol trimethyl ether; abbr. GTME or Trimer). In column 4 are given those products which might exist but could not be detected, or which existed as only trace amounts.

Table II. Products of Hg photosensitized reactions

Initial			
DME, mmHg	100	100	
N_2O, mmHg	0	300	
Temp., °C	30	30	Compds. not detected or <0.0% in both cases
Irradiation	15 min.	1 hr.	
Product mol. % to charged DME			
DME	−20.3	−58.2	CO_2
N_2	—	30.0	O_2
H_2	13.4	3.1	CH_4
CO	0.0	2.0	C_2H_6
H_2O	0.0	27.6	C_2H_4
CH_3OH	0.0	3.8	H_2O_2
HCHO	0.0	0.7	$CH_3OC_2H_5$
Dimer*	4.8	4.6	$CH_3OCH_2OCH_3$
GTME} Trimer*	0.8	1.9	CH_3OOCH_3
BMEE}	0.3	0.5	Ethylene oxide
$CH_3OCH_2CH_2OH$	0.0	0.4	1, 4-Dioxane
$HCOOCH_3$	0.0	0.2	CH_2OHCH_2OH
Unidentified high boil. compds.		4 kinds each ca. 0.2%	CH_3CHO
			Oxides of N

* For abbreviations see the text.

The present results generally agree with those of Marcus[11] obtained at room temperature except for the additional observation of trimers; these products may be explained by:

$$\left.\begin{aligned} &CH_3OCH_3 + Hg^* \rightarrow CH_3OCH_2 + H + Hg \\ &CH_3OCH_3 + R \rightarrow CH_3OCH_2 + RH \\ &2CH_3OCH_2 \rightarrow (CH_3OCH_2)_2 \text{ Dimer} \end{aligned}\right\} \text{(Marcus)}^{11)}\ R=H \text{ or any radical}$$

$$(CH_3OCH_2)_2 + R \begin{cases} \rightarrow CH_3OCH_2CH_2OCH_2\cdot \\ \xrightarrow{+CH_3OCH_2} CH_3OCH_2CH_2OCH_2CH_2OCH_3 \text{ (BMEE)} \\ \rightarrow CH_3OCH_2\dot{C}HOCH_3 \\ \xrightarrow{+CH_3OCH_2} CH_3OCH_2CH(OCH_3)CH_2OCH_3 \text{ (GTME)}\cdot \end{cases}$$

One point to be noticed in connection with the following discussion is the absence of carbon monoxide, methane, ethane, methanol, formaldehyde, 1, 4-dioxane and ethylene oxide, which would rule out the possibilities of the $CH_3OCH_2 \rightarrow CH_3 + CH_2O$ and $CH_3OCH_2 + R \rightarrow \cdot CH_2OCH_2\cdot + RH$ reactions at room temperature.

In this study it is necessary to know the ratio of the decomposition of DME by the excited mercury to that of N_2O; the effective quenching cross-section of N_2O decomposition (Reaction 2 in the next scheme) has been given by Cvetanović[12] as 12.6 Å^2, but concerning DME the only available value is for the total quenching (7 Å^2 for (1)+(1′)[13]). Therefore, a rough estimation was made, according

11) R. A. Marcus, B. deB. Darwent and E. W. R. Steacie, *J. Chem. Phys.*, **16**, 987 (1948).
12) R. J. Cvetanović, ibid., **23**, 1208 (1955).
13) B. deB. Darwent and M. K. Phibbs, ibid., **22**, 110 (1954).

to the following scheme, of the effective cross section for DME decomposition, (1), from the rate measurements of the hydrogen formation in DME alone and of the nitrogen formation in the mixture of DME and nitrous oxide. The results are represented in Fig. 1.

			Rate const.
$Hg(^1S_0)+h\nu$	$\rightarrow Hg^*(^3P_1)$		
Hg^*	$\rightarrow Hg+h\nu$		(k_0)
Hg^*+DME	$\rightarrow Hg+CH_3OCH_2+H$	(1)	(k_1)
	$\rightarrow Hg'(^3P_0)+DME$	(1')	(k_1')
Hg^*+N_2O	$\rightarrow Hg+N_2+O(^3P_2)$	(2)	(k_2)
	$\rightarrow Hg'+N_2O$	(2')	(k_2')

We then have, in DME alone:

$$1/(\text{rate } H_2) = (1/I_{abs})(1 + k_1'/k_1) + (k_0/k_1I_{abs})/(DME) \quad \text{(Fig. 1-A)}$$

and in the mixture of DME and N_2O:

$$1/(\text{rate } N_2) = (1/I_{abs})(1 + k_1'/k_1)(k_1/k_2)\times\{(k_2+k_2')/(k_1+k_1') + (DME)/(N_2O)\} \quad \text{(Fig. 1-B)}$$

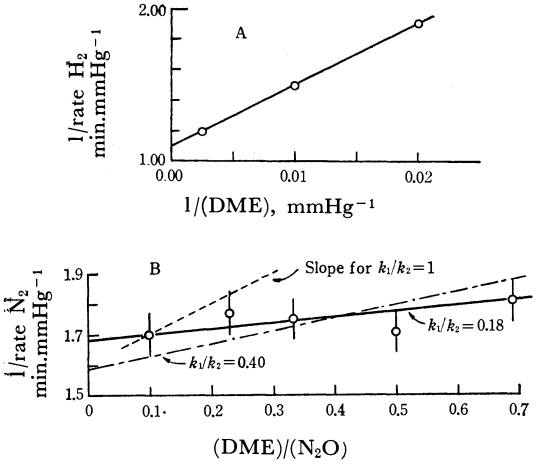

Fig. 1. Determination of cross section of DME.

	k_1/k_2	$(k_2+k_2')/(k_1+k_1')$	$k_0/(k_1+k_1')$
mean	0.18	9.55	3.83 mmHg
max.	0.40	3.92	

In this treatment we have omitted the further reactions of Hg', $Hg'+N_2O\rightarrow Hg+N_2+O$ and $Hg'+DME\rightarrow Hg+CH_3OCH_2+H$, following the argument of Cvetanović;[12] though the apparatus used here was not adequate for the exact determination, we have the cross section of $\sigma_{DME} \doteqdot 2$ Å^2 with the upper limit of 5 Å^2 for (1).

The Reaction of Oxygen Atoms with DME. —In the photo-reaction of a mixture of DME, nitrous oxide and mercury, an effort has been made to determine as many reaction products as possible in a large reactor ($88\phi\times612$ mm., 2941 cc.; lamp coaxially enclosed in a Vycor sheath) and with prolonged irradiation. The results are given in Table II, columns 3 and 4, together with the conditions.

Characteristic products are water, methanol, formaldehyde, carbon monoxide, methoxy ethanol and methyl formate; moreover, though in quite small quantities, at least four kinds of peaks were observed in the gas chromatogram after the elution of the trimers. As may be seen in the last column of Table II, no lower hydrocarbons and carbon dioxide were present, and no molecular oxygen could be found, even after a long irradiation, if DME was present in an amount 1/80 of nitrous oxide at the beginning.

In Fig. 2 the variation of products with the irradiation time in a standard reactor is represented; the N_2O/DME ratio was kept high so as to reduce the mercury-photosensitized decomposition of DME (these conditions will be referred to as the standard conditions hereafter). Most of the oxygen atoms produced seem to appear as water, and from the features of the curves we see that the formation of the dimer is followed by subsequent reactions leading to trimers and other unknowns, and that carbon monoxide is produced by a sequence of steps.

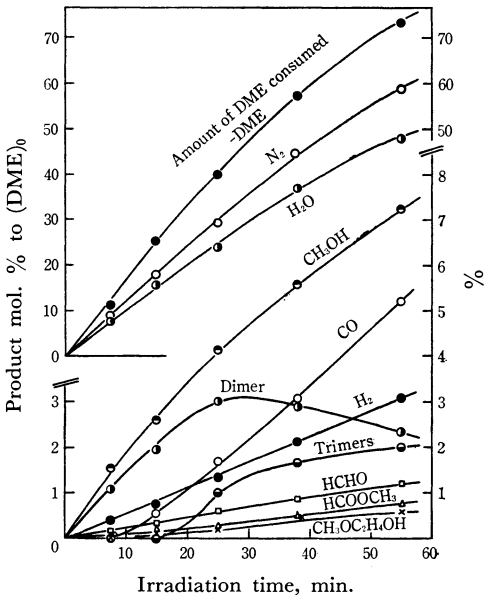

Fig. 2. Time dependence of products.
Standard condition: $(DME)_0=50$ mmHg, $(N_2O)_0=500$ mmHg, 30°C

The material balances on C, H and O in terms of the identified products are:

$$N_2 = H_2O + HCOOCH_3 + 1/2(CH_3OH + CH_3OC_2H_4OH + HCHO + CO)$$

Obs. $N_2 = 30.0\%$ to $(DME)_0$

Calc. $= 31.1\%$,

$$\text{Consumed DME} = 2H_2O + 3/2CH_3OH + 1/2CH_3OC_2H_4OH + 2H_2 - (\text{Trimers} + 1/2HCHO + 5/2CO + HCOOCH_3)$$

Obs. consumed DME=58.2%

Calc. =61.0%,

$$H_2O = \text{Dimer} + 2\text{Trimers} + 1/2CH_3OC_2H_4OH + 1/2HCHO + 3/2CO - (H_2 + HCOOCH_3 + 1/2CH_3OH)$$

Obs. H_2O=27.6%

Calc. 10.5% .

In these equations the balances not involving dimer are fairly good, but the last one is far from sufficient, probably due to a number of missing higher products small in quantity.

Discussion of the Mechanism

The Mode of the O Attack on DME.—Following elementary steps may be conceivable in the initial attack of oxygen atoms according to the classification given in the introduction:

$O + DME \rightarrow$:

1. $\rightarrow OH + CH_3OCH_2$,
   $OH + CH_3OCH_3 \rightarrow H_2O + CH_3OCH_2$,
2. $\left.\begin{array}{l}\longrightarrow \\ \rightarrow CH_3OOCH_3 \rightarrow\end{array}\right\} 2CH_3O$, (a)
   $\rightarrow CH_3OCH_2OH \rightarrow \begin{cases} CH_3O + CH_2OH & \text{(b)} \\ CH_3OCH_2 + OH, & \text{(c)} \end{cases}$
3. $\rightarrow HCOOCH_3 + H_2$ or 2H, (a)
   $\rightarrow CH_3O + CH_2O + H$, (b)
4. $\rightarrow CH_3OCH{:} + H_2O$,
   $\rightarrow \cdot CH_2OCH_2\cdot + H_2O$.

Case 1 is quite attractive to account for the production of a large amount of water, an amount which is close to that of the oxygen atoms produced, which in turn corresponds to about a half of the DME consumed. However, other possibilities leading to the water formation should be considered here; in the present study the following three processes can conceivably account for the origins of OH:

$$H + O + M \rightarrow OH + M, \quad H + N_2O \rightarrow OH + N_2 \text{ and } H_2 + O \rightarrow OH + H.$$

However, since these hydrogens can all originate from the photosensitized decomposition of DME, calculation has been made on the rate of hydrogen atom formation in the competitive quenching of Hg* in the mixture of DME and nitrous oxide under the standard experimental conditions ($(N_2O)_0$= 500 mmHg, $(DME)_0$=50 mmHg, 30°C) using the effective cross section, σ_{DME}, obtained in the preceding section. Then, by comparing the calculated rate of hydrogen atom production (0.023 mmHg/min.) with the observed rate of water formation (0.47 mmHg/min. in Fig. 2), it could be concluded that the photosensitized decomposition of DME contributes at most 5% to the total water formation. (It is of interest to note that the observed rate of hydrogen production (0.027 mmHg/min.) is close to the calculated rate of hydrogen atom production.)

Case 2 involves direct double decomposition into two radicals or insertion into a C–H or O–C bond; but since the insertion reactions are highly exothermic, since the O–O bond energy is only 36.9 kcal. in dimethyl peroxide,[14] and since the hemiacetal is known to be too unstable to exist in a free state, the inserted molecules will eventually decompose into the radicals shown in the scheme. We could not prove the presence of dimethyl peroxide.

The two steps, 2 (a) and 2 (b), cannot be the main courses of the oxygen attack, however, since they fail to explain the formation of a large amount of water, and the sum of methanol (resulting from $RH+CH_3O$ or $RH+CH_2OH$) and its decomposition products, formaldehyde and carbon monoxide and methoxy ethanol (assuming the reaction $CH_2OH+CH_2OCH_3$), is much less than the amount of oxygen produced. Further, ethylene glycol (by $2CH_2OH$) and formal (by $CH_2OCH_3+CH_3O$) could not be detected; they may be supposed to be produced if these mechanisms are predominantly operative. Case 2 (c) is not distinguished from Case 1. However, in any case, it should be admitted that for these insertion reactions to take place, spin conservation rule has to be violated, because the oxygen atom participating here is in the triplet state.

In Case 3, (a) would contribute at most a small portion of the total oxygen attack, as judged from the minuteness of methyl formate which, according to the result of Thynne's experiments,[15] has the usual reactivity towards the subsequent radical attack. Further, as will be shown later, there is evidence that methyl formate can be produced by the reaction of OH+DME in the absence of oxygen atoms. The fact that the total amount of $1/2H_2O+H_2$ is by far greater than that of $CH_3OH+HCHO+CO+CH_3OC_2H_4OH$ excludes 3-(b) as the main course of oxygen atom reaction.

As for Case 4, none of the recombination products expected from this mechanism (ethylene oxide, 1, 4-dioxane and $(CH_3OCH{:})_2$) were found. Although this does not lead to the complete exclusion of this mechanism, the elementary reactions involving biradical formation in one process do not seem to proceed so easily as to compete with monoradical formation steps, even for the

14) Y. Takezaki and C. Takeuchi, ibid., **22**, 1527 (1954).

15) C. J. Thynne and P. Gray, *Trans. Faraday Soc.*, **59**, 1140 (1963); C. J. Thynne, ibid., **58**, 676 (1962).

exothermic reaction, at least to an extent enough to account for a large amount of water.

Thus the abstraction of the hydrogen atom (Case 1) may be concluded to be the most predominant process, although the minor contributions of other modes cannot be entirely ruled out.

Another oxygen atom reaction to be considered is $CH_3OCH_2+O \rightarrow CH_3OCH_2O$ or $CH_3O+HCHO$; the former must have a large rate constant and has been taken into account in the argument of Wright on the reaction of oxygen atoms with isobutane.[6] However, both these reactions can be shown to be negligible under the present experimental conditions by the following considerations.

Consider the following scheme which is simplified but sufficient to get the upper limit values necessary for the present discussion:

$$Hg+h\nu \rightarrow Hg^*$$

		Rate const.
$N_2O+Hg^* \rightarrow N_2+O+Hg$		
$O+DME \rightarrow CH_3OCH_2+OH$	(E)	k_E
$OH+DME \rightarrow CH_3OCH_2+H_2O$	(E')	k_E'
$2CH_3OCH_2 \rightarrow (CH_3OCH_2)_2$	(3)	k_3
$O+CH_3OCH_2 \rightarrow CH_3OCH_2O \rightarrow \cdots$	(4)	k_4
$\rightarrow CH_3O + CH_2O\cdot$	(4')	k_4' .

The steady concentration of the O atom is:

$$(O) = \frac{I_{abs}}{k_E(DME) + k_4'(CH_3OCH_2) + \cdots} \leq \frac{d(N_2)/dt}{k_E(DME)} .$$

Therefore, under the standard conditions (rate N_2(obs.) = 0.65 mmHg/min. $= 5.8\times10^{-7}$ mol./l. sec. at 30°C, (DME) = 50 mmHg $= 2.68\times10^{-3}$ mol./l.), we have $(O)\leq 7.7\times10^{-12}$ g.-atom/l. and $\beta\equiv(DME)/(O)\geq 3.5\times10^{8}$.

Now, k_3 and k_4 should be close to the collision numbers, i. e., $k_4'<k_3\fallingdotseq k_4\fallingdotseq 10^{11}$ l./mol.sec. and $k_E=2.8\times10^{7}$ l./mol.sec. at 30°C, as will be established later; then, dropping unimportant terms in numerical calculation, we have $(CH_3OCH_2)\fallingdotseq\{(O)(DME)k_E/k_3\}^{1/2}$ within an accuracy of 0.2%; finally the following expressions are obtained:

$$\frac{\text{rate (4')}}{\text{rate (3)}} < \frac{\text{rate (4)}}{\text{rate (3)}} \fallingdotseq \left(\frac{k_3}{2k_E\beta}\right)^{1/2} \leq 1.6\times10^{-3} \text{ and}$$

$$\frac{\text{rate (4')}}{\text{rate (E)}} < \frac{\text{rate (4)}}{\text{rate (E)}} \fallingdotseq \left(\frac{k_4}{k_E\beta}\right)^{1/2} \leq 3.2\times10^{-3}.$$

Thus the reactions between the oxygen atom and CH_3OCH_2 can well be ignored with respect to both reactants.

The Origin of Methanol and Methoxy Ethanol.—Since the $CH_3OCH_2\rightarrow CH_3+CH_2O$ decomposition has been proved to be unlikely in the preceding section, combination of CH_3 and OH cannot be the source of methanol. Hence, the steps responsible for the formation of methanol are probably the C–O bond fission of DME or derived radicals to produce CH_3O or CH_2OH; however, $CH_3OCH_2\rightarrow CH_3O+:CH_2$ is too endothermic to occur at normal temperatures, and the elementary steps, $O+DME\rightarrow 2CH_3O$, CH_3O+CH_2OH, or CH_3O+CH_2O+H and $O+CH_3OCH_2\rightarrow CH_3O+CH_2O$, have already been ruled out. Therefore, we would like to propose here:

$$CH_3OCH_2 + OH \rightarrow (CH_3OCH_2\cdots OH) \rightarrow CH_3O+CH_2OH+21 \text{ kcal./mol.} \quad (5)^*$$

The assumption that the transient complex of the hemiacetal type decomposes instantly at the weakest methyl C–O bond would be reasonable because of the extreme instability of hemiacetal just mentioned. Moreover, since OH and $CH_3\cdot OCH_2$ are the most abundant radicals during the reaction, this inter-radical process may explain the medium amount of methanol and also the minute amount of methoxy ethanol* which have resulted from

$$CH_2OH \text{ or } CH_3O + RH \rightarrow CH_3OH + R$$
$$CH_3OH + R \rightarrow CH_2OH + RH$$
$$CH_2OH + CH_3OCH_2 \rightarrow CH_3OCH_2CH_2OH.$$

However, no positive evidence was obtained on the presence of the products to be expected from the following equations when CH_3O and CH_2OH were present:

$$2CH_2OH \rightarrow (CH_2OH)_2 \quad \text{(trace?)}$$
$$CH_3O + CH_2OCH_3 \rightarrow CH_3OCH_2OCH_3 \quad \text{(rather unstable?)}$$

Further, the possibility of the $OH+CH_3OCH_2\rightarrow CH_3OH+HCHO$ reaction cannot be entirely ruled out, though this cannot be the main source of methanol since the observed methanol /(HCHO + CO) ratio is less than unity.

In order to test above-mentioned postulate—methanol formation without the participation of the oxygen atom, a supplementary study was made on the reaction of DME with the OH radicals produced by the photolysis of hydrogen peroxide. It has been well established that H_2O_2 produces

* The heat of reaction is calculated using the data given by Gray[16] and Field[17]. The approximate calculation as before has given the lower limit of rate(5)/rate(E') or rate(5)/rate(3) as ca. 0.02 when kE' $= 10^{11}\exp(-6000/RT)$ l./mol.sec., which is assumed, by referring to other OH reactions[18], to be the highest value for this reaction.

18) Ref. lf, p. 32.

2OH by 2537 Å light,[19] and the decomposition into $O+H_2O$ has been stated to be implausible at least in the gas phase.[19] The results are as follows:

DME 93 mmHg, H_2O_2 (87% concn.), 70°C, 2537 Å, 1 hr.;

CH_3OH 3.7%, HCHO 0.3%, $CH_3OC_2H_4OH$ 0.2%, Dimer 4.0%, GTME 1.0%, BMEE 0.2%, CO 1.2%, $HCOOCH_3$ 0.7%, relative to $(DME)_0$ respectively.

Of course, no methanol, formaldehyde or carbon monoxide could be found, either when the mixture of DME and hydrogen peroxide was merely kept at 70°C, or when the mixture of DME and oxygen, the latter being a product on the heating of hydrogen peroxide, were irradiated by a 2537 Å light. The presence of the expected products supports the proposed mechanism strongly; furthermore, the methyl formate found here suggests that the presence of this compound in the reaction of the oxygen atom cannot be evidence for Case 3-(a) in the preceding section.

The Rate Constant of $O+CH_3OCH_3 \rightarrow OH+CH_3OCH_2$.—With the aim of determining the absolute rate constant of the first attack of oxygen on DME, the rate of the consumption of each substrate has been measured in the competetive reaction of oxygen atoms with DME and *n*-butane; the rate for the latter had been determined to be $k_B=(3.01\pm0.96)\times10^{10}\exp(-4200\mp200)/RT$ l./mol.sec. by Elias and Schiff.[4]

According to the discussion above, we take:

	Rate const.
$O + CH_3OCH_3 \rightarrow OH + CH_3OCH_2$	k_E
$OH + CH_3OCH_3 \rightarrow H_2O + CH_3OCH_2$	k_E'
$O + n\text{-}C_4H_{10} \rightarrow OH + C_4H_9$	k_B
$OH + n\text{-}C_4H_{10} \rightarrow H_2O + C_4H_9$	k_B'

as the sole substrate-consuming steps. This scheme should hold only for the early stage of the reaction; further, it implies the neglect of the following cross reaction:

$C_4H_9 + CH_3OCH_3 \rightleftarrows C_4H_{10} + CH_3OCH_2 - 0.6$ kcal.** k_E'' and k_B'',

that is, we are to assume *tentatively* that the net extent of this reaction (second term) is negligible as compared with the main substrate-consuming reactions (first term) in

$$\frac{-d(DME)}{dt} = \{k_E(O) + k_E'(OH)\}(DME) + \{k_E''(C_4H_9)(DME) - k_B''(C_4H_{10})(CH_3OCH_2)\},$$

$$\frac{-d(C_4H_{10})}{dt} = \{k_B(O) + k_B'(OH)\}(C_4H_{10}) - \{k_E''(C_4H_9)(DME) - k_B''(C_4H_{10})(CH_3OCH_2)\}.$$

Therefore, we have

$$\alpha \equiv \frac{\ln[(DME)_0/(DME)_t]}{\ln[(C_4H_{10})_0/(C_4H_{10})_t]} = \frac{\int_o^t(O)dt + (k_E'/k_E)\int_o^t(OH)dt}{\int_o^t(O)dt + (k_B'/k_B)\int_o^t(OH)dt} \cdot \frac{k_E}{k_B}.$$

In solving this, a further assumption is made that the ratios of the reaction rates between O and OH are the same for both substrates, i. e., $k_E'/k_E=k_B'/k_B$; then we get a simple relation $\alpha=k_E/k_B$. In order for this assumption to hold over the entire range of temperature, however, the next two conditions must be satisfied:

$$\frac{Z_E'/Z_E}{Z_B'/Z_B} \cdot \frac{P_E'/P_E}{P_B'/P_B} = 1$$

and $E_E - E_E' = E_B - E_B'$.

(Z, P and E have the usual meanings.)

As to the collision numbers, this ratio has been shown to be unity by calculation, but, strictly speaking, there is no such intrinsic necessity for the remaining two factors. However, the thermodynamical situations are almost the same in these two sets of exothermic reactions,

$\Delta H_E = -8.4$ kcal./mol. $\Delta H_B = -7.8$**

$\Delta H_E' = -25.2$ $\Delta H_B' = -24.6$,

and the reaction center in the configuration of the activated complex is, in all these cases, thought to be the same, $-O\cdots H\cdots C\equiv$. Such being the case, the approximation of the equality of the ratios of steric factors and of the differences in activation heats may be accepted as being fairly reasonable.

Moreover, the correction factor by which the observed α should be multiplied to obtain k_E/k_B when the above-mentioned ratio deviates from unity is only 2 or so against a tenfold deviation of that ratio in both directions, as is seen in the next table calculated using the values obtained with the present approximation.

○	24	24	405
●	43	22	419
◑	24	45	415
◓	42	44	395

As may be seen in Fig. 3, the α's lie near unity in the temperature range examined, but tend to increase as the decomposition proceeds, probably as a result of the accumulation of the primary products which would produce other radicals which replace the rôle of oxygen atom. Though the slopes differ according to the amounts of the reactants, the curves converge to one point at zero conversion, so the extrapolated values at zero conversion have been adopted. From the Arrhenius plot (Fig. 4), we find the activation heat to be

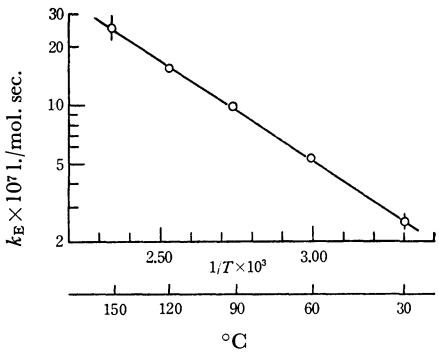

Fig. 4. Arrhenius plot of k_E.

4.7 kcal./mol.; finally, the rate expression is given as:

$$k_E = (6.3\pm3.5)\times10^{10}\exp(-4710\mp400)/\boldsymbol{RT}$$ l./mol.sec.

Although the experimental error is less than about 5%, the combined allowance is rather large, and if the afore-mentioned two assumptions do not hold, the error in k_E will become still larger. However, the frequency factor found here seems to be of the usual order of magnitude for the abstraction reactions of atoms.

The Quenching Action of Benzoic Acid and Methyl Benzoate on the Fluorescene of Naphthalene Derivatives. II

By Takuji MIWA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received November 8, 1965)

The quenching action of benzoic acid on the fluorescence of naphthalene derivatives, for instance, *N*, *N*-dimethyl-2-naphthylamine, is phenomenologically ascribed to its dimer. In order to examine its molecular mechanism, absorption and fluorescence spectra have been measured on solutions of *N*, *N*-dimethyl-2-naphthylamine with and without benzoic acid, using as a solvent cyclohexane to which various amounts of dioxane or ethyl ether has been added. The quenching action of benzoic acid has also been measured in similar solvents. A good parallelism has been found between the change in the absorption spectra of benzoic acid and the change in the quenching action of benzoic acid when both are examined as functions of the concentration of dioxane or ether. From this finding, and from the more precise analysis of the data described in a previous paper (This Bulletin, **38**, 529 (1965)), it has been concluded that the quenching action of benzoic acid may be ascribed to the direct interaction between the fluorescer and the benzoic acid dimer. Further, similar quenching actions have been observed in *o*-, *m*- and *p*-toluic acids, and *p*-methoxybonzoic acid.

In a previous paper,[1] the authors investigated the quenching action of benzoic acid and methyl benzoate on the fluorescence of naphthalene derivatives from the standpoint of the charge-transfer mechanism of quenching. It was shown that benzoic acid has a rather large quenching action on *N*, *N*-dimethyl-2-naphthylamine and 2-naphthyl methyl ether compared with that of methyl benzoate; this quenching action was phenomenologically attributed to the benzoic acid dimer. As for the molecular mechanism, the charge transfer interaction between the fluorescer and the benzoic acid dimer seemed plausible. However, it was not yet quite clear whether the benzoic acid ring dimer itself really has a quenching action or whethere the ring dimer dissociates partially (this produces the linear dimer) and gives rise to quenching by forming a hydrogen bond with an excited fluorescer molecule. The present paper deals with: i) the effect of the addition of ether-type compounds on the quenching action of benzoic acid and methyl benzoate on the fluorescence of *N*, *N*-dimethyl-2-naphthylamine, and ii) the quenching action of benzoic acid derivatives on the fluorescence of *N*, *N*-dimethyl-2-naphthylamine. The results lead to the conclusion that the dimer itself has the quenching action.

Experimental

p-Dioxane was purified by the method of Eigenberger.[2] Benzoic acid from the Natural Resources Institute (standard sample for calorimetry) was zone-refined ten times, and then recrystallized from benzene. *o*-Toluic acid of Wako Junyaku (G. R. grade) was recrystallized four times from a benzene - *n*-hexane mixture. *m*-Toluic acid of Wako Junyaku (G. R. grade) was recrystallized once from benzene, twice from *n*-hexane, and once from a water-methanol mixture. *p*-Toluic acid of Tokyo Kasei (G. R. grade) was recrystallized three times from benzene. *o*-Methoxy- and *p*-methoxybenzoic acid of Tokyo Kasei (G. R. grade) were recrystallized twice from benzene, and twice from a ligroin-benzene mixture. Naphthalene of Kanto Kagaku (G. R. grade) was recrystallized three times from ethanol, and then zone-refined ten times. Benzene and cyclohexane were purified in the manner described in the previous paper. The *N*, *N*-dimethyl-2-naphthylamine was the same sample as in the earlier work. The absorption spectra were measured with a Hitachi EPS spectrophotometer. The fluorescence and action spectra were measured with an Aminco-Bowman spectrofluorimeter. Measurements were made for both degassed and non-degassed solutions at room temperature.

Results and Discussion

I) The Effect of the Addition of Ether-type Compounds on the Quenching Action of Benzoic Acid.—This effect was studied in a cyclohexane solution of *N*, *N*-dimethyl-2-naphthylamine. Before investigating the quenching action, the hydrogen bonding equilibrium in the ground state was studied by analyzing the absorption spectra. In nonpolar solvents, benzoic acid exists mainly

of which is capable of forming a hydrogen bond with benzoic acid, is added, a newly-established equlibrium of hydrogen bonding causes a considerable change in the absorption spectra as the concentration of the added substance is increased. The results are shown in Figs. 1a, 1b and 2.

The spectral behavior is very regular, and we can evaluate the equilibrium constant of hydrogen bond ing between benzoic acid and dioxane or ethyl ether in the following way. The optical density at a fixed wavelength is given by:

$$op.\,d. = (\varepsilon_{A_2}[A_2] + \varepsilon_A[A] + \varepsilon_{AB}[AB])d \qquad (1)$$

where A_2, A, AB, ε and d are, respectively, the benzoic acid dimer, its monomer, the hydrogen-bonded complex between benzoic acid and an added substance, the molar extinction coefficient, and the depth of the optical path. If one makes the plausible assumption that $\varepsilon_{AB}\approx\varepsilon_A$,[3-5] Eq. 1

* Hereafter, "the dimer" means the benzoic acid ring dimer and not the linear dimer.

od.d.: *op.d.* at 284.1 mμ, $R\equiv op.d.-\varepsilon_A[A]_0d$.

can be rewritten as:

$$op.\ d.=[A_2](\varepsilon_{A_2}-2\varepsilon_A)d+\varepsilon_A[A]_0d$$

where $[A]_0$ is the added concentration of benzoic acid. Hence:

$$[A_2]=(op.d.-\varepsilon_A[A]_0d)/(\varepsilon_{A_2}-2\varepsilon_A)d \qquad (2)$$

Since ε_{A_2} and ε_A can be estimated from the extreme cases, $[A_2]$ can be calculated with the above formula. In the actual calculation, the optical densities of the dimer peak at 284.1 mμ, and the value of $K_1=7950$ reported by Hosoya et al.[3] for the solution of benzoic acid in *n*-heptane at 30°C, were used. Then, from the following relations:

$$\left.\begin{aligned}[A] &= \sqrt{[A_2]/K_1}\\ [AB] &= P-[A]=P-\sqrt{[A_2]/K_1}\\ [B] &= [B]_0-[A]\\ P &= [A]_0-2[A_2]\end{aligned}\right\} \qquad (3)$$

[A], [AB] and [B] were evaluated, and the formation constant of the hydrogen bond between benzoic acid and the added compound, $K_2=[AB]/([A]\cdot[B])$, could be obtained. The results obtained are given in Tables I and II. The K_2 values between benzoic acid and dioxane or ether are about 40 and 30 respectively.

The next item was to investigate how the quenching effect of benzoic acid depends on the amount of added dioxane or ether. First, the effect of the addition of benzoic acid on the absorption spectra of *N*, *N*-dimethyl-2-naphthylamine in cyclohexane containing various amounts of dioxane or ethyl ether was examined; it was confirmed that there

3) $(F_0/F)-1$.

is not essential effect. This means that there is no appreciable interaction between the ground-state fluorescer and the benzoic acid dimer or monomer (hydrogen-bonded with ether or dioxane). Next, the fluorescence intensity, F_0, of *N*, *N*-dimethyl-2-naphthylamine 10^{-4} M in the above solvent system and that, F, of a similar solution containing 1.5×10^{-2} M or 1.0×10^{-2} M benzoic acid were measured in order to evaluate the quenching effect of benzoic acid. In Figs. 3, 4 and 5, the values of of $(F_0/F)-1$ and the optical densities of benzoic acid at several wavelengths are plotted against the concentration of dioxane or ether. In Fig. 4, the filled circles and triangles show the results for non-degassed and degassed solutions respectively. The quenching action of benzoic acid on the fluorescence is greater in the degassed solutions than in the non-degassed solutions, but no anomaly due to the dissolved oxygen was observed. Figures 3, 4 and 5 show a very good correlation between the spectral change in benzoic acid and the change in the quenching action of benzoic acid. Since the optical densities at 277 and 284 mμ, which are the absorption maxima of the dimer, give the measure for the dimer concentration, this correlation enables us to rule out a quenching mechanism in which the benzoic acid dimer dissociates partially or completely and forms a hydrogen bond with the excited fluorescer. If such were the case, the benzoic acid monomer hydrogen-bonded with dioxane or ether, the formation constant of which is much smaller than that of the dimer, would have a larger quenching action than the dimer. This expectation does not fit the results obtained; one can, therefore, safely conclude that if the dimer does act as a quencher, it really remains as the dimer throughout the quenching process.

II) The Effect of the Addition of an Ether-type Compound on the Quenching Action of Methyl Benzoate.—Similar experiments have been made using methyl benzoate as a quencher and *N*, *N*-dimethyl-2-naphthylamine as a fluorescer, in order to get a better understanding of the quenching action of benzoic acid. First, the absorption and fluorescence spectra of the solutions of methyl benzoate and *N*, *N*-dimethyl-2-naphthylamine were measured using dioxane-cyclohexane mixtures of various compositions as solvents. The absorption spectra of methyl benzoate in cyclohexane do not change when a small amount of dioxane is added. With the increase in dioxane concentration, the spectra of methyl benzoate gradually become broad as a result of the so-called solvent effect, but there is no marked effect. Next, the absorption and fluorescence spectra and the fluorescence intensity of *N*, *N*-dimethyl-2-naphthylamine were measured with and without 0.800 M methyl benzoate, using the above-mentioned solvents. The addition of methyl benzoate intensifies the absorption spectra of *N*, *N*-dimethyl-2-naphthylamine and causes a shift to longer wavelengths; the fluorescence spectra also shift to red and become broad. These shifts are more marked than the shifts observed in absorption spectra. On the further addition of methyl benzoate, a new emission band appears near 480 mμ.* The quenching action of methyl benzoate increases with the increase in the dioxane concentration. The fluorescence intensity (F) of the solution with the quencher and that of the solution without it (F_0) were determined at the maxima of the

* The details will be described elsewhere.

fluorescence spectra. No correction was made for the spectral sensitivity distribution of the fluorimeter. The calculated values are summarized in Fig. 6.

In this figure, the open circles show the values for the aerated solutions, while the filled circles show the values for the deaerated solutions. It is evident that there is no extraordinary effect of the dissolved oxygen. It is worthwhile to note here that a similar effect was also found in the case of benzoic acid systems. Thus, as may be seen from Fig. 4, the quenching action of benzoic acid at an extremely high concentration region of dioxane, begins to increase to some extent after having passed through a minimum, at which point the absorption spectra of the benzoic acid dimer must have completely turned to monomer-type ones (hydrogen-bonded with dioxane). At the same time, the absorption spectra of the hydrogen-bonded complex with dioxane begin to suffer the so-called solvent effect and the spectra become broad, as in the case of methyl benzoate (see Fig. 1b). These results strongly suggest the same quenching mechanism in both cases and favors the C. T. quenching mechanism which was assumed for the quenching action of the methyl benzoate in a previous paper.[1]

III) The Quenching Action of the Benzoic Acid Derivatives on the Fluorescence of *N*, *N*-Dimethyl-2-naphthylamine.—In order to find other examples of quenching action similar to that of benzoic acid and to examine the relation between the quenching constants and the formation constants of the ring dimer, we have examined the quenching action of the benzoic acid derivatives on the fluorescence of *N*, *N*-dimethyl-2-naphthylamine. This was investigated only with aerated solutions, because it had already been confirmed that there is no extraordinary effect due to dissolved oxygen. The benzoic acid derivatives used as quenchers were *o*-, *m*-, *p*-toluic acid, and *o*-, *p*-methoxybenzoic acid.

Cyclohexane Solution.—The absorption spectra of these substituents of benzoic acid show a concentration effect analogous to that of benzoic acid. The dimerizations of benzoic acid and its derivatives have been extensively investigated on the basis of the concentration dependence of their absorption spectra. Especially, Forbes et al.[6,7] measured the absorption spectra of benzoic acid and its derivatives systematically, and also examined the relationship between the molecular structure and the tendency toward dimerization. They expressed the ability to dimerize by "critical maximal concentration," which is the concentration above which the values of ε_{max} become approximately independent of the concentration, and below which the acid appreciably exists in the monomeric form. The values in Table III are quoted from their paper, thus facilitating an examination of the correlation between the ability to dimerize and the ability to quench. When benzoic acid derivatives are added to a solution of *N*, *N*-dimethyl-2-naphthylamine, the absorption and fluorescence spectra

* Same as in Table III.

of the fluorescer do not change, but the fluorescence intensity decreases considerably. The phenomena are quite similar to those observed with benzoic acid. The fluorescence intensities of the solutions of *N*,*N*-dimethyl-2-naphthylamine with the quenchers (F) and without them (F_0) were measured, and the quenching constants were determined from the slope of the $(F_0/F)-1$ vs. $[A]_0$ plot. This treatment is approximately correct, since, in the concentration range of the present experiments, the quenchers examined exist almost entirely in the dimeric form, as judged from the values of the critical maximal concentration and from the linearity of the $(F_0/F)-1$ vs. $[A]_0$ plot. The quenching constants obtained are summarized in Table III. By comparing the quenching constants with the critical maximal concentration, it may be observed that although the critical maximal concentrations are distinctly different from compound to compound, the quenching constants are almost the same, and there is no correlation between the two quantities.

Benzene Solutions.—Since benzene absorbs the light at wavelengths shorter than 280 mμ, one can not measure the absorption spectra of benzoic acid and its derivatives. It may be assumed, however, that the behavior of benzoic acid and its derivatives in benzene is essentially the same as that in cyclohexane. The absorption spectra and the fluorescence spectra of *N*,*N*-dimethyl-2-naphthylamine are scarcely affected, but its fluorescence intensity is considerably quenched by the addition of benzoic acid and its derivatives. The results are quite similar to those for cyclohexane solutions. In the lower concentration range of quenchers, the plots of $(F_0/F)-1$ against the quencher concentrations are nearly linear, but in the higher concentration range, the plots deviate upwards. The quenching constants obtained from the slope of the $(F_0/F)-1$ vs. $[A]_0$ plot at the low concentration range are summarized in Table IV.

The critical maximal concentration of those derivatives obtained with cyclohexane solutions or with a cyclohexane-ether mixture are also listed. From this table, it may be seen that there are appreciable differences among the quenching constants of benzoic acid, *o*- and *m*-toluic acid. This finding is different from that in the case of a cyclohexane solution.

It is remarkable that *o*-methoxybenzoic acid has a very large quenching constant. As has been pointed out by Forbes et al.,[6,7] this substance scarcely exists as a dimer, but it exists in the form of a monomer with an intramolecular hydrogen bond between methoxy and carbonyl groups. It is interesting that such an intramolecularly hydrogen-bonded monomer has a large quenching action. It should be noted, however, that the apparent quenching constants for the other compounds forming a ring dimer are refered to the monomer unit and that the quenching constant of the dimer is about twice the apparent one. Therefore, it can be said that the quenching power of the intramolecularly hydrogen-bonded monomer of *o*-methoxybenzoic acid is almost the same as that of the intermolecularly hydrogen-bonded dimer of other benzoic acid derivatives. Another notable result is that *p*-substituted compounds with a rather large tendency toward dimerization are less powerful quenchers than other compounds. In summary, there is no correlation between the dimerization tendency and the quenching efficiency.

IV) A More Rigorous Analysis of the Quenching Data.—Although all the results described in I), II) and III) favor the view that the dimer and not the monomer of benzoic acid or its derivatives acts as a quencher, still this is not conclusive. Hence, it is desirable to examine further whether only the dimer or only the free monomer, which exists in a small quantity, or both, act as quenchers; this examination is to be done by a more rigorous analysis of the quenching data. As has been stated in the previous paper, the $(F_0/F)-1$ vs. $[A]_0$ plot is linear, but this treatment is approximate in nature if only the dimer is a quencher. It is only when the dimer acts as twice as efficient a quencher as the monomer that this relation strictly holds. However, the mechanism for quenching by the monomer, if it exists, is considered to be quite different from that of the dimer, and this possibility seems improbable. Therefore, an analysis will be given below for the case when only the dimer or only the monomer acts as a quencher.

i) The Quenching Action of Benzoic Acid on N, N-Dimethyl-2-naphthylamine, 2-Naphthyl Methyl Ether or 2-Naphthol.—In these cases the addition of benzoic acid does not affect the absorption spectra nor the fluorescence spectra in spite of a large quenching effect.

a) If the dimer acts as a quencher and the monomer does not, the following scheme holds:

$$D + h\nu \rightarrow D^*$$

$$D^* \xrightarrow{k_d} D$$

$$D^* \xrightarrow{k_f} D + h\nu$$

$$D^* + A_2 \xrightarrow{k_q} D + A_2$$

$$A + A \underset{K_1}{\rightleftarrows} A_2$$

and the steady-state method leads to the following formula:

$$F_0/F = 1 + \{k_q/(k_f+k_d)\}[A_2] \qquad (4)$$

It should be noted that, in this case, the formation of a molecular complex between the fluorescer and a free monomer of benzoic acid need not be taken into account, because it scarcely affects the concentration of the dimer as long as the equilibrium constant of this reaction is not very large.

b) When only the monomer acts as a quencher, the scheme may be written as follows (in this case the possibility of the fluorescer being hydrogen-bonded with the quencher is taken into account because the monomer has a free carboxyl group):

$$\begin{array}{ccc} D^* + A & \xrightarrow{k_q} & D^*A \\ {\scriptstyle k_d+k_f}\downarrow\uparrow & & \downarrow\uparrow \\ D + A & \underset{K_3}{\rightleftarrows} & DA \end{array}$$

From this scheme the following relation is derived:

$$\frac{F_0}{F} = 1 + \left\{\frac{k_q}{k_d+k_f} + K_3\right\}[A] + K_3\frac{k_q}{k_d+k_f}[A]^2 \qquad (5)$$

The concentrations of the benzoic acid monomer and the dimer are calculated from the analytical concentration of benzoic acid, using the value of $K_1=7950$.[3] When the solvent is cyclohexane, the results of analyses are as follows. The linear relationship is slightly better in the $(F_0/F)-1$ vs. $[A_2]$ plot than in the $(F_0/F)-1$ vs. $[A]_0$ plot. The slopes of these plots are given in Tables V and VI. The $(F_0/F)-1$ vs. $[A]$ plot is concave upwards, while the $\{(F_0/F)-1\}/[A]$ vs. $[A]$ plot is nearly linear. The values of the slopes and intercepts are also given in Tables V and VI. For benzene solutions, the results are quite similar to those for cyclohexane solutions as long as the quencher concentration is $0—5\times10^{-2}$ M. At higher concentrations of the quencher, however, both the $(F_0/F)-1$ vs. $[A_2]$ plot and the $\{(F_0/F)-1\}/[A]$ vs. $[A]$ plot deviate upward from linearity. Some examples of these analyses are shown in Figs. 7, 8, 9 and 10, and the results are summarized in Table VI.

From the above results one can rule out the mechanism in which only the free monomer acts as a quencher (case b). As may be seen in Tables

Table V. The values of the slope of $(F_0/F)-1$ vs. $[A]_0$ and $(F_0/F)-1$ vs. $[A_2]$ plots, and the values of the slope and the intercept of $\{(F_0/F)-1\}/[A]$ vs. $[A]$ plot

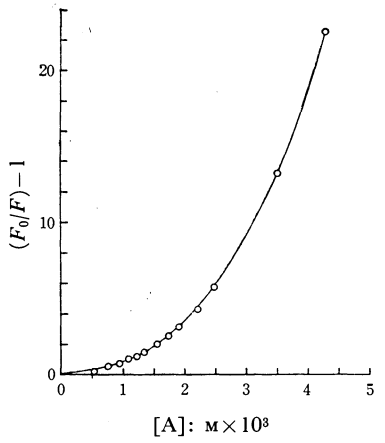

Fig. 9. $(F_0/F)-1$ vs. [A] plot in the system of *N*, *N*-dimethyl-2-naphthylamine (1.00×10^{-4} M)-benzoic acid (0—4.00×10^{-1} M) in benzene. Excitation wavelength: 350 mμ.

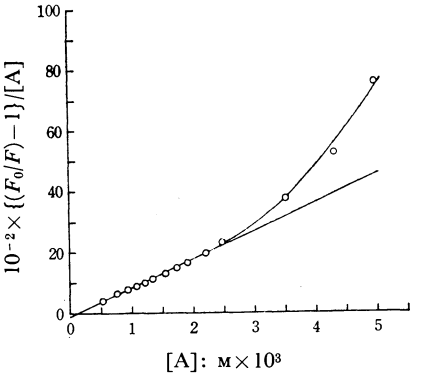

Fig. 10. $\{(F_0/F)-1\}/[A]$ vs. [A] plot in the system of *N*, *N*-dimethyl-2-naphthylamine (1.00×10^{-4} M)-benzoic acid (0—4.00×10^{-1} M) in benzene. Excitation wavelength: 350 mμ.

V and VI, each $\{(F_0/F)-1/\}[A]$ vs. [A] plot has an intercept that is nearly zero or that has a small negative value. However, this is not conceivable, because the intercept which corresponds to $K_3+k_q/(k_d+k_f)$ can never be negative. Furthermore, all the values of the slopes, which are K_3 multiplied by the quenching constant, $k_q/(k_d+k_f)$, are larger than 3×10^5; these figures cannot be reconciled with the b) mechanism for the following reason. The value of K_3 is estimated to be 100* at most, and so the quenching constant is estimated to be larger than 3×10^3; this is far too large for a value expected from the diffusion controlled process.[8] Such a large value can only be interpreted on the basis of static quenching mechanism, which would contradict the present situation. Thus, it seems impossible that only the benzoic acid monomer is responsible for the quenching action.

It should be added that the above discussion is scarcely affected even when the values of K_1 are

8) T. Miwa and M. Koizumi, This Bulletin, **36**, 1619 (1963).

* In the system consisting of 2-naphthylamine (fluorescer) and benzoic acid (quencher), which will be described later, the hydrogen bond is formed between the fluorescer and the quencher, to an extent observable by means of a study of the ultraviolet absorption spectra. From the spectral change the hydrogen bond formation constant is evaluated as 110.

changed over a wide range. The result that the $\{(F_0/F)-1\}/[A]$ vs. [A] plot deviates from linearity is also not affected by changing K_1 over a wide range. Thus, the above analysis leads to the conclusion that only the a) mechanism is reasonable. The deviation from linearity shown by the $(F_0/F)-1$ vs. $[A_2]$ plot in benzene solutions may be ascribed to static quenching by A_2; in this case the $(F_0/F)-1$ vs. $[A_2]$ plot is not essentially affected by the value of K_1, since K_1 is large enough for most of the benzoic acid molecules to exist in the dimeric form.

ii) The Quenching Action of Benzoic Acid on 2-Naphthylamine.—The solutions of 2-naphthylamine in cyclohexane show no spectral change with the addition of benzoic acid up to the limit of solubility. The solutions of 2-naphthylamine in benzene show a remarkable change in absorption spectra due to hydrogen bonding (Fig. 11), but they do

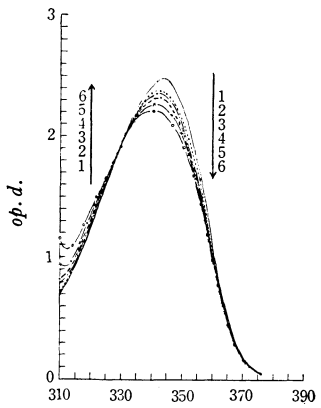

Fig. 11. Absorption spectra of the solutions containing 2-naphthylamine (1.00×10^{-4} M) and benzoic acid (0—4.00×10^{-1} M). Solvent: cyclohexane.
The concentrations (M) of benzoic acid are as follows.
1) 0, 2) 2.00×10^{-2}, 3) 6.00×10^{-2}, 4) 1.00×10^{-1}, 5) 2.00×10^{-1}, 6) 4.00×10^{-1}

not show any change in fluorescence spectra. Therefore, the hydrogen-bonded complex in this case is also nonfluorescent. In the previous paper, the equilibrium constant of hydrogen bonding was calculated from the spectral data, using an analytical concentration of benzoic acid. However, this procedure was not rigorous, and so first a more exact value was calculated, using 7950 as K_1[3]:

$$A + D \rightleftarrows AD: K_3$$

$$K_3=\frac{[AD]}{([A]_0-2[A_2]-[AD])([D]_0-[AD])}$$

$$\approx\frac{[AD]}{([A]_0-2[A_2])([D]_0-[AD])} \quad (6)$$

$[D]_0$: 1.00×10^{-4} M

At 5.00×10^{-4} M of benzoic acid, the lowest concentration used in this experiment, [A] is equal to 1.49×10^{-4} M when [D] is zero. Therefore, K_3 may be approximated as above by neglecting [AD], so long as the equilibrium constant, K_3, is of the order of a few hundred. By combining Eq. 6 and $op.d.=(\varepsilon_{AD}[AD]+\varepsilon_D[D])d$ at a suitable wavelength, one at which there is no absorption of benzoic acid or of its dimer, the following formula is obtained:

$$\frac{1}{P}K_3(\varepsilon_{AD}-\varepsilon_D)[D]_0\frac{1}{op.d.-\varepsilon_D[D]_0d}-K_3 \quad (7)$$

$$P\equiv[A]_0-2[A_2]=[A]+[AD]\approx[A]$$

As Fig. 12 shows, the $1/P$ vs. $[D]_0/(op.d.-\varepsilon_D[D]_0d)$ plot is linear. From the intercept and the slope

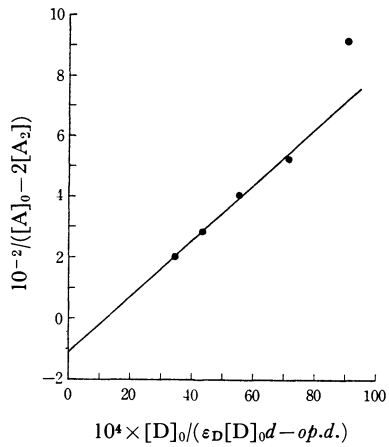

Fig. 12. The evaluation of the hydrogen-bond formation constant between 2-naphthylamine (1.00×10^{-4} M) and benzoic acid (0—4.00×10^{-1} M), using the formula (4) and the *op.d.* at 350 mμ. Solvent: benzene, temperature: 20°C.

of this plot, $K_3=110$ and $\varepsilon_{AD}\doteqdot1400$ are obtained respectively. The fluorescence intensity is analyzed as in the case of *N, N*-dimethyl-2-methylamine under the assumption that the formation of the hydrogen-bonded complex, AD, causes scarcely any change in the concentration of A. The results obtained are very similar to those obtained for *N, N*-dimethyl-2-naphthylamine, etc. At higher concentrations of benzoic acid, the $\{(F_0/F)-1\}/[A]$ vs. [A] curve deviates from linearity, while the curve has a very large slope, 8.90×10^5, at lower concentrations of benzoic acid. When 110 is used as K_3, the quenching constant becomes 8.01×10^3, which is ridiculous as a dynamical quenching constant. Thus, in this case also, it can be concluded that the quenching of the fluorescence is not due to the direct action of the monomer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1660—1670 (1966)

Sensitization in the Photoconductance of Poly-*N*-vinylcarbazole

By Yoshiki HAYASHI, Makoto KURODA and Akira INAMI

Research Laboratory, Wireless Division, Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka

(Received November 8, 1965)

The sensitization in photoconductive poly-*N*-vinylcarbazole was studied systematically. The sensitizers were conveniently divided into two types, *optical* and *chemical*. The optical sensitization occurs with a smaller content of a dye, which extends the photoconductivity spectrum to its absorption band. Effective optical (or dye) sensitizers are found to be themselves photoconductive and *n*-type cationic and to have a slow photoresponse. The chemical sensitization occurs through the formation of a charge transfer complex with a considerable amount of a Lewis acid. The simultaneous addition of optical and chemical sensitizers induces amplified or additive effects; an amplified effect is observed when a strong acid is employed as a chemical sensitizer. A sensitized system with a strong acid shows a very slow photoresponse and may have fairly deep traps which act as a cause of the memory effect.

In a previous paper,[1] the authors reported that *poly-N-vinylcarbazole* (PVCZ) film has a small peak of its action spectrum for photoconduction and that the threshold of its optical absorption is in the near-ultraviolet region. Because of its transparency, it is expected that this film is applicable to a transparent, sensitive, electrophotographic layer which prints by a conventional technique. However, pure PVCZ has a low potentiality as a material for electrophotographic purposes since it has only a slight sensitivity in the visible spectrum.

According to a patent by Kalle & Co.,[2] it is possible to sensitize the photoconduction of PVCZ film by the addition of a small amount of certain dyes or by the addition of Lewis acid-type organic compounds. The cause or mechanism of the sensitization is not clear in the patent. The present authors conjecture that the dye sensitization or optical sensitization in this case is analogous to that of cadmium sulfide or glass, which have been investigated by Nelson,[3-6] and that the chemical sensitization occurs by means of the formation of charge transfer complexes between PVCZ and the sensitizers. The terms "optical sensitization" and "chemical sensitization" are empirically proposed by the authors for the sake of convenience in the classification of sensitizers after the model of silver halide photography.

From this point of view, we have investigated the electrophotographic behavior of PVCZ thin films sensitized with commercial dyes or electron acceptor compounds, and have examined the combined effects on sensitization when two different types of sensitizers are added to the PVCZ matrix. Recently, Hoegl[7] presented a paper in which the photosensitometries of doped PVCZ with miscellaneous acceptors were studied. In view of his results, our view of charge transfer in chemical sensitization seems to be pertinent.

In this paper, the authors will describe the results obtained from systems to which about forty dyes and fifty chemical sensitizers have been added, from the standpoint of improving the practical electrophotographic sensitivity.

Experimental

Materials.—PVCZ powder (Luvican M-170, Badische A. G.) was purified by the reprecipitation method described in the previous paper.[1] The dyestuffs and chemical sensitizers used were the GR-grade reagents listed in Tables I and III.

The Addition of Dyestuffs.—To a 10% solution of PVCZ dissolved in purified methylene chloride, a 1% dye solution in methanol was dropped; then the solution was stirred until it was homogeneously colored by the dye.

The solubilities of dyes in such organic solutions were so small that the micro crystals of dyes were deposited if added in excess. By preliminary tests, the optimum concentrations of dyes were found to lie between 0.02 and 0.06%, where the sensitization data of the same dye showed no remarkable difference. To compare dye sensitizers, all the concentrations were fixed at 0.05% by weight.

The Addition of Chemical Sensitizers.—Lewis acid-type sensitizers, such as acids, acid anhydrides, aldehydes, ketones, quinones, and polynitrated derivatives, were used. Their solubilities in PVCZ varied. For example, 2-methylanthraquinone was soluble to 25%, whereas monochloroacetic acid was soluble to 3% and the polymer solution showed a co-

agulation tendency at this concentration. As a whole, except for the quinone compounds, they have low solubilities.

As it was troublesome to find the optimum concentration of each sensitizer, the addition quantities of the less soluble compounds were fixed at 1%, and those of the quinone groups, at 10%. For only a few good sensitizers (see Table II) were the optimum concentrations examined.

When sensitization with a dye - Lewis acid system was investigated, the Lewis acid was added to the above dye-polymer solution. The final solution was stirred until it became transparent. The process of film formation from the final solution was carried out by a method similar to that described in the previous paper.[1]

Electrophotographic Sensitivities.—To compare the sensitivities of the specimens, the electrophotographic charge-decay method was used. In another paper[8] the present authors have explained the physical aspects of the method, the principle of which is almost analogous to that of the ordinary method for measuring photoconduction. The experimental set-up is presented schematically in Fig. 1. The sample was mounted on a

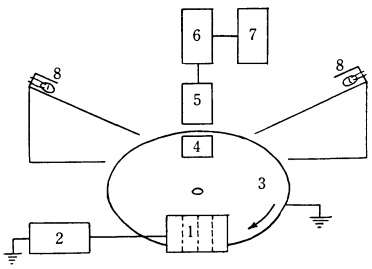

Fig. 1. Schematic representation of experimental set up for charge and light decay recording: 1, corona discharge device; 2, high voltage source; 3, turntable; 4, a sample; 5, 6, electrometer probe and amplifier; 7, recorder; 8, light sources.

grounded aluminum turntable rotating at 78 r. p. m. Above the periphery of the disc, a corona wire unit, an exposure unit, and a probe of a sector-type electrometer were fixed. A specimen which had been stored in the dark for at least 48 hr. was positively charged at 7 kV. by the corona to a saturation potential. Then the corona discharge and the turntable were simultaneously stopped, and the dark decay due to the dark resistance was measured under the probe. Several seconds later, an incandescent light was applied to the specimen and the light decay was measured. An example of the recorded data is shown in Fig. 2. As a representation of sensitivity, the authors adopted the half-decay exposure, $E_{1/2}$, obtained from the diagram, which corresponds to the half-decay time, $t_{1/2}$.

In order to study the spectral sensitivity, a charged specimen was put into a grating spectrograph (Narumi & Co., investigated by J. Koana).[9] The surface exposed to the continuous spectrum generated a latent static image. A negatively-charged xerographic toner was then dispersed onto the surface, and the visible image was printed. All the processes mentioned above were carried out in the dark.

Photoconductivity.—The photoconductivity was measured by using the same types of cells and apparatus as have been described in a previous paper.[1]

Optical Absorption.—A photometer (Hitachi EPS-II) was used for the determination of the optical absorption. The samples used were of a dilute solution in a certain medium or of a solid, thin film laminated onto a quartz plate by the same method as used with the conductivity cell.

Results and Discussion

Spectral Responses of Sensitized Systems by a Conventional Electrophotographic Technique.—We classified the sensitizers into two types, the optical sensitizers and the chemical sensitizers.

From the spectral responses obtained by a grating spectrograph, we found that the dye sensitization was similar to the optical sensitization with dyes used in silver-halide photographic techniques. For instance, a spectral response of the PVCZ-crystal violet system is shown in Fig. 3B. In addition to the original small response at 356 mμ, a large peak is found at 592 mμ which corresponds to the optical absorption or photoconduction peak of crystal violet.

As an example of chemical sensitization, a spectral response of the PVCZ - trichloroacetic acid system is presented in Fig. 3C, where the exposure time was 5 min. The behavior in a longer exposure is shown in Fig. 3D. Here, in addition to the amplified original response of PVCZ, the series of peaks between 400 mμ and 600 mμ is found. This fact seems to be contrary to our assumed definition of chemical sensitization. However, when the single system of PVCZ has been exposed for 2 hr., a similar series of peaks was found (see Fig. 3E).

This series of peaks appears to be due to sensitization by unknown original impurities; this impurity sensitization effect seems to be so small that no response can be found by the ordinary method of photoconductivity measurement described in our previous paper.

With other chemical sensitizers, the peaks are amplified as well as with trichloroacetic acid, and the impurity effect is also observed. Upon the addition of only a chemical sensitizer, the PVCZ film becomes a little more sensitive in tungsten light, and its sensitization is of the order of a bad dye sensitizer.

As is shown in Fig. 3F, picric acid behaves as another type of chemical sensitizer. As a whole, acid, acid anhydrides, aldehydes, and ketones which were colorless behave as chemical sensitizers.

Next, an example of the photoresponse of a

Fig. 3. Spectral responses of some sensitized or unsensitized samples by grating spectrographic measurements.

system formed of three components (PVCZ-crystal violet - trichloroacetic acid) is presented in Fig. 3G. Upon the addition of trichloroacetic acid, the spectral response of crystal violet at 600 mμ becomes very high after only five seconds' exposure (cf. Fig. 3B).

On the other hand, sensitized systems with a quinone compound behave differently than with

the five kinds of Lewis acids mentioned above. As may be seen in Fig. 3H, the spectral response of the PVCZ-2-methylanthraquinone system has a peak in 440 mμ, while its optical absorption spectrum rises at 400 mμ and shows a strong and broad absorption to the short wavelength side (dotted line in Fig. 3H). The peak wavelength at 440 mμ obtained by the electrophotographic process has been found by our preliminary experiment*[1] to correspond with the wavelength of the photoconduction peak of 2-methylanthraquinone itself.

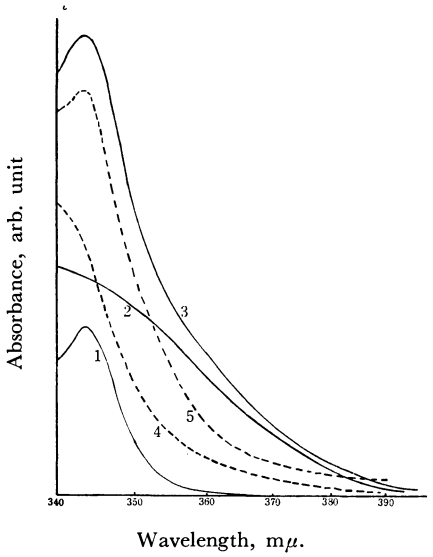

Fig. 4. Absorption spectra of picric acid and 2-methylanthraquinone (dotted line) doped samples: 1, pure PVCZ; 2, pure picric acid; 3, equivalent mixture of 1 and 2 ; 4 pure 2-methylanthraquinone; 5, equivalent mixture of 1 and 4. All samples are diluted with *sym*-dichloroethane.

Almost all the quinone compounds investigated here show the same sensitization as 2-methylanthraquinone. From these results the members of the quinone group which are classified as "chemical sensitizers" might rather be called "optical sensitizers." The quinones are as photoconductive themselves as such optical dye sensitizers as triphenylmethane or cyanine dyes. However, we dare to regard them as chemical sensitizers because the difference in effective amount is found to be appreciable between quinones and dyes.

Absorption Spectra in Sensitized Systems. —It is assumed that a new peak absorption spectrum which belongs to neither PVCZ nor a sensitizers may be realized if a chemical reaction or a charge transfer occurs between them. A part of the dye sensitizers are considered to be adsorbed in the amorphous regions of the polymer in the dried glassy state. However, no new absorption spectrum was found in the PVCZ-dye system.

No chemical sensitizers (except *p*-chloranil) which are regarded as usual electron acceptors afford any new absorption band when mixed with PVCZ. When a chemical sensitizer is added, the intensity of the absorption of PVCZ increases considerably in comparison with that of the parent polymer. Upon the addition of some quinones or polynitrated derivatives, such as 2-methylanthraquinone or picric acid, a slight red shift of the long wavelength edge of the spectrum

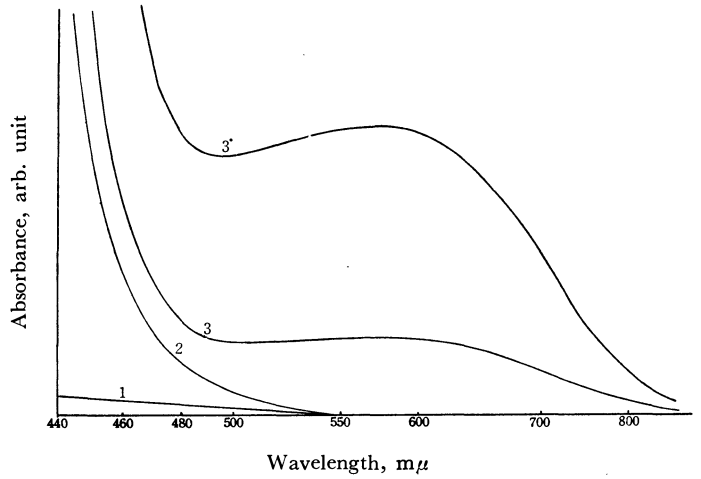

Fig. 5. Charge transfer band of *p*-chloranil doped sample: 1, pure PVCZ; 2; pure *p*-chloranil; 3, equivalent mixture of 1 and 2; 3', twice of 3 in conc. All samples are diluted with benzene.

*[1] From a spectral response measurement on 2-methylanthraquinone film evaporated on NESA glass (for a sandwich cell), we found a weak response peak at 440 mμ.

occurs. Figure 4 presents curves showing the red shifts produced by the addition of picric acid or 2-methylanthraquinone.

Chloroanil, which is well known as a strong acceptor, produces a new peak at 574 mμ as a result of forming a charge transfer complex with the polymer (Fig. 5). The shape of the broad charge transfer band (between 500 and 800 mμ) coincides with the electrophotographic spectral image in Fig. 3K, indicating that the chloranil sensitization is due to the formation of a new absorption band in the visible spectral region.

Optical (Dye) Sensitizations.—From Table I, crystal violet, methyl violet, and malachite green (triphenylmethane derivatives) rhodamine 6G, rhodamine B (xanthene derivatives), and methylene blue (thiazine derivative) may be seen to be good sensitizers. All of them have $=N^+<$ and are called basic dyes (or cationics).

Acid violet 6B and naphthalene green from triphenylmethane, and acid rhodamine G, eosine A, eosine S, fluorescein, rose bengale, and phloxine from xanthene are all acidic dyes (or anionics). From Table I, an interesting tendency is found: the effective dyes for PVCZ sensitization are not acidic dyes but cationics. As in rhodamine homologues, a sulfonated derivative, namely, sulforhodamine B (acidic), shows a considerably weak sensitizability compared to rhodamine B (basic). The oil-soluble nonionic dyes show no effect.

Nelson suggested that there is a general tendency for cationic dyes to be *n*-type and anionic *p*-type conductors.[10] In Table II, some dyes which have already been classified experimentally into the *p*- or *n*-type by other authors are summarized. From this table it may be seen that most *n*-type dyes seem to be effective for PVCZ except pinacyanole. This result contrasts with a considerable effect of acidic *p*-type dyes in the zinc oxide (*n*-type) photosensitive layer of the Electrofax*[2] process. In the previous paper, the present authors specified that the sign of charge carriers in PVCZ might be positive. Judging from this fact, there seems to be an empirical tendency for an organic *p*-type photoconductor to become more sensitive when doped with an *n*-type dye.

Pinacyanole, which is a good sensitizer for cadmium sulfide crystal, shows no effect. In Fig. 3J, no peak is found at the wavelength of 640 mμ, which is an absorption peak of the dye in the visible region. According to the works of Terenin[11] and Nelson,[3] a dye sensitization may occur by the following processes: electron-hole pairs (they might better be called "excitons") are produced by light; then they are separated

into charge carriers, which are injected into *N*-vinylcarbazole unit molecules.*3 If all dye sensitization were caused by this process, pinacyanole in cyanines should be just as effective as crystal violet in triphenylmethanes.

It may, therefore, be assumed that the difference in sensitization ability between pinacyanole and crystal violet may be casued by a difference in their photoconductive characteristics in their pure, solid states. There are many triphenylmethane dyes with slow responses of rise and decay, while pinacyanole has a very rapid response.[11] Moreover, the former has many trapping centers, while the latter is considered to have fewer.[10] From these facts, the electron-hole pairs produced by irradiation may not separate easily and are likely to have a longer life in the case of crystal violet than in that of pinacyanole.*4 As the distance between dye molecules in the polymer is considered to be rather longer than

*3 We substitute the inorganic photoconductive substrates (e. g., cadmium sulfide, zinc oxide, silver halide, etc.) for a vitreus polymeric photoconductor.

that in the pure, solid state, the longer the life of the electron-hole pair, the higher the injection probability for the polymer will be.

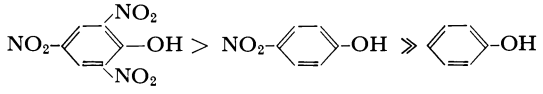
From Table I, crystal violet may be found to be the best optical sensitizer. Therefore, we adopted it as the dye component for tertiary systems (PVCZ, dye and Lewis acid). In the next section, the sensitivities of binary systems (PVCZ and Lewis acids) and of tertiary systems will be compared (see Table III).

Chemical (Lewis Acid) Sensitization.—Under the practical incandescent light used for electrophotography, usual acid and ketone derivatives are almost ineffective. On the other hand, picric acid in the acid group, *p*-nitroaldehyde, bromal in aldehydes, and most quinones are effective. It can be said that all of these effective chemical sensitizers are slightly colored themselves, and even after being doped into PVCZ solutions, they maintain their original color fairly well. (As a special case, chloranil changed from its original color (pale yellow) to dark green.)

From Table III, we can deduce the following information: with a small amount of crystal violet, an acid shows a tendency to sensitize more in conformity with an increase in the halogenation or nitration degree in its homologue; i. e.,

$$Cl_3CCOOH,\ Cl_2CHCOOH$$
$$> ClCH_2COOH \gg CH_3COOH$$

or



It is known that trichloroacetic acid is a stronger acid than di, mono, or unsubstituted acetic acid because of the inductive effect by Cl, the key atom. The same behavior exists in the latter case of the phenol homologue. Next, free acids are stronger sensitizers than anhydrides; i. e.,

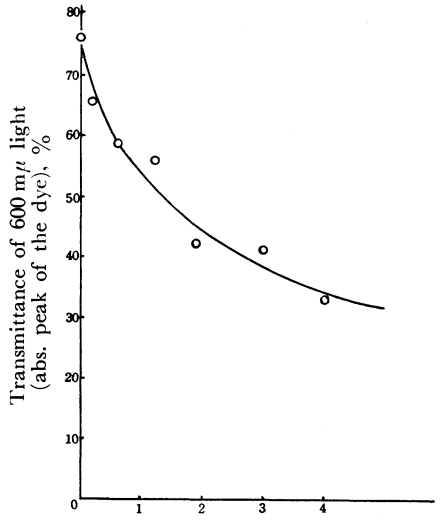
maleic acid > maleic anhydride

phthalic acid > phthalic anhydride

These results suggest that the acidity seems to be a key point in the sensitization ability in white incandescent light when an effective dye is used. Colorless aldehydes also behave in the same way as colorless acids.

As has been mentioned above, these colorless acids, aldehydes, or ketones have a small effect in the visual spectral region when the smaples have been exposed for long periods. However, in the practical exposure of the electrophotographic process, these samples show no response.

Each quinone investigated here has a fair sensitization ability without a dye except for anthraquinone-2-sulfonic acid, which is less soluble to the polymer than the other quinones. As a dye is added, anthaquinone-2-sulfonic acid becomes sensitive. Thus, the acidic group ($-SO_3H$)



Weight ratio: $\frac{\text{wt. of dichloroacetic acid}}{\text{wt. of crystal violet}}$ in constant volume of benzene, arb. unit.

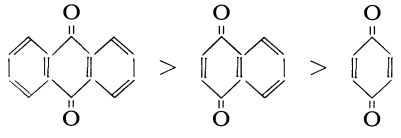
Fig. 6. Variation of solubility of crystal violet to benzene with increase of dichloroacetic acid concn.

seems to play a subsidiary role in the dye sensitization.

Some quinones were found to be organic photoconductors similar to many dyestuffs. Some anthraquinone and naphthoquinone derivatives are themselves dyestuffs or the intermediate products of dyestuffs.

These facts suggest that the members of the quinone group may be classified as optical sensitizers. However, their effective quantities are considerably larger (1—10%) than those of the dyes (10^{-3}—10^{-2}%); that is, as has been stated in the foregoing section, 2-methylanthraquinone is soluble into PVCZ to 20% by weight. The difference in effective concentration between quinones and dyes suggests some discrepancies between their sensitizing mechanisms.

Regarding the quinone group, the following empirical tendency is obtained from Table III:



Thus the numbers of aromatic π electrons may contribute to the sensitization ability.

Polynitrated aromatic compounds, such as trinitrobenzene and picric acid, are good sensitizers under an incandescent light. Each of them has a slight yellowish color initially; the original slight yellow deepens bathochromatically when joined in a PVCZ solution. With 2-methylanthraquinone this tendency is also observed. This phenomenon is related clearly to a slight red shift in Fig. 4 (dotted line); it can be explained in terms of the formation of a weak charge transfer complex between 2-methylanthraquinone or picric acid and PVCZ. Picric acid seems to have two sensitizing functions, as acid and as nitro compound.

A chloroanil-added sample had a low sensitivity in spite of forming a stable charge transfer complex. Its optimum exposure in the electrophotographic process was 1500 lux. sec., about twice

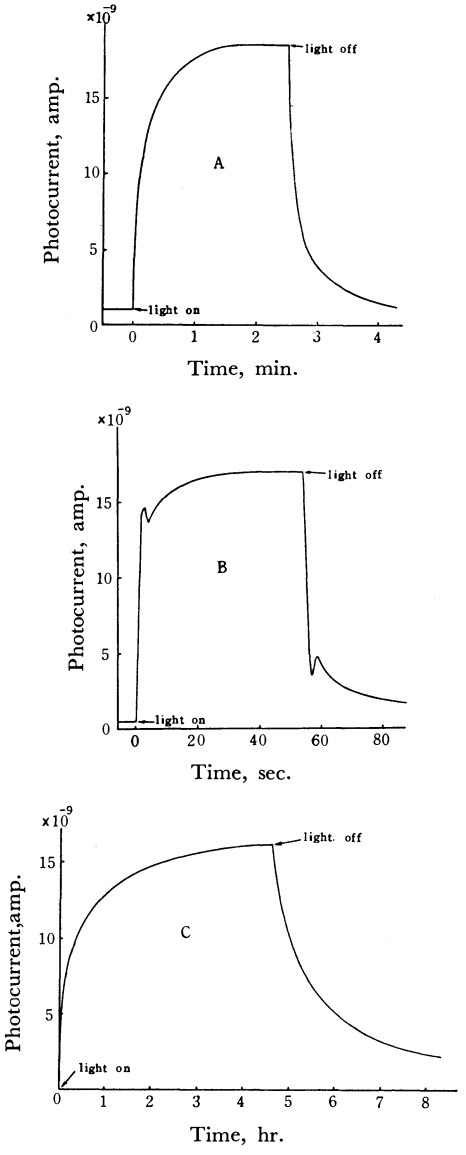


Fig. 7. Photoconduction responses on sandwich cells of PVCZ and the sensitized systems: A, PVCZ, 2μ (thickness), 5V. (applied voltage), 1000 lux. (illuminance); B, PVCZ with crystal violet 0.05%, 2μ, 5V., 20 lux.; C, PVCZ with 0.05% of crystal violet and 1% of trichloroacetic acid, 57μ, 10V., 100 lux., the illuminated electrodes positive, 3.1 cm^2 in area.

that in the foregoing two. One reason for this result may be the considerable decrease in dark resistivity with the formation of a charge transfer complex.

The Combined Effect of a Dye-acid System. —As has been mentioned in the foregoing section, an acid is an effective chemical sensitizer when used with a dye. It was observed that all the cationic dyes investigated dissolve slightly in benzene, and that their solubilities increase upon the slight addition of an acid. Figure 6 shows an example of the use of crystal violet and dichloroacetic acid. It is there shown that the solubility of crystal violet in benzene increases with an increase in the amount of dichloroacetic acid added. Consequently, the dye dispersion is converted into a solution and the chain unit of the polymer seems to be dyed smoothly.

Figure 3G indicates that an amplified sensitization is achieved by the PVCZ-dye-acid system in comparison with a system containing only a dye (Fig. 3B). On the contrary, the PVCZ - crystal violet - 2-methylanthraquinone system shows only an additional sensitization (Figs. 3H and I). An ordinary photoconduction measurement clearly shows that the response rate of the PVCZ-trichloroacetic acid system is much lower than that of the PVCZ - 2-methylanthraquinone system or the PVCZ - crystal violet system (Figs. 7A, B, and C). A chemical sensitizer with an amplification ability with a dye seems to show a slow rise and then a decay in its photoconduction response. Such a chemical sensitizer may increase the number of carrier-trapping centers as well as the number of photo-induced carriers.

Fatigue in the Photoresponse upon Repeated Use.—It is well known that a vitreus selenium layer loses its electrophotographic sensitivity upon the repetition of the charge-light decay cycle within a short period because of the space charge generation by trapped holes. To examine such memory effects in the organic photoconductors, a few higher sensitive systems were investigated. An example of the effect of repetition on a PVCZ-crystal violet - trichloacetic acid system is shown in Fig. 8. In one cycle, the sample was charged up by a positive corona discharge of 7000 V. for 1 min.; after it had then been put in the dark for 10 sec., it was exposed with an incandescent light of 500 lux. for 30 sec. The initial voltage, V_0, decreases and $E_{1/2}$ increased with the repetition of the cycle. Only at the tenth cycle was the exposure period extended to 10 min.; the conditions after the eleventh cycle was similar to the starting conditions. The dark voltage and $E_{1/2}$ at the eleventh cycle were very low and high respectively;

then they approached the dotted saturation lines with repetition cycles. After the eleventh exposure, the values should have lain on the extrapolated constant line if a longer exposure had not been applied at the tenth cycle. The constant line may result from the balance between the fatigue by irradiation and the recovery by the high tension given in the dark. The fatigue is to be attributed to irradiation and not to charging.

In Figs. 9 and 10, the variations in V_0 and $E_{1/2}$ are shown. The dye-added sample (1) and the quinone-added sample (2) show few memory effects. Weak acid-added samples (4, 5) show the same. On the other hand, the samples with strong acids or strong acceptors (6, 7, 8) have large variations. These characteristics are parallel to the results from the photoconduction measurements described in the foregoing section. As is shown in Fig. 7B, a sample sensitized with crystal violet alone quickly loses its resistivity to a certain value upon irradiation, and then it turns back to the original value after the light is switched off. In the case of strong acids or strong acceptors, these responses are very slow. From these results, the fatigue (in other words, the hysteresis) is assumed to occur through the traps of carriers.

Some Aspects in Charge Porality.—Hoegl reported that a system of PVCZ doped with a Lewis acid-type acceptor (e. g., chloranil, anthraquinone and TCNE) acts as a *p*-type photoconductor because it has a higher discharge rate when positively

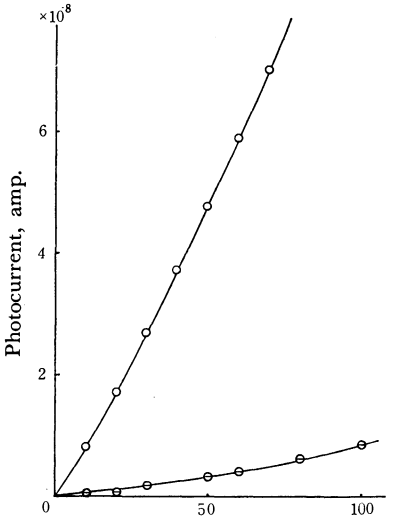

Fig. 11. V-I relations of sandwich cell as the illuminated electrode is positive (○) or negative (⊖) respectively: 20 lux. (illuminance), the same sample as used in Fig 7C.

charged than when negatively charged. In this case the dopants are assumed to be traps for electrons. Our data from the photoconduction measurements show similar results. In Fig. 11, a large photocurrent value is observed for the PVCZ-crystal violet - trichloroacetic acid system when the illuminated electrode is positive. On the other hand, the data from the charge decay method showed little difference between the two sign-charged samples. Actually in a practical process in electrophotography, the optimum printing exposure of a positively-charged sample is equivalent to that of negatively-charged one.

Conclusions

From the studies of sensitization in photoconductive poly-*N*-vinylcarbazole, some conclusions can be deduced: (1) It is convenient to divide the sensitization into two types, "optical sensitization" and "chemical sensitization." The former occurs at a smaller dye content, which extends the photoconduction spectrum of the polymer to the dye's absorption bands, while the latter is induced by the formation of a charge transfer complex in the presence of a considerable amount of a Lewis acid; (2) The most effective dyes are *n*-type cationics with slow photoresponses in their pure, solid states; (3) In the sensitization with two different types of components (dye and Lewis acid), an amplified effect or an additive effect is obtained. The former case occurs frequently when a strong acid is employed as a chemical sensitizer; (4) A sensitized system with a strong

acid shows very slow rates of rise and decay in the photoconduction measurements.

Although the systems containing strong acids show high sensitivities ($E_{1/2}<100$), they are not always of practical use for electrophotography because of their rapid dark decays and their intense memory effects.

The most useful photoconductive systems are those containing quinones, in spite of their showing only additive effects with crystal violet. 2-Methylanthraquinone is especially useful: (1) its solubility with PVCZ is large, (2) its charge transfer color is pale, and (3) its memory effect is very small. The xerographic characteristics of the practical sample were as follows. The maximum and minimum image densities were 3.0 and 0.1 respectively; the exposure was about 300 lux. sec. at the optimum range, and the γ value was 1.5 when a commercial xerographic toner was used.

The authors wish to express their thanks to Dr. Shunkichi Kisaka, Manager of their Laboratory, for his kind guidance and encouragement throughout the work, and to Mr. Tetsuro Ohtsuka for his helpful suggestions in the physical field.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1670—1673 (1966)

Sensitization in the Photoconductance of Polyacenaphthylene

By Yoshiki HAYASHI, Makoto KURODA and Akira INAMI

Research Laboratory, Wireless Division, Matsushita Electric Industrial Co., Ltd., Kadoma, Osaka

(Received November 8, 1965)

The sensitization of the photoconductivity in polyacenaphthylene by a dye and/or a Lewis acid was investigated. The most effective materials are methylene blue ($E_{1/2}$= 1500 lux. sec.), rhodamine 6G (6000 lux. sec.), and victoria pure blue (6500 lux. sec.) in the dye sensitization, and 1-nitroanthraquinone (1200 lux. sec.), 2, 3-dichloronaphthoquinone (1400 lux. sec.), 1, 5-dichloroanthraquinone (1500 lux. sec.), chloranil (1800 lux. sec.), and 2-chloroanthraquinone (1900 lux. sec.) in the Lewis-acid sensitization. The combined effects of a dye and a strong acid were determined in the case of polyacenaphthylene as well as poly-*N*-vinylcarbazole.

In a previous paper,[1] the authors reported that polyacenaphthylene showed only a low photoconductivity, while the nitrated polymer obtained by the partial nitration of polyacenaphthylene showed a considerable photoconductivity. The effect of the nitration on photoconductivity may be interpreted by means of a charged transfer mechanism. The nitrated acenaphthylene group is considered to be an electron acceptor. This process may be called the intramolecular chemical sensitization.

Slough studied the semiconductivity of charge transfer complexes of polyacenaphthylene with Lewis acids in the dark,[2] and Hoegl reported in a recent paper that a charge transfer complex of polyacenaphthylene doped with hexabromonaphthalic anhydride could be made to show photoconductive behavior with the aid of the electrophotographic printing process.[3] The present authors found the same behavior: polyacenaphthylene, which is regarded as a polymeric donor, is sensitized by doping miscellaneous dyes and/or Lewis acids, just as poly-*N*-vinylcarbazole can be sensitized with them.[4]

This paper will report the experimental results obtained by adding dyes and Lewis acids to polyacenaphthylene in order to determine a useful composition of photosensitive material for the electrophotographic process.

Experimental

The Polymerization of Acenaphthylene.[5]—Ten grams of acenaphthylene was dissolved in 10 ml. of ethyl benzene and emulsified with 100 ml. of a sodium stearate solution.*1 As an initiator, 0.4 g. of potassium persulfate was added to the emulsion; then the mixture was agitated in a closed container for 10 hr. at 45°C. The resultant polymer was coagulated from the solution by dropping it slowly into dilute hydrochloric acid. The coagulated polymer was then filtered off, dissolved in benzene, and precipitated into methyl alcohol. Yield, 74%; $[\eta]$=0.53 (at 25°C in benzene).

3) H. Hoegl, *J. Phys. Chem.*, **69**, 755 (1965).
4) Y. Hayashi, M. Kuroda and A. Inami, This Bulletin, **39**, 1660 (1966).
5) U. S. Pat. 2563524 (1951).
*1 This emulsion consisted of 600 ml. of water, 14 g. of stearic acid, and 6 g. of potassium hydroxide.

The Preparation of a Photosensitive Specimen.—The method of preparation was substantially the same as to that used for poly-*N*-vinylcarbazole and reported previously.[4] Here, toluene was used as the solvent, and the dye concentration was fixed at 0.05% by weight for the solid polymer powder. The Lewis acids (chemical sensitizer) concentrations were fixed at 1% by weight in the case of acids, acid anhydrides, aldehydes, and ketones. In the case of the quinone group, however, all the addition amounts were fixed at 10%.

The final polymer solutions were coated onto aluminum plates 0.1 mm. thick with the aid of a Baker-type applicator; then the solvent was thoroughly evaporated in the drying oven. After the solvent had been evaporated, the specimen films were about 15 μ thick. The parent polymer was so brittle in the thin film form that, after the solvent had been evaporated, numerous cracks generated if the drying speed was too high. Therefore, the drying temperature was kept below 50°C at atmospheric pressure.

Sensitometry.—The photoconductive sensitivities of the doped samples were measured by the electrophotographic charge-decay method described in previous papers.[1,4] The sensitivities were represented as the half decay exposure, $E_{1/2}$, which serves as an index of the photoconduction. In this experiment, two light intensities were applied, i. e., 1000 lux. in less sensitive materials ($E_{1/2}>1000$ lux. sec.), and 100 lux. in highly sensitive materials ($E_{1/2}<1000$ lux. sec.). In order to indicate the dark decay due to the dark resistivity of a sample, the initial voltage, V_0, at the starting point of the light decay is listed along with $E_{1/2}$. These data were obtained at a constant temperature (20°C) and humidity (50%).

Results

Dye Sensitization.—It can be seen from Table I that the most effective dye is methylene blue ($E_{1/2}=1500$ lux. sec.), and the next is rhodamine 6G ($E_{1/2}=6000$ lux. sec.). Crystal violet, rhodamine B, and malachite green, which were very effective on poly-*N*-vinylcarbazole, show a lower sensitizability than the foregoing.

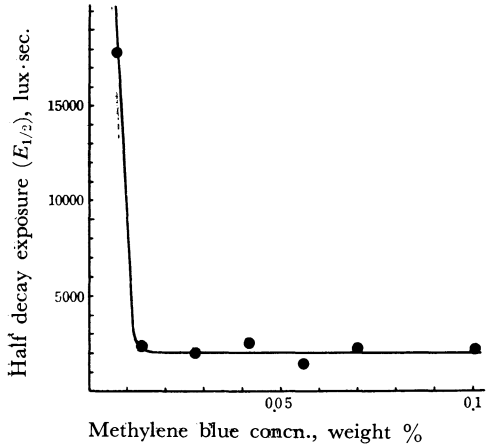

Fig. 1. Relation between sensitivity of dyed polyacenaphthylene and methylene blue concn.

Fast light yellow G	1680	74000

In the case of sensitization on poly-*N*-vinylcarbazole, methylene blue is a little less sensitive than crystal violet. It is not evident why a large difference occurs between methylene blue and new methylene blue, because the two chemical formulas are very similar to each other. Methylene blue, rhodamine 6G, and victoria pure blue are all cationic dyes. The empirical tendency for the effective dyes to be cationics in the dye sensitization of poly-*N*-vinylcarbazole may also be applied in the case of polyacenaphthylene. Methylene blue, a thiazine dye, is known as a desensitizer in the silver

halide emulsions. This dye has positive effects, and cyanine dyes which are good sensitizers for the silver halides have no effect on the polymeric donor-type photoconductors.

Effective Dye Concentration.—In Fig. 1, a relation between the photosensitivity and the doping concentration of methylene blue is presented. In view of the accuracy of measuring, it can be said that the optimum dye concentration range is 0.03—0.1%. As the dye concentration increases, the dark decay rate increases as a result of a decrease in the dark resistivity.

Lewis Acid Sensitization.—The pure polyacenaphthylene showed an $E_{1/2}$ value of 1.6×10^5—1.8×10^5 lux. sec. and a V_0 value of 1400—1600 V. The dark decay rate was about 5 times that of poly-*N*-vinylcarbazole. These results imply that polyacenaphthylene has a lower value in the dark resistivity and a higher value in the light resistivity.*2

From Table II, it can be said that quinone derivatives are effective. 1-Nitroanthraquinone, 2, 3-dichloronaphthoquinone, 1, 5-dichloroanthraquinone, chloranil, and 2-chloroanthraquinone, which are strongly electron-attractive, show high sensitizabilities in white light without dye. This shows that the clear formation of a charge transfer complex is a favorable method for the sensitization when an effective dye is not used. The $E_{1/2}$ values of 1-nitroanthraquinone (1.2×10^3 lux. sec.) and 2, 3-dichloroanthraquinone (1.4×10^3 lux. sec.) are comparable with that of methylene blue (1.5×10^3 lux. sec.).

The Combined Effect of a Dye and a Strong Acid.—It has already been found that poly-*N*-vinylcarbazole was sensitized very highly with a cationic dye and a strong acid. Such a combined effect with a dye and acid might also be expected in the case of polyacenaphthylene. A compounded system of methylene blue (0.05%)+2, 4, 6-trinitrobenzoic acid (1%) shows 250 lux. sec., while a system of methylene blue (0.05%)+1-nitroanthraquinone (10%) or methylene blue (0.05%) + chloranil (10%) shows 1.3×10^3 or 2.5×10^3 lux.sec. respectively (see Fig. 2). Thus, an amplified

*2 The $E_{1/2}$ value of pure poly-*N*-vinylcarbazole was found to be about 4000 lux.sec.

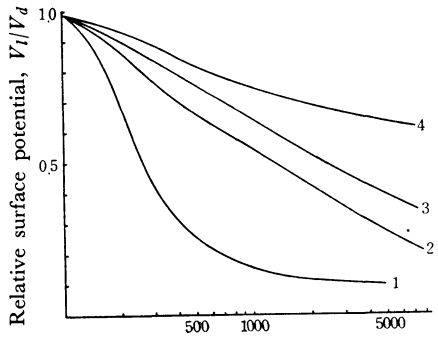

Fig. 2. Electrophotographic characteristic curves of some sensitized polyacenaphthylene: 1, doped with 0.05% of methylene blue and 1% of 2,4,6-trinitrobenzoic acid; 2, doped with 0.05% of methylene blue and 10% of 1-nitroanthraquinone; 3, doped with 0.05% of methylene blue and 10% of chloranil; 4, doped with 0.05% of methylene blue and 10% of 2,3-dichloronaphthoquinone.

effect by using a dye and an acid is also to be seen in the sensitization of polyacenaphthylene.

From the view point of practical use in electrophotography, only methylene blue is found to be a significant dye.

Conclusion

The sensitized polyacenaphthylene with 0.05% of methylene blue and 1% of 2, 4, 6-trinitrobenzoic acid shows 250 lux. sec. in sensitometry with a half decay exposure. Nitrated polyacenaphthylene, which has an optimum degree of nitration (20—40 mol. %),[6] shows about 2×10^3 lux.sec. The methylene blue-sensitized sample of the nitrated derivative was found to be 550 lux. sec., which is about twice the foregoing system of polyacenaphthylene. From these results, the nitration is not likely to be a practical method for preparing elctrophotographic-sensitive material.

The authors express their hearty thanks to Dr. Shunkichi Kisaka, the manager of the laboratory for his kind guidance and encouragement through the work.

Reactive Species in the Photochemical Hydrogenation of Acridine in Ethanol

By Akira KIRA, Yoshinori IKEDA and Masao KOIZUMI

(Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received November 24, 1965)

In order to determine the reactive state of acridine when it is photoreduced by ethanol, two types of experiments were undertaken. The first was to study the concentration effect of ethanol on the quantum yield in a benzene solution. These results, however, could not give any unequivocal answer. The second type of experiment was, therefore, made from the standpoint of the triplet energy transfer, using eosine as an energy acceptor for the photoreduction of acridine in an ethanol solution. It was found that, in a deaerated solution, the quantum yield of acridine photoreduction is not affected by the addition of eosine, whereas it was established by the flash technique that, under similar conditions, the energy transfer from the acridine triplet state to eosine occurs at approximately the diffusion-controlled rate. These results lead to the conclusion that the reactive state is not the lowest triplet state.

In a previous paper[1] two paths have been presented for the photochemical reduction of acridine in ethanol. One was:

$$\left.\begin{array}{l} A + h\nu \rightarrow A^* \\ A^* + RH_2 \rightarrow \left(A\begin{array}{c}H\\H\end{array}R\right) - AH_2 + R \end{array}\right\} \quad (1)$$

where A* is the singlet excited state of acridine and RH_2 is ethanol. The other was:

$$\left.\begin{array}{ll} & A^* + RH_2 \rightarrow AH + RH \quad (a) \\ \text{or} & A^T + RH_2 \rightarrow AH + RH \quad (b) \\ & (2AH \rightarrow A + AH_2) \end{array}\right\} \quad (2)$$

where A^T is the triplet state of acridine. When oxygen is present, only (1) occurs, since the half hydrogenated acridine produced by (2a) or (2b)

1) A. Kira, S. Kato and M. Koizumi, This Bulletin, **39**, 1221 (1966).

reverts to acridine by means of:

$$AH + O_2 \rightarrow A + HO_2$$

The question whether A* or A^T is involved in path 2, however, has not yet been decided. In the present paper attempts will be made to give an unequivocal answer to this question.

Results and Discussion

The Reaction between Acridine and Ethanol in a Benzene Solution.—It is expected that if AH is to be produced by (2a), then a rather high concentration of ethanol would be required for the reaction to occur because the lifetime of A* is 7.2×10^{-10} sec.[2] On the other hand, if AH is produced via the triplet state, it is possible that a rather low concentration of ethanol is enough for the reaction rate to become measurable, although it all depends upon the magnitude of the rate constant of $A^T+RH_2\rightarrow AH+RH$. Since, for the aerated solution, it has already been determined that the reaction really occurs at A*, there is a possibility that the problem can be answered by comparing the concentration effect of ethanol on the rate in aerated and deaerated benzene solutions.

The concentration of acridine was chosen as 5×10^{-5} M, while the concentration of ethanol was varied from 1×10^{-2} M to 17.3 M (pure ethanol). Changes in the absorption spectra in the course of the reaction were quite similar to those in the pure ethanol solution. The $\ln(e^{acd}-1)$ vs. t plots were satisfactorily linear, and the value of the quantum yield was determined from the slope of the plot. The results are shown in Table I.

It is notable that the ratio of Φ_{dea} to Φ_{aer} is almost constant, independent of the concentration of ethanol. When the reaction occurs at the singlet excited state, the quantum yield, Φ, for the simplest case is given as follows:

$$\Phi = \frac{k_r[RH_2]}{k_d + k_r^s[RH_2]} \quad (1)^{*1}$$

where k_r, k_r^s and k_d are the rate constants for, respectively, the genuine reaction with ethanol, the total reaction with ethanol (including simple deactivation), and the first-order decay constant in benzene. From Eq. 1 one gets:

$$\frac{\Phi}{1-\Phi}\times\left\{1+\frac{(k_r^s-k_r)}{k_d}[RH_2]\right\}=\frac{k_r}{k_d}[RH_2] \quad (2)$$

On the other hand, when the triplet state is a reactive species:

$$\Phi = \varphi_{S-T}^{A}\frac{k_r'[RH_2]}{k_d'+k_r^s'[RH_2]} \quad (3)$$

where φ_{S-T}^{A} is the probability of the intersystem crossing[3] and where k_r', k_r^s' and k_d' are the analogous rate constants for the triplet state, just as k_r, k_r^s and k_d are for A*. From Eq. 3:

$$\frac{\Phi}{\varphi_{S-T}^{A}-\Phi}\times\left\{1+\frac{(k_r^s'-k_r')[RH_2]}{k_d}\right\}=\frac{k_r'}{k_d'}[RH_2] \quad (4)$$

As may be expected from Eq. 2, the plot of $\log[\Phi_{aer}/(1-\Phi_{aer})]$ against $\log[RH_2]$ for the aerated solution does not give the slope of unity; rather, it gives approximately 0.8. In the same way, when both $\log[\Delta\Phi/(1-\Delta\Phi)]$ and $\log[\Delta\Phi/(\varphi_{S-T}^{A}-\Delta\Phi)]$ ($\Delta\Phi=\Phi_{dea}-\Phi_{aer}$) are plotted against $\log[RH_2]$ for the dearated solution, the slopes of the curves also have similar values. This deviation from unity might be due partly to the dependence of k_r's and k_d's on the composition of the solution, but it is more plausible to attribute this deviation mainly to the assumption that $k_r^s=k_r$, especially in the lower concentration region of ethanol. If one takes proper $(k_r^s-k_r)/k_d$ values, which are ca.

TABLE I. QUANTUM YIELDS* OF THE PHOTOREDUCTION OF ACRIDINE BY ETHANOL IN BENZENE
[acridine]: 5×10^{-6} M, Temperature: 25°C

* Correction is made for the quantum yield in pure benzene.
** Φ_{dea} and Φ_{aer} are respectively the quantum yield for the deaerated and aerated solutions.

2) H. Kokubum, Symposium of Photochemistry, Sendai, 1963.

*1 In general a factor depending on the succeeding steps should be multiplied.

3) According to our unpublished findings, the value of φ_{S-T}^{A} in a benzene solution is about 0.24.

1 in all cases, then the plot of the logarithm of the left side of Eqs. 2 and 4 against log[RH_2] can be made to have a slope of 1. The results are shown in Fig. 1.

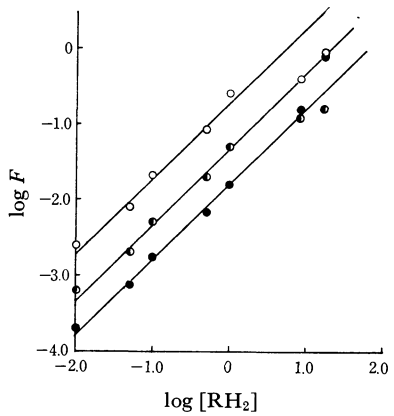

Fig. 1. Plots of log F vs. log [RH_2].
$F = \Delta\Phi \cdot K/(\varphi^{A}_{ST} - \Delta\Phi)$ for ○,
$\Delta\Phi \cdot K/(1-\Delta\Phi)$ for ◐ and
$\Phi_{aer} \cdot K/(1-\Phi_{aer})$ for ●,
where $K = \left\{1+\frac{(k_r^s - k_r)}{k_d}[RH_2]\right\}$ etc.
and where the coefficients of [RH_2] are put unity.

The values of k_r/k_d's are evaluted from the point at log[RH_2]=0. For the deaerated solution, the values of k_r and k_r^s are:

$$\begin{cases} k_r' = 2.0\times10^{-1}k_d' \\ k_r^s' = 1.2k_d' \end{cases} \qquad \begin{cases} k_r = 4.6\times10^{-2}k_d \\ k_r^s = 1.05k_d \end{cases}$$

and for the aerated solution:

$$\begin{cases} k_r = 1.6\times10^{-2}k_d \\ k_r^s = 1.02k_d \end{cases}$$

If one assumes $k_d \simeq 10^{10}$ sec^{-1} and $k_d' \approx 2\times10^3$ sec^{-1},[4] then for the reaction 2a:

$$k_r = 4.6\times10^8 \text{ M}^{-1}\text{ sec}^{-1}, \quad k_r^s = 10^{10} \text{ M}^{-1}\text{ sec}^{-1}$$

and for (2b):

$$k_r' = 4\times10^2 \text{ M}^{-1}\text{ sec}^{-1}, \quad k_r^s' = 2.4\times10^3 \text{ M}^{-1}\text{ sec}^{-1}.$$

Thus, the above values of the rate constants can make both the reactions, 2a and 2b, consistent with the experimental results, and so no definite answer can be given. However, the results in Table I, particularly the constancy of Φ_{dea}/Φ_{aer}, seem to favor the view that a reactive state is S* and not T. Even if A^T reacts with ethanol, there is no doubt that its reactivity is exceedingly small.

The Effect of the Addition of Eosine on the Photoreduction of Acridine in Ethanol.— In principle, the present problem can be solved if an effective quencher of A^T is added and if its effect on the rate of photoreduction is examined. Thus, if a reactive species is triplet acridine, then the rate may be expected to decrease to about one-third of the original value, whereas the rate should be scarcely affected if the reactive species is A*. However, we do not know what substance is a suitable triplet quencher. We have tried eosine as a test substance, since this dye has a triplet level definitely lower than that of acridine[5] and since its absorbance at 365 mμ is very small. It was found that the addition of eosine (5×10^{-6} M or 1×10^{-5} M) did not affect the rate beyond the limits of experimental error, and yet the optical density of eosine was found to decrease beyond the limit of experimental error, though to a small extent. The results are shown in Table II, where ΔD is the difference in the optical density of eosine before and after 5 minutes' irradition.

It should be noted that, according to our preliminary experiments, eosine is rapidly photoreduced by a 365 mμ light in the presence of 10^{-4} M acridan. In spite of this fact, it is believed that the ΔD value in Table II is not due to the produced acridan, though the bad reproducibility of the data might partially be due to it.

From the above results, there is scarcely any doubt that the addition of eosine does not affect the rate of the photoreduction of acridine. However, there still seems to be some doubt as to whether eosine is really acting as an efficient quencher under the present experimental conditions, since the decrease in the optical density of eosine is quite small. The order of the magnitude of ΔD to be expected can be estimated in the following way. If the above results are to be explained by the following scheme:

$$A + h\nu \rightarrow A^*$$
$$A^* + RH_2 \rightarrow AH_2 + R \qquad (1)$$
$$\quad \rightarrow AH + RH \qquad (2a)$$
$$A^* \rightarrow A^T \qquad (3)$$
$$A^T + E \rightarrow A + E^T \qquad (4)$$
$$E^T + RH_2 \rightarrow (EH + RH) \rightarrow EH_2 + R \qquad (5)$$

where E is eosine, then the decrease in the eosine concentration, −d[E], should be given by:

$$-\text{d[E]} = I^{A}_{ab} \cdot \varphi^{A}_{S-T} \cdot \alpha \cdot \beta \, dt$$

where I^{A}_{ab} is the quantity of light absorbed by acridine, where φ^{A}_{S-T} is the probability of the intersystem crossing of acridine, and where α and β are, respectively, a parameter for the efficiency of the energy transfer (process 4) and the probability that the triplet eosine reacts with ethanol.

4) To be published.

5) According to G. N. Lewis and M. Kasha (*J. Am. Chem. Soc.*, **66**, 2100 (1944)), the triplet level of eosine is 14900 cm^{-1}, while D. F. Evans (*J. Chem. Soc.*, **1957**, 1351) reported that the triplet level of acridine is 15840 cm^{-1}. See also Hammond et. al., *J. Am. Chem. Soc.*, **86**, 3197 (1964).

Controle (deaerated)			
0	1×10^{-5}		0.005 (after 3 min.) 0.08 (after 30 min.)
0	1×10^{-5}		0.025 (after 3 min.) 0.04 (after 30 min.)

Since

$$-\mathrm{d[A]} = I^{\mathrm{A}}_{ab}\cdot\Phi^{\mathrm{A}}_{dea}\,\mathrm{d}t$$

one gets:

$$-\mathrm{d[E]} = -\mathrm{d[A]}\times\frac{\varphi^{\mathrm{A}}_{\mathrm{S}-\mathrm{T}}\cdot\alpha\cdot\beta}{\Phi^{\mathrm{A}}_{dea}}$$

Integration gives:

$$\Delta[\mathrm{E}] = \Delta[\mathrm{A}]\times\frac{\varphi^{\mathrm{A}}_{\mathrm{S}-\mathrm{T}}\cdot\alpha\cdot\beta}{\Phi^{\mathrm{A}}_{dea}}$$

Φ^{A}_{dea} is $\simeq0.1$; if one tentatively puts $\varphi^{\mathrm{A}}_{\mathrm{S}-\mathrm{T}}\approx0.1$,[3] $\alpha\approx1$, and $\beta\approx0.01$,[6] then:

$$\Delta[\mathrm{E}] = \Delta[\mathrm{A}]\times\frac{1}{100}$$

When the concentration of acridine is 5×10^{-5} M and 1×10^{-4} M, the ΔD values should be 0.05 and 0.10 respectively after 5 minutes' illumination, by which time acridine disappears almost quantitatively. These values are perhaps the upper limit which can be expected, and the experimental values are quite reasonable, at least in the order of magnitude.

Thus, it seems quite plausible that the reactive species of acridine is the singlet excited state and not the triplet state. It is worthwhile to add here that the above results obviate any appreciable occurence of such a process as $\mathrm{AH}+\mathrm{E}\rightarrow\mathrm{A}+\mathrm{EH}$, i. e., the transfer of the hydrogen atom from semi reduced acridine to eosine. If this reaction were to occur, then the reduction of the acridine concentration should be caused by the addition of eosine.

Direct Proof of the $\mathrm{A^T}+\mathrm{E}\rightarrow\mathrm{A}+\mathrm{E^T}$ Process by Flash Photolytic Experiments. — In order to establish the $\mathrm{A^T}+\mathrm{E}\rightarrow\mathrm{A}+\mathrm{E^T}$ process more conclusively, flash photolytic studies were made of a solution of acridine and eosine in ethanol. The experimental conditions, such as the concentration of acridine, the flash intensity, and the filter system, are similar to those used for the acridine solution in ethanol.[1] The concentration of eosine was changed from 3×10^{-6} to 2×10^{-5} M. The filter transmits only the light in the absorption region of acridine.

An example of the transient absorption spectra is shown in Fig. 2.
The concentration of acridine in this case is 1×10^{-5} M. At 93 μ sec. after the flash, the absorption spectra are quite similar to those of the acridine triplet state.[1] At 360 μ sec., the shape of the spectra becomes quite different and resembles rather those of eosine intermediates,[7] although it is not exactly identical.

Judging from the decay of the triplet acridine,

6) According to M. Imamura and M. Koizumi (This Bulletin, **29**, 899 (1956)), the quantum yield of the photoreduction of eosine in ethanol is $\sim5\times10^{-4}$. The value of $\varphi^{\mathrm{E}}_{\mathrm{S}-\mathrm{T}}$ is 0.023 according to C. A. Parker (*Trans. Faraday Soc.*, **57**, 1894 (1961)), while in our unpublished results it is >0.05. The molar extinction coefficient of eosine in ethanol is $\sim10^5$.

7) A. Kira and S. Kato, *Science Rep. Tohoku Univ., Ser. 1*, **48**, 232 (1965).

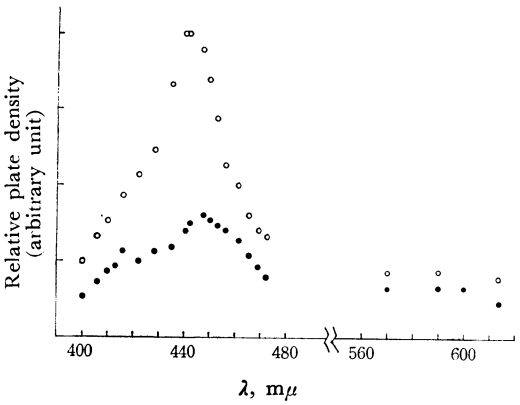

Fig. 2. Transient spectra of acridine in degassed ethanol solution containing eosine.
Acridine 1×10^{-4} M Eosine 1×10^{-5} M
○ 93 μ sec. and ● 360 μ sec. after the flash irradiation

its quantity at this stage is expected to be practically nil, so that there is no doubt that the absorption spectra at this stage are due to the transient intermediates originating from eosine. However, since the lifetime of the singlet excited state of acridine A* is of the order of 10^{-10} sec., there is no possibility for 10^{-5} M of eosine to react with A*. Besides, when a degassed solution of eosine in ethanol is irradiated under conditions similar to those above, no transient absorption is observable at 440 mμ. Therefore, it can be colculded that the transient species in question is produced by the reaction of the triplet state acridine, A^T, and eosine.

The decay curves of the optical density at 440 mμ for several eosine concentrations are shown in Fig. 3. The following features are to be noted; 1) The later stage of the decay curves, after ~300 μ sec., is exponential and has the same rate

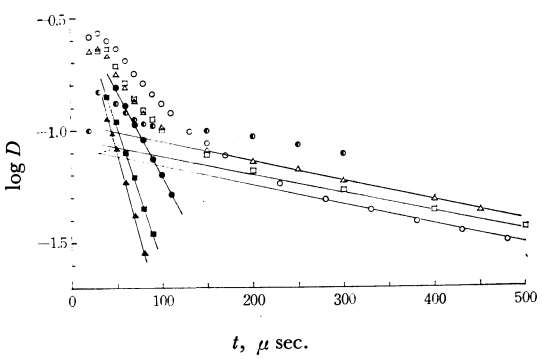

Fig. 3. Decay curves of the absorption at 440 mμ.
White symbols refer to observed data and black symbols, to the decay of the triplet state evaluted from them.
Acridine 3×10^{-5} M
Eosine concentrations: ○ and ● 3×10^{-6} M, □ and ■ 6×10^{-6} M, △ and ▲ 8×10^{-6} M and ◐ 2×10^{-5} M

constant, $k=2\times10^3$ sec^{-1}, irrespective of the eosine concentration. 2) The first stage decays much faster, but the effect of the eosine concentration on the decay rate is not appreciable. 3) At the initial stage, the optical density becomes smaller with the increase in the eosine concentration, whereas 4) in the later stage, it becomes higher with the increase in the eosine concentration.

Findings 1 and 4 lead to the view that the later stage involves a certain intermediate produced from eosine. Furthermore, the value of k and the spectral feature support the view that this is mainly the triplet state of eosine, E^T. Findings 2 and 3 can then be interpreted in terms of the superposition of the decay of A^T and the rise in E^T.

The above interpretation is further supported by the finding that the solution of acridine and eosine in ethanol ([A]: 5×10^{-5} M, [E]: 8×10^{-6} M), when irradiated by the light absorbed only by eosine, displays the transient absorption spectra the decay constant of which is $k=2.4\times10^3$ sec^{-7}, i. e., just the same as that above. This value also agrees with the decay constant of E^T in ethanol.[7]

Thus, the present results naturally lead to the following scheme:

$$A^T \xrightarrow{k_d^A} A \qquad A^T + E \xrightarrow{k_4} A + E^T$$

$$E^T \xrightarrow{k^E} E^X \text{ or } E \text{ (the yield of } E^X \text{ being } \beta)$$

where E^X is a secondary intermediate of eosine (probably semiquinone) but with a longer life. Since the initial concentration of A^T is 10^{-6} M at most, the following equations can easily be derived on the basis of the above scheme:

$$\begin{cases} [A^T] = [A^T]_0 e^{-(k_d^A + k_4[E]_0)t} = [A^T]_0 e^{-\kappa t} \\ [E^T] = \dfrac{k_4[E]_0[A^T]_0}{\kappa - E}(-e^{-\kappa t} + e^{-k^E t}) \\ \dfrac{1}{\beta}[E^X] = \dfrac{k_4[E]_0[A^T]_0}{\kappa} + \dfrac{k^E k_4[E]_0[A^T]_0}{\kappa - k^E} \\ \qquad \times\left(\dfrac{1}{\kappa}e^{-\kappa t} - \dfrac{1}{k^E}e^{-k^E t}\right) \end{cases}$$

However, since β is very small, as has been estimated above, the optical density at 440 mμ is given by:

$$D = (\varepsilon[A^T] + \varepsilon'[E^T])d \qquad (5)$$

with a good approximation, where ε and ε' are, respectively, the molar extinction coefficients of A^T and E^T.

The decay at the later stage is then given by:

$$\frac{k_4[E]_0[A^T]_0 d\varepsilon'}{\kappa - k^E} e^{-k^E t} \qquad (6)$$

This interprets quantitatively the increase in the optical density with the eosine concentration. In the initial stage, two terms containing $e^{-\kappa t}$ and $e^{-k^E t}$ superpose, and the contribution of the second

term increases with $[E]_0$, this is the reason why the apparent decay is not so much affected by the eosine concentration.

In order to evaluate κ, one has to subtract Eq. 6 from Eq. 5 and has to plot the logarithm of the residue against the time. The results are shown in Fig. 3 with black symbols. The observed κ-values thus obtained are plotted against the eosine concentrations in Fig. 4.

The value of k_4 obtained is 3.4×10^9 M^{-1}sec^{-1}. Although the above analysis is approximate in nature on account of the neglect of the second-order decay of A^T, yet it seems quite satisfactory, even quantitatively. Thus it may be concluded that the $A^T+E\rightarrow A+E^T$ process can occur very quickly, perhaps with a diffusion-controlled rate constant.

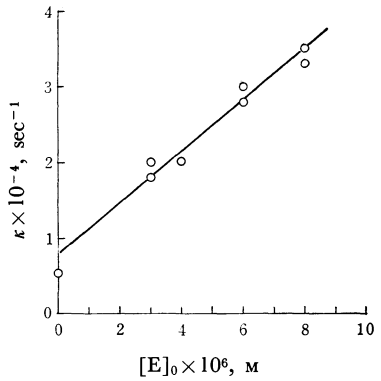

Fig. 4. The relation between the observed first order rate constant of triplet acridine and the eosine concentration.

Conclusion

The present study has shown that: 1) The energy transfer between the acridine triplet state and the ground state eosine occurs very efficiently, and that 2) in spite of this triplet energy transfer, the photoreduction of acridine is scarcely affected at all by the presence of eosine.

It may, therefore, be concluded that the reactive state of acridine is not the triplet state. As Kellmann and Dubois have proposed,[8] however, there is a possiblity of the $n-\pi^*$ T state being the reactive one. This state, according to them, has a lifetime of the order of 10^{-8} sec., so the presence of 10^{-5} M of eosine will scarcely affect this state. It is a problem for the future to decide how much of the reaction occurs at the S* and at the $n-\pi^*$ T states and, further, to decide the fraction of molecular and radical mechanisms in each reactive state.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1678—1681 (1966)

Ammoniak-Synthese an einigen legierten Katalysatoren

Von Rudolf BRILL und Yoshio OHSUMI*

Fritz-Haber-Institut der Max-Planck-Gesellschaft, Berlin Dahlem

(Eingegangen am 25 November, 1965)

Es wird versucht, Eisenkatalysatoren für die Ammoniak-Synthese herzustellen, bei denen dem Eisen Fremdmetalle (Chrom, Nickel, Kupfer) zulegiert sind. Um Katalysatoren mit einer Struktur zu erhalten, die der Struktur der aus reinem Eisen hergestellten vergleichbar ist, wurden die Fremdmetalle als solche oder als Oxide dem Carbonyleisen beigemischt, das dann in üblicher Weise durch Schmelzen im Sauerstoffstrom in Magnetit übergeführt wurde. Eine Mischkristallbildung in der Magnetitphase wurde nur bei Nickel und Chrom gefunden. Durch Reduktion der Spinelle wurde nur bei Nickel eine Legierungsbildung festgestellt. Cr_2FeO_4 war unter unseren Bedingungen (Reduktion bei 400°C mit Wassersoff-Stickstoff-Gemisch) nicht reduzierbar. Alle mit Kupfer hergestellten Katalysatoren zeigten im reduzierten Zustand Kupfer neben Eisen. Die Legierungskatalysatoren mit Nickel zeigten bei Gehalten bis zu 5% Nickel innerhalb der Fehlergrenze dieselbe Aktivierungsenergie wie reines Eisen, während Katalysatoren mit 10—30% Nickel eine merklich geringere Aktivierungsenergie aufweisen, jedoch tritt dabei ein Kompensationseffekt auf.

Einleitung

Die vorliegenden Untersuchungen befassen sich mit dem Problem der Beeinflussung der katalytischen Eigenschaften des Eisens für die Ammoniak-Synthese durch Legierungsbildung. Als Legierungspartner wurden zunächst Chrom, Nickel und

* Die jetzige Adresse: Zentrale Forschungsinstitut der Mitsubishi Chem. Ind., Kawasaki, Japan.

Kupfer herangezogen. Um mit reinem Eisen vergleichbare Werte zu erhalten, wurden auch die Legierungen durch Reduktion von Oxiden hergestellt. Die in der Technik gebräuchliche Methode besteht in der oxidativen Verbrennung reinen Eisens (mit geeigneten Zusätzen), wobei sich in weitaus überwiegender Menge der Spinell Fe_3O_4, der gegebenenfalls einige "Promotoren" unter Bildung eines Mischspinells in Lösung enthält, bildet. Um übersichtlichere Verhältnisse zu haben, wurde auf den Zusatz von Promotoren verzichtet und durch Verbrennung von Carbonyleisen erhaltenes Fe_3O_4 nach der Reduktion zu Eisen als Vergleichskatalysator benützt.

Experimentelle Methode

Die oxidischen Legierungskatalysatoren wurden durch Mischung von Carbonyleisen mit Carbonyl-Nickel, Chromtrioxid oder Kupfer(II)-oxid und Verbrennen der Mischung im Sauerstoffstrom erhalten. Auf diesem Wege könnten Mischspinelle erhalten werden ($Fe_3O_4+NiFe_2O_4$: $Fe_3O_4+FeCr_2O_4$; $Fe_3O_4+CuFe_2O_4$), die bei der Reduktion die Legierungen ergeben können.

Die Ammoniak-Synthese an den erwähnten Katalysatoren wurde teils nach der bei Brill und Tauster[1] angegebenen Methode (I), teils in einer Apparatur ausgeführt, die der von Ozaki, Taylor und Boudart[2] angegebenen (II) entspricht.

Experimentelle Ergebnisse und Diskussion

(1) Röntgenprüfung. — Die röntgenographische Untersuchung zeigte indessen, dass die Legierungsbildung auf diesem Wege unvollständig ist. Die Gitterkonstanten von so hergestellten Legierungen waren zwar, z. B. bei Zusatz von 10% oder 30% Nickel, gegenüber der des reinen Eisens vergrössert. Wegen der äusserst geringen Unterschiede zwischen dem metallischen Atomradius des Eisens (1.241 Å) und dem des Nickels (1.246 Å) konnte jedoch die röntgenographische Methode zur genauen Bestimmung des Nickelgehaltes nicht herangezogen werden.

Die Ergebnisse der röntgenographischen Analyse der untersuchten Katalysatoren sind in Tablle I zusammengefasst.

Der bete Literaturwert für reines Eisen ist 2.8664 Å bei 20°. Die Abweichung der in Tabelle I für reines Eisen gegebenen Zahl 2.865 von diesem Wert kennzeichnet etwa die Genauigkeit unserer Messungen, d. h. bei den Legierungen mit 5 und 10% Nickel ist eine Gitteraufweitung nicht zu konstatieren, während die nach dem Sintern der Legierung mit 10% sowie die bei den höherprozentigen Legierungen gefundenen Werte auf eine

Tabelle I. Gitterkonstanten von Eisen-Nickel-Katalysatoren (in Å)

%, Ni	Gitterkonstante der innenzentrierten Phase	Gitterkonstante der flächenzentrierten Phase	Bemerkungen
0	2.865	—	—
1	2.867	—	—
5	2.867	—	—
10	2.867	—	—
10	2.869	3.587	gesintert
20	2.870	3.587	—
30	2.868	3.578	—
30	2.869	3.587	gesintert

Aufweitung des Eisengitters durch eingebautes Nickel hinweisen. Die Probe mit 10% zeigte nach der Reduktion bei 350° im Röntgenogramm keinerlei Linie von Nickel. Nach dem Sintern bei 450° treten jedoch Nickel-Linien sehr schwach hervor.

Die Probe mit 30% Nickel zeigt diese Effekte nicht. Das Sintern ändert das Intensitätsverhältnis zwischen Eisen- und Nickel-Linien nicht. Eisen sollte in der Lage sein, Nickel bis zu 30% in sein Gitter aufzunehmen unter Erhaltung des kubisch-innenzentrierten Gitters des Alpha-Eisens. Diese Phase soll jedoch metastabil sein und sich in die kubisch-flächenzentrierte Struktur umwandeln.[3] Die neben den Eisenlinien in den Röntgenogrammen gefundenen Nickel-Linien zeigen nun interessanterweise eine Gitterkonstante, die erheblich von der des reinen Nickels abweicht. Sie ergibt sich bei allen Diagrammen zu 3.587 Å (bzw. in unbeträchtlicher Abweichung zu 3.587 Å) gegen 3.525 Å für reines Nickel. Für Gamma-Eisen bei Zimmertemperatur wird als Gitterkonstante 3.567 Å angegeben, woraus folgt, dass das Eisen in dieser Phase mehr Raum beansprucht als Nickel. Die gefundene Aufweitung deutet also darauf hin, dass ein Teil des Eisens auch in flächenzentrierter Phase vorliegt. Damit erklärt sich das Erscheinen von Nickel-Linien nach dem Sintern des 10% Nickel enthaltenden Katalysators als eine Ausscheidung der kubisch-flächenzentrierten Eisen-Nickel-Phase beim Sintern. Die beobachtete zusätzliche Aufweitung des Eisen-Gitters beim Sintern ist dann allerdings nicht erklärlich. Jedoch liegt diese Aufweitung innerhalb der Fehlergrenze.

Machen die vorliegenden Befunde bereits wahrscheinlich, dass in der oxidischen Phase Mischkristalle zwischen $NiFe_3O_4$ und Fe_3O_4 vorlagen, so wird dies durch die Röntgenogramme der oxidischen Katalysatoren bestätigt. Die Literaturwerte für $NiFe_2O_4$ und Fe_3O_4 sind 8.377 bzw. 8.407 Å. Unsere Messungen ergaben für den 10% Nickel enthaltenden oxidischen Katalysator 8.384 Å, für den mit 20% Nickel 8.382 und 8.386 Å (aus zwei verschiedenen Diagrammen) und für den mit

1) R. Brill und S. Tauster, *Ber. d. Bunsen Ges. f. phys. Chemie,* **67**, 390 (1963).
2) A. Ozaki, H. S. Taylor und M. Boudart, *Proc. Roy. Soc.,* **258**, 47 (1960).
3) R. E. Cech, *J. Metals, N. Y.,* **8**, 585 (1956).

30% Nickel 8.373 Å. Der letztere kommt der Zusammensetzung des reinen Spinells $NiFe_2O_4$ mit 34.4% Nickel sehr nahe.

Die röntgenographischen Untersuchungen zeigen also, dass im Falle des Nickels zwar die Verteilung dieses Elements im Eisen durch Mischkristallbildung in der Oxidphase bewirkt wird, dass jedoch eine Entmischung im festen Zustand stattfindet, wobei sich ein Teil des Nickel in Form der wahrscheinlich mit Eisen gesättigten Gamma-Phase ausscheidet. Die Vergleichsaufnahme einer mechanischen Mischung von Carbonyleisenpulver mit Carbonylnickelpulver im Verhältnis 70 : 30 zeigt, dass der grösste Teil des Nickels mit Eisen legiert ist und (im Falle des 30% Nickel enthaltenden Katalysators) nur ein kleiner Teil (höchstens 10%) in Form der Gamma-Phase vorliegt.

Der Versuch, Chrom in gleicher Weise in Eisen einzubauen wie Nickel scheitert an der Tatsache, dass der Spinell Cr_2FeO_4 unter unseren Versuchsbedingungen nicht reduziert wird. Dementsprechend treten in den Diagrammen reduzierter Katalysatoren die Linien dieses Spinells auf. Desgleichen besitzen die mit Chrom-Zusatz hergestellten Katalysatoren eine etwa 10 mal so grosse Oberfläche wie die aus reinem Eisen oder Eisen-Nickel-Legierungen bestehenden. Der Grund dafür liegt darin, dass sich der unreduzierte Spinell in sehr feinverteilter Form während der Reduktion zwischen den Eisenkristalliten ausscheidet und so die Bildung grosser Kriställchen hindert. Genau der gleiche Effekt wird bekanntlich durch den Zusatz von Al_2O_3 bewirkt. Ein kleiner Teil des Chroms könnte indessen im Eisen nach der Reduktion vorhanden sein, weil die Gitterkonstante des Eisens bei einem mit 5% hergestellten Katalysator ein wenig vergrössert ist (2,869 Å).

In gleicher Weise war der Einbau von Kupfer in Eisen in Form einer Legierung röntgenographisch nicht nachweisbar. In oxidischer Form zeigte der Katalysator die Linien des Fe_3O_4 und neben diesen noch andere, die vermutlich von $CuFe_2O_4$ herrühren. Im reduzierten Zustand erschienen bei Zumischung von 20% Kupfer die Linien des Eisens mit normaler Gitterkonstanten und daneben die des Kupfer gleichfalls mit normaler Gitterkonstanten. Da im System Eisen-Kupfer eine Mischungslücke existiert und nur bis etwa 6% Kupfer vom Eisen aufgenommen werden, könnte die durch Bildung dieser Legierung verursachte Vergrösserung der Gitterkonstanten noch gerade im Bereich unserer Fehlergrenze liegen. Jodoch treten bei einem 5% Kupfer enthaltenden Katalysator immer noch die Linien des Kupfer mit normaler Gitterkonstanten auf, so dass im Höchstfalle nur ein sehr geringer Teil des Kupfer mit Eisen legiert vorliegen könnte.

(2) Kinetik.—Die Geschwindigkeitskonstanten der Ammoniak-Synthese wurden mittels der Gleichung:

$$k = \frac{1}{t} \cdot \frac{p_{NH_3,gl}}{p_{N_2}} \times \left\{ \frac{1+a^2}{2} \ln \frac{1+x}{1-x} - a \ln(1-x^2) - a^2 x \right\}$$

ermittelt.[4] Hier ist $p_{NH_3,gl}$, der Gleichgewichtspartialdruck des NH_3, $x = p_{NH_3}/p_{NH_3,gl}$ und a eine temperaturabhängige Konstante, die ausserdem vom Gleichgewichtsdruck des Ammoniaks und vom Partialdruck des Wasserstoffes abhängt. Der letztere kann aber hier, ebenso wie der Stickstoffpartialdruck p_{N_2}, als konstant angesehen werden, weil die Ammoniak-Ausbeuten immer sehr klein waren.

Die Versuchstemperaturen lagen zwischen 225 und 350°C. Die aus der Temperaturabhängigkeit der Geschwindigkeitskonstanten gefundenen Aktivierungsenergien sind in der nachstehenden Tabelle II angeführt.

Tabelle II. Aktivierungsenergien der untersuchten Legierungskatalysatoren

Zusammensetzung des Katalysators	Aktivierungsenergie kcal		Oberfläche m^2/g des Katalysators
	Methode I	Methode II	
Reines Eisen	24.6	23.0	1.55
Eisen + 4% Al_2O_3	22.3 23.2	— —	— 28.2
Fe + 0.1% Ni	—	23.9	—
Fe + 1% Ni	23.9	26.3	—
Fe + 5% Ni	23.5	20.5	1.38
Fe + 10% Ni	17.1	—	—
Fe + 30% Ni	17.5	—	2.3
Fe + 0.1% Cr	—	22.3	—
Fe + 1% Cr	—	18.0	13.5
Fe + 5% Cr	23.4 24.2	21.1	13.5
Fe + 0.1% Cu	—	24.3	—
Fe + 1% Cu	—	19.9	—

Die Messwerte nach Methode I sind die zuverlässigeren. Eine Beeinflussung der Aktivierungsenergie ist nur beim Zusatz von Nickel mit hinreichender Sicherheit zu beobachten und dort auch nur bei den höheren Konzentrationen. Man könnte denken, dass die gefundene Erniedrigung mit dem Auftreten der Gamma-Phase bei diesen Zusammensetzungen verknüpft ist, weil der Frequenzfaktor der Arrhenius-Gleichung bei diesen Katalysatoren um einen Faktor von fast 10^3 kleiner ist. Die Ausbeuten, die mit diesen Katalysatoren erreicht werden, waren daher nicht grösser, als die von niedriger legierten oder unlegierten Kontakten (S. Tabelle III).

4) R. Brill und S. Tauster (1. c.), sowie R. Krabetz und Cl. Peters, *Ber. Bunsen Ges.*, **67**, 381 (1963).

Tablle III Verhältnis der Bildungsgeschwindigkeiten von Ammoniak an dem 30% Nickel enthaltenden zu dem 5% Nickel enthaltenden Katalysator pro Oberflächeneinheit unter gleichen Bedingungen für verschiedene Temperaturen

Temp., °C	Verhältnis der Bildungsgeschwindigkeit
200	1.02
300	0.38
400	0.18

Jedoch müsste dann zusätzlich angenommen werden, dass die Alpha-Phase in diesem Falle inaktiv ist. Einen gewissen Hinweis auf die zunehmende Desaktivierung der Alpha-Phase mit zunehmendem Nickel-Gehalt zeigen allerdings die Frequenzfaktoren der Arrhenius-Gleichung, die mit zunehmendem Nickel-Gehalt abnehmen, wie Tabelle IV zeigt:

Tabelle IV. Aktivierungsenergie und Frequenzfaktor von Eisen-Nickel-Katalysatoren im Vergeich zum Eisen

Katalysator	Aktivierungsenergie	Frequenzfaktor
Fe	24.6	2.4×10^{8}
Fe Ni (1%)	23.9	7.8×10^{7}
Fe Ni (5%)	23.5	3.8×10^{7}
Fe Ni (10%)	17.1	0.9×10^{5}
Fe Ni (30%)	17.5	1.3×10^{5}

Die Tabelle zeigt weiterhin, dass der Frequenzfaktor bei den hohen Nickel-Gehalten (10 und 30%) mit zunehmender Menge der Gamma-Phase wieder zunimmt. Eine endgültige Entscheidung können erst weitere Versuche ergeben.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1681—1683 (1966)

The Dipole Moments of the Oligomer of Ethylenediamine

By Ko KIMURA, Yoshio TOSHIYASU and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received November 29, 1965)

The dipole moments of ethylenediamine ($N=1$), diethylenetriamine ($N=2$), triethylenetetramine ($N=3$), and tetraethylenepentamine ($N=4$) were measured in a benzene solution at 25°C and 45°C. The observed dipole moments of $N=1$, $N=2$, $N=3$, and $N=4$ are 1.89 D, 2.22 D, 2.37 D, and 2.56 D respectively at 25°C, and 1.84 D, 2.22 D, 2.36 D, and 2.58 D respectively at 45°C. The dipole moments were theoretically calculated on the assumptions that; (i) the dipole moments of these chain molecules are given by the vector sum of the dipole moments of the polar groups of amine, and (ii) all internal rotations about single bonds are free. The calculated values of $N=1$, $N=2$, $N=3$, and $N=4$ are 1.84 D, 2.15 D, 2.43 D, and 2.68 D respectively. The agreement between the observed values and the calculated values is satisfactory. It may, therefore, be expected that the molecular chains will be in the random coil state. The intramolecular hydrogen-bonding is very weak, as there is no temperature dependence of the observed dipole moments.

The study of the electric dipole moments of the oligomer of ethylenediamine in solutions is important from the point of view of thermodynamic property of solutions as well as from that of the molecular structure. The dipole moments of oligomers such as those of ethylene glycol and oxymethylene have been measured and discussed by some authors[1] in terms of their molecular structures. This paper will present a similar study of the dipole moments of ethylenediamine, diethylenetriamine, triethylenetetramine, and tetraethylenepentamine in a benzene solution, and will give some information about the molecular configurations in solutions. Unfortunately, this oligomer is not dissolved in any nonpolar solvent other than benzene. The temperature dependence of dipole moments will be discussed in connection with the intramolecular hydrogen bond.

Experimental

The oligomer (a product of the Tokyo Kasei Chemicals Co., Ltd.) was dried over fresh sodium and distilled several times under a nitrogen atmosphere. The benzene was purified by shaking it with concentrated sulfuric acid, dried over phosphorus pentoxide, and distilled through a 100-cm. column packed with stainless steel helices.

The measurements of the dielectric constants, ε, and the specific volumes, v, were carried out with an apparatus devised by Le Fevre and his collaborators.[2]

Results

The observed values of ε and v are expressed by equations linear in solute concentrations; they and the w values (the weight fraction of solutes) are summarized in Table I. The range of w values used in the present measurements ranged up to about 0.025. Measurements were carried out at 25°C and 45°C. The calculation of the molecular polarizations, P, from these experimental data was performed according to the standard method.[3] Molecular refractions, R_D, for the sodium D line were calculated on the assumption of the additivity of bond refractions, and distortion polarizations were assumed to be equal to $1.05\times R_D$. The polarization values and the observed dipole moments, μ, are tabulated in Table II, together with the theoretically-calculated dipole moments, which will be discussed in the next section.

Discussion

The dipole moment of a chain molecule (N-mer), consisting of $(n+1)$ polar units, is given by:

$$\vec{\mu} = \sum_{i=0}^{n}\vec{\mu}_{3i} = \vec{\mu}_0 + \sum_{k=1}^{n-1}\vec{\mu}_{3k} + \vec{\mu}_{3n} \qquad (1)$$

where $\vec{\mu}_{3i}$ is the dipole moment of amine, and the suffix "$3i$" indicates the location of a dipole in the chain schematically shown in Fig. 1. The

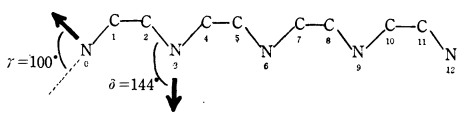

Fig. 1. Numbering of a chain of tetraethylenepentamine.

end groups of $\vec{\mu}_0$ and $\vec{\mu}_{3n}$ are primary amine. Its group moment is assumed to be 1.30 D.[4] This moment lies in the bisecting plane of the H–N–H valence angle, and it is directed along an arrow which makes an obtuse angle, $\gamma=100°$, with the $\vec{CN}$ bond, as is shown in Fig. 1. In the middle part of a chain, there is secondary amine. Its group moment is assumed to be 1.10 D.[4] This moment lies in the bisecting plane of the C–N–C valence angle, and it is directed along an arrow which makes obtuse angles, $\delta=144°$ with the $\vec{NC}$ bond and $\delta=146°$ with the $\vec{NH}$ bond of secondary amine, as is also shown in Fig. 1. The average value of μ^2 over all the angles of internal rotation is given by:

$$\overline{\mu^2} = \mu_0^2 + \sum_{k=1}^{n-1}\mu_{3k}^2 + \mu_{3n}^2 + 2(\overline{\vec{\mu}_0\cdot\vec{\mu}_{3n}}) + 2\sum_{k=1}^{n-1}(\overline{\vec{\mu}_0\cdot\vec{\mu}_{3k}}) + 2\sum_{k=1}^{n-1}(\overline{\vec{\mu}_{3k}\cdot\vec{\mu}_{3n}}) + 2\sum_{\substack{k,k'=1\\k<k'}}^{n-1}(\overline{\vec{\mu}_{3k}\cdot\vec{\mu}_{3k'}}). \qquad (2)$$

In order to calculate the fourth term in the right hand side of Eq. 2, two vectors, $\vec{\mu}_0$ and $\vec{\mu}_{3n}$ must be expressed with reference to the same coordinate system. This procedure has been used by many authors.[5] The x axis is chosen in the direction of each bond axis of a chain. For example, the coordinate system (x_2, y_2, z_2) of the C_2 origin is fixed as follows: the x_2 axis is taken in the direction of the $\vec{C_2N_3}$ vector, the z_2 axis is directed along the

vector product of $\overrightarrow{C_2N_3}$ and $\overrightarrow{C_1C_2}$, and the y_2 axis is determined by the x_2 axis and z_2 axis in order that the three axes may constitute a right-handed coordinate system. The same procedure is taken for the coordinate system (x_1, y_1, z_1) of the C_1 origin. The transformation of (x_2, y_2, z_2) to (x_1, y_1, z_1) is easily carried out by the help of the following transformation matrix, $\boldsymbol{T}_{12}$:

$$\boldsymbol{T}_{12} = \begin{pmatrix} \cos\omega & \sin\omega & 0 \\ -\sin\omega\cos\varphi_1 & \cos\omega\cos\varphi_1 & -\sin\varphi_1 \\ -\sin\omega\sin\varphi_1 & \cos\omega\sin\varphi_1 & \cos\varphi_1 \end{pmatrix}$$

where the valence angles $(\pi-\omega)$ are assumed to be tetrahedral about nitrogen atoms of amine as well as carbon atoms, and where φ_1 is an angle of the internal rotation about the C_1—C_2 bond (or an angle between the z_1 axis and the z_2 axis). Then the transformation of (x_2, y_2, z_2) to (x_0, y_0, z_0) is performed by the successive operation of $\boldsymbol{T}_{01}$ on $\boldsymbol{T}_{12}$. For example, the two vectors of $\vec{\mu}_0$ and $\vec{\mu}_3$ for $N=1$ are thus represented by the (x_0, y_0, z_0) coordinate system. If all the internal rotations are free, the average value of the scalar product $(\vec{\mu}_0\cdot\vec{\mu}_3)$ becomes independent of both φ_0 and φ_1, and is given by:

$$\cos^2\omega\cos^2\gamma\,\mu_0\mu_3 \qquad (4)$$

for $N=1$. The same procedure is applied to $N\geqq 2$. The calculated result may be summarized as follows:

$$\overline{\mu^2} = 2\mu^2_p(1-\xi^2\lambda^2) \quad \text{for} \quad N=1,$$

$$\overline{\mu^2} = 2\mu^2_p(1-\xi^2\lambda^5)+\mu^2_s+2\mu_p\mu_s\xi\eta(\lambda^2-\lambda^3) \quad \text{for} \quad N=2,$$

$$\overline{\mu^2} = 2\mu^2_p(1-\xi^2\lambda^{3N-1}) + \mu^2_s\left[N-1+\frac{2\eta^2\lambda^3}{1-\lambda^3}\left\{N-2-\frac{\lambda^3(1-\lambda^{3N-6})}{1-\lambda^3}\right\}\right] + 2\mu_p\mu_s\xi\eta(\lambda^2-\lambda^3)\frac{1-\lambda^{3N-3}}{1-\lambda^3} \quad \text{for} \quad N\geqq 3, \qquad (5)$$

where μ_p and μ_s are 1.30 D and 1.10 D respectively, and λ, ξ, and η are $\cos\omega$, $\cos\gamma$, and $\cos\delta$ respectively. The calculated dipole moments for $N=1$, $N=2$, $N=3$, and $N=4$ are 1.84 D, 2.15 D, 2.43 D, and 2.68 D respectively. The agreement between the calculated dipole moments and the observed ones is satisfactory in view of the model used in the above calculation. Strictly speaking, the effect of the excluded volume on dipole moments must be taken into consideration, but this effect may make only a minor contribution to dipole moments for such short chains as those considered here. It may, therefore, be inferred that the oligomer of ethylenediamine in a benzene solution is in the random coil state. This is also supported by the fact that the observed dipole moments do not show any temperature dependence. This suggests that the intramolecular hydrogen-bonding is very weak or that it does not occur at all in this case.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1683—1689 (1966)

The Catalytic Hydrogen Exchange of Aniline on Supported Metal Catalysts[1)]

By Hiroshi HAGIWARA* and Etsuro ECHIGOYA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 7, 1965)

The hydrogen exchange reaction of aniline with deuterium was investigated on supported nickel, cobalt and platinum. The following results were obtained: 1) At 150°C, the hydrogen of the amino group of aniline exchanges at a higher velocity than the hydrogen attached to the benzene ring. At temperatures as high as 300°C, the hydrogen exchange in the benzene ring increases further. 2) The suggested hydrogenation mechanism obtained from the results of the exchange reaction can not be correlated with that obtained from the kinetic study. 3) The catalytic activity for the exchange reaction in the benzene ring is in the order Pt>Co>Ni. 4) The basic oxide support seems to suppress the adsorption of the amino group. 5) The relationship between the adsorption state of the aniline on the catalyst surface and the various reaction products, such as cyclohexylamine, benzene and dicyclohexylamine, has been well established.

1) Presented in part at the 17th Discussion Meeting on Catalysis of the Catalysis Society of Japan, Tokyo, October, 1965.

In experiments previously reported by the present authors,[2] it was observed that the hydrogenation of aniline to cyclohexylamine and to the secondary amines occurred in the temperature range from 150 to 250°C while the fission of the carbon-nitrogen bond (the hydrogenolysis) of aniline took place at temperatures above 250°C.

In order to understand this change in reactivity, it would be useful to know the adsorption state of the aniline molecule on the metal catalysts. Many reports have been published with respect to the metal-catalyzed exchange between aniline and deuterium oxide,[3-5] but few regarding the relationship between reactivities and the adsorption state. The aim of the present experiments was to investigate the catalytic activity of various kinds of catalyst in the hydrogen exchange reaction of aniline with deuterium, and then to deduce the relationship between reactivities and the adsorption state.

Experimental

Material.—Deuterium oxide obtained from the Showa Denko Co. (99.75% D_2O) was used without any additional purification. Deuterium was obtained from the electrolysis of deuterium oxide containing 20% sodium deuteroxide. The electrode was a nickel plate (see Fig. 1). Aniline (technical grade) was shaken with zinc powder and then purified by fractional distillation. The catalysts were prepared by the impregnation method.[6] Powdered support was added to a solution of metal nitrate. The slurry was stirred for some time, and then to it there was slowly added, at 20°C, a water solution of ammonium carbonate in a slight excess. After the precipitate had been filtered and washed, it was dried at 100°C and then calcined at 450°C for 2 hr.

Procedure.—*The Experimental Method of the Hydrogenation of Aniline and Benzene.*—The hydrogenation experiments were perforemed in a fixed-bed apparatus of the flow type. The products were analyzed by gas chromatography.

The Experimental Method of the Hydrogen Exchange of Aniline with Deuterium Oxide.—The metal catalyst was reduced by hydrogen inside the reaction tube, into which aniline and deuterium oxide were then introduced by distillation from their respective vessels.[7] The tube was kept at the reaction temperature in a thermostatic bath. After the reaction, both aniline and deuterium oxide were separated from the catalyst by distillation, and condensed in a cold trap. The aniline layer was treated with an amount of water about 20 times its volume in order to transform all the N-D bonds to N-H bonds. The aniline layer was then extracted with benzene, and the mixture of benzene and aniline was dehydrated by anhydrous sodium sulfate and separated by the gas chromatographic technique.

The Experimental Method of the Hydrogen Exchange of Aniline with Deuterium.—Figure 1 shows the flow diagram.[8] A mixture of aniline vapor and deuterium was introduced into a fixed-bed reactor. The reaction temperature was maintained by external electric heating. The gaseous products leaving the reaction zone were caught in a dry ice-and-methanol-cooled trap, from which condensates were drawn for the gas chromatographic analysis. The oxide catalysts were placed in the same fixed-bed apparatus used for the reaction, and reduced to the metal by a flow of hydrogen at the rate of 50 cc./min.* After the reduction procedure, the catalyst was cooled in a deuterium stream to the reaction temperature, and then a run of the hydrogenation of aniline with deuterium was carried out.

The Analysis of the Products.—The infrared, mass-spectroscopic and NMR methods were used. In addition, in order to determine the distribution of the deuterium in the aromatic nucleus, the aniline hydrobromide and the brominated derivatives of aniline (*p*-bromoacetanilide and 2, 4, 6-tribromoaniline) were prepared, and the percent-distribution of deuterium in the ring was determined by the calculation of the

$$D_{meta} = \frac{\text{peak height of the 2, 4, 6-tribromoaniline}}{\text{peak height of the aniline hydrobromide}} \times 100$$

$$D_{para} = \frac{\left(\text{peak height of the } p\text{-bromoacetanilide} - \text{peak height of 2, 4, 6-tribromoaniline}\right)}{\text{peak height of the aniline hydrobromide}} \times 100$$

Results

The Catalyst Activity in the Hydrogenation of Aniline and Benzene.—The results of the activity test for the hydrogenation reaction are presented in Figs. 2, 3 and 4.

From these data, it can be concluded that:

1) For the nickel-magnesia catalyst, the hydrogenation reaction occurred above 120°C. for aniline, while benzene was hydrogenated at lower temperatures.

2) The platinum catalyst showed the same tendency in acting in the hydrogenation of aniline and benzene. With both catalysts, under the same reaction conditions, the rate of the hydrogenation of benzene was higher than that of the hydrogenation of aniline.

3) The hydrogenation of benzene on nickel or on the platinum catalyst was inhibited by the presence of aniline or cyclohexylamine.

4) The hydrogenolysis of cyclohexylamine on the platinum catalyst yielded benzene rather than cyclohexane at 170—200°C.

of highly-deuterated aniline in the case of the platinum catalyst indicates that all the hydrogen molecules in aniline are exchangable.

The Exchange Reaction of Aniline with Deuterium.—The data on the activities of all the catalysts used are summarized in Table II. From Table II, the following conclusions may be drawn:

1) At 150°C, the exchange in the amino group predomoninated in the deuteration of aniline. These results can perhaps be accounted for by assuming that the aniline molecule is anchored to the catalyst through the electron pair of the nitrogen.

2) At 300°C, the amount of the exchange of hydrogen-deuterium had further progressed, and the d_3- and d_4- species increased in proportion. At temperatures as high at 300°C, the exchange in the benzene ring of aniline was found to occur at the ortho, para and meta positions.

3) The difference in the catalytic activities of nickel, cobalt and platinum were shown by the amounts of d_3- and d_4-species produced. The order of d_3- and d_4-species production capacity was platinum>cobalt>nickel (see also Figs. 8 and 9).

4) No definite difference in activity between nickel-magnesia and nickel-alumina catalysts was observed. However, the proportion of the d_3- and d_4-species increased when nickel-magnesia was used.

Discussion

In order to discuss the adsorption state of aniline on the surface of the catalyst on the basis of the experimental results, it is neccessary to check the partial pressure of deuterium in the reaction atmosphere. An evaluation of the fraction of deuterium in the reactant gases shows that the pressure of deuterium is predominant compared with that of hydrogen; thus it may be reasonable to assume that all the exchange occurring takes place through the adsorption of aniline on the surface of the catalyst with deuterium under the adsorption equilibrium conditions. The results show that, at 150°C the amino group strongly interacts with the metal surface. The formation of the strong nitrogen-metal bond may be considered to play an important role in the production of secondary amines (dicyclohexylamine and phenylcyclohexylamine). The experimental results of the hydrogen exchange reaction at 150°C cannot, however, account for the ring hydrogenation of aniline established by the kinetic study: a) judging from the results obtained by the hydrogen exchange reaction, it seems that the ring-hydrogenation of aniline proceeds via a step-by-step addition of adsorbed hydrogen atoms to the benzene nucleus of the adsorbed aniline but, b) judging from the kinetic study of the hydrogenation reaction, the ring hydrogenation proceeds via the addition of adsorbed hydrogen molecules to the benzene nucleus of the adsorbed aniline. This apparent contradiction seems to indicate that the hydrogenation reaction and the hydrogen exchange reaction proceed via different courses.

At temperatures as high as 300°C, the formation of the ring-metal bond or the formation of some dehydrogenated complex such as $C_6H_xNH_y$ on the surface (for instance, $C_6H_{11}NH_2 \rightarrow C_6H_xNH_y + (13\text{-}x\text{-}y)H$) was thought to take place.

The stronger the adsorption, the smaller the $(x+y)$ value will be. Hence the fission of the C–N bond will result. According to our experiments, the basic oxide support brought about a weak adsorption of amine, this effect will probably lead to the efficient hydrogenation of the ring, as was the case in the hydrogenation of ethylene on nickel.[9] Reference should be made here to the work by Morikawa et al.,[10] who found, studying the hydrogenolysis of ethane on nickel with or without added alkali oxides, that the addition of an alkali oxide to nickel causes the suppression of the stripping of hydrogen from the hydrocarbon. In the hydrogenolysis of cyclohexylamine over platinum-alumina between 170 and 200°C, the hydrocarbon product was mostly benzene, plus a little cyclohexane. It is thought that, before decomposing, some of the adsorbed cyclohexylamine loses hydrogen atoms from the ring. Hydrogenolysis then leads to benzene. This mechanism seems reasonable from the standpoint of chemical thermodynamic calculation. That is, in the following equations, the course of Eq. 2 is important.

(2)

Summary

The hydrogen exchange reaction of aniline with deuterium has been investigated on the supported nickel, cobalt and platinum. The following results have been obtained:

1) At 150°C, the hydrogen of the amino group of aniline exchanges more easily than the hydrogen in the benzene ring. At temperatures as high as 300°C, the exchange in the benzene ring progresses further.

2) The suggested hydrogenation mechanism obtained from the results of the exchange reaction could not be correlated with that of the kinetic study.

3) The catalytic activity for the exchange reaction in the benzene ring was in the order platinum>cobalt>nickel.

9) S. T. Thomson and J. L. Wishlade, *Trans. Faraday Soc.*, **58**, 1170 (1962).

10) K. Morikawa, A. Ozaki and F. Nozaki, *Shokubai (Catalyst)*, **4**, 8 (1962).

4) The effect of basic oxide support seems to suppress the adsorption of the amino group.

5) The adsorption state of aniline on the catalyst surface is correlated with the variety in reactivity.

The authors wish to thank Professor Kiyoshi Morikawa for his useful discussion and guidance. Thanks are also due to Mr. Haruyoshi Sakurai for his kind assistance in the mass spectrum analyses.

Theoretical Studies of the Use of the Double Extrapolation Method to Determine the Forward Scattering of Light by Spherical Colloidal Particles

By Masayuki NAKAGAKI

Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto

(Received December 16, 1965)

An application of the double extrapolation method (the Zimm-plot method) for the reduced intensity of light scattered by colloidal dispersions, instead of polymer solutions, is discussed theoretically on the basis of the Mie theory. The correction factor, F, required to recalculate the experimental value of the molecular weight, M_R, to the true value, M ($M=FM_R$), is equal to unity in the case of the Rayleigh scattering ($\alpha\to 0$) and the Rayleigh-Gans-Debye (R-G-D) scattering ($|m-1|\to 0$, where m is the relative refractive index of the sphere to the medium). Usually, however, the value of F is not equal to unity, but is found to be given by an empirical equation, $F=1-0.155\ Q+bQ^{1.5}$, where Q is a quantity proportional to the reduced specific scattering intensity at $\theta\to 0$. For the determination of the radius of gyration from the "initial slope," the R-G-D equation is applicable even in cases where $|m-1|$ is not small. In order to determine the true molecular weight from the molecular weight, M_τ, obtained from the specific turbidity at the infinite dilution, the factor Φ is needed ($M=\Phi M_\tau$). The factor Φ is considered to be a product; that is, $\Phi=F\varphi$, where the factor φ seems to be independent of the m value. The empirical equation obtained was $\varphi=1+0.537\ \alpha^{2.08}$

In the studies of the light scattering of polymer solutions, a double extrapolation method, the so-called Zimm-plot method, is used extensively in order to determine the molecular weight, the radius of gyration, and so forth, according to the Debye theory. The method gives the molecular weight from the scattered light intensity doubly extrapolated to the forward direction ($\theta\to 0$) and to an infinite dilution ($c\to 0$). However, the application of the double extrapolation method to colloidal dispersions is justified only when the light scattering of the systems can be treated according to either the Rayleigh theory ($\alpha\to 0$) or the Rayleigh-Gans-Debye (to be abbreviated as R-G-D) theory ($|m-1|\to 0$). The method must not be applied, without corrections, to the colloidal systems for which neither $\alpha\to 0$ nor $|m-1|\to 0$ holds.

In the present paper,[1] the values of the correction factors to be used for colorless colloidal spheres are calculated according to the Mie theory, since the author believes that the application of the double extrapolation method in the studies of colloidal dispersions is useful because, first, the use of the scattered light intensity in the forward direction ($\theta\to 0$) has the theoretical advantage that maxima and minima on the curve of the scattered light intensity vs. the particle radius occur less frequently in the forward direction than in any other direction,[2] and because, second, it is convenient to use the experimental technique which is used so extensively in the studies of the polymer solutions.

Double Extrapolation Method.—The double extrapolation method is usually based on the following equation, derived by Debye[3] and modified by Zimm[4]:

$$Kc/R_u(\theta) = 1/MP(x) + 2A_2c \qquad (1)$$

where c is the concentration; $P(x)$ is the interference factor; M is the molecular weight of the polymer

1) Presented at the 18 th Annual Meeting of the Chemical Society of Japan, Kansai University, Osaka, April, 1965.

2) W. Heller, M. Nakagaki and M. L. Wallach, *J. Chem. Phys.*, **30**, 444 (1959).

3) P. Debye, *J. Appl. Phys.*, **15**, 338 (1944).

4) B. H. Zimm, *J. Chem. Phys.*, **16**, 1093 (1948).

or the colloid particle; A_2 is the second virial coefficient, and $R_u(\theta)$ is the reduced scattering intensity for unpolarized incident light;

$$R_u(\theta) = (r^2 I_u/I_0)/(1 + \cos^2\theta) \quad (2)$$

and K is a constant defined by:

$$K = (2\pi^2/N_A\lambda^4\mu_1^2)(\mathrm{d}\mu_{12}/\mathrm{d}c)^2 \quad (3)$$

Here $(r^2 I_u/I_0)$ is the Rayleigh ratio, r is the photometric distance; I_0 is the intensity of the incident light; I_u is the intensity of the scattered light at the scattering angle, θ; N_A is the Avogadro number; μ_{12} is the refractive index of the solution or dispersion, and λ is the wavelength of light in the medium, which is related to the wavelength in the vacuum, λ_0, and the refractive index of the medium, μ_1, according to the relation:

$$\lambda = \lambda_0/\mu_1 \quad (4)$$

In the double extrapolation method named the Zimm-plot method, the value of $Kc/R_u(\theta)$ is taken on the ordinate and the value of $\sin^2(\theta/2)+kc$ is taken on the abscissa, where k is an arbitrary constant. The data are extrapolated to an infinite dilution, and a curve for $c\to 0$ is drawn. This curve corresponds to the equation:

$$Kc/R_u(\theta) = 1/MP(x) \quad (5)$$

where x is defined by the equations:

$$x = 2\alpha \sin(\theta/2) \quad (6)$$

and

$$\alpha = 2\pi a/\lambda \quad (7)$$

Here, a is the radius of a spherical colloidal particle. A further extrapolation to $\theta\to 0$ yields an apparent value of molecular weight, M_R, according to the equation:

$$Kc/R_u(0) = 1/M_R \quad (8)$$

The value of M_R is, in general, not equal to the molecular weight, M. The factor F is, therefore, required in order to obtain the value of M from the value of M_R:

$$M = F \cdot M_R \quad (9)$$

If Eq. 5 is used,

$$F = 1/P(0) = MKc/R_u(0) \quad (10)$$

where $P(0)$ is the value of $P(x)$ at $x\to 0$ or $\theta\to 0$.

Theoretical Value of the Factor F.—The reduced scattering intensity for unpolarized incident light is given theoretically by the following equation:

$$R_u(\theta) = (\lambda^2/8\pi^2)Ni_T(\theta)/(1 + \cos^2\theta) \quad (11)$$

where N is the number of particles per unit of volume and where:

$$i_T(\theta) = 2i_u(\theta) = 2(4\pi^2/\lambda^2)(r^2 I_u/I_0)/N \quad (12)$$

The numerical value of $i_T(\theta)$ calculated according to the Mie theory[5] has been given by Pangonis and Heller[6] for colorless spherical particles. In order to calculate the value of K according to Eq. 3, the value of $(\mathrm{d}\mu_{12}/\mathrm{d}c)$ is required. The latter can be expressed by the equation:

$$\mathrm{d}\mu_{12}/\mathrm{d}c = (m' - 1)\mu_1/\rho_2 \quad (13)$$

where ρ_2 is the density of the particles and m' is the apparent relative refractive index. The theoretical values of m' calculated for colorless spherical particles according to the Mie theory have been given by Nakagaki and Heller.[7] Using these values, together with the equations:

$$c = (\lambda^3/6\pi^2)\rho_2 N\alpha^3 \quad (14)$$

$$M = (\lambda^3/6\pi^2)\rho_2 N_A\alpha^3 \quad (15)$$

Eq. 10 can be rewritten as:

$$F = (8/9)(m' - 1)^2\alpha^6/i_T(0) \quad (16)$$

In the case of the Rayleigh scattering,

$$F = 1 \quad (\alpha\to 0) \quad (17a)$$

is obtained from Eq. 16, because

$$i_T(0) = 2i_u(0) = 2[(m^2-1)/(m^2+2)]^2\alpha^6 \quad (17b)$$

and[7]

$$m' - 1 = (3/2)(m^2 - 1)/(m^2 + 2) \quad (17c)$$

where m is the relative refractive index of the sphere to the medium.

In the case of the R-G-D scattering, the intensity of the scattered light is equal to the Rayleigh value multiplied by $P(x)$, where:

$$P(x) = 9(\sin x - x\cos x)^2/x^6 \quad \text{(R-G-D)} \quad (18)$$

Since $P(0)=1$, the value of F given by Eq. 10 is:

$$F = 1 \quad (|m - 1| \to 0) \quad (19)$$

Therefore, the apparent molecular weight, M_R, obtained by the double extrapolation method[8] is equal to the true molecular weight, M, if either $\alpha\to 0$ or $|m-1|\to 0$ holds.

The theoretically calculated values of F for general cases ($\alpha \neq 0$ and $m \neq 1$) are shown in Fig. 1, where the quantity, Q, taken on the abscissa is a quantity proportional to the reduced specific scattering, $R_u(\theta)/c$, at $\theta\to 0$; that is:

$$Q = (8\lambda\rho_2/3)R_u(0)/c \quad (20)$$

Here the proportionality factor $(8\lambda\rho_2/3)$ is a constant for a given particle and a given wavelength. Therefore, the value of Q can be obtained

7) M. Nakagaki and W. Heller, *J. Appl. Phys.*, **27**, 975 (1956).

8) In the case of the random coil of high polymer molecules, it may also be concluded that $F=1$ and $M_R=M$, because $P(0)=1$ if the segments are considered to be Rayleigh spheres, where $P(x)=(2/x^4)[\exp(-x^2)-(1-x^2)]$.

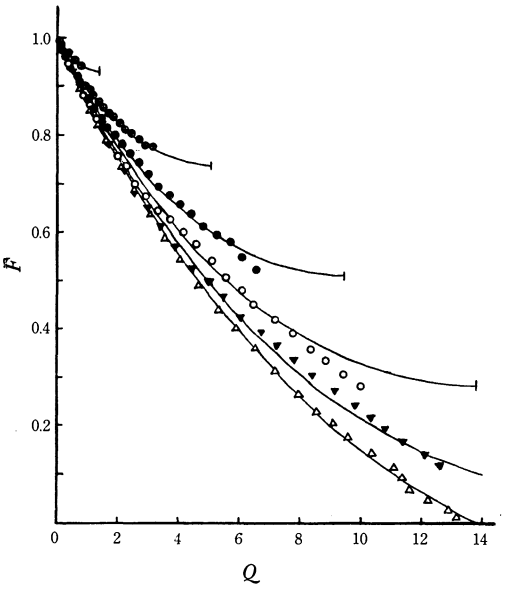

Fig. 1. Relation between F and Q.
$m=1.05$ (⊗), 1.10 (⊕), 1.15 (●), 1.20 (○), 1.25 (▼), and 1.30 (△)

experimentally. On the other hand, the theoretical value of Q is;

$$Q = i_T/\alpha^3 \tag{21}$$

It may be seen from Fig. 1 that an appreciable error will be introduced if the correction factor, F, is not used.

An empirical equation to find the value of F from the experimental value of Q was looked for. The equation obtained is:

$$F = 1 - 0.155\,Q + bQ^{1.5} \tag{22}$$

where;

$$b = 0.0115 + 0.00310(m - 1.01) \tag{23}$$

The solid lines of Fig. 1 show the values obtained from these empirical equations. The equations cannot be used, however, when Q is greater than Q^*;

$$Q^* = 0.01068/b^2 \tag{24}$$

The values of Q^* are shown in Fig. 1 by short vertical lines.

Initial Slope.—The double extrapolation method is used to determine the radius of gyration or the radius of the particles, besides the molecular weight or particle weight. In determining radius, the initial slope of the experimental curves drawn by taking $Kc/R_u(\theta)$ on the ordinate and $\sin^2(\theta/2)$ on the abscissa is used. It is, therefore, necessary to understand thoroughly what the theory will predict about the shape of the curves for spherical colloidal particles. For this purpose, a quantity, ξ, proportional to the $Kc/R_u(\theta)$ is used:

$$\xi = [Kc/R_u(\theta)]/[Kc/R_u(0)] \tag{25}$$

where $kc/R_u(0)$ is constant for a given colloidal system, as has been discussed above. On the other hand, the theoretical values of ξ can be calculated according to the relationship:

$$\xi = [i_T(0)/i_T(\theta)][(1 + \cos^2\theta)/2] \tag{26}$$

The results of the calculation are shown in Fig. 2 for $m=1.20$ and in Fig. 3 for $m=1.30$.

According to Eq. 5, it is obvious that the following equation holds:

$$\xi = P(0)/P(x) = 1/FP(x) \tag{27}$$

Therefore, in the case of the Rayleigh scattering, $\xi=1$, and in the case of the R–G–D scattering:

$$\xi = 1/P(x) = x^6/9(\sin x - x\cos x)^2 \tag{28}$$

In Figs. 2 and 3, the R-G-D values, too, are shown by the solid curves; the broken lines show the initial slope, and the dotted lines show the range of deviation from the R-G-D values. From these figures, it was concluded that the initial slope is

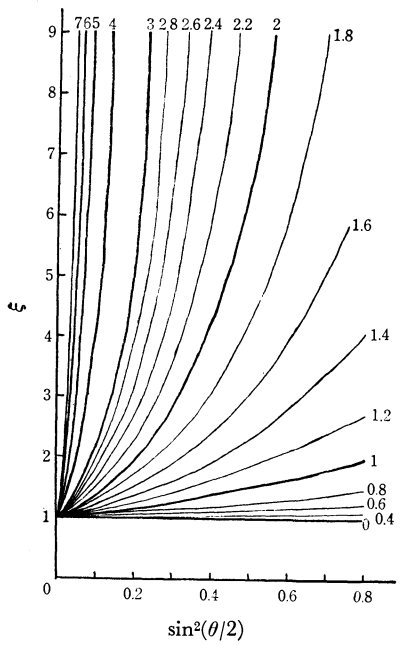

Fig. 4. Relation between ξ and $\sin^2(\theta/2)$ for various α-values.

approximated well enough by the R-G-D equation, irrespective of the values of m and α, if, at least, $m \leq 1.30$, $\alpha \leq 7.0$, and $x \leq 1.0$.

From the experimental point of view, however, it may be worthwhile to point out that the quantity to be taken on the abscissa is not x^2 but $\sin^2(\theta/2)$. This means that the scattering angle to make the value of x small enough is very small when the particle size or α is large, as may readily be understood from Eq. 6. The relation between ξ and $\sin^2(\theta/2)$, instead of x^2, is shown in Fig. 4 for the R-G-D scattering and for various α values. It may be seen that measurements in the range of very small θ values are required for the determination of the "initial" slope when α is large. The measurement of the scattering at such a small angle will be possible after the development of an apparatus which can provide a very narrow incident beam.

Extrapolated Values of Specific Turbidity. —In the studies of polymer solutions, Eq. 1 for the reduced scattering intensity, $R_u(\theta)$, is used exclusively. In the studies of colloidal dispersion, however, the turbidity, τ, may be used instead of the reduced scattering intensity, because the turbidity of the colloidal dispersions is not so small as that of polymer solutions, even in a fairly dilute concentration range.

It is well known historically that Debye's fluctuation theory was, at first, applied to the turbidity, τ, resulting in:

$$Hc/\tau = 1/M_\tau + 2A_2c \tag{29}$$

This equation was, then, rewritten to Eq. 1, by replacing the turbidity with the reduced scattering intensity and H with K, where:

$$H = (16\pi/3)K \tag{30}$$

The latter is an equation justifiable only in the case of the Rayleigh scattering ($\alpha \ll 1$).

If the particles are not so small that the Rayleigh theory does not hold, the molecular weight, M_τ, obtained by Eq. 29, or by the equation:

$$M_\tau = (1/H)(\tau/c)_0 \tag{31}$$

is not equal to the true molecular weight, M. Here, $(\tau/c)_0$ is the specifice turbidity at an infinite dilution. A factor Φ, just like the factor F in Eq. 9, is required to obtain M from M_τ:

$$M = \Phi M_\tau \tag{32}$$

The factor Φ may be considered to be a product of the above-mentioned factor, F, and another factor, φ:

$$\Phi = F\varphi \tag{33}$$

where:

$$\varphi = M_R/M_\tau \tag{34}$$

The theoretical expression of φ is given by:

$$\varphi = (16\pi/3)R_u(0)/\tau = (2/3)i_T(0)/\sum \tag{35}$$

where $\sum$ is a quantity related to the turbidity by the equation:

$$\tau = (\lambda^2/2\pi)N\sum \tag{36}$$

Numerical values of the factor φ can be calculated for colorless spherical particles according to Eq. 35 and by using the numerical values of $\sum$ given by Pangonis, Heller and Jacobson,[9] together with the numerical values of $i_T(0)$ already mentioned.[6] The numerical values of Φ, too, can be calculated according to Eq. 33 by using the values of F obtained above. The resulting Φ values are shown in Fig. 5 as a function of Q_τ. Here, the quantity Q_τ is defined as a quantity proportional to the specific turbidity at the infinite dilution $(\tau/c)_0$ by the following equation;

$$Q_\tau = (\lambda\rho_2/3\pi)(\tau/c)_0 \tag{37}$$

and the theoretical values of Q_τ can be obtained according to the following relation:

$$Q_\tau = \sum/\alpha^3 \tag{38}$$

In the case of the Rayleigh scattering ($\alpha \to 0$ or $Q_\tau \to 0$):

$$\varphi = 1, \quad \Phi = 1 \quad (\alpha \to 0) \tag{39a}$$

are obtained from Eq. 35, since the following equation:

$$\sum = (4/3)[(m^2-1)/(m^2+2)]^2\alpha^6 \tag{39b}$$

holds, besides Eqs. 17a and 17b.

9) W. J. Pangonis, W. Heller and A. Jacobson, "Tables of Light Scattering Functions for Spherical Particles," Wayne State University Press, Detroit (1957).

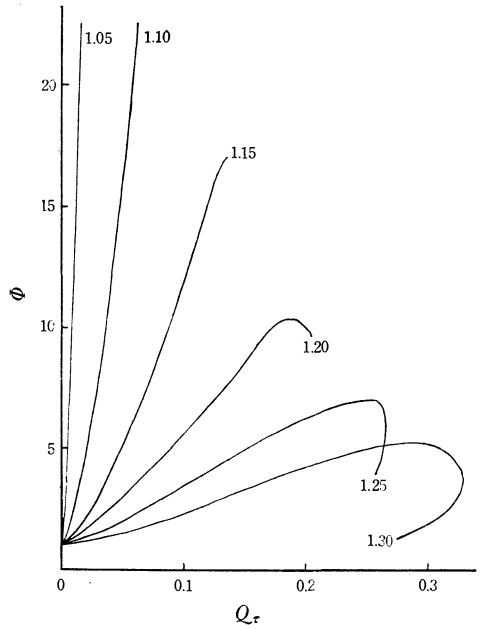

Fig. 5. Relation between Φ and Q_τ for various m-values.

On the other hand, a theoretical equation corresponding to Eq. 5 is also known:

$$Hc/\tau = 1/M\Pi \quad (c\to 0) \tag{40}$$

where Π is given by an integral containing $P(x)$:

$$\Pi = (3/4)\int_0^\pi [(1+\cos^2\theta)/2]P(x)\sin\theta\, d\theta \tag{41}$$

By reference to Eq. 32, it is obvious that:

$$\Pi = 1/\Phi \tag{42}$$

In the case of the Rayleigh scattering, Eq. 39a may be concluded from Eqs. 41 and 42, because $P(x)=1$ in this case.

In the case of the R-G-D scattering ($|m-1|\to 0$), Eq. 41 was solved, together with $P(x)$ of Eq. 18. The result:

$$\begin{aligned}\Pi = (27/64\alpha^4)\{&-7(1-\cos 4\alpha)/8\alpha^2\\ &-(\sin 4\alpha)/2\alpha+5+4\alpha^2\\ &+[(1/\alpha^2)-4][\gamma+\ln 4\alpha-\mathrm{Ci}(4\alpha)]\}\end{aligned} \tag{43}$$

was already known, and its numerical values, too, had been given.[10,11] Therefore, according to Eqs. 19 and 43, it may be concluded that:

$$\Phi = \varphi = 1/\Pi \quad (|m-1|\to 0) \tag{44}$$

When Eq. 44 is drawn on Fig. 5, the curve coincides with the ordinate, because $Q_\tau\to 0$ if $|m-1|\to 0$.

Usually the relation between Φ and Q_τ is expressed by the rather complicated curves shown in Fig. 5. The complication arises because the Φ quantity is a product of F and φ. Since F has already been discussed it is important now to study how simple the relations between φ vs. m and α will be. As the result of the numerical calculations, it is found that the value of φ scarcely depends at all on the m-value, at least in the range of $m\leq$ 1.30 and $\alpha=0.4$—7.0. This empirical conclusion is important, because it also states that the ratio between the reduced scattering intensity in the forward direction ($\theta\to 0$) and the turbidity is independent of the m-value (cf. Eq. 35), and that the forward scattering is, therefore, more important than the scattering at $\theta=90°$, although the latter has been used extensively in various experimental works.

Since the independence of φ from m holds even when $|m-1|\to 0$, the relation between φ and α should be given by:

$$\varphi = 1/\Pi \tag{45}$$

For Π, Eq. 43 is used as a fairly good approximation for various m values (at least for $m\leq$1.30, and very probably for higher m-values also), although this statement has not yet been justified theoretically. Equation 43 is, however, rather complicated. It is, therefore, of some interest to find a simple empirical relation between φ and α. According to Fig. 6, the following one seems to be acceptable:

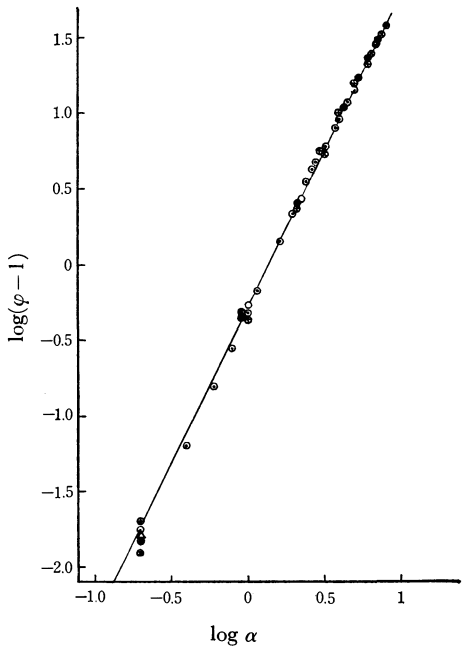

Fig. 6. Relation between $\log(\varphi-1)$ and $\log\alpha$. $m=1.05$ (⊗), 1.10 (⊕), 1.15 (●), 1.20 (○), 1.25 (▼), and 1.30 (△).

$$\varphi = 1+0.537\,\alpha^{2.08} \tag{46}$$

The independence of φ from m is a natural consequence if the relation between ξ and x^2 is independent of m, as has been stated above, although the latter statement might not hold for larger x-values.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1694—1700 (1966)

On the Photochemical Behavior of Some Xanthenes and Xanthones and the Photochemical Formation of Dixanthenes, Mono-, and Dihydroxydixanthenes*

By V. ZANKER and E. EHRHARDT

Institute of Physical Chemistry, Technische Hochschule München

(Received December 20, 1965)

By ultraviolet spectrometric measurements we studied the photochemical behavior of xanthene, xanthone, 9, 9'-dihydroxydixanthene and dixanthene in aerated and deaerated ethanolic solutions in the range of concentration $5 \cdot 10^{-3}$ M to 10^{-4} M by Osram-HBO 200- and Hanau TQ 81- lamps. We found: Xanthenes are photostable similar to monoacridans in the absence of oxygen; in the presence of oxygen photooxidation to the corresponding xanthones takes place. The xanthones are photochemically unstable; in oxygen free solvents containing H-atoms, like methanol, ethanol, benzene, cyclohexane, dioxane, they are reduced to xanthenes. In cyclohexane we found a soluble xanthene, 9-cyclohexylxanthydrol. In hexane there is formed a precipitate with a yield above 80%; this is the dimeric xanthene 9, 9'-dihydroxydixanthene. The photoreaction presumably is going over a diradical, H-atom transfer from the solvent and formation of a xanthydrol monoradical in the primary step and dimerization to the 9, 9'-dihydroxydixanthene. Irradiation of solutions of xanthone and xanthene in benzene furnish 9-hydroxydixanthene. Solutions of equal molarity of xanthone and acridan yield under irradiation also a solid photoproduct; this is 9, 9'-diacridan. The first step of reaction is photoreduction, where xanthene tranfers a H-atom to xanthone and the hydroxyxanthyl radical dimerizes with the xanthyl radical or the acridanyl radical dimerizes with themselves and forms the diacridan.

In connection with studies about the spectroscopy and photochemistry of the acridines and acridine dyes,[1-6] we also began a few years ago, to investgate the photochemical and spectroscopic behavior of the cations and dianions of the fluorescein dyes.[7-11] Decisive and accurate investigations on this photochemical special field were especially carried out by the Japanese researchers Imamura, Koizumi, Kato and others;[12-16] Lindqvist[17] and Grossweiner[18] also contributed by their flash photolytic experiments to the elucidation of the mechanism of photo-reduction respectively oxidation of some substances of this class of dyes.

Our own investigations are still being fully ellaborated, and we hope that we can finish these studies in the next time. Similar to earlier experiments on the acridines,[19] we believe, that we

can analyze the absorption bands of di- and tetrahalide fluoresceins, starting from the parent substances of this dyestuff class and the monohydroxy derivatives. For this purpose we also have synthesized a series of xanthones, xanthenes, xanthydrols, and xanthylium cations and have carried out spectroscopic and photochemical experiments. The absorption spectroscopy and photochemistry of these compounds are very interesting for us, because so far we have had little knowledge about the parent substances of fluorescein and the other dyestuffs. On the other side the photochemical investigation of acridine and acridine cations lead us to the acridans and diacridans.[5,6] Analogously we could hope, to get similar results in the case of the xanthenes and xanthons. The results will be reported here in a short paper.

Experimental

The substances which we have used for our photochemical and spectroscopical investigations as xanthone, xanthene and the dixanthenes were prepared in optical purity by repeated crystallization out of hexane or ethanol. The solutions of a molarity of 10^{-3} to 10^{-4} were used and in most cases they were deoxygenized by repeated boiling and cooling under N_2-gassing. The last traces of oxygen were removed by aluminumtriethyl. The photolytical conversion was controlled spectrometrically by means of a Zeiss PM Q II and we also identified partly in this way the photochemical converted substances.

Results of the Photolytical Investigations and Discussion

As an example for the study of the photochemical behavior of the monoxanthenes we show at first a measurement of xanthene itself on Fig. 1. In the non-illuminated state this compound shows an electronic band with a vibrational structure at 34300 and 35500 cm^{-1}, classified in the terminology given by Platt[20] as a transition to the ^1L_b-state and at 40500 cm^{-1} it shows the transition to ^1L_a-state, mostly unstructured and of a higher intensity. Further to shorter wavelengths, we can see another very intensive band presumably due to the transition to the ^1B_b-state (^1B_b-band). Irradiating an air saturated ethanolic solution by a Mercury lamp HBO 200, an oxidation reaction quickly starts. In this case we see an increase but no decrease of the xanthene bands at 34000 to 35000 cm^{-1}. In the wavelength region longer than that of xanthene a new band appears and increases up to a yield of about 18%. Then this band decreases again and a second new band at 32000 to 33000 cm^{-1} arises. We suppose, that there is formed an intermediate out of xanthene and xanthone, but we have not yet identified this. In

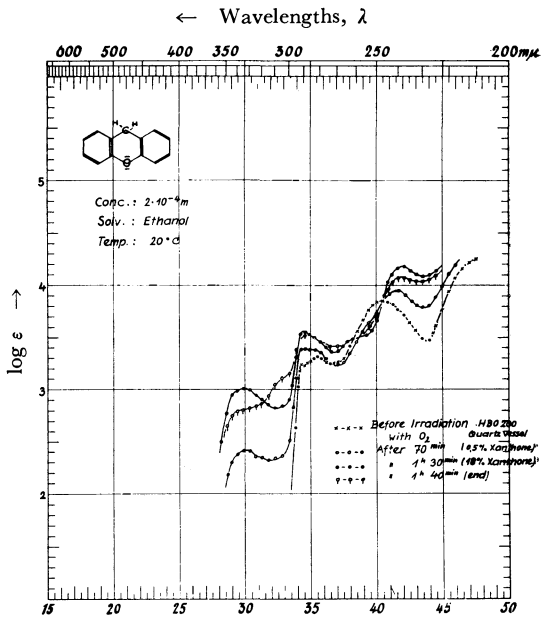

Fig. 1. Absorption spectra of xanthene during photolysis in oxygen containing solution.

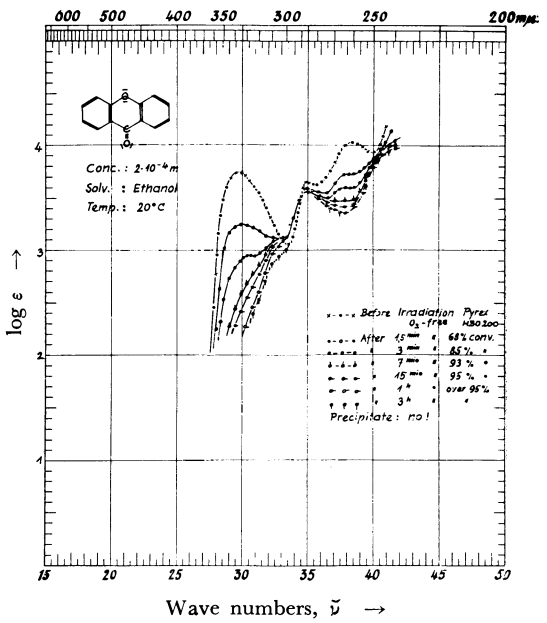

Fig. 2. Absorption spectra of xanthone during photolysis in oxygen free solution.

deoxygenized ethanolic and other polar and homopolar solutions the xanthenes, like the acridans, are photostable. Pure xanthone formed by photooxidation of the xanthene shows a spectrum as is shown on Fig. 2. Characteristic bands of it are an unstructured band at 29000 cm^{-1} and two bands

20) J. R. Platt, *J. Chem. Phys.*, **17**, 470, 484 (1949).

at 34700 and 38400 cm^{-1}. These intensive bands of the xanthone are responsible for the apparent rise of the xanthene bands under the photolysis in oxygen containing solutions. If a deoxygenized ethanolic solution of xanthone is illuminated in a pyrex vessel, xanthone undergoes quickly a photochemical reduction to xanthene, as is demonstrated by a very weak decrease of the band at 34500 cm^{-1}, the minimum at 38000 cm^{-1}, and the increase of the bands at 41000 to 42000 cm^{-1}. After an irradiation of 15 min. we reached a conversion of 95% out of 25 ml. solution and a concentration of 2×10^{-4} M: *we could not observe any formation of a solid photoproduct!*

In this case also, the band at 32000 to 33000 cm^{-1} is changed a little; this indicates again an intermediate between the generated xanthene and the xanthone.

If we irradiate an ethanolic solution of equal concentration in a quartz vessel, we get the same course of reaction; this is plotted on Fig. 3. Again we find that preferentially the formation of xanthene and an intermediate occurs. Under this condition we also find no precipitate or a solid product.

Proceeding from ethanol to dioxane as solvent and irradiating in a quartz vessel, no change in the reaction is detectable. This is shown on Fig. 4. The structure of the individual electronic transitions is indeed better resolved, but the photolysis itself is not influenced. We tried to separate the xanthene which was formed in these solvents. The crystallization from the oily residue was very

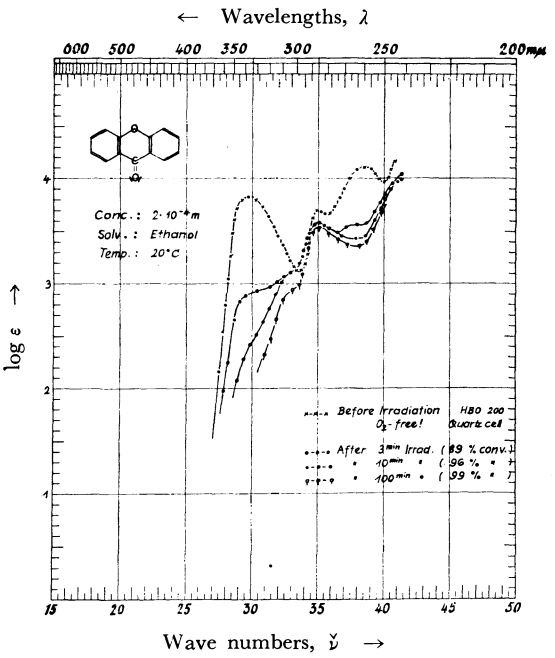

Fig. 3. Absorption spectra of xanthone during photolysis in oxygen free solution in a quartz cell.

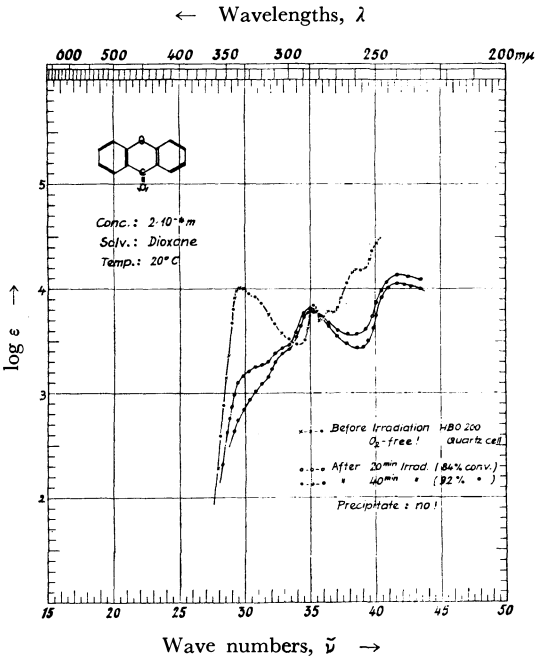

Fig. 4. Absorption spectra of xanthone during photolysis in oxygen free solution of dioxane.

bad and we were not successful. Always again we found bands at 32000 to 33000 cm^{-1}, indicating an unidentified intermediate.

Finally, our experiments to indentify the photolytical final product were successful. In this case we used a homopolar solvent, cyclohexane. We found the same course of reaction as for ethanol and dioxane, and again there was no formation of a solid product. If we remove here the greater part of cyclohexane out of the solution, we obtain a crystalline, colorless product. After repeated crystallization the constitution of the final product of the photolysis could be identified by elementary analysis, molecular weight and ultraviolet spectrum, as a 9-cyclohexylxanthydrol. This result is analogous to the behavior of acridine in deoxygenized cyclohexane or dioxane; we likewise have found for this compound a photochemical reduction to 9-cyclohexyl or 9-dihydroxanyl-substituted monoacridans. From this result we have to conclude, that the photoreactions of the xanthenes in ethanol, dioxane and other polar solvents also form similar soluble xanthydrols, with the corresponding solvent fragment in 9-C-position. But hitherto we could not isolate and identify these compounds.

If we use *n*-hexene as a solvent, we get the following somewhat surprising result. As plotted on Fig. 5, we observe a quick conversion from xanthone to xanthene. After 10 min. 95% are converted and we observe a precipitate of a solid photoproduct. After filtration and determination of the weight, we found over 80% of the substance which we had put in. The low solubility and the high melting

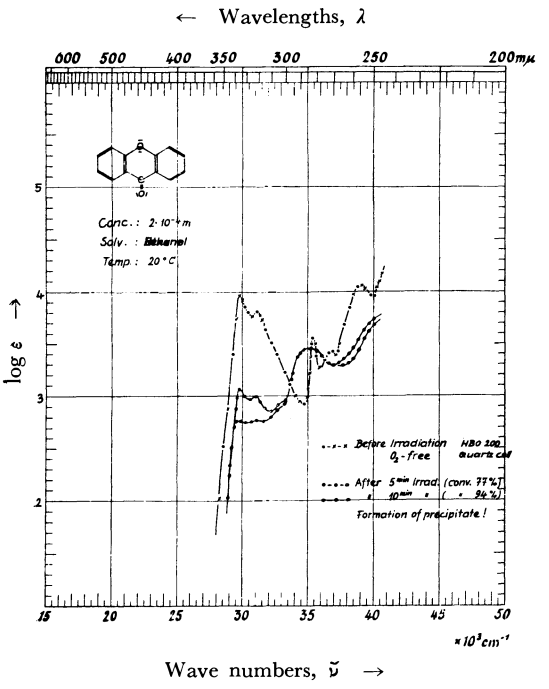

Fig. 5. Absorption spectra of xanthone during photolysis in oxygen free solution of hexane.

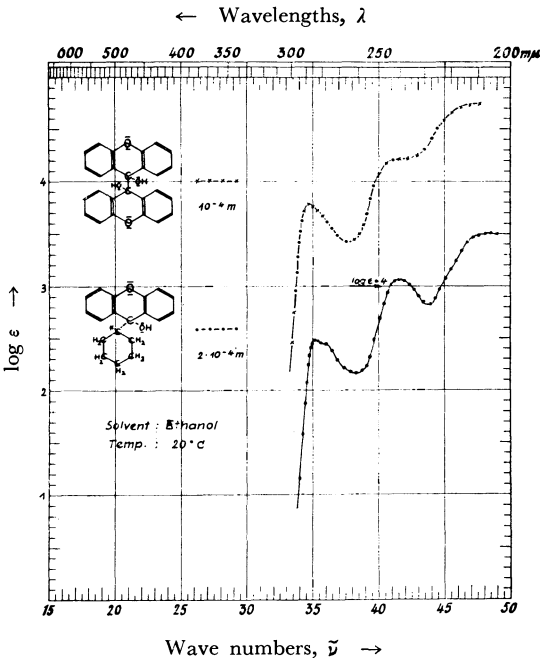

Fig. 6. Absorption spectra of 9, 9′-dihydroxydixanthene and 9-hydroxy-9-cyclohexylxanthene.

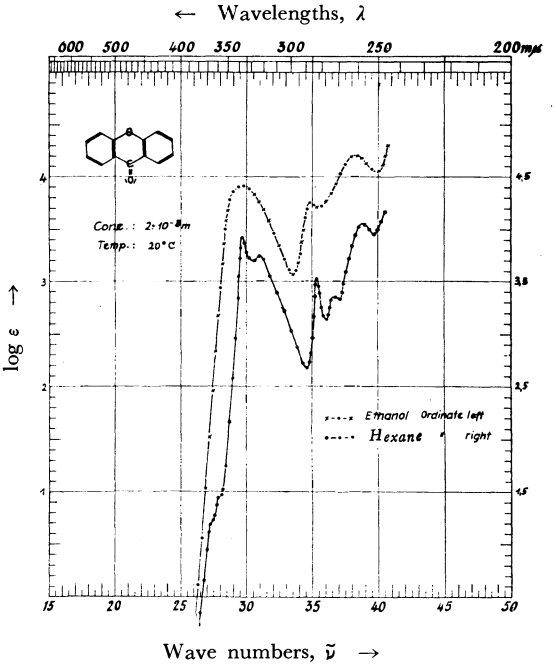

Fig. 7. Absorption spectra of xanthone in ethanol and hexane.

point of this substance gave us the first advice that in this case we had obtained a dimer. The elementary analysis and the determination of the molecular weight showed us, that we have here a double xanthydrol. By synthesis of a 9, 9′-dihydroxydixanthene according to literature[21] and by comparison with the photolytical substance, we found a complete agreement in ultraviolet and infrared spectrum, molecular weight and melting point. Thus we have proved, that this product is a 9, 9′-dihydroxydixanthene. From this we could show for the first time, that in the series of xanthones a photochemical dimerization out of equal building stones is also possible.

On Fig. 6 we demonstrate the ultraviolet spectra of 9-hydroxy-9-cyclohexylxanthene and 9, 9′-dihydroxy-9, 9′-dixanthene, which we have got in solutions of hexane and cyclohexane by photolysis. If we compare these spectra with the spectrum of xanthene, as plotted on Fig. 1, we see only a little difference in these two compounds against the parent substance. The dihydroxy derivative has the most intensive 0→0 transition of the ^1L_b-band, whereas the monohydroxy derivative shows 0→0 and 0→1 transitions of equal intensity; on the other hand, in the case of xanthene, the 0→1 transition is favored. In an opposite sequence, the intensity of this band increases from log $\varepsilon = 3.25$ over log $\varepsilon = 3.45$ to log $\varepsilon = 3.80$ of the dihydroxy derivative. From the appearance of their vibration structure, these three xanthenes are distinguishable. In the case of the dihydroxy derivative, also the minimum, following the ^1L_b-band, is most strongly marked.

21) M. Gomberg and W. E. Bachmann, *J. Am. Chem. Soc.*, **49**, 253 (1927).

To the Mechanism of Photochemical Formation of Mono- and Dihydroxyxanthenes out of Xanthone.—The first information about the course of the photolysis of the xanthone, can be got from the spectrum of the xanthone itself. Therefore, we give the enlarged plotting, down to log $\varepsilon=0$, for various solvents, on Fig. 7. The spectrum, measured in the polar ethanol, displays a striking little structure and especially the band at the longest wavelengths is strongly broadened and without vibrational structure. On the contrary, all electronic transitions in hexane show a very well marked structure and the band at the longest wavelengths from 29000 to 33000 cm^{-1}, especially responsible for the primary process of the photoreaction, shows a well marked $0\rightarrow0$ transition with two exponentially decreasing vibration bands. We doubtless have here a $\pi\rightarrow\pi^*$ transition, with all three rings coupling aromatically. For the spectrum in hexane, we find in the wavelength region longer than that of the xanthenes two weak attendants at 27500 and 28000 cm^{-1}; these we have interprete as members of a $n\rightarrow\pi^*$ transition of absorption band.

We can expect such transitions for the compounds with heteroatoms on which lone pair electrons appear. A $n\rightarrow\pi^*$ transition in ethanol is not observable; but this does not mean, that this transition is not present. We think, that this transition is shifted to shorter wavelengths due to the rising polarity of the solvent and it is superposed with the intensive $\pi\rightarrow\pi^*$ absorption band. This also is consistent to $n\rightarrow\pi^*$ transitions; they are usually shifted to shorter wavelengths with increasing polarity of the solvent.

Superposition of two bands goes mostly together with a loss of structure. Generally we can explain the big differences of the spectra measured in ethanol and *n*-hexane as due to the interaction with the solvent molecules. In ethanol, the solvent molecules interact distinctly with the solute xanthone molecule; this interaction is especially specific to the polar carbonyl group. The xanthone molecule in hexane is free and displays a spectrum, similar to that in gas phase. Therefore, the explanation for the various behavior, seems to be given by a strong or a weak interaction with the solvent.

On Figs. 8 and 9, we have pointed out reaction schedules, set up to elucidate the photochemical reduction of xanthone or generally of the xanthones. As to the formation of monohydroxy and dihydroxydixanthenes (xanthydrols) respectively we have the following conception: xanthone absorbs at the free electron pair of the CO-group a quantum ($n\rightarrow\pi^*$ transition) and passes over to a diradical. The high affinity of a O-radical position to H-atoms is responsible for the transfer of an H-atom from solvents with H-atoms resulting the reductive formation of a xanthydrol- or a hydroxyxanthyl-

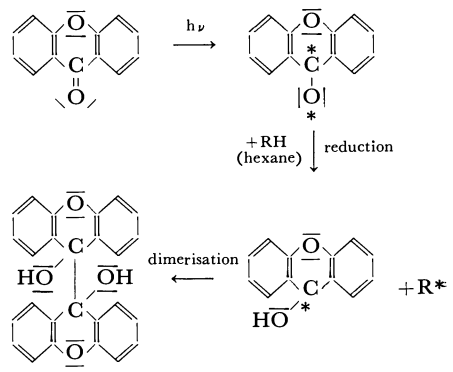

Fig. 8. Schedule of photoreaction of xanthone in solution of hexane.

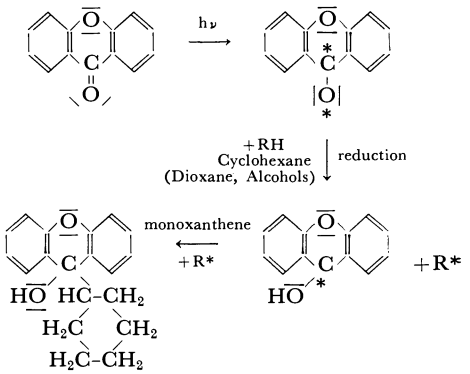

Fig. 9. Schedule of photoreaction of xanthone in solution of cyclohexane, dioxane and alcohols.

radical. Simultaneously the solvent ethanol is oxidized to aldehyde. This C-radical has the tendence to react with other C-radicals and to form stable hydroxyxanthene molecules. Therefore, we can realize two ways of reaction: On the one side the combination of two equal xanthyl radicals to dihydroxydixanthyl, and on the other side an association of the xanthyl radical with a solvent radical generated at the H-atom transfer. As is mentioned above, the latter seems to be especially favoured in the case of strong interaction of the solvent molecule with the CO-group, where only a small distance holds permanently between CO-group and solvent molecule. On the other side the probability of association with an equal xanthyl radical is similarly high, and according to low solubility of the dimer, this aggregation is in the foreground.

Photolytical Investigations on 9, 9'-Dihydroxy- and Dixanthenes.—In connection with the photochemical behavior of the diacridans, we were interested in the stability of the dixanthenes and in the question, if the dixanthenes, corresponding to the diacridans, decompose heterolytically to xanthylium cations and anions or to

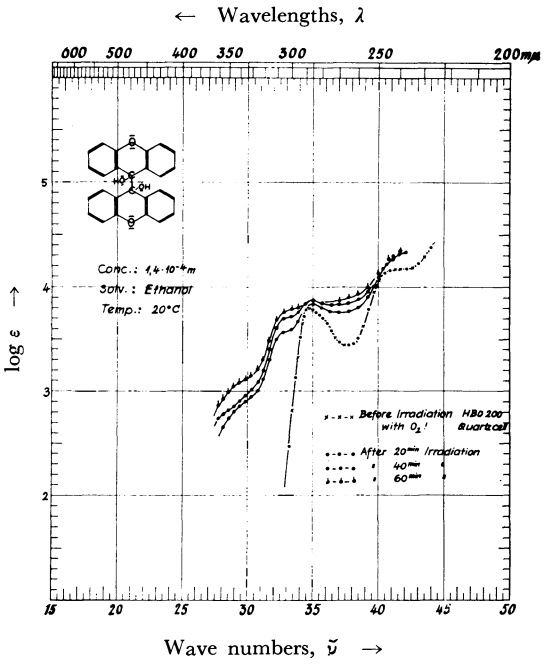

Fig. 10. Absorption spectra during photolysis of 9,9'-dihydroxydixanthene in oxygen containing solution.

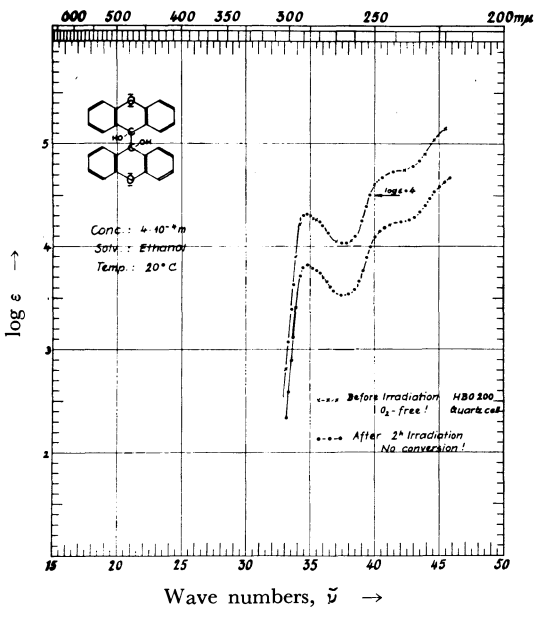

Fig. 11. Absorption spectra of 9,9'-dihydroxydixanthene before and after irradiation.

xanthydrols (hydroxyxanthenes). In order to investigate this, we have irradiated air saturated and deoxygenized ethanolic solutions of 9, 9'-dihydroxydixanthene. The results of this investigation are plotted on Figs. 10 and 11.

In the case of oxygen containing solutions, we

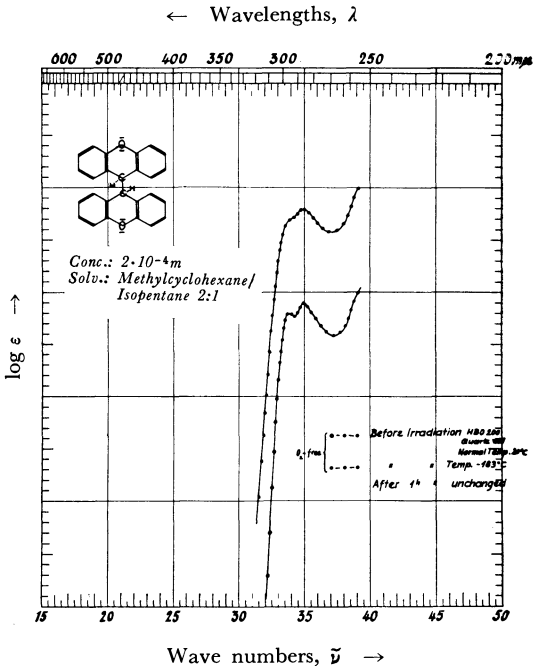

Fig. 12. Absorption spectra of dixanthene before and after irradiation.

have obtained an oxidation to xanthone; this result if it is compared to the reaction of the diacridans but here the oxidation leads to the acridine and partly to acridan, is not extraordinary. This is proved by the appearnce of a band at 30000 cm^{-1}. As in the case of the photoreduction of xanthone or the oxidation of xanthene, here also appears another product absorbing at 33000 cm^{-1} This is like before but not yet identified in its constitution.

In deoxygenized solutions the dixanthenes are photostable. This is shown by the experiments, carried out on 9, 9'-dihydroxydixanthene and 9, 9-'dixanthene. The results are pointed out on Figs. 11 and 12. After an illumination of two hours by a HBO 200 mercury lamp at a concentration of $4 \cdot 10^{-4}$ M, no change is observable. The same result we have got for chemically synthesized 9, 9'-dixanthene. In this case also no photolytical reaction is detectable. This substance is so far not yet synthesized by photolysis.

This behavior of the dixanthenes differs from that of the diacridans. There we find photoinstability, with an exception of 9, 9'-diphenyldiacridan. Now we have the problem to understand the properties of these compounds out of their spectroscopic data. As was demonstrated in a previous paper, the monoacridans differ essentially from the diacridans by an absorption band situated in the long wave absorption region. The intensity of this band is $\log \varepsilon = 3.4 - 3.5$. The appearance of this band is indicative of $\pi \rightarrow \pi^*$-interaction between the two acridan nuclei

of the diacridan, via the 9, 9'-bond. Light excitation especially affects this 9, 9'-bond and breaks it photochemically.

With the dixanthenes we miss completely such a band and they differ from the monoxanthene derivatives only little by intensity. This has been plotted on Figs. 11 and 12. The two chromophores are practically completely isolated from each other, and at the excitation no stressing of the 9, 9'-bond and no photosensibility is observable.

Photosynthesis of Further Dixanthenes.— Starting from the above mentioned results, which guided us to a reaction schedule shown before, we have supposed, that it may be possible to synthesize photolytically besides the symmetrical and unsymmetrical dixanthenes. Using a stronger H-donor than the solvent itself, we must get such products, if we would have the right conception. The stronger donor in the class of our compounds is the xanthene, respectively 9-alkyl- or 9-aryl-monoxanthenes.

If we add equimolar amounts of xanthone and xanthene in benzene solution and irradiate this mixture, we get indeed a solid photoproduct. We determined the melting point and the molecular weight and found this to be a 9-*hydroxydixanthene*. This compound was prepared already photochemically by Schönberg;[22] we now synthesized this substnace by another idea. Including the other H-donors for this synthesis, we also used acridan as an H-donor. If we irradiate equimolar solutions of xanthone and acridan in benzene, we can quickly observe the precipitate of a colorless solid substance. After repeated crystallization, we have found from molecular weight, elementary analysis, and ultraviolet and infrared spectra, that here is formed a *9, 9'-diacridan*.

In the last Fig. 13, we show a schedule to these dimerizations, which enlarges the mechanisms pointed out previously. Using suitable combination of filters, we irradiated only in the long wave absorption range of xanthone. This causes again the formation of a xanthone-diradical, fixed at the CO-group. This diradical takes over an H-atom from the stronger donor of xanthene and acridan and forms a 9-hydroxyxanthyl radical. The xanthene itself, which has the function as an H-donor, dismisses an H-atom and goes to a xanthyl radical. Combination of these two C-radicals yields the 9-hydroxydixanthene. In the second case, the xanthone diradical takes over an H-atom

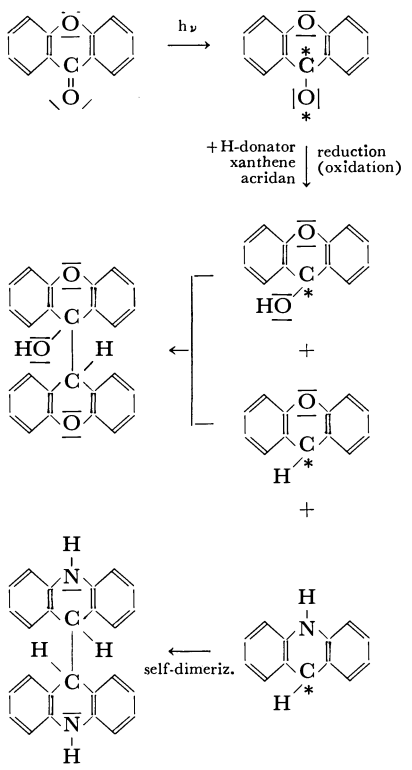

Fig. 13. Schedule of photoreaction of xanthone with xanthene resp. acridan.

from the acridan and passes over to a 9-hydroxydixanthyl-radical. Simultaneously the acridan is oxydized to acridanyl-radical furnishing H-atoms. We could expect here also the formation of a mixed xanthylacridanyl dimer. But this is not occurring or presumably occurring little. The extraordinary low solubility of this substance ($4 \cdot 10^{-5}$ molar against $5 \cdot 10^{-3}$ molar of the dixanthenes) prevents the formation of a mixed product or the likewise possible dihydroxydixanthene.

So we have settled a bridge to the photolytical formation of diacridans and have found a new way, to synthesize this dimer diacridan.

We wish to express our thanks to the Deutsche Forschungsgemeinschaft and the Verband der Chemischen Industrie, Federal Republic Germany, for personal help and especially to Professor Masao Koizumi for his invitation to the informal meeting on photochemistry at Sendai, Septmeber, 1965, on which we could discuss the present results.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1701—1705 (1966)

A Molecular Compound between Glutamic Acid and Pyroglutamic Acid*

By Yoshihisa SUZUKI and Nobuya NAGASHIMA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki

(Received January 13, 1966)

A new molecular compound, which consists of L-glutamic acid, L-pyroglutamic acid and water of crystallization in a 1 : 1 : 1 mole ratio, has been discovered. In its crystal, the unit-cell is monoclinic with $a=5.10$, $b=7.20$, $c=18.38$ Å, and $\beta=96.6°$, and the space group has been determined to be $P2_1$. Equilibrium measurements in the system of L-glutamic acid, L-pyroglutamic acid and water at 20°C, 30°C, and 50°C, showed that the transition temperature from the molecular compound to L-pyroglutamic acid and α-form L-glutamic acid is 35.5°C, while that to L-pyroglutamic acid and β-form L-glutamic acid is 20.5°C. Thus, the molecular compound is stable only below this temperature. This molecular compound has an incongruent solubility. When it is placed in water, a crystallization of L-glutamic acid takes place as the molecular compound is dissolved. A similar molecular compound consisting of D-glutamic acid and D-pyroglutamic acid is also obtained, but no molecular compound of the L-glutamic acid and D-pyroglutamic acid, or vice versa, is obtainable. On the basis of these facts, an optical resolution is actually possible for glutamic acid. When this molecular compound is heated, it is converted into another molecular compound at about 70°C due to the loss of the water of crystallization; then it is decomposed to L-glutamic acid (β-form) and L-pyroglutamic acid at about 90°C.

A new molecular compound, which consists of L-glutamic acid, L-pyroglutamic acid and water of crystallization in a 1 : 1 : 1 mole ratio, was discovered, although complex of these two acids in solution had been assumed without any confirmation by Kergle.[1] It is prepared[2] in the following way: 10 g. of L-glutamic acid and 60 g. of L-pyroglutamic acid are dissolved in 100 g. of hot water, and then the solution is cooled to 20°C. After several hours, crystals with a shape of rhombic plate are obtained. The chemical analysis shows that these crystals are the 1 : 1 : 1 molecular compound.

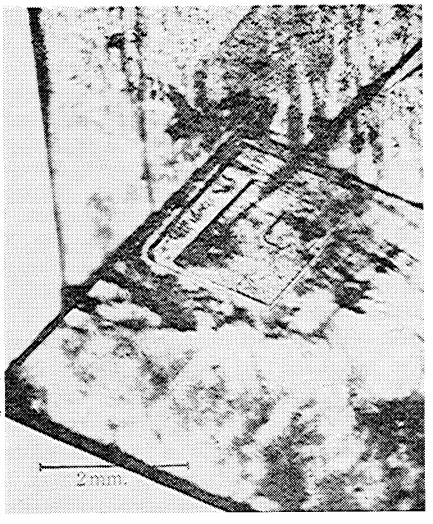

Fig. 1. A large spiral layer on the crystal surface of the molecular compound, which consists of L-glutamic acid, L-pyrroglutamic acid, and water of crystallization.

Found: C, 40.99; H, 6.30; N, 9.54; Amino-N, 4.81 (Van Slyke); L-glutamic acid, 50.8 (enzymatic analysis). Calcd. for L-glutamic acid - L-pyroglutamic acid - water: C, 40.81; H, 6.17; N, 9.52; Amino-N, 4.77; L-glutamic acid, 50.0%.

On the surface of one of these molecular compound crystals, a large spiral layer was found (Fig. 1).

Crystallographic Examination

X-Ray diffraction studies were carried out of the crystals obtained with CuK_α radiation. The oscillation and Weissenberg methods were used for single crystals, and diffractometer techniques, for powder specimens. The unit-cell is monoclinic with $a=5.10$, $b=7.20$, $c=18.38$ Å, and $\beta=96.6°$.

For reference, the cell dimensions of L-glutamic acid and L-pyroglutamic acid are shown below:

L-glutamic acid:

(α-form)[3] $a=7.06$, $b=10.3$, $c=8.75$kX

(β-form)[4] $a=5.17$, $b=17.34$, $c=6.95$Å

L-pyroglutamic acid:

* Presented in part at 14 th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

2) Japanese Pat. 414586 (Japanese Publ. 11140/1963).

3) J. D. Bernal, *Z. Krist.*, **78**, 363 (1931).

4) S. Hirokawa, *Acta Cryst.*, **8**, 637 (1955).

$a=14.6,\ b=8.99,\ c=13.5$Å

The Weissenberg pattern shows a systematic absence of $(0k0)$ reflections with $k \neq 2n$. This indicates that the space group is either $P2_1$ or $P2_1/m$. The density measurements ($d_0=1.454$, $d_c=1.456$ g. cm^{-3}) show that there are two molecular compounds (L-glutamic acid - L-pyroglutamic acid - water) in the unit cell. Accordingly, the possibility of $P2_1/m$ is eliminated, and the space group is determined to be $P2_1$. The X-ray powder diffraction data are shown in Table I. The intensities reported in Table I are peak heights above the background, so scaled that the most intense line is given a value of 100.

The Determination of the Conditions of the Molecular Compound Formation

In an attempt to determine the conditions under which the molecular compound is formed, solubility measurements of various saturated solutions of L-glutamic acid, L-pyroglutamic acid and water have been made. For each set of solubility measurements, an examination was also made of the constitution of the solid phase which is in equilibrium with the saturated solution in question.

Material.—*α-Form L-Glutamic Acid.*—The pH of a solution of 300 g. of commercial mono-sodium L-glutamate mono-hydrate dissolved in 10 l. of water was brought to about 3.2 by promptly adding 35% hydrochloric acid at room temperature. The crystals thus formed were filtered, washed with water, and dried in vacuo. The results of the analysis of this L-glutamic acid were as follows:

Found: N, 9.53%; $[\alpha]_D^{20}$ + 31.7 (*c* 8, 2N HCl).
Calcd.: N, 9.52%.

These crystals were found by the X-ray diffraction method[5] to be α-form, with a 98% purity.

β-Form L-Glutamic Acid.—First, a glutamate solution was prepared by dissolving 300 g. of mono-sodium L-glutamate monohydrate in 1.5 l. of water. Into this solution 35% hydrochloric acid was slowly stirred at 80°C. After 1 hour, the pH of the solution reached about 3.2; then the solution was cooled to room temperature. The crystals formed were filtered, washed with water, and dried in vacuo. The results of the analysis of this L-glutamic acid were as follows:

Found: N, 9.52%; $[\alpha]_D^{20}$ +31.8 (*c* 8, 2N HCl).

These crystals were found by the X-ray method to be 100% pure β-form L-glutamic acid.

L-Pyroglutamic Acid.—L-Glutamic acid was suspended in five times as much water and kept at 120°C for about 20 hr. The solution was then decolorized by active charcoal and passed through a column of the cation exchange resin (Diaion SK in H^+-form) in order to remove the unreacted glutamic acid. The effluent was concentrated in vacuo, the crystals first deposited were removed (DL-pyroglutamic acid), and then the resultant solution was cooled. The crystals formed in this stage were filtered, washed with cold water, and dried in vacuo. The results of the analysis of these crystals were as follows:

Found: N, 10.82%; $[\alpha]_D^{20}$, −11.3 (*c* 4, water).
Calcd.: N, 10.85%.

Procedure.—L-Glutamic acid, L-pyroglutamic acid and water were mixed in a glass tube with a spiral stirrer. The tube was placed for at least six hours in a water bath regulated at 20°C, 30°C, or 50°C. The temperature fluctuation of the bath was within ±0.1°C. An aliquot was taken with a cotton-stoppered pipet (warmed when necessary), and the concentration of L-glutamic acid in the filtrate was determined by the Warburg method with a decarboxylase from squash. The L-pyroglutamic acid content was determined as the difference between the total nitrogen determined by the Kjeldahl method and the amino nitrogen as calculated from the L-glutamic acid content. The solid-phase constitution was examined by the X-ray powder diffraction method. The equilibrium was sometimes reached from the under-saturation side, and sometimes from the supersaturation side.

Results.—The results of the solubility measurements are tabulated in Table II and are given graphically in Figs. 2, 3 and 4. The solubility of L-glutamic acid is somewhat different according to whether the solid phase is α-form glutamic acid or β-form glutamic acid.[6] It has been reported by Sakata[7] that L-glutamic acid in the α-form as a solid phase in a saturated aqueous solution gradually transforms into β-form, and that some amino acids have an inhibitory action on this transition. The present experiment showed

5) H. Takahashi, T. Takenishi and N. Nagashima, This Bulletin, **35**, 923 (1962).
6) Y. Sakata, *Agr. Biol. Chem.*, **25**, 835 (1961).
7) Y. Sakata, ibid., **25**, 829 (1961).

that L-glutamic acid tends to be crystallized in the α-form from the supersaturated solution in the presence of L-pyroglutamic acid, and that such an α-form crystal does not readily transform into the β-form in the solution.

As may be seen in Figs. 2, 3, and 4, the isotherm at 20°C shows a clear stable zone of the molecular compound, only a short stable zone at 30°C, and no stable zone, only a metastable zone, at 50°C. In the metastable zone, however, the molecular compound is easily crystallized by the cooling of the saturated solution at an elevated temperature.

The molecular compound was obtained only from the supersaturated side in the temperature range examined.

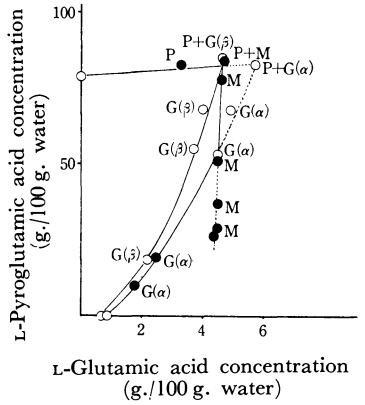

Fig. 2. Composition of the liquid phase in the system of L-glutamic acid, L-pyroglutamic acid and water at 20°C.
○ means the data from unsaturation side, and ● from supersaturation side. For each point observed, the constitution of the solid phase in equilibrium with the liquid phase in question is shown by P, M, G(α), and (β). The notations are the same as in Table II.

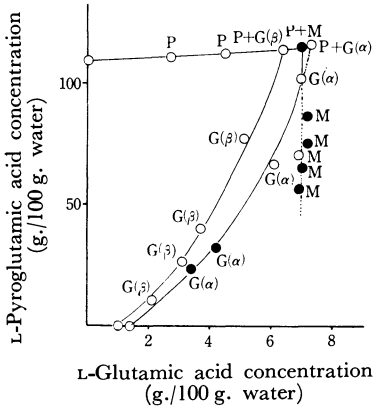

Fig. 3. Composition of the liquid phase and the constitution of the solid phase in the system of L-glutamic acid, L-pyroglutamic acid and water at 30°C. The notations are the same as in Table II.

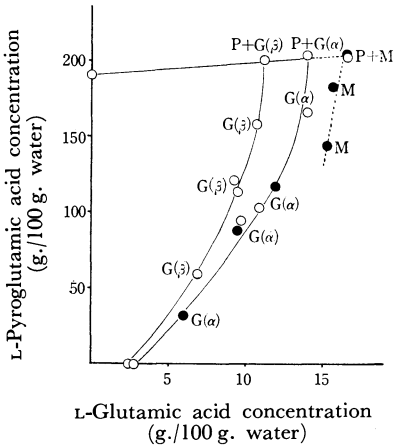

Fig. 4. Composition of the liquid phase and the constitution of the solid phase in the system of L-glutamic acid, L-pyroglutamic acid and water at 50°C. The notations are the same as in Table II.

Since this molecular compound has an incongruent solubility, it is decomposed by water, and at the same time a precipitation of L-glutamic acid takes place.

At each temperature three invariant points can be determined: at one of them, the solid phase is composed of both L-pyroglutamic acid and α-form L-glutamic acid; at the second point, the solid phase is composed of both L-pyroglutamic acid and β-form L-glutamic acid; and at the third point, the solid phase is composed of L-pyroglutamic acid and the molecular compound. The logarithm of the L-glutamic acid concentrations at the invariant points are plotted against the temperature in Fig. 5. Here three straight lines are obtained. The intersecting points of these lines give the transition temperatures from the molecular compound to the mixtures of the two acids. Thus the transition temperature from the molecular compound to L-glutamic acid in the α-form and L-pyroglutamic acid is about

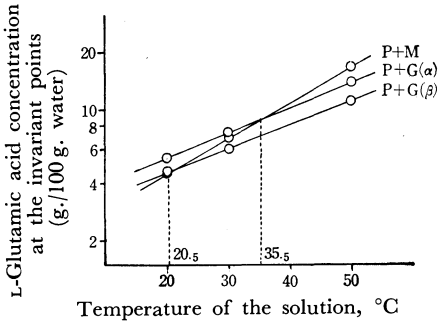

Fig. 5. Estimation of the transition points by three different invariant points.
The notations of the solid phase are the same as in Table II.

35.5°C, and the transition temperature from the molecular compound to L-glutamic acid in the β-form and L-pyroglutamic acid is about 20.5°C. The molecular compound is stable below this temperature.

The Optical Resolution of DL-Glutamic Acid by the Use of the Molecular Compound[8]

A similar molecular compound which consists of D-glutamic acid, D-pyroglutamic acid and water was also ascertained to be formed. It was found, however, that no molecular compound which consists of L-glutamic acid and D-pyroglutamic acid or vice versa can be obtained. It may be expected that, taking advantage of these facts, one can resolve the racemic form of glutamic acid or pyroglutamic acid. Such an optical resolution is actually possible for glutamic acid, but it is not for pyroglutamic acid.

Materials.—The racemic glutamic acid monohydrate and racemic pyroglutamic acid were presented by Dr. T. Akashi.* The results of the analysis of these two materials were as follows:

DL-glutamic acid monohydrate:
Found: N, 8.49%; $[\alpha]_D^{20}$, ±0.00 (*c* 8, 2 N HCl). Calcd.: N, 8.48%.

DL-pyroglutamic acid:
Found: N, 10.84%; $[\alpha]_D^{20}$, ±0.00 (*c* 4, water). Calcd.: N, 10.85%.

8) Japanese Pat. 412634 (Japanese Publ. 8311/1963).

* Chief Chemist in the Central Research Laboratories of Ajinomoto Co., Inc.

Procedure and Results.—I) A mixture of 13.6 g. of DL-glutamic acid mono-hydrate and 54.5 g. of L-pyroglutamic acid in 60 g. of water was heated until it dissolved at 80°C; then the solution was cooled at 20°C under stirring, with a slight seeding of the molecular compound between L-glutamic acid and L-pyroglutamic acid. After 4 hr. the precipitated crystals were filtered out. In the analysis of the crystals and the mother liquor, the method of amino-nitrogen determination in the ninhydrin method was adapted, as well as the two methods of analysis in the solubility measurements described above. The total concentration of optically active and inactive glutamic acid was determined by the amino-nitrogen measurements. The concentration of L-glutamic acid was determined by the enzymatic method.

The crystals were weighed (8.6 g.) and were found to be 68% the molecular compound (L-glutamic acid, L-pyroglutamic acid and water), 17% DL-glutamic acid monohydrate, and 10% L-pyroglutamic acid. The mother liquor was also weighed (103 g.); its concentration was as follows; DL-glutamic acid 4.0%, D-glutamic acid 2.6%, L-pyroglutamic acid 44%.

II) Into a mixture of 10.1 g. of DL-glutamic acid mono-hydrate and 24 g. of L-pyroglutamic acid in 31 g. of 5% hydrochloric acid, about 6 g. of 15% caustic soda, including 1.8 g. of L-pyroglutamic acid, was stirred. By cooling at 20°C with a slight seeding of the molecular compound (L-glutamic acid, L-pyroglutamic acid and water), 2 g. of the crystals were obtained after 1 hr. The crystals were 90% the molecular compound (L-glutamic acid, L-pyroglutamic acid and water) and 10% L-pyroglutamic acid. L-Glutamic acid was obtained from the decomposition of these crystals by water.

III) A mixture of 10 g. of DL-pyroglutamic acid and 2.5 g. of L-glutamic acid in 100 g. of water was cooled in an ice box. After 5 days the crystals precipitated were examined by the X-ray powder diffraction method; they were thus shown to be a mixture of the two acids, with none of the molecular compound present.

An Anhydrous Molecular Compound

A thermal analysis of the above-described molecular compound has been made. It was shwon that the compound is converted into another molecular compound of L-glutamic acid and L-pyroglutamic acid (1 : 1) at about 70°C; then it is decomposed to L-glutamic acid (β-form) and L-pyroglutamic acid at about 90°C. This transformation was shown in the differential thermal analysis curve, and in the X-ray diffraction patterns and the IR spectra of the specimens of all the stages. The results of the elementary analysis of the latter molecular compound were:

Found: C, 43.67; H, 5.95; N, 10.18. Calcd.: C, 43.4; H, 5.84; N, 10.14%.

This anhydrous molecular compound could not be obtained from the aqueous solution. The X-ray powder diffraction data are shown in Table I.

We wish to express our thanks to Professor Masamichi Tsuboi of the University of Tokyo for reading the manuscript of this paper, and also to Drs. Haruomi Oeda, Shinichi Motozaki, Mei Ohno and Tadao Takenishi in the Central Research Laboratories, Ajinomoto Co., Inc., for their encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1705—1715 (1966)

The Chemistry of Protactinium. II. The Behavior of Pentavalent Protactinium in a Perchloric Acid Solution

By Shin SUZUKI and Yasushi INOUE

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira-cho, Sendai

(Received July 23, 1965)

Studies of the chemical behavior of protactinium(V) were carried out with the TTA-benzene extraction method, the ion exchange method and the filtration method. When the protactinium concentration is less than 10^{-6} M and the perchloric acid concentration is 0.3—2.0 N, the reaction of TTA extraction may proceed as:

$$PaO_m(OH)_n^{5-2m-n} + 4HT \rightleftarrows Pa(OH)T_4 + (m+n-1)H_2O + (5-2m-n)H^+$$

where $2m+n$ is 3 and 4, or as:

$$PaO_m(OH)_nT^{4-2m-n} + 4HT \rightleftarrows PaT_5 + (m+n)H_2O + (4-2m-n)H^+$$

where $2m+n$ is 2 and 3.

The cation exchange experiment gives results consistent with this conclusion. On the other hand, when the concentration of protactinium is higher than 10^{-6} M, the above relation does not hold, even in the 5 N perchloric acid solution, because protactinium forms the aggregates to a great extent. This has been confirmed by the filtration experiment.

It has been stated earlier that the results of investigations of the aqueous chemistry of protactinium are not always acceptable,[1] because the instability of the aqueous solution has resulted in some confusion on published works. This is true in investigations of the chemical behavior of pentavalent protactinium even in a perchloric acid solution, which is considered to be the most fundamental of the various aqueous systems. For example, Welch[2] assumed the existence of protactinyl ion in this medium from its behavior towards cation exchange resin, but Elson[3] concluded that, in weakly acid solutions, protactinium would be found in such hydrolyzed forms as $Pa_2(OH)_9^+$ and $Pa_2O_2(OH)_5^+$; in solutions of moderate acidity, in the form of PaO^{3+} or $Pa(OH)_2^{3+}$; and in a strong acid solution, perhaps in the hydrated form of Pa^{5+}. On the other hand, Bouiséres and his co-workers[4] assumed, from their TTA-benzene extraction experiments, that, in 0.9—3 M perchloric acid solutions, this element would be found in the form of $Pa(OH)_3^{2+}$ or $Pa(OH)_2A^{2+}$ (where A is the anion of TTA), and in 1.5×10^{-3}—2×10^{-5} M perchloric acid solutions, in the form of $Pa(OH)_2A_2^+$ or $PaO(OH)_2^+$. As to the stability of pentavalent protactinium, Guillaumont and his co-workers[5] reported that a weak absorption peak at 210 mμ which appeared in 2.4—11.8 M perchloric acid solutions containing about 10^{-5} M pentavalent protactinium disappeared in eight to ten days. Thus, the conclusions differ with the authors. For this reason, it is necessary to investigate more fully the chemical properties of pentavalent protactinium in a perchloric acid solution.

Thenoyl trifluoroacetone (TTA), as compared with the other organic complexing reagents, has a comparatively high acid dissociation constant; therefore, it is applicable even when the acidity of a solution is high. This is the reason why the TTA extraction method is frequently used for the separation of protactinium[6-11] as well as for fundamental research.

The purpose of this investigation is to elucidate the nature of pentavalent protactinium in a perchloric acid solution by the TTA-benzene extraction method, coupled with the ion exchange and filtration methods.

Experiments

Reagents and Apparatus.—*^{233}Pa and ^{231}Pa.*—Stock solutions of these isotopes were prepared by the methods reported previously.[1] Aliquots of these solutions were transferred into a platinum dish and evaporated almost to dryness, initially on a hot plate and finally on a water bath. The residue was then dissolved by heating it with concentrated perchloric acid, and again evaporated to dryness. This was cooled and diluted to the desired concentration with respect to protactinium with a perchloric acid solution of a suitable concentration.

Ion Exchange Resins.—Dowex-50×8 and Dowex-1×8, 200—400 mesh, were used for the cation and anion exchange experiments respectively. Before use, they were converted to the desired forms (Dowex-50 to the H^+ form; Dowex-1 to the ClO_4^- form), washed with distilled water, and dried in air.

Benzene was purified by distillation, and doubly-distilled water was used throughout this experiment. The other chemicals, such as thenoyl trifluoroacetone and perchloric acid, were of the highest-purity grade.

For the solvent extraction procedure, a Hiranuma-Seiki magnemixer, Model MMC-8, was used. All the vessels and radiation measurement instruments were those described in the foregoing report.[1]

Procedures.—Each value given was the average of the results of at least two determinations; care was taken to ascertain the material balance in each case.

TTA Extraction.—Ten milliliters of a perchloric acid solution of protactinium which had been adjusted to the desired condition and 10 ml. of a benzene solution of TTA in the desired concentration were mixed for 30 min. with a magnemixer in a thermostat at 30°C. After the two phases had completely separated, an aliquot of each phase was taken out and counted for γ radioactivity; the apparent distribution coefficient was calculated by means of the usual relationship:

$$K_d' = \frac{\dfrac{\text{Radioactivity in the org. phase}}{\text{Vol. of the org. phase (ml.)}}}{\dfrac{\text{Radioactivity in the aq. phase}}{\text{Vol. of the aq. phase (ml.)}}}$$

Ion Exchange.—The apparent distribution coefficient

was determined by equilibrating 500 mg. of air-dried ion exchange resin with 20 ml. of a 10^{-8} M protactinium solution under the desired condition for 2 days with intermittent shaking. Then the slurry was centrifuged in order to accelerate the complete separation of the two phases. In centrifugation, care was taken not to exceed 2000 r. p. m. because such a high speed is in danger of producing the sedimentation of some protactinium. An aliquot of the supernatant liquid was taken for the measurement of the γ radioactivity. The apparent distribution coefficient was calculated from the following equation:

$$K_d' = \frac{\dfrac{\text{Radioactivity in resin}}{\text{Amount of resin (g.)}}}{\dfrac{\text{Radioactivity in soln.}}{\text{Vol. of soln. (ml.)}}}$$

The radioactivity in the resin after equilibration was estimated from the difference between the total activity and the final activity present in the solutions.

Filtration.—Toyo-Roshi No. 5C filter paper (fine filter for quantitative use) and a membrane filter (supplied by Membrane-Filter-Gesellschaft, Göttingen), with diameters of 26 mm. and 30 mm. respectively, were used in this investigation. Filtration was performed under suction with a glass filtration apparatus with a perforated filter disk, the diameter of which was 18 mm. One or two milliliters of a sample solution was filtered, and then the filter paper was washed with 4 or 3 ml. of distilled water respectively. The filtrate and washings were then put together in the same polyethylene test tube. The radioactivities of its contents and of the filter paper were measured under the same geometrical conditions. The percentage of protactinium retained on the filter paper was then calculated from these values.

Results

TTA-benzene Extraction.—*The Relation between the Apparent Distribution Coefficient and the TTA Concentration.*—The influence of the TTA concentration on the apparent distribution coefficient was investigated by means of the constant acidity of the solution. The concentrations of protactinium used were 10^{-7} M and 10^{-10} M. The logarithm of the apparent distribution coefficient was plotted as a function of the logarithm of the TTA activity in the benzene phase, as is shown in Fig. 1.

The activity of TTA in the benzene phase at equilibrium was calculated from its initial concentration by the following equations:

$$\frac{(\mathrm{HT})_i}{(\mathrm{HT})_B} = 1.02 + 10^{-8}/\mathrm{H}^+ \qquad (1)^{12)}$$

$$f_{\mathrm{HT}} = 1 - 0.25(\mathrm{HT})_B^{0.48} \qquad (2)^{13)}$$

where f_{HT} is the activity coefficient of TTA in benzene; $(\mathrm{HT})_B$, the final concentration in benzene when equilibrated with an equal volume of an aqueous phase, and $(\mathrm{HT})_i$, the initial concentration.

It is clear from Fig. 1 that, in the case of a directly-prepared solution, the log-log plot of the apparent distribution coefficient and the activity of TTA shows a good linearity, with a slope of about 4 over a wide range of reagent concentration, except in the case of an extremely low acidity, where exact linearity does not hold. The difference between solutions containing protactinium concentrations of 10^{-7} M and 10^{-10} M is not obvious. Furthermore, even when the solution is left to stand for a long time, these relationships do not change beyond the range of experimental error.

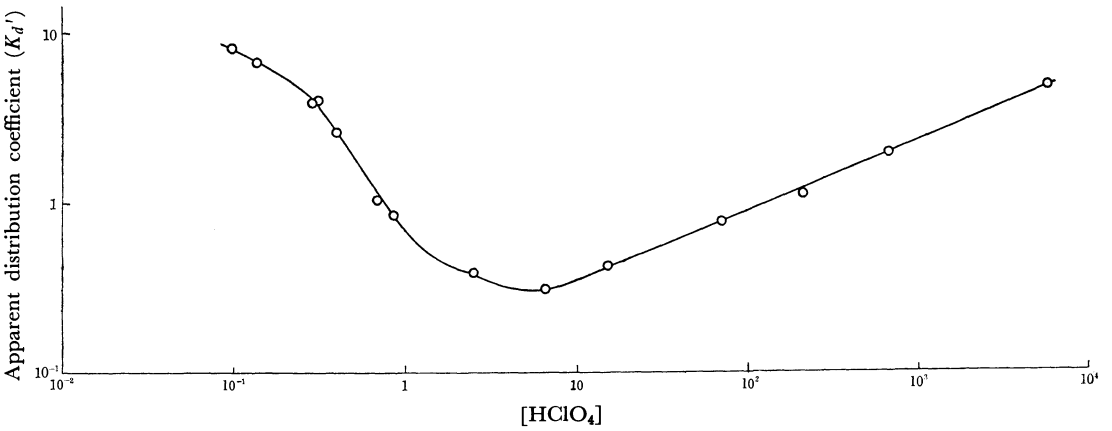

Fig. 2. Dependence of distribution coefficient of TTA extraction on perchloric acid activity.

On the contrary, when a sample solution is prepared indirectly from a 10^{-5} M stock solution, the range bearing a linear relation is narrower and the slope of the straight line is smaller than in the former case, decreasing as the aging time increases.

The Relation between the Apparent Distribution Coefficient and the Perchloric Acid Concentration.—Experiments were performed on the effect of perchloric acid concentration on the extraction of a 10^{-7} M solution of protactinium with 0.12 M TTA. The results are shown in Fig. 2. The activity of perchloric acid was calculated from the activity coefficient obtained by Robinson and Stokes.[14] As is shown in Fig. 2, the apparent distribution coefficient decreases with an increase in the concentration of perchloric acid, reaching a minimum at about 3 N acid, and then it increases with an increase in the acidity. In the range of acidity from 0.4 N to 1 N, the plot of the logarithm of the apparent distribution coefficient against the logarithm of the activity of perchloric acid shows a linear relationship with a slope of -1.45, whereas above 4 N it shows a straight line with a slope of 0.41.

The Relation between the Apparent Distribution Coefficient and the Hydrogen Ion Concentration in a Constant Ionic Srength Medium.—The effect of the acidity of the aqueous phase was studied at a constant ionic strength (2.03) by using various mixtures of perchloric acid and lithium perchlorate. Benzene solution of 0.07 M and 0.12 M TTA were used for the extraction. As is shown in Fig. 3, curves with a maximum were thus obtained, the position of the maximum differing with the difference in the TTA concentration used; with 0.12 M TTA the maximum is at 0.3 M acidity, while with 0.07 M TTA, it is at 0.1 M acidity. In a higher acidity range than the acidity that corresponds to the maximum point, the log-log plot of the apparent distribution coefficient and the hydrogen

ion concentration shows a linear relationship with a slope of -1.6. This observation is different from that of Bouissieres and his co-workers[4], who obtained a slope of -2.0 in the acidity range higher than 1 N.

The Variation in the Apparent Distribution Coefficient with the Concentration of Protactinium.—The relation between the apparent distribution coefficient and the protactinium concentration, from carrier-free to 10^{-6} M, was investigated at the constant acidities of 0.47, 1.0 and 5.0 N. The concentrations of TTA solution were 0.06, 0.10 and 0.12 M respectively. The results are shown in Fig. 4. Although at an acidity of 0.47 N the apparent distribution coefficient of carrier-free ^{233}Pa solutions is higher than that

of a more concentrated solution, this may be attributed to the ill reproducibility of the experiment in a trace concentration; therefore, it is considered that the apparent distribution coefficient is virtually constant in the concentration range below 10^{-6} M.

The Effect of Aging of the Solution on the Apparent Distribution Coefficient.—The relation between the apparent distribution coefficient and the aging time after the preparation of 10^{-7} M solutions of protactinium in various concentrations of perchloric acid was examined at a TTA concentration of 0.12 M. The results are presented in Fig. 5a. When the concentration of perchloric acid is low, the apparent distribution coefficient changes somewhat, but above an acidity of 0.6 N it does not change, at least not for 90 days. Then the solutions, 10^{-7} M in protactinium, were prepared just before use by the dilution of a 10^{-5} M solution which

had an acidity of 5.165 N and which had been aged for a definite time. This was then extracted with a 0.12 M TTA-benzene solution in order to obtain the apparent distribution coefficients. The relations between the aging time and the distribution coefficients are shown in Fig. 5b. In contrast with the former case, the apparent distribution coefficient decreases appreciably with the time of standing.

Ion Exchange.—The apparent distribution coefficient of protactinium was determined for cation and anion exchange resins at various concentrations of perchloric acid. As is shown in Fig. 6, protactinium is adsorbed on cation exchange resin to a considerable extent, and the distribution coefficient decreases with an increase in the concentration of perchloric acid, reaching a minimum at about 3 N; then it increases with an increase in the acidity. In the ranges from 0.4 M to 1.0 N and over 3 N, plots of the logarithm of the apparent distribution coefficient against the logarithm of the activity of perchloric acid show linear relationships, with slope of −1.5 and 0.5 respectively. As to anion exchange, the apparent distribution coefficient is lower by one order than in the case of cation exchange over the entire range of acidity, but the relation between the apparent distribution coefficient and the acidity is similar to that in cation exchange.

In order to examine the adaptability of the mass action law to cation exchange, the distribution of

volume and the amount of resin. The concentration of protactinium in the resin phase was plotted as an ordinate against the concentration of protactinium in the aqueous phase as abscissa, as is shown in Fig. 7. Experiments were undertaken at the acidities of 0.5 N and 3.10 N. In both cases,

linear relationships were observed which did not surpass the original.

Filtration.—*By Filter Paper.*—The effect of acidity on the removal of protactinium from a perchloric acid solution by filtration through filter paper is shown in Table I. In this case, 2 ml. of a sample solution was used. Furthermore, the effects of aging at various acidities and at various protactinium concentrations are presented in Fig. 8. The removal of protactinium decreases with an increase in the acidity, reaching a minimum at about 0.3 M; then it increases with an increase in the acidity. In the cases of carrier-free and 10^{-1} M solutions, the difference between the two cases is not obvious and virtually no effect of aging is recognized except for the drastic initial changes in carrier-free solutions. In contrast with this, in the case of a 10^{-1} M solution the removal is increased with the lapse of aging time, attaining a value of 45 per cent after 80 days.

* Paper is the abbreviation of Toyo-roshi No. filter paper.

** Membrane is the abbreviation of membrane filter supplied from Membrane-Filter-Gesellschaft, Göttingen.

*** C.F. is the carrier-free ^{233}Pa solution.

By a Membrane Filter.—The percentage of the removal of protactinium by membrane filters with various pore sizes was determined at a perchloric acid concentration of 5 N. In this experiment, 1 ml. of a sample solution was used. As is apparent in Table II, the percentage of removal increases with the decrease in pore size; this effect is especially noticeable when the protactinium concentration is 10^{-5} M.

Discussion

If the species extractable into the organic phase are considered not to have any charge, the general equation for the TTA extraction reaction can be written by modifying Connick and McVey's treatment[15] as:

$$\begin{aligned}PaO_m(OH)_nT_r^{5-2m-n-r}(aq.) &+ (5-2p-q-r)\\ &\times HT(org.) = PaO_p(OH)_qT_{5-2p-q}(org.)\\ &+ (m+n-p-q)H_2O(org.)\\ &+ (5-2m-n-r)H^+(aq.) \qquad (3)\end{aligned}$$

where HT represents the TTA molecule and T^-, the dissociated TTA anion. The equilibrium constants can then be defined as:

$$K_{m,n,p,q,r} = \frac{[PaO_p(OH)_qT_{5-2p-q}][H_2O]^{m+n-p-q}\times[H^+]^{5-2m-n-r}}{[PaO_m(OH)_nT_r^{5-2m-n-r}]\times[HT]^{5-2p-q-r}} \qquad (4)$$

where brackets have been used to represent the activities of the enclosed species. The designation of the phase in which each species exists has been omitted in order to simplify the writing of the equation. A distribution coefficient expressed in terms of activities is defined as the sum of the activities of protactinium species in the benzene phase divided by the sum of the activities of protactinium species in the aqueous phase;

$$K_d = \frac{\sum_{p,q}[PaO_p(OH)_qT_{5-2p-q}]}{\sum_{m,n,r}[PaO_m(OH)_nT_r^{5-2m-n-r}]} \qquad (5)$$

From Eq. 4, we obtain:

$$[PaO_m(OH)_nT_r^{5-2m-n-r}] = \frac{[PaO_p(OH)_qT_{5-2p-q}][H_2O]^{m+n-p-q}\times[H^+]^{5-2n-n-r}}{K_{m,n,p,q,r}[HT]^{5-2p-q-r}} \qquad (6)$$

15) R. E. Connick and W. H. McVey, *J. Am. Chem. Soc.*, **71**, 3182 (1949).

Since this equation holds for any set of values of p and q, we shall, for the sake of simplicity, choose $p=q=0$.

$$[PaO_m(OH)_nT_r^{5-2m-n-r}] = \frac{[PaT_5][H_2O]^{m+n}[H^+]^{5-2m-n-r}}{K_{m,n,o,o,r}[HT]^{5-r}} \quad (7)$$

From Eqs. 6 and 7, we obtain:

$$[PaO_p(OH)_qT_{5-2p-q}] = \frac{K_{m,n,p,q,r}[PaT_5][H_2O]^{p+q}}{K_{m,n,o,o,r}[HT]^{2p+q}} \quad (8)$$

Since Eq. 8 holds for any set of values of m, n and r, we shall choose these values to be zero.

$$[PaO_p(OH)_qT_{5-2p-q}] = \frac{K_{o,o,p,q,o}[PaT_5][H_2O]^{p+q}}{K_{o,o,o,o,o}[HT]^{2p+q}} \quad (9)$$

By substituting Eqs. 7 and 9 into Eq. 5, we obtain:

$$K_d = \frac{\sum_{p,q} \frac{K_{o,o,p,q,o}[H_2O]^{p+q}}{K_{o,o,o,o,o}[HT]^{2p+q}}}{\sum_{m,n,r} \frac{[H_2O]^{m+n}[H^+]^{5-2m-n-r}}{K_{m,n,o,o,r}[HT]^{5-r}}} \quad (10)$$

By taking the logarithm, we obtain:

$$\ln K_d = \ln \sum_{p,q} \frac{K_{o,o,p,q,o}[H_2O]^{p+q}}{K_{o,o,o,o,o}[HT]^{2p+q}} - \ln \sum_{m,n,r} \frac{[H_2O]^{m+n}[H^+]^{5-2m-n-r}}{K_{m,n,o,o,r}[HT]^{5-r}} \quad (11)$$

By taking the partial derivative of the logarithm of K_d with respect to the logarithm of the activity of HT and by substituting Eqs. 7 and 9, we obtain:

$$\frac{\partial \ln K_d}{\partial \ln [HT]} = \frac{-\sum_{p,q}(2p+q)[PaO_p(OH)_qT_{5-2p-q}]}{\sum_{p,q}[PaO_p(OH)_qT_{5-2p-q}]} + \frac{\sum_{m,n,r}(5-r)[PaO_m(OH)_nT_r^{5-2m-n-r}}{\sum_{m,n,r}[PaO_m(OH)_nT_r^{5-2m-n-r}]} = 5 - \sum_{p,q}(2p+q)f_{p,q} - \sum_{m,n,r} rf_{m,n,r} \quad (12)$$

where $f_{p,q}$ is the fraction of the total activity of the benzene phase contributed by the $PaO_p(OH)_qY_{5-2p-q}$ species, and where $f_{m,n,r}$ is that of the aqueous phase contributed by the $PaO_m(OH)_nT_r^{5-2m-n-r}$ species.

Hence:

$$\sum_{p,q} f_{p,q} = 1 \quad \text{and} \quad \sum_{m,n,r} f_{m,n,r} = 1 \quad (13)$$

Furthermore, as at least one molecule of TTA is co-ordinated to one atom of protactinium in the organic phase

$$2p + q \leqq 4 \quad (14)$$

holds.

If the activity coefficients of protactinium species are assumed to be constant, irrespective of the TTA concentration, the apparent distribution coefficient obtained empirically can be replaced for the thermodynamic distribution coefficient, K_d, expressed in terms of activity; no appreciable error should be introduced by this assumption. The curves in Fig. 1 show straight lines, with a slope of 4, in the range of TTA concentration, so that $\sum_{p,q}(2r+q)\cdot f_{p,q} + \sum_{m,n,r} rf_{m,n,r}$ should be unity. Suppose r is unity; that is, the average number of TTA molecules attached to protactinium in the aqueous phase is one; species extracted into the benzene phase should, then, have the PaT_5 form. If we can neglect the species having a TTA molecule in a perchloric acid solution, the $2p+q=1$ relation holds, so the average number of TTA attached to protactinium in the organic phase becomes 4 and then $Pa(OH)T_5$ predominates. It is clear that $r \geqq 2$ is impossible. The decrease in the slope in the higher concentration range of TTA can be explained by the increase in the average numbers of TTA attached to protactinium in the aqueous phase, and that in the range of lower concentration of TTA, by the decrease in the average number of TTA attached to protactinium in the benzene phase.

Taking the partial derivative of the logarithm of K_d with respect to the logarithm of the activity of hydrogen ion and by substituting Eq. 7, we can get:

$$\frac{\partial \ln K_d}{\partial \ln [H^+]} = -\frac{\sum_{m,n,r}(5-2m-n-r)PaO_m(OH)_n \times T_r^{5-2m-n-r}}{\sum_{m,n,r} PaO_m(OH)_nT_r^{5-2m-n-r}} = -5 + \sum_{m,n,r}(2m+n+r)f_{m,n,r} \quad (15)$$

If the activity coefficients of protactinium species and of hydrogen ion are assumed to be constant over the entire range of acidity when the ionic strength of a solution is held constant, the apparent distribution coefficient (K_d') obtained empirically can be replaced by the thermodynamic distribution coefficient(K_d) expressed in terms of activity; no appreciable error should be introduced by this assumption. As is clear from Fig. 3, the linear relationship with a slope of -1.6 holds between the logarithm of the apparent distribution coefficient and the logarithm of the hydrogen ion concentration with acidities of over 0.3 N and 0.1 N when the TTA concentrations are 0.12 M and 0.07 M respectively. Therefore,

$$-5 + \sum_{m,n,r}(2m+n+r)f_{m,n,r} = -1.6 \quad (16)$$

When $r=0$,

$$\sum_{m,n,o}(2m+n)f_{m,n,o} = 3.4 \quad (16')$$

Therefore, protactinium in a perchloric acid solution may be found in the forms $Pa(OH)_3^{2+}$ or $PaO(OH)^{2+}$ and $Pa(OH)_4^{+}$, $PaO(OH)_2^{+}$ or PaO_2^{+}. When $r=1$,

$$\sum_{m,n,1}(2m+n+1)f_{m,n,1}=3.4 \qquad (16'')$$

Species in perchloric acid may be in the forms $Pa(OH)_2T^{2+}$ or $PaOT^{2+}$ and $Pa(OH)_3T^{+}$ or $PaO(OH)T^{+}$.

From the above considerations, one can represent the reaction mechanism as:

$$PaO_m(OH)_n^{5-2m-n}+4HT \rightleftarrows Pa(OH)T_4 + (m+n-1)H_2O+(5-2m-n)H^+ \qquad (17)$$

where $2m+n$ is 3 and 4, or as:

$$PaO_m(OH)_nT^{4-2m-n}+4HT \rightleftarrows PaT_5 + (m+n)H_2O+(4-2m-n)H^+ \qquad (18)$$

where $2m+n$ is 2 and 3.

The reason for the phenomenon that the lower the perchloric acid concentration, the more remarkable the decrease in the slope of the curves in Fig. 1 at higher TTA concentrations, may be considered to be as follows. The solubility of TTA in the aqueous phase increases with the decrease in acidity, as is clear from Eq. 1, and the lower the acidity, the more easily TTA is dissociable. Therefore, TTA can form a complex with protactinium more easily in an aqueous solution with a low acidity. Similarly, in a weakly acidic solution, a high concentration of TTA facilitates the formation of anionic species, so that the maximum of the curves in Fig. 3 appears in the higher acidity region when the concentration of TTA is high. The curve in Fig. 2, the dependence of the apparent distribution coefficient on the perchloric acid concentration at a TTA concentration of 0.12 M, shows a straight line in the 0.3—1.0 N acidity range, with a slope of −1.5; this agrees with that in Fig. 3. The curve of an acidity below 0.3 N, however, is completely different from the results of Fig. 3. With an acidity of above 3 N, the apparent distribution coefficient increases with the increase in acidity, but this can not be understood in terms of the above-mentioned considerations, because the assumptions made in the preceding discussion are not applicable. In other words, the activity coefficients of protactinium species may change with the ionic strength; if so, in Eq. 15 the apparent distribution coefficient should not be used instead of the true distribution coefficient (K_d). Furthermore, it should be pointed out that, in performing the differentiation leading to Eq. 15, it was necessary that the activity of water remain constant, but this assumption may not hold in a case of a remarkable change in ionic strength.

For cation exchange reaction, we can write the general equation as:

$$PaO_m(OH)_n^{5-2m-n}+(5-2p-q)HR \rightleftarrows PaO_p(OH_qR_{5-2p-q}+(m+n-p-q)H_2O+(5-2m-n)H^+ \qquad (19)$$

where HR represents cation exchange resin. The equilibrium constant for this reaction can be defined as:

$$K_{m,n,p,q}=\frac{[PaO_p(OH)_qR_{5-2p-q}][H_2O]^{m+n-p-q}\times[H^+]^{5-2m-n}}{[PaO_m(OH)_n^{5-2m-n}][HR]^{5-2p-q}} \qquad (20)$$

and the distribution coefficient, as:

$$K_d=\frac{\sum_{p,q}[Pa(OH)_qR_{5-2p-q}]}{\sum_{m,n}[PaO_m(OH)_n^{5-2m-n}]} \qquad (21)$$

Proceeding as before gives:

$$\frac{\partial \ln K_d}{\partial \ln [H^+]}=-5+\sum_{m,n}(2m+n)f_{m,n} \qquad (22)$$

This equation is in the same form as (16''), so that the similarity between curves in Fig. 2 and Fig. 6 is not surprising. The difference between these curves may be due mainly to the following two reasons: first, the difference in the dependency of the activity coefficient on the perchloric acid concentration between the benzene phase and the resin phase, and second, the presence of non-adsorbable species on ion exchange resin.

Although no meaningful difference was observed between 10^{-7} M and 10^{-10} M protactinium solutions, a great difference in the stability of the solutions was observed between 10^{-5} M and 10^{-7} M solutions. This is probably due to the ease with which the 10^{-5} M solution polymerizes. It is interesting to note that this concentration is just below the limit of the solubility of protactinium in a 5 N perchloric acid solution.[6)]

To clarify this point, the effect of the protactinium concentration on the distribution coefficient for extraction was examined. It is apparent from Fig. 4, with a protactinium concentration of below 10^{-6} M, that the apparent distribution coefficient for TTA extraction is almost constant, regardless of the protactinium concentration, so this phenomenon may be characteristic of concentrated solutions such as 10^{-5} M. This is confirmed by the results of filtration experiments; that is, the amount uptaken on the filter from the solution of 10^{-5} M is extremely large. Above all, the results obtained by using a membrane filter may be an indication of the presence of colloidal aggregates of protactinium species. Furthermore, the remarkable dependence on the aging time encountered in the filtration of a 10^{-5} M solution through filter paper is consistent with the observation on the solvent extraction experiments.

16) R. Thompson, U. S. A. E. C., AECD-1897 (1948).

Even when the concentration of protactinium is lower than 10^{-6} M, a membrane filter with smaller pores removes radioactivity more effectively than one with larger pores. This is an indication of the presence of a small amount of colloidal aggregates. This assumption is also supported by the following consideration.

We suppose that one or more species, which are nonadsorbable on cation exchange resin and which do not reach equilibrium rapidly with adsorbable species, would be present in a solution and that the fraction of such species may be expressed by a. Under identical experimental conditions, one can assume that the activity coefficients of protactinium species are constant; therefore, the protactinium concentration, namely, the radioactivity in unit volume, might be proportional to the activity of protactinium species. For this reason, the radioactivity of protactinium, instead of its activity, will be used in the following discussion for the sake of simplicity. The distribution coefficient of the species adsorbable on the cation exchange resin can be defined as:

$$K_d = \frac{A_r/M}{A_{aq}/V} \tag{23}$$

where M represents the amount of cation exchange resin per gram; V, the volume of solution in ml. and A_r and A_{aq}, the radioactivity in each phase respectively. Let A, A'_r and A'_{aq} be the total radioactivity and the radioactivities in the resin phase and in the aqueous phase at equilibrium respectively; we can then write:

$$A'_r = A_r \tag{24}$$

$$A'_{aq} = A_{aq} - aA \tag{25}$$

By combining Eqs. 23, 24 and 25, we can get:

$$\frac{K_d}{V}(A'_{aq} - aA) = \frac{A'_r}{M} \tag{26}$$

From Eq. 26 we then obtain:

$$S_r = K_d S_{aq} - \frac{aA}{V} K_d \tag{27}$$

where:

$$A'_{aq}/V = S_{aq} \qquad A'_r/M = S_r \tag{28}$$

Equation 27 represents the relationship between S_{aq} and S_r to be linear and the slope to be K_d, namely, the distribution coefficient of the adsorbable species. If we represent the intercept of abscissa as $(S_{aq})_0$,

$$a = \frac{(S_{aq})_0}{A/V} \tag{29}$$

The ratio of the value of the intercept of abscissa to the initial activity in the unit volume of solution gives the fraction of nonadsorbable species. For a solution containing only adsorbable species in rapid equilibrium, we may obtain a straight line which passes through the point of origin. Figures 7a and b give the plot for solutions of about 10^{-8} M protactinium in 0.50 N and in 3.10 N perchloric acid respectively. These figures indicate that approximately 17% and 44% of nonadsorbable protactinium species are present in these media respectively. These results are compatible with the observations of the filtration experiment. No such phenomenon, however, can be observed in the solvent extraction. This difference between solvent extraction and ion exchange can be explained by the existence of a dynamic equilibrium in the solvent extraction, which in turn destroys the colloidal aggregates to some degree by means of the strong complexing action of TTA. This offers one reason for the small difference in behavior towards solvent extraction and cation exchange. The similarity between the effects of cation and anion exchange resins on the perchloric acid concentration seems curious, but in anion exchange experiments no such simple relation as Eq. 27 could be obtained and, therefore, further investigation is needed in order to illustrate the mechanism of anion exchange.

Summary

The chemical behavior of pentavalent protactinium in perchloric acid solutions has been investigated by TTA-benzene extraction, ion exchange and filtration methods. When the protactinium concentration is less than 10^{-6} M, the log-log plot of the apparent distribution coefficient and the activity of TTA in the benzene phase gives a straight line with a slope of 4, while the plot of the apparent distribution coefficient and the acidity in a constant ionic strength medium shows a linear relationship with a slope of -1.6 over the 0.3—2.0 N range of acidity. This relationship does not change with the aging of the solution.

Thus, under these conditions, the reaction of TTA extraction may proceed as:

$$PaO_m(OH)_n^{5-2m-n} + 4HT \rightleftarrows Pa(OH)T_4 + (m+n-1)H_2O + (5-2m-n)H^+$$

where $2m+n$ is 3 and 4, or as:

$$PaO_m(OH)_nT^{4-2m-n} + 4HT \rightleftarrows PaT_5 + (m+n)H_2O + (4-2m-n)H^+$$

where $2m+n$ is 2 and 3.

The cation exchange experiments give consistent results, leading to these conclusions. Contrary to this, when the concentration of protactinium is higher than 10^{-6} M, this relation does not hold and the apparent distribution coefficient decreases with the increase in aging time, even in a 5 N perchloric acid solution; therefore, it is considered that protactinium forms colloidal aggregates to a greater extent. This is also confirmed by the

filtration experiment; that is, the effect of the pore size of the filter and that of the aging time on the removal of protactinium from a solution by filtration are noticeable, especially when the concentration of protactinium is higher than 10^{-6} M. The behavior towards anion exchange resin can not be explained, however, and so further experiments are needed.

Part of the expenses for this investigation have been defrayed by a grant-in-aid by the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1715—1720 (1966)

Studies of Mixed Cyano Cobalt(III) Complexes. II.[1] The Geometrical Isomers of $[CoX(CN)en_2]^+$

By Kuwako OHKAWA, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received November 30, 1965)

Two new mixed cyano complexes, *cis*-$[CoCl(CN)en_2]Cl$ (red) and *cis*-$[CoBr(CN)en_2]Br$ (deep rose), have been synthesized and resolved into their optical isomers. The splitting patterns of the ligand field absorption bands of the cis and the trans isomers of the halogenocyanobis(ethylenediamine)cobalt(III) ion have been discussed in relation to the geometrical configurations of the complexes and to the σ- and π-antibonding contribution of the cyanide or the halide ligands to the metal d-orbitals. These studies have been made successfully using the circular dichroism data of the optically active *cis*-$[CoX(CN)en_2]X$ (X=Cl, Br).

Recently several papers[1-4] have appeared dealing with the mixed cyano-ammine or the mixed cyano-diamine complexes of cobalt(III). A rather normal character of cyanide as a ligand for cobalt(III) has been well established, although the ligand has an exceptionally high position in the spectrochemical series. From a spectrochemical point of view, the mixed cyano cobalt(III) complexes which contain the halogeno ligands or both the halogeno and the ammine ligands are very interesting, since the position of a halogeno ligand in the spectrochemical series is well separated from the position of an ammine ligand in the direction opposite to that of the cyanide ligand. Chan and Tobe[5,6] prepared some such complexes, namely, the trans forms of $[CoX(CN)en_2]X$ (X=Cl, Br); however, the corresponding cis forms are yet unknown.

In the present paper, the syntheses of the missing cis forms of $[CoX(CN)en_2]X$ (X=Cl, Br) and their resolution into their optical isomers will be described. Besides proving the cis structure, the optical resolution will give a convenient tool for the assignment of the d-d absorption bands; the splitting patterns of the so-called first and second absorption bands are reflected profoundly in the circular dichroism spectra. The geometrical structures of the related mixed cyano cobalt(III) complexes will also be discussed.

Experimental

Materials.—*The Dark Yellow Form of* $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot 6H_2O$.—To a solution of 15 g. of sodium cyanide in 200 ml. of water, 36 g. of $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$[7] was added. The desired complex precipitated gradually, and ammonia was evolved simultaneously. After about three hours, the resulting mixture was cooled in an ice bath and filtered. Another crop of the crude complex was obtained from the filtrate by cooling it in an ice bath and by adding alcohol. The yield was 37 g. This yellow complex was recrystallized from water below 35—40°C.

Found: C, 6.64; H, 1.61; N, 15.50. Calcd. for $C_2H_6N_4O_6S_2Na_3Co = Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]$: C, 6.42; H, 1.62; N, 14.98%.

Found: H_2O, 22.28. Calcd. for $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot 6H_2O$: 22.41%.

The Orange-yellow form of $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot 5H_2O$.—To a solution of 10 g. of sodium cyanide in 150 ml. of water, 24 g. of $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$[7] was added. The mixture was then warmed on a water bath and evaporated gently. When orange crystals began to appear, the reaction mixture was cooled in an ice bath. The complex was filtered and recrystallized from hot water by the addition of ethanol. Yield: 9 g.

Found: C, 6.82; H, 1.87; N, 14.45. Calcd. for $C_2H_6N_4O_6S_2Na_3Co = Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]$: C, 6.42; H, 1.62; N, 14.98%.

Found: H_2O, 19.08. Calcd. for $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot 5H_2O$: 19.40%.

The Dark Yellow Form of $K_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot H_2O$.—This was prepared by the same method as was the dark yellow form of $Na_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot 6H_2O$. To a solution of 20 g. of potassium cyanide in 100 ml. of water, 28 g. of $NH_4[Co(SO_3)_2(NH_3)_4]\cdot 3H_2O$[7] was added. To complete the reaction the mixture was then stirred. After the solution had been cooled in an ice bath for one hour, the dark yellow complex which had deposited was filtered and washed with water-methanol (1 : 1) and methanol. Another crop of the complex was obtained from the filtrate by the addition of methanol. The crude complex was recrystallized from water by the addition of methanol. Yield: 25 g.

Found: C, 5.89; H, 1.75; N, 13.66. Calcd. for $C_2H_6N_4O_6S_2K_3Co = K_3[Co(CN)_2(SO_3)_2(NH_3)_2]$: C, 5.69; H, 1.43; N, 13.26%.

Found: H_2O, 4.14. Calcd. for $K_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot H_2O$: 4.09%.

cis-$[Co(CN)(SO_3)en_2]$.—Thirty grams of the orange-yellow or the dark-yellow form of $M_3[Co(CN)_2(SO_3)_2(NH_3)_2]\cdot xH_2O$ (M=Na or K) was covered with 300 ml. of a 10% aqueous solution of ethylenediamine. When the mixture was heated on a water bath, it changed to a brown solution. After several minutes, a glittering complex began to crystallize. The mixture was kept on a water bath about three hours and then filtered. The crude complex was washed with a little of hot water about three times, with water, and finally with ethanol. Yield: 5.8 g.

The crystals which were recrystallized from hot water were pale brownish yellow and anhydrous.

Found: C, 20.22; H, 6.07; N, 23.47. Calcd. for $C_5H_{16}N_5O_3SCo = [Co(CN)(SO_3)en_2]$: C, 21.07; H, 5.65; N, 24.57%.

cis-$[CoCl(CN)en_2]Cl\cdot H_2O$.—In 135ml. of concentrated hydrochloric acid, 13 g. of *cis*-$[Co(CN)(SO_3)en_2]$ was suspended; this solution was then warmed on a water bath for about three hours. The color of the solution changed from yellow to red. After the solution had been evaporated to half of the original volume, it was filtered and 70 ml. of ethanol was added to the filtrate. The solution was then cooled in an ice bath; a red complex deposited gradually. The product was recrystallized from warm water by the addition of alcohol and washed with a water-ethanol mixture (1 : 2) and then with ethanol several times. Yield: 3.8 g.

Found: C, 21.71; H, 6.00; N, 24.97. Calcd. for $C_5H_{16}N_5Cl_2Co = [CoCl(CN)en_2]Cl$: C, 21.75; H, 5.84; N, 25.37%.

Found: H_2O, 6.56; Cl, 24.60. Calcd. for $[CoCl(CN)en_2]Cl\cdot H_2O$: H_2O, 6.12; Cl, 24.12%.

cis-$[CoBr(CN)en_2]Br\cdot H_2O$. — This complex was prepared by the same method as was the chloro complex, using 9.5 g. of *cis*-$[Co(CN)(SO_3)en_2]$ and 100 ml. of concentrated hydrobromic acid. Yield: 3 g.

Found: C, 16.46; H, 4.71; N, 19.00; Br, 43.63. Calcd. for $C_5H_{16}N_5Br_2Co = [CoBr(CN)en_2]Br$; C, 16.48; H, 4.42; N, 19.21; Br, 43.90%.

Found: H_2O, 4.73. Calcd. for $[CoBr(CN)en_2]Br\cdot H_2O$: 4.60%.

The Optical Resolution of cis-$[CoCl(CN)en]_2]^+$.—Racemic *cis*-$[CoCl(CN)en_2]Cl\cdot H_2O$ (9.06 g.) was dissolved in 90 ml. of water at about 35°C by rigorous shaking. To this solution, a solution of 5.31 g. of ammonium (+)-*d*-bromocamphor-π-sulfonate (NH_4-*d*-BCS) in 50 ml. of water was added at room temperature. After a few minutes, the diastereomer $(+)_{589}$-$[CoCl(CN)en_2]$-(*d*-BCS) began to separate as rosy crystals. To complete the reaction, the mixture was stirred, allowed to stand for about ten minutes, and then filtered. The diastereomer was washed with a little ice water five times and then with ethanol, and dried in air. The yield was 6.6 g. The recrystallization was made from a little water by the addition of alcohol. The diastereo mer is optically stable in water.

Found: C, 32.66; H, 5.54; N, 12.98. Calcd. for $C_{15}H_{30}N_5O_4SClBrCo = [CoCl(CN)en_2](C_{10}H_{14}O_4SBr)$: C, 32.74; H, 5.50; N, 12.73%.

For a 0.05% solution of the diastereomer in a 2 dm. tube:

$\alpha_{589} = (+)\ 0.14°$, $\alpha_{546} = (+)\ 0.11°$.

The recrystallized diastereomer (2.26 g.) and potassium iodide (7 g.) were ground in a mortar with a few drops of water. Ten milliliters of water was then added the mixture, and the resultant mixture was triturated for about half an hour. The complex thus deposited was separated by suction, and washed with a little ice water three times and then with alcohol. The complex was then recrystallized from warm water by the addition of alcohol in an ice bath.

Found: C, 16.57; H, 4.50; N, 19.32. Calcd. for $C_5H_{16}N_5ClICo = [CoCl(CN)en_2]I$: C, 16.34; H, 4.39; N, 19.06%.

For a 1/150 F solution of the complex in a 1/2 dm. tube:

$\alpha_{589} = (+)\ 0.02°$, $\alpha_{546} = (-)\ 0.10°$.

The Optical Resolution of cis-$[CoBr(CN)en_2]^+$—This complex was resolved by the same method as was the chloro complex. Racemic *cis*-$[CoBr(CN)en_2]Br\cdot H_2O$ (4.43 g.) was dissolved in 50 ml. of water at about 45°C by rigorous shaking. To this solution, a solution of 3.66 g. of ammonium (+)-*d*-bromocamphor-π-sulfonate in 20 ml. of water was added. After a few minutes, the precipitated diastereomer $(+)_{589}$-$[CoBr(CN)en_2]$-(*d*-BCS) was filtered, washed with a little ice water several times and then with ethanol, and dried in air. The yield was 2.9 g. The diastereomer is optically unstable in water.

For a 0.05% solution of the diastereomer in a 2 dm. tube:

$\alpha_{589} = (+)0.12°$, $\alpha_{546} = (-)0.10°$

The diastereomer (3.0 g.) was ground in a mortar with 6 ml. of concentrated hydrobromic acid; the complex thus deposited was filtered and washed with ethanol. The complwx recrystallized was anhydrous.

Found: C, 16.60; H, 4.52; N, 19.40. Calcd. for $C_5H_{16}N_5Br_2Co = [CoBr(CN)en_2]Br$: C, 16.48; H, 4.42; N, 19.21%.

For a 1/150 F solution of the complex;
in a 1/2 dm. tube, $\alpha_{589} = (+)\ 0.06°$;
in a 1/5 dm. tube, $\alpha_{546} = (-)\ 0.12°$.

trans-$[CoCl(CN)(NH_3)_4]Cl$.—The orange-colored complex[3] of $[Co(CN)(SO_3)(NH_3)_4]$ (10 g.) was suspended in 100 ml. of concentrated hydrochloric acid and warmed gently on a water bath. The color of the mixture became orange yellow, and sulfur dioxide gas was evolved. After about half an hour, the supernatant liquid was

decanted off; another 100 ml. of concentrated hydrochloric acid was added to the residue. The resulting mixture was warmed on a water bath for an hour, cooled to room temperature, and then allowed to stand overnight. The complex was separated from the liquid and washed several times by decantation using concentrated hydrochloric acid. This was washed with alcohol and dried in air. Yield: 9 g. This orange-yellow complex is rapidly aquated in water. No recystallization was made.

Found: C, 5.07; H, 5.59; N, 28.68; Cl, 31.58. Calcd. for $CH_{12}N_5Cl_2Co$ = [CoCl(CN)$(NH_3)_4$]Cl: C, 5.36; H, 5.40; N, 31.26; Cl, 31.68%.

trans-[CoBr(CN)$(NH_3)_4$]Br.—This complex was prepared by the same method as was the chloro complex, using 10 g. of [Co(CN)$(SO_3)(NH_3)_4$][3] and 100 ml. of concentrated hydrobromic acid. Yield: 10 g.

Found: C, 3.53; H, 3.93; N, 20.26; Br, 52.78. Calcd. for $CH_{12}N_5Br_2Co$ = [CoBr(CN)$(NH_3)_4$]Br: C, 3.84; H, 3.86; N, 22.40; Br, 51.10%.

The trans forms of [CoX(CN)en_2]X (X=Cl, Br) were prepared by the method of Chan.[5,6]

Measurements. — The absorption spectra were measured by a Beckman DU Spectrophotometer. The solvent employed for *cis*-[CoX(CN)en_2]X (X=Cl, Br) was water, and for *trans*-[CoX(CN)en_2]X, 70% perchloric acid. The circular dichroism spectra were recorded on a Spectropolarimeter, ORD/UV-5, of the Japan Spectroscopic Co. A Rudolph photoelectric spectropolarimeter, Model 200S-80, was used to check the optical rotation. All the measurements were made at room temperature.

Results and Discussion

The Geometrical Configurations of the Complexes.—Chan and Tobe[5] derived *trans*-[CoCl(CN)en_2]Cl from the orange-colored form of [Co(CN)$(SO_3)en_2$]. In the present study of the synthesis of the corresponding cis isomer, a new isomer of [Co(CN)$(SO_3)en_2$] was used as the parent compound; it was pale brownish-yellow in color and was derived from the brown form of $[Co(SO_3)_2(NH_3)_4]^-$ through an intermediate complex $[Co(CN)_2(SO_3)_2(NH_3)_2]^{3-}$. Two isomers of $M_3[Co(CN)_2(SO_3)_2(NH_3)_2]$, dark-yellow and orange-yellow, were obtained from the reaction between $[Co(SO_3)_2(NH_3)_4]^-$ and alkali cyanide. Babaeva and Baranovskii[8] had already obtained the yellow potassium salt as dihydrate and had assigned the cis(CN)-cis(SO_3)-trans(NH_3) structure to the complex. The structure of the new orange-yellow complex is unknown, At any rate, both the isomers produced the same yellow form of [C(CN)$(SO_3)en_2$]. This yellow-[Co(CN)(SO_3)·en_2] is less soluble in water than its orange-colored isomer, which has been prepared by Chan and Tobe. The cis configuration of the red-[CoCl·(CN)en_2]Cl, which was derived from the yellow-[Co(CN)$(SO_3)en_2$], was established by its optical

resolution; accordingly, it is certain that the yellow-[Co(CN)$(SO_3)en_2$] is the cis isomer, and the orange-[Co(CN)$(SO_3)en_2$], the trans isomer (see Fig. 1).

The corresponding tetrammin complex, [Co·(CN)$(SO_3)(NH_3)_4$], which is known only in one form (an orange colored form[3]), may be the trans isomer. The diffuse reflectance spectra of [CoX·(CN)$(NH_3)_4$]X (X=Cl, Br) support the theory that all these tetrammine complexes are trans isomers (see Table I).

The Ligand Field Absorption Bands.— The absorption curves of *cis*- and *trans*-$[CoCl(CN)en_2]^+$ are shown in Fig. 2 with the circular dichroism (CD) curve of $(-)_{546}$-*cis*-$[CoCl(CN)en_2]^+$. The absorption data of this and related complexes are summarized in Table I. The main difference between the absorption curves of the two geometrical isomers occurs in the first band region. That is, the first band of the trans isomer does not show any split, while that of the cis isomer seems to split into two components. This behavior is considerably different from that of the first bands of *cis*- and *trans*-$[CoCl_2en_2]^+$.[9] Basolo et al. have already pointed out a similar fact about the absorption bands of *cis*- and *trans*-$[CoCl(NO_2)en_2]^+$.[10]

The absorption behavior in the first bands of *cis*- and *trans*-$[CoCl(CN)en_2]^+$ can reasonably be elucidated on the basis of Yamatera's theoretical treatment.[11] The expected patterns of the split and shift of the first and second bands can be seen in Table III, in which those of two geometrical isomers of the $[CoXYN_4]$ type are newly constructed. The *trans*-$[CoCl(CN)en_2]^+$ ion belongs to the approximate symmetry of C_{4v}, and the cis isomer, to the C_s symmetry. It may be expected that the first band of the trans isomer splits into two components, A' and E, and the cis siomer, into three components, A' and 2A''. Now, the expected components of the first bands of the two geometrical isomers can be calculated by using some parameters, δ, which can be estimated from the observed values of the first bands of $[Co\,en_3]^{3+}$, $[Co(CN)_6]^{3-}$ and *trans*-$[CoCl_2en_2]^+$. The calculation are based on the following definitions:

$$\delta(X) = \delta_\sigma(X) + \delta_\pi(X)$$

$$\delta(Y) = \delta_\sigma(Y) + \delta_\pi(Y)$$

The results are shown in Table IV, along with the observed data. When the observed bands are considered in connection with the calculated values, it may be understood that the two expected components for the trans isomer are located so close to each other that the observed band does not split. The three expected components of the cis isomer correspond with the three CD bands of $(-)_{546}$-*cis*-$[CoCl(CN)en_2]^+$ in their first band region, as is shown in Table IV.

Thus, it can easily be explained that the superposition of the expected absorption components which correspond to the three CD bands gives the two-maxima in the absorption curve measured. The parameter values, δ(Cl)=−32.2 and δ(CN)=32.9, which were used here are also fit for the first band region (the absorption and CD bands[12,13]) of *cis*-$[CoCl_2en_2]^+$ or *cis*-$[Co(CN)_2en_2]^+$.

As may be seen in Fig. 3 and Tables I, II and IV, the splitting patterns of the first band of the *cis*- and *trans*-$[CoBr(CN)en_2]^+$ closely resemble

those of the corresponding isomers of $[CoCl(CN)\cdot en_2]^+$, and the expected components of the cis isomer also match the observed CD bands of $(-)_{546}$-*cis*-$[CoBr(CN)en_2]^+$.

In general, no distinct splitting has been observed in the second absorption band of the cobalt(III) complexes. The second band of *cis*-$[CoCl(CN)\cdot en_2]^+$ is no exception, as may be seen in Fig. 2. According to the theoretical consideration, however, the second band of *trans*-$[CoCl(CN)en_2]^+$ may be expected to split into two components (B_2 and E), and that of the cis isomer, into three components (A′ and 2A″). In fact, the CD curve of $(-)_{546}$-*cis*-$[CoCl(CN)en_2]^+$ shows three CD bands in its second band region, that is, a negative band (at about $79.2\times10^{13}sec^{-1}$), another negative band ($85.0\times10^{13}sec^{-1}$) and a positive band, ($96.2\times10^{13}sec^{-1}$) listing from the longer to the shorter wavelengths.

In the same way as in the first band region, the parameters, δ_σ and δ_π, in the second band of *cis*-$[CoCl(CN)en_2]^+$ can be estimated by using the observed values; the following parameter values can thus be reasonably obtained:

$$\delta_\sigma(CN)=36.5 \qquad \delta_\pi(CN)=-8.4$$
$$\delta_\sigma(Cl)=-30.5 \qquad \delta_\pi(Cl)=-7.4.$$

The two expected components in the second band of the trans isomer are also derived from these four parameters (Table IV). Recently, the CD curve of $(+)_{546}$-*cis*-$[Co(CN)_2en_2]^+$ has been reported by McCaffery et al.[13] in the 515—260 mμ region. The observed CD bands agree well with the values calculated from the present parameter values (Table IV). The CD spectrum of $(-)_{546}$-*cis*-$[CoBr(CN)en_2]^+$ in the second band region is overlapped by the charge transfer absorption band due to the coordinated bromo ligand, and so the evaluation of the parameter values, $\delta_\sigma(Br)$ and $\delta_\pi(Br)$, was impracticable.

4---- absorption curve of $K_3[CoBr(CN)_5]$ in aqueous solution.
5—— CD curve of $(-)_{546}$-*cis*-$[CoBr(CN)en_2]Br$ in aqueous solution.

The Charge Transfer Absorption Bands.— The present halogenocomplexes show two intense charge-transfer absorption bands due to the coordinated halogeno ligand X. The maxima of the shorter wavelength band, which was assigned to a $p_\sigma(X)$—d_{z^2} transfer,[14] are summarized in Table V, along with those of the related monohalogeno complexes.

From Figs. 2 and 3 and Table V, it may be seen that the bands of *cis*-$[CoX(CN)en_2]^+$ are located at longer wavelengths than those of the trans isomer. The band position of a cis isomer is about the same as that of the corresponding halogeno-pentammine complex; these are in the range from 130 to 133 ($\times10^{13}sec^{-1}$) for the chloro-complexes and from 117 to 120 ($\times10^{13}sec^{-1}$) for the bromo-complexes. On the other hand, the band position of *trans*-$[CoX(CN\ en_2]^+$ is about the same as that of the corresponding halogeno-pentacyano complexes. These facts suggest that the position of a charge transfer band depends on which kind of ligand occupies the trans position on the halogeno ligand, and that it does not depend on the kind of ligand in cis positions.

Studies of Calcichrome as a Spectrophotometric Reagent. IV. A New Spectrophotometric Method for the Determination of Aluminum with Calcichrome and Its Basic Study*

By Hajime Ishii and Hisahiko Einaga

Central Research Laboratory, Onoda Cement Co., Ltd., Koto-ku, Tokyo

(Received December 7, 1965)

It has been found that Calcichrome forms a stable complex with aluminum; the reaction has been studied spectrophotometrically in order to find the optimum conditions for the determination of aluminum. The aluminum-Calcichrome complex is formed gradually at about pH 6; its composition has been found to be 1 to 1. The complex has two absorption maxima, at approximately 312 and 560 mμ, when measured against water. On the other hand, two absorption maxima were found, at approximately 317 and 620 mμ, in the curve obtained as the difference between Calcichrome and its aluminum complex. A linear relationship was noticed between the concentration of aluminum and the absorbance under the conditions recommended. The molar extinction coefficients of the complex at 317 and 620 mμ were 11500 and 7200. and the sensitivities were 2.3×10^{-3} and 3.7×10^{-3} μg. Al/cm^2 respectively, which correspond to $\log(I_0/I)=0.001$. Some other metals, such as copper(II), iron(III), titanium(IV), vanadium(V), and zirconium(IV), interfere with the determination.

The present authors have found that Calcichrome, reported by Close and West[1] to be a reagent useful in the determination of calcium, forms stable complexes with copper(I and II) and iron(III); they have already reported new spectrophotometric methods for the determination of copper[2,3] and iron[4] on the basis of the formation of each complex. Furthermore, the present authors have recently discovered that this reagent also forms a stable complex with aluminum. The present paper will describe a direct spectrophotometric method for the determination of aluminum with Calcichrome and the results of its basic study.

Experimental

Reagents.—*Calcichrome Solution.* — A Calcichrome solution (2×10^{-4} M) was prepared by dissolving 0.1982 g. of Calcichrome in distilled water and by then diluting the mixture to 1 l. The Calcichrome used in this study was synthesized and purified by the method described in an earlier paper.[3]

Standard Aluminum(III) Solution.—A standard aluminum solution corresponding to 1×10^{-2} mol./l. of aluminum was prepared by dissolving 4.744 g. of aluminum potassium sulfate in distilled water, then adding small amounts of sulfuric acid to prevent any possible hydrolysis and diluting the mixture to 1 l. Working solutions of aluminum were prepared from this solution by dilution.

Buffer Solutions.—Buffer solutions were prepared by mixing 1 M acetic acid and 1 M sodium acetate in the ratios required.

Apparatus.—A Hitachi automatic recording spectrophotometer, model EPS-2, and a Hitachi spectrophotometer, model 139, were used, with 1 cm. matched cells, for obtaining absorption curves and for all the other absorbance measurements respectively. A Toa Dempa glass-electrode pH meter, model HM-5A, was used for all the pH measurements.

The Recommended Procedure for the Determination.—To a sample solution containing aluminum in a 25-ml. volumetric flask, 5 ml. of the Calcichrome solution and 5 ml. of a buffer solution (pH 6.0) are added. The solution is diluted with distilled water to the mark. After the solution has stood for 30 min., the absorbance of the solution is measured at 620 mμ against a reagent blank treated in a similar manner.

Results and Discussion

Absorption Curves.—From the results of preliminary experiments, it was found that Calcichrome forms a stable bluish-violet complex with aluminum in a neutral and/or a weak acidic medium. The ultraviolet and visible absorption curves of the complex at pH 6.0 are shown in Fig. 1, from which it will be found that the complex has two absorption maxima in the ultraviolet (λ_{max} 312 mμ) and visible (λ_{max} 560 mμ) regions, as may be seen from curve I obtained against water. On the other hand, in the curve III (the apparent absorption curve), which is obtained as the difference between Calcichrome and its aluminum complex,

two absorption maxima are found, at approximately 317 and 620 mμ. Figure 2 shows the apparent absorption curves of the complex at various pH values, from which it may be seen that the maximum absorption wavelength does not vary with the pH value. Taking account of this fact and of those described in the following paragraph, one species of the complex is considered to be formed under the conditions studied.

The Effect of pH on the Color Development.—The effect of pH on the color development of the aluminum-Calcichrome complex was examined at 620 mμ, with the concentrations of aluminum and Calcichrome made to 4×10^{-5} mol./l. The results are shown in Fig. 3, from which it can be seen that the maximum color can be obtained at approximately pH 6, and that the pH range in which nearly the same absorbance can be obtained is rather narrow. Therefore, the pH should be carefully controlled in the determination of aluminum.

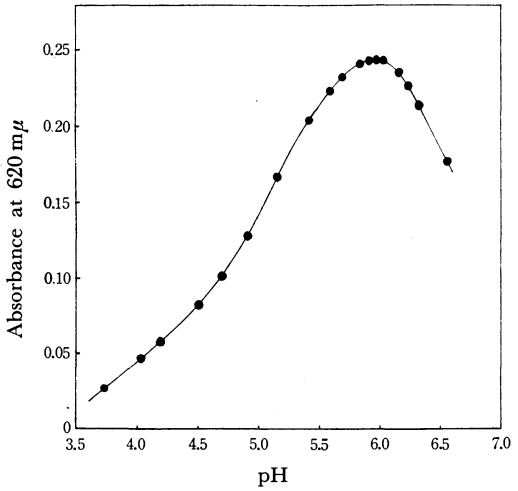

Fig. 3. Effect of pH on absorbance of the Al-(III)-Calcichrome complex.
Calcichrome: 4×10^{-5} mol./l.
Aluminum: 4×10^{-5} mol./l.

The Stability of the Color.—The color of the aluminum-Calcichrome complex develops gradually at room temperature; the full color is obtained 20 min. after the reagent is added. The time required to reach the full color can be, however, shortened remarkably by heating the solution to about 90°C. The color, once developed to the full, is very stable, and there is no change in absorbance over a period of 24 hr. Figure 4 shows the effect of the standing time on the absorbance.

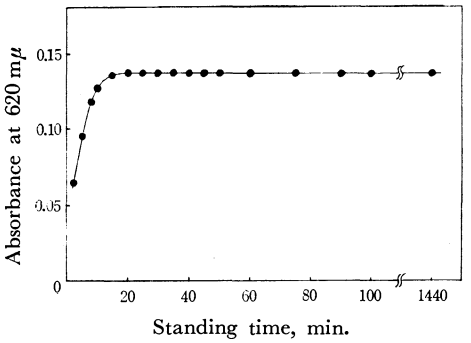

Fig. 4. Effect of standing time.
Calcichrome: 4×10^{-5} mol./l.
Aluminum: 2×10^{-5} mol./l.
pH: 6.0

The Effect of the Amount of Calcichrome.—The effect of the reagent concentration on color development was next examined, with the concentration of aluminum kept constant at 2×10^{-5} mol./l., with the pH values of the solutions at 6.0, and with the absorbance measurements carried out at 620 mμ. The results are shown in Fig. 5, from which it may be noticed that approximately a two-fold excess of the reagent over the aluminum concentration is necessary to obtain the maximum color intensity.

Fig. 5. Effect of amount of Calcichrome.
Aluminum: 2×10^{-5} mol./l.
pH: 6.0
Reference: Reagent blank

The Relationship between the Concentration of Aluminum and the Absorbance.—A linear relationship was found between the concentration of aluminum and the absorbance. The range of the aluminum concentration in which the linearity was noticed was, however, dependent upon the Calcichrome concentration; linearity was noticed up to the molar ratio of aluminum to Calcichrome of about 0.8. Figure 6 shows calibration curves for aluminum at 620 and 317 mμ. The molar extinction coefficient and the sensitivity which corresponds to $\log(I_0/I)=0.001$ are summarized in Table I. As may be seen from Fig. 6 and Table I, approximately 1.6 times as much sensitivity can be obtained when the

absorbance of the solution is measured at 317 mμ as when it is measured at 620 mμ, however, the latter wavelength was employed in the recommended procedure because it seems to be more convenient than the former.

The Effect of Diverse Ions.—The effect of diverse ions on the determination of aluminum was examined at pH 6.0. The results are summarized in Table II. From this it can be concluded that cobalt(II), chromium(III), copper(II), iron(III), mercury(II), magnesium(II), nickel(II), titanium-(IV), vanadium(V), and zirconium(IV) interfere; this is considered to be due to the formation of their complexes with Calcichrome. The tendency for a negative error to be given with increasing amounts of such cations as iron(III), titanium(IV), and zirconium(IV) is probably to be attributed to the easier complex formation of Calcichrome with these cations than that with aluminum, and to the diminution of the effective amounts of Calcichrome for complexing with aluminum. The interference of oxalate is probably due to complex formation with aluminum.

The Composition of the Complex.—Attempts to determine the composition of the complex were carried out by two methods; the continuous variation method and the mole ratio method. These attempts were made at pH 6.0, and the absorbance measurements were made at three wavelengths, 520, 605, and 620 mμ. Both methods revealed that aluminum forms a 1 to 1 complex with Calcichrome. As an example, the results obtained by the continuous variation method are shown in Fig. 7. The results by the mole ratio method, which are omitted to avoid duplication, are clear from Fig. 5.

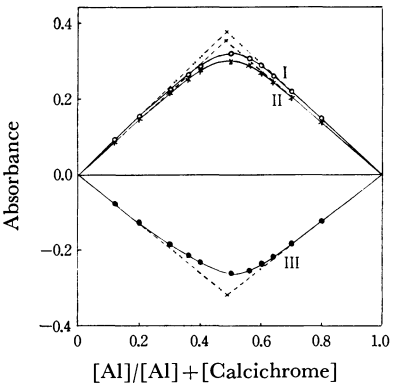

Fig. 7. Determination of mole ratio of Al(III)-Calcichrome complex.
[Al]+[Calcichrome]=1×10^{-4} mol./l.
pH: 6.0
I: 620 mμ, II: 605 mμ, III: 520 mμ

Conclusion

It has been found that Calcichrome forms a 1 to 1 complex with aluminum, and a new spectrophotometric method for the determination of traces of aluminum has been proposed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1724—1729 (1966)

Compounds Related to Imido-Substituted Ethylenes. I.* The Preparation of Diimido-Substituted Ethylenes

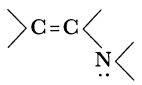
By Otohiko TSUGE, Kiyoshi YANAGI and Shōji FUKUHARA

The Research Institute of Science and Industry, Kyushu University, Hakozaki, Fukuoka

(Received August 31, 1965)

Methods for the preparation of *cis*-, *trans*-1, 2-diphthalimidoethylene, its nitro derivative, 1, 1-diphthalimido- and 1, 2-bis(*o*-sulfobenzimido)ethylene are described. In this connection, the thermal, irradiated and iodine-catalyzed isomerization of *cis*- and *trans*-1, 2-diphthalimidoethylene have also been studied in detail.

Unsaturated compounds I in which an unsaturated group is bonded with the nitrogen atom in an amino or imido group are expected to exhibit an interesting property under the influence of the unshared electron pair on the nitrogen atom.



I

Particularly, it is presumed that the preparation of polyamino- or polyimido-substituted ethylenes becomes more difficult than that of mono-substituted ethylenes, and that the poly-substituted ethylenes exhibit an unusual reactivity under the influence both of the steric effect of the substituents and of the unshared electron pair on the nitrogen atom.

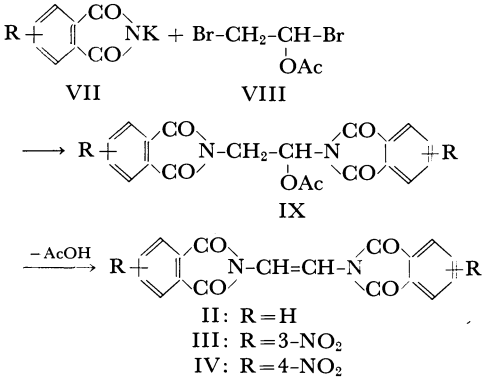
* Presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

Although monoimido-substituted ethylenes such as *N*-vinyl-phthalimide have been well studied,[1] no information has been available regarding polyimido-substituted ethylenes.

Therefore, in this work, the preparation of 1, 2-diphthalimidoethylenes (II—IV), 1, 1-diphthalimido- (V) and 1, 2-bis-(*o*-sulfobenzimido)ethylene (VI) has been attempted in the expectation that the diimido-substituted ethylenes would exhibit an unexpected reactivity.[2] In this connection, the present paper will describe the results of our experiments with the *cis-trans* isomerization of II under various conditions.

Results and Discussion

The Preparation of 1, 2-Diphthalimidoethylenes (II—IV).—1, 2-Diphthalimidoethylenes (II—IV) were synthesized by the pyrolytic elimination of acetic acid at about 250°C from the corresponding 1, 2-diphthalimido-1-acetoxyethane (IX), which had been prepared by the condensation of the potassium phthalimide (VII) and 1, 2-dibromo-1-acetoxyethane (VIII)[3] in dimethylformamide (DMF).



The crude II was recrystallized from DMF to give two compounds, whose solubilities in organic solvents were very small. The infrared spectrum of the more soluble, pale yellow needles (IIb) was in agreement with that of the crude II, but that of the less soluble, bright yellow grains or needles (IIa) was not.

As is shown in Fig. 1, the infrared spectra of IIa and IIb exhibit bands at 713 and 960 cm^{-1} which are to be ascribed to the -CH=CH- (*cis*) and -CH=CH- (*trans*) linkage respectively.[4] As

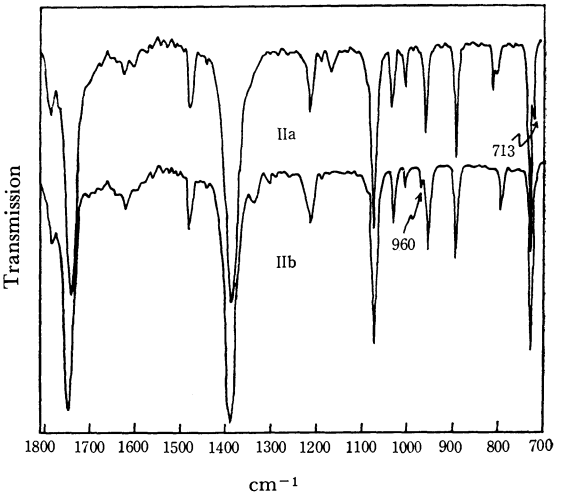


Fig. 1. Infrared spectra of IIa and IIb in KBr disks.

no suitable solvent of II could be found, the measurement of the NMR spectrum or of the dipole moment was not carried out.

On the basis of the infrared spectra as well as of elemental analyses, however, IIa and IIb were assumed to be *cis-* and *trans*-form respectively. In view of this fact, it may be suggested that *cis-trans* isomerization took place during recrystallization.

Furthermore, the ultraviolet spectra of IIa and IIb were almost the same (Fig. 2), and the two

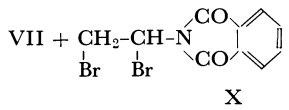
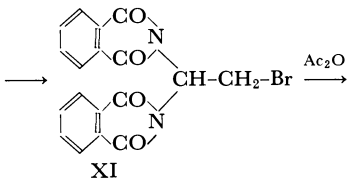
4) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules," John Wiley & Sons. Inc., New York (1954), p. 40.

isomers have the same melting point; however, IIa does not exhibit its own melting point, because IIa is easily isomerized to IIb by irradiation with light and by heating, as will be mentioned below. The geometric isomerism of III and of IV is not yet clear.

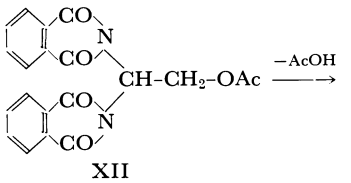
The Preparation of 1, 1-Diphthalimidoethylene (V).—1, 1-Diphthalimidoethylene (V) was synthesized by the pyrolytic elimination of acetic acid at 600°C from 1, 1-diphthalimido-2-acetoxyethane (XII) which had been prepared by the action of acetic anhydride on 1, 1-diphthalimido--2-bromoethane (XI), which had been obtained from VII and 1, 2-dibromo-1-phthalimidoethane (X)[1] in DMF.



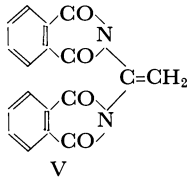
X



XI



XII



V

The formation of only XI in the reaction of VII with X suggests that VII attacked selectively at the α-carbon atom of X. The structure of XI was proved by the fact that XII was different from the IX isomer (R=H) as well as by elemental analyses.

The ultraviolet spectrum of V is also shown in Fig. 2. The ultraviolet spectrum of II is different from those of phthalimide derivatives, but the spectrum of V is very similar to those of the latter. These observations indicate that the electronic state of II is quite different from that of the phthalimide because of the interaction between the π-electron in the carbon-carbon double bond and unshared electron pairs on the nitrogen atoms, and that the interaction mentioned above does not exist in V, since the two phthalimido groups and the carbon-carbon double bond are not in the same plane because of the steric effect of the bulky phthalimido group.

The Preparation of 1, 2-Bis(*o*-sulfobenzimido)ethylene (VI). — The similar pyrolytic elimination of acetic acid from 1-acetoxy-1, 2-bis(*o*-sulfobenzimido)ethane (XIV) which had been prepared by the treatment of sodium salt of *o*-sulfobenzimide (XIII) with VIII in DMF, afforded 1, 2-bis(*o*-sulfobenzimido)ethylene (VI).

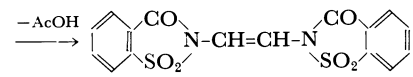
XIV



VI

The *cis-trans* Isomerization of IIa and IIb. —In order to obtain further information concerning the *cis-trans* isomerization of IIa and IIb, the isomerization reaction was carried out under various conditions.

The quantitative estimation of IIa and IIb in II was established by using the ratio method,[5] which was carried out by the measurement of the absorbances, A_1 and A_2, for the bands at 800 and 792 cm^{-1} respectively. Thus, samples of a mixture consisting of specified amounts of IIa and IIb in KBr were prepared and the absorbances, A_1 and A_2, were measured according to the respective baseline method. The calibration curves plotting

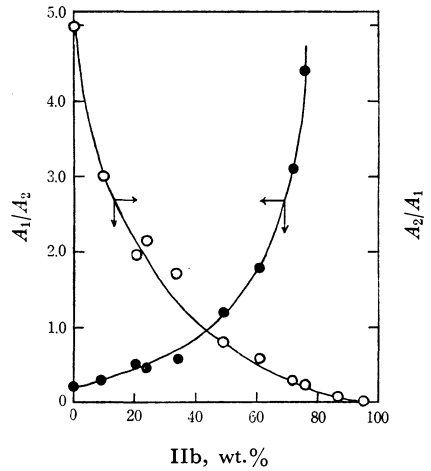


Fig. 3. Calibration curve.

5) S. Takagi, "Teiryō Bunseki no Jikken to Keisan (Experiment and Calculation of Quantitative Analyses)" (in Japanese), Vol. III, Kyoritsu, Tokyo (1961), p. 91.

the relationship between A_1/A_2 or A_2/A_1 and the concentration (wt. %) of IIb are shown in Fig. 3.

Thermal Isomerization.—The isomerization was observed on the recrystallization of II, as has been mentioned above; therefore, the thermal isomerization was examined in the solid state or in a solution.

The isomerization of IIa to IIb in the solid state was carried out in a sealed capillary tube under a nitrogen atmosphere. The results are shown in Table I.

Table I. The thermal isomerization of IIa to IIb

Temp. °C	Time min.	Degree of isomerization %	Temp. °C	Time min.	Degree of isomerization, %
100	60	0	200	5	12
100	180	4	250	5	100
150	30	0	300	5	100
150	60	4			

As is shown in Table I, the transition temperature from IIa to IIb in the solid state may be expected to be in the range from 200 to 250°C; hence, differential thermal analyses of IIa and IIb were carried out in order to establish the accurate transition temperature. The results are shown in Fig. 4. Although IIa showed a thermal abnormality at 220.5°C and melted at about 320°C, IIb showed no such anomalous curve and melted at about 320°C. Consequently, the transition temperature of IIa to IIb in the solid state may be concluded to be 220.5°C.

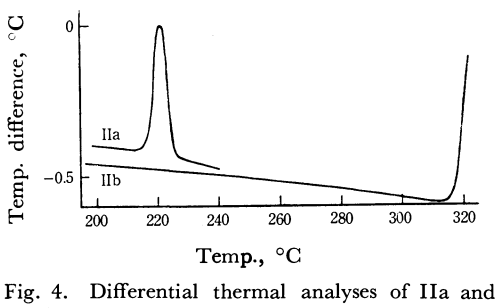

Fig. 4. Differential thermal analyses of IIa and IIb.

On the other hand, it was found that, in the isomerization in a solvent such as dioxane, tetrachloroethane, DMF or diethyleneglycol, IIb was isomerized to IIa in the range from 100 to 150°C, whereas IIa was isomerized to IIb above 150°C.

Iodine-Catalyzed Isomerization.—The isomerization under the influence of a catalytic amount of iodine was carried out in a tetrachloroethane solution at 20°C. The results are shown in Table II.

As Table II shows, the degree of isomerization of IIa to IIb in the presence of iodine increases with the increase in the reaction time, but in the absence of a catalyst neither form was isomerized.

While the recovered amount of IIb decreased as the iodine-catalyzed reaction time increased, the isomerization of IIb to IIa was not observed; the purple color of iodine and the yellow color of IIb disappeared after 24 hr., and an unidentified compound of colorless needles, m. p. 166—169°C, was formed. The same phenomenon was also observed in the treatment of IIa with iodine for a long while. The investigation of this side reaction is in progress and will be reported in the near future.

Table II. Iodine-catalyzed isomerization[a]

a) A solution of 40 mg. of the starting material in 50 ml. of tetrachloroethane was treated with 1 mg. of iodine in 10 ml. of tetrachloroethane.
b) The wt.% of IIb or IIa in the product.
c) In the absence of iodine.

Isomerization by Irradiation with Light.—The isomerization by irradiation with light (3500—4000 Å) was carried out in a tetrachloroethane solution at 18—20°C. The isomerization of IIa to IIb was brought about, but that of IIb to IIa was not. As is shown in Fig. 2, the ultraviolet spectra of the two isomers are almost the same. This suggests either that both isomers are in nearly the same electronic state or that isomerization from one to another takes place during the measurement. In order to elucidate which of the alternatives is true, the isomerization was examined under the same conditions as when the spectrum was measured. As it was found that the *cis*-form was converted into the *trans*-form, the spectrum of IIa shown in Fig. 2 is that of the *trans*-form.

Experimental[6]

1, 2-Diphthalimido-1-acetoxyethane (IX, R=H).—To a suspension of 185 g. of potassium phthalimide (VII, R=H)[7] in DMF (450 ml.) 123 g. of 1, 2-dibromo-1-acetoxyethane (VIII)[3] was slowly added, drop by drop, while the temperature was kept below 55°C with cooling. After the addition had been completed, the reaction mixture was stirred at room temperature for 2hr., and then water (4 l.) was poured into it. After a white precipitate had been collected by filtration, washed with water, and dried, recrystallization from glacial acetic acid gave colorless prisms. Yield, about 200 g.; m. p. 232—233°C.

6) All melting points are uncorrected.
7) "Organic Syntheses," Coll. Vol. I, 119 (1948)

Found: C, 63.64; H, 3.73; N, 7.41. Calcd. for $C_{20}H_{14}O_6N_2$: C, 63.49; H, 3.73; N, 7.41%.

1, 2-Bis(3-nitrophthalimido)-1-acetoxyethane (IX, R=3-NO_2).—A mixture of 7.85 g. of potassium 3-nitrophthalimide (VII, R=3-NO_2)[8] and VIII (4.2 g.) in DMF (35 ml.) was heated at 100°C for 15 min., and then stirred at room temperature for another 5 hr. The reaction mixture was poured into ice water, and the precipitate was collected, washed with water, and dried. The acetic acid solution of the crude product was diluted with water, and the crystalline product was collected by filtration. Yield, 6.5 g. (81%); m. p. 115—116°C. The compound was not further refined.

1, 2-Bis(4-nitrophthalimido)-1-acetoxyethane (IX, R=4-NO_2).—A mixture of 4.6 g. of potassium 4-nitrophthalimide (VII, R=4-NO_2)[9] and VIII (2.46 g.) in DMF (30 ml.) was stirred at room temperature for 5 hr., and then the reaction mixture was poured into ice water (300 ml.). Recrystallization from glacial acetic acid gave IX (R=4-NO_2) as palely colored rods melting at 207—208.5°C; yield, 4.7 g. (48.5%).

Found: C, 51.45; H, 2.64; N, 12.15. Calcd. for $C_{20}H_{12}O_{10}N_4$: C, 51.29; H, 2.58; N, 11.96%.

1, 1-Diphthalimido-2-bromoethane (XI).—After a mixture of VII (11.12 g.) and 1, 2-dibromo-1-phthalimidoethane (X)[10] in DMF (70 ml.) had been stirred at room temperature for 9 hr., ice water (500 ml.) was added to the reaction mixture. The precipitate was collected by filtration; recrystallization from ethyl acetate gave XI as colorless grains melting at 206—207°C. Yield, 22.35 g. (93%).

Found: C, 54.14; H, 2.90; N, 7.19. Calcd. for $C_{18}H_{11}O_4N_2Br$: C, 54.16; H, 2.78; N, 7.02%.

1, 1-Diphthalimido-2-acetoxyethane (XII).—A mixture of XI (6.6 g.), fused potassium acetate (6.6 g.) and acetic anhydride (60 ml.) was heated under reflux for 9 hr. After it had then cooled, the mixture was poured into ice water (400 ml.) and allowed to stand overnight. The precipitate was collected and washed with water. Recrystallization from glacial acetic acid gave XII as colorless prismatic rods; m. p. 207—208°C. Yield, 4.0 g. (64%).

Found: C, 63.60; H, 3.74; N, 7.53. Calcd. for $C_{20}H_{14}O_6N_2$: C, 63.49; H, 3.73; N, 7.41%.

1-Acetoxy-1,2-bis(*o*-sulfobenzimido)ethane (XIV).—A mixture of 20.5 g. of sodium salt of commercial *o*-sulfobenzimide (XIII) and VIII (12.3 g.) in DMF (40 ml.) was heated for 1 hr. at 100°C, and then refluxed for another 2 hr. After the reaction mixture had cooled to room temperature, water (400 ml.) was added to it and the precipitate was collected and washed with water. Recrystallization from glacial acetic acid gave XIV as palely colored needles; yield, 15.03 g. (67%); m. p. 221.5—222.5°C.

Found: C, 47.97; H, 3.19; N, 6.24. Calcd. for $C_{18}H_{14}O_8N_2S_2$: C, 48.00; H, 3.13; N, 6.22%.

1, 2-Diphthalimidoethylene (II).—In a 500 ml. separable flask, 200 g. of IX (R=H) was heated at 250°C for 15 min. As acetic acid was eliminated, the reaction mixture was gradually solidified. The crude product was washed with alcohol and then with hot acetic acid to remove phthalimide and tarry material respectively. Recrystallization from DMF afforded yellow crystals, which were identified, by means of the infrared spectrum, as a mixture of *cis*- (IIa) and *trans*-form (IIb); yield, 118 g. (70%).

Pure *cis*-form (IIa), bright yellow grains or needles, was obtained quantitatively by heating the recrystallized product (10 g.) in dioxane (20 ml.) for 4—5 hr. at 100°C.

Found: C, 68.01; H, 3.26; N, 8.79. Calcd. for $C_{18}H_{10}O_4N_2$: C, 67.92; H, 3.17; N, 8.80%.

Pure *trans*-form (IIb) was prepared by heating a saturated DMF solution of the recrystallized product at 150°C, and by then rapidly cooling the solution to room temperature. Pale yellow needles; m. p. 318.5—319.5°C.

Found: C, 67.87; H, 3.23; N, 9.09. Calcd. for $C_{18}H_{10}O_4N_2$: C, 67.92; H, 3.17; N, 8.80%.

1, 2-Bis (3-nitrophthalimido) ethylene (III).—After 5 g. of IX (R=3-NO_2) had been heated by the procedure used to prepare II, recrystallization from DMF gave III as deep yellow needles melting at 344—344.5°C; yield, 1.3 g. (30%).

Found: C, 52.99; H, 2.02; N, 13.65. Calcd. for $C_{18}H_8O_8N_4$: C, 52.95; H, 1.98; N, 13.72%.

1, 2-Bis (4-nitrophthalimido)ethylene (IV).—After 1.7 g. of IX (R=4-NO_2) had been heated at 260°C for 15 min., recrystallization from DMF afforded 0.3 g. (20%) of IV as deep yellow needles; m. p. 334°C (decomp.).

Found: C, 53.21; H, 1.85; N, 13.80. Calcd. for $C_{18}H_8O_8N_4$: C, 52.95; H, 1.98; N, 13.72%.

From the filtrate, 1.17 g. (69%) of IX (R=4-NO_2) was recovered.

1, 1-Diphthalimidoethylene (V).—A solution of XII (30 g.) in acetone (700 ml.) was added, drop by drop, to a pyrolytic tube which had been placed in an electric furnace at 550°C. After about two-thirds of the acetone had been distilled out from the reaction mixture, which had been collected in the receiver, the residue was poured into water to separate the precipitate. The precipitate was collected by filtration and washed with water. Recrystallization from ethyl acetate gave V as palely-colored plates; m. p. 247—248°C. Yield, 5 g. (20%).

Found: C, 67.88; H, 3.17; N, 8.83. Calcd. for $C_{18}H_{10}O_4N_2$: C, 67.93; H, 3.17; N, 8.80%.

1, 2-Bis(*o* - sulfobenzimido)ethylene (VI).—After XIV (6.75 g.) had been heated at 250°C for 10 min. in a 10 ml. thin-walled flask, the reaction mixture was washed with 15 ml. of hot acetic acid. Recrystallization from DMF gave VI as pale brown grains; m. p. 283—284°C (decomp.). Yield, 5.3 g. (90%).

Found: C, 49.07; H, 2.54; N, 7.29. Calcd. for $C_{16}H_{10}O_6N_2S_2$: C, 49.23; H, 2.58; N, 7.18%.

Thermal Isomerization.—The thermal isomerization of *cis*- (IIa) and *trans*-form (IIb) in the solid state was carried out in a sealed tube under a nitrogen atmosphere. The effect of the reaction conditions on the isomerization is shown in Table I.

In this and in other isomerizations, the IIa and IIb in the reaction mixture were analyzed quantitatively by using the ratio method (Fig. 3).

Differential Thermal Analyses.—The differential thermal analyses were carried out by using the Rigaku Denki Type-V apparatus. Alumina was used as the reference compound, and the heating rate was kept

8) M. T. Bogert and V. J. Chambers, *J. Am. Chem. Soc.*, **27**, 652 (1905).
9) M. T. Bogert and L. Boroschek, ibid., **23**, 755 (1901).

constant at 0.7°C/min. The temperature of the sample was higher than that of alumina throughout the run (Fig. 4). Perhaps this is caused by the difference in specific heat between sample and alumina.

Iodine-Catalyzed Isomerization.—To a solution of 40 mg. of IIa or IIb in tetrachloroethane (50 ml.), a solution of iodine (1 mg.) in tetrachloroethane (10 ml.) was added. After the reaction mixture had been allowed to stand at 20°C for a certain time, it was poured into petroleum ether (500 ml.). The precipitate was filtered and analyzed. The results are shown in Table II.

In a reaction of IIb with iodine, the reaction mixture was allowed to stand for a week, and then tetrachloroethane was distilled out in vacuo. The residue was recrystallized from dichloroethane to give colorless needles; m. p. 166—169°C.

Found: C, 64.55; H, 3.70; N, 9.09%.

Beilstein's test of the compound was negative, and its infrared spectrum exhibits the bands at 1770 and 1710 cm^{-1} ascribed to the phthalimido group. The investigation of this side reaction is now in progress; the structure of the compound will be described elsewhere in the near future.

Isomerization by Irradiation with Light.—Irradiations were carried out employing a 150 W., high-pressure mercury lamp with a water-cooled, quartz immersion well (Taika Kogyo, HLV-B Type). A solution of 400 mg. of IIa or IIb in tetrachloroethane (500 ml.) was irradiated with light (3500—4000 Å) under nitrogen at 18—20°C for 6 hr. The reaction mixture was poured into petroleum ether, and the precipitate was collected by filtration and then analyzed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1729—1733 (1966)

Specific Effects in Acid Catalysis by Polymeric Sulfonic Acids in the Hydrolysis of the Amino Ester and Related Compounds

By Sadao YOSHIKAWA and Oh-Kil KIM[1]

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received October 25, 1965)

The amino ester hydrolysis by polymeric sulfonic acids increased as the concentration ratio, C_{ester}/C_{acid}, was lowered, and a maximum in the plot of the rate constant, k, against the C_{ester}/C_{acid} ratio was attained near the ratio=0.4 in the case of the β-alanine methyl ester as well as in the case of γ-methyl L-glutamate. At this optimum concentration, the catalytic effect of polyvinylsulfonic acid (A), for example, in the hydrolysis of the β-alanine methyl ester was 16 times greater than that of hydrochloric acid, while the effect of polystyrenesulfonic acid was about 7 times greater. The catalytic effects of hydrochloric acid and ethanesulfonic acid were the same in all cases, and there was no such specific behavior as in the former. Furthermore, the catalytic efficiency of polyvinylsulfonic acid in amino ester hydrolysis increased with an increase in the polymer molecular weight, in contrast with the case of the carboxylic ester, while no such correlation was found in the polystyrenesulfonic acid. Besides, the catalytic effect of partially-neutralized polymeric sulfonic acid, polyvinylsulfonic acid especially, decreased remarkably with the degree of neutralization. These different kinds of behavior can be interpreted as being due to the difference in the expansion in solutions and in the geometrical distances between nearest-neighboring sulfonic acid groups on the polymer chain.

A number of studies[2] have been carried out in recent years on the charge interaction in the reactions using polyelectrolytes in order to reveal the mechanism of enzyme action. When organic reactions are carried out between a polymeric molecule and a simple substrate, functional interactions not only between neighboring groups, but also between polymer and substrate, especially when electrically-charged, are very often responsible for a change in the reaction path, consequently, they provide additional information regarding the mode of action of the enzyme. Since polymeric sulfonic acids with ionic groups along the polymer chain show properties of both electrolytes and polymers, one possible mechanism of enzyme specificity may be expected to be due to the electrostatic attraction of the poly-anion with the cationic reagent, when it is used as a catalyst in the reaction with a basic substrate. In a previous paper,[3] we have

demonstrated that the acid-catalyzed hydrolysis of carboxylic esters by polymeric sulfonic acid was governed by the hydrophobic interaction between the polymer catalyst and the substrate and, moreover, influenced by the molecular weight of the polymer.

The present work was undertaken in an attempt to find how the charge interaction of the polymeric acid on amino esters is operative with the hydrolysis rate in a homogeneous solution and to explain the mechanism of hydrolysis upon the basis of the charge density of the polymer acid. In this study we selected the hydrolysis of amino ester and related compounds using polyvinylsulfonic acid (PVSH), polystyrenesulfonic acid (PSSH) and sulfonated polystyrene sulfonic acid ((PS)SH), in addition to the monomeric analogue, ethanesulfonic acid, and hydrochloric acid, in order to compare the hydrolysis with that of uncharged carboxylic esters. The sulfonic acids were prepared by different polymerizing processes from their respective monomers (except for sulfonated polystyrene sulfonic acid), and all were water-soluble.

Experimental

Amino Esters.—Glycine methyl ester hydrochloride was prepared by refluxing a solution of glycine in absolute methanol containing anhydrous hydrogen chloride. α- and β-Alanine methyl esters, the γ-aminobutyric acid methyl ester and γ-methyl L-glutamate were prepared by treating each amino acid with methanolic hydrogen chloride. All the esters were recrystallized from anhydrous methanol-ether and dried in vacuo over sodium hydroxide. Acetylcholine chloride was obtained commercially.

Polymeric Sulfonic Acid.—The monomers, sodium vinylsulfonate and potassium *p*-styrenesulfonate, were prepared from sodium β-bromoethanesulfonate and sodium hydroxide by modifying the patent directions,[4] and from β-bromoethylbenzenesulfonyl chloride and potassium hydroxide according to the method of Wiley and Reed.[5] The polymerizations of sodium vinylsulfonate and potassium *p*-styrenesulfonate were carried out by three different methods.

Poly-(sodium vinylsulfonate) was obtained as follows:

PVSH(A).—Five grams of sodium vinylsulfonate in 4.9 ml. of water was poured into an ampoule, chilled in ice, and evacuated to about 2 mmHg, the evacuation and pressuring with nitrogen was repeated, and then the ampoule was sealed. The polymerization was carried out by exposing it to a ^{60}Co source, yielding about 2×10^5 r./hr., for 72 hr. at 0°C. The resulting sticky solid was dissolved in 30 ml. of water and precipitated by adding 45 ml. of methanol. Treating the gummy precipitate with methanol yielded 3.5 g. of straw-colored polymer after it had been dried in vacuo over phosphorus pentoxide. The intrinsic viscosity[6] of the polymer was 12.8, and the molecular weight[6] was 20000.

PVSH(R).—Twelve grams of a 50% aqueous solution of sodium vinylsulfonate containing 0.057 g. of potassium persulfate and 0.023 g. of sodium bisulfite was poured into an ampoule; the ampoule was then evacuated, repeatedly filled with nitrogen, and then sealed. After the ampoule had been tumbled in a bath at 18°C for 72 hr., the resulting viscous oil was dissolved in 30 ml. of water and precipitated with 45 ml. of methanol; 4.08 g. of polymer was obtained after drying in vacuo over phosphorus pentoxide. The intrinsic viscosity was 7.20, and the molecular weight was 12000.

PVSH(S).—Five grams of finely-powdered and dried crystalline sodium vinylsulfonate was sealed in an ampoule and then exposed to a ^{60}Co source, yielding about 2.5×10^5 r./hr., for 72 hr. at room temperature. The irradiated crystals, after precipitation with 70% aqueous methanol in the usual fashion in order to remove monomers, gave 2.5 g. of the polymer. The intrinsic viscosity and the molecular weight of the polymer were 1.70 and 3000 respectively.

Poly-(potassium *p*-styrenesulfonate) was obtained as follows:

PSSH(A).—Four grams of potassium *p*-styrenesulfonate in 16 ml. of water was poured into an ampoule. Polymerization reactions were then carried out in the same manner, with γ-irradiation, as in the case of PVSH(A), except that this was done at room temperature. The polymer formed was precipitated from 70% aqueous dioxane. After drying in vacuo over phosphorus pentoxide, 2.5 g. of the polymer was yielded. The intrinsic viscosity[7] of the polymer was 42.0.

PSSH(R).—Five grams of potassium *p*-styrenesulfonate in 15 ml. of water was placed into an ampoule, and then a solution of 1.35 g. of potassium persulfate and 0.66 g. of sodium bisulfite in 2 ml. of water was added as an initiator. The polymerization was carried out in the same manner as has been described in the case of PVSH(R). The resulting viscous oil was precipitated from 70% aqueous dioxane; 3.2 g. of polymer was thus obtained after drying in vacuo over phosphorus pentoxide. The intrinsic viscosity was 30.7.

PSSH(S).—Five grams of finely-powdered and dried crystalline potassium *p*-styrenesulfonate was sealed in an ampoule and exposed to radiation under the same conditions as have been described in the case of PVSH(S). The irradiated crystals yielded 2.3 g. of the polymer after precipitation with 75% aqueous methanol; the polymer was dried according to the usual fashion. The intrinsic viscosity was 18.09. All the sodium and potassium polymer sulfonates were completely converted into free acids by passing them through a column of cation exchange resin in a hydrogen form such as Amberlite IR-120.

(PS)SH (69%).*—The sulfonation of polystyrene ($\overline{M}_w=15\times10^4$) was carried out, using the addition-compound of sulfur trioxide and dioxane, by the method

described by Signer and his co-workers.[8] To a finely-divided suspension of the adduct, consisting of 20 g. of sulfur trioxide and 26 ml. of dioxane in 140 ml. of dichloroethane, a solution of 26 g. of polystyrene in 140 ml. of dichloroethane was added in one portion, then the mixture was agitated for several minutes. The sulfonation proceeded to 69% after the mixture had stood at 20°C for 24 hr. The reaction was then stopped by the addition of water. The polymer was dissolved easily in water and neutralized with sodium hydroxide. The sulfonated polymer salt was dialyzed to remove sulfuric acid through a semipermeable membrane by keeping it in distilled water for one month. The dialyzed sulfonated polymer salt was converted into free acid through ion exchange resin in the hydrogen form by the usual method.

Ethanesulfonic acid (Et.-SO_3H) was prepared from ethyl bromide, sodium sulfite and water according to the directions of Houlton and Tartar.[9]

Hydrolysis Procedure.—All the kinetic studies reported here were carried out in aqueous solution at 45±0.01°C. The initial concentrations of amino acid ester hydrochlorides were adjusted to 0.20, 0.10, 0.05, 0.033, 0.025 and 0.020 mol./l., and the acid catalyst concentration, to 0.08 N. Three or four samples were used in each run, and each reaction mixture was made up by taking 4 ml. of the ester and an equal volume of the acid, both concentrations being initially adjusted. The reaction mixtures were contained in 10 ml. glass-stoppered bottles suspended in a thermostat controlled bath. The tubes were removed at suitable intervals and placed in an ice bath. After hydrolysis, the tubes were opened, and the contents were washed from the tube with water into a 100 ml. beaker; to this 10 ml. of the 37.5% formaldehyde solution, which had been neutralized with basic magnesium carbonate just before use, was added. A modified form of the Sörensen formol titration proposed by Dunn and Loshakoff[10] was used to determine the extent of hydrolysis. Titrations were made with 0.05 N sodium hydroxide, using an automatic titrator (Metrohm Co. potentiograph E336), in order to determine the end point. The titration of the known amino acid showed that this method gave satisfactory results, within ±0.2%. The hydrolysis rate constants were calculated using the first-order rate equation. The efficiency of the catalyst, q, was defined as the ratio of the specific rate of hydrolysis catalyzed by polymeric sulfonic acid to that catalyzed by hydrochloric acid.

Results and Discussion

Several series of experiments have been carried out, at a constant acid concentration (0.04 mol./l.), in order to examine the influence of the ester concentration on the order of the hydrolysis reaction. The experimental apparent first-order rate constant was evaluated from the slopes of the plots of the logarithm of the ester concentration against the time; it was found that the hydrolysis reaction proceeds through a first-order mechanism with respect to the ester concentration, as is shown in Fig. 1.

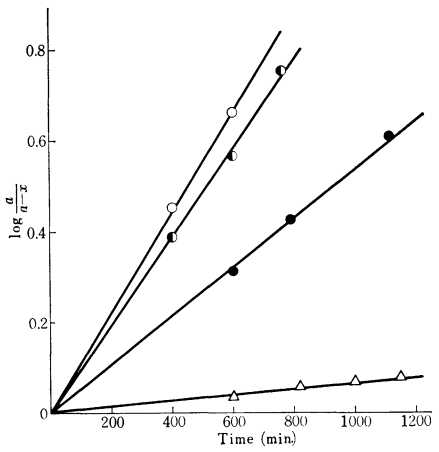

Fig. 1. Hydrolysis of β-alanine methyl ester catalyzed by 0.0405 N HCl and 0.0421 N PVSH-(A) in different ester concentrations (as indicated in the following parenthesis) at 45°C.
△ (0.0511 mol./l.) by HCl; ● (0.0511 mol./l.), ◐ (0.0255 mol./l.) and ○ (0.0170 mol./l.) by PVSH(A).

The effect of the structure of the amino ester on the rate of its hydrolysis can only be touched on here. One general point was that the α-amino ester tends to be less readily hydrolyzed than the β- or the γ-amino ester; this can be attributed to the fact that the former ester bond is nearer the positively-charged amino group in the amino ester. The results, given in Table I, indicate that all amino esters are hydrolyzed much more rapidly by polymeric sulfonic acids, especially PVSH(A), than by hydrochloric acid; the β-alanine methyl ester,

for instance, was hydrolyzed 8.6 times faster by PVSH(A) than by hydrochloric acid.

Moreover, PVSH was a more effective catalyst than PSSH and (PS)SH (69%). A striking change was observed on varying the ester concentration in the hydrolysis of every amino ester with polymeric sulfonic acids, as is tabulated in Table II. The effect of the substrate concentration on the rates of hydrolysis with polymeric sulfonic acids at a constant acid concentration was determined. The hydrolysis rate constant increased with a decrease in the ester concentration (at a constant acid concentration), but subsequently rose to a maximum. It was reproduced in the plot of the ratio of the concentration of the ester-to-polymer catalyst, C_{ester}/C_{acid}, against the hydrolysis rate constant, k, with respect to the reaction of the β-alanine methyl ester, as is illustrated in Fig. 2. A maximum was attained near the concentration ratio of 0.4 in the case of the β-alanine methyl ester as well as in that of γ-methyl L-glutamate. No such specific behavior was, however, found in either the hydrolysis by hydrochloric acid or that by ethanesulfonic acid; the catalytic effects of these two acids were the same.

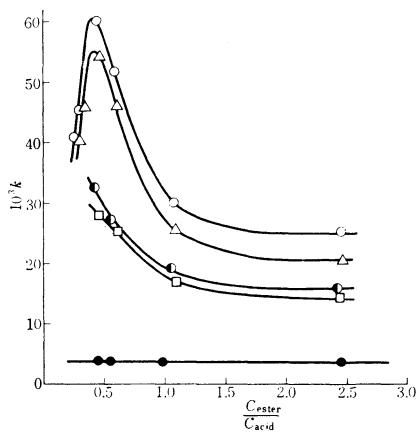

Fig. 2. Rate dependence as a function of the ratio of the concentration of the ester to the acid in the hydrolysis of β-alanine methyl ester:
●, HCl; □, PVSH(S); △, PVSH(R); ○, PVSH(A); ◐, (PS)SH (69%).

This accounts for the fact that hydrolysis takes place more easily at the optimum concentration of the ester within the domain of the polymer molecules. In other words, a larger value of the concentration ratio (over 0.4) leads to a shortage of the catalytically available neighboring free acid group towards the polymeric acid-substrate complex, while a smaller one (below 0.4) leads to a shortage of the complex available to attack by the nieghboring free acid group. This phenomenon is of interest in discussing the reaction mechanism in connection with the findings that the solvolytic rates of potassium 3-nitro-4-acetoxybenzenesulfonate catalyzed by 0.010 base molar poly-(4-vinylpyridine) increase as the pH is lowered and that a

maximum in the k - α plot (k is the rate constant, and α is the fraction of nitrogen present as the free base) is attained near $\alpha=0.6$ (pH 3.6), as has been reported by Letsinger and Savereide.[2c]

This specific effect in acid catalysis by polymeric sulfonic acids proves especially interesting when the catalytic activity relating to the structure of the polymer catalyst is discussed. The above data support the hypotheses that a free amino group must be present on the substrate if the anion of polymeric sulfonic acid is to be catalytically active, and that a complex is formed between the amino group of the substrate and the charged sulfonate group of the polymer catalyst before hydrolysis takes place.

Moreover, it was found that a methyl-substituted amino group of the substrate, such as acetylcholine chloride, also underwent the same specificity. This means that the reaction is governed only by the charged interaction between the polymer catalyst and the substrate insensitive to the steric factor of the substituents on the amino group. These observations are supported by the fact that the catalytic effects of polymeric sulfonic acids in the hydrolysis of the acetylglycine methyl ester were nearly the same as that of hydrochloric acid; the rate constants of HCl, PVSH(R) and PSSH(R), under the same conditions as is shown in Table II except for the ester concentration (0.021 mol./l.), were 9.08×10^{-3}, 9.45×10^{-3} and 9.81×10^{-3} respectively, which leads to the conclusion that there is no interaction between the substrate and polymeric sulfonic acid.

Furthermore, the difference in the catalytic effects between PVSH and PSSH can be attributed to the difference in the expansion in solutions and in the geometrical distances between sulfonic acid groups on the polymer chain, as has been described in a previous paper[3] with respect to the hydrolysis of carboxylic esters. The molecules of PVSH in solutions are possibly not greatly expanded as compared to that of PSSH; therefore, the localized protons along the polymer are confined within an extremely limited region in the reaction system in proportion to the magnitude of the molecular weight of PVSH. This interpretation is probably closely related to the fact that the catalytic efficiency, q, of PVSH increases gradually with the magnitude of its molecular weight, as is shown in Fig. 3, though no such correlation was found with PSSH-type catalysts. This observation can be explained by the fact that the complex formed by the preferential binding of the poly-anion to the positively-charged amino group of the substrate was surrounded by a high proton concentration in the polymer coil arising from the limited expansion of PVSH compared to that of PSSH.

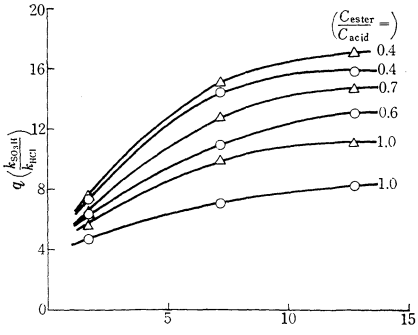

Fig. 3. Relation between the catalytic efficiency and the molecular weight of polyvinylsulfonic acid at constant C_{ester}/C_{acid} in the hydrolysis of β-alanine methyl ester (○) and L-glutamic acid γ-methyl ester (△).

Therefore, the local condensation of protons in the reaction system caused by the limited expansion of the polymer is largely responsible for the specific behavior of polymer catalysts, especially PVSH. The hydrolysis rate constants of the β-alanine methyl ester hydrolyzed by 30% neutralized PVSH(S) (0.0554 N) and by 30% neutralized (PS)SH (69%) (0.0620 N), both neutralized with barium hydroxide and where the ester concentration was 0.100 mol./l., were 6.84×10^{-3} and 12.57×10^{-3} (l. mol^{-1} min^{-1}) respectively, while the rate constants for the ester hydrolyzed by un-neutralized PVSH(S) and (PS)SH (69%) under the same conditions were 14.8×10^{-3} and 16.9×10^{-3} (l. mol^{-1} min^{-1}) respectively.

Such markedly different catalytic behavior of the two types of polymer catalysts can be attributed to the difference in the molecular expansion. The difference in the catalytic effects between sulfonated isotactic polystyrene sulfonic acid (70% sulfonation)[11] and the atactic one ((PS)SH(69%)) was, however, not very distinct for the series of amino esters; the hydrolysis rates with the former were 19.04×10^{-3} for the β-alanine methyl ester (0.0170 mol./l.), 35.16×10^{-3} for methyl γ-aminobutyrate (0.0501 mol./l.), and 44.10×10^{-3} for acetylcholine chloride (0.0501 mol./l.) at 45°C. These observations can be interpreted to mean that the difference in the geometrical distances between sulfonic acid groups on the polymer differing in configuration was not distinct enough in a solution to cause a difference in the catalytic activity.

11) Sulfonation of isotactic polystyrene ($\overline{M}_w>5\times 10^5$) was carried out in sulfuric acid for 6 hr. at 95°C using 10 g. of finely powdered isotactic polystyrene, 0.5 g. of silver sulfate and 100 ml. of concentrated sulfuric acid by modifying the directions by Takahashi and co-workers (*J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zassi)*, **61**, 1617 (1958)).

Methylene-hydantoin and Related Compounds. III. Synthesis of 5-Ethylidene-hydantoin: Attempts to Synthesize 5-Vinyl-hydantoin

By Shunsuke MURAHASHI,

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka

and Heimei YUKI and Koichi KOSAI

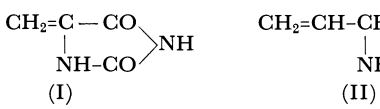
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received November 10, 1965)

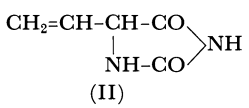
A number of methods of preparation were studied in an attempt to synthesize 5-vinyl-hydantoin using acrolein as a starting material. There were three possible routes: 1) the thermal decomposition of 5-(9, 10-dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin at 400°C; 2) that of 5-(2-acetoxyethyl)-hydantoin and 3) the elimination reaction of dimethyl 2-(5-hydantoin)-ethyl sulfonium iodide in dimethyl sulfoxide by potassium *t*-butoxide. However, all the reactions gave 5-ethylidene-hydantoin as the product instead of 5-vinyl-hydantoin. An extreme ease of isomerization from 5-vinyl-hydantoin to 5-ethylidene-hydantoin was caused by the highly stable structure of the latter compound. The strong resonance stabilization of 5-ethylidene-hydantoin was observed in the ultraviolet spectrum. 5-Methyl-5-vinyl-hydantoin, which has no migrating hydrogen, could not be obtained from the 5-methyl derivatives of the above compounds.

In previous papers the present authors reported the synthesis of 5-methylene-hydantoin[1] (I) and its polymerization.[2] As an extension of these studies, the synthesis of 5-vinyl-hydantoin (II) was attempted. *C*-Vinyl-glycine and 5-vinyl-hydantoin are expected to form a new amino acid and new types of vinyl monomers, but these compounds have never been prepared, although their homologues, such as 5-allyl-hydantoin,[3] 5-(3-butenyl)-hydantoin,[4] and the corresponding amino acids derived from them, have been reported.

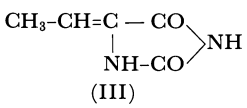
Among the several routes investigated, it seemed that three routes could give 5-vinyl-hydantoin. These are: (1) the retro Diels-Alder reaction of 5-(9, 10-dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin (IV); (2) the elimination of acetic acid from 5-(2-acetoxyethyl)-hydantoin (V), and (3) the decomposition of dimethyl 2-(5-hydantoin)-ethyl sulfonium iodide (VI).



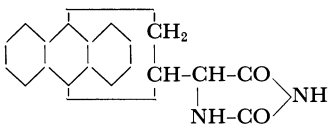
(I)



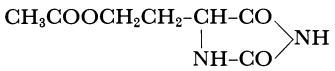
(II)



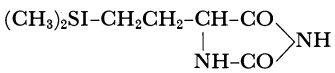
(III)



(IV)



(V)



(VI)

In the present work, however, 5-vinyl-hydantoin could not be obtained; therefore, its isomer, 5-ethylidene-hydantoin (III) was taken as the product. 5-Ethylidene-hydantoin had been known since 1887,[5] and recently Guyot has prepared it by the decarboxylation of 5-carboxyethylidene-hydantoin.[6] This paper will give information on new methods of preparing 5-ethylidene-hydantoin.

Results and Discussion

The Decomposition of 5-(9, 10-Dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin (IV). —5-Vinyl-hydantoin might seem to be easily prepared from acrolein in one step by Bucherer's

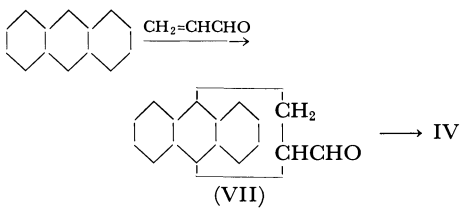
method[7] if the method could be applied to it. However, the addition of hydrogen cyanide to the C=C, instead of the C=O double bond, in acrolein takes place by Bucherer's reaction in a methanol-water mixture. Küchlin[8] has reported that the cyanohydrin could be obtained from acrolein and hydrogen cyanide in anhydrous ether, but in the presence of water the cyanohydrin dissociates to acrolein and hydrogen cyanide and gives an addition compound of hydrogen cyanide to the C=C double bond.

The difficulty in preparing 5-vinyl-hydantoin by a straightforward method from acrolein suggested to us that we employ an indirect route, including the Diels-Alder addition of acrolein and retro-reaction after the conversion of the adduct to its hydantoin derivative. In the present study anthracene was used as the diene because of the moderate stability of its acrolein adduct. 9, 10-Dihydroanthracene-9, 10-*endo*-α, β-propionaldehyde (VII) was obtained by heating a mixture of the components at 150°C.



This was then converted to 5-(9, 10-dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin (IV) by Bucherer's reaction in a methanol-water mixture. The decomposition of IV was carried out above 250°C in a stream of nitrogen by dropping a solution of IV in glacial acetic acid through a packed quartz tube (Table I). It was found that copper pellets have a good catalytic action in the retro-reaction. The efficiency was improved by using a copper gauze; the decomposition product was then obtained in a 85% yield at 400°C. However, as has been described above, the product was not 5-vinyl-hydantoin, but its isomer, 5-ethylidene-hydantoin. This was confirmed by the absorption band at 826 cm^{-1} due to $R_2C=CHR$ in its infrared spectrum (Fig. 1). The reaction was carried out at a lower temperature to avoid isomerization, but this resulted only in a lower yield of 5-ethylidene-hydantoin. The use of a silver gauze as a packing did not improve the reaction. When silica gel or alumina was used as the packing material, the decomposition occurred at the hydantoin group.

The decomposition of IV could not take place in a solution, in such a solvent as benzene, *o*-dichlorobenzene, nitrobenzene, decalin or acetic acid, at the boiling point. The dienophile exchange

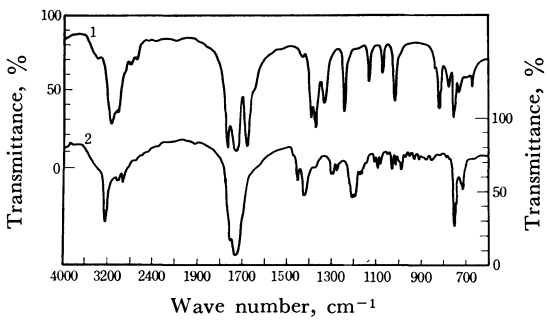

Fig. 1. Absorption spectra of: 1, 5-ethylidene-hydantoin; 2, 5-(9, 10-dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin (in KBr disks).

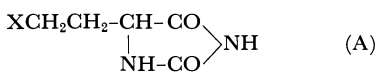
reaction also did not proceed in these solvents. In the reaction, dimethyl acetylenedicarboxylate, maleic anhydride and dimethyl maleate were employed as dienophiles.

The Elimination of Acetic Acid from 5-(2-Acetoxyethyl)-hydantoin (V).—The next route investigated to approach 5-vinyl-hydantoin was the elimination of HX from the compounds of the type A:



(A)

X: Br, I, OH or AcO

When 5-(2-halogenoethyl)-hydantoin was treated with strong bases, such as sodium methoxide and sodium hydroxide, in anhydrous alcohol, the decomposition took place at the hydantoin group.

7) H. Th. Bucherer, *J. prakt. Chem.*, **141**, 23 (1934).
8) A. T. Küchlin, Jr., *Rec. trav. chim.*, **49**, 705 (1930).

Silver oxide and morpholin did not react with the halogeno-compound. The compound gave only its pyridinium salt when heated in pyridine.

5-(2-Acetoxyethyl)-hydantoin was prepared from 5-(2-halogenoethyl)-hydantoin and potassium acetate. It was found that the elimination of acetic acid from 5-(2-acetoxyethyl)-hydantoin gave 5-ethylidene-hydantoin in a good yield. The elimination reaction was conducted with a procedure similar to that used in the retro-reaction of the anthracene adduct described above (Table II).

TABLE II. PYROLYSIS OF 5-(2-ACETOXYETHYL)-HYDANTOIN

Acetate g.	(Solvent)	ml.	Temp. °C	5-Et-Hyd. g.	Unreacted g.

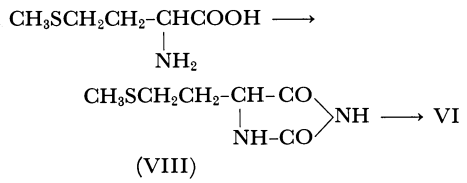
1.0	*t*-BuOH	(100)	300	0.40	0.37
1.0	*t*-BuOH	(100)	400	0.42	0.16
1.0	*t*-BuOH	(100)	500	0.39	0.07

The Decomposition of Dimethyl 2-(5-Hydantoin)-ethyl Sulfonium Iodide (VI).—The cause of the isomerization of 5-vinyl-hydantoin to 5-ethylidene-hydantoin during the reaction, described in the preceding sections, was supposed to be the high reaction temperature. As a third attempt, the decomposition of dimethyl 2-(5-hydantoin)-ethyl sulfonium iodide (VI) was investigated, as the reaction was expected to proceed under milder conditions. As the starting material, the sulfonium salt was prepared from *dl*-methionine:



(VIII)

The salt was decomposed into dimethyl sulfide and 5-(2-iodoethyl)-hydantoin by heating it in *n*-butanol. By a reaction with sodium ethoxide in absolute ethanol, it gave a small quantity of 5-(2-ethoxyethyl)-hydantoin, and the residual part of the iodide was decomposed at the hydantoin group. In dimethyl sulfoxide, the hydantoin group was decomposed by potassium *t*-butoxide at 80°C, and 5-ethylidene-hydantoin was obtained from the sulfonium salt in a good yield at 20°C. In this case, also, no 5-vinyl-hydantoin was obtained, and the isomerization proceeded very easily and completely at such a low reaction temperature, even if the isomerization could be catalyzed by the base in the polar solvent.

The Stability of 5-Ethylidene-hydantoin.—Vinylacetic acid exists with sufficient stability, as does its isomer, crotonic acid. On the other hand, 5-vinyl-hydantoin, the derivative of vinylacetic acid, could not be obtained. The extreme ease of the isomerization of 5-vinyl-hydantoin to 5-ethylidene-hydantoin suggests that the high stability of 5-ethylidene-hydantoin is due to the resonance between the C=C double bond and the hydantoin group. This was proved by the strong absorption band of 5-ethylidene-hydantoin at 270 mμ, which was absent in the spectra of acrylic acid and 5-methyl-hydantoin (Fig. 2). The same band was observed in the spectrum of 5-methylene-hydantoin, which showed a large Q-value, a factor correlated with the resonance stabilization, in Alfrey-Price's Q-e scheme.[2]

5-Ethylidene-hydantoin not only polymerized by itself with a radical initiator, but even inhibited the polymerization of styrene in the copolymerization reaction with the latter monomer.

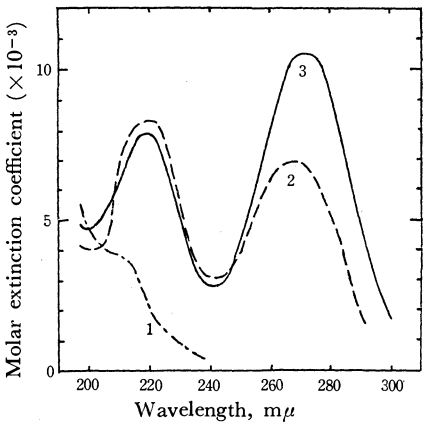


Fig. 2. Absorption spectra of: 1, 5-methyl-hydantoin in H_2O; 2, 5-methylene-hydantoin in H_2O (λ_{max} 268 mμ, ε_{max} 7×10^3); 3, 5-ethylidene-hydantoin in EtOH (λ_{max} 272 mμ, ε_{max} 10.5×10^3).

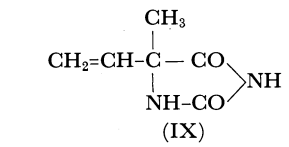
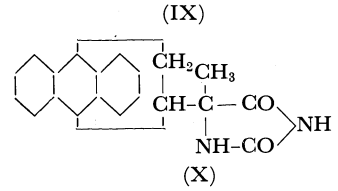
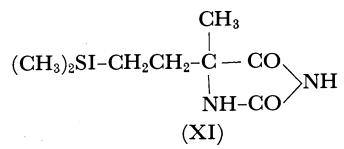
Furthermore, it was found that 5-vinyl-5-methyl-hydantoin (IX), which has no migrant hydrogen, could not be obtained from either 5-(9, 10-dihydroanthracene-9, 10-*endo*-α, β-ethyl)-5-methyl-hydantoin (X) or dimethyl 2-(5-(5-methyl)-hydantoin)-ethyl sulfonium iodide (XI) by the pro-



(IX)



(X)



(XI)

cedures described previously. That is, these compounds not only gave 5-vinyl-5-methyl-hydantoin, but showed no decomposition reaction which did not destroy the hydantoin group in the course of the treatment.

These facts seem to explain the stable conjugate structure of 5-ethylidene-hydantoin and the ease of the isomerization of 5-vinyl-hydantoin to it.

Experimental

9, 10-Dihydroanthracene-9, 10-*endo*-α, β-propionaldehyde (VII).—A mixture of anthracene (40 g., 0.23 mol.), freshly-distilled acrolein (12 g., 0.21 mol.), benzene (90 ml.) and a small amount of hydroquinone was heated in an autoclave at 140—150°C for 12 hr. The reaction mixture was then concentrated under reduced pressure. The residual syrup was dissolved in methanol (250 ml.), and a small amount of the unreacted anthracene was removed by filtration. An equal amount of water was then added to the filtrate, and the mixture was left to stand overnight. Fine crystals of the adduct monohydrate were thus obtained almost quantitatively. The hydrate was recrystallized from acetone; m. p. 100°C.

Found: C, 81.15; H, 6.28. Calcd. for $C_{17}H_{14}O \cdot H_2O$: C, 80.92; H, 6.37%.

The hydrate was soluble in acetone and benzene, but insoluble in water and methanol. Its infrared spectrum showed no absorption band resulting from the carbonyl group of the aldehyde, but it did show the absorption band at 3300 cm^{-1} resulting from the hydroxy group of $-CH(OH)_2$. It gave anhydrous aldehyde when heated at 80°C under reduced pressure. The anhydrous aldehyde was a crystalline compound which melted at 95°C (lit.,[9] 95°C) and which was soluble in methanol. It was gradually converted into the monohydrate in moist air.

5-(9, 10-Dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin (IV).—Into a solution of ammonium carbonate (92 g.) and sodium cyanide (20 g.) in water (200 ml.), a solution of the anhydrous aldehyde (VII) (50 g.) in methanol (250 ml.) was stirred at 60°C; the reaction was then continued for 10 hr. After the solution had cooled, the precipitates produced were filtered, washed with water, and then suspended in 6 N hydrochloric acid. The suspension was heated at 90°C for 2 hr., and the solid was filtered, washed with water, and dried. The raw product was then extracted with three portions of hot acetone (500 ml.). The concentration of the acetone solution gave the hydantoin (51 g.), which was recrystallized from acetic acid (800 ml.). Yield, 46 g. (71%); m. p. 225°C; colorless crystals sublimed at 220°C/30 mmHg; soluble in hot acetone and hot acetic acid, and insoluble in water, benzene and petroleum ether.

Found: C, 74.86; H, 5.24; N, 9.12. Calcd. for $C_{19}H_{16}N_2O_2$: C, 74.98; H, 5.30; N, 9.20%.

The Decomposition of 5-(9, 10-Dihydroanthracene-9, 10-*endo*-α, β-ethyl)-hydantoin.—A quartz tube (60 cm. long and 5.2 cm. in diameter) packed with the material described in Table I was placed vertically in an electric furnace and heated. The solution of IV in 100 parts of acetic acid was then introduced drop by drop into the tube under a nitrogen stream at atmospheric pressure or at a pressure of about 100 mmHg. The products were collected in two traps connected in a series, one cooled with ice water and the other with dry ice - acetone. After the solution had been added, the inside of the tube was washed with acetic acid (50 ml.) drop by drop. The products and the washings were then combined and evaporated to dryness under a reduced pressure of nitrogen. The residues were extracted with hot water, and the aqueous solution was concentrated under reduced pressure to give 5-ethylidene-hydantoin. The water-insoluble part was fractionated by extraction with hot acetic acid into anthracene and unreacted hydantoin. 5-Ethylidene-hydantoin was recrystallized from water. Colorless crystals subliming at 200°C; m. p. 265°C (lit.,[6] 265°C). The infrared spectrum is shown in Fig. 1.

Found: C, 47.69; H, 4.87; N, 21.50. Calcd. for $C_5H_6N_2O_2$: C, 47.62; H, 4.80; N, 22.21%.

5-(2-Acetoxyethyl)-hydantoin (V).—According to the method of Nyberg,[10] 5-(2-hydroxyethyl)-hydantoin and its brom- and iodo-derivatives were prepared from γ-butyrolactone. A solution of freshly-fused potassium acetate (9.8 g., 0.1 mol.) and 5-(2-iodoethyl)-hydantoin (25.4 g., 0.1 mol.) in ethyl methyl ketone (400 ml.) was refluxed for 10 hr. After the solution had then cooled, the precipitates were filtered off, and the filtrate was evaporated under reduced pressure. By the recrystallization of the residue from a mixture of equal amounts of chloroform and benzene, 5-(2-acetoxyethyl)-hydantoin (12 g.) was obtained in a 65% yield; m. p. 122°C; soluble in water, alcohol, acetone and chloroform, and slightly soluble in ethyl ether and benzene.

Found: C, 44.96; H, 5.45; N, 14.47. Calcd. for $C_7H_{10}N_2O_4$: C, 45.16; H, 5.42; N, 15.05%.

The same product was also obtained from 5-(2-bromoethyl)-hydantoin.

The Decomposition of 5-(2-Acetoxyethyl)-hydantoin.—The same apparatus and procedures described in the pyrolysis of IV were used, employing a copper gauze as a packing material. A solution of 5-(2-acetoxyethyl)-hydantoin in *t*-butyl alcohol was added, drop by drop and under a stream of nitrogen at atmospheric pressure, over a 2 hr. period. The products were fractionated into water-soluble and water-insoluble parts. 5-Ethylidene-hydantoin was obtained from the water-insoluble fraction. When acetic acid was used as a solvent for pyrolysis, the acetate was recovered almost unchanged. The results of the reaction are shown in Table II.

5-(2-Methylmercaptoethyl) - hydantoin (VIII).—This compound was synthesized from commercial *dl*-methionine according to the method of Livak.[11] Yield, 85.5%; m. p. 107°C (lit.[11] 105—106°C).

Dimethyl 2 - (5 - Hydantoin) - ethyl Sulfonium Iodide (VI).—VIII (10 g., 0.06 mol.) was dissolved in acetonitrile, and then methyl iodide (10 ml., 0.16 mol.) was added. Colorless crystals of the sulfonium salt were obtained from the solution after it had stood in

a refrigerator for several hours. A recrystallization of the raw product (18 g.) from water (70 ml.) gave pure crystals (14 g.) (m. p. 168°C (decomp.); soluble in water and methanol, and sparingly soluble in ether and acetone).

Found: C, 26.59; H, 4.14. Calcd. for $C_7H_{13}N_2O_2IS$: C, 26.67; H, 4.12%.

The Decomposition of Dimethyl 2-(5-Hydantoin)-ethyl Sulfonium Iodide.—To a solution of VI (5.4 g., 0.017 mol.) in purified dimethyl sulfoxide (170 ml.), a solution of potassium *t*-butoxide (6.5 g., 0.033 mol.) in the same solvent (80 ml.) was added. The reaction mixture was then stirred at 20°C under a stream of dry nitrogen, and the dimethyl sulfide evolved was introduced into a 1% solution of mercuric chloride in water through a drying tube containing 4A molecular sieves. The progress of the reaction was observed by the precipitation of the dimethyl sulfide-mercuric chloride complex. After 48 hr. the reaction mixture was neutralized with acetic acid and concentrated to a syrup under reduced pressure. The syrup gave crystals when 5 ml. of water was added. By recrystallization from water, pure 5-ethylidene-hydantoin (1.7 g., 81%) was obtained.

When VI was heated in morpholin or in *N*-methyl morpholin at 100°C, a vigorous evolution of dimethyl sulfide was observed. After the evolution had ended, the reaction mixture was concentrated to dryness under reduced pressure. The obtained residue was, however, found to be 5-(2-iodoethyl)-hydantoin.

9, 10 - Dihydroanthracene-9, 10 - *endo*-α, β - ethyl Methyl Ketone.—This compound was prepared from anthracene and methyl vinyl ketone by a method which has been described for VII. The reaction mixture was then concentrated to dryness, and the residue was recrystallized from acetone. The adduct was thus obtained; yield, 72%; colorless crystals subliming at 100°C; m. p. 150°C.

Found: C, 87.29; H, 6.38. Calcd. for $C_{18}H_{16}O$: C, 87.06; H, 6.49%.

5-(9, 10-Dihydroanthracene-9, 10-*endo*-α, β-ethyl)-5-methyl-hydantoin (X).—This hydantoin was prepared, in a 78% yield, from the ketone by the method which has been described for IV. It did not melt below 300°C, it sublimed at 130°C/10 mmHg, and it was soluble in acetone, slightly soluble in acetic acid and benzene, and insoluble in water and methanol.

Found: C, 75.36; H, 5.72; N, 8.63. Calcd. for $C_{20}H_{18}N_2O_2$: C, 75.44; H, 5.69; N, 8.80%.

This compound could not be decomposed, even at 500°C, by the procedure used for IV, but its hydantoin group was decomposed at higher temperatures.

Dimethyl 2-(5-(5-Methyl)-hydantoin)-ethyl Sulfonium Iodide (XI).—A concentrated solution of 5-(2-methylmercaptoethyl)-5-methyl-hydantoin[12] (17 g.) in dry methanol was mixed with methyl iodide (20 g.). The precipitates thus produced were then filtered and dried. Recrystallization from methanol gave pure crystals; yield, 21 g.; m. p. 169°C (decomp.); soluble in water, methanol and dimethyl sulfoxide, slightly soluble in acetone and ether, and insoluble in benzene.

Found: C, 29.29; H, 4.53. Calcd. for $C_9H_{15}N_2O_2IS$: C, 29.10; H, 4.58%.

This compound was treated with potassium *t*-butoxide in dimethyl sulfoxide by the procedure described for VI. Dimethyl sulfide was observed to evolve at a very slow rate, but there was also a simultaneous decomposition of the hydantoin group. The expected compound was not obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1738—1747 (1966)

Studies of Peptide Antibiotics. IV. The Synthesis of Tyrocidine A*

By Motonori OHNO, Tetsuo KATO, Satoru MAKISUMI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka

(Received November 15, 1965)

The synthesis of a cyclic decapeptide, cyclo-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl, which has an amino acid sequence determined by Craig et al. for natural antibiotics, tyrocidine A, has been described. The chemical and biological properties of the synthetic product have been shown to be in agreement with those of the natural tyrocidine A.

Tyrocidine A is a basic polypeptide isolated as a hydrochloride by Battersby and Craig,[1] using a technique of countercurrent distribution, from the family of closely-related substances present in tyrocidine which is produced in autolyzed cultures of *Bacillus brevis*. Its structure has been determined by Craig and his colleagues[2,3] by means of a

* A part of this work has been briefly communicated: M. Ohno and N. Izumiya, *J. Am. Chem. Soc.*, **88**, 376 (1966).

1) A. R. Battersby and L. C. Craig, ibid., **74**, 4019 (1952).

2) A. R. Battersby and L. C. Craig, ibid., **74**, 4023 (1952).

3) A. Paladini and L. C. Craig, ibid., **76**, 688 (1954).

partial hydrolysis and by means of a study of the countercurrent distribution. Tyrocidine A is, like gramicidin S,[4,5] a cyclic decapeptide; it is constructed from three molecules of phenylalanine and one each of asparagine, glutamine, tyrosine, valine, ornithine, leucine and proline. All amino acid residues except two molecules of D-phenylalanine have a L-configuration. Figure 1 indicates

L-Phe-D-Phe-L-Asp(NH_2)-L-Glu(NH_2)-L-Tyr

Fig. 1. Constructional formula of tyrocidine A.

the constructional formula of tyrocidine A. The pentapeptide sequence, L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl, is also found in gramicidin S, tyrocidine B[6] and tyrocidine C.[7] The syntheses of the linear penta-[8] and decapeptide derivatives[9] related to tyrocidine A have been reported by Schwyzer et al., but the complete synthesis of tyrocidine A has not yet been accomplished. We, therefore, have here attempted to synthesize this cyclic decapeptide. This paper will describe the synthesis of the cyclic decapeptide hydrochloride (I_s) having the amino acid sequence of tyrocidine A (Fig. 1) and will attempt to establish the identity of the synthetic product (I_s) with natural tyrocidine A hydrochloride (I_n) in chemical and biological properties.

The cyclization of a linear decapeptide was carried out by a *p*-nitrophenyl ester method. Di-*p*-nitrophenyl sulfite was used as a reagent of the *p*-nitrophenyl esterification reaction.[10] It has been observed that, when *N*-protected peptide is treated with di-*p*-nitrophenyl sulfite in an attempt to obtain a corresponding *p*-nitrophenyl ester, the *C*-terminal amino acid residue is subjected to partial racemization, with the exception of glycine and proline residues.[10,11] For this reason, the proline residue was selected as the *C*-terminal amino acid in a linear decapeptide to be activated to the *p*-nitrophenyl ester (see the compound XXI in Fig. 5).[12]

p-Methoxybenzyloxycarbonyl[13] and benzyloxycarbonyl groups were employed for the selective blocking of the *N*-terminal amino group and the δ-amino group of ornithine residue respectively.

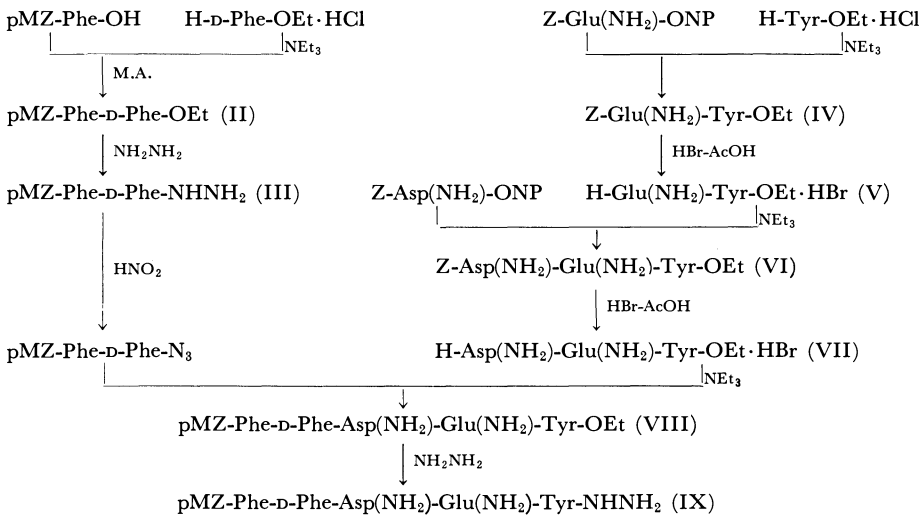

Fig. 2. Synthesis of pMZ-pentapeptide hydrazide (IX): prefix L for amino acids of L-configuration is omitted; pMZ, *p*-methoxybenzyloxycarbonyl; Z, benzyloxycarbonyl; Et, ethyl; NP, *p*-nitrophenyl; NEt_3, triethylamine; AcOH, acetic acid; M. A., mixed anhydride method.

12) In the synthesis of evolidin, natural cyclic heptapeptide, a leucine residue was selected as a *C*-terminal amino acid of a linear heptapeptide to be activated to the *p*-nitrophenyl ester by using di-*p*-nitrophenyl sulfite, in spite of the presence of a proline residue as a constituent. Nevertheless, the resulting cyclic heptapeptide was proved to be homogeneous with regard to the leucine residue; it was identical to the natural product in many properties (R. O. Studer and W. Lergier, *Helv. Chim. Acta*, **48**, 460 (1965)).

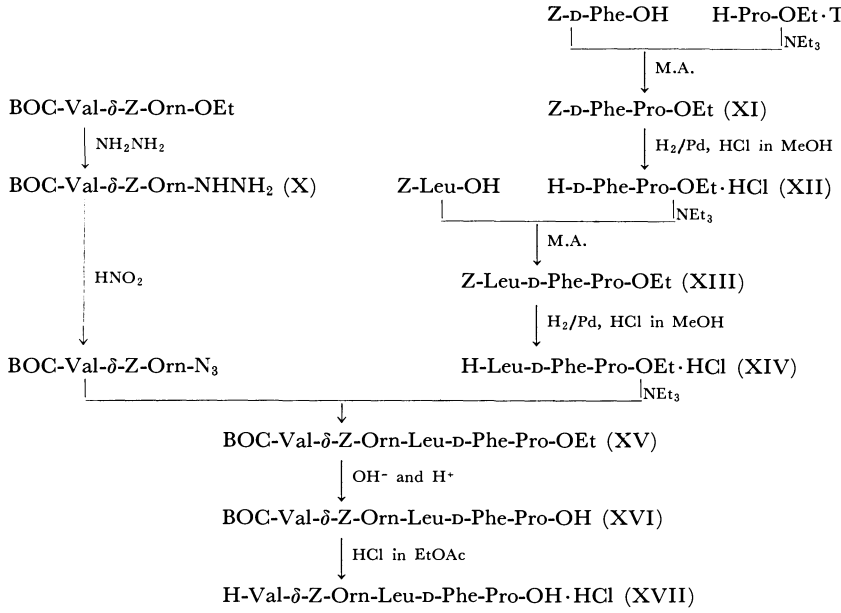

Fig. 3. Synthesis of pentapeptide hydrochloride (XVII): BOC, *t*-butyloxycarbonyl; TsOH, *p*-toluenesulfonic acid; MeOH, methanol; EtOAc, ethyl acetate.

As has been described in a previous paper, the *p*-methoxybenzyloxycarbonyl group is so available that it is released easily with the action of anhydrous trifluoroacetic acid, without hurt to the sensitive *p*-nitrophenyl ester group.[11]

The scheme for the synthesis of the *N*-terminal pentapeptide derivative, *p*-methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosine hydrazide (IX), is presented in Fig. 2. *p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanine ethyl ester (II) was prepared by the reaction of *p*-methoxybenzyloxycarbonyl-L-phenylalanine[13] with D-phenylalanine ethyl ester by means of the mixed anhydride procedure. The subsequent treatment of II with twenty equivalents of hydrazine in dimethylformamide gave the hydrazide (III) in a 96% yield. The *C*-terminal tripeptide derivative (VI) was prepared by step-by-step elongation by means of the *p*-nitrophenyl ester method. The reaction of benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester with tyrosine ethyl ester gave the crystalline dipeptide derivative (IV). This was treated with hydrogen bromide in acetic acid and then allowed to react with benzyloxycarbonyl-L-asparagine *p*-nitrophenyl ester. VI was thus obtained in a crystalline form. The azide, which had been derived from III, was made to react with the tripeptide ester (VII) prepared from VI with the action of hydrogen bromide in acetic acid; the protected pentapeptide ester (VIII) was thus obtained in a 75% yield. VIII was converted to the hydrazide (IX) in a 86% yield by treatment with hydrazine.

Figure 3 indicates the scheme for the synthesis of the *C*-terminal pentapeptide derivative, L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline hydrochloride (XVII). *t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine hydrazide (X) was obtained in a 83% yeild by the treatment of the *t*-butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine ethyl ester[14] with hydrazine. The tripeptide derivative (XIII) was synthesized by a step-by-step reaction by means of the mixed anhydride method. The reaction of the anhydride prepared from benzyloxycarbonyl-D-phenylalanine and isobutyl chloroformate with L-proline ethyl ester afforded the oily dipeptide derivative (XI) in a 86% yield. This was hydrogenolyzed in the presence of palladium black and then allowed to react with the anhydride derived from benzyloxycarbonyl-L-leucine. XIII was thus obtained in a 95% yield as an oily substance. The catalytic hydrogenolysis of XIII also gave the oily tripeptide ester hydrochloride (XIV), which was found to be homogeneous in paper chromatography. The azide, which had been derived from X, was made to react with XIV to give the pure crystalline, protected pentapeptide ester (XV) in a 69% yield. The saponification of XV afforded the crystals of the protected pentapeptide (XVI). The subsequent treatment of XVI with twenty equivalents of hydrogen chloride in ethyl acetate yielded the pentapeptide hydrochloride (XVII) in a crystalline form. On the other hand, the same treatment of XV afforded the crystalline pentapeptide ester hydrochloride (XVIII) (see Fig. 4).

Two approaches were applied to the synthesis

14) N. Izumiya, T. Kato, Y. Fujita, M. Ohno and M. Kondo, This Bulletin, **37**, 1809 (1964).

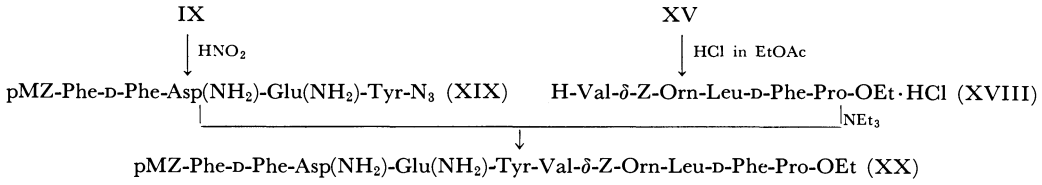

Fig. 4. Synthesis of pMZ - decapeptide ester (XX).

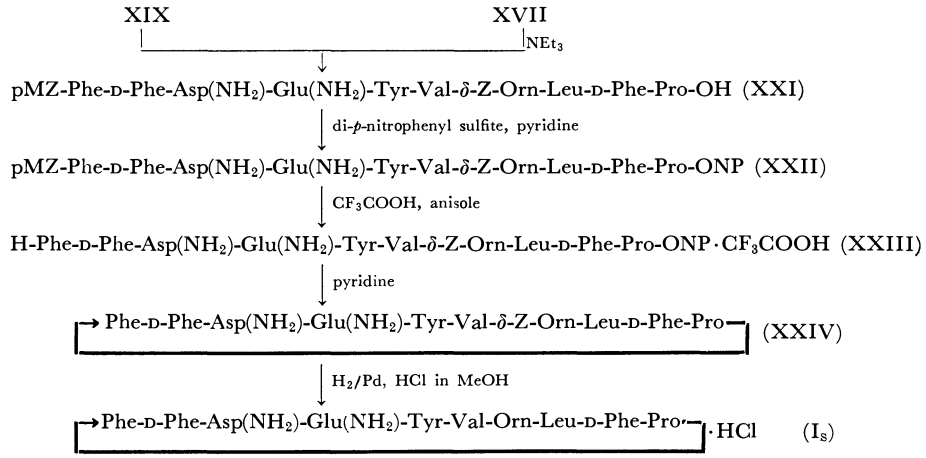

Fig. 5. Synthesis of cyclic decapeptide hydrochloride (I_s).

of the decapeptide derivative (XXI). The one route, via the synthesis of the protected decapeptide ester (XX), is presented in Fig. 4. The protected pentapeptide azide (XIX), which had been derived from IX, was allowed to react with XVIII in the presence of an equivalent amount of triethylamine. XX was thus obtained as an analytically-pure, crystalline product in a 70% yield. However, this approach was not feasible because the saponification of the ester (XX) by alkali was unsuccessful.

Figure 5 indicates another route for the synthesis of the protected decapeptide (XXI) and the subsequent synthesis of the cyclic decapeptides (XXIV and I_s). The reaction of the azide (XIX) with XVII in the presence of two equivalents of triethylamine gave the pure crystalline, protected decapeptide (XXI) in an yield of 75%. XXI was converted to the protected decapeptide *p*-nitrophenyl ester (XXII) with the action of ten equivalents of di-*p*-nitrophenyl sulfite in the presence of pyridine. The removal of the *p*-methoxybenzyloxycarbonyl group from XXII by treatment with trifluoroacetic acid yielded the amorphous decapeptide *p*-nitrophenyl ester trifluroacetate (XXIII) in an excellent yield. The cyclization reaction of XXIII in a large amount of pyridine gave the crude benzyloxycarbonyl-substituted cyclic peptide (XXIV), which was then purified by passing it through columns of strongly acidic and weakly basic ion exchangers. The yield of XXIV from XXI was excellent—60% after the recrystallization. The homogeneity of XXIV was established by the criteria of thin-layer and paper chromatographies and by elemental analysis. The molecular weight determination using the vapor pressure osmometer demonstrated that the molecular size of XXIV corresponded to that of cyclic decapeptide. The catalytic hydrogenolysis of XXIV in the presence of an equivalent amount of hydrogen chloride in methanol afforded the cyclic decapeptide hydrochloride (I_s) in a 74% yield. Although Battersby and Craig[2] found that the treatment of tyrocidine A hydrochloride (I_n) with excess hydrogen chloride in methanol formed its transformation product by the conversion of one primary amide group of asparagine or the glutamine residue to the methyl ester group, it has been shown, from the detection of two moles of ammonia in the amino acid analysis of the acid hydrolysate of I_s, that no such reaction occurred under the above conditions.

The synthetic cyclic decapeptide hydrochloride (I_s) was then compared with the natural product (I_n). In addition to having the same R_f values in paper and thin-layer chromatographies and having indistinguishable paper electrophoretic patterns (Fig. 6), I_s and I_n had superimposable infrared and well-agreeing ultraviolet spectra (Figs. 7 and 8), identical behaviors in the carboxymethylcellulose column (Fig. 9), and the same value in optical rotation. Furthermore, very close similarities were seen in the antibacterial activities

of the two compounds with regard to microorganisms (see Table I). These results show that the synthetic product is identical to natural tyrocidine A. The structure of tyrocidine A offered by Craig et al. has been further confirmed by the present synthesis.

Experimental

The melting points were not corrected. The optical rotations were measured on a Yanagimoto Photometric Polarimeter, OR-20 type. The paper chromatography was carried out on Toyo Roshi No. 52 chromatography paper. The thin-layer chromatography was carried out on Merck silica gel G. The developing solvents commonly used were *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2 v/v) and *t*-butanol - formic acid - water (75 : 15 : 10 v/v). Spots of materials possessing a free amino group on a thin-layer plate were detected by spraying ninhydrin, and those of the amino group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin. Prior to analysis, the compounds were dried over phosphorus pentoxide at 100°C and 2 mmHg to a constant weight except for the compound I_S.

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanine Ethyl Ester (II).**—To a mixed anhydride prepared at −5°C from 6.58 g. (20 mmol.) of *p*-methoxybenzyloxycarbonyl-L-phenylalanine,[13] 2.60 ml. (20 mmol.) of isobutyl chloroformate and 2.80 ml. (20 mmol.) of triethylamine in 60 ml. of tetrahydrofuran, a chilled solution of 4.60 g. (20 mmol.) of D-phenylalanine ethyl ester hydrochloride dissolved in a mixture of 2.80 ml. (20 mmol.) of triethylamine and 60 ml. of chloroform was added. The reaction mixture was then allowed to stand overnight and then evaporated in vacuo. The oily residue was dissolved in 80 ml. of ethyl acetate, and the solution was washed successively with 0.5 M citric acid, a 3% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated in vacuo. The oily residue was solidified by adding petroleum ether (8.68 g.). The product was recrystallized from ethanol - ether - petroleum ether. Yield, 8.0 g. (79%); m. p. 126—128°C; $[\alpha]_D^{20}$ −2.8° (*c* 4.4, dimethylformamide).

Found: C, 69.18; H, 6.13; N, 5.66. Calcd. for $C_{29}H_{32}O_6N_2$: C, 69.03; H, 6.39; N, 5.55%.

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanine Hydrazide (III).**—A solution of 6.06 g. (12 mmol.) of II and 12 ml. (240 mmol.) of hydrazine hydrate in 18 ml. of dimethylformamide was allowed to stand at room temperature for 2 days. The solution was then evaporated in vacuo in order to remove the excess hydrazine, after which 180 ml. of water was added to the residual solution; the resulting crystals were collected by filtration (5.80 g.). The crude hydrazide was purified by recrystallization from dimethylformamide - ether - petroleum ether. Yield, 5.64 g. (96%); m. p. 194—195°C; $[\alpha]_D^{20}$ −3.4° (*c* 5.0, dimethylformamide).

Found: C, 66.21; H, 6.03; N, 11.23. Calcd. for $C_{27}H_{30}O_5N_4$: C, 66.10; H, 6.16; N, 11.42%.

Benzyloxycarbonyl-L-glutaminyl-L-tyrosine Ethyl Ester (IV).—To a solution of 7.37 g. (30 mmol.) of L-tyrosine ethyl ester hydrochloride dissolved in a mixture of 8.40 ml. (60 mmol.) of triethylamine and 40 ml. of dimethylformamide, a solution of 12.0 g. (30 mmol.) of benzyloxycarbonyl-L-glutamine *p*-nitrophenyl ester in 40 ml. of dimethylformamide was added. After the solution had been allowed to stand for 4 hr. at room temperature, it was diluted with 1.5 l. of water. The crystalline precipitate was collected by filtration and washed successively with 2 N hydrochloric acid, a 3% sodium bicarbonate solution, and water (12.0 g.). It was recrystallized from ethanol-ether. Yield, 9.96 g. (70%); m. p. 197—199°C; $[\alpha]_D^{20}$ +1.8° (*c* 4.5, dimethylformamide).

Found: C, 61.18; H, 6.27; N, 8.81. Calcd. for $C_{24}H_{29}O_7N_3$: C, 61.13; H, 6.20; N, 8.91%.

L-Glutaminyl-L-tyrosine Ethyl Ester Hydrobromide (V).—To a suspension of 5.66 g. (12 mmol.) of IV in 24 ml. of acetic acid, 12 ml. of 6 N dry hydrogen bromide in acetic acid was added. After it had stood for one hour, the solution was evaporated to dryness in vacuo, and then ether was added. The oily residue was further washed with ether by decantation and dried over calcium chloride and sodium hydroxide. It weighed 4.61 g. (94%).

Benzyloxycarbonyl-L-asparaginyl-L-glutaminyl-L-tyrosine Ethyl Ester (VI).—To a solution of 4.61 g. (11.3 mmol.) of V in 20 ml. of dimethylformamide, 3 ml. of triethylamine was added, followed by a solution of 3.87 g. (10 mmol.) of the benzyloxycarbonyl-L-asparagine *p*-nitrophenyl ester in 10 ml. of dimethylformamide. After it had stood for 6 hr. at room temperature, the solution was diluted with 400 ml. of water. The crystalline product deposited was collected by filtration and washed successively with 2 N hydrochloric acid, a 3% sodium bicarbonate solution, and water (4.51 g.). It was then recrystallized from dimethylformamide-ether. Yield, 4.22 g. (72%); m. p. 224—225°C (decomp.), $[\alpha]_D^{20}$ −11.6° (*c* 2.45, dimethylformamide).

Found: C, 56.74; H, 6.33; N, 11.53. Calcd. for $C_{28}H_{35}O_9N_5 \cdot 1/2H_2O$: C, 56.56; H, 6.27; N, 11.78%.

L-Asparaginyl-L-glutaminyl-L-tyrosine Ethyl Ester Hydrobromide (VII).—To a suspension of 2.93 g. (5 mmol.) of VI in 12 ml. of acetic acid, 6.3 ml. of 6 N dry hydrogen bromide in acetic acid was added. After it had stood for one hour, the solution was evaporated to dryness in vacuo. The oily residue was then treated as has been described in the previous paragraph. The oil weighed 2.61 g. (98%).

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosine Ethyl Ester (VIII).**—A solution of 1.96 g. (4 mmol.) of III dissolved in a mixture of 15 ml. of dimethylformamide and 24 ml. of acetic aicd was cooled to −5°C. To this, 8.8 ml. (8.8 mmol.) of N hydrochloric acid was added, followed by 2.2 ml. (4.4 mmol.) of 2 N sodium nitrite. After it had sood for 5 min. at this temperature, the solution was diluted with 200 ml. of cold water. The precipitated azide was collected by filtration, washed with a 3% sodium bicarbonate solution and water, and then dried in vacuo at 0°C. To a chilled (−5°) solution of 2.24 g. (4.2 mmol.) of VII dissolved in 15 ml. of dimethylformamide, 2 ml. of triethylamine was added, followed by the azide crystals prepared above. The solution was stirred for 2 days at 0°C and then diluted with 200

ml. of water. The precipitate was collected by filtration and washed successively with 0.5 M citric acid, a 3% sodium bicarbonate solution and water (3.05 g.). The product was recrystallized from dimethylformamide-ether. Yield, 2.73 g. (75%); m. p. 206—209°C (decomp.); $[\alpha]_D^{20}$ −10.4° (*c* 2.9, dimethylformamide).

Found: C, 62.58; H, 6.35; N, 11.00. Calcd. for $C_{47}H_{55}O_{12}N_7$: C, 62.03; H, 6.09; N, 10.78%.

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosine Hydrazide (IX).**—This compound was prepared by the same procedure as has been described for the preparation of III. One and eighty-two hundredths grams (2 mmol.) of VIII and 2.0 ml. (40 mmol.) of hydrazine hydrate gave 1.64 g. of the crude product. It was recrystallized from dimethylformamide-ether. Yield, 1.54 g. (86%); m. p. 225—227°C (decomp.); $[\alpha]_D^{20}$ −26.0° (*c* 2.05, dimethylformamide).

Found: C, 59.44; H, 5.96; N, 13.62. Calcd. for $C_{45}H_{53}O_{11}N_9$: C, 60.32; H, 5.96; N, 14.07%.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine Hydrazide (X).**—This compound was also prepared by the same procedure as has been described for the preparation of III. Seven and forty hundredths grams (15 mmol.) of *t*-butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithine ethyl ester[14] and 15 ml. (300 mmol.) of hydrazine hydrate afforded 6.35 g. of the crude product. It was recrystallized from ethanol - ether - petroleum ether. Yield, 5.96 g. (83%); m. p. 175°C; $[\alpha]_D^{20}$ −14.1° (*c* 2.35, dimethylformamide).

Found: C, 57.40; H, 7.94; N, 14.34. Calcd. for $C_{23}H_{37}O_6N_5$: C, 57.60; H, 7.78; N, 14.60%.

Benzyloxycarbonyl-D-phenylalanyl-L-proline Ethyl Ester (XI).—To a mixed anhydride prepared at −5°C from 4.0 g. (16.7 mmol.) of benzyloxycarbonyl-D-phenylalanine, 2.16 ml. (16.7 mmol.) of isobutyl chloroformate and 2.36 ml. (16.7 mmol.) of triethylamine in 25 ml. of chloroform, a chilled solution of 6.60 g. (20.9 mmol.) of L-proline ethyl ester *p*-toluenesulfonate[15] dissolved in a mixture of 2.93 ml. (20.9 mmol.) of triethylamine and 25 ml. of chloroform was added. After the reaction mixture had been allowed to stand overnight, it was evaporated in vacuo. The residue was dissolved in 80 ml. of ethyl acetate, and the solution was washed with 2 N hydrochloric acid, a 3% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated to dryness in vacuo. The residual oil weighed 6.08 g. (86%). All attempts to crystallize this oil failed, so it was used as such for the next step.

D-Phenylalanyl-L-proline Ethyl Ester Hydrochloride (XII).—A solution of 5.80 g. (13.7 mmol.) of XI dissolved in a mixture of 12.7 ml. (15.0 mmol.) of 1.18 N dry hydrogen chloride in methanol and 30 ml. of methanol was hydrogenolyzed in the presence of palladium black. After 5 hr. the filtrate from the catalyst was evaporated to dryness in vacuo. The oil weighed 4.36 g. (98%). The homogeneity of this oil was certified by paper chromatography, in which only one spot was detected, R_f 0.88.[16]

Benzyloxycarbonyl-L-leucyl-D-phenylalanyl-L-proline Ethyl Ester (XIII).—This compound was prepared by the same anhydride method as has been described for the preparation of XI. Three and forty-four hundredths grams (13 mmol.) of benzyloxycarbonyl-L-leucine and 4.36 g. (13.4 mmol.) of XII gave 6.64 g. (95%) of XIII as an oily product.

L-Leucyl-D-phenylalanyl-L-proline Ethyl Ester Hydrochloride (XIV).—This compound was prepared by the same procedure as has been described for the preparation of XII. The hydrogenolysis of 3.37 g. (6.26 mmol.) of XIII in the presence of a 1.1 equivalent of hydrogen chloride afforded 2.59 g. (94%) of XIV as an oil. This gave only one spot in paper chromatography, R_f 0.92.[16] It was used for the next reaction without further purification.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline Ethyl Ester (XV).**—A solution of 2.88 g. (6 mmol.) of X dissolved in a mixture of 8 ml. of dimethylformamide and 45 ml. of acetic acid was cooled to −5°C. To this, 6.6 ml. (6.6 mmol.) of N hydrochloric acid was added, followed by 2.2 ml. (6.6 mmol.) of 3 N sodium nitrite and then 6.6 ml. (6.6 mmol.) of N hydrochloric acid. After it had stood for 5 min. at this temperature, with occasional stirring, the solution was diluted with 250 ml. of water. The azide separated as a viscous mass was twice extracted with 40-ml. portions of ethyl acetate, and the combined ethyl acetate solution was washed thoroughly with a cold 3% sodium bicarbonate solution and cold water. After it had been dried over sodium sulfate for 10 min. at 0°C, this solution was added to a chilled (−5°C) solution of 2.70 g. (6.13 mmol.) of XIV dissolved in a mixture of 0.86 ml. (6.13 mmol.) of triethylamine and 15 ml. of dimethylformamide. After it had then been stirred for 2 days at 0°C, the solution was diluted with 20 ml. of ethyl acetate and washed successively with 0.5 M citric acid, a 3% sodium bicarbonate solution and water, dried over sodium sulfate, and then evaporated in vacuo. The resulting crystals were collected by filtration with the aid of petroleum ether (4.07 g.). The product was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 3.53 g. (69%); m. p. 167—170°C; $[\alpha]_D^{20}$ −32.1° (*c* 2.05, dimethylformamide), R_f 0.96.[17]

Found: C, 63.28; H, 7.76; N, 10.17. Calcd. for $C_{45}H_{66}O_{10}N_6$: C, 63.51; H, 7.82; N, 9.88%.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline (XVI).**—To a solution of 3.40 g. (4 mmol.) of XV dissolved in 30 ml. of methanol, 8 ml. (8 mmol.) of N sodium hydroxide was added. Saponification was carried out at room temperature, and the progress of the reaction was checked by thin-layer chromatography. The reaction was complete after 6 hr. The solution was evaporated in vacuo to a volume of about 12 ml., after which the residual solution was diluted with 40 ml. of water and then acidified with 10 ml. (10 mmol.) of M citric acid. The precipitated crystalline solid was taken up twice with 25-ml. portions of ethyl acetate, and the combined ethyl acetate solution was washed with water, dried over sodium sulfate, and then evaporated in vacuo.

15) T. Kato, S. Makisumi, M. Ohno and N. Izumiya, *J. Chem. Soc. Japan, Pure Chem. Sect. (Nippon Kagaku Zasshi)*, **83**, 1151 (1962).

16) The R_f value refers to the paper chromatography with the solvent system of *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2 v/v).

17) The R_f value refers to the thin-layer chromatography using a solvent system of *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2 v/v).

The resulting crystalline product was collected by filtration with the aid of a mixture of ether and petroleum ether (1 : 2) (3.06 g.). It was recrystallized from ethyl acetate - ether - petroleum ether. Yield, 2.92 g. (86%); m. p. 122—125°C; $[\alpha]_D^{20}$ −39.0° (*c* 2.05, dimethylformamide), R_f 0.82.[17]

Found: C, 62.42; H, 7.57; N, 10.14. Calcd. for $C_{43}H_{62}O_{10}N_6$: C, 62.75; H, 7.59; N, 10.21%.

L-Valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline Hydrochloride (XVII).*—To a suspension of 1.24 g. (1.5 mmol.) of XVI in 5 ml. of ethyl acetate, 12 ml. (30 mmol.) of 2.5 N dry hydrogen chloride in ethyl acetate was added; meanwhile the material dissolved to form a clear solution. The solution was then allowed to stand at room temperature, and the reaction was followed by thin-layer chromatography. After 2 hr. the solution was evaporated in vacuo to afford crystals, which were then filtered off with the aid of ether and washed thoroughly with ether. Yield, 1.09 g. (95%); m. p. 195—200°C (decomp.); $[\alpha]_D^{20}$ −22.5° (*c* 2.12 dimethylformamide), R_f 0.66.[17]

Found: N, 10.89. Calcd. for $C_{38}H_{54}O_8N_6 \cdot HCl$: N, 11.07%. This product was used as such for the next reaction.

L-Valyl-δ-benzyloxycarbonyl-L-ornithyl-D-phenylalanyl-L-leucyl-L-proline Ethyl Ester Hydrochloride (XVIII).—To a suspension of 1.02 g. (1.2 mmol.) of XV in 6 ml. of ethyl acetate, 6 ml. (24 mmol.) of 4 N dry hydrogen chloride in ethyl acetate was added. The reaction mixture formed a clear solution. The solution was then allowed to stand at room temperature, and the progress of the reaction was checked by thin-layer chromatography. After 5 hr. the solution was evaporated to dryness in vacuo. The resulting oily residue was crystallized by the addition of ether (0.882 g.). The product was recrystallized from ethanol-ether. Yield, 0.811 g. (86%); m. p. 183—185°C; $[\alpha]_D^{20}$ −19.0° (*c* 2.1, dimethylformamide), R_f 0.73.[17]

Found: C, 60.65; H, 7.63; N, 10.78. Calcd. for $C_{40}H_{58}O_8N_6 \cdot HCl$: C, 61.01; H, 7.55; N, 10.67%.

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline Ethyl Ester (XX).**—A solution of 0.488 g. (0.5 mmol.) of IX dissolved in 6 ml. of dimethylformamide was cooled to −5°C. To this, 1.4 ml. (1.4 mmol.) of N hydrochloric acid was added, followed by 0.55 ml. (0.55 mmol.) of N sodium nitrite. After it had stood for 5 min. at −5°C, the solution was diluted with 50 ml. of cold water. The precipitated azide (XIX) was collected by filtration, washed with a cold 3% sodium bicarbonate solution and cold water, and then dried in vacuo at 0°C. The dried azide was added to a chilled (−5°C) solution of 0.394 g. (0.5 mmol.) of XVIII dissolved in a mixture of 0.07 ml. (0.5 mmol.) of triethylamine and 8 ml. of dimethylformamide; the solution was stirred for 2 days at 0°C, and then diluted with 80 ml. of water. The crystalline precipitate was collected by filtration and washed thoroughly with 0.5 M citric acid, a 3% sodium bicarbonate solution and water (0.596 g.). It was recrystallized from dimethylformamide-methanol-ether. Yield, 0.564 g. (70%); m. p. 242—243°C (decomp.); $[\alpha]_D^{20}$ −27.9° (*c* 0.62, dimethylformamide). The homogeneity was certified by thin-layer chromatography with regard to the hydrogenolyzed product, R_f 0.86.[17]

Found: C, 63.30; H, 6.80; N, 11.37. Calcd. for $C_{89}H_{107}O_{19}N_{13}$: C, 63.30; H, 6.56; N, 11.29%.

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline (XXI).**—The azide (XIX), which had been freshly prepared from 0.896 g. (1.0 mmol.) of IX by the procedure described just above, was added to a chilled (−5°C) solution of 0.911 g. (1.2 mmol.) of XVII dissolved in a mixture of 0.34 ml. (2.4 mmol.) of triethylamine and 8 ml. of dimethylformamide. The solution was then stirred for 2 days at 0°C, and the small amount of insoluble materials was filtered off. The filtrate was evaporated in vacuo, and the resulting semi-solid mass was triturated with a mixture of 15 ml. of ethyl acetate and 5 ml. of ether, and collected by filtration with the aid of ether. The solid mass crystallized when it was treated with a citric acid solution. The crystals were collected by filtration, and further washed with a dilute citric acid solution and then water (1.24 g.). The product was recrystallized from dimethylformamide-ether. Yield, 1.19 g. (75%); m. p. 233—236°C (decomp.); $[\alpha]_D^{20}$ −31.6° (*c* 0.58, dimethylformamide). The homogeneity of this product was established by thin-layer chromatography after hydrogenolysis, R_f 0.80.[17]

Found: C, 62.58; H, 6.57; N, 11.63. Calcd. for $C_{83}H_{103}O_{19}N_{13}$: C, 62.82; H, 6.57; N, 11.48%.

***p*-Methoxybenzyloxycarbonyl-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline *p*-Nitrophenyl Ester (XXII).**—To a solution of 0.300 g. (0.189 mmol.) of XXI dissolved in 3.5 ml. of dimethylformamide, 5 ml. of anhydrous pyridine was added, followed by 0.612 g. (1.89 mmol.) of di-*p*-nitrophenyl sulfite. The faintly yellow solution was allowed to stand for 16 hr. at room temperature and then evaporated in vacuo. The oily residue was triturated with a mixture of ether and petroleum ether (1 : 1). The solid mass was collected by filtration and washed with a mixture of ether and petroleum ether (1 : 1) unitil the yellow color could not be discerned upon the addition of N sodium hydroxide to the filtrate. A faintly yellow product was thus obtained (0.325 g.). The *p*-nitrophenyl ester content of this product was estimated to be 110% by means of the method described by Schwyzer and Sieber,[5] except that a mixture of dimethylformamide and N sodium hydroxide (1 : 1) was used as the solvent and the absorption measurements were performed at the wavelength of 411 mμ. This product was used for the next reaction without further purification.

L-Phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-proline *p*-Nitrophenyl Ester Trifluoroacetate (XXIII).—To a mixture of 0.325 g. of XXII and 0.4 ml. of anisole, 4 ml. of anhydrous trifluoroacetic acid was added at −5°C. When swirled, the reaction mixture formed a solution after 10 min. The solution was then evaporated in vacuo at 0°C, and the resulting oily residue was triturated by

* An attempt to crystallize the HCl-free pentapeptide failed. When an aqueous solution of XVII was neutralized by the addition of triethylamine, the oil separated. This oil did not crystallize on prolonged standing in a refrigerator.

ether. The product was collected by filtration and washed with ether (0.292 g.). The *p*-nitrophenyl ester content of this product was estimated to be 95% by the procedure described in the preceding paragraph. This material was used as such in the next step.

Cyclo-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl (XXIV).—A solution of 0.292 g. of XXIII dissolved in a mixture of 0.5 ml. of acetic acid and 10 ml. of dimethylformamide was stirred, drop by drop, into 100 ml. of anhydrous pyridine kept at 70—75°C over a 3.5-hr. period. The solution was further stirred for 1.5 hr. at this temperature, and then evaporated to dryness in vacuo. The resulting residue was collected by filtration with the aid of water, dried in vacuo (0.235 g.), and then dissolved in 50 ml. of a mixture of dioxane and water (5 : 2). This solution was passed successively through columns (2×4.5 cm.) of Dowex-50 (H^+ form) and Amberlite IR-4B (OH^- form) which had been washed with a mixture of dioxane and water (5 : 2). The columns were then washed with the same solvent. The filtrate and washings were combined (total 150 ml.) and lyophilized to afford the crystalline product (0.175 g.). It was recrystallized from dioxane-ether-petroleum ether. Yield, 0.160 g. (60% from XXI); m. p. 263—265°C (decomp.); $[\alpha]_D^{20}$ −111° (*c* 0.65, dimethylformamide). The homogeneity was certified by thin-layer chromatography, R_f 0.94.[17]

Found: C, 63.42; H, 6.86; N. 12.77. Calcd. for $C_{74}H_{93}O_{15}N_{13}$: C, 63.27; H, 6.67; N, 12.96%.

The molecular weight was measured on a vapor pressure osmometer of Mechrolab, Inc., model 301 A, using methanol as the solvent.* Found: 1422. Calcd. for the benzyloxycarbonyl-substituted cyclic decapeptide: 1405.

Cyclo-L-phenylalanyl-D-phenylalanyl-L-asparaginyl-L-glutaminyl-L-tyrosyl-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolyl Hydrochloride (I_s).—A solution of 86.5 mg. (0.062 mmol.) of XXIV dissolved in a mixture of 0.32 ml. (0.064 mmol.) of 0.20 N dry hydrogen chloride in methanol and 3 ml. of methanol was hydrogenolyzed in the presence of palladium black. The progress of the reaction was checked by thin-layer chromatography. After 2.5 hr. the filtrate from the catalyst was concentrated to a small volume (0.1 ml.), and 2 ml. of ether was added to afford crystals; yield, 70 mg. Recrystallization from methanol-ether gave 65 mg. (74%) as the air-dried product (m. p. 239—240°C (decomp.)). Only one spot was obtained in thin-layer chromatography, R_f 0.76.[17] The elemental analysis was carried out using a desiccator-dried sample.

Found: C, 57.12; H, 6.96; N, 12.79. Calcd. for $C_{68}H_{87}O_{13}N_{13}\cdot HCl\cdot 5H_2O$: C, 56.75; H, 7.00; N, 13.03%.

When dried at 110°C (2 mmHg), this desiccator-dried sample lost 6.2% of its weight. Calcd. for $5H_2O$: 6.3%. On the other hand, the air-dried sample lost 8.8% of its weight after being dried for 2 hr. at 110°C (2 mmHg). Calcd. for $7H_2O$: 8.81%.

Amino acid analysis gave the molar ratios: leucine 1.0, phenylalanine 3.0, aspartic acid 1.0, glutamic acid 1.0, tyrosine 0.8, valine 1.0, ornithine 1.0, proline 1.0 and ammonia 2.1.

A Comparison of I_s and Natural Tyrocidine A Hydrochloride (I_n). — *(a) Paper Chromatography.* — This was carried out in two solvents. Both compounds gave a single spot and the same R_f values. R_f values of I_s: 0.92,[16] 0.95.[18] R_f values of I_n: 0.92,[16] 0.95.[18]

(b) Thin-layer Chromatography.—The R_f values of both compounds were exactly the same. R_f value of I_s: 0.76.[17] R_f value of I_n: 0.76.[17]

(c) Paper Electrophoresis.—This was carried out under the following conditions: paper, Toyo Roshi No. 52 chromatography paper; solvent, formic acid-acetic acid-methanol-water (1 : 3 : 6 : 10 v/v) (pH 1.8); voltage gradient, 17 V./cm.; charged period, 2.5 hr. Gramicidin S dihydrochloride was used as the reference compound. Figure 6 demonstrates the electrophoretic patterns of I_s, I_n and gramicidin S dihydrochloride. The mobility of I_s was indistinguishable from that of I_n.

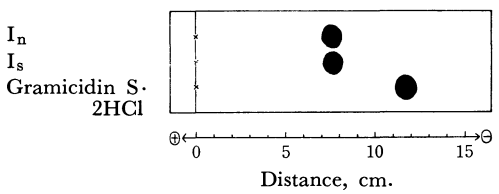

Fig. 6. Paper electrophoreses of I_s, I_n and gramicidin S dihydrochloride.

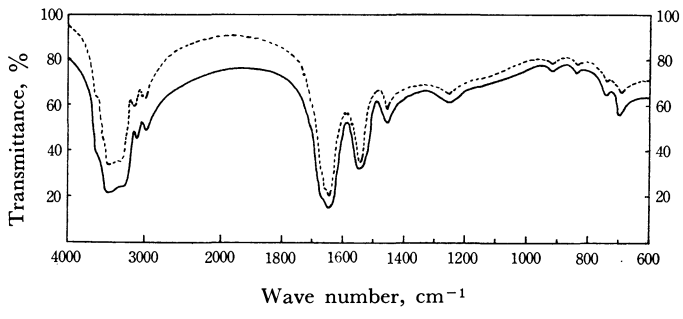

Fig. 7. Infrared spectra of I_s (——) and I_n (----).

* The atuhors are indebted to Mr. Michinori Waki of this laboratory for the molecular weight measurements.

18) The R_f value refers to paper chromatography with the solvent system of *t*-butanol-formic acid-water (75 : 15 : 10 v/v).

Table I. Inhibitory activity of I_s, I_n and gramicidin S on microorganisms
Minimum inhibitory concentrations, μg./ml.

A. Bouillon agar medium[a]

	Escherichia coli	*Proteus vulgaris*	*Staphylococcus aureus*	*Bacillus subtilis*	*Mycobacterium avium*	*Mycobacterium avium* (Streptomycin resistant St.)

B. Synthetic medium[c]

	Escherichia coli	*Proteus vulgaris*	*Staphylococcus aureus*	*Bacillus subtilis*	*Mycobacterium avium*	*Mycobacterium avium* (Streptomycin resistant St.)
I_s[b]	>100	>100	20	10	>100	>100
I_n[b]	>100	50	20	20	>100	>100
Gramicidin S·2HCl	>100	>100	5	5	>100	>100

a) Usual bouillon agar medium, pH 7.0.
b) Air-dried samples were employed.
c) Stephenson-Whetham's medium (modified); K_2HPO_4 0.1%, NaCl 0.1%, $MgSO_4 \cdot 7H_2O$ 0.05%, Na-glutamate 0.4%, casamino acid 0.2%, yeast-extract 0.05% and agar 2.0%, pH 7.0.

(d) Infrared Spectra.—These were obtained on a Hitachi EPI-2 spectrophotometer. The spectra of both I_s and I_n are presented in Fig. 7. The spectrum of I_s is superimposable on that of I_n.

(e) Ultraviolet Spectra.—These were obtained on a Hitachi EPS-2 spectrophotometer using a pair of 1-cm. quartz cells. Figure 8 indicates the spectra of I_s and I_n in 50% ethanol; here their absorption maxima agree well with each other.

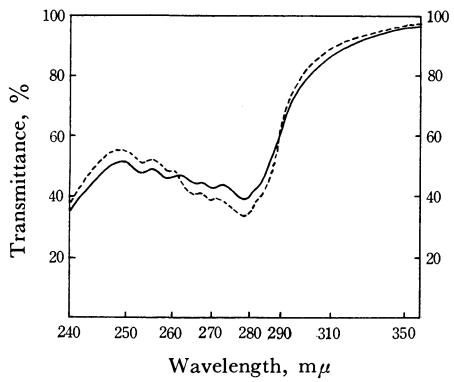

Fig. 8. Ultraviolet spectra of I_s (——) and I_n (----) in 50% ethanol; concentrations of I_s and I_n are 1.74×10^{-4} M and 1.85×10^{-4} M, respectively.

*(f) Carboxymethylcellulose (CMC) Column Chromatography.**—A 0.9×100 cm. CMC column was employed. The solvent used here was a methanol-containing (50%, v/v) 0.2 M pyridine-acetate buffer (pH 5.0). About 0.5 mg. of the sample was placed in 0.4 ml. of this solvent in the column, and the mixture was eluted with the same solvent. One milliliter fractions were collected at a flow rate of 7 ml. per hour. Each of them was kept for one hour at 90°C in order to remove methanol, and then 1 ml. of N sodium hydroxide was added to the residual solution and left to hydrolyze for 3 hr. at 90°C. After the solution had been neutralized by the addition of 0.5 ml. of 30% acetic acid, the components were determined by the Yemm-Cocking method.[19]

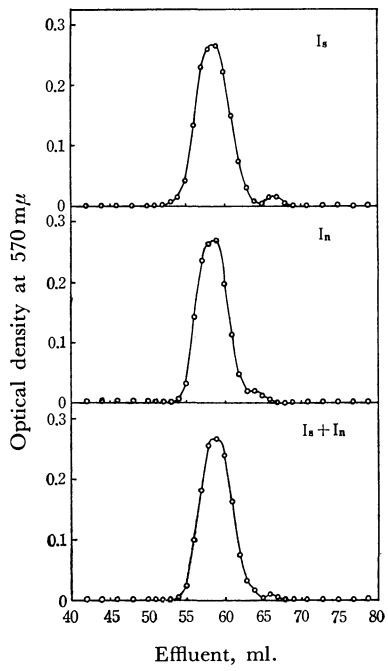

Fig. 9. CMC column chromatography of I_s, I_n and admixture of I_s and I_n.

* The authors are indebted to Mr. Haruhiko Aoyagi of this laboratory, who found the usefulness of the application of the CMC column chromatography in the separation of mixture of basic cyclic peptides.

19) E. W. Yemm and E. C. Cocking, *Analyst*, **80**, 209 (1955); *Biochem. J.*, **59**, xii (1954).

This procedure was applied to I_s, I_n and an equivalent admixture of I_s and I_n respectively. The results are shown in Fig. 9. The same chromatographic pattern was obtained in each of the three samples.

(g) Optical Rotation.—Air-dried samples were employed for the measurement, using 50% ethanol as the solvent: $[\alpha]_D^{20}$ of I_s $-108°$ (*c* 0.141); $[\alpha]_D^{20}$ of I_n $-108°$ (*c* 0.126). Lit.[1] $[\alpha]_D^{25}$ $-111°$ (*c* 1.37, 50% ethanol) for a sample dried at 110°C.

(h) Microbiological Assays.—The microorganisms employed are listed in Table I. The minimum amount of the compound necessary for the complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. In addition to I_s and I_n, gramicidin S dihydrochloride was examined as a reference compound. Although, in the synthetic medium, small differences were observed in the effects of I_s and I_n on the *Proteus vulgaris* and *Bacillus subtilis*, the antibacterial spectra of the two compounds can be considered to be in agreement with one other.

The authors wish to express their thanks to Dr. Lyman C. Craig of Rockefeller Institute, U. S. A., for the generous gift of a smaple of the natural tyrocidine A hydrochloride. The authors are also much indebted to Dr. Motoo Shibata of Takeda Chemical Industries, Ltd. for the microbiological assays, and Kyowa Hakko Kogyo Co., Ltd. and Ajinomoto Co., Inc. for supplying some amino acids.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1747—1753 (1966)

Studies of Peptide Antibiotics. V. Syntheses of Cyclic Penta- and Decapeptides with the L-Valyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosyl Sequence

By Haruhiko AOYAGI and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka

(Received November 15, 1965)

A cyclic decapeptide dihydrochloride cyclo-(L-valyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosyl)$_2$·2HCl, which is an analog of gramicidin S and a cyclic pentapeptide monohydrochloride cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosyl·HCl, were synthesized for the purpose of comparing their antibacterial activities with gramicidin S. The cyclic decapeptide dihydrochloride was obtained by hydrogenolysis in the presence of hydrogen chloride of a cyclic benzyloxycarbonyl-substituted decapeptide, which had been prepared by the cyclization of a corresponding linear decapeptide active ester. The cyclization reaction of a linear pentapeptide active ester yielded a mixture of a cyclic benzyloxycarbonyl-substituted pentapeptide as a major component, and a cyclic decapeptide and an unidentified cyclic peptide as minor components. The effects of two cyclic peptide hydrochlorides on bacterial growth were tested. The cyclic decapeptide was as active as gramicidin S; however, the cyclic pentapeptide showed no activity in relation to any of the microorganisms tested.

In connection with a series of studies in this laboratory on the significance of the chemical functional groups of gramicidin S (I) to its biological activities, the authors reported, in a previous paper, the synthesis of an analog of gramicidin S wherein proline residues in the 5 and 5′ positions of the molecule were replaced by glycines.[1] This 5, 5′-glycine-gramicidin S was found to possess approximately 10 times the antibacterial activity of natural gramicidin S in the test with a synthetic medium, while it possessed about half the activity of gramicidin S with a bouillon agar medium. In the light of the considerable antibacterial potency of this analog, the decision was made to investigate the effect of replacing the proline residues by sarcosines. The present paper will describe the syntheses and the antibacterial properties of this cyclic decapeptide, 5, 5′-sarcosine-gramicidin S (II), and of the cyclic pentapeptide, cyclo-L-valyl-L-ornithyl L-leucyl-D-phenylalanylsarcosyl (III), related to I and II.

(III)

The sequence of reactions employed for the synthesis of II is shown in Fig. 1. The condensation of the azide derived from acylpentapeptide hydrazide (XII) with pentapeptide (XI) gave acyldecapeptide (XIII) in a yield of 73%. The treatment of XIII with an excess of di-*p*-nitrophenyl sulfite gave an amorphous acyldecapeptide *p*-nitrophenyl ester (XIV). The *p*-methoxybenzyloxycarbonyl group of XIV was removed by the action of trifluoroacetic acid, and the decapeptide *p*-nitrophenyl ester trifluoroacetate (XV) thus obtained was treated with a large amount of hot pyridine for the cyclization reaction. The benzyloxycarbonyl-substituted cyclic peptide obtained in a yield of 45% (from XIII) was found to be a monomer, shown as XVI, from the result of the molecular weight determination. In this connection, it is of interest to note that the cyclization reaction of the decapeptide active ester yields monomer, cyclic decapeptide.[1,2] The final product (II·2HCl) was obtained as colorless

crystals containing seven moles of the water of crystallization. Its homogeneity was demonstrated by CM-cellulose column chromatography (Fig. 3) and paper electrophoresis (Fig. 4).

The synthesis of the protected cyclic decapeptide (XVI) was also attempted by the dimerization reaction of the pentapeptide active ester (XVIII). As is shown in Fig. 2, the treatment of the pentapeptide active ester (XVIII) gave a product (XX) with the character of benzyloxycarbonyl-substituted cyclic peptide in a fairly good yield. After the experiments of CM-cellulose column chromatography and paper electrophoresis (Figs. 3 and 4) with a hydrogenated material (XXI) of the product, this product (XX) was found to be a mixture of three components, namely, a protected cyclic pentapeptide (XIX) as a major component, and the protected cyclic decapeptide (XVI) and an unidentified cyclic peptide as minor components.

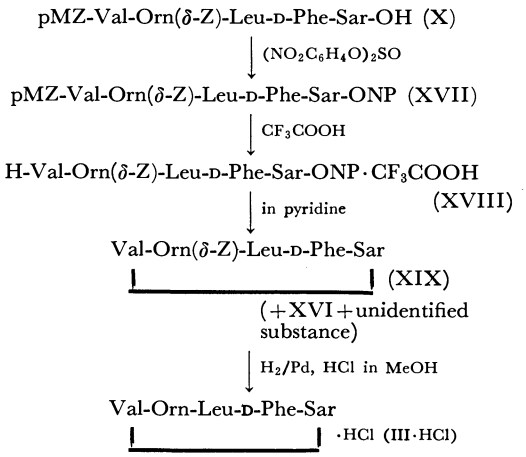

Fig. 2.

It was determined further, by analysis by means of the CM-cellulose column chromatography of the material (XXI) that the molar ratio between XIX and XVI was 92 : 8. The protected cyclic pentapeptide (XIX) in a pure state was obtained easily by several recrystallizations from methanol-ether of the product (XX); XIX was less soluble in methanol than XVI or the unidentified cyclic peptide. The fact that this major product is a monomer, shown as XIX, was denomstrated by the result of the molecular weight determination. The hydrogenation of XIX in the presence of equivalent hydrogen chloride yielded a cyclic pentapeptide hydrochloride (III·HCl) as colorless crystals, with three moles of the water of crystallization.

In a previous paper,[1] we observed that the cyclization reaction of the L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl- D - phenylalanylglycine active ester yielded a large amount of the pyridine-insoluble cyclic peptide, besides a small amount of the desired protected cyclic decapeptide. This pyridine-insoluble substance appears, from the results of the experiment of CM-cellulose chromatography, to be a cyclic benzyloxycarbonyl-substituted pentapeptide.[3] In this connection, it would be of interest to note that two reports have described that cyclization reaction of pentapeptide active esters, wherein *C*-terminal amino acid residues were glycine and isoleucine, yields a monomer cyclic pentapeptide.[4] On the contrary, several experiments have shown that the pentapeptide active ester, wherein the partial sequence at the *C*-terminal part is D - phenylalanyl - L - proline, yielded cyclic decapeptide by dimerization reaction.[5]

In order to ascertain whether or not the cyclic peptides, II and III, possess antibacterial activities, the effect of various levels of II and III on the growth of several microorganisms was examined (Table I). It was found that II was as active as gramicidin S in affecting several microorganisms. This result demonstrates further that the side chain of proline of gramicidin S is not absolutely required for its full activity. On the other hand, III exhibited no antibacterial activity in relation to any of the microorganisms tested. A communication from this laboratory has also described that a cyclic hexapeptide related to gramicidin S, cyclo-L-valyl-L-ornithyl- L - leucyl-D-phenylalanyl-L-prolylglycyl, showed no such activity either.[6] These results suggest that a certain ring size of a molecule, besides a specific amino acid sequence, will be necessary for the exhibition of activity.

Experimental

All melting points are uncorrected. Prior to analysis, the compounds were dried over phosphorus pentoxide at 80°C and 2 mmHg to a constant weight, except in the cases of II·2HCl and III·HCl.

Sarcosine Ethyl Ester *p*-Toluenesulfonate (IV). —This compound was prepared according to the general procedure of Kato et al.[7] A solution of sarcosine (4.0 g.) and *p*-toluenesulfonic acid monohydrate (9.4 g.) in a mixture of ethanol (20 ml.) and carbon tetrachloride (100 ml.) was refluxed, and the water thus liberated was removed as an azeotropic mixture. The reaction mixture was concentrated in vacuo, and the residual oil was treated with ether and petroleum ether. The product was very hygroscopic; yield, 12.0 g.

(92%); R_f 0.61.[8]

Benzyloxycarbonyl - D - phenylalanylsarcosine Ethyl Ester (V).—Into a solution of benzyloxycarbonyl-D-phenylalanine (6.71 g.) and IV (6.5 g.) in chloroform (80 ml.) there were stirred triethylamine (3.14 ml.) and dicyclohexylcarbodiimide[9] (4.61 g.) at 0°C. After it had been permitted to stand overnight at 0°C, the mixture was evaporated in vacuo and the residue was diluted with ethyl acetate; then the dicyclohexylurea thus precipitated was filtered off. The filtrate was washed successively with 4% sodium bicarbonate, 3% hydrochloric acid and water, and dried over anhydrous sodium sulfate. The filtered solution was evaporated in vacuo. The product was obtained as an oil; yield, 7.68 g. (86%); R_f 0.73.[8]

D-Phenylalanylsarcosine Ethyl Ester Hydrochloride (VI).—V (7.68 g.) was subjected to hydrogenolysis in the presence of palladium black and 0.44 N methanolic hydrogen chloride (46.5 ml.). The filtrate from the catalyst was evaporated to dryness in vacuo; yield of oil, 5.80 g. (100%); R_f 0.70.[8]

Benzyloxycarbonyl - L - leucyl - D - phenylalanylsarcosine Ethyl Ester (VII).—To a chilled solution of benzyloxycarbonyl-L-leucine (5.11 g.) and triethylamine (2.70 ml.) in tetrahydrofuran (40 ml.), isobutyl chloroformate (2.52 ml.) was added. After 15 min. a mixture of VI (5.80 g.), triethylamine (2.70 ml.) and chloroform (40 ml.) was added to the solution. The mixture was left overnight at room temperature, and then evaporated in vacuo. The residual oil was dissolved in ethyl acetate and treated as has been described in connection with the preparation of V. The oily residue wieghed 6.45 g. (66%); R_f 0.88.[8]

L-Leucyl-D-phenylalanylsarcosine Ethyl Ester Hydrochloride (VIII).—VII (2.96 g.) was subjected to hydrogenolysis in the presence of palladium black and 0.40 N methanolic hydrogen chloride (16.6 ml.), and then treated as has been described in connection with the preparation of VI. The yield of oily product was 2.28 g. (91%); R_f 0.59[8] and 0.62.[10]

***p*-Methoxybenzyloxycarbonyl-L-valyl - δ - benzyloxycarbonyl-L-ornithyl-L - leucyl - D - phenylalanyl - sarcosine Ethyl Ester (IX).**—The following operations were carried out in a cold room. To a chilled solution *p*-methoxybenzyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl - L - ornithine hydrazide[6] (1.47 g.) in glacial acetic acid (30 ml.) there were stirred N hydrochloric acid (4.1 ml.) and sodium nitrite (210 mg.) in water (1 ml.). After 6 min., cold water (200 ml.) was added to the solution. The azide which thereupon precipitated as a white mass was collected by filtration and washed with water, 4% sodium bicarbonate and water, and then dried under a vacuum in a desiccator over phosphorus pentoxiede and potassium hydroxide. The azide was added to a solution of VIII (1.12 g.) and triethylamine (0.38 ml.) in dimethylformamide (20 ml.). The mixture was stirred for 3 days at 0°C and evaporated in vacuo. The precipitate which formed upon the addition of water (30 ml.) to the syrup was collected, wahsed with 4% sodium bicarbonate, 10% citric acid and water, and dried. It was recrystallized from methanol - ether - petroleum ether; yield, 1.82 g. (75%); m. p. 143—146°C; $[\alpha]_D^{26}$ —28.4° (*c* 0.5, acetic acid); R_f 0.73.[8]

Found: C, 62.79; H, 7.52; N, 9.70. Calcd. for $C_{47}H_{64}O_{11}N_6 \cdot {}^1/_2H_2O$: C, 62.86; H, 7.30; N, 9.40%.

***p*-Methoxybenzyloxycarbonyl- L -valyl- δ -benzyloxycarbonyl - L - ornithyl-L-leucyl -D- phenylalanyl-sarcosine (X).**—To a solution of IX (1.16 g.) in a mixture of methanol (30 ml.) and dioxane (10 ml.), 2 N sodium hydroxide (2 ml.) was added, and the solution was allowed to stand for 4 hr. at room temperature. After the addition of 10% citric acid (15 ml.) under cooling, the solution was concentrated in vacuo at a low temperature and the residue treated with water (100 ml.). After it had been stored in a refrigerator for several hours, the precipitate was collected by filtration, washed with water, and dried. The product was recrystallized from methanol - ether - petroleum ether; yield, 0.96 g. (86%); m. p. 151—153°C; $[\alpha]_D^{26}$ −26.8° (*c* 0.5, acetic acid); R_f 0.75.[8]

Found: C, 61.90; H, 7.20; N, 9.73. Calcd. for $C_{45}H_{60}O_{11}N_6 \cdot {}^1/_2H_2O$: C, 62.12; H, 7.07; N, 9.66%.

L -Valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosine Hydrochloride (XI).—To a solution of X (1.64 g.) in dioxane (20 ml.), there was added 4.0 N hydrogen chloride in dioxane (20 ml.). After it had been permitted to stand for 2 hr. at room temperature, the solution was evaporated in vacuo. The residue was triturated with ether and washed repeatedly with ether by decantation. The crystalline product was collected by filtration with the aid of ether; yield, 1.38 g. (98%); m. p. 162°C; $[\alpha]_D^{20}$ −15.4° (*c* 0.5, acetic acid); R_f 0.67.[8]

Found: C, 58.69; H, 7.47; N, 11.31. Calcd. for $C_{36}H_{53}O_8N_6Cl$: C, 58.96; H, 7.28; N, 11.46%.

An attempt to crystallize the HCl-free pentapeptide failed.

***p*-Methoxybenzyloxycarbonyl- L -valyl- δ -benzyloxycarbonyl- L -ornithyl- L -leucyl- D -phenylalanyl-sarcosine Hydrazide (XII).**—To a solution of IX (2.30 g.) in dimethylformamide (10 ml.), hydrazine hydrate (2.5 ml.) was added and the solution was allowed to stand for 2 days at 30°C. The reaction mixture was then evaporated in vacuo. The hydrazide which precipitated upon the addition of water (30 ml.) was collected by filtration and dried; yield, 2.19 g. (98%); m. p. 172—175°C; $[\alpha]_D^{26}$ −32.8° (*c* 0.5, acetic acid); R_f 0.74.[8]

Found: C, 60.76; H, 7.18; N, 12.55. Calcd. for $C_{45}H_{62}O_{10}N_8 \cdot H_2O$: C, 60.52; H, 7.22; N, 12.55%.

***p* - Methoxybenzyloxycarbonyl -L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L - leucyl - D - phenylalanyl-sarcosyl-L-valyl-δ- benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosine (XIII).** — Into a chilled solution of XII (0.79 g.) in a mixture of dimethylformamide (10 ml.) and glacial acetic acid (10 ml.), 1.2 N hydrochloric acid (2.4 ml.) and sodium nitrite (70 mg.) in water (4 ml.) were stirred. After 5 min., cold water (200 ml.) was added to the solution. The azide which thereupon precipitated was collected by

8) The R_f value refers to the thin-layer chromatography with Merck silica gel G and to the *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2, v/v) system. Compounds possessing a free amino group were detected by spraying them with ninhydrin, and those with blocked amino groups, by spraying them with 47% hydrobromic acid, and then with ninhydrin.

filtration and treated as has been described in connection with the preparation of IX. The azide was added to a solution of XI (0.66 g.) in a mixture of dimethylformamide (20 ml.) and triethylamine (0.26 ml.), and the mixture was stirred for 3 days at 0°C. The insoluble material was removed by filtration, and the filtrate was evaporated in vacuo. The precipitate which formed upon the addition of 10% citric acid (30 ml.) was collected, washed with 10% citric acid and water and dried. Recrystallization from dioxane-ether gave 1.02 g. (73%) of XIII; m. p. 208—209°C; $[\alpha]_D^{26}$ −45.6° (*c* 0.5, acetic acid); R_f 0.76.[8]

Found: C, 62.44; H, 7.53; N, 10.82. Calcd. for $C_{81}H_{110}O_{18}N_{12}\cdot H_2O$: C, 62.45; H, 7.25; N, 10.79%.

Cyclo-(L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosyl)$_2$ (XVI).—To a solution of XIII (467 mg.) in pyridine (6 ml.), di-*p*-nitrophenyl sulfite[11] (972 mg.) was added, and the reaction mixture was allowed to stand for 24 hr. at room temperature. After evaporation, the oily product was triturated with petroleum ether and washed repeatedly with a mixture of ether and petroleum ether (1 : 1) by decantation until no yellow color could be discerned on the addition of a sodium hydroxide solution to the washings. The product was collected by filtration, washed with a mixture of ether and petroleum ether, and dried. It weighed 444 mg. A small portion of this product (1.1 mg.) was dissolved in 25 ml. of dimethylformamide - N sodium hydroxide (1 : 1) (2.64×10^{-5} M/l.); the *p*-nitrophenyl ester content was estimated by measuring the optical density of the solution at 412 mμ.[2] The purity of the compound was estimated to be 88%.

To the *p*-nitrophenyl ester (XIV) (442 mg.), anisole (0.5 ml.) and trifluoroacetic acid (3.5 ml.) were added at 0°C. The solution was then evaporated in vacuo at 0°C, and the residue was triturated with ether. The decapeptide *p*-nitrophenyl ester trifluoroacetate (XV) was collected, washed with ether, and dissolved in dimethylformamide (9 ml.) containing glacial acetic acid (0.1 ml.). The solution was stirred, drop by drop, into pyridine (150 ml.) kept at 55—60°C over a period of 3.5 hr.; the stirring was then continued for an additional 2 hr. at the same temperature. After the solvent had been removed, the residual oil was dissolved in a mixture of methanol (100 ml.) and water (20 ml.). An insoluble substance was removed by filtration, and the filtrate was passed successively through columns of Dowex 1 (OH^- form, 2×10 cm.) and Dowex 50 (H^+ form, 2×7 cm.). The columns were washed with the same solvent (150 ml.), the combined effluent was evaporated to dryness in vacuo, and the product was suspended in water (50 ml.), collected by filtration, and dried (219 mg.). The product was recrystallized from methanol - ether - petroleum ether; yield, 186 mg. (45% from XIII); m. p. 165°C; $[\alpha]_D^{26}$ −139° (*c* 0.3, acetic acid); R_f 0.93.[8]

Found: C, 62.76; H, 7.61; N, 12.24. Calcd. for $C_{72}H_{100}O_{14}N_{12}\cdot H_2O$: C, 62.86; H, 7.47; N, 12.22%.

The molecular weight of XVI was determined by a Model 301 A Osmometer, Mechrolab Inc. (solvent: methanol).[12]

Found: 1240. Calcd. for $C_{72}H_{100}O_{14}N_{12}\cdot H_2O$: 1376.

Cyclo-(L-valyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosyl)$_2$ Dihydrochloride (II·2HCl).—XVI (41 mg.), dissolved in methanol (0.6 ml.) and 0.24 N methanolic hydrogen chloride (0.3 ml.), was subjected to hydrogenolysis in the presence of palladium black. The solution, after being filtered from the calalyst, was evaporated to dryness in vacuo. The powder which remained was collected with the aid of ether; the yield of the air-dried product, 32 mg. (92%); m. p. 212—214°C; $[\alpha]_D^{20}$ −157° (*c* 0.3, ethanol); R_f 0.68,[8] 0.89,[10] 0.71[13] and 0.88.[14]

Found: C, 52.51; H, 7.87; N, 12.50. Calcd. for $C_{56}H_{90}O_{10}N_{12}Cl_2\cdot 7H_2O$: C, 52.20; H, 8.12; N, 13.05%.

The molecular weight was determined by the procedure described above (solvent: methanol).

Found: 510.[15] Calcd. for $(1/3)\times(C_{56}H_{90}O_{10}N_{12}Cl_2\cdot 7H_2O)$: 429.

The air-dried product lost 1.5% of its weight when it was left in a desiccator over calcium chloride at room temperature. Calcd. for H_2O: 1.4%. The air-dried product lost 7.4% of its weight after drying over phosphorus pentoxide for 3 hr. at 80°C (2mmHg), Calcd. for $5H_2O$: 7.0%. The product was treated with dinitrofluorobenzene in the manner described by Sanger et al.[16] After the hydrolysis of the dinitrophenylated compound (DNP-II), only one DNP-amino acid, identified as δ-DNP-ornithine, was detected on a paper chromatogram; R_f 0.68.[8]

Cyclo-L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylsarcosyl (XIX).—To a solution of X (610 mg.) in pyridine (5 ml.), di-*p*-nitrophenyl sulfite (920 mg.) was added. The reaction mixture was allowed to stand for 24 hr. at room temperature and then treated as has been described in connection with the preparation of XVI. The product (XVII) obtained weighed 605 mg. The purity of the compound was estimated to be 107%. To the *p*-nitrophenyl ester (XVII) (600 mg.), anisole (0.5 ml.) and trifluoroacetic acid (3.5 ml.) were then added. The solution was evaporated in vacuo, and the residue was triturated with ether. The pentapeptide *p*-nitrophenyl ester trifluoroacetate (XVIII) was collected by filtration and dissolved in dimethylformamide (10 ml.) containing glacial acetic acid (0.1 ml.). The solution was then stirred, drop by drop, into pyridine (180 ml.) kept at 55—60°C over a period of 5 hr.; the stirring was then continued for an additional 2 hr. at the same temperature. After the solvent had been removed, the residual oil was dissolved in a mixture of methanol (100 ml.) and water (20 ml.). An insoluble substance was removed by filtration, and the filtrate was treated with the columns of Dowex 1 and 50 described in connection with the preparation of XVI. It weighed 183 mg. (XX). A few mg. of XX were subjected to hydrogenolysis; the hydrogenated material was designated as

XXI. XXI was found to be a mixture of II, III and an unidentified substance (XXII) (Figs. 3 and 4). Several recrystallizations of XX from methanol-ether gave 95 mg. (20% from X) of pure XIX; m. p. 224—227°C; $[\alpha]_D^{26}$ +0.7° (*c* 0.3, acetic acid); R_f 0.93.[8]

Found: C, 62.80; H, 7.50; N, 12.44. Calcd. for $C_{36}H_{50}O_7N_6 \cdot {}^1/_2H_2O$: C, 62.86; H, 7.47; N, 12.22%.

The molecular weight of XIX was determined by a Model 301 A osmometer (solvent: methanol).

Found: 750. Calcd. for $C_{36}H_{50}O_7N_6 \cdot {}^1/_2H_2O$: 689.

Cyclo - L - valyl - L - ornithyl- L -leucyl- D -phenylalanylsarcosyl Hydrochloride (III · HCl). — XIX (34.4 mg.) was dissolved in methanol (1.5 ml.) and 0.24 N methanolic hydrogen chloride (0.25 ml.) and treated as has been described in connection with the preparation of II·2HCl; yield, 22.4 mg. (77%); m. p. 198°C; $[\alpha]_D^{20}$ −26.8° (*c* 0.3, ethanol); R_f, 0.69,[8] 0.88,[10] 0.70[13] and 0.87.[14]

Found: C, 53.20; H, 7.94; N, 13.13. Calcd. for $C_{28}H_{45}O_5N_6Cl \cdot 3H_2O$: C, 52.94; H, 8.09; N, 13.23%.

The molecular weight was determined by the procedure described above (solvent: methanol).

Found: 340.[17] Calcd. for $(1/2) \times (C_{28}H_{45}O_5N_6Cl \cdot 3H_2O)$: 318.

The air-dried product lost 5.4% of its weight when it was left in a desiccator over calcium chloride at room temperature. Calcd. for $2H_2O$: 5.7%. The air-dried product lost 8.3% of its weight after having been dried over phosphorus pentoxide for 3 hr. at 80°C, 2 mmHg. Calcd. for $3H_2O$: 8.5%. After the hydrolysis of the dinitrophenylated compound (DNP-III), only δ-DNP-ornithine was detected on a paper chromatogram; R_f 0.68.[10]

Amino Acid Analyses of II and III.—A complete amino acid analysis except for the sarcosine of each compound was carried out according to the procedure described in a previous paper.[1] Amino acid determinations of II and III gave the molar ratios of 1.0 : 1.0 : 1.1 : 1.0 and 1.0 : 0.9 : 1.0 : 1.1 for valine, ornithine, leucine and phenylalanine respectively. In order to determine the sarcosine content, a mixture of sarcosine (0.5 μmol.) and leucine (0.5 μmol.) was dinitophenylated[18] and subjected to thin-layer chromatography.[19] Each band of DNP-sarcosine and DNP-leucine was eluted with methanol, the eluent was evaporated, and the residue was dissolved in 1% sodium bicarbonate (10 ml.) for spectrophotometric determination. It was found that the intensities at 380—385 mμ for DNP-sarcosine and at 360 mμ for DNP-leucine were almost the same. The same operations were carried out for the hydrolysates of II and III; the molar ratios for sarcosine and leucine are of 0.9 : 1.0 and 0.9 : 1.0 respectively.

Chromatography and Electrophoresis of II, III, XXI and Gramicidin S.—Carboxymethylcellulose column chromatography was performed as follows: Each portion (0.5—1 mg.) of hydrochlorides of II, III, XXI and gramicidin S was dissolved in 0.2—0.3 ml. of 0.2 M pyridinium acetate containing 30% methanol (pH 5.0), and then the solution was applied to a column (0.9×50 cm.) of carboxymethyl cellulose (Eastman Organic Chem. 7796). When elution was carried out with the same solvent at 20—25°C, and a flow rate was about 20 ml. per hr., 2 ml. fractions were collected. The peptide content in the fractions was determined by the method described by Yemm and Cocking.[20] Gramicidin S was used as a control. The results are shown in Fig. 3. In order to examine the molar ratio between XIX and XVI in the cyclization product (XX) from the pentapeptide active ester (XVIII), a solution containing 1 μmol. of III and 0.5 μmol. of II was subjected to column chromatography; the ratio of intensities resulting from ninhydrin between III and II was found to be 80 : 100 by calculating the areas on a chromatogram of the optical density-fraction number. By the use of the value obtained above, it was calculated from Fig. 3 that the molar ratio between III and II in XXI was about 92 : 8. Therefore, it was deduced that the cyclization reaction of the pentapeptide active ester (XVIII) gave the cyclic pentapeptide (XIX) predominantly. Their analyses were also carried out by electrophoresis. An appropriate amount of the material was placed on a paper of Toyo Roshi No. 52, and 500 V./30 cm. were applied for 3 hr. at room temperature, using a formic acid - acetic acid-methanol - water (1 : 3 : 6 : 10, v/v) system at pH

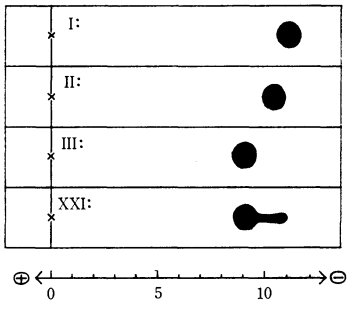

Fig. 4. Paper electrophoresis of hydrochlorides of gramicidin (I), II, III and XXI.

1.8 (Fig. 4). Figure 4 shows also that the cyclization product (XX) contained the cyclic pentapeptide (XIX) as a major component.

Microbiological Assays. — The microorganisms employed are shown in Table I. The minimum amount of the compounds needed for a complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. As is shown in Table I, the cyclic decapeptide II was found to be as active as gramicidin S against *B. subtilis* and *Staph. aureus*. II appears to exhibit weak antibacterial activity against *Mycobact. avium* (streptomycin-resistant) and *Mycobact. avium*. The cyclic pentapeptide III exhibited no activity with relation to any of the organisms tested.

The authors wish to express their thanks to Dr. Motoo Shibata of Takeda Chemical Industries, Ltd., for the microbiological assays. Thanks are also due to the Ajinomoto Co., Inc., and to Kyowa Hakko Kogyo Co., Ltd., for supplying some of the amino acids.

The Knoevenagel Reaction between Hydroxybenzaldehydes and Ethyl Cyanoacetate

By Heinosuke YASUDA* and Hiroshi MIDORIKAWA

The Institute of Physical and Chemical Research, Bunkyo-ku, Tokyo

(Received November 30, 1965)

Substituted 2-hydroxybenzaldehydes react with two equivalents of ethyl cyanoacetate to give α-amino-β-(substituted 3-coumarinyl)-β-cyano-β-ethoxycarbonylethylenes in the presence of piperidine. When equivalent aldehyde and the cyanoacetate are used, substituted 2-imino-3-ethoxycarbonyl-2*H*-chromenes result, without the isolation of arylidenecyanoacetates. In *o*-hydroxyaryls, salicylic and *o*-thymotinic aldehydes, which give benzopyrane derivatives, are exceptional cases. 5-Phenylazo- and 5-nitro-2-hydroxybenzaldehydes result in the formation of coumarin derivatives. An abnormal condensation is also shown in the cases of 3, 5-dibromo-2, 4-dihydroxy-, 2-hydroxy-3-methoxy- and 2-hydroxy-4-methoxybenzaldehydes; i. e., the first one yields a 1 : 1-condensation product, while the last two give 3-cyanocoumarin derivatives, even with an excess of ethyl cyanoacetate. The condensation of *m*- and *p*-hydroxybenzaldehydes with ethyl cyanoacetate give the normally-expected arylidenecyanoacetates, even in the presence of a large excess of the cyanoacetate.

The base-catalyzed condensation of salicylaldehyde with ethyl cyanoacetate has already been described by Bechart[1] and by Knoevenagel et al.,[2] as giving an abnormal condensation product. They assigned the product to diethyl α, γ-dicyano-β-(2-hydroxyphenyl)-glutarate (Ia). Recently, however, Matsumura[3] established that this product has the structure of 2-amino-2-(cyano-ethoxycarbonylmethyl)-3-ethoxycarbonyl-α-benzopyrane (IIa) and not Ia. Sastry et al.[4] reported that ethyl 3-cyano-3, 4-dihydrocoumarin-4-cyanoacetate (III) was formed when Ia was refluxed in ethanol containing piperidine, but Matsumura gave the structure of α-amino-α-(3-coumarinyl)-β-cyano-β-ethoxycarbonylethylene (IV) instead of III.

The present investigation will be concerned with the condensation of various *o*-hydroxyaromatic aldehydes with ethyl cyanoacetate in the presence of piperidine. In addition, *m*- and *p*-hydroxyaryls will also be investigated.

Results and Discussion

The condensation between salicylaldehyde and ethyl cyanoacetate was re-investigated. The condensation was attempted by heating the aldehyde with an equivalent amount of the cyanoacetate in ethanol containing piperidine or by letting the reactants stand; however, the required condensations could not be effected, and only negligible products were obtained.

The condensation was positive only with two equivalent amounts of the cyanoacetate; that is, only when the reaction mixture was heated for a short time at the boiling point of the solvent, two compounds (m. p. 239—240°C and m. p. 137.5—138.5°C) could be readily isolated.

On investigation, the product melting at 239—240°C was found to be devoid of saturated nitriles. This was confirmed by the infrared absorption spectrum, which showed no characteristic bands for the nitriles. However, two medium bands were shown near 3400 and near 3300 cm^{-1}, indicating a primary amino group; also, the spectrum exhibited an absorption near 2200 cm^{-1} for α, β-unsaturated nitrile. These facts, together with the analytical results, were in full agreement with the IV structure originally proposed by Matsumura. On the other hand, the spectrum of the compound melting at 137.5—138.5°C revealed two relatively intense bands near 3460

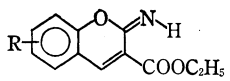
and near 3300 cm^{-1}; these were attributed to a primary amino group. The infrared and analytical data are in essential agreement with the IIa structure formulated by Matsumura.

The investigation was then extended to the action of the ethyl cyanoacetate on substituted 2-hydroxybenzaldehydes with the view of obtaining the IIa and/or the IV type. Using a 2 : 1 molar ratio of the aldehydes to the cyanoacetate, α-amino-α-(substituted 3-coumarinyl)-β-cyano-β-ethoxycarbonylethylenes (Va—Vf) (see Tables I and II), which very closely resemble the IV type, were regularly obtained, but the expected α-benzopyrane derivatives (the IIa type) could not be isolated; with a molar ratio of the aldehydes and the cyanoacetate, only the 1 : 1-condensation products were obtained.

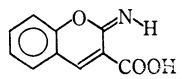
The 1 : 1-condensation products mentioned above did not exhibit the characteristic C≡N stretching vibration in each infrared spectrum examined; therefore, the following structure, VI, was considered to hold for the products concerned.

Apparently, the spectrum of the 1 : 1-product obtained from 5-chlorosalicylaldehyde and ethyl cyanoacetate, for example, supported the structure



VI

of 2-imino-3-ethoxycarbonyl-6-chloro-2*H*-chromene (VIa), since three recognizable bands, at 3380, 1710 and 1635 cm^{-1} which due to an N–H, an α, β-unsaturated ester C=O and a C=N stretching vibrations respectively, were detected. A medium band at 1615 cm^{-1} attributable to the C=C stretching mode adjacent to the ester residue was also observed. Baker and Howea[5] have already inferred that, in the conversion of 2-hydroxybenzylidenecyanoacetic acid into 3-coumarincarboxylic acid in boiling water, an imino-lactone (VII) is the intermediate.



VII

The 1: 1-products investigated, accordingly, were considered to have the structure of 2-imino-3-ethoxycarbonyl-2*H*-chromenes (VIa—VIf) and not substituted arylidenecyanoacetates (see Tables III and IV). As may be seen in Table IV, α, β-unsaturated ester C=O bands of all the compounds measured in KBr disk are shifted to lower frequencies as compared with the normal spectral region of ester carbonyls vicinal to α, β-unsaturation. It is likely, judging from the infrared results, that these 2*H*-chromenes have the hydrogen-bonded chelate form in the solid state.

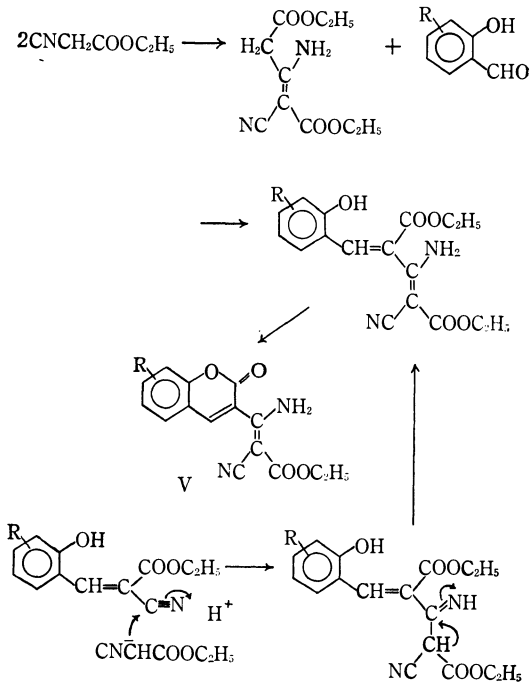
The problem of the mechanism of the formation of the β-ethoxycarbonylethylenes (Va—Vf) is reduced to the question of whether the condensation involves a self-condensation of the cyanoacetate forming an enamine-type dimer via a ketimine-type dimer following the dehydration reaction between the dimer and the aldehydes, or, alternatively, the formation of normal dehydration products without cyclization and a nucleophilic addition reaction by the cyanoacetate on the dehydration products. The two possibilities are illustrated in Scheme 1.



Scheme 1

When the *o*-hydroxyaryls were treated with an equivalent ethyl cyanoacetate, no β-ethoxycarbonylethylene derivatives occurred; only 1 : 1-products

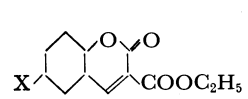
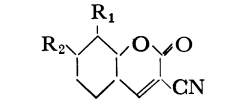
via intermediate arylidenecyanoacetates were obtained, as has been described above. These facts indicate that the latter mechanism, which involves the carbanion of the cyanoacetate attacking the possibly-polarized nitrile carbon atom of the resulting intermediates, may be more possible than the former mechanism. However, salicylaldehyde condensed with the dimer of ethyl cyanoacetate to give the β-ethoxycarbonylethylene (IV), as has been reported earlier.[3]

A definitive proof for the latter mechanism is lacking. Attempts to obtain the IV type by treating the appropriate 2*H*-chromene derivatives with ethyl cyanoacetate in boiling ethanol containing piperidine were unsuccessful.

5-Phenylazo-2-hydroxy- and 3, 5-dibromo-2, 4-dihydroxybenzaldehydes behaved "abnormally" in the condensation with an excess of ethyl cyanoacetate, giving ethyl 6-phenylazo-3-coumarincarboxylate (VIIa) and the 2*H*-chromene derivative (VIe) (see Table III), respectively. 5-Nitrosalicylaldehyde reacted with an equimolar ethyl cyanoacetate to yield an unexpected product, ethyl 6-nitro-3-coumarincarboxylate (VIIb); also, 2-hydroxy-3-methoxy- and 2-hydroxy-4-methoxybenzaldehydes resulted in the formation of 8-methoxy-3-cyanocoumarin (VIIIa) (C≡N stretching 2220 cm^{-1} in KBr disk) and 7-methoxy-3-cyanocoumarin (VIIIb) (C≡N 2220 cm^{-1}) respectively when an equimolar ethyl cyanoacetate was used. These were exceptional cases in the *o*-hydroxyaryl series.



VIIa, X=Ph-N=N-
VIIb, X=NO_2



VIIIa, R_1=OCH_3 R_2=H
VIIIb, R_1=H R_2=OCH_3

The condensation of *m*- and *p*-hydroxybenzaldehydes with ethyl cyanoacetate gave the normally expected products, substituted ethyl *m*- and *p*-hydroxy-*α*-cyanocinnamates (IX—XVII), even with a large excess of the cyanoacetate. The results obtained are listed in Table V.

3, 4-Dihydroxybenzaldehyde reacted with an equivalent ethyl cyanoacetate to form ethyl α-cyano - β - hydroxy -β- (3, 4-dihydroxyphenyl)-propionate (XVIII); on subsequent treatment with acetic anhydride, this yielded ethyl α-cyano-3, 4-diacetyloxycinnamate (XIX). On the other hand, 2-imino-3-ethoxycarbonyl-7-hydroxy -2*H*- chromene (VIb), when refluxed with acetic anhydride, was converted into ethyl 7-acetyloxy-3-coumarincarboxylate (XX).

XXI

Previously, one of the present authors[6] has reported that the condensation between 2-hydroxy-3-isopropyl - 6 - methylbenzaldehyde, *o*-thymotinic aldehyde, gave mainly diethyl β, γ-dicyano-β-(2-hydroxy -3- isopropyl -6- methyl)-glutarate (Ib). The present infrared study shows that the condensation product formulated as Ib has the structure of 2-amino-2-(cyanoethoxycarbonylmethyl) -3-ethoxycarbonyl-5-methyl-8-isopropyl-α-benzopyrane (IIb). The infrared spectrum of Compound IIb exhibited characteristic absorption bands at 3460 and at 3380 cm^{-1} for the primary amino group; at 2245 cm^{-1} for the non-conjugated C≡N; at 1746 cm^{-1} for the saturated ester C=O; at 1645 cm^{-1} for the ester C=O conjugated with the unstauration bond and at 1640 cm^{-1} for an absorption attributable to NH_2 deformation vibration. This compound afforded methyl 5-methyl-8-isopropyl-3-coumarincarboxylate (XXI) in boiling methanol containing concentrated sulfuric acid.

Experimental*

Condensation of Salicylaldehyde and Ethyl Cyanoacetate.—Three grams (0.0246 mol.) of the aldehyde was dissolved in 15 ml. of ethanol containing 5.6 g. (0.0496 mol.) of the ester. To the refluxing solution was added one drop of piperidine. The solution was refluxed for an additional one hour and allowed to stand overnight at room temperature. The crude α-amino-α-(3-coumarinyl)-β-cyano-β-ethoxycarbonylethylene (IV) separated was collected, washed with ethanol and weighed 1.3 g. One recrystallization from ethanol gave slightly yellowish micro crystals melting at 245—246°C (Lit.,[3] 245—246°C). The initial filtrate and washings from crude IV were combined and diluted with water. An oily matter was extracted with ether, and ethreal extract was dried over sodium sulfate. The residual oil, on removal of the ether, was shaken with methanol, and the crude 2-amino-2-(cyanoethoxycarbonylmethyl) - 3 - ethoxycarbonyl - α - benzopyrane (IIa) was recrystallized from ethanol-water in almost colorless plates melting at 137.5—138.5°C, and which weighed 3.3 g. Lit.,[3] m. p. 137°C.

Synthesis of α-Amino-α-(6-bromo-3-coumarinyl)-β-cyano-β-ethoxycarbonylethylene (Va).—The preparation of this compound is typical of the preparation of the substituted β-ethoxycarbonylethylenes and is described in detail.

Two grams (0.01 mol.) of 5-bromo-2-hydroxybenzaldehyde was dissolved in 20 ml. of ethanol containing 2.3 g. (0.02 mol.) of ethyl cyanoacetate and one drop of piperidine. The mixture was warmed on a water-bath for 1 hr., and being allowed to stand overnight. The precipitates were collected, washed with ethanol and recrystallized from *n*-butanol, giving the required compound melting at 272—273°C with decomposition. The melting points and analytical data of the β-ethoxycarbonylethylenes are summarized in Table I.

Synthesis of 2-Imino-3-ethoxycarbonyl-6-chloro-2*H*-chromene (VIa).—The 2*H*-chromenes synthesized in this study are listed in Table III. All of these were prepared from ethyl cyanoacetate and the corresponding aldehyde. The physical properties are also included in Table III.

An example of the preparation of the 2*H*-chromenes is described.

5-Chloro-2-hydroxybenzaldehyde (0.18 g., 0.00115 mol.) and 0.13 g. (0.00115 mol.) of ethyl cyanoacetate were dissolved in 2 ml. of hot ethanol containing one drop of piperidine. The solution was allowed to stand overnight at room temperature. The precipitates were collected, washed with methanol and recrystallized from ethanol in yellowish micro crystals melting at 119—120°C. The resulting VIa weighed 0.1 g.

Synthesis of Ethyl 6-Phenylazo-3-coumarincarboxylate (VIIa).—5-Phenylazo-2-hydroxybenzaldehyde (0.5 g., 0.0022 mol.) and ethyl cyanoacetate (0.25 g., 0.0022 mol.) were mixed in 10 ml. of ethanol containing one drop of piperidine. The mixture was warmed on a water-bath for 1 hr., and being allowed to stand overnight. The crystals separated were collected, washed with ethanol and recrystallized from dioxane-water in lustrous yellowish brown needles melting at 153—154°C, and which weighed 0.2 g.

Found: C, 67.07; H, 4.48; N, 8.77. Calcd. for $C_{18}H_{14}O_4N_2$: C, 67.07; H, 4.38; N, 8.69%.

Synthesis of Ethyl 6-Nitro-3-coumarincarboxylate (VIIb).—To a solution of 0.24 g. of 5-nitro-2-hydroxybenzaldehyde and 0.16 g. of ethyl cyanoacetate in 2 ml. of ethanol was added one drop of piperidine. The solution was allowed to stand overnight at room temperature. The crude VIIb separated as a crystalline

6) H. Yasuda, *Sci. Papers Inst. Phys. Chem Res.* (*Tokyo*), **52**, 83 (1958).

* All melting points are uncorrected.

product was collected, washed with ethanol and recrystallized from *n*-butanol, giving almost colorless lustrous short needles melting at 193—194°C, and which weighed 0.27 g.

Found: C, 54.44; H, 3.49; N, 5.54. Calcd. for $C_{12}H_9O_6N$: C, 54.76; H, 3.45; N, 5.32%.

Synthesis of 8-Methoxy-3-cyanocoumarin (VIIIa).—A solution of 0.5 g. of 2-hydroxy-3-methoxybenzaldehyde and 0.4 g. of ethyl cyanoacetate in 5 ml. of ethanol containing one drop of piperidine was warmed on a water-bath for 20 min. The precipitates, on cooling, was collected, washed with ethanol and weighed 0.4 g. One recrystallization from *n*-butanol gave yellowish short needles melting at 222—223°C.

Found: C, 64.99; H, 3.48; N, 7.05. Calcd. for $C_{11}H_7O_3N$: C, 65.67; H, 3.51; N, 6.96%.

Synthesis of 7-Methoxy-3-cyanocoumarin (VIIIb).—2-Hydroxy-4-methoxybenzaldehyde (0.38 g.) was dissolved in 5 ml. of ethanol containing 0.28 g. of ethyl cyanoacetate and one drop of piperidine. The solution was allowed to stand overnight at room temperature. The solid separated was collected, washed with ethanol and recrystallized from *n*-butanol in slightly yellowish short needles melting at 218—219°C.

Found; C, 65.38; H, 3.72; N, 6.79. Calcd. for $C_{11}H_7O_3N$: C, 65.67; H, 3.51; N, 6.96%.

Synthesis of Ethyl *m*- or *p*-Hydroxy-α-cyanocinnamates (IX—XVII).—The method for the preparation of this series is illustrated by the synthesis of ethyl *m*-hydroxy-α-cyanocinnamate (IX). To a solution of 0.001 mol. of *m*-hydroxybenzaldehyde and 0.001 mol. of ethyl cyanoacetate in 5 ml. of ethanol was added one drop of piperidine. The solution was warmed on a water-bath for a few minutes, and being allowed to stand overnight at room temperature. The solid separated was collected, and recrystallized from ethanol-water. See Table V for the melting point and the analysis.

Condensation of 3, 4-Dihydroxybenzaldehyde and Ethyl Cyanoacetate.—To a solution of 1.0 g. of the aldehyde and 0.81 g. of the ester in 5 ml. of ethanol was added three drops of piperidine. After standing overnight, the solution was diluted with water, and the precipitates were recrystallized from ethanol-water to give yellowish needles melting at 166—167°C, and which weighed 1.5 g. The analytical values were identical with that of ethyl α-cyano-β-hydroxy-β-(3, 4-dihydroxyphenyl)-propionate (XVIII).

Found: C, 57.97; H, 5.08; N, 5.58. Calcd. for $C_{12}H_{13}O_5N$: C, 57.37; H, 5.22; N, 5.58%.

Reaction of XVIII and Acetic Anhydride to Ethyl α-Cyano-3, 4-diacetyloxycinnamate (XIX).—An appropriate amount of XVIII was refluxed with an appropriate amount of the anhydride for two hours, and then acetic acid and the anhydride were recovered under water-pump pressure. The residual solid was recrystallized from ethanol-water in colorless plates melting at 103—104°C. The analytical data were identical with that of XIX.

Found: C, 60.28; H, 4.74; N, 4.39. Calcd. for $C_{16}H_{15}O_6N$: C, 60.50; H, 4.77; N, 4.41%.

Conversion of 2-Imino-3-ethoxycarbonyl-7-hydroxy-2*H*-chromene (VIb) into Ethyl 7-Acetyloxy-3-coumarincarboxylate (XX).—An appropriate amount of VIb was heated to reflux with an appropriate amount of acetic anhydride for 1 hr. The residual solid, after removal of the anhydride, was recrystallized from methanol-water in slightly brownish needles melting at 147—148°C.

Found: C, 60.16; H, 4.46. Calcd. for $C_{14}H_{12}O_6$: C, 60.87; H, 4.38%.

Conversion of 2-Amino-2-(cyano-ethoxycarbonylmethyl)-3-ethoxycarbonyl-5-methyl-8-isopropyl-α-benzopyrane (IIb) into Methyl 5-Methyl-8-isopropyl-3-coumarincarboxylate (XXI).—One gram of IIb was refluxed with 10 ml. of ethanol containing 1 ml. of concentrated sulfuric acid for 1 hr. after which colorless crystals separated, on cooling, were collected, washed with water and recrystallized from methanol-water to give lustrous colorless needles melting at 120—120.5°C.

Found: C, 69.14; H, 6.23. Calcd. for $C_{15}H_{16}O_4$: C, 69.21; H, 6.20%.

The authors are indebted to Professor Taro Hayashi and Professor Tatsuo Takeshima for their advice, encouragement and suggestions during the course of this investigation.

Studies on D-Glucosamine Derivatives. XII.*1 The Synthesis of *N*-Acetyl-3-*O*- and -4-*O*-aminoacyl-D-glucosamines

By Juji YOSHIMURA, Masuo FUNABASHI, Sadao ISHIGE and Tetsuo SATO

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 9, 1965)

As a part of the investigation of the stabilities of the esters between *N*-acetyl-D-glucosamine and various amino acids, *N*-acetyl-3-*O*- and 4-*O*-aminoacyl-D-glucosamines were synthesized. Benzyl *N*-acetyl-4, 6-*O*-benzylidene-α- and -β-D-glucosaminide, and benzyl *N*-acetyl-3-*O*-benzyl-6-*O*-trityl-α- and -β-D-glucosaminide were condensed with *N*-benzyloxycarbonyl-amino acids by the dicyclohexylcarbodiimide method, followed by the step-by-step removal of the protecting groups. The α-Glycosidic benzyl group, however, could not be removed by the catalytic hydrogenolysis in the presence of oxalic acid, probably because of a steric hindrance.

In a previous report[1] of this series, 1, 2-dideoxy-1-glycylamino-2-acetamido-D-glucosamines have been synthesized. Such a *N*-acyl-glycosylamine linkage between sugars and amino acids has already been ascertained in glycoproteins[2] and in the process of the biological nucleotide synthesis[3].

However, the corresponding ester linkage[4] has been scarcely found, probably because of its instability. In order to examine the stabilities of the ester linkage between sugars and amino acids, we have synthesized the simple ester compounds between *N*-acetyl-D-glucosamine and various amino acids, of which the selective synthesis of *N*-acetyl-6-*O*-aminoacyl-D-glucosamines was reported in the previous paper.

In the present paper, the synthesis of 3-*O*- and 4-*O*-aminoacyl derivatives of *N*-acetyl-D-glucosamine will be described.

Results

The Synthesis of *N*-Acetyl-3-*O*-aminoacyl-D-glucosamines.—Kochetkov et al.[5] isolated 3-*O*-(*N*-benzyloxycabonyl*2-glycyl)-D-glucose as a by-product in the synthesis of 6-*O*-(*N*-Z-glycyl)-D-glucose from D-glucose and *N*-Z-glycine, while the homologues were synthesized by Muramatsu[6] by the condensation of 1, 2 ; 5, 6-di-*O*-isopropylidene-D-glucofuranose with *N*-Z-amino acids.

For the purpose of introducing the aminoacyl groups into the C-3 hydroxyl group of *N*-acetyl-D-glucosamine, we prepared benzyl *N*-acetyl-4, 6-*O*-benzylidene-α-[7] and -β-D-glucosaminide (A-I and B-I)*3 as starting materials.

The compound B-I was newly prepared by the benzylidenation of benzyl *N*-acetyl-β-D-glucosaminide, which had been isolated from the corresponding α, β-mixture[8] by the fractional crystallization of its acetate.

First of all, A-I was condensed with an equimolar amount of *N*-Z-amino acids (a: *N*-Z-glycine, b: *N*, *N'*-di-Z-L-lysine) in pyridine by dicyclohexylcarbodiimide (DCC) to give benzyl *N*-acetyl-3-*O*-(*N*-Z-aminoacyl)-4, 6-*O*-benzylidene-α-D-glucosaminides (A-II) in 72—84% yields. In the case of B-I, which is much less soluble than A-I in pyridine, such a condensation procedure as A-I gave the corresponding product in a low yield, accompanied by the ureide. In order to avoid the formation of the ureide,[9] a large quantity of *N*-Z-amino-acids (a, b, c; β-benzyl-*N*-Z-L-aspartate) were preliminary converted to the corresponding acid anhydrides by DCC in dioxane. After the dioxane had been removed, a solution of B-I in pyridine was added to the concentrated residue without isolating the acid anhydrides, and the mixed solution was allowed to stand at room temperature

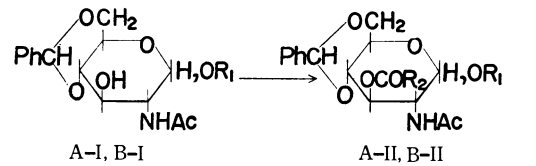
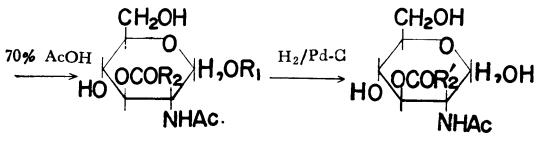
for 24 hours. In this way benzyl *N*-acetyl-3-*O*-(*N*-Z-aminoacyl)-4, 6-*O*-benzylidene-β-D-glucosaminides (B-II) were obtained in 60—70% yields. The infrared spectra of A-II and B-II showed no absorption band of hydroxyl (at ca. 3500 cm^{-1}), but it did show absorption bands of ester carbonyl (at 1730—1750 cm^{-1}) and urethane carbonyl (at 1690—1710 cm^{-1}).

The next step, involving the hydrolysis of the benzylidene group of A-II and B-II with 70% acetic acid, gave benzyl *N*-acetyl-3-*O*-(*N*-Z-aminoacyl)-α- and -β-D-glucosaminides (A-III and B-III) in 60—75% yields.



A-I, B-I A-II, B-II



A-III, B-III IV

R_1 = $-CH_2C_6H_5$
Ph = $-C_6H_5$
Ac = $-COCH_3$
Z = $-COOCH_2C_6H_5$

a) $R_2 = -CH_2NHZ$
b) $R_2 = -CH(CH_2)_4NHZ$ (NHZ)

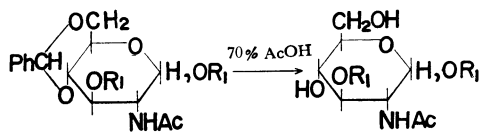
c) $R'_2 = -CHCH_2COOH \cdot 2H_2O$ (NH_2)

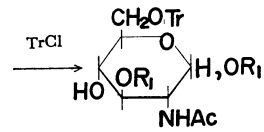
The hydrogenolysis of benzyl and benzyloxycarbonyl groups in A-III and B-III with palladium-charcoal (10%) gave 3-*O*-aminoacyl derivatives (IV) in ca. a 30% yield in the case of B-III, but the α-glycoside benzyl group of A-III could not be eliminated. This fact may be explained in terms of the steric hindrance of the C-2 *cis* acetamide group in the α-configuration, as was found in the case of phenyl 2, 3, 4, 6-tetra-*O*-acetyl-α- and -β-D-glucoside.[10]

The constants of the series of new compounds up to A, B-III and IV are shown in Tables I and II respectively.

The Synthesis of *N*-Acetyl-4-*O*-aminoacyl-D-glucosamines.—As a starting material to prepare 4-*O*-aminoacyl derivatives, benzyl *N*-acetyl-3-*O*-benzyl-6-*O*-trityl-α- and -β-D-glucosaminide (A-VII and B-VII) were synthesized in the following way.



A-V, B-V A-VI, B-VI



A-VII, B-VII

$Tr = -C(C_6H_5)_3$

Benzyl *N*-acetyl-3-*O*-benzyl-4, 6-*O*-benzylidene-α- and -β-D-glucosaminide (A-IV and B-IV) were obtained in 74—80% yields by reacting A-I or B-I with benzylchloride in dimethylformamide in the presence of potassium hydroxide respectively. When the benzylation of B-I was effected in dimethylsulfoxide with sodium hydride, the tribenzylated product (probably the *N*-benzylated derivative) was isolated as a by-product.

For the removal of the benzylidene group, A-V and B-V were then hydrolyzed in 70% acetic acid by refluxing them for an hour; this gave benzyl *N*-acetyl-3-*O*-benzyl-α- and -β-D-glucosaminide (A-VI and B-VI) in 72—85% yields. Finally, A-VII and B-VII were obtained by the triphenylmethylation of A-VI and B-VI in the usual method.

b) $R'_2 = -CH(CH_2)_4NH_2 \cdot (COOH)_2 \cdot 3H_2O$ (NH_2)

The condensation of A-VII and B-VI with an equimolar amount of *N*-Z-amino acids (a and b) was carried out in a small amount of pyridine using DCC to give benzyl *N*-acetyl-3-*O*-benzyl-4-*O*-(*N*-Z-aminoacyl)-6-*O*-trityl-α- and -β-D-glucosaminides (A-VIII and B-VIII).

The partial hydrolysis of A-VIII and B-VIII with 70% acetic acid at 100°C gave benzyl *N*-

acetyl-3-*O*-benzyl-4-*O*-(*N*-Z-aminoacyl)-α- and -β-D-glucosaminides (A-IX and B-IX) in 70—80% yields.

The glycosidic α-benzyl group of A-IX could not be removed by catalytic hydrogenolysis in the presence of oxalic acid, as has been shown in the case of A-III.

The protecting groups of B-VIII could be successfully eliminated, and 4-*O*-aminoacyl derivatives (X) could be isolated as oxalates.

The constants of the *N*-Z-aminoacyl compound of this series and X are shown in Tables III and II respectively.

Experimental

Melting points were uncorrected. Optical rotations were measured at 578 mμ with a Carl-Zeis Polarimeter. Paper chromatography was carried out by the ascending technique on Toyo Roshi No. 50 filter paper, using an upper layer of *n*-buthanol, acetic acid and water (4 : 1 : 5) as a developer, and a 0.1% ninhydrin solution in *n*-butanol as a spray reagent.

The Preparation of Benzyl *N*-Acetyl-β-D-glucosaminide.—Benzyl *N*-acetyl-α, β-D-glucosaminide (50 g.; ca. an equimolar mixture), prepared by the convenient glycosidation method[7] of *N*-acetyl-D-glucosamine, was dissolved in dry pyridine (100 ml.) and acetic anhydride (70 ml.), and then allowed to stand overnight at room temperature. The reaction mixture was then poured into a large amount of ice water. The precipitated crystal was filtered, washed several times with water, and dried in vacuo. The fractional crystallization of the crude product (70 g.) was repeated several times from methanol to give benzyl *N*-acetyl-3, 4, 6-tri-*O*-acetyl-β-D-glucosaminide (20 g.), m. p. 163—164°C (Lit.,[11] m. p. 165—167°C). The corresponding α-

11) R. Kuhn and W. Kirschenlohr, *Ber.*, **86**, 1331 (1953).

anomer (30 g.) was obtained from the mother liquor, m. p. 108°C, $[\alpha]_D^{20}$ +120° (*c* 1.0, methanol).

Found: C, 57.87; H, 6.21; N, 3.32. Calcd. for $C_{21}H_{27}O_9N$(437): C, 57.66; H, 6.22; N, 3.22%.

A more effective separation of the α, β-anomer is attained by a previous separation of the mixture by the decantation of the ether suspension, in which the β-anomer is much lighter than the α-anomer.

The β-acetate was then deacetylated with CH_3ONa to give benzyl *N*-acetyl-β-D-glucosaminide in a 85% yield. M. p. 203—204°C (Lit.,[11] m. p. 205—206°C).

Benzyl *N*-Acetyl-4, 6-*O*-benzyliden-β-D-glucosaminide (B-I).—A mixture of benzyl *N*-acetyl-β-D-glucosaminide (25 g.), freshly fused and powdered $ZnCl_2$ (25 g.), and benzaldehyde (90 ml.) was shaken at 60°C for an hour. The homogeneous reaction mixture was then agitated with petroleum ether.

The resulting crystalline mass was filtered, and washed several times with petroleum ether, with water, and then with a mixture of methanol and petroleum ether.

The dried crude product (36 g.) was recrystallized from methanol (800 ml.) and pyridine (200 ml.); yield, 26 g. m. p. 251—252°C (decomp.).

A small part was recrystallized twice from methanol. M. p. 260—261°C (decomp.) $[\alpha]_{578}^{20}$ −40° (*c* 0.50, pyridine).

Found: C, 65.87; H, 6.48; N, 3.56. Calcd. for $C_{22}H_{25}O_6N$: C, 66.15; H, 6.31; N, 3.51%.

This compound was converted to the corresponding 3-*O*-acetate by the usual acetylation method. M. p. 258—259°C (decomp.), $[\alpha]_{578}^{20}$ −56° (*c* 0.30, pyridine).

Found: C, 65.24; H, 5.98; N, 3.41. Calcd. for $C_{24}H_{27}O_7N$ (441): C, 65.29; H, 6.16; N, 3.17%.

Benzyl *N*-Acetyl-3-*O*-(*N*-benzyloxycarbonyl-aminoacyl)-4, 6-*O*-benzylidene-α-D-glucosaminides (A-II).—0.015 mol. of *N*-Z-amino acids (a; *N*-Z-glycine, b; *N*, *N'*-di-Z-L-lysine) and DCC (0.018 mol.) were added to a solution of benzyl *N*-acetyl-4, 6-*O*-benzylidene-α-D-glucosaminide (0.012 mol.) in pyridine (50 ml.), and the mixture was allowed to stand in a refrigerator overnight. The precipitate of dicyclohexylurea was filtered off, and the filtrate was concentrated under reduced pressure. The gelatinous residue was washed several times with ether and then dried in vacuo.

The crude product was recrystallized from ethanol and a small amount of pyridine; yield, 72—79%.

Benzyl *N*-Acetyl-3-*O*-(*N*-benzyloxycarbonyl-aminoacyl)-4, 6-*O*-benzylidene-β-D-glucosaminides (B-II).—0.03 mol. of *N*-Z-amino acids (a, b, c; β-benzyl *N*-Z-L-aspartate) and DCC (0.036 mol.) were dissolved in dry dioxane (40 ml.) and stirred at room temperature for 2 hr. The precipitate was filtered and washed twice with dry dioxane. The combined dioxane was evaporated in vacuo, a cold pyridine solution (160 ml.) of B-I was then added to the resulting residue, and the mixture was kept at room temperature overnight.

After the pyridine had been completely removed, the gelatinous residue was washed several times with ether or ethyl acetate. The semi-crystalline product was recrystallized from ethanol and pyridine (1 : 1); yield, 60—75%.

Benzyl *N*-Acetyl-3-*O*-(*N*-benzyloxycarbonyl-aminoacyl)-α- and -β-D-glucosaminides (A-III and B-III).—A-II or B-II (0.005 mol.) was suspended in 70% acetic acid (100 ml.) and heated on a boiling-water bath for 30 min. with occasional stirring. After the solution had been concentrated in vacuo, the gelatinous residue was then washed once with ether and recrystallized from ethanol, or from ethanol and ether; yield, 68—78%.

The Hydrogenolysis of Benzyl *N*-Acetyl-3-*O*-(*N*-benzyloxycarbonyl-glycyl)-α-D-glucosaminide (A-IIIa).—Three grams of A-IIIa and 0.45 g. of oxalic acid were dissolved in 50 ml. of methanol, and then 2 g. of Pd-C (5%) was added. The mixture was shaken at room temperature with hydrogen for about 5 hr. After the catalyst had been removed, the filtrate was concentrated in vacuo, and ethanol was added. The precipitate was filtered, washed with ethanol and dried in vacuo. The white amorphous powder (1.2 g.), which had a molecular formula consistent with $C_{17}H_{24}O_7N_2 \cdot 1/2(COOH)_2 \cdot 2H_2O$, did not reduce Fehling's solution.

Found: C, 48.24; H, 6.29; N, 5.63. Calcd.: C, 48.12; H, 6.50; N, 6.23%.

***N*-Acetyl-3-*O*-aminoacyl-D-glucosamines (IV).**—0.002 mol. of B-III and oxalic acid (0.003—0.004 mol.) were dissolved in 80% methanol (15—20 ml.), and 10% Pd-C (1.0—1.5 g.) was added. The mixture was then shaken at room temperature with hydrogen until the absorption had substantially ceased (20—48 hr.).

After the catalyst had been removed, ether was added to the filtrate and centrifugation was carried out to collect the precipitate. For the purification, the precipitated oil or solid was dissolved in several drops of water, reprecipitated with ethanol, centrifugated, and dried in vacuo. The amorphous hygroscopic powder, which reduced Fehling's solution and which gave a single ninhydrin positive spot in paper chromatography and paper electrophoresis, was obtained in ca. a 30% yield.

Benzyl *N*-Acetyl-3-*O*-benzyl-4, 6-*O*-benzylidene-α- and -β-D-glucosaminide (A-V and B-V).—(a) Into a mixture of 5 g. of A-I or B-I in dimethylformamide (100—150 ml.) and potassium hydroxide (3.5 g.), benzyl chloride (7.8 g.) was added drop-by-drop over a 15—20 min. period with vigorous stirring at 70—75°C. The reaction conditions were then maintained for a further 30 min. In the case of the compound A-I, the reaction solution was then poured into a large amount of ice water. The precipitate was filtered, washed several times with water and methanol, and dried in vacuo. The crude product (5.1 g.) was recrystallized from hot pyridine-water (100 ml.+50 ml.). Yield, 5 g. (80%).

In the case of B-I, the reaction solution was allowed to stand at room temperature. The crystalline product was filtered, washed several times with methanol and recrystallized from pyridine (70 ml.) and DMF (20 ml.); yield, 4.5 g. (74%).

A-V: m. p. 264—265°C (decomp.), $[\alpha]_{578}^{13}$ +85° (*c* 0.50, pyridine).

Found: C, 70.79; H, 6.79; N, 3.11%.

B-V: m. p. 266—267°C (decomp.), $[\alpha]_{578}^{17}$ −75° (*c* 0.20, dimethylformamide).

Found: C, 71.62; H, 6.31; N, 2.97. Calcd. for $C_{29}H_{31}O_6N$ (399): C, 71.74; H, 6.38; N, 2.86%.

(b) Compound B-I (10 g.) was dissolved in dimethylsulfoxide (150 ml.) at 60°C and NaH (2.5 g.) was gradually added. Into this opaque solution, benzylchloride (16 g.) was added drop-by-drop over a 10 min. period with stirring and with keeping the

temperature at 70—80°C. The reaction solution was then poured into a large amount of ice water, and the precipitate was filtered, washed several times with water, and then with methanol.

The crude product was recrystallized from pyridine (20 ml.) and DMF (40 ml.); yield, 7.0 g. (57%).

From methanol washings, a tribenzylated product (1 g.) which showed no infrared absorption band (1550 cm^{-1}) of the secondary amido, was obtained. M. p. 116—118°C, $[\alpha]_{578}^{15}$ −29° (*c* 0.56, pyridine).

Found: C, 74.81; H, 6.21; N, 2.51. Calcd. for $C_{36}H_{37}O_6N$ (579): C, 74.59; H, 6.43; N, 2.42%.

Benzyl *N*-Acetyl-3-*O*-benzyl-α- and -β-D-glucosaminide (A-VI and B-VI).—A-V or B-V (14 g.) was suspended in 400—500 ml. of 70% acetic acid and refluxed for an hour. The reaction solution was then concentrated under reduced pressure to a crystalline residue. The product was washed with ether and recrystallized from ethanol; yield, 72—85%.

A-VI: m. p. 178—179°C, $[\alpha]_{578}^{13}$ +165° (*c* 0.51, methanol).

Found: C, 65.69; H, 7.06; N, 3.71%.

B-VI: m. p. 169—170°C, $[\alpha]_{578}^{15}$ −20° (*c* 0.50, ethanol).

Found: C, 65.39; H, 6.81; N, 3.46. Calcd. for $C_{22}H_{27}O_6N$: C, 65.82; H, 6.78; N, 3.49%.

Benzyl *N*-Acetyl-3-*O*-benzyl-6-*O*-trityl-α- and -β-D-glucosaminide (A-VII and B-VII).—A-VI or B-VI (4 g.) and tritylchloride (3.3 g.) were dissolved in pyridine (30 ml.) and heated on a boiling-water bath for 2 hr. The reaction solution was then poured into ice water, and the gummy precipitate was extracted with methylene chloride, washed with water, and dried over sodium sulfate.

After the methylene chloride had been removed, the resulting syrup was crystallized from ethanol-petroleum ether. Yield, 70—72%.

A-VII: m. p. 169°C, $[\alpha]_{578}^{13}$ +85° (*c* 0.50, methanol).

Found: C, 76.38; H, 6.52; N, 2.39%.

B-VII: m. p. 143—145°C, $[\alpha]_{578}^{18}$ −19° (*c* 0.27, methanol).

Found: C, 76.16; H, 6.53; N, 2.14. Calcd. for $C_{41}H_{41}O_6N$ (643): C, 76.49; H, 6.42; N, 2.18%.

Benzyl *N*-Acetyl-3-*O*-benzyl-4-*O*-(*N*-benzyloxycarbonyl-aminoacyl)-6-*O*-trityl-α- and -β-D-glucosaminides. (A-VIII and B-VIII).—A-VII or B-VII (0.003 mol.), *N*-Z-amino acids (a or b, 0.003 mol.) and DCC (0.0036 mol.) were dissolved in dry pyridine (10 ml.) and then allowed to stand overnight in a refrigerator. The precipitate was filtered and washed with toluene. The filtrate and washings were concentrated in vacuo to a syrup. The product was dissolved in a small amount of ethanol, and treated with active carbon, and an equal amount of ether was added. Finally petroleum ether was added until a turbidity had appeared. Yield, 70—73%.

Benzyl *N*-Acetyl-3-*O*-benzyl-4-*O*-(*N*-benzyloxycarbonyl-aminoacyl)-α- and -β-D-glucosaminides (A-IX and B-IX).—A-VIII or B-VIII (0.005 mol.) was suspended in 70% acetic acid (30—50 ml.) and heated on a boiling-water bath while being stirred until it had dissolved completely. The reaction solution was then cooled with ice water to precipitate triphenyl carbinol, this was filtered off, and the filtate was concentrated in vacuo. The gelatinous residue was recrystallized from ethanol or ethanol and ether. Yield, 70—80%.

***N*-Acetyl-4-*O*-aminoacyl-D-glucosamines (X).**—B-IX (0.0012 mol.) and oxalic acid (0.0018—0.0036 mol.) were dissolved in 80% methanol (20 ml.), and 10% Pd-C (1.0—1.5 g.) was added. The reaction mixture was then shaken at room temperature with hydrogen until absorption had substantially ceased (20—24 hr.). After the catalyst had then been removed, a large amount of ether was added to the filtrate and centrifugation was carried out to collect the precipitate. The supernatant was removed, and the precipitate was dissolved in several drops of water, reprecipitated with ethanol, and centrifugated. The ethanol was decanted, and the resulting residue was dried in vacuo. The amorphous hygroscopic powder, which reduced Fehling's solution and which gave single ninhydrin-positive spot in paper chromatography and paper electrophoresis, was obtained. Yield, 39% (Xa), 51% (Xb).

The authors wish to thank the members of Laboratory of Organic Analysis for their elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1765—1767 (1966)

The Reaction of 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline

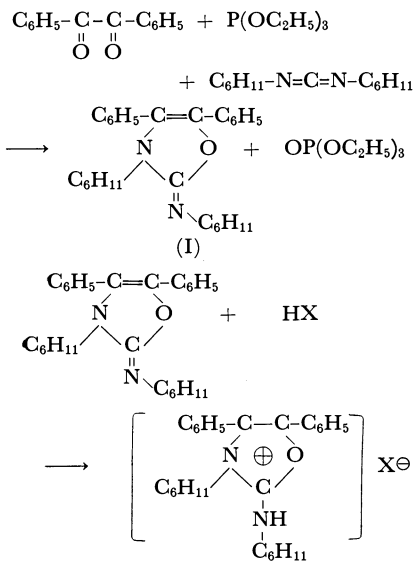
By Takanobu KUMAMOTO, Takenori NAGAOKA and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

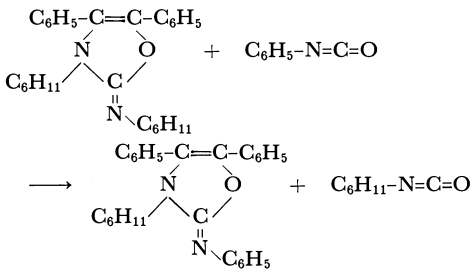
(Received December 9, 1965)

The reaction of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline with isocyanate or isothiocyanate was studied. When the oxazoline was treated with isocyanate, an exchange reaction took place, thus forming new 2-imino-oxazoline and cyclohexyl isocyanate. Similarly, the reaction of the oxazoline with carbon disulfide resulted in the formation of 3-cyclohexyl-4, 5-diphenyl-4-oxazoline-2-thione and cyclohexyl isothiocyanate. Further, cyclohexyl isothiocyanate was obtained by the reaction of dicyclohexylcarbodiimide or cyclohexyl isocyanate with carbon disulfide.

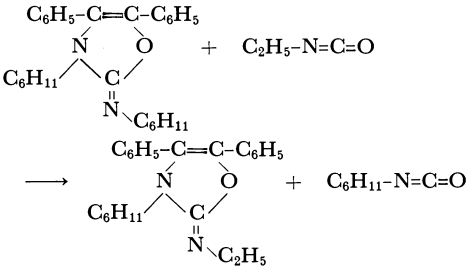
It has recently been found[1] that 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline was obtained in a good yield, along with triethyl phosphate, when a toluene solution of benzil, triethyl phosphite and dicyclohexylcarbodiimide was refluxed in the presence of copper powder. Further, it has been shown that the oxazoline gave the stable salts with protonic acids:



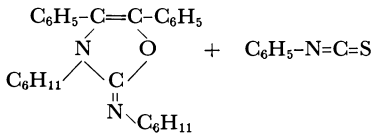
In the present study, it was found that the reactions of the oxazoline with isocyanate, isothiocyanate and carbon disulfide resulted in the formation of new oxazolines and oxazoline-2-thione. When a mixture of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline and phenyl isocyanate was stirred in petroleum ether at room temperature for 3 hr., 2-phenylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline and cyclohexyl isocyanate were obtained in 72% and 69% yields respectively. These results show that the *exo*-imino group of the oxazoline is replaced by the phenylimino group of phenyl isocyanate:



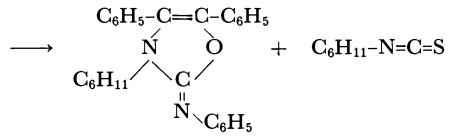
The same exchange reaction was expected to occur in the case of ethyl isocyanate, which is considered to have a more enhanced reactivity than the cyclohexyl isocyanate produced. Indeed, when oxazoline (I) and ethyl isocyanate were heated at 120°C for 4 hr. in a sealed tube, 2-ethylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline was obtained in a 24% yield:



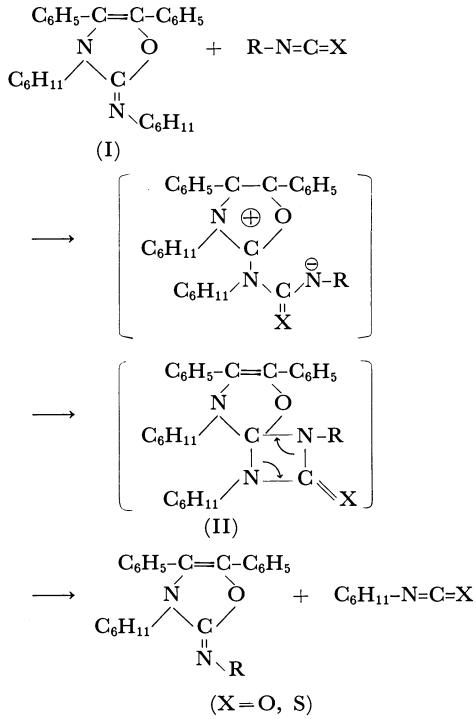
Further, when a solution of oxazoline (I) and phenyl isothiocyanate was stirred in petroleum ether at room temperature for 4 hr., 2-phenylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline (80% yield) and cyclohexyl isothiocyanate (92% yield) were obtained:



1) T. Mukaiyama, T. Kumamoto and T. Nagaoka, Part XVIII: Annual Meeting of The Chemical Society of Japan, Preliminary Issue (1965), p. 248.



The above-mentioned exchange reactions are considered to proceed through the initial formation of an unstable four-membered intermediate (II) which is formed by the electrophilic attack of isocyanate or isothiocyanate on the *exo*-imino group of the oxazoline (I). By the transfer of electrons, II in turn changes into new 2-imino-oxazoline and cyclohexyl isocyanate or isothiocyanate:

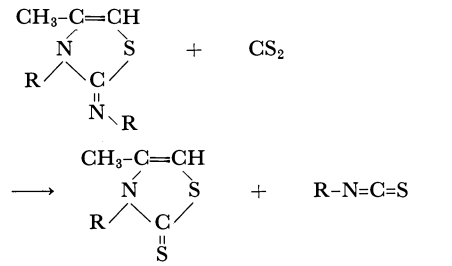


(I)

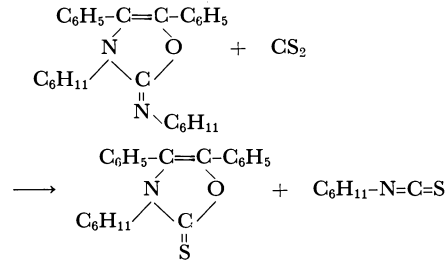
(II)

(X=O, S)

Concerning this type of exchange reaction, Bartoszewski and Jerzmanowska have already reported that[2] thiazoline-2-thione is produced by the reaction of 2-imino-thiazoline, the sulfur isomer of the oxazoline, with carbon disulfide:

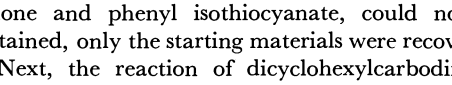


It was also established by the present experiment that the treatment of the oxazoline (I) with excess carbon disulfide at 150°C resulted in the formation of 3-cyclohexyl-4, 5-diphenyl-4-oxazoline-2-thione (90% yield) and cyclohexyl isothiocyanate (83% yield):



However, when 2-phenylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline and carbon disulfide were heated under the same conditions, the expected products, 3-cyclohexyl-4, 5-diphenyl-4-oxazoline-2-thione and phenyl isothiocyanate, could not be obtained, only the starting materials were recovered.

Next, the reaction of dicyclohexylcarbodiimide and carbon disulfide was attempted in expectation that cyclohexyl isothiocyanate would be formed in a way similar to that described in the above exchange reaction. When they were heated at 150°C for 10 hr., cyclohexyl isothiocyanate was obtained in a 25% yield, and 55% of the dicyclohexylcarbodiimide was recovered:



Further, it was established that cyclohexyl isothiocyanate was obtained in a 41% yield when a mixture of cyclohexyl isocyanate and carbon disulfide was heated under the same conditions in the presence of triethylamine:

Experimental

The Reaction of 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline with Phenyl Isocyanate.—A solution of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline (2.00 g., 0.005 mol.) and phenyl isocyanate (0.60 g., 0.005 mol.) in petroleum ether was stirred for 3 hr. at room temperature. After the petroleum ether, had been removed, a white precipitate was obtained. It was recrystallized from ethyl acetate to give 2-phenylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline, 1.98 g. (72%); m. p. 182—183°C.

Found: C, 81.82; H, 6.65; N, 7.34. Calcd. for $C_{27}H_{26}N_2O$: C, 82.20; H, 6.64; N, 7.10%.

The residue was distilled in vacuo, giving cyclohexyl isocyanate, 0.42 g. (63%); b. p. 62—67°C/20 mmHg.

The Reaction of 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline with Ethyl Isocyantate.—A mixture of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline (1.00 g., 0.0025 mol.) and an excess of ethyl isocyanate (0.71 g., 0.01 mol.) was heated at

2) J. Bartoszewski and Z. Jerzmanowska, *Roczniki. Chem.*, **37**, 11 (1963); *Chem. Abstr.*, **59**, 7510 (1963).

120°C for 4 hr. in a sealed tube. The removal of the excess ethyl isocyanate gave a white precipitate. It was then recrystallized from ethyl acetate, giving 2-ethylimino-3-cyclohexyl- 4, 5 - diphenyl - 4 - oxazoline, 0.21 g. (24%); m. p. 112—114°C.

Found: C, 79.42; H, 7.82; N, 8.30. Calcd. for $C_{23}H_{26}N_2O$: C, 79.73; H, 7.56; N, 8.09%.

The Reaction of 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline with Phenyl Isothiocyanate.—A solution of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline (2.00 g., 0.005 mol.) and phenyl isothiocyanate (0.68 g., 0.005 mol.) in petroleum ether was stirred at room temperature for 4 hr. After the solvent had been removed, a white crystalline solid was obtained. This was then filtered and recrystallized from ethyl acetate, giving 2-phenylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline, 1.58 g. (80%); m. p. 183—184°C.

The fractional distillation of the residue gave cyclohexyl isothiocyanate, 0.51 g. (72%); b. p. 102—103°C/10 mmHg.

The Reaction of 2-Cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline with Carbon Disulfide.—A mixture of 2-cyclohexylimino-3-cyclohexyl-4, 5-diphenyl-4-oxazoline (4.00 g., 0.01 mol.) and an excess of carbon disufide (4 ml.) was heated at 150°C for 5 hr. in a sealed tube. The removal of the excess carbon disulfide gave a white precipitate. This was then recrystallized from ethanol, giving 3-cyclohexyl-4, 5-diphenyl-4-oxazoline-2-thione, 3.03 g. (90%); m. p. 201°C.

Found: C, 75.17; H, 5.96; N, 4.09. Calcd. for $C_{21}H_{22}NOS$: C, 75.00; H, 6.53; N, 4.19%.

The distillation of the residue under reduced pressure gave cyclohexyl isothiocyanate, 1.17 g. (83%); b. p. 101—104°C/10 mmHg.

The Reaction of Dicyclohexylcarbodiimide and Carbon Disulfide.—A mixture of dicyclohexylcarbodiimide (2.06 g., 0.01 mol.) and carbon disulfide (5 ml.) was heated at 150°C for 10 hr. in a sealed tube. After the excess carbon disulfide had been removed, cyclohexyl isothiocyanate, 0.75 g. (27%); b. p. 100—105°C/10 mmHg, was obtained, and 1.14 g. of dicyclohexylcarbodiimide (55%), b. p. 149—151°C/10 mmHg, was reccovered.

When dicyclohexylcarbodiimide (2.06 g., 0.01 mol.) and carbon disulfide (5 ml.) were heated in the presence of triethylamine (0.1 ml.) in a sealed tube at 150°C for 5 hr., cyclohexyl isothiocyanate, 0.36 g. (13%); b. p. 108—110°C/12 mmHg was obtained, and dicyclohexylcarbodiimide, 1.24 g. (60%); b. p. 152—154°C/12 mmHg, was recovered.

When a catalytic amount of boron trifluoride etherate was used in the above experiment, cyclohexyl isothiocyanate 0.20 g. (7%); b. p. 115—117°C/13 mmHg, was obtained, and 1.35 g. of dicyclohexylcarbodiimide (66%), b. p. 152—155°C/12 mmHg, was recovered.

The Reaction of Cyclohexyl Isocyanate with Carbon Disulfide in the Presence of Triethylamine.—A mixture of cyclohexyl isocyanate (2.50 g., 0.01 mol.), carbon disulfide (2 ml.) and triethylamine (2 ml.) was heated at 150°C for 5 hr. in a sealed tube. Distillation in vacuo gave cyclohexyl isothiocyanate, 1.17 g. (42%); b. p. 95—97°C/10 mmHg.

Rearrangement. IV.[1] Pyrolysis and Acetolysis of Some Sulfonic Esters

By Ryotaro KOTANI

Research Laboratory, Kureha Spinning Company, Ltd., Takatsuki, Osaka

(Received December 14, 1965)

The pyrolysis of cyclohexanemethyl methanesulfonate and 1-methylcyclohexanemethyl *p*-toluenesulfonate has been investigated, yielding predominantly rearranged cycloalkenes, with lesser amounts of cycloalkanes. The experiments support the suggestion that the pyrolysis may proceed, at least in part, through a free radical process. The methanesulfonic ester, on acetolysis in a 50% aqueous acetic acid solution, gave rearranged-unrearranged cycloalkenes and alcohols, and an unrearranged acetate, whereas the *p*-toluenesulfonic ester gave exclusively rearranged cycloalkenes, alcohols and acetates.

The availability of a *cis*-β-hydrogen in cyclohexanemethyl derivatives of acids or amines suggests that the pyrolysis of these compounds could involve a cis elimination,[2] giving predominantly methylenecyclohexane. Indeed, the pyrolysis of cyclohexanemethyl acetate[3] and *N*, *N*-dimethylcyclohexanemethylamine oxide[3,4] gave exclusively methylenecyclohexane; in contrast, however, cyclohexanemethyl borate[5] underwent pyrolytic change, chiefly into rearranged cycloalkenes, the formation of which was interpreted in terms of a carbonium ion-type rearrangement. Previous work in this

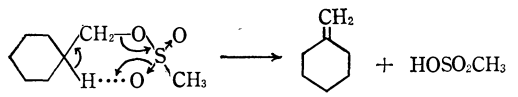
series[6] has shown that the pyrolysis of cyclohexanemethyl *p*-toluenesulfonate (I) at 200°C under reduced pressure gave predominantly rearranged cycloalkenes. The saturated hydrocarbon methylcyclohexane was also formed in a fairly high yield, whereas it was not mentioned as a pyrolytic product of the above acetate, amine oxide or borate. The nature of the pyrolysis of the sulfonate, however, remained to be determined, and such is the purpose of the present study.

Cyclohexanemethyl methanesulfonate (II) was pyrolyzed in the manner described earlier for I. No solvent was used. The crude product was analyzed by gas chromatography. Each component was separated by preparative-scale gas chromatography and identified by comparing its relative retention time and NMR spectrum with those of an authentic sample. The products were methylcyclohexane, 1-methylcyclohexene, 3-methylcyclohexene, methylenecyclohexane, cycloheptene, and cyclohexene. Except for the absence of toluene[7] the product composition was essentially the same as that obtained from I.

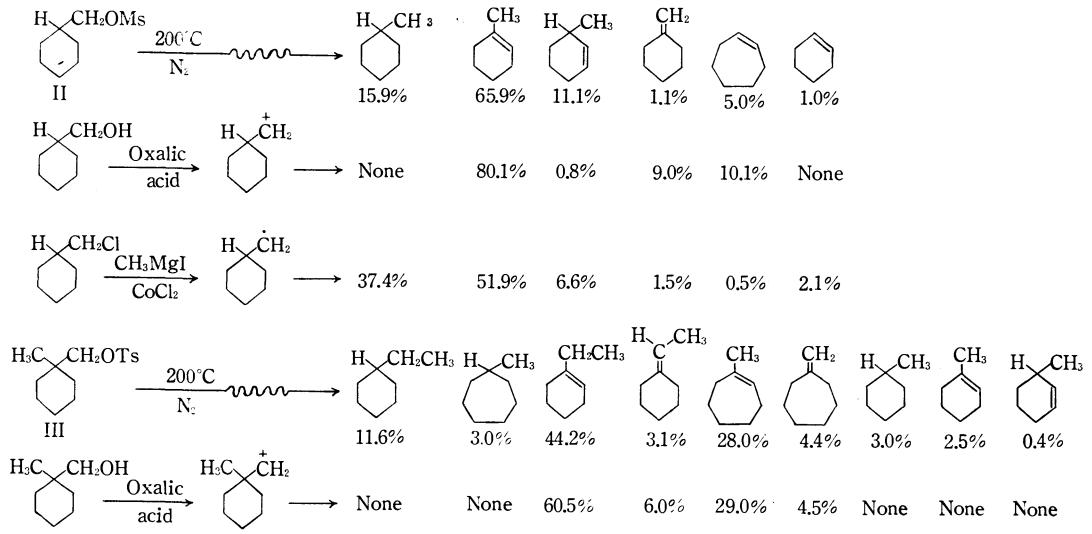


IV

It would not be unreasonable to expect that II might decompose predominantly, with the elimination of a *cis*-β-hydrogen through a quasi, six-membered ring (IV) as a transition state,[8] to give methylenecyclohexane, as has been observed in the runs with the acetate and amine oxide. That it does not do so is, however, evident from a consideration of the following facts: (1) the relative yield of methylenecyclohexane was only 1.1%; (2) rearranged cycloalkenes predominated (82.0%), and (3) a control experiment showed that the isomerization of exocyclic to endocyclic double bonds scarcely occurred under the experimental conditions employed.

1-Methylcyclohexanemethyl *p*-toluenesulfonate (III) was selected for study because it has no β-hydrogen for any possible participation in a cis elimination mechanism. Since III is a neoalkyl type of ester, it was expected that its pyrolysis would involve a complicated rearrangement of the carbon skeleton. Indeed, this was found. The product was separated into six fractions by preparative-scale gas chromatography; each fraction was characterized as has been described above under II. The products were methylcyclohexane, ethylcyclohexane, methylcycloheptane, 1-ethylcyclohexene, ethylidenecyclohexane, 1-methylcycloheptene, methylenecycloheptane, 1-methylcyclohexene, 3-methylcyclohexene, and an unidentified saturated compound (1.7%).[9]

The dehydration of cyclohexanemethanol and 1-methylcyclohexanemethanol was carried out at 150°C in the presence of oxalic acid to obtain an indication of the product ratios in a simple carbonium ion reaction. The dehydration of cyclohexanemethanol[10] gave 1-methylcyclohexene, 3-



6) R. Kotani and S. Satoh, ibid., **30**, 3245 (1965).

7) The nonformation of toluene with II, but its formation with III, support the previous conclusion[6] that it arose from the *p*-toluenesulfonate group.

8) C. D. Hurd and F. H. Blunk [*J. Am. Chem. Soc.*, **60**, 2419 (1938)] first proposed a cyclic, concerted mechanism for stereospecific cis elimination.

9) A small amount of toluene was also formed. It obviously arose from the *p*-toluenesulfonate group, as has been discussed elsewhere.[6]

10) Chapman and Borden[5] reported that the dehydration of cyclohexanemethanol at 135°C in the presence of oxalic acid gave 1-methylcyclohexene (82.2%), methylenecyclohexane (10.2%), and cycloheptene (7.6%).

methylcyclohexene, methylenecyclohexane and cycloheptene, while that of 1-methylcyclohexanemethanol gave 1-ethylcyclohexene, ethylidenecyclohexane, 1-methylcycloheptene and methylenecycloheptane. No saturated hydrocarbon was formed from either alcohol; its nonformation was in contrast to its formation in the pyrolysis of the sulfonic esters.

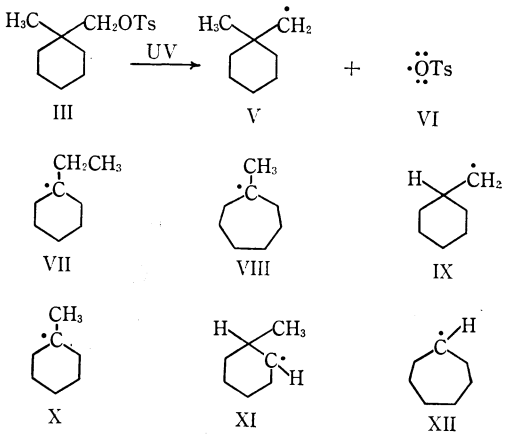
A carbonium ion mechanism would account readily for the formation of cycloalkenes; it may, indeed, account for many of these products. It is questionable, however, if a carbonium ion intermediate participates in the formation of the observed cycloalkanes (16—20% yields), since this would require the unreasonable assumption of the abstraction of hydride ions from some other part of the reacting system.[6] The latter conclusion is supported experimentally by the absence of acetylenes or dienes in the products and by the nonformation of the cycloalkanes during the dehydration of the alcohols with oxalic acid.

The cycloalkanes could be explained readily by way of a radical mechanism; this idea was next explored. Some pyrolytic elimination reactions suggestive of or proceeding through a radical-chain process have been reported,[8,11] namely, the pyrolysis of carboxylic esters with no β-hydrogen and certain sorts of xanthates and sulfoxides.

The reaction of cyclohexanemethyl chloride with methylmagnesium iodide in the presence of cobalt(II) chloride was carried out in order to obtain an indication of the product ratios in a simple free radical process.[12] This reaction gave methylcyclohexane, 1-methylcyclohexene, 3-methylcyclohexene, methylenecyclohexane, cycloheptene, and cyclohexene. This composition was virtually the same as those obtained from I and II.

In an attempt to learn if free radicals participated in the present reactions, I, II and III were heated in the presence of a free radical inhibitor, and then in that of a free radical initiator. The addition of *p*-benzoquinone to I or II caused a change in the ratio of cycloalkane to cycloalkene (approximately 1 : 6.8 and 1 : 8.5 compared to 1 : 3.7 and 1 : 5.3, respectively), and also a decrease in the yield of the product (it was reduced by approximately 30% in both instances). The addition of *p*-benzoquinone to III exerted no appreciable influence on the product composition, but caused a decrease in its yield (approximately a 40% decrease). The decrease in yield and the change in product composition suggest that the free radicals formed would partially be trapped by the quinone. I, II or III, when heated with benzoyl peroxide at 100—105°C for a few minutes, yielded small amounts of cycloalkenes and cycloalkanes, whereas heating the sulfonic ester alone under the same conditions gave no product. No free radical chain reaction, however, was initiated by the addition of benzoyl peroxide.

III was selected for electron spin resonance (ESR) study because the nonavailability of a β-hydrogen would make its ESR spectrum simple. III was irradiated with ultraviolet rays for 1 hour at room temperature, and then it was cooled by liquid nitrogen. The ESR spectrum of its primary product showed a triplet with a relative intensity ratio of about 1 : 2 : 1. The spectrum suggests a free radical whose unpaired electron interacts equally with two protons; it was identified as the free radical V. The supperposed spectrum appearing in the central peak of V may be due to the free radical VI. When the irradiated III was taken out of the liquid nitrogen and kept at room temperature for a few minutes, the triplet spectrum changed into a poorly-resolved complex spectrum consisting of 15 hyperfine lines. The ESR spectrum of the free radical VII may consist of 7 hyperfine lines, and that of the free radical VIII, of 8 hyperfine lines. The observed change in the ESR



spectrum suggests the rearrangement of the less stable primary free radical, V, to the more stable tertiary free radicals, VII and VIII. The above ESR study also suggests indirectly, if not directly, the fate of the primary product of the pyrolysis of III.

The experimental data described above support the suggestion that the pyrolysis of I, II and III proceeds, at least in part, through a free radical process. I and II, on pyrolysis, would give a presumably less stable primary free radical (IX), which would predominantly rearrange to a presumably more stable tertiary free radical (X) by a 1, 2-hydrogen shift. Part of IX would give

12) M. S. Kharasch and W. H. Urry [*J. Org. Chem.*, **13**, 101 (1948)] investigated the reaction of alkylmagnesium halides with alkyl halides in the presence of cobalt(II) chloride.

methylenecyclohexane by the loss of a hydrogen. X would lose a hydrogen, thus yielding 1-methylcyclohexene and methylenecyclohexane, the former predominating. Part of X would subsequently rearrange to a presumably less stable secondary free radical (XI) through a 1, 2-hydrogen shift, which by the loss of hydrogen would yield 1-methylcyclohexene and 3-methylcyclohexene. The abstraction of hydrogen by IX, X or XI would give the saturated hydrocarbon methylcyclohexane. Another secondary free radical (XII) would also come from IX, but by ring enlargement rather than by hydrogen shift, and it would lead to cycloheptene. The primary product of III on pyrolysis would be the presumably less stable primary free radical V, which would subsequently rearrange to the presumably more stable tertiary free radicals, VII and VIII; this would be followed by the loss of hydrogen atoms, leading to the formation of the corresponding unsaturated hydrocarbons. The abstraction of hydrogen atoms by VII and VIII would yield the corresponding saturated hydrocarbons.

The acetolysis of II, III and 1-methylcyclohexanemethyl methanesulfonate (XIII) was carried out in a 50% aqueous acetic acid solution containing catalytic amounts of sodium acetate at reflux temperatures. From II there was formed 1-methylcyclohexene (27.3%), 3-methylcyclohexene (0.5%), methylenecyclohexane (0.5%), cycloheptene (1.5%), 1-methylcyclohexanol (15%), cyclohexanemethanol (7.0%), cycloheptanol (3.6 %), cyclohexanemethyl acetate (44.2%), and 1-methylcyclohexyl acetate (a trace). Bly and Dryden[13] have reported that II, when acetolyzed in the presence of acetic anhydride and an excess of sodium acetate, gave exclusively the unrearranged cyclohexanemethyl acetate, free from any cycloalkenes, alcohols or rearranged acetates. In contrast to this, the addition of water to the solvolysis system of II caused the formation of rearranged-unrearranged cycloalkenes and alcohols in about 30 and 26% yields. The formation of alcohols may be expected from the fact that water is much more nucleophilic than acetic acid.[14] The rearranged alcohols may be formed through rearrangement of the unstable primary carbonium ion initially formed to the more stable tertiary or secondary carbonium ions. The formation of the rearranged alcohols from the corresponding cycloalkenes and water in the presence of an acid may not be negligible.[15] The predominance of 1-methylcyclohexene among the cycloalkenes formed may be due to the relative stabilities of carbonium ions involved and to the acid-catalyzed exocyclic-endocyclic olefin isomerization. The experimental conditions used are quite favorable to such an isomerization.[15] No explanation is, however, apparent to account for cycloalkene formation in the presence of water, but its failure to be formed in the absence of water. It seems unlikely that the unrearranged acetate (44%) arose predominantly from the cyclohexanemethyl carbonium ion, because the unstable primary carbonium ions would mainly rearrange to the more stable tertiary or secondary carbonium ions, as evidenced by the formation of the rearranged alcohols (rearranged: unrearranged=2.7 : 1). The absence of rearranged acetate is in keeping with this suggestion. In view of these facts, the most probable conclusion is that two processes are competitively operative in the acetolysis of II under the conditions employed: (1) the S_N1 reaction, followed by rearrangement and elimination, and (2) the S_N2 displacement of the methanesulfonate group by solvents.

The products from III and XIII had essentially the same product composition; the products were 1-ethylcyclohexene (42.2 and 44.6%), ethylidenecyclohexane (1.3 and 0.6%), 1-methylcycloheptene (38.9 and 40.1%), methylenecycloheptane (1.3 and 1.4%), 1-ethylcyclohexanol (8.5 and 6.7%), 1-methylcycloheptanol (7.8 and 6.6%), and trace amounts of acetates of the above alcohols. Unrearranged alcohol or its acetate was not found in the products within the limits of detectability by gas chromatography under the conditions used. The addition of acetic anhydride and an excess of sodium acetate to III and XIII eliminated the formation of alcohols and acetates, but it gave exclusively rearranged cycloalkenes; the products were 1-ethylcyclohexene (52.5 and 50.0%), ethylidenecyclohexane (1.0 and 1.5%), 1-methylcycloheptene (45.5 and 47.5%), and methylenecycloheptane (1.0 and 1.0%).[16] The exclusive formation of the rearranged compounds in the acetolysis of III and XIII, neoalkyl-type esters, was in accord with that observed in the Demjanov rearrangement of 1-methylcyclohexanemethylamine, a neoalkyl-type amine.[17] The lack of unrearranged product may be explained in a manner similar to that presented in connection with the above amine.

Experimental[18]

Gas Chromatographic Analysis of Products.— The analysis was carried out using 500×0.35 cm. (A, B and D) and 1100×0.35 cm. (C) columns packed with 80—100 mesh Celite which was coated with the appropriate stationary phase. The stationary phases

16) Bly and Dryden[13] have reported that XIII, when acetolyzed under the same conditions, gave ethylcyclohexane and methylcycloheptane (after the hydrogenation of the product cycloalkenes).
17) R. Kotani, *J. Org. Chem.*, **30**, 350 (1965).

employed were: (A) 30% (by weight) of a 40% solution of silver nitrate in tetraethylene glycol, (B) 25% (by weight) of octyl phthalate, (C) 30% (by weight) of polyethylene glycol, and (D) 30% (by weight) of Apiezon grease L. Columns A, B and C were used to analyze hydrocarbons at 60, 100 and 110°C respectively. Alcohols and acetates were analyzed using a column, D, at 150°C. The helium outlet flow rates were 45 (A), 55(B), 60(C), and 60(D) cc./min. The relative retention time is the ratio of the retention time of a substance to the retention time of benzene as measured from an air peak. Quantitative analysis was done as follows; the relative thermal conductivity cell response per mole of the authentic samples of the compounds under discussion was determined using benzene as an internal standard, following the procedure of Messner et al.[19] The mole ratio of the compounds in the product was determined from the above relative response and from the apparent peak area, which was obtained by half-width and peak-height measurements. The relative response of the unidentified compound obtained from the pyrolysis of III (1.7%) was arbitrarily assigned the value of 145 (100 for benzene, 145 for ethylcyclohexane, and so on).

NMR Analysis of Products.—The analysis was run at 25°C for cycloalkenes and at 70°C for alcohols in carbon tetrachloride (5—10%) on a Varian Associates Model V-4311 high resolution spectrometer operating at 60 Mc., using tetramethylsilane (τ 10.00) as an internal standard, unless otherwise noted. The resonance line shapes and chemical shifts (τ-value) used for the structural assignments[20] were as follows: cyclohexene (a triplet, 4.43 J=1.5 c. p. s., olefinic protons), 1-methylcyclohexene (an incompletely resolved multiplet,[21] 4.71, an olefinic proton; an incompletely resolved doublet, 8.40, methyl protons), 3-methylcyclohexene (a complex multiplet, three main lines, 4.44, 4.47 and 4.53, olefinic protons; an asymmetrical doublet, 9.00 and 9.11, J=6.6 c. p. s., methyl protons), methylenecyclohexane (a quintet, 5.47, terminal methylene protons), cycloheptene (a triplet, 4.30, J=3.7 c. p. s., olefinic protons), 1-ethylcyclohexene (an incompletely resolved multiplet, 4.65, an olefinic proton; a triplet, 9.03, methyl protons), ethylidenecyclohexane (two lines,[22] 4.90 and 4.99, an olefinic proton), 1-methylcycloheptene (a triplet, 4.51, an olefinic proton; an incompletely resolved doublet, 8.35, methyl protons), methylenecycloheptane (a quintet, 5.37, terminal methylene protons), methylcyclohexane (an asymmetrical doublet,[23] 9.07 and 9.14, J=4.2 c. p. s., methyl protons), cyclohexanemethanol (a doublet, 6.66, methylene protons of the $-CH_2OH$), 1-methylcyclohexanol (a singlet, 8.85, methyl protons), cycloheptanol (a broad absorption, 6.25, a methine proton), 1-ethylcyclohexanol[24] (a triplet, 9.14, methyl protons), and 1-methylcycloheptanol[24] (a singlet, 8.83, methyl protons).

ESR Analysis.—The ESR spectra were measured with a Varian x-band EPR spectrometer, Model V-4566, using field modulation at 100 kc./sec.

1-Methylcyclohexanemethyl *p*-toluenesulfonate was irradiated under nitrogen with ultraviolet rays for 1 hr. at room temperature, using a Toshiba SHLS-100 2B ultraviolet lamp set at the distance of 5 cm. from the sample. During the irradiation, the sample was dipped in liquid nitrogen to prevent heating, and then subjected to ESR spectroscopy.

Pyrolysis of Sulfonic Esters.—The pyrolysis was conducted in a 100-ml. flask equipped with a side arm for introduction of nitrogen. The flask was connected to a 40-cm. distilling column, which was connected in turn to a trap immersed in a dry ice-methanol bath, and then to a water pump. The flask was then charged with the sulfonic ester (0.03 mol. each), evacuated to 40 mmHg, and immersed in an oil bath. The bath was heated rapidly to 200—205°C. After a few minutes, the sulfonic ester began to decompose; this decomposition continued for 30—45 sec. The product in the trap was then taken up with ether, washed with a dilute sodium hydroxide solution and water, and dried over anhydrous magnesium sulfate, and the ether was removed, leaving a hydrocarbon mixture weighing between 1.92—2.19 (I), 1.71—1.98 (II), and 2.11—2.42 g. (III). Considerable amounts of tar-like substances remained in the reaction flask, but no attempt was made to identify them.

I, II and III (0.03 mol. each) were similarly pyrolyzed at 80 mmHg in the presence of *p*-benzoquinone (0.01 mol.), giving 1.15—1.40, 1.20—1.38, and 1.30—1.45 g. of hydrocarbons, respectively. I and II gave cyclohexene (2.1% and a trace), 1-methylcyclohexene (66.1 and 74.3%), 3-methylcyclohexene (9.7 and 9.3%), methylenecyclohexane (1.2 and 1.2%), cycloheptene (4.1 and 4.8%), methylcyclohexane (12.3 and 10.5%), and toluene (4.7% and none).

A mixture of I (0.03 mol.) and benzoyl peroxide (0.01 mol.) was rapidly heated to 100—105°C at 40 mmHg under nitrogen. II and III were treated in this way also. After 2 min. benzoyl peroxide began to decompose; this decomposition continued for several minutes. The heating was then discontinued. The products collected in the trap immersed in a dry ice-methanol bath weighed 0.38—0.42, 0.35—0.40, and 0.57—0.62 g., respectively. The residues consisted mainly of the unreacted sulfonic ester. I and II gave cyclohexene (a trace), 1-methylcyclohexene (5.5 and 5.3%), 3-methylcyclohexene (a trace), methylenecyclohexane (0.3 and 0.3%), methylcyclohexane (1.3

18) All melting points and boiling points are uncorrected.

19) A. E. Messner, D. M. Rosie and P. A. Argabright, *Anal. Chem.*, **31**, 230 (1959).

20) Signals due to the ring methylene protons are not described.

21) The signal determined at 40 Mc. was reported to be a triplet by G. V. D. Tiers, "Table of Characteristic NMR Shielding Values."

22) Since a sufficient quantity of ethylidenecyclohexane could not be isolated, its NMR spectrum was determined using a mixture of ethylidenecyclohexane and 1-ethylcyclohexene. The olefinic proton of the former would be expected to show a quartet by spin-spin coupling with methyl protons with the relative intensities of 1 : 3 : 3 : 1, but only two lines were detected. The proton showed a sharp single line (τ 4.95) when the spin-decoupling technique was applied.

23) The signal determined at 40 Mc. was reported to be a singlet.[21]

24) The NMR spectra of 1-ethylcyclohexanol and 1-methylcycloheptanol were determined at 120°C without a solvent and using cyclohexane (τ 8.56) as an internal standard.

and 1.1%), and benzene (92.7 and 93.3%), respectively. III gave 1-methylcyclohexene (a trace), 1-ethylcyclohexene (3.2%), 1-methylcycloheptene (2.5%), ethylcyclohexane (0.9%), and benzene (93.4%).

Evidence for the saturated compounds was obtained as follows: (1) the whole reaction product was treated with bromine in ether at 0°C, and then gas chromatographed; (2) the whole reaction product was analyzed on a 30 cm. column of 30% concentrated sulfuric acid on 40—60 mesh silica gel, which was connected to the end of the above octyl phthalate column; (3) by a comparison of the relative retention times with those of authentic samples (using an authentic sample alone and in admixture), and (4), in the case of the isolated methylcyclohexane or ethylcyclohexane, the NMR spectrum of each compound was exactly identical with that of an authentic sample, showing the absence of any resonance line due to olefinic protons.

Oxalic Acid-Catalyzed Dehydration of Cyclohexanemethanol and 1-Methylcyclohexanemethanol.—The dehydration was conducted following the procedure of Chapman and Borden.[5] A mixture of cyclohexanemethanol (0.05 mol.) or 1-methylcyclohexanemethanol (0.05 mol.) and oxalic acid (0.4 mol.) was heated to 150°C. The olefinic product was dried over anhydrous magnesium sulfate, and then analyzed by gas chromatography.

Cobalt(II) Chloride-Catalyzed Reaction of Cyclohexanemethyl Chloride.—In a 500-ml. three-necked flask fitted with a mechanical stirrer, a dropping funnel and a reflux condenser, there were placed magnesium (0.1 mol.) and 30 ml. of dry ether. Methyl iodide (0.1 mol.) in 20 ml. of dry ether was then added dropwise into the flask with stirring. Cyclohexanemethyl chloride (0.1 mol.) in 50 ml. of dry ether was then added. Cobalt(II) chloride (0.05 mol.) was added in portions into the reaction mixture with stirring. After the exothermic reaction had ceased, 20 ml. of water was added, and the ether layer was separated and dried over anhydrous magnesium sulfate. Distillation gave 3.5 g. of a hydrocarbon mixture. The mixture was analyzed by gas chromatography and NMR spectroscopy.

Acetolysis of Sulfonic Esters.—In a 500-ml. flask equipped with a reflux condenser, the top of which was connected to a trap immersed in a dry ice-methanol bath, there were placed the sulfonic ester (0.05 mol. each), sodium acetate (0.05 mol.), glacial acetic acid (1 mol.), and water (1 mol.). The flask was heated for 48 hr. in an oil bath under gentle reflux, and then cooled to 0—5°C. The contents were neutralized with a dilute sodium hydroxide solution and extracted with ether. The trap and condenser were rinsed with ether. The combined extracts were dried over anhydrous magnesium sulfate, and then fractionally distilled into 2 fractions. II gave 0.93 g. of a low-boiling fraction (b. p. 90—113°C) and 3.2 g. of a high-boiling fraction (b. p. 55°C at 20 mmHg to 85°C at 15 mmHg), while III gave 3.2 g. (b. p. 110—139°C) and 0.6 g. (b. p. 70—80°C at 20 mmHg) portions, and XIII, 3.6 g. (b. p. 110—139°C) and 0.6 g. (70—80°C at 20 mmHg) portions, respectively. No attempt was made to identify the residue.

III and XIII (0.05 mol. each) were similarly solvolyzed in glacial acetic acid (1 mol.) containing acetic anhydride (0.035 mol.) and sodium acetate (0.1 mol.); they gave 3.4 and 3.1 g. of cycloalkenes, respectively.

Preparation of Sulfonic Esters.—Cyclohexanemethyl *p*-toluenesulfonate, m. p. 32—33°C (lit.[25] m. p. 32—33°C), cyclohexanemethyl methanesulfonate, m. p. 43—44°C, 1-methylcyclohexanemethyl *p*-toluenesulfonate, m. p. 37—38°C (lit.[25] m. p. 37—38°C), and 1-methylcyclohexanemethyl methanesulfonate,[26] were prepared from the corresponding alcohols and methanesulfonyl or *p*-toluenesulfonyl chlorides in pyridine at room temperature. The crude products were then recrystallized twice from hexane, in 65—70% yields.

Preparation of Alcohols.—1-Methylcyclohexanol, b. p. 68°C at 20 mmHg (lit.[27] b. p. 72°C at 22 mmHg), 1-ethylcyclohexanol, b. p. 76.5°C at 20 mmHg (lit.[28] b. p. 77°C at 20 mmHg), and 1-methylcycloheptanol, b. p. 83—85°C at 20 mmHg (lit.[27] b. p. 82—85°C at 20 mmHg) were prepared following the directions of Mosher.[29] Cyclohexanemethanol, b. p. 91—92°C at 18 mmHg (lit.[30] b. p. 88—93°C at 18 mmHg), cycloheptanol, b. p. 184—185°C (lit.[31] b. p. 184—187°C), and 1-methylcyclohexanemethanol, b. p. 88°C at 17 mmHg (lit.[32] b. p. 85°C at 14 mmHg), were prepared by the methods of Gilman and Catlin, Matthews and Becker, and Koch and Haaf respectively.

Preparation of Acetates. — Cyclohexanemethyl acetate, b. p. 83—85°C at 15.5 mmHg (lit.[33] b. p. 199—201°C) at 740 mmHg, 1-methylcyclohexyl acetate b. p. 177°C (lit.[34] b. p. 178—179°C), 1-ethylcyclohexyl acetate, b. p. 190—192°C, and cycloheptyl acetate, b. p. 199°C (lit.[35] b. p. 199—200.5°C) were prepared from the corresponding alcohols and an excess of acetic anhydride in the presence of anhydrous sodium acetate.

Preparation of Cycloalkenes.— 1-Methylcyclohexanol, 1-ethylcyclohexanol, and 1-methylcycloheptanol were dehydrated following the method of Traynelis et al.,[36] thus yielding mixtures of 1-methylcyclohexene and methylenecyclohexane, (94 : 6), 1-ethylcyclohexene and ethylidenecyclohexane (95 : 5), and 1-methylcyclohexene and methylenecycloheptane (90 : 10) respectively. 1-Methylcyclohexene, b. p. 110°C (lit.[37] b. p. 110.2°C), methylenecyclohexane, b. p. 102°C (lit.[37] b. p. 102.5°C), 1-ethylcyclohexene,

The X-Ray Structure Determination of Dihydroteleocidin B Monobromoacetate

By Hirokichi HARADA,* Noriyoshi SAKABE and Yoshimasa HIRATA

Chemical Institute, Faculty of Science, Nagoya University, Chigusa-ku, Nagoya

and Yujirō TOMIIE and Isamu NITTA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received December 15, 1965)

The structure of dihydroteleocidin B monobromoacetate, the derivative of a toxic substance teleocidin B produced by some streptomyces, has been determined by X-ray analysis. Crystals of the derivative, $C_{30}H_{44}O_3N_3Br$, are orthorhombic ($a=14.50$, $b=26.60$, $c=7.93$Å, $z=4$, the space group is $P2_12_12_1$). The intensities of 2053 reflections were measured using Cu$K\alpha$ radiation. The bromine position was determined by Patterson methods, and all the carbon, oxygen and nitrogen atoms were elucidated by three-dimensional minimum function methods. A three-dimensional Fourier synthesis and the least squares methods completed the refinement, giving a final R value of 16.4%. The derivative has a substituted indole nucleus with a nine-membered lactum ring.

Teleocidin B is one of the principal toxic elements isolated from the mycelia of some streptomyces.[1]

Recently, a structure containing a nine-membered lactum ring with a substituted indole nucleus has been suggested for dihydroteleocidin B,[2] which was derived from teleocidin B by catalytic hydrogenation.

In the course of that chemical investigation it, appeared desirable to confirm this rather unusual skeleton and the complete structure of this substance by X-ray crystallographic studies.

Dihydroteleocidin B monobromoacetate was selected for the X-ray crystal analysis. Three-dimensional Patterson and Fourier methods were employed for the determination of the crystal structure. Our results established the whole structure

Experimental and Structure Determination

Dihydroteleocidin B monobromoacetate, $C_{30}H_{44}O_3N_3Br$, was obtained from dihydroteleocidin B and monobromo-acetylbromide by the usual method. The crystals melt at 214—216°C. The crystal belongs to the orthorhombic system (space group $P2_12_12_1$), with four molecules in the unit cell with dimensions of $a=14.50\pm0.03$, $b=26.60\pm0.04$ and $c=7.39\pm0.03$ Å.

The intensities of the three-dimensional reflections were measured visually from integrated Weissenberg photographs around a and c axes taken by means of filtered Cu$K\alpha$ radiation. The relative values of the observed structure factors of 2053 reflections were then converted into the absolute scale by Wilson's method.[3] The position of the bromine atom was determined by the three-dimensional Patterson function. The three-dimensional minimum function[4] was calculated in order to elucidate the positions of light atoms. It seemed reasonable to regard several peaks found in this figure as light atoms. Then the projection of the electron density distribution was calculated along the b axis. However, since the distribution in some area is so complicated, another projection was calculated along the c axis, from which the positions of thirty-five atoms were determined. The structure so obtained was refined by three-dimentional Fourier syntheses and by the least-squares methods. The final atomic co-ordinates and temperature factors are listed in Table I. The interatomic distances and valency angles in Table II were then calculated.

The final R factor is 16.18%. The F_o-F_c values are shown in Table III.* Figure 1 shows the final three-dimentional electron density distribution viewed along the c axis, and Fig. 2, the complete chemical formula of dihydroteleocidin B monobromoacetate.

The calculations were performed on a NEAC-2206 electronic computer using our own programs.

The authors wish to express their deep thanks to the Takeda Chemical Industries, Ltd., for the computer used in this investigation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1775—1778 (1966)

The Synthesis of 2, 7-Dideoxy-L-*manno*-heptose*[1]

By Juji YOSHIMURA, Hachiro KOMOTO,*[2] Hiroaki ANDO and Toshio NAKAGAWA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 17, 1965)

2, 7-Dideoxy-L-*manno*-heptose was synthesized from 1-*C*-nitro-1, 7-dideoxy-L-*glycero*-L-*talo*-heptitol by the elimination of the *C*-2 hydroxyl group (nitroolefin formation), by hydrogenation and by the Nef reaction. The corresponding ethyl α-glycoside, its acetate, and a few related 1-amino-1-deoxy derivatives were also described.

A number of dideoxy sugars, almost all of them belonging to the 2, 6-, 3, 6- and 4, 6-dideoxyaldohexoses,[1] have been found in numerous heterosides and antibiotics. The specific role of the sugars in relation to physiological activities remains, however, still unrevealed; knowledge of their synthesis is also limited.

In the course of their studies of nitrosugars, the present authors have synthesised 2, 7-dideoxy-L-*manno*-heptose; they would like to describe it in this paper. In a previous paper[2] some of the present authors reported a modification of Sowden's aldose-nitromethane condensation[3], using barium hydroxide instead of sodium alcoholate as a catalyst in a small amount of water; it was pointed out that the new method generally gave results equal

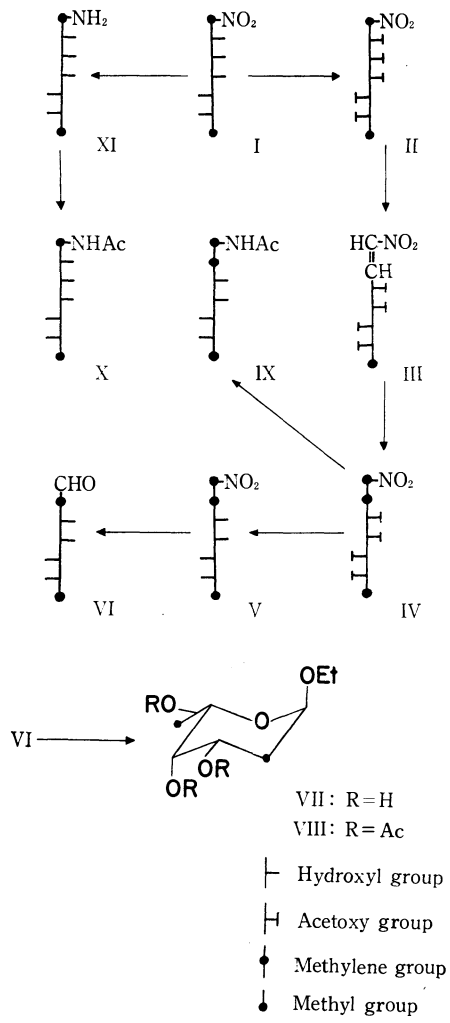
or superior to those obtained by Sowden's method, even when the amount of nitromethane used was less and the reaction time was shorter.

1-*C*-Nitro-1, 7-dideoxy-L-*talo*-heptitol (I), prepared thus from L-rhamnose, was converted to the corresponding acetate (II) and then heated in dried benzene with sodium bicarbonate[3] to give L-*manno*-3,4,5,6-tetra-*O*-acetyl-1-nitro-heptene-1 (III) as a sirup; this was identified by means of elementary analysis and a study of its infrared absorption spectra (–HC=CH– at 1660-cm^{-1}, $-NO_2$ at 1540 cm^{-1}). III was once subjected to high-vacuum distillation in order to purify it, but a considerable decomposition took place, and only a small amount of a distillate (b. p. 123—132°C/0.05 mmHg; m. p. 86—88°C) was obtained. The analytical values correspond with the formula $C_{13}H_{19}O_9N$, which is consistent with the one which results when one acetyl group is removed from III. Therefore, III was used without purification in the following experiments. The catalytic hydrogenation of III with palladium-charcoal, on the absorption of an equimolar amount of hydrogen, afforded 1-*C*-nitro-3, 4, 5, 6-tetra-*O*-acetyl-1, 2, 7-trideoxy-L-*manno*-heptitol (IV), which failed to crystallize. Infrared spectrometric analysis showed the disappearance of the double bond linkage in IV. On de-*O*-acetylation with sodium methoxide in absolute methanol, IV afforded crystalline 1-*C*-nitro-1, 2, 7-trideoxy-L-*manno*-heptitol (V). On the other hand, IV was converted to the corresponding 1-acetamido-heptitol (IX). The sodium salt of V was treated with sulfuric acid (Nef reactions) in the manner described by Sowden[4] for the preparation of 2-deoxy-D-ribose, the reaction mixture was neutralized with solid barium carbonate (pH 3.6) and the filtrate was concentrated to a sirup. On repeated evaporation with ethanol, it did not afford the expected heptose but a crystalline ethyl heptoside (VII), m. p. 152—154°C; $[\alpha]_D^{20}$ −129° (*c* 1.5, water). The product did not reduce the Fehling's solution, but after having been refluxed in 2 N sulfuric acid it showed a positive reaction.

The glycosidic configuration of VII was deduced to be α from the intensively negative rotational value, while the ring-size was determined by the cuprammonium-complex method.[5] If VII takes a furanoside ring, a cuprammonium-glycol complex should be formed with the hydroxyl groups on *C*-5 and *C*-6 out of the hemiacetal ring; therefore, one could not expect a dramatic change in the optical rotation. If it takes a pyranoside ring, on the other hand, the complex formation with the hydroxyl groups on *C*-3 and *C*-4 (equatorial and



axial respectively) in the hemiacetal ring should change the rotational value strongly in the positive direction. The $\Delta[M]_{436}^{\text{Cupra A}}$ +318° and $\Delta[M]_{578}^{\text{Cupra A}}$ +345° values of VII were consistent with the latter results; consequently, VII was identified as ethyl 2, 7-dideoxy-α-L-*manno*-heptopyranoside. On acetylation, VII afforded the corresponding tri-*O*-acetate (VIII).

The direct formation of VII from V is caused by the remaining sulfuric acid; no crystalline product was obtained by a re-examination of the Nef reaction of V in which the acid was carefully neutralized with barium hydroxide. For the purposes of its hydrolysis to VI, the heptoside was dissolved in 2 N sulfuric acid and allowed to stand at room temperature. The specific rotation became more and more positive (−88° (13 min.); −83° (1 hr.); −63° (10 hr.); −50° (24 hr.)), until it reached to the equilibrated value of −40° (48 hr.). Then the solution was neutralised with 2 N barium hydroxide, filtered off, and the filtrate

was completely deionized with a small amount of IRC-120. The removal of the solvent in vacuo left a colorless sirup ($[\alpha]_D^{21}$ −47.1° (*c* 1.72, water)), which showed no mutarotation. All the attempts to isolate the crystalline free heptose and its hydrazones have been in vain.

I and II were also converted to crystalline 1-amino- and 1-acetamide-1, 7-dideoxy-L-*glycero*-L-*talo*-heptitol (XI and X) respectively.

Experimental

1, 7-Dideoxy-1-*C*-nitro-2, 3, 4, 5, 6-penta-*O*-acetyl-L-*glycero*-L-*talo*-heptitol (II).—One drop of concentrated sulfuric acid from a capillary was added to a stirred suspension of compound I[2] (2.5 g.) in 25 ml. of acetic anhydride. The resulting solution was allowed to stand at room temperature for 4 hr. and then poured into ice water. It was extracted three times with chloroform, and the extract was washed with an aqueous solution of sodium bicarbonate, dried over anhydrous sodium sulfate, and concentrated to dryness in vacuo at 40°C, thus yielding colorless crystals. Two recrystallizations from ethanol gave 4.3 g. (86.8%) of plates with a m. p. of 133°C and $[\alpha]_D^{20}$ −3.0° (*c* 0.8, acetone).

Found: C, 46.62; H, 5.53; N, 3.30. Calcd. for $C_{17}H_{25}O_{12}N$ (435.38): C, 46.90; H, 5.79; N, 3.23%.

L-*manno*-3,4, 5, 6-Tetra-*O*-acetyl-1-nitroheptene-1 (III).—A solution of 2.5 g. of II in 50 ml. of dried benzene was refluxed for 2.5 hr. with 2.5 g. of sodium bicarbonate. After the mixture had then been cooled the precipitates were filtered off and the filtrate was concentrated to dryness in vacuo at 40°C thus giving a sirup (1.8 g., 83%). The sirup could not be crystallized, but its infrared absorptions and analytical values were consistent with those of III.

Found: C, 47.32; H, 5.85; N, 3.80. Calcd. for $C_{15}H_{21}O_{10}N$ (375.33): C, 48.00; H, 5.64; N, 3.73%.

The high-vacuum distillation of III gave, accompanied by a considerable decomposition, a small amount of a distillate, b. p. 123—132°C/0.05 mmHg, which crystallized on standing (m. p. 86—88°C). However, the analytical values (C, 46.93; H, 5.81; N, 4.42%) corresponded with the formula $C_{13}H_{19}O_9N$, which is consistent with the one which holds when one acetyl group is removed from III.

L-*C*-Nitro-3, 4, 5, 6-Tetra-*O*-acetyl-1, 2, 7-trideoxy-L-*manno*-heptitol (IV).—A crude sirup III (1.2 g.) was dissolved in 30 ml. of absolute alcohol and subjected to hydrogenation in the presence of 5% palladium-charcoal. The hydrogenation was stopped when the hydrogen-uptake reached an equimolar amount (79 ml.). The removal of the catalyst and the solvent left a colorless sirup (1.15 g., 95%), which failed to crystallize. Infrared spectrometric analysis showed the absence of a double-bond linkage.

1-*C*-Nitro-1, 2, 7-trideoxy-L-*manno*-heptitol (V).—To a solution of 2 g. of crude IV in 5 ml. of ethanol, 10 ml. of 0.65 N sodium methoxide in methanol was added drop by drop. The solution turned yellow, the temperature rose slightly, and colorless crystals appeared. After the solution had stood for 3 hr., 10 ml. of 2 N acetic acid were added to the mixture and the resulting clear solution was deionized with an ion exchanger, IR-120 (30 ml.).

The concentration of the solution gave 0.9 g. (59.7%) of crystals. It was recrystallized twice from ethanol; yield, 0.6 g.; m. p. 122.5—123.5°C; $[\alpha]_D^{21}$ −10.0° (*c* 1.8, ethanol).

Found: C, 40.09; H, 7.06; N, 6.86. Calcd. for $C_7H_{15}O_6N$ (209.20): C, 40.19; H, 7.23; N, 6.70%.

Ethyl 2, 7-Dideoxy-α-L-*manno*-heptopyranoside (VII).—a) Into a mixture of 10 ml. of concentrated sulfuric acid and 15 ml. of water, 4.4 g. of V in N sodium hydroxide (25 ml.) was swirled at 0°C. The reaction mixture was then diluted with 50 ml. of ice water and neutralized by stirring it with solid barium carbonate (pH 3.6). The mixture was filtered, and the filtrate was concentrated in vacuo to a sirup. By the repeated evaporation of the water with ethanol, it weighed 3.45 g. and crystallized from ethanol or ethanol-ether. After two recrystallizations from ethanol, it showed a m. p. of 152—154°C and $[\alpha]_D^{20}$ −129° (*c* 1.5, water). Yield, 1.1 g. (25.4%).

Found: C, 52.66; H, 9.11. Calcd. for $C_9H_{18}O_5$ (206.23): C, 52.41; H, 8.80%.

The product did not reduce the Fehling solution, but its hydrolysate in 2 N sulfuric acid showed a positive reaction. $\Delta[M]_{486}^{\text{Cupra A}}$ +318° or $\Delta[M]_{78}^{\text{Cupra A}}$ +345 means that VII has a pyranoside ring.

b) The glycosidation of VI with ethanol in the presence of a small amount of sulfuric acid in the usual manner gave the corresponding ethyl glycoside in a 75% yield; the m. p. was 153—154°C, and it showed no depression on admixture with an authentic sample.

Ethyl 2,7-Dideoxy-3,4,6-tri-*O*-acetyl-α-L-*manno*-heptopyranoside (VIII).—One hundred milligrams of VII was dissolved in a mixture of 3 ml. of anhydrous pyridine and 3 ml. of acetic anhydride. The solution was allowed to stand overnight at room temperature and then swirled into ice water. The crystals which appeared were filtered, dissolved in 3 ml. of ethanol, treated with charcoal, and then poured again into ice water to give colorless crystals, m. p. 90°C and $[\alpha]_D^{21}$ −157° (*c* 0.9, ethanol). Yield 110 mg. (68.2%).

Found: C, 54.25; H, 7.56. Calcd. for $C_{15}H_{24}O_8$ (332.34): C, 54.21; H, 7.28%.

2,7-Dideoxy-L-*manno*-heptose (VI).—One hundred and eighty milligrams of VII was allowed to dissolve in 8 ml. of 2 N sulfuric acid, and then left to stand for 2 days at room temperature while the change of the rotation was being traced. The acidic solution was then neutralized with 2 N barium hydroxide, the precipitates were filtered off, and the filtrate was exhaustly deionized with a small amount of IRC-120. The removal of the solvent in vacuo yielded a colorless sirup (86 mg.), which failed to crystallize. $[\alpha]_D^{20}$ −47.1° (*c* 1.72, water). No mutarotation was observed.

1-Acetamido-1, 2, 7-trideoxy-L-*manno*-heptitol (IX).—A solution of 2 g. of a crude sirup, IV, in 30 ml. of absolute ethanol was shaken with hydrogen in the presence of 0.2 g. of a platinum catalyst until the hydrogen uptake ceased. After the catalyst and the solvent had been removed, the sirup yielded was acetylated in the usual manner with 10 ml. of acetic anhydride and 10 ml. of pyridine, but the product failed to crystallize. Subsequently, it (1.4 g.) was subjected to de *O*-acetylation with sodium methoxide in absolute methanol. The concentration of the mixture in vacuo yielded crystals, which were then recrystallized from methanol; m. p. 140.5—141°C and

$[\alpha]_D^{20}$ −14.8° (*c* 1.0, water). Yield, 0.6 g. (52.5%).

Found: C, 49.04; H, 8.65; N, 6.25. Calcd. for $C_9H_{19}O_5N$(221.25): C, 48.85; H, 8.66; N, 6.33%.

1-Acetamido-1, 7-dideoxy-L-*glycero*-L-*talo*-heptitol (X).—a) Using the procedure described above, 2.8 g. of II was subjected to hydrogenation and then *N*-acetylation. Neither product could be crystallized. Then the latter was de-*O*-acetylated to give crystals; m. p. 202—204°C and $[\alpha]_D^{20}$ +31.0° (*c* 0.31, water). Yield, 0.6 g. (55.4%).

Found: C, 45.49; H, 8.26; N, 5.89. Calcd. for $C_9H_{19}O_6N$ (237.25): C, 45.56; H, 8.07; N, 5.90%.

b) The same product was obtained in a 80% yield by the *N*-acetylation of XI in the usual manner.

1-Amino-1, 7-dideoxy-L-*glycero*-L-*talo*-heptitol (XI).—A solution of 2 g. of I in 30 ml. of 80% ethanol was subjected to hydrogenation by the procedure described before. The crystals obtained were recrystallized from ethanol; m. p. 144—145°C and $[\alpha]_D^{20}$ +8.3° (*c* 0.24, methanol). Yield, 1.6 g. (92.4%).

Found: C, 42.82; H, 8.79; N, 6.86. Calcd. for $C_7H_{17}O_5N$ (195.21): C, 43.05; H, 8.78; N, 7.16%.

The authors would like to express their gratitude to Professor Tetsuo Sato of the Tokyo Institute of Technology for his encouragement throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1778—1782 (1966)

Organic Sulfur Compounds. IX. The Reactions of *N*-Sulfinylamines with Nitrogen Tetroxide and Nitrosyl Chloride

By Michio KOBAYASHI* and Koichi HONDA

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received January 5, 1966)

N-Sulfinylaniline reacted with nitrogen tetroxide to form the anhydrous benzenediazonium nitrate. The reactions of *N*-sulfinylaniline and several of its *p*-substituted derivatives with nitrosyl chloride also gave the anhydrous diazonium chlorides in the crystalline state. Aliphatic *N*-sulfinylamines reacted with nitrosyl chloride to form alkyl chlorides, probably by the decomposition of the initially-formed diazonium chlorides; during this reaction, no rearrangement of the alkyl group was observed.

Recent a short communication[1] which described the formation of benzenediazonium fluoroborate and hexafluoroantimonate from *N*-sulfinylaniline and, respectively, nitrosyl fluoroborate and hexafluoroantimonate prompted us to publish our similar studies of the reactions of *N*-sulfinylamines with nitrogen tetroxide or nitrosyl chloride.

Several addition reactions to *N*-sulfinylamines (I), in which a cationic part of the attacking reagent became attached to the nitrogen, and an anionoid part to the sulfur atoms, of I, have been known.[2,3]

$$R\text{-}N{=}S{=}O + ArSH \rightarrow R\text{-}\underset{\underset{H}{|}}{N}\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}S\text{-}Ar \qquad (1)$$

(I)

$$R\text{-}N{=}S{=}O + R'MgX \rightarrow R\text{-}\underset{\underset{XMg}{|}}{N}\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}R' \qquad (2)$$

On the other hand, many carbonyl compounds give condensation products with such reactive *N*-sulfinylamines as *N*-sulfinyl sulfonamides,[4] as shown below:

$$R\text{-}N{=}S{=}O + R'CHO \rightarrow R\text{-}N{=}CH\text{-}R' + SO_2 \qquad (3)$$

Analogous condensation between the nitroso compounds and *N*-sulfinylamines could take place according to the following equation:

$$R\text{-}N{=}S{=}O + X\text{-}NO \rightarrow R\text{-}N{=}N\text{-}X + SO_2 \qquad (4)$$

If X-NO is an ionic compound, which could dissociate to form a nitrosonium cation and an anion X^-, the above condensation would lead to the formation of the diazonium salts:

$$R\text{-}N{=}S{=}O + NO^+X^- \rightarrow [R\text{-}N{\equiv}N]^+X^- \qquad (5)$$

In the case of the aliphatic *N*-sulfinylamines, the primary product, alkyldiazonium salt with a well-known low stability, would decompose to RX and nitrogen:

$$[R\text{-}N{\equiv}N]^+X^- \rightarrow RX + N_2 \qquad (6)$$

These expectations have been fully realized, as will be described in this paper.

Results and Discussion

When an ether solution of *N*-sulfinylaniline was added to a solution of nitrogen tetroxide in ether at −10°C, the reaction started immediately, forming a white precipitate. The filtrate of this precipitate began to form a similar precipitate at once, and even after the second filtration of the second precipitate, a substantial amount of the fresh precipitate was obtained. These precipitates were shown, by their infrared spectra in a KBr disk, to be benzenediazonium nitrate. In the dry state, this compound tends to decompose violently upon a slight shock. It was easily soluble in water, and an aqueous solution gave a coupling product with an alkaline solution of β-naphthol. The ether filtrate of the diazonium nitrate smelled strongly of sulfur dioxide. Due to the hygroscopic and explosive nature of the diazonium salt, its exact yield could not be determined as such. In a separate experiment, the first, second and third precipitate were dissolved in water immediately after the filtration, and then subjected to a coupling reaction with β-naphthol to give α-phenylazo-β-naphthol, the combined yield of which was 80% of the theoretical yield based on *N*-sulfinylaniline. Since the third filtrate gave some diazonium nitrate too, the yield of the diazonium salt was considered to be almost quantitative. The third filtrate was mixed with water and sulfate anions were precipitated as barium sulfate, which amounted to 6% of the theoretical yield based on sulfinylaniline. Therefore, most of the sulfur of sulfinylaniline was converted into sulfur dioxide, of which only a small fraction underwent oxidation to a higher oxidation state such as nitrosyl sulfate by means of excess dinitrogen tetroxide. The above result may be formulated as below:

$$C_6H_5N{=}S{=}O + N_2O_4 \rightarrow C_6H_5N_2{}^+NO_3{}^- + SO_2 \quad (7)$$

When a solution of an equimolar nitrosyl chloride in carbon tetrachloride was added to an ether solution of sulfinylaniline cooled at −70°C, a white precipitate started to form immediately. After a few minutes this precipitate was filtered off and the filtrate was stored in a refrigerator overnight, during which time a considerable amount of the same precipitate was deposited. The infrared spectrum of this precipitate exhibited strong absorptions at 2270, 1570, 1456, 1303, 1080, and 760 cm^{-1}, just as authentic benzenediazonium chloride. The first precipitate gave α-phenylazo-β-naphthol in a 33% yield in a coupling reaction with β-naphthol.

In a similar manner, *p*-nitro-*N*-sulfinylaniline rapidly reacted with nitrosyl chloride at −70°C to form the copious precipitate of *p*-nitrobenzenediazonium chloride, which gave α-*p*-nitrophenylazo-β-naphthol upon coupling with alkaline β-naphthol.

p-Methoxy-*N*-sulfinylaniline reacted slowly with nitrosyl chloride at a low temperature. After the reaction mixture had been kept in a refrigerator for 3 days, the precipitated diazonium salt was filtered off and coupled with β-naphthol to give α-*p*-methoxyphenyl-β-naphthol in a 36% yield. The filtrate of the diazonium salt was then kept for another 3 days in a refrigerator; it thus gave the same precipitate, the yield of which was estimated to be 24% by the coupling method. The total yield of *p*-methoxybenzenediazonium chloride was over 60%. The crude diazonium salt exhibited an infrared absorption at 2225 cm^{-1} the same region as in an authentic specimen of *p*-methoxybenzenediazonium chloride.

In a similar way, *p*-chloro-*N*-sulfinylaniline reacted with nitrosyl chloride in an ether - carbon tetrachloride mixture to give a white precipitate, supposed to be *p*-chlorobenzenediazonium chloride, which coupled with β-naphthol to give α-chlorophenylazo-β-naphthol in a 44% yield based on sulfinylamine. The relative velocity of the reaction of the *p*-substituted sulfinylaniline derivatives with nitrosyl chloride, as judged from the apparent velocity of the precipitation of the diazonium salts, was:

$$p\text{-nitro} > p\text{-chloro} > H > p\text{-methoxy}.$$

In every case, the filtrate of the diazonium salt smelled strongly of sulfur dioxide.

On the basis of the above results, the reaction of *N*-sulfinylanilines with nitrosyl chloride can be expressed by the following formula, which is of the same type as is seen in the reaction with nitrogen tetroxide:

$$Ar{-}N{=}S{=}O + NOCl \rightarrow ArN_2{}^+Cl^- + SO_2 \quad (8)$$

Considering the possiblity of the equilibrium:

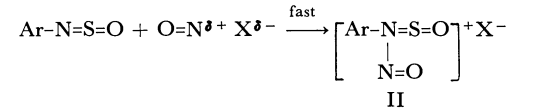
$$N_2O_4 \rightleftarrows NO^+NO_3{}^- \quad (9)$$

both reactions may be regarded as starting with the electrophilic attack of nitrosonium cations on the nitrogen atom of *N*-sulfinylanilines.

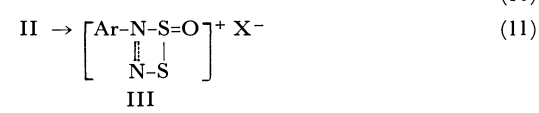
The facts that the amount of precipitated diazonium salt obtained by the first filtration did not exceed certain percentages of the theoretical yield, and that the fresh precipitate began to form immediately after the filtration, suggest the existence of some kind of equilibrium between the starting materials or one of the intermediates and the diazonium salt. A similar equilibrium phenomenon has been observed in the reaction of benzalaniline with nitrosyl chloride or nitrogen tetroxide to give the diazonium salts.[5]

The following reaction mechanism may be proposed:

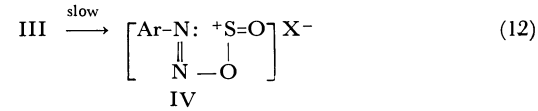
5) J. Turcan, *Bull. soc. chim. France,* [5]**2**, 627 (1935); c. f. R. M. Scribner, *J. Org. Chem.,* **29**, 3429 (1964).



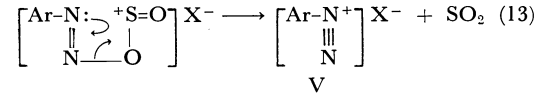
II (10)



III (11)

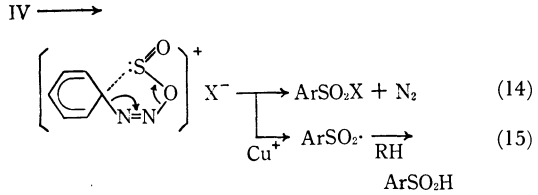


IV (12)



V (13)

Well-known reactions of the diazonium salts with sulfur dioxide in the presence of a copper catalyst to form the sulfinic acids or sulfonyl chlorides[6] may be attributed to the formation of IV by the reverse reaction of (13), which collapses, thus resulting in sulfonyl chloride (reaction 14) or in sulfinic acid, according to the reaction 15:



(14)

(15)

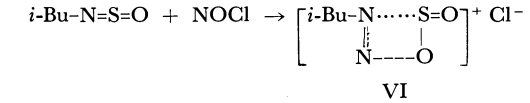
Reaction 10 seems to be very fast and irreversible, since the characteristic color of nitrosyl chloride faded almost instantly after the reactants were mixed. Only small fractions of the liberated sulfur dioxide were oxidized by nitrogen tetroxide to a higher oxidation state, suggesting that most of nitrogen tetroxide had been consumed, leaving only a small amount of it available for the oxidation when free sulfur dioxide was liberated in the reaction 13. Consequently, the reaction 10 could not be a rate determining step. Reactions 11 and 12 may form a concerted one-step process; they are probably the rate determining.

The order of the rate of the formation of the diazonium salt was *p*-nitro > *p*-chloro > unsubstituted > *p*-methoxy, as has been described above. Since the reaction 10 is a cationoid attack by nitrosonium ion, the reverse order would be expected if this reaction were the rate determining step. On the other hand, if the reaction 11 or 12, in which the adduct II rearranges to IV with a long conjugated system, is the rate determining step, the acceleration by an electron-attractive substituent is quite understandable.

6) H. Meerwein, G. Dittmar, R. Göllner, K. Hafner, F. Mensch and O. Steinfort, *Chem. Ber.*, **90**, 841 (1957).

Alkyldiazonium salts are known to be very unstable, and they have never been isolated. In this connection, the reaction mechanism of the aliphatic *N*-sulfinylamines with nitrosyl chloride seemed to be interesting. Although the reaction of *N*-sulfinylethylamine and nitrosyl chloride failed to give any definite product attributable to the diazonium salt formation, the reactions of *N*-sulfinyl-*n*-butylamine and *N*-sulfinyl-isobutylamine with nitrosyl chloride gave *n*-butyl chloride and isobutyl chloride respectively. In both cases, no isomeric chloride was observed to be formed.

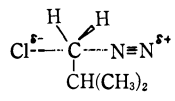
These butyl chlorides are considered to be the decomposition products of the intermediate butyldiazonium chlorides. The above results definitely exclude the formation of a free butyl cation during the decomposition, since the *n*-butyl carbonium ion is known to rearrange readily to the *s*-butyl cation, and the isobutyl carbonium ion, to *s*-butyl and *t*-butyl cations.



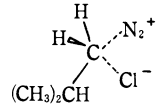
VI (16)

VII (17)

Therefore, the decomposition of the diazonium chloride VII to butyl chloride and nitrogen molecule must be a concerted process, in which the bond breaking between carbon and nitrogen and the bond forming between carbon and chlorine proceed simultaneously in an ion pair VII. The following two transition states, namely the S_N2 type (VIII) and the S_Ni type (IX), are conceivable for the last reaction:



VIII



IX

Since the bond between carbon and the positively charged N_2^+ group is considered to be very weak, the nucleophilic assistance by the chloride ion in the splitting of this bond can not be important in any way. The rapid collapse of the tightly-bound ion pair VIII will result in the formation of either the inverted or the retained product, or both, depending on the location of the chloride ion in this ion pair intermediate.

In the reaction of the aliphatic amines with nitrous acid to give the alcohols, the rearrangement of the alkyl groups has been reported,[7]

7) V. Meyer, J. Barbieri and F. Forster, *Ber.*, **10**, 130 (1877); This problem has been discussed in great detail in lit. 9 and many examples are cited in that paper.

while their reactions with nitrosyl chloride to form the alkyl chlorides are accompanied by no such rearrangement,[8] just as in our case. The proposed explanation for the above difference was that the former reaction consisted of the reaction of the free alkyl carbonium ion, separated from the counter ion by a water molecule, whereas the latter reaction occurred within the ion pair in the early stage along the reaction coordinate.[9] Probably the same explanation is applicable in the present case.

Experimental

Materials.—Sulfinylaniline was prepared from aniline hydrochloride and thionyl chloride.[10] B. p. 88°C/12 mmHg. *p*-Nitro-*N*-sulfinylaniline[11] was prepared by refluxing *p*-nitroaniline with thionyl chloride in benzene. M. p. 70°C.

p-Methoxy-*N*-sulfinylaniline, b. p. 146.5°C/25 mmHg (lit.[12] b. p. 132°C/15 mmHg), and *p*-chloro-*N*-sulfinylaniline, b. p. 136°C/40 mmHg (lit.[13] b. p. 237°C), were prepared in a similar way. *N*-Sulfinylethylamine[14] was prepared as follows: To 15 g. of ethylamine cooled in ice water, there was added a solution of 46.5 g. of *N*-sulfinylaniline in 50 ml. of ether over a 30 min. period; the mixture was kept overnight at room temperature. After repeated fractional distillations, a fraction boiling 73—74°C was retained (6.5 g.).

***N*-Sulfinyl-*n*-butylamine.**—To an ice-cooled solution of 25 g. of *n*-butylamine in a mixture of 55 g. of dry pyridine and 50 ml. of ether, a solution of 41 g. of thionyl chloride in ether was slowly added; the reaction mixture was then stirred for 30 min., filtered, and vacuum-distilled to give 17 g. of sulfinyl-*n*-butylamine, b. p. 47°C/50 mmHg (lit.[15] 38°C/10 mmHg). *N*-Sulfinyl-isobutylamine was prepared from 25 g. of isobutylamine in a similar way. B. p. 44°C/60 mmHg; the yield was 26.8 g. (65%). Nitrogen tetroxide was obtained by the pyrolysis, at 260°C, of nitrogen pentoxide.[16] Nitrosyl chloride was generated from sodium nitrite and concentrated hydrochloric acid; dried by passing it over sodium nitrite, hydrated potassium chloride and calcium chloride successively,and finally purified by fractional distillation.[17]

The Reaction of *N*-Sulfinylaniline and Nitrogen Tetroxide.—i) A solution of 1 g. of nitrogen tetroxide in ether was cooled to −10°C. When a solution of 1 g. of sulfinylaniline in ether was added to this solution, drop by drop, a white precipitate began to form at once. As soon as this precipitate had been filtered off, a new precipitate started to form in the filtrate; from the second filtrate, third white crystalline precipitate was obtained. The infrared spectra of the first and second precipitates in the KBr disk completely coincided with that of the authentic benzenediazonium nitrate prepared by the diazotation of aniline nitrate with isoamyl nitrite.[18] When a minute crystal of the product was crushed on a porous plate, it exploded violently. The filtrate of the diazonium salt smelled strongly of sulfur dioxide. ii) In a similar way, 1.5 g. of sulfinylaniline and 1.3 g. of nitrogen tetroxide were mixed in ether and the successively-precipitating diazonium nitrate was taken off by filtration up to the third crop. The combined yield was estimated by coupling with β-naphthol to be 80% (α-phenylazo-β-naphthol, m. p. 206°C; 2.2 g.; identified by infrared spectrum). The filtrate of the third precipitate was mixed with water, and the ether was evaporated at room temperature. To the remaining solution the diluted hydrochloric acid was added and sulfur dioxide was expelled by warming the solution on a water bath. The addition of 0.1 N barium chloride to the above solution while it was hot gave 0.148 g. of barium sulfate, in 6% yield based on sulfinylaniline.

The Reaction of Sulfinylaniline with Nitrosyl Chloride.—When 1.0 g. of nitrosyl chloride (15 mmol.) in 8 ml. of carbon tetrachloride was added to a solution of 2.2 g. of sulfinylaniline (16 mmol.) in 10 ml. of ether, a white precipitate appeared immediately. After a few min., this precipitate was filtered through a fritted glass funnel, whereupon a new precipitate started to fill the filtrate. The first precipitate was dissolved in water and coupled with β-naphthol to give 1.2 g. of α-phenylazo-β-naphthol (33%).

The Reaction of *p*-Nitro-*N*-sulfinylaniline with Nitrosyl Chloride.—The reaction between 2.6 g. of *p*-nitrosulfinylaniline and 0.8 g. of nitrosyl chloride was carried out at −70°C in a similar way. The immediately-formed white precipitate was filtered off after a few minutes. Its infrared spectrum in a KBr disk was superimposable upon that of *p*-nitrobenzenediazonium chloride prepared by the diazotation of *p*-nitroaniline hydrochloride with isoamyl nitrite in acetic acid.[19] The coupling of the first precipitate with β-naphthol gave 1.5 g. of α-*p*-nitrophenylazo-β-naphthol (40%).

The Reaction of *p*-Methoxy-*N*-sulfinylaniline with Nitrosyl Chloride.—When 2.5 g. of *p*-methoxysulfinylaniline and 1.0 g. of nitrosyl chloride were treated at −70°C as above, the rate of the precipitation of the diazonium salt was much slower than the precipitation rates of the other diazonium salts described in this paper. After it had been stored for 3 days in a refrigerator, the reaction mixture was filtered off, and the precipitated diazonium chloride was dissolved

in water and subjected to a coupling reaction with β-naphtol to give 1.0 g. of α-*p*-methoxyphenylazo-β-naphthol (the total yield was 2.5 g.). Infrared absorption of this diazonium salt exhibited N≡N absorption at 2225 cm^{-1} in a KBr disk and coincided with that of the authentic specimen prepared from *p*-anisidine hydrochloride and isoamyl nitrite.[19]

The Reaction of *p*-Chloro-*N*-sulfinylaniline with Nitrosyl Chloride.—After a reaction mixture of 2.8 g. of *p*-chlorosulfinylaniline and 1.0 g. of nitrosyl chloride, treated as above at −70°C, was kept for a week in a refrigerator, the white precipitate was taken up by suction. Coupling with β-naphthol gave 1.7 g. of α-*p*-chlorophenylazo-β-naphthol in 44% yield. All the azo-β-naphthols described above were identified by means of their infrared spectrum.

The Reaction of *N*-Sulfinyl-*n*-butylamine with Nitrosyl Chloride.—To a solution of 8.5 g. of nitrosyl chloride in 20 ml. of ether, cooled at −70°C, there was added, drop by drop, a solution of 15.5 g. of sulfinyl-*n*-butylamine in 20 ml. of ether. The evolution of gas started immediately, accompanied by the copious formation of the white precipitate. When the reaction mixture was allowed to warm to room temperature, gas evolved vigorously from the precipitate, which turned into a spongy mass which floated over the surface and finally settled at bottom as a black oil. The reaction mixture smelled strongly of sulfur dioxide. The upper layer was separated, washed with water, dried over magnesium sulfate, and fractionally distilled to give 2 g. of a colorless liquid, b. p. 77.5°C, which was identified as *n*-butyl chloride by its infrared spectrum. No *s*-butyl chloride was detected. The yield was 20% of the theoretical.

The Reaction of *N*-Sulfinyl-isobutylamine with Nitrosyl Chloride.—The reaction of 9.0 g. of sulfinyl-isobutylamine with 16.5 g. of nitrosyl chloride was carried out in a way similar to that used for the *n*-butyl derivative. The white crystals which formed at −70°C decomposed at room temperature with the evolution of gas and gave white leaflet crystals and an oil layer, both insoluble in ether. This leaflet (0.5 g.), m. p. 157—159°C, was readily soluble in water and identified as isobutylamine hydrochloride by its infrared spectrum and by a Kjeldahl nitrogen determination (Found: N, 11.4%; Calcd. for $C_4H_9NH_3Cl$: 12.5%). The ether layer was washed with water and fractionally distilled to give 1.5 g. of isobutyl chloride, which was identified by means of its infrared spectrum and boiling point. No indication of the presence of *s*-butyl chloride or *t*-butyl chloride was observed by infrared spectroscopy or the gas liquid chromatography.

Organic Sulfur Compound. X. The Mechanism of the Carboxylic Ester Formation from Carboxylic Sulfurous Anhydrides

By Michio KOBAYASHI*

Department of Chemittry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

and Reiko KIRITANI

Department of Chemistry, Radiation Center of Osaka Prefecture, Sakai, Osaka

(Received January 5, 1966)

Sodium benzoate-^{18}O reacts with methyl chlorosulfite to give methyl benzoate-^{18}O in a low yield; the excess ^{18}O content has been found to be exactly one-half of that in the starting benzoic acid. Another reaction of the labeled benzoic acid with phenyl chlorosulfite gives phenyl benzoate-^{18}O; its excess ^{18}O atom% is also one-half of that of benzoic acid. Both reactions are considered to proceed by way of the intermediate formation of the benzoic sulfurous mixed anhydrides, the decomposition of which by acyl-oxygen splitting affords the carboxylic esters labeled only in the carbonyl group.

The formation of the mixed anhydride (I) of the carboxylic acid and the sulfurous acid monoester (reaction 1) and its thermal decomposition at a relatively low temperature to give the carboxylic anhydride and the sulfurous acid diester (reaction 2) have been described in a preceding paper.[1] When the reaction mixture of the carboxylic acid salt with the chlorosulfite ester was heated at a high temperature until the evolution of sulfur dioxide was completed, the carboxylic ester has been reported to be formed in a good yield, probably by means of the intermediate formation of I (reaction 3):[2,3]

* Present address: Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo.

3) M. S. Newman and W. S. Fones, *J. Am. Chem. Soc.,* **69**, 1046 (1947).

$$RCO_2Na + Cl\text{-}S\text{-}OR' \longrightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OR' \quad (1)$$

$$I \longrightarrow {}^1/_2(RCO)_2O + {}^1/_2(R'O)_2SO + {}^1/_2SO_2 \quad (2)$$

$$I \longrightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}OR' + SO_2 \quad (3)$$

It has not been established which bond in I is broken in the last reaction. Moreover, there is another possible course by which the carboxylic ester is formed from the salt of the carboxylic acid and the chlorosulfite ester—namely, a secondary reaction between two primary products of the decomposition reaction 2 of I, the carboxylic anhydride and sulfurous acid diester, — besides the direct decomposition of I (reaction 3) to the carboxylic ester. In order to obtain information about these points, the present investigation, using the ^{18}O-labeling method, was carried out.

Results and Discussion

The ^{18}O labeled sodium benzoate and methyl chlorosulfite were mixed, and the resulting jelly-like mixture was heated in an oil bath for 4 hr., until the evolution of sulfur dioxide had ceased. The products were then spearated by fractional distillation into benzoic anhydride (50% yield), dimethyl sulfite (25% yield) and methyl benzoate (about a 5% yield). The excess ^{18}O atom percentage of methyl benzoate was found to be exactly a half of that of the starting sodium benzoate. This reaction may be formulated as follows:

$$Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}{}^{18}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OCH_3 \longrightarrow \quad (4)$$

Ia

$$Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}OCH_3 + SO^{18}O$$

Ethyl benzoyloxysulfinate Ib, which is a close analog of the methyl ester Ia postulated above, had previously been obtained in a solution or in the sirupy liquid state.[1] This compound has now been found to be distillable in a high vacuum with only slight decomposition. The infrared spectrum of the distillated sample was almost the same as that already reported.[1]

Equimolar amounts of the labeled benzoic acid and phenyl chlorosulfite were treated with triethylamine in ether, whereas triethylamine hydrochloride was precipitated quantitatively. The filtrate exhibited strong infrared absorption bands at 1729 cm^{-1} (C=O) and 1230 cm^{-1} (S-O), suggesting the formation of phenyl benzoyloxysulfinate Ic. The evaporation of ether in a vacuum gave a colorless residue; this residue was pyrolyzed at 90—140°C for 2 hr., until no more sulfur dioxide evolved. When the product mixture was treated with aniline in carbon tetrachloride, 55 mol.% of benzanilide was precipitated. The filtrate was then evaporated, and the remaining oil was chromatographed to give 20 mol.% of phenyl benzoate. Its excess ^{18}O atom% was again almost one-half of that in the original benzoic acid. Consequently, the decomposition of the intermediate Ic may be considered to proceed by the acyl-oxygen splitting shown below:

$$Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}{}^{18}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OPh \longrightarrow$$

Ic

$$Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}OPh + SO^{18}O \quad (5)$$

The ^{18}O atom% of benzanilide should be the same as that of the carbonyl group of benzoic anhydride, which in turn may be expected to be the same as that in the original benzoic acid, provided this anhydride was formed straightforward, by disproportionation (6):

$$Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}{}^{18}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OPh \longrightarrow {}^1/_2Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}{}^{18}O\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}Ph$$

Ic

$$+ {}^1/_2(PhO)_2SO + {}^1/_2SO^{18}O \quad (6)$$

Actually, the ^{18}O atom % of benzanilide was found to be definitely lower than that of benzoic acid. This suggests that some kind of discrimination of the oxygen atoms must occur in the mixed anhydride, Ic.

If the ^{18}O atom% of the carbonyl group of benzoic anhydride could be postulated to be the same as that of benzanilide (1.29%), the ^{18}O atom % of phenyl benzoate, which would be formed by the interaction of two primary products (benzoic anhydride and diphenyl sulfite) in the reaction 7, as has been pointed out above, should be 0.75%:

$$Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}O\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}Ph + (PhO)_2SO$$

$$\longrightarrow 2\,Ph\text{-}\underset{\underset{{}^{18}O}{\|}}{C}\text{-}OPh + SO^{18}O \quad (7)$$

(the ether oxygen atom of benzoic anhydride may contain ^{18}O. In the reaction 7, Ph-O bond is assumed to be reserved.)

Actually, the value found (0.98 atom%) was much higher than that, and it coincided rather well with the figure calculated on the basis of the reaction 5. Therefore, the carboxylic ester may be considered to be formed by the direct decomposition of the mixed anhydride Ic, not by a secondary reaction such as 7, at least not in this case.

Experimental

The Preparation of Benzoic Acid-^{18}O.—A mixture of 25 g. of benzotrichloride and 10 g. of $H_2{}^{18}O$

(1.52 atom%) was refluxed for 15 hr., protected against atmospheric moisture. The resultant crystalline mass was warmed under reduced pressure in a water bath for 2 hr. in order to expel the hydrogen chloride formed and excess water. The residue was dissolved in a solution of 8 g. of sodium hydroxide in 50 ml. of water and concentrated. The sodium benzoate thus separated was recrystallized once from the distilled water and dried in a vacuum for 2 hr. at 100°C. The white mass was powdered finely and dried once more in a vacuum at 100°C for a few hours to give about 15 g. of sodium benzoate-^{18}O (first crop). The concentration of the mother liquid gave another 9 g. of the same salt (2nd crop), which was dissolved in water and acidified with diluted hydrochloric acid to give 6 g. of benzoic acid-^{18}O. The ^{18}O atom% of the first crop was 1.49%.

Methyl Chlorosulfite.—To 40 g. of thionyl chloride 10 g. of anhydrous methanol was slowly added; the mixture was left at room temperature for several days. Distillation under reduced pressure gave 24 g. of a fraction boiling at 35—37°C/60 mmHg.

The Reaction of the Labeled Sodium Benzoate with Methyl Chlorosulfite.—To 10.0 g. of sodium benzoate-^{18}O (first crop) 16 g. of methyl chlorosulfite (2 mol.) was added, whereupon the exothermic reaction occurred. The milky reaction mixture was then heated in an oil bath at 110—130°C for 2 hr., during which time a vigorous evolution of sulfur dioxide was observed. The residue was refluxed for 2 hr., while the bath temperature was slowly raised to 190°C. The cooled reaction mixture was treated with ether and water; the ether layer was separated, washed with a sodium hydrogen carbonate solution, and dried over magnesium sulfate, and finally the solvent was removed in a vacuum. The residue was repeatedly fractionally distilled under reduced pressure to give 1 g. of dimethyl sulfite (b. p. 40—45°C/25 mmHg), 0.5 g. of methyl benzoate (the purity was checked by the infrared spectrum), and about 4 g. of benzoic anhydride. The acidification of the alkaline washing gave 0.8 g. of the unchanged benzoic acid. The ^{18}O atom% of methyl benzoate was 0.83%. (The calculated value on the basis of the formula 4 is 0.85%.)

The Reaction of Benzoic Acid-^{18}O with Phenyl Chlorosulfite.—To a solution of 3.0 g. of benzoic acid-^{18}O (^{18}O: 1.65 atom%) and 4.4 g. of phenyl chlorosulfite (equimolar) in 55 ml. of anhydrous ether, 2.5 g. of triethylamine in 10 ml. of ether was added, whereupon the reaction started at once, forming a white crystalline precipitate. After a half hour, the mixture was filtered; this precipitate was recrystallized from ethanol-ether, and identified by means its infrared spectrum as triethylamine hydrochloride (its yield of the crude state was almost the theoretical). The ether filtrate of this salt exhibited infrared absorption at 1729, 1590, 1230, 770, 710, and 690 cm^{-1} (the 1500—1300, and 1200—1000 cm^{-1} regions could not be measured because of the strong absorption of ether). No absorption of benzoic acid at 1690 cm^{-1} was observed. Since phenyl chlorosulfite has a strong absorption at 1228 cm^{-1} and diphenyl sulfite, at 1230 cm^{-1}, the 1230 cm^{-1} band of the product may be attributed to the S–O stretching vibration. Ether was expelled from this solution on a water bath (no sulfur dioxide evolution was observed), and the residue was heated in an oil bath at 80°C in the beginning and then at 140°C in the last stage of the reaction. During the last stage sulfur dioxide evolved vigorously. Finally the oily residue was treated with water and ether, and the ether layer was washed with alkali, dried, and evaporated, leaving about 4 g. of the colorless oil. Since its infrared spectrum indicated the presence of a large amount of benzoic anhydride, the oil was dissolved in carbon tetrachloride and treated with 3 g. of aniline. The separated crystals (3.2 g.) were washed with water and recrystallized from ethanol to give 1.3 g. of benzanilide (identified by its infrared spectrum and m. p.). The carbon tetrachloride filtrate was washed with a sodium hydrogen carbonate solution, water, and diluted hydrochloric acid successively, dried, and evaporated to give 3 g. of a colorless sirup. The chromatography of this sirup on alumina with benzene gave 1.0 g. of phenyl benzoate-^{18}O, m. p. 64°C. The ^{18}O atom% of this specimen was 0.98%. (The value calculated on the basis of the formula 5 was 0.93%.)

Ethyl Benzoyloxysulfinate.—To 5.5 g. of dried sodium benzoate, 7.0 g. of ethyl chlorosulfite was added, and the reaction mixture was vacuum distilled. A colorless liquid was obtained at 85°C/0.2 mmHg; this liquid contained a slight amount of the leaflet of benzoic acid. The infrared spectrum of this ester was almost superimposable upon that reported in the preceding paper.[1] The formation of some benzoyl chloride was noticed in a low-boiling fraction.

Ib: 84.43 mg.; $BaSO_4$: 78.94 mg.

Found: S, 12.8%. Calcd. for $C_9H_{10}O_4S$: 14.9%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1785—1787 (1966)

Organic Sulfur Compounds. XI. The Reactions of the Cyclic Sulfites with the Aromatic Aldehydes

By Michio KOBAYASHI* and Akira YABE

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

and Reiko KIRITANI

Department of Chemistry, Radiation Center of Osaka Prefecture, Sakai, Osaka

(Received January 5, 1966)

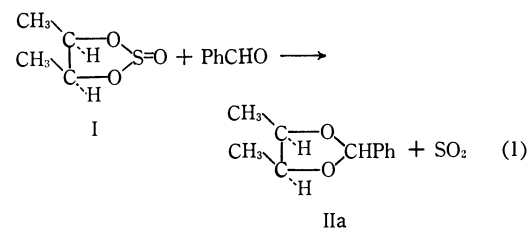
The reactions of the cyclic sulfites with aldehydes to give the cyclic acetals have been investigated with the stereochemical and with the ^{18}O tracer technique. Both groups of evidence have indicated that the bonds broken are the S–O, not the C–O bond, of the sulfites.

The formation of the acetals from the aldehydes and alkyl sulfites has long been known.[1] Recently, the reaction of ethylene sulfite with the carbonyl compounds to give the cyclic acetals or ketals has also been described.[2] These reactions are catalyzed with hydrogen chloride, without which no reaction has been observed. In order to clarify the mechanism of the latter reaction, the present investigation has been carried out.

Results and Discussion

Stereochemical Study.—The reaction of *meso*-2, 3-butylene sulfite (2-oxo-4, 5-dimethyl-1, 3, 2-dioxothiolane) (I) with benzaldehyde was examined in an attempt to find which bond in the cyclic sulfite was broken in the acetal formation. I was prepared from thionyl chloride and *meso*-2, 3-butanediol. There could exist two configurational isomers in I, one with sulfoxide oxygen in an axial position, Ia, and the other with that oxygen in an equatorial position, Ib. This kind of problem has attracted much interest recently, and several studies by means of infrared spectroscopy or NMR have been published.[3,4] In the case of *meso*-diphenylethylene sulfite, these two isomers have been isolated in the crystalline state.[4] Indeed, it has been pointed out that the ordinary I is a mixture of Ia and Ib, which could be separated incompletely by the gas liquid chromatography.[4] However, these two isomerides, the existence of which depends on the pyramidal configuration of the sulfoxide group, would be tautomerized to each other in the presence of the acid catalyst, since the optically active sulfoxides have been reported to undergo racemization very easily in the presence of hydrochloric acid.[5] Therefore, no effort was made to use the pure configurational isomer in the present investigation. (Incidentally, the configuration of *dl*-2, 3-butanediol has been shown not to change during the formation of the cyclic sulfite, *dl*-2, 3-butylene sulfite.[4])

When I and benzaldehyde were refluxed in dioxane in the presence of hydrogen chloride, 2-phenyl-4, 5-dimethyl-1, 3-dioxolane (II) was obtained in a 50% yield. The identity of this product with 2-phenyl-*cis*-4, 5-dimethyl-1, 3-dioxolane IIa, prepared directly from *meso*-2, 3-butanediol and benzaldehyde, was established by the infrared spectroscopy and gas liquid chromatography. Symmetric structure of II was confirmed by NMR spectroscopy.



(1)

On the other hand, the reaction of *dl*-2, 3-butanediol with benzaldehyde gave 2-phenyl-*dl*-*trans*-4, 5-dimethyl-1, 3-dioxolane IIb, which exhibited the different NMR and infrared spectrum from those of the product II. The retention time of IIb in the gas liquid chromatography was shorter than that of II.

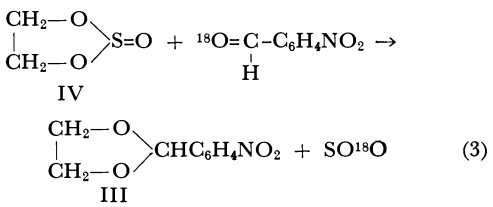
Since it seems to be well understood that the C–O bond of the alcohols is retained in the acetal formation,[6] the above result may be considered to indicate the retention of the C–O bond in the cyclic sulfite in the reaction with aldehydes.

Isotope Tracer Study.—However, in the reaction described above, two successive inversions of the configuration around the asymmetric carbon atoms of the cyclic sulfite, one in each step involving C–O fission in the sulfite, could give *meso*-acetal from *meso*-sulfite. To confirm further the absence of the C–O bond fission of the sulfite in this type of reaction, the reaction of ethylene sulfite, IV, with *p*-nitrobenzaldehyde-[carbonyl-^{18}O] was examined. In the presence of hydrogen chloride, 2-*p*-nitrophenyl-1, 3-dioxolane III was produced in a 60% yield; this was found to contain no excess ^{18}O.



IV

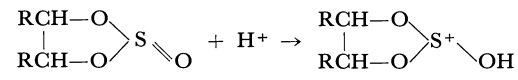
III (3)

Consequently, from both of the stereochemical results and the isotope tracer study, it may be concluded that the C–O bond of the cyclic sulfite remained intact in the reaction with aldehydes to form the cyclic acetals.

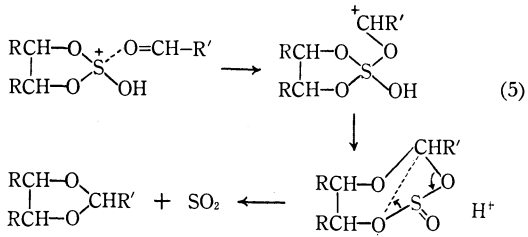
The mechanism of the hydrolysis of the cyclic sulfites has been investigated kinetically,[7-8] with the ^{18}O tracer technique[10] and stereochemically;[11] it is now firmly established that S–O bonds are broken in the reaction under acidic conditions, and that C–O bond fission has never been observed. Also, the reaction of alcohols with the carbonyl compounds to form acetals or ketals,[6] and the hydrolysis of the acetals or ketals to reverse the above reaction,[12] are both considered to involve the retention of the C–O bond in the alcohol part. The formation of the cyclic acetals from the sulfites investigated in the present research seems to conform with these findings regarding related reactions.

The reaction of IV with benzaldehyde was carried out in the presence of boron trifluoride etherate or trifluoroacetic acid in order to examine their catalytic properties. In the presence of boron trifluoride, IV gave no cyclic acetal; instead, a large amount of the polymeric substance was produced. With trifluoroacetic acid, the formation of acetal, 2-phenyl-1, 3-dioxolane (V), was observed, but the yield was not improved over that obtained with hydrogen chloride.

The following reaction mechanism may tentatively be considered as one possibility for the reaction investigated in this paper:



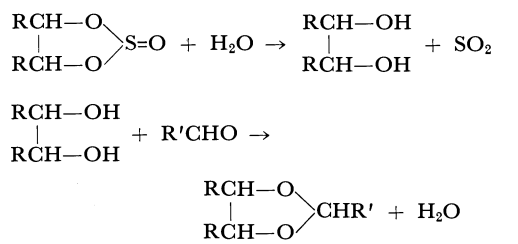
(4)



(5)

The addition of the proton to the cyclic sulfite (reaction 4) is a reversible, very fast step.[8] The attack on this protonated species by the nucleophilic reagent, somewhat as in the reaction 5, has been postulated to explain the catalytic property of the halides anion in the hydrolysis of the sulfites.[7,8]

Finally, it should be noticed that the following possibility can not be lightly excluded despite the denial of Hesse[2]—the possibility that the sulfite is hydrolyzed by a trace of water to give the glycols, which in turn react with aldehydes to form the cyclic acetals and to regenerate the equimolar water, with this water starting a new cycle. In the present stage of investigation, there is at least no definite evidence against this alternative.



Experimental

***meso*-2, 3-Butylene Sulfite (I).**—The starting material, *meso*-2, 3-butanediol, was a commercial product and was purified by distillation twice before use; b. p. 65°C/7 mmHg; lit.[13] 89°C/16 mmHg; 127°C/101 mmHg.[10] It gave di-*p*-nitrobenzoate, m. p. 188°C,

13) C. E. Wilson and H. J. Lucas, ibid., **58**, 2396 (1936).

in a yield more than 80%. *meso*-2, 3-Butylene sulfite was prepared from 17 g. of the above glycol and 23 g. of thionyl chloride at 40°C, and a fraction boiling at 83—85°C/35 mmHg was collected (lit.[10] b. p. 67°C/8 mmHg; 181—189°C[14]). The infrared spectrum of the product coincided with that in the literature,[10] except for the presence of a 1059 cm^{-1} absorption instead of the 1099 cm^{-1} in that paper.

2-Phenyl-*cis*-4, 5-dimethyl-1, 3-dioxolane (IIa).—A mixture of 5 g. of *meso*-2, 3-butanediol, 6 g. of benzaldehyde and a few drops of 40% sulfuric acid was warmed on a water bath for 28 hr. and extracted with benzene; the product was purified by the vacuum distillation twice. B. p. 97—99°C/5 mmHg; lit.[15] 109—110°C/10 mmHg.

The Reaction of *meso*-2, 3-Butylene Sulfite with Benzaldehyde.—Hydrogen chloride was bubbled into a mixture of 6 g. of I, 5 g. of freshly-distilled benzaldehyde and 10 ml. of purified dioxane.[16] After it had been refluxed for 25.5 hr., the mixture was diluted with benzene, washed with a sodium hydrogen carbonate solution, water, and a sodium hydrogen sulfite solution, warmed with a sodium hydroxide solution, dried, and finally vacuum distilled to give a fraction boiling at 93—94°C/4 mmHg. Its infrared spectrum was superimposable upon that of IIa.

dl-2, 3-Butanediol was prepared from the *meso*-isomer by the following reaction sequence: *meso*-glycol→*meso*-2, 3-diacetate (b. p. 90—93°C/20 mmHg; lit.[13] 66°C/5.5 mmHg)→*dl-threo*-3-chloro-2-butanol (b. p. 52°C/28—30 mmHg; lit.[17] 52°C/30 mmHg)→*cis*-2, 3-epoxybutane[17]→*dl-trans*-2, 3-butanediol (b. p. 71°C/4 mmHg; lit.[13] 86°C/16 mmHg). It gave *dl*-di-*p*-nitrobenzoate, m. p. 130°C; lit. 128.5°C.

2-Phenyl-*dl-trans*-4, 5-dimethyl-1, 3-dioxolane (IIb).—A mixture of 1.2 g. of *dl*-2, 3-butanediol, 1.48 g. of benzaldehyde, and one drop of 40% sulfuric acid was heated on a water bath for 26 hr. The reaction mixture was then treated as in the case of *meso*-isomer, and finally purified by chromatography on alumina with petroleum ether, followed by vacuum distillation; this gave 90 mg. of IIb as a colorless liquid.

Found: C, 74.43; H, 8.19. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.91%.

The Preparation of *p*-Nitrobenzaldehyde-[carbonyl-^{18}O].—To a solution of *p*-nitrobenzylidenaniline (10 g.), and 10 g. of $H_2{}^{18}O$ (1.52 atom%) in 80 ml. of anhydrous dioxane, 5 ml. of concentrated sulfuric acid was added. After the mixture had been warmed on a water bath, two layers were separated. After it had been diluted with 150 ml. of benzene, the organic layer was washed with a sodium hydrogen carbonate solution and water, dried over magnesium sulfate, and evaporated. The crystalline residue was purified from petroleum ether to give 5.5 g. of the labeled aldehyde (84%). Its ^{18}O atom% was 0.61%.

Ethylene Sulfite.—Prepared from ethylene glycol and thionyl chloride; b. p. 72°C/22 mmHg. Lit. 94°C/43 mmHg, 84°C/38 mmHg[9]; 88°C/52 mmHg[10]; 86—88°C/38 mmHg[18]; 90°C/42 mmHg[19]; 63°C/13 mmHg[3].

The Reaction of Ethylene Sulfite with *p*-Nitrobenzaldehyde-^{18}O.—Hydrogen chloride was introduced into a solution of 5 g. of the labeled aldehyde and 4 g. of ethylene sulfite in 20 ml. of anhydrous dioxane, and the mixture was refluxed in an oil bath for 34 hr. Dioxane was removed in a vacuum, and the residue was dissolved in 100 ml. of benzene, washed with aqueous sodium hydrogen carbonate, dried, and evaporated. The remaining crystals were purified by chromatography on alumina with benzene and recrystallization from petroleum ether or carbon tetrachloride to give 3.10 g. of 2-*p*-nitrophenyl-1, 3-dioxolane (III), m. p. 89—91°C, in a 46% yield. Its ^{18}O atom % was normal (0.21%). The infrared spectrum of this specimen was the same as that of the product, m. p. 90°C, prepared by warming 20 g. of ethylene glycol, 3 g. of *p*-nitrobenzaldehyde, and a few drops of 40% sulfuric acid for 33 hr. The ^{18}O atom% of the unchanged *p*-nitrobenzaldehyde recovered in a low yield, contaminated with some acetal (III), was 0.35%.

Gas liquid chromatography measurements were performed on Hitachi KGL-2 using 6 m column packed with silicone KF 54. The column was operated at 206°C with a flow of 30 ml. nitrogen per minute. Retention times were: II and IIa, 14.2 min; IIb, 12.0 min.

NMR spectra were run on a Varian A 60A NMR Spectrometer operating 60 Mc./sec. TMS was used as an internal standard for solutions in carbon tetrachloride. The chemical shift values of II was as shown below:

Chemical shift (τ)	Number of H	Splitting	Assignment
8.83	6	Doublet $J=6.0$ c/s	Methyl
5.83	2	Multiplet	H at C_4 and C_5
2.72	5	Multiplet	Aromatic

Thanks are due to Mr. Shozo Masuda of the Department of Chemistry, The University of Tokyo, for his elemental analyses.

Organic Sulfur Compounds. XII. The Ultraviolet and Infrared Spectra of the Substituted Benzenesulfinic Acids and Their Esters

By Michio KOBAYASHI* and Nobuko KOGA

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received January 7, 1966)

The ultraviolet spectra of several substituted benzenesulfinic acids and their ethyl esters have been recorded, and the assignments of the absorption have been disucssed briefly.

There have been relatively few studies of the ultraviolet spectra of the sulfinic acids and their esters, although many systematic investigations have been published on the related sulfoxides, sulfones and sulfides.[1-3] Detoni and her collaborator[4] measured the ultraviolet spectra of benzenesulfinic acid and *p*-toluenesulfinic acid in ethanol, but no discussion was given. Bredereck et al.[5] studied the ultraviolet spectra of the above two compounds in heptane, methanol and water; they found that the spectra of the dissociated anion was overlapped on those of the free acid in the hydroxylic solvents. They pointed out the close similarity between the spectrum of the undissociated acid and that of the corresponding ester, and also the presence of a similar absorption band in the spectrum of the sulfoxide. Later, Ritchie[6] estimated the dissociation constants of several benzenesulfinic acid derivatives by the ultraviolet spectroscopic method, but he presented no details of the spectra themselves.

Results and Discussion

The ultraviolet Spectra of the Sulfinic Acids in Water.—The ultraviolet spectrum of the sulfinic acid in water is actually that of the completely dissociated anion, as has been pointed out by Bredereck,[5] since the sulfinic acid has a rather strong acid character. When the solution was increased in acidity by the addition of hydrochloric acid, the absorption spectrum of the undissociated acid appeared, making it possible to estimate the dissociation constant of the sulfinic acid. For example, the pK_a of *p*-chlorobenzenesulfinic acid could be estimated as 1.14 from the absorption curves shown in Fig. 1.

Aliphatic sulfinic acid exhibited no absorption maximum in the ordinary ultraviolet region, as may be seen in Fig. 2. This fact indicates that both the π-π^* and n-dπ transitions in the SO_2H or the SO_2^- group need high energies corresponding to absorptions well below 200 mμ; This situation may be easily understood by considering that the aliphatic sulfoxides have an n-dπ absorption at around 210 mμ.[1e]

The values of the absorption maxima of the substituted benzenesulfinic acids and their anion are listed in Table I.

The spectra of the anions are very close to those of the parent mono-substituted benzenes in the shape of the absorption curve and also in the wavelength of the band maximum. Only slight red shifts

are observed in the maximum of the ^1L_a band compared to those of the corresponding mono-substituted benzenes, suggesting the weakness of the interaction between the sulfinate anion group and the π-electron orbitals of the benzene ring.

The Stuart model of the molecule suggested the presence of a large steric interference between the sulfinate group and a bulky *o*-substituent. Although *o*-nitrobenzenesulfinic acid has almost the same absorption maximum as that of the *p*-isomer, its extinction coefficient is smaller by 0.3 unit in log ε, suggesting that the nitro group is rotated out of the benzene plane to some degree.

In the absorption spectra of the undissociated acids, the presence in 240—260 mμ of a new absorption should be noticed, an absorption which is not observed in the anion. Since similar absorptions are observed in the alkyl aryl sulfoxides, this band will here be designated as the W-band, according to the Jaffé's notation.[3c] A similar band exists in the spectrum of the corresponding ethyl sulfinates, as is shown in Table II. This W-band may be attributed to an excitation of the lone pair electrons of the sulfur atom into an antibonding orbital of the S–O bond or into a vacant 3d orbital of the sulfur atom (this difference depends only on the amount of the double bond character of the sulfoxide S–O bond; the exact estimation is still open to debate); the band appears in a longer wavelength region than the bands of the aliphatic sulfoxides, as a result of the conjugation to the benzene ring. Another postulation involving the excitation of a lone pair of the sulfur atom to an unoccupied orbitals of the aromatic electron system rather than to the sulfinyl group is also possible. With *p*-toluenesulfinic acid, this W-band shifts its maximum from 255 mμ in heptane,[5] over 245 mμ in ethanol to 240 mμ in diluted hydrochloric acid, and thus reveals its n-electron donating character. In the sulfinate anions, this W-band shifts to a much lower wavelength, under 200 mμ, as a result of the contribution of the negatively charged oxygen atom; this situation is the same as in the case of the carboxylic acid and its anion. Since *o*-toluenesulfinic acid, in which the sulfinoxy group is considered to rotate out of the benzene plane due to interaction with a bulky *o*-methyl group, shows its W-band at nearly the same wavelength as in the *p*-isomer, the coplanarity seems

not to be an important requirement in the conjugation between the sulfinyl group and the aromatic π-electron system, as is the case in the aromatic sulfones.[3a,3c,7,8] The existence of the W-band in nitro or carboxyl substituted benzenesulfinic acids is not clear due to the superposition of a strong charge transfer band in these compounds.

The Ultraviolet Absorption of the Ethyl Ester of the Substituted Benzenesulfinic Acids. —These are shown in Table II. Aliphatic sulfinate ester exhibited only an end absorption in the ultraviolet region, as in the free acid, indicating the high transition energy of the n-dπ excitation in the sulfinate ester group (Fig. 2).

TABLE II. ULTRAVIOLET SPECTRA OF ETHYL BENZENESULFINATES

λ_{max} (mμ) and log ε (in parenthesis)

Substituent	Solvent	^1L_a	W+^1L_b
H	Methanol	216 (3.89)	246 (3.52)
	n-Hexane	215 (3.96)	257 (3.46)

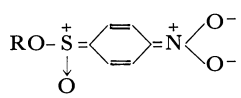
* Broad band, probably superposition of ^1L_a and W+^1L_b.
** Charge transfer band.
*** Shoulder.

There are two absorptions of distinctly different characters in the ultraviolet spectra of the substituted benzenesulfinic esters, one at a short wavelength, similar to the ^1L_a band of the corresponding mono-substituted benzenes, and the other in the long wavelength side. The shifts of the ^1L_a band from the position of the parent mono-substituted benzene are slightly larger than those in the sulfinate anion, suggesting a somewhat stronger interaction of the sulfinate ester group with the aromatic π-orbital than that of the sulfinate anion group, although the interaction is still weak compared with those of nitro or carbonyl groups.

The long wavelength band is considered to be an overlapping of the W-band and ^1L_b band. The optical active property of the W-band has been demonstrated clearly by optical rotatory dispersion and circular dichroism measurements of the optically active *l*-menthyl *p*-toluenesulfinate and *p*-methoxybenzenesulfinate,[7] thus confirming the assignment of this transition to a sulfinyl group origin, although in that earlier paper the long wavelength band has been postulated to be an overlapping of a pertubed ^1L_a benzene transition and the W-band. Discussing the problem of the stereochemistry of the sulfoxides and sulfinate esters, Mislow et al.[8b] assumed the long wavelength band to be arisen from the interaction of the ^1L_b band with the sulfoxide $(3sp^3)^2 \rightarrow (3sp^3)(3d)$ transition.

The absorption maximum of the long wavelength band does not vary much with the kind of substituent. In the *p*-methoxy derivative, the W-band shows slight blue shift, which is characteristic of n-π transition. In *p*-nitro and *p*-cyano derivatives, the existence of the W-band again becomes uncertain; probably it is covered by the absorption of the strong charge transfer band. The 250 mμ absorption of ethyl *p*-nitrobenzenesulfinate shows a red shift in a polar solvent, suggesting that this band is a charge transfer band, similar to that of nitrobenzene.[9] Since the absorption maximum of this compound does not differ much compared with that of nitrobenzene itself (252 mμ in heptane, 259.5 mμ in ethanol), the contribution of the lone pair of the sulfur atom could not be ascertained reliably, but the increased extinction coefficient of the long wavelength band suggests the overlapping of the W-band on the 280 mμ band of nitrobenzene or on the 271 mμ band of *p*-cyano derivative (both ^1L_b bands). The hypsochromic shift of these long wavelength bands in a polar solvent also supports this interpretation. If this could be true, the W-band may be said to show a large red shift upon coupling with an electron attractive substituent. On the other hand, the nearly-same position of the charge transfer excitation around 250 mμ seems to indicate the absence of a large contribution of the electrometric polar form in the excited state, as shown below:



In this respect, the sulfinoxy group differs greatly from the sulfide group (for instance, *p*-nitrothioanisol has λ_{max} at 338 mμ, with log ε=4.12).

In conclusion, the sulfinoxy group and the alkoxysulfinyl group may be considered to have only a weak electron attractive conjugation property,

and at the same time to be very weakly electron donating.

The Infrared Spectra of the Ethyl Esters of Substituted Benzenesulfinic Acids.—The spectra were measured in carbon tetrachloride and also in the pure liquid state. The wave numbers of the S–O stretching vibration are shown in Table III. The absorption maximum in the pure liquid is slightly lower in wave number (2—9 cm^{-1}) than that in a solution, probably because of the association. Ethyl *n*-butanesulfinate absorbs at 1132 cm^{-1} (CCl_4, and neat), which is almost the same as, or even rather lower than, the S–O stretching of ethyl benzenesulfinate. A similar phenomenon has been observed in the sulfoxides[10] and interpreted as indicating the absence of any strong conjugation between the aromatic ring and the sulfinyl group.

Table III. Infrared spectra of ethyl benzenesulfinates. S–O Stretching vibration in cm^{-1}

Substituent	H	*p*-CH_3	*p*-CH_3O	*p*-Cl	*p*-Br	*p*-NO_2
Neat	1132	1134	1126	1136	1138	1138
in CCl_4	1136	1136	1135	1142	1142	1149

The Hammett plot of the wave numbers of the S–O stretching against σ value shows a approximately linear correlation. Since there have been closely related studies of the methyl esters of the substituted benzenesulfinic acids,[11] further discussion will be omitted here.

Experimental

Materials.—*n*-Butanesulfinic acid was prepared from *n*-butyl bromide by the Grignard method.[12] Ethyl *n*-butanesulfinate was synthesized from sulfinyl chloride and ethanol, and boiled at 80°C/10 mmHg.[13] *o*-Toluenesulfinic acid, m. p. 80°C, was prepared from sulfonyl chloride by reduction with zinc. *p*-Chlorobenzenesulfinic acid, m. p. 93—94°C, was obtained by saturating a *p*-chlorobenzenediazonium chloride solution with sulfur dioxide.[14] *p*-Bromobenzenesulfinic acid, m. p. 114°C, was prepared by Friedel-Crafts' synthesis from bromobenzene and sulfur dioxide.[15] *p*-Methoxybenzenesulfinic acid, m. p. 97—98°C, was prepared from anisol in a similar way and was purified from water.[15] *o*-Methoxy derivative, m. p. 98—99°C, was prepared from diazotized *p*-anisidine.[16] *p*-Acetylaminobenzenesulfinic acid, m. p. 155°C (with decomposition), was prepared by reducing sulfonyl chloride with sodium sulfite.[17] *p*-Nitrobenzenesulfinic acid, m. p. 135°C, was obtained in a similar way.[18] *o*-Nitro-derivative, m. p. 130°C, was prepared by reducing sulfonyl chloride with stannous chloride and hydrochloric acid in ethanol.[19] *o*-Carboxybenzenesulfinic acid, m. p. 125°C, was obtained by the diazonium method and was recrystallized from acetic acid.[16] Ethyl esters of the benzenesulfinic acids was prepared by treating the sodium salt with ethyl chlorocarbonate in ethanol.[20]

The ultraviolet spectra were taken on a Beckmann DU quartz spectrophotometer. The concentration of the solution was 10^{-4}—10^{-5} mol./l. The infrared spectra were recorded with a Perkin-Elmer infrared spectrometer Model 21. The dissociation constants were calculated from the variation of the transmission with the change in pH. The pK_a values obtained for benzenesulfinic acid, *p*-toluenesulfinic acid and *p*-chlorobenzenesulfinic acid were 1.58, 1.70 and 1.14 respectively. The figures in the literature are 1.29,[21] 1.46,[22] 1.84,[23] 1.21[6] for the first compound; 1.60,[22] 1.99,[23] 1.24[6] for the second, and 1.09 for *p*-bromobenzenesulfinic acid.[6]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1792—1795 (1966)

Studies on Reactions of Polypropyrene. VI. The Thermal Degradation of Polypropylene Accelerated by the Fine Powdery Polymer with Closslinkage

By Yukio MIZUTANI, Keiichi YAMAMOTO and Seishiro MATSUOKA

Tokuyama Soda Co., Ltd., Tokuyama, Yamaguchi

(Received November 29, 1965)

The thermal degradation of polypropylene was investigated in the presence of the fine powdery polymer with crosslinkage by the use of an extruder under a nitrogen atmosphere. The fine powdery polymer was thus found to be effective as an accelerator for the thermal degradation of polypropylene. The fine powdery polymer used was prepared by the emulsion polymerization of some vinyl monomers and divinyl benzene or by the polymerization of glycidyl methacrylate and divinyl benzene in *n*-heptane. The fine powdery polymer consisting of glycidyl methacrylate and divinyl benzene was preferable to that with no reactive functional group, because of the reactivity of the glycidyl group. The polypropylene was modified and made dyeable by the thermal degradation accelerated by the fine powdery polymer.

It is well known that there are a few drawbacks to the practical uses of polypropylene; such as the poor flow properties resulting from its very high molecular weight, and the poor dyeability resulting from its nonpolarity and its high crystallinity. Therefore, many processes have been proposed to overcome these drawbacks.[1-10] In the thermal degradative process accelerated by such vinyl polymers as polystyrene and polymethyl methacrylate, graft or block copolymers were formed, and the poor dyeability of polypropylene could be modified.[11] However, some of the vinyl polymers used in this process were extractable by acetone, and it was considered to be undesirable for practical use.

In this paper, the fine powdery polymer with crosslinkage (FPC) was used as an accelerator for the thermal degradation of polypropylene. The thermal degradation was carried out by the use of an extruder, so this simple process should be practically useful.

Experimental

Materials.—The polypropylene (PP) powder used was under 30 mesh and contained no stabilizer. The properties of the polypropylene samples were as follows:

PP(A) melt index (at 230°C, load: 2.16 kg./cm.^{2}): 0.25 g./10 min., specific gravity: 0.912, and grain size: under 30 mesh.

PP(B) melt index (at 230°C, load: 2.16 kg./cm.^{2}): less than 0.01 g./10 min., specific gravity: 0.913, and grain size: under 30 mesh.

All the reagents, such as vinyl monomers, divinyl benzene (DVB), and solvents, were of chemical grade. The DVB content in commercial DVB was 50% by weight.

The Preparation of the Fine Powdery Polymer by the Emulsion Polymerization (EPC·E).—The vinyl monomers and DVB were polymerized by stirring at 80°C for 2—3 hr. under a nitrogen atomsphere. Then, the polymer was salted out, washed with water,

TABLE I. THE EXAMPLES OE THE PREPARATION OF FPC·E

Sample	Vinyl monomer, g.			DVB g.	Yield %
	Styrene	2-Methyl 5-vinyl pyridine	Methyl acrylate		
FPC·E-1	24	—	—	1	84
FPC·E-2	—	12	12	1	80
FPC·E-3	—	24	—	1	80
FPC·E-4	—	—	24	1	82

The quantities of water and Monogen-W were 300 cc. and 2 g. respectively.

Monogen-W was the emulsifier from Daiichi Kogyo Seiyaku Co., Ltd.

and dried at 70°C under a vacuum. An example of the polymerization is shown in Table I. Potassium persulfate was used as an initiator of the polymerization.

The Preparation of the Fine Powdery Polymer by the Polymerization of Glycidyl Methacrylate and DVB in *n*-Heptane (FPC·H).—Glycidyl methacrylate (GMA) and DVB were polymerized in *n*-heptane by stirring at 70°C for 5—6 hr. under a nitrogen atmosphere. Benzoyl peroxide was used as an initiator of the polymerization. The polymer prepared was filtered, washed with petroleum ether and dried under a vacuum. An example of the polymerization is shown in Table II.

Table II. The examples of the preparation of FPC·H

Sample	GMA g.	DVB g.	DVB*/(GMA+DVB)	*n*-Heptane cc.	BPO** g.	Yield %
FPC·H-1	190	10	0.025	2800	10	83
FPC·H-2	180	20	0.050	2800	10	82
FPC·H-3	170	30	0.075	2800	10	84

* Pure DVB
** Benzoyl peroxide

Blending.—FPC was dispersed in a solvent beforehand by the use of a mixer; then the polypropylene powder was added to the mixer, and the slurry was well mixed. The polymers were then filtered out and dried under a vacuum. The solvents used were methanol for FPC·E and *n*-heptane for FPC·H.

The Thermal Degradation.—The thermal degradation was carried out by the use of the extruder, which was a modification[11] of Type MK-1 from Modern Machinery Co., Ltd. The heating zone of the extruder was divided into three parts: T_1, T_2, and T_3, which show the temperatures of the three parts, the part near the sample inlet, the middle part, and the part near the sample outlet respectively, as has been shown in a preceding paper.[11]

The Determination of the Glycidyl Group Content.—The polymer extruded was powdered by reprecipitation; the polymer was then dissolved in hot *p*-xylene, and the hot solution was cooled slowly. Then the slurry obtained was stirred into methanol in a mixer. The powdered polymer was filtered, washed with methanol, and dried under a vacuum. The content of the glycidyl group was determined by the method used by Iwakura et al.[4] The powdered polymer (2 g.) was immersed in a solution of 25 ml. of dioxane and 20 ml. of a 0.1 N dioxane solution of hydrochloric acid. The mixture was then allowed to stand overnight, and the excess hydrochloric acid was titrated with a 0.1 N aqueous solution of sodium hydroxide, using phenolphthalein as an indicator.

Results and Discussion

The Thermal Degradation Accelerated by FPC·E.—It is beyond question that the change in intrinsic viscosity is the most preferable measure of the degree of the degradation, but the melt index was used in this study because FPC used was insoluble in any solvent.

Table III. The results of the thermal degradation of PP(A) accelerated by EPC·E

Sample	Reaction temp., °C T_1	T_2	T_3	Melt index g./10 min.
PP(A)	220	300	270	0.6
PP(A)	220	320	290	0.8
PP(A)-FPC·E-1	220	320	290	4.2
PP(A)-FPC·E-2	220	300	270	3.2
PP(A)-FPC·E-3	220	320	290	3.2
PP(A)-FPC·E-4	220	320	290	3.4

The quantity of FPC added was 5% by weight
The rotating speed of the screw shaft was 20 r.p.m.

Table III shows the results of the thermal degradation. It was established that FPC·E was effective as an accelerator for the thermal degradation of polypropylene. No vinyl polymer was extracted by acetone from the extruded polymer. This was considered to be reasonable, because FPC·E was crosslinked by DVB. However, although FPC·E was effective as an accelerator, FPC·E is practically inferior to FPC·H for the following reasons:

1) FPC·E is contaminated by the emulsifier, so the surface of FPC·E is hydrophilic and is therefore poor in affinity with polypropylene.

2) FPC·E is separated by salting-out from the emulsion and is strongly agglomerated; therefore, it is inferior to FPC·H because the blend of FPC·E to polypropylene is not easier than that of FPC·H.

3) FPC·E is prepared in water, so monomers with a reactive functional group can not be polymerized often.

The Thermal Degradation Accelerated by FPC·H.—In Table IV, it is shown that FPC·H was effective as an accelerator for the thermal degradation of polypropylene and that the degree of degradation increased with the elevating of the reaction temperature.

Table IV. The temperature effect on the thermal degradation of PP(B) accelerated by FPC·H-2

The quantity of FPC·H-2 added, %	Reaction temp., °C T_1	T_2	T_3	Melt index g./10 min.
0	220	325	280	0.01
6.5	220	280	280	0.12
6.5	220	310	280	0.6
6.5	220	325	280	2.6

The rotating speed of the screw shaft was 20 r.p.m.

Figure 1 shows the effect of the rotating speed of the screw shaft, which was related to the retention time of the polymer in the extruder. With the increase in the rotating speed, namely, with the decrease in the retention time of the polymer, the degree of degradation decreased. The shearing

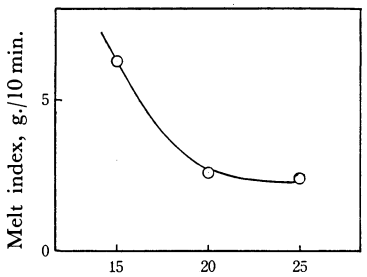

Fig. 1. The effect of the rotating speed of the screw shaft of the extruder on the thermal degradation of PP(B).
The content of FPC·H-2 added: 6.5%
Reaction temperature: T_1=230°C, T_2=325°C, and T_3=280°C
Retention time: about 5 min. for 15 r.p.m.
about 4 min. for 20 r.p.m.
and about 3 min. for 25 r.p.m.

effect of the screw shaft is negligible, because the shearing effect has a negative temperature coefficient;[12] no degradation of polypropylene ([η]: 4.3 dl./g. at 135°C in tetraline) was observed under the following conditions: T_1: 190°C, T_2: 240°C, T_3: 200°C, and the rotating speed of the screw shaft: 30 r. p. m.[11] The mixing effect of the screw shaft and the trace of oxygen due to the imperfect air-tightness of the extruder are questionable; however, they can not be explained in detail now.

Fig. 2 shows that with the increase in the FPC·H content, the melt index increased.

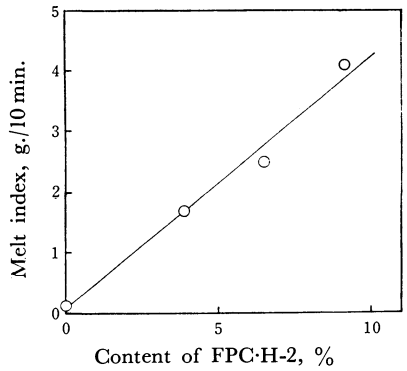

Fig. 2. The effect of the content of FPC·H-2 on the thermal degradation of PP(B).
Reaction temperature: T_1=220°C, T_2=325°C, and T_3=280°C
The rotating speed of the screw shaft: 20 r.p.m.

Figure 3 shows the effect of the DVB content of FPC·H. With the increase in the DVB content, the melt index decreased; namely, the accelerating effect of FPC·H decreased. This can be explained

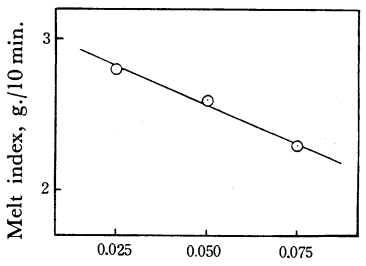

Fig. 3. The effect of the DVB content of EPC·H on the thermal degradation of PP(B).
The content of FPC·H: 6.5%
Reaction temperature: T_1=220°C, T_2=325°C, and T_3=280°C
The rotating speed of the screw shaft: 20 r.p.m.

in term of the fact that the rate of the degradation of polystyrene crosslinked by DVB decreases with the increase in the DVB content.[13]

As has been described above, FPC·H containing the glycidyl group was effective in accelerating the thermal degradation of polypropylene. Furthermore, the glycidyl group must survive after the degradation of polypropylene in order to hold its reactivity. Therefore, the change in the content of the glycidyl group was determined by measuring the contents before and after extruding. Table V shows that the greater part of the glycidyl group

TABLE V. THE GLYCIDYL GROUP CONTENTS BEFORE AND AFTER EXTRUDING

Sample	Reaction temp. °C			Glycidyl group content	Ratio of glycidyl group content S-2/S-1 or S-3/S-1
	T_1	T_2	T_3	mmol./g	
S-1	—	—	—	0.33	—
S-2	220	240	220	0.31	0.91
S-3	220	325	280	0.25	0.76

The rotating speed of the screw shaft was 20-r.p.m.
PP(B) and FPC·H-2 were used.

survived after extruding. This could be explained in terms of the fact that the glycidyl group generally reacts under ionic conditions and is not changed by the radical polymerization for the preparation of FPC·H or by the thermal degradation of polypropylene, which is also a radical reaction.[14]

Because the smell of glycidyl methacrylate was perceived during the extrusion, the degradation of FPC·H to the monomer seems to have occurred, although the quantity of the monomer liberated was probably not much. The active radical generated in the degradation of FPC to the monomer

may be effective in accelerating the thermal degradation of polypropylene, but the accelerating effect of FPC should be inferior to that of a linear vinyl polymer, as FPC was crosslinked by DVB, and the degradation rate of FPC should be slower than that of a linear vinyl polymer. Furthermore, interactions among the vinyl monomer liberated, FPC radicals, polypropylene radicals, and polypropylene molecules may be presumed to have occurred. This presumption is supported by the fact that, when a linear vinyl polymer was used in place of FPC, graft or block copolymer were detected.[11]

Dyeability.—The utility of a reactive polymer is well known.[15-17] The modification of polypropylene by glycidyl methacrylate has been reported already: the graft copolymer has been prepared[4] and the glycidyl methacrylate copolymer has been blended to polypropylene.[7] When the fiber of the modified polypropylene was dyed by a dye which has a functional group reactive with the glycidyl group, the dye could be perfectly fixed in the fiber, as determined by extraction with acetone.[7] The thin film (0.15 mm. in thickness) was molded from the extruded polymer and was dyed with such dispersion dyes as Estrol Fast Violet B, Estrol Orange 5R and Celliton Blue Extra by the ordinary method.[7] The film containg FPC·E was well dyed, but the dyed film was decolored by the extraction with acetone. On the other hand, the film containing the glycidyl group (FPC·H) was well dyed and the dyed film was not decolored with acetone. This fact was an evidence showing the utility of FPC·H as a reactive polymer. Also, it was elucidated by microscopic observation that FPC dispersed in polypropylene was well dyed, while polypropylene itself was not dyed.

Conclusion

The fine powdery polymer with crosslinkage was effective as an accelerator in the thermal degradation of polypropylene and also as a mordant in the dyeing of polypropylene. Among several polymeric systems, the fine powder of the glycidyl methacrylate - divinyl benzene polymer was preferable because of the reactivity of the glycidyl group.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1795—1800 (1966)

The Syntheses of Polypyromellitimide-amides*

By Motoo SAGA, Toshiyuki SHONO and Koichiro SHINRA

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received December 6, 1965)

Dibasic acids containing a pyromellitimide ring were synthesized by the reaction of pyromellitic dianhydride with such ω-aminoacids as glycine, ε-amino-caproic acid and *p*-amino-benzoic acid. By the condensation polymerization of the dibasic acids obtained above with diamines, polypyromellitimide-amides were synthesized. The polymers were soluble in *m*-cresol and sulfuric acid, and the inherent viscosities of the polymers ranged from 0.21 to 0.42 (in *m*-cresol). The polymers were found to be considerably heat-stable.

It is generally recognized that the polymers with recurring aromatic units have a high thermal stability, and several synthetic studies of various polymers have been conducted. For example, the polypyromellitimide developed by the duPont Company and already commercialized as "H-film"[1] possesses an excellent heat-resistant property, a cold-proof property, a corrosion-resistant property for various chemicals, and a pronounced film-forming capability.

The method of synthesizing such material is shown as Formula 1 below:

* Presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

(1)

Polyimide

However, the polypyromellitimide has the disadvantage that it has no solubility in many organic solvents. One method of correcting this defect may be the introduction of the amide-linkages or straight-chain methylene groups into the polymer backbone, in addition to the imide-linkage.

In the present study, dibasic acids, as is generally shown by the Formula 2 were synthesized by the reaction of pyromellitic dianhydride with such ω-aminoacids as glycine, ε-amino-caproic acid and *p*-amino-benzoic acid. The polypyromellitimide-amides, generally shown by the Formula 3, were synthesized by the condensation polymerization of these dibasic acids with diamines.

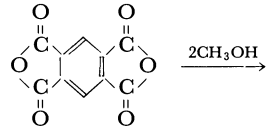
Polypyromellitimide-amide

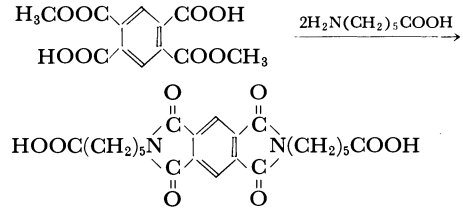
The structures of these compounds were confirmed through elementary analyses and a study of the infrared absorption spectra.

On compounds similar to those reported here, some descriptions have appeared in the Japanese patents,[2] and there has been a brief report by K. Mienes.[3]

Experimental

The Synthesis of Pyromellitimide Caproic Acid (I).



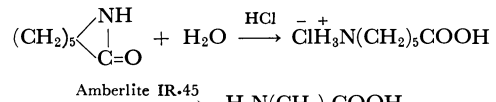


(I)

(4)

Pyromellitic Dianhydride. — Commercial pyromellitic dianhydride was recrystallized twice from acetic anhydride. This material was confirmed to be anhydride by study of its infrared absorption spectrum ($\nu_{C=O}$ 1775, and 1859 cm^{-1}). m. p. 285.5°C (lit.[4] m. p. 286°C).

ε-Amino-caproic Acid.—Synthesized from ε-caprolactam by the method described in Org. Synth.[5]:



m. p. 202°C (lit.[5] m. p. 202°C)

Pyromellitic dianhydride (6.08 g. (0.0279 mol.)) and 30 ml. of anhydrous methanol were placed in a 100-ml. three-necked flask equipped with a drying tube. This mixture was then shaken by hand and gently warmed on a water bath until the solution became clear. After the reaction mixture had become transparent (in about 1 hour), 7.32 g. (0.0558 mol.) of ε-amino-caproic acid was added. The ε-amino-caproic acid immediately dissolved, and the solution became transparent again after it had been heated on a water bath for an hour. After this procedure the solvent was distilled off, and the product thus obtained was dried under reduced pressure for about 24 hr. The white product obtained was then recrystallized from acetic acid. The infrared absorption spectrum of the dibasic acid (I) is shown in Fig. 1. The characteristic absorption bands of the imide ring[6,7] were recognized at 730, 1380, and 1780 cm^{-1}.

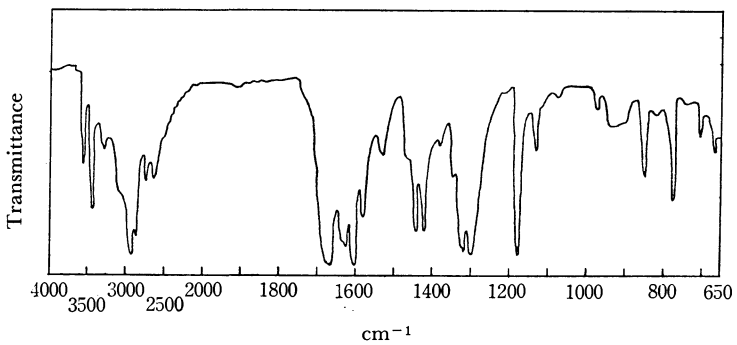

Fig. 2. Infrared spectrum of pyromellitimide benzoic acid (II) (Nujol). (unimidized)

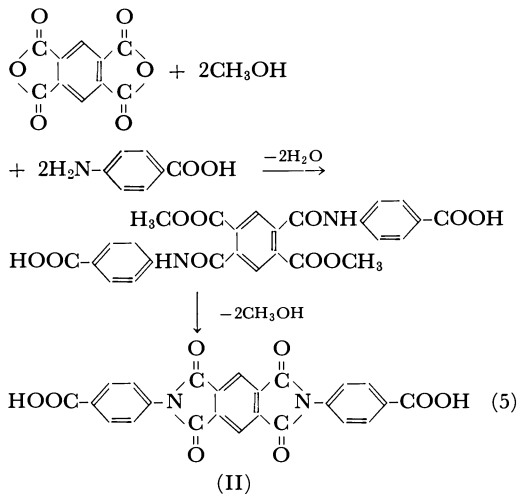
Yield 88%; m. p. 231°C.

Found: C, 59.44; H, 5.41; N, 6.33. Calcd. for $C_{22}H_{24}O_8N_2$: C, 58.91; H, 5.49; N, 6.30%.

The Synthesis of Pyromellitimide Benzoic Acid (II).



(II)

p-Amino-benzoic Acid.—Purified by recrystallization of the commercial-grade product from ethanol. White needles were thus obtained. m. p. 187°C (lit.[8] m. p. 187—187.5°C), II was prepared by a method similar to that used for pyromellitimide caproic acid I.

In this case, however, the imidization reaction could occur only with difficulty. A completely imidized substance was not obtained, even after drying under reduced pressure for several days at 60—70°C. By drying under reduced pressure at 250°C, a completely imidized substance was, however, obtained.

The pyromellitimide benzoic acid (II) obtained being insoluble in all organic solvents, the unreacted starting material was removed by extraction with glacial acetic acid and ethanol.

Yield 92%; m. p. 350°C.

Found: C, 62.73 H, 2.93. Calcd. for $C_{24}H_{12}O_8N_2$: C, 63.15 H, 2.65%.

The infrared absorption spectra of the dibasic acid (II) before and after the imidization reaction are shown in Fig. 2 and Fig. 3 respectively. The characteristic absorption bands due to amide CO and NH stretching vibration existing in the 1600—1650 and 3400—3500 cm^{-1} ranges before the imidization (Fig. 2) disappeared after imidization.

After imidization (Fig. 3), those which appear to have come from the characteristic absorption bands of the imide ring were recognized at 720, 1380, and 1780 cm^{-1}.

The material before the imidization reaction was a yellow powder and was soluble in many organic solvents, but after the imidization reaction it became a brown powder and was insoluble in an organic solvent.

(III)

Glycine. — A commercial product was purified by recrystallization from methanol. *m*-Cresol (50 ml.) was taken into a 100-ml. three-necked flask, to which was then added 7.5 g. (0.1 mol.) of glycine. This mixture was heated to 100°C while being stirred. After the reaction had been completed, the product was recrystallized from dioxane, yielding light yellowish crystals.

The product obtained in this way was found by a study of its infrared absorption spectrum to be completely imidized.

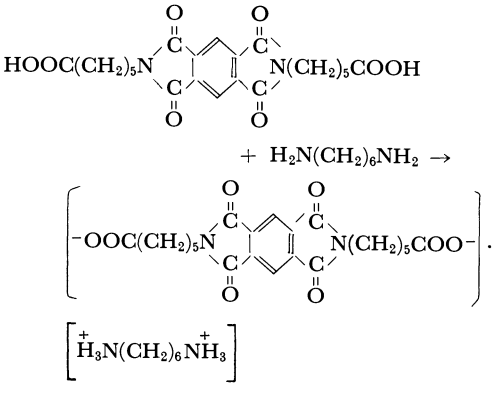
Yield 81.3%; m. p.>320°C

Found: C, 50.72 H, 2.82. Calcd. for $C_{14}H_8O_8N_2$: C, 50.60 H, 2.55%.

The Synthesis of Nylon Salt.—In order to increase the degree of polymerization, and also in order to utilize the insoluble dibasic acid (II) as the polymer component, nylon salt was prepared by the following method.

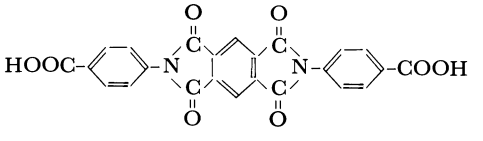
To the dibasic acids suspended in hot water, diamines were added gradually. After the filtration of the transparent solution thus obtained, ethanol was added. Precipitated nylon salts were filtered and dried in a vacuum. The nylon salts obtained in this manner were as follows:

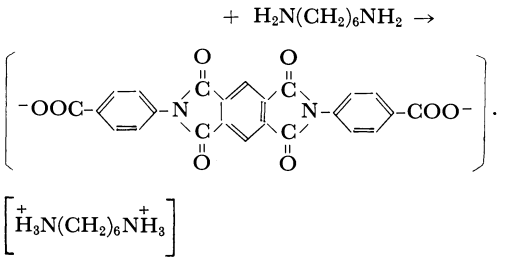
(a) Nylon salt derived from pyromellitimide caproic acid (I) and hexamethylene diamine:



Found: N, 10.21. Calcd. for $C_{28}H_{40}O_8N_4$: N, 10.00%.

(b) Nylon salt derived from pyromellitimide benzoic acid (II) and hexamethylene diamines:





Found: N, 9.85. Calcd. for $C_{30}H_{28}O_8N_4$: N, 9.79%.

Condensation Polymerization between Dibasic Acids and Diamines.—An equimolar reaction between dibasic acid and diamine was carried out. 0.05 mol. of each component dissolved in 15 ml. of purified *m*-cresol was mixed in a thick test bube, the mixture was then heated under dry nitrogen.

When the nylon salts were employed, the condensation polymerization reaction was carried out in a similar way, dissolving 4—5 g. of nylon salts in 30 ml. of *m*-cresol.

The reaction temperature was gradually elevated for about one hour. Thereafter, the reaction was continued at 180°C until the viscosity of the reaction mixture seemed to have reached to the maximum. The polymer solution was then gradually dropped into methanol in order to precipitate the polymer. The precipitated polymer was filtered, and washed with water and acetone. The polymer was refined by repeating the procedure of dissolving the product into *m*-cresol, followed by reprecipitation. The results are shown in Table I.

The infrared absorption spectrum of the polymer I is shown in Fig. 4. In addition to the bands due to imide linkage, the characteristic absorption band for the amide NH stretching vibration was recognized near 3400 cm^{-1}.

The Heat Decomposition of the Polymers.—The thermal gravimetric analysis in atomospheric air of the polymer was undertaken by using a thermanobalance (Hitachi Thermano Balance Electric Furnace). The results of the measurements on the three types of polymers with different unit structures, are shown in Fig. 5.

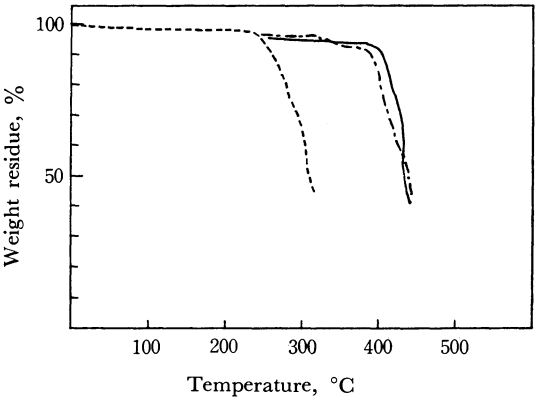


Fig. 5. Thermogravimetric analyses for polymers. ---- polymer I, ---- polymer IX, —— polymer X

Summary

Pyromellitimide caproic acid (I), pyromellitimide benzoic acid (II), and pyromellitimide acetic acid (III) have been synthesized in high yields by the reaction of pyromellitic dianhydride with three types of ω-amino acids, and their structures have been confirmed by elementary analyses and by a study of their infrared absorption spectra.

By the condensation polymerization between the dibasic acids described above and diamines, polypyromellitimide-amides with an imide ring and amide linkage in their molecule have been synthesized. The polymers obtained are generally soluble in *m*-cresol and sulfuric acid, but insoluble in other common organic solvents.

Such structures as the IX and X polymers in which the methylene chain in the molecule is short, and the aromatic unit is rich, were hard to dissolve in all the solvents mentioned above.

The results of the thermal gravimetric analyses indicated that, when the methylene chain is introduced into the polymer backbone, its heat stability appreciably decrease and that the polymer behaves like aliphatic polyamide. Those polymers such as the IX polymer which take a large part of the aromatic unit and a short methylene chain in repeating unit seem to have a good heat stability.

The authors wish to thank Dr. Yoshikazu Hachihama for his many helpful discussions and suggestions during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1800—1806 (1966)

Kinetics of the Hydrogenation of Aniline in the Vapor Phase on a Cobalt-Alumina Catalyst[1)]

By Hiroshi HAGIWARA,* Eiichi KOJIMA and Etsuro ECHIGOYA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 7, 1965)

The kinetics of the catalytic hydrogenation of aniline with a cobalt-alumina catalyst in the temperature range from 160° to 210°C was studied by a differential flow reactor with a fixed bed. (1) The rate of reaction reaches a maximum in the 180—190°C range for the hydrogenation of aniline. From the thermodynamic calculations and the experimental results for a fluidized-bed reactor, the reverse reaction was found to be almost negligible below 200°C under the conditions of the reaction. This phenomenon was explained by the proposed kinetics of the reaction. (2) The initial rate of reaction without cyclohexylamine, and the rate when some cyclohexylamine was added to the reactants, were measured at atmospheric pressure over the following range of conditions of partial pressures; hydrogen 0.3—0.92 atm., aniline 0.05—0.2 atm., cyclohexylamine 0—0.24 atm. It was concluded that a plausible rate-controlling step was the surface reaction, i. e., the reaction between the adsorbed aniline and hydrogen on the surface of the catalyst. The equation for the vapor phase hydrogenation of aniline on a cobalt-alumina catalyst in the temperature range from 150°C to 210°C was determined to be:

$$r = k\frac{K_H^3 K_A P_H^3 P_A}{(1 + K_H P_H + K_A P_A + K_C P_C)^4}$$

No reports concerning the kinetic study of the catalytic hydrogenation of aniline in the vapor phase are to be found in the literature. We ourselves have, however, previously reported on our kinetic study of the catalytic hydrogenation of aniline on a nickel-diatomaceous earth catalyst.[2)] In the catalytic hydrogenation experiments, the highest conversion of aniline to cyclohexylamine was obtained in the temperature range from 180°C to 190°C.[3)] At higher temperatures, the degree of hydrogenation decreased. It is uncertain whether this phenomenon is caused by the nature of the chemical thermodynamic equilibrium or by the reaction kinetics. In order to clear up this point, the experiments reported here were planned.

Experimental

Catalyst Preparation.—The powdered alumina was added to a solution of cobalt nitrate, and the slurry was

* Present address: Yoshitomi Pharmaceutical Co. Ltd., Yoshitomi, Fukuoka

2) E. Echigoya, H. Hagiwara and K. Morikawa, presented on the 29th Annual Meeting of the Society of Chemical Engineers, Tokyo, March., 1964.

3) H. Hagiwara and E. Echigoya, *Shokubai* (*Catalyst*), **6**, 324 (1964).

stirred for some time; to it was then added, at room temperature, a 1 N ammonium carbonate solution in a slight excess. After it had been kept for one hour at 50°C without stirring, the slurry was filtered, and the filter cake was washed, dried at 100°C, and calcined at 500°C for 2 hr. The cobalt oxide content was about 20%. Before use, the catalyst was reduced at 450°C for 2 hr. with 250 ml./min. of hydrogen inside the same fixed-bed apparatus later used for the hydrogenation reaction. A series of experiments was carried out using powder of the 150—100-mesh range.

Reaction using Fluidized-bed Equipment.—The equipment used for the fluidization experiments consisted of a glass tube 90 cm. long and 5 cm. in diameter. The fluidized-bed runs were made over the temperature range from 150°C to 230°C, using 50—400 g. of 100—150-mesh-size catalysts. The average value of the minimum fluidization velocity used was 2 cm./sec. over the temperature range from 160 to 200°C. A detailed report will be presented in the near future.

Reaction using a Fixed Bed.—The apparatus is shown in Fig. 1. The mixture of reactants entered the

catalyst bed, which was maintained at the desired temperature by a solid-particle fluidized thermal bath. The gaseous products leaving the reaction zone were caught in a condenser trap cooled with a mixture of dry ice and methanol, from which condensates were drawn every thirty minutes for gas chromatographic analysis. The aniline and hydrogen concentrations in the reactants were varied by mixing in known amounts of nitrogen gas.

Results and Discussion

The Study of the Chemical Reaction Equilibrium for the Aniline Cyclohexylamine System.—Equilibrium constants for the aniline-cyclohexylamine system are little known compared with those of the benzene-cyclohexane system.[4]

Figure 2 shows the thermodynamic chemical

4) G. I. Janz, *J. Chem. Phys.*, **22**, 75 (1954).

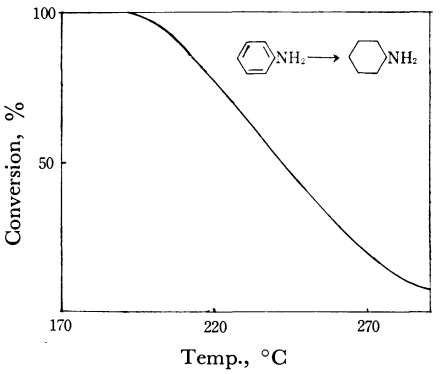

Fig. 2. Relationship between equilibrium conversion and reaction temperature $H_2/C_6H_5NH_2$ mole ratio 10.

equilibrium values calculated using Nernst's equation at a 10 to 1 mol. ratio of hydrogen to aniline. From Fig. 2, the dehydrogenation may be seen to be almost negligible below 200°C under these conditions. From the standpoint of the chemical reaction equilibrium, it is difficult to understand why the conversion obtained using a fixed-bed reactor should pass through a maximum value below 200°C. However, the hydrogenation reaction of aniline is an exothermic one. Thus it is difficult to measure a true reaction temperature in the fixed bed, which produces a large temperature gradient along its axial length. Accordingly, the fluidized bed, which has a large heat-transfer coefficient, was used to get a conversion at a true reaction temperature for this reaction.

The experimental results obtained at a uniform temperature within a fluidized bed are shown in Figs. 3 and 4. From the data, it may be seen that

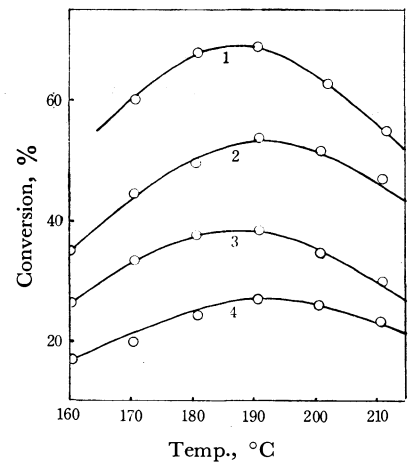

Fig. 3. Experimental data using a fluidized bed.

(1) the points of maximum conversion at the various space velocities were found in the temperature range from 180°C to 195°C, as in the fixed-bed experiments, and (2) the dehydrogenation reaction of cyclohexylamine was comparatively small below 210°C.

From the results obtained above, it may be assumed that the phenomenon of a negative temperature coefficient is caused by the reaction kinetics, not by chemical thermodynamic factors.

The following experiments were designed with this viewpoint in mind.

The Variation in the Catalyst Activity with the Reaction Time.—The changes in the catalyst's activity are shown in Fig. 5. The constant activity of the catalyst was obtained after about an hour and a half and did not change for about 6 hr., but then it gradually decreased. The catalyst was regenerated by passing hydrogen through it at 450°C for 1.5 hr.

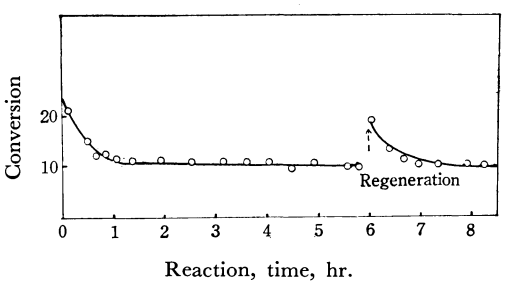

Fig. 5. Variation of catalyst activity with reaction time.
Temp. 180°C $H_2/C_6H_5NH_2$ molar ratio 10
$W/F \simeq 2$

The Dependency of the Fraction of Aniline Converted upon the Gas Space Velocity.—Experiments were first carried out to establish the range of conditions of the linear dependence between the reciprocal of space velocity and the conversion. The space velocity was here given as the volume (ml. at the reaction temperature) of gas coming in contact with 1 cc. of the catalyst per hour.

A series of runs were carried out under identical conditions, using powders of the 100—150-mesh-size range. In Fig. 6, the mole fraction of aniline converted against the reciprocal of space velocity was plotted, where F is a total flow rate [cc./hr]. The results obtained in this range could be treated as those of a differential reactor. A differential rate of reaction could then be calculated by the following approximate equation:

$$r = \Delta x_c/(W/f) \qquad (1)$$

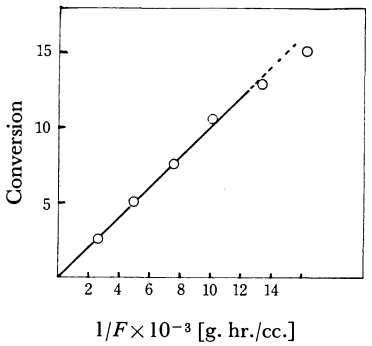

Fig. 6. Relationship between conversion vs. reciprocal of space velocity.
Reaction temp. 180°C
$H_2/C_6H_5NH_2$ mole ratio 10

where r: reaction rate [g.-mol./g. hr.], Δx_c: conversion in the differential reactor, W: catalyst weight [g.], and f: molar flow rate of an aniline-and-cyclohexylamine mixture [g. mol./hr.]. No by-products such as dicyclohexylamine could be found under these reaction conditions.

The Effects of Catalyst-particle Size.—The influence of the mass transfer on the over-all reaction rate was examined by using different sizes of catalyst (i. e., 100—150 mesh, 50—60 mesh, and 10—30 mesh). The results obtained were not at all different, and the effects of the mass transfer were concluded to be negligible.

The Initial Reaction Rate.—*The Dependence of the Initial Reaction Rate on Aniline and on the Hydrogen Partial Pressure.*—The experimental data obtained are summarized in Table I. The initial reaction rate can be expressed as follows:

$$r_0 = kP_A{}^{\alpha}P_H{}^{\beta}$$

where r_0: initial reaction rate, P_A and P_H: partial pressure of aniline and hydrogen, respectively [atm]. The order of the initial reaction as to aniline and to hydrogen partial pressure is given in Table II. From the table, it may be seen that the order

TABLE II. THE ORDERS WITH RESPECT TO HYDROGEN PARTIAL PRESSURES AT VARIOUS TEMPERATURES

T °C	α Order with respect to hydrogen partial pressure	β Order with respect to aniline partial pressure
165	when $P_A=0.09$, 1.3	when $P_H=0.8$, ≈ 0
180	when $P_A=0.09$, 1.5	when $P_H=0.8$, ≈ 0.1
195	when $P_A=0.09$, 1.6	when $P_H=0.8$, ≈ 0.15
210	when $P_A=0.09$, 1.7	when $P_H=0.8$, ≈ 0.17

regarding the aniline partial pressure varied between 0 and 0.15 with the temperature, while the order regarding the hydrogen pressure varied between 1.3 and 1.7 with the temperature.

The Determination of the Rate Equation.—According to the Langmuir-Hinshelwood mechanism, the experimental data were discussed on the assumption that the surface reaction was the rate-controlling step. Different mechanisms may be presented for the hydrogenation of aniline, either the following possibilities or a combination of them:

1) Hydrogen is in the molecular state or is dissociated into atoms when adsorbed on the surface of a catalyst.

2) The mode of the addition of hydrogen to aniline is either step-by-step or simultaneous.

3) The adsorption of aniline and hydrogen takes place on the same active sites or on different ones.

4) Hydrogenation takes place between an aniline molecule in the gas phase and a hydrogen molecule adsorbed on the catalyst.

All the mechanisms were checked by comparing the experimental data on the initial rates with the characteristic curves of the modified rate equations. The results indicate that the data obtained can be fairly well correlated by the following rate equation:

$$r_0 = k \frac{K_A K_H^3 P_A P_H^3}{(1 + K_A P_A + K_H P_H)^4} \qquad (2)$$

where k: reaction rate constant [g.-mol./g. hr.],

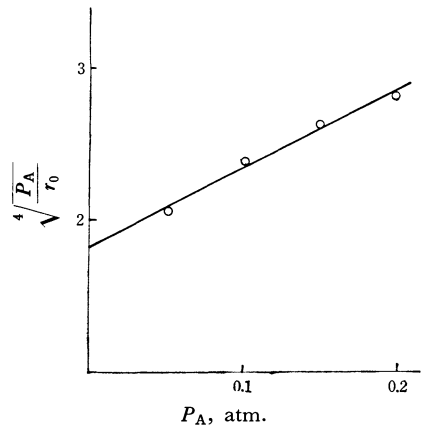

Fig. 7A. Verification of the Langmuir equation. Experiment at $P_H=0.8$ $T=180°C$ P_A variable

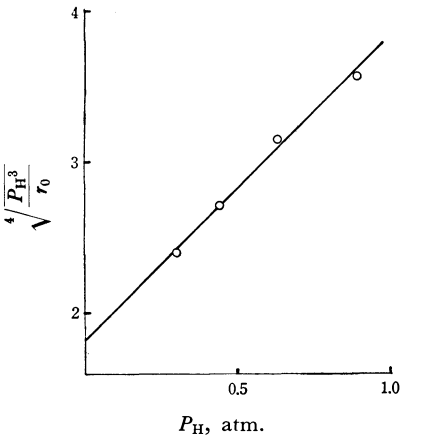

Fig. 7B. Verification of the Langmuir equation. Experiment at $P_A=0.09$ $T=180°C$ P_H variable

K_A and K_H: adsorption equilibrium constant of aniline and hydrogen, respectively [atm^{-1}].

In the above equation, when the hydrogen pressure, P_H, is constant, Eq. 2 can be transformed to the following:

$$\sqrt[4]{\frac{P_A}{r_0}} = \frac{1+K_AP_A+K_HP_H}{\sqrt[4]{kK_AK_H{}^3P_H{}^3}} = \varphi(P_A) \qquad (3)$$

This correlation is shown in Fig. 7A. A linear relationship was obtained between $\sqrt[4]{P_A/r_0}$ and P_A. At the constant aniline partial pressure, P_A, Eq. 2 can also be transformed into Eq. 4:

$$\sqrt[4]{\frac{P_H{}^3}{r_0}} = \frac{1+K_AP_A+K_HP_H}{\sqrt[4]{kK_AK_H{}^3P_A}} = \varphi(P_H) \qquad (4)$$

The correlation is shown in Fig. 7B. A linear relationship was obtained between $\sqrt[4]{P_H{}^3/r_0}$ and P_H. The values of K_H, K_A and k were obtained in the following manner. When P_H is constant, as in Fig. 7A, the gradient gives:

$$A = K_A/\sqrt[4]{kK_AK_H{}^3P_H{}^3}$$

and the point of intersection with the $\sqrt[4]{P_A/r_0}$ axis gives:

$$B = (1+K_HP_H)/\sqrt[4]{kK_AK_H{}^3P_H{}^3}$$

When P_A is constant, as in Fig. 7B, the gradient gives:

$$C = K_H/\sqrt[4]{kK_A{}^3K_H{}^3P_A}$$

and the point of intersection with the $\sqrt[4]{P_H{}^3/r_0}$ axis gives:

$$D = (1+K_AP_A)/\sqrt[4]{kK_AK_H{}^3P_A}$$

From A, B, C and D, the following equation is directly obtained:

$$\frac{B}{A} = \frac{1+K_HP_H}{K_A}, \quad \frac{D}{C} = \frac{1+K_AP_A}{K_H} \qquad (5)$$

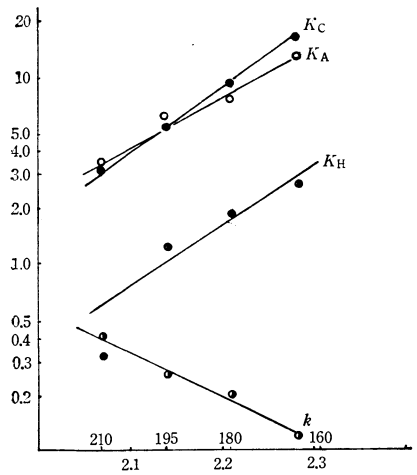

Fig. 8. Diagram showing the temperature dependence of rate constant and adsorption equilibrium constants.

TABLE III. THE VALUES OF THE ADSORPTION EQUILIBRIUM CONSTANTS AND RATE CONSTANT

	165°C	180°C	195°C	210°C	E or Q kcal./mol.
K_H	2.5	1.78	1.20	0.3	13.5
K_A	11.8	7.0	5.8	3.4	12.5
k	0.118	0.20	0.252	0.40	11
K_C	15.5	8.9	6.0	3.1	1.5

Using the above equations, the calculated values of K_A, K_H and k are shown in Table III. These values are reasonable for $K_A > K_H$, and the adsorption coefficient diminishes as the temperature becomes higher. The variation in k with the temperature yields an activation energy of 11.0 kcal./mol. The heats of adsorption of aniline and hydrogen are 12.5 kcal./mol. and 13.5 kcal./mol. respectively (Fig. 8).

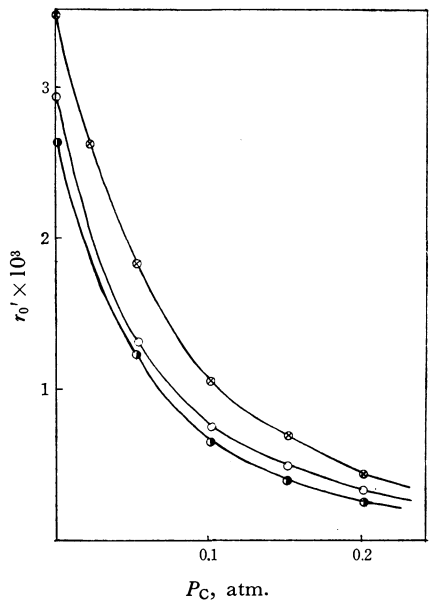

Fig. 9. Inhibition effect of cyclohexylamine. Reaction rate vs. cyclohexylamine partial pressure. $P_H=0.7$ $P_A=0.06$ P_C variable
○ 195°C, ⊗ 185°C ◑ 165°C

The Rate Equation with Cyclohexylamine. —The rate of reaction was measured by varying the cyclohexylamine concentration in the stream entering the reactor, while maintaining constant hydrogen and aniline partial pressures. The inhibition effect of cyclohexylamine was very clear throughout the whole range of temperatures (Fig. 9). The logarithmic transformation of this curve, $\log r_0' - \log P_C$, gave curves with negative gradients (Fig. 10). The value of K_C was obtained in the following way. The Langmuir rate equation might be written as follows:

$$r_0' = \frac{kK_AK_H{}^3P_AP_H{}^3}{(1+K_AP_A+K_CP_C+K_HP_H)^4} \qquad (6)$$

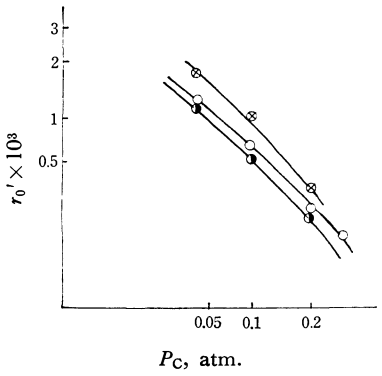

Fig. 10. Orders with respect to cyclohexylamine partial pressure.
○ 195°C ⊗ 180°C ◑ 165°C

where r_0': initial reaction rate with cyclohexylamine, P_C: partial pressure of cyclohexylamine [atm.] and K_C: adsorption equilibrium constant of cyclohexylamine [atm^{-1}]. The modified rate equation was obtained as follows:

$$\left(\frac{kK_H^3K_AP_H^3P_A}{r_0'}\right)^{1/4} = 1+K_AP_A+K_CP_C+K_HP_H \tag{7}$$

When P_A and P_H were kept constant, the following equation could be obtained:

$$\left(\frac{1}{r_0'}\right)^{1/4} = E+GP_C \tag{8}$$

$$\frac{E}{G} = \frac{1+K_AP_A+K_HP_H}{K_C} \tag{9}$$

The correlation in Eq. 8 was verified at a constant reaction temperature (Fig. 11). Using the values of K_A and K_H found before, the values of K_C were calculated. From the calculated value of K_C, the heat of adsorption of cyclohexylamine was found to be 15 kcal./mol.

As a final result, the following rate equation gives

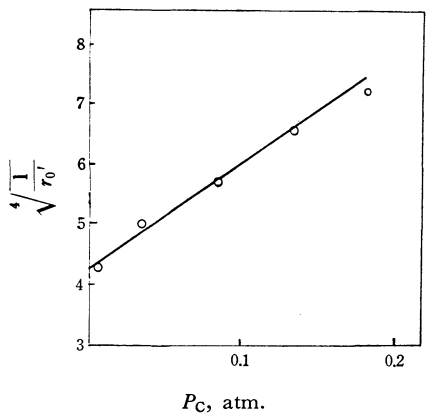

Fig. 11. Verification of the Langmuir equation.
Reaction temp. 180°C

the vapor-phase hydrogenation of aniline to cyclohexylamine on the cobalt-alumina catalyst:

$$r = k\frac{K_AK_H^3P_AP_H^3}{(1+K_HP_H+K_AP_A+K_CP_C)^4} \tag{10}$$

The average deviation of the proposed equation from the experimental values is about 10%.

A Test of the Rate Equation Obtained by the Differential-type Flow Reactor.—The conversion as a function of W/F (F: total flow rate [g.-mol./hr.]) was calculated numerically by Eq. 10, and it is plotted in Fig. 12. The data obtained using the integral-type flow reactor are superimposed on the plots in Fig. 12. Qualitatively the data and the plots show an approximate correspondence even though they have been determined by different methods.

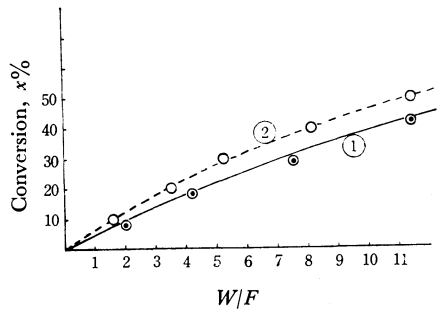

Fig. 12. Comparison of the conversion vs. W/F for the integral method data ① and the calculated values ②.

Summary

1) The rate of reaction reaches a maximum value at about 180—190°C in the hydrogenation of aniline. According to thermodynamic calculation and experiments using a fluidized bed, the reverse reaction is almost negligible below 200°C under the conditions of the reaction. Therefore, this phenomenon has been assumed to be caused by the reaction kinetics.

2) The kinetics of the catalytic hydrogenation of aniline using a cobalt-alumina catalyst in the temperature range from 160 to 210°C was studied by a differential-type fixed-bed flow reactor. The initial rate of reaction without cyclohexylamine, and the rate when some cyclohexylamine was added to the reactants, were measured at atmospheric pressure over the following range of conditions:

hydrogen	0.3—0.92 atm.
aniline	0.05—0.2 atm.
cyclohexylamine	0—0.24 atm.

As a result of these experiments, it was concluded that the most plausible rate-controlling step was the surface reaction, i. e., the reaction between the

aniline and hydrogen adsorbed on the surface of the catalyst. The final equation for the vapor-phase hydrogenation of aniline on a cobalt-alumina catalyst in the temperature range from 150°C to 210°C was as follows:

$$r = k\frac{K_H{}^3 K_A P_H{}^3 P_A}{(1+K_H P_H+K_A P_A+K_C P_C)^4} \qquad (10)$$

Eq. 10 will be useful if it can be used to predict the rate over a wide range of conditions and, hence, be suitable for use in reactor design. However, it is not possible by kinetic study alone to determine the true mechanism of this reaction.

The authors wish to thank Professor Kiyoshi Morikawa for his useful discussions and guidance.

NOTES

Organic Photochemical Reactions. IV. Photoaddition Reactions of Various Carbonyl Compounds to Furan[1]

By Kensuke SHIMA and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received September 13, 1965)

In an earlier paper dealing with the photoaddition of propionaldehyde or benzaldehyde to furan,[2] it was shown that this addition gives oxetanes (Ia, Ib) without the ketones which are formed by the addition of acyl radical to olefins. The present investigation was undertaken to extend this photoaddition to some aliphatic and alicyclic aldehydes, unsaturated aldehydes and several ketones.

In these experiments, ultraviolet light from a 350 W. high pressure mercury lamp was used. A mixture of the carbonyl compound and furan was placed in a 180-ml. reaction vessel and irradiated at 5—10°C in a nitrogen atmosphere[3]: the reaction product was then isolated by distillation under reduced pressure.

The reaction conditions and the yields of the products are summarized in Table I.

The distilled fraction in each case was identified as an oxethane on the basis of an elementary analysis, a molecular weight determination, and a study of the infrared and NMR spectra.[4]

These oxetanes showed a strong band in the infrared region near 980 cm^{-1}, and no absorption

In the photoreaction of various aliphatic, alicyclic and unsaturated aldehydes with furan, oxetanes (Ic—Ik) were obtained. However, although in the case of n-butyraldehyde, acrolein and crotonaldehyde with furan, the main product was an oxetane, this fraction could not be purified by distillation. The properties of the oxetanes are shown in Table III.

Recently, Schenck et al.[5] reported that, in the photoreaction of dimethylmaleic anhydride with furan in the presence of benzophenone as a sensitizer,

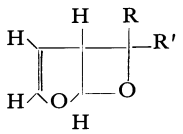
the oxetane (IIa) are formed. This structure was confirmed on the basis of its NMR spectrum by Gagnaire et al.[6] The photoreactions of acetone, methyl ethyl ketone and acetophenone with furan were undertaken to determine if these ketones would add to furan much as aldehydes adds to furan. It was observed that, in these photoreactions, the corresponding oxetanes (IIb—IId) are formed, but the yields of the oxetanes are very low compared with that of aldehydes to furan. It is interesting



IIa R=R′=C_6H_5

c R=CH_3, R′=C_2H_5
d R=CH_3, R′=C_6H_5

that there is a very large difference in the oxetane yield between benzaldehyde and acetophenone. Yang et al.[7] pointed out that, in the photoaddition reactions of benzaldehyde, acetophenone and benzophenone to 2-methyl-2-butene, the low-lying triplet states of these carbonyl compounds are $n\rightarrow\pi^*$ in nature, that they are the reactive species in these reactions, and that the quantum yield of the oxetane formation from benzaldehyde is 0.45, and 0.1, from acetophenone. However, they did not discuss the difference in the oxetane yield. Our results are comparable with theirs. We are now studying the reaction mechanism in order to clarify the reason why there is a difference in oxetane yield.

The authors with to thank Dr. Angelo A. Lamola (University of Notre Dame) for his helpful discussions.

The Mass Spectrometric Determination of Gases Evolved in the Shell Mould Process for Iron Founding

By Hiroko HOSHINO, Nobuhide WASADA and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received September 16, 1965)

Resins, such as phenol resin, are used as binders in order to form a shell mould for casting or to manufacture resin-bonded grinding wheels. When molten metal is poured into such a mould or when an article is ground with such a wheel, the binder is thermally decomposed and the decomposed gases contaminate the atmosphere of the work shop, unfavorably influencing the health of the workers.[1] The species of gases evolved are considered to depend to a large extent upon the nature of the binder used, upon the manufacturing process employed, and upon the operating condition of the mould or the grinding wheel.

Information about the evolved gases is necessary before proper measures can be taken to protect the workers from the noxious effects of the gases, but very little is known about them. Tubich et al.[2] have, however, reported that furfural, ammonia, phenol, aldehydes and carbon monoxide are evolved from shell moulds. We have now analysed the gases evolved from shell moulds in a foundry and have detected compounds which have not yet been reported.

The binder used in this mould was a kind of novolak resin. When molten iron was poured into a shell mould, an irritating gas evolved from the mould. The air around the surface was collected in a glass gas-collecting bottle which had been evacuated beforehand. The compounds present in the air of the bottle were then collected by the freeze-out technique reported previously.[3] The frozen-out substance was separated into three parts by isothermal distillation or by sublimation[4] at $-196°C$, $-78°C$ and room temperature. Each fraction was analysed by means of a CEC 21-103C mass spectrometer. The results are shown in Table I. When the gas was evacuated off, some residual substances remained in the sample bottle. After 60 days, appreciable amounts of ammonia and carbon dioxide were still found in the sample bottle. A part of the residue seems to have decomposed into these compounds.

TABLE 1. APPROXIMATE AMOUNT OF ORGANIC COMPOUNDS FOUND IN 760 mmHg OF AIR

Compound	Amount found in μHg
Benzene	8
Toluene	4
Xylene	<2
Phenol	2
Cresol	1
Benzaldehyde	trace

Those compounds which have a low boiling point, such as hydrogen, methane and carbon monoxide, may not be, or cannot be effectively collected by this freeze-out technique. Moreover, we cannot expect as reliable a result concerning those compounds which react with magnesium perchlorate, the drying agent for the isolated concentrate used in the procedure. That is, of the compounds detected, with benzaldehyde only a part of the amount originally present in the air may be collected. Though no acetone or alcohols were detected, it cannot be concluded legitimately that these compounds were not present in the air.

Considering the composition of novolak, it is not unreasonable for the compounds in the table to be detected. Actually, in a study of the mechanism of pyrolysis, between 500°C and 100°C, of novolak in a vacuum, we have identified all the compounds listed in the table as pyrolytic products of the resin,[5] though the mechanism of the production of the compounds in the foundry is considered to be somewhat different from that used under our experimental conditions, since the temperature of a part of the mould is much higher, moreover, the sand of the mould may act as a catalyst for the decomposition of the resin, and at least a part of the reaction proceeds in the presence of oxygen and water.

The authors are indebted to Dr. Hajime Matsufuji for bringing Refs. 1 and 2 to their attention, and to Mr. Ryuzo Shiota for his kind discussions and survey of the manuscript.

The Solvent Extraction of Metal Ions in the Presence of Two Different Chelating Agents

By Hiroyuki YOSHIDA

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received September 27, 1965)

In the study of 2-thenoyltrifluoroacetone (TTA) solvent extraction, synergic effects were observed in the extraction of some metals in the presence of 8-quinolinol. Many studies of the synergic effects have been carried out. Most of these extraction systems contain complexing acids and other neutral ligands which form adduct compounds. The synergic effects in the presence of two different chelating agents are interesting,[1,2] because these agents can react as both chelate-forming and adduct-forming agents. In this paper, the extraction of uranyl and europium ions will be studied in the presence of TTA and 8-quinolinol and the stabilization factor will be calculated. It is well known that these metal ions are extracted into the organic phase as TTA[3] or 8-quinolinol[4] complexes under the present conditions.

Experimental

Reagents and Apparatus.—Uranium-237 was prepared by the (γ, n) reactions of natural uranium in a 20 MeV-electron linear accelerator of the Japan Atomic Energy Research Institute.[5] Europium-152+154 was supplied by the Radiochemical Centre, Amersham. Appropriate amounts of TTA and 8-quinolinol were dissolved in distilled benzene and were stored in a refrigerator. Radioactivity measurements were made with a Kobe Kogyo SA-230 scintillation counter.

The Determination of the Distribution Ratio.—Five ml. of an acetic acid - sodium acetate buffer solution (pH 3.5) and 1 ml. of the standard metal solution were transferred into a separatory funnel. Appropriate amounts of sodium perchlorate solution were then added to keep the ionic strength of the aqueous phase at 1 M. After the aqueous phase had been diluted to 10 ml. with water, TTA and 8-quinolinol solutions were added and the organic phase was diluted to 10 ml. with benzene. The system was then shaken for 5 min. at 25±2°C. The distribution ratio (D) was determined by the γ-counting of each phase. D was defined as the ratio of counts from the organic to those from the aqueous phase.

Results and Discussion

Determinations of D were carried out in the presence of TTA, 8-quinolinol, and a combination of the two. The results are shown in Tables I, II and III, respectively. $(D_M)_{TTA}$, $(D_M)_{OX}$ and $(D_M)_{TTA+OX}$ represent the distribution ratios of the elements in the presence of TTA, 8-quinolinol, and a combination of the two. β, the stabilization factors, $(D_M)_{TTA+OX}/((D_M)_{TTA}+(D_M)_{OX})$, are given in Tables II and III. The distribution ratio increases remarkably in the presence of two chelating agents. The extraction mechanism was not studied in this paper. Both agents (HA and HB) are able to form adduct compounds such as $MA_n(HA)_m$ with their acid forms as is shown in the extraction

A Phase Transition in Phenanthrene Crystal*

By Shoichi MATSUMOTO

Central Research Laboratory, Tokyo Shibaura Electric Co., Ltd., Komukai, Kawasaki, Kanagawa

(Received October 19, 1965)

In a previous paper,[1] we reported that phenanthrene shows an anomaly at around 64—71°C in the temperature dependence of its electrical conductivity; the resistivity increases abruptly with the rising temperature and becomes 6—7 times greater than that below 64°C, while the linear relationship between the logarithm of resistivity and the reciprocal absolute temperature remains kept both below and above the anomaly. We also suggested in that paper that this anomaly may be attributed to a phase transition of the crystal.

In this paper, a differential thermal analysis and a dilatometric investigation of phenanthrene will be presented, and the phase transition confirmed by the results will be discussed.

Experimental

Material.—Phenanthrene of a chemical purpose-grade (Eastman Kodak Co.) was recrystallized three times from an ethanol solution, and then purified further by the zone-melting technique.

The recrystallized specimen was introduced into a Telex-glass tube with a diameter of 10 mm., and the tube was sealed under a vacuum after it had been evacuated for about 12 hr. Then the tube was subjected to forty-five passes in an automatic zone refiner, clamped in a vertical position. The molten zone about 5 mm. long was controlled to move downward at the speed of 20 mm. per hour.

Differential Thermal Analysis (DTA).—The measurements were performed with a recording differential thermal analysis apparatus (Shimadzu DT-10B), using α-alumina powder as the reference substance. In order to avoid possible effects by oxygen and humidity, the procedure was carried out, with nitrogen gas passed through slowly. For most measurements, the specimen was heated at the rate of 4—6°C per minute.

Dilatometric Measurements. — A dilatometric investigation was made by using a modified differential dilatometer of the type originated by Chevenard.[2] Our dilatometer was designed to magnify the differential expansion between a specimen and an equal length of fused silica used as the standard specimen 2000 times.

In this study, the heating rate was about 0.8°C per minute, except in the vicinity of the anomalous point, where temperature was raised as slowly as possible. The temperatures were measured by means of a calibrated chromel-alumel thermocouple; they were accurate to ±0.2°C.

Samples were prepared by casting molten rods of zone-refined phenanthrene, rods which were 9 mm. both in length and in diameter.

Results and Discussion

In the DTA investigation, upon heating we found a new endothermic peak at about 71°C on the thermogram of phenanthrene. A typical thermogram is shown in Fig. 1.

The endothermic peak at 71°C is very small, compared with the peak beginning at 100°C, which is the melting temperature of the substance, the area of this endothermic peak for each thermogram is approximately one-seventeenth of that for melting.

TABLE I. THE OBSERVED VALUES FOR ENDOTHERMIC PEAKS ON THE DTA THERMOGRAMS OF PHENANTHRENE

one on the right of it. T_p is the temperature at the vertex of the peak.

In the dilatometric study, we found a distinct discontinuity in the expansion-temperature relation of phenanthrene at 68.7°C. Figure 2 gives, as a typical example, a graphical representation of the total linear expansion of Sample 11-11 plotted aginst the temperature, where the curve consists of two distinct lines; the lines intersect at 68.7°C, although the slope below about 50°C gradually becomes smaller. These phenomena were quite reversible with the temperature. These features of the expansion-temperature relation show that the thermal expansion coefficient of

Table II. The mean coefficient of linear thermal expansion of phenanthrene measured with a dilatometer

Trial	$T_{tr.}$, °C	β_I	β_{II}
Sample 11-11	68.7	1.67×10^{-4}	1.05×10^{-4}
Sample 11-12	68.8	1.61×10^{-4}	1.08×10^{-4}
Sample 11-13	68.7	1.66×10^{-4}	1.03×10^{-4}
Average	68.7	1.65×10^{-4}	1.05×10^{-4}

the specimen is almost constant below or above 68.7°C, but that it undergoes a conspicuous, abrupt change at that temperature. Each expansion coefficient can be evaluated from the slope of each line. The results are summarized in Table II, where β_I is the mean coefficient of the linear thermal expansion between the temperature of 50°C and $T_{tr.}$, the transitional point, and where β_{II} is the coefficient between $T_{tr.}$ and 80°C.

Generally, a substance with a phase transition shows an endothermic peak corresponding to the transition on a thermogram of DTA, and the transition point exists between the T_i—T_p temperatures. The thermogram obtained for phenanthrene shows the presence of an endothermic peak with T_i=60°C and T_p=71°C, as is summarized in Table I. This result, in addition to the anomaly in the temperature dependence of the electrical conductivity,[1] reveals the presence of a phase transition in the phenanthrene crystal; this transition point is expected to exist between the temperature of 60 and 71°C.

The present attempt to make dilatometric measurements of phenanthrene indicates that the coefficient of the thermal expansion definitely undergoes a conspicuous change at 68.7°C; the value of 1.67×10^{-4} abruptly changes to 1.05×10^{-4} at this point, as is shown in Table II. This result shows that the transition point of phenanthrene crystal is 68.7°C.

In order to determine the heat associated with this phase transition, the ratio of the area of the endothermic peak at the transition to that for melting observed on the thermogram of DTA, 1 : 17, was conveniently applied. Phenanthrene melts at 100°C with a latent heat of fusion, ΔH= 4.45 kcal./mol.,[3] so the heat of the transition was evaluated as ΔH=0.26 kcal./mol., while the associated entropy change at the transition was estimated to be ΔS=0.77 e.u.

The estimated entropy change at this transition is much smaller than the change for the melting, ΔS=11.9 e. u. This indicates that the modification of phenanthrene above the transition point is at least not a so-called plastic crystal. It is not exactly clear at the present stage that what other kind of phase transition this transition belongs to, but as the shape of a graphical representation of

3) Landalt - Börnstein, Physikalisch - Chemischen Tabellen, 6 Auflage, II Band, 4 Teil.

the expansion plotted against the temperature and its reversibility with temperature, as is shown in Fig. 2, are characteristic of what is called a high-order transition, it seems that the phase transition of the phenanthrene crystal is not polymorphic.

For an accurate treatment of this transition from the point of view of structural chemistry, it is necessary to determine the crystal structure above the transition point. For this purpose, an X-ray analysis of the structure is now being made in our laboratory.

The Absorption Spectra of Bis(ethylenediamine)copper(II) Complexes in Various Solutions

By Kôzô Sone

Chemical Laboratory, Department of General Education, Nagoya University, Chikusa-ku, Nagoya

and Shunji Utsuno

Chemical Laboratory, Aichi Gakugei University, Higashi-ku, Nagoya

(Received December 4, 1965)

Recently we have carried out a series of measurements of the visible absorption spectra of bis(ethylenediamine)copper(II) complexes in a variety of solvents. Form the results, which are summarized in Table I, we can obtain some information on the states of the complex ion in these media.[1)]

Since the perchlorate ion is practically unable to form a complex in a solution, the complex $[Cuen_2](ClO_4)_2$ is considered to be the most favorable for studying the effects of various media on the bis(ethylenediamine)copper(II) ion. The absorption measurements of this complex in water, ethanol, acetone and nitromethane reveal that the λ_{max} and ε_{max} values are not very different in each case, and that the λ_{max} value is shifted toward a shorter wavelength in the order of water→(ethanol and acetone)→nitromethane. In an aqueous solution it may be assumed that two water molecules are loosely bound above and below the copper atom in each planar bis(ethylenediamine)copper(II) ion, forming an elongated octahedral structure; the same situation can also be assumed in ethanol and acetone solutions, but the bondings of the respective solvent molecules will be somewhat weaker than those in an aqueous solution. In a nitromethane solution, the additional coordination of the solvent molecules will be even weaker.[2)] Therefore, we can conclude that the weaker the bondings of the solvent molecules are, i. e., the higher the tetragonality of the bis(ethylenediamine)copper(II) ion in a solution is, the shorter will its λ_{max} value be.

Table I. Absorption maxima of $[Cu\ en_2]X_2$ in various solutions[a,b)]

X	Solvent	λ_{max}(mμ)	ε_{max}
ClO_4	H_2O	550	64
	C_2H_5OH*	547	63
	CH_3COCH_3	547	63
	CH_3NO_2	534	60
	$H_2O+NaClO_4$ (4M)	538	61
	$H_2O+NaClO_4$ (8M)	528	61
	$H_2O+Mg(ClO_4)_2$ (4M)	530	58
	C_5H_5N	582	96
NO_3	H_2O	550	64
	C_2H_5OH*	547	63
	$H_2O+NaNO_3$ (8M)	540	62
Cl	H_2O	550	64
	C_2H_5OH	575	84
	$H_2O+LiCl$ (10M)	553	73

a) Temp.: 20—25°C; chelate concentration: $7\times10^{-3}-8\times10^{-3}$ M (7×10^{-4} M in the cases marked with *).

b) Each absorption curve shows only a simple and approximately symmetrical absorption band.

Of special interest is the effect of concentrated aqueous solutions of sodium perchlorate and magnesium perchlorate. Here we can expect that most of the water molecules will be so strongly attracted by the ions of these salts that the bondings of water molecules above and below the bis(ethylenediamine)copper(II) ions will be more or less disturbed. In fact, we find that the λ_{max} values in these solutions are markedly smaller than that in pure water, and that the value in a 8 M solution of sodium perchlorate is even smaller than that in

1) A part of our conclusion does not agree with the opinion of C. K. Jørgensen, "Inorganic Complexes," Academic Press, New York (1963), p. 100. Cf. also F. Rosenblatt, *Z. anorg. u. allgem. Chem.*, **204**, 351 (1932) and H. Ojima and K. Sone, *Naturwiss.*, **51**, 105 (1964).

2) On the small coordination ability of nitromethane, cf. B. J. Hathaway and D. G. Holah, *J. Chem. Soc.*, **1964**, 2408.

nitromethane.[3] Similar effects can be found also in the case of $[Cu\ en_2](NO_3)_2$ in a concentrated sodium nitrate solution (see Table I), and also in solutions of some other copper complexes, e. g., $[Cu\ trien]^{2+}$ or $[Cu\ glycine_2]$ in the presence of a large amount of sodium perchlorate or sodium nitrate.[4,5]

In pyridine solutions of $[Cu\ en_2](ClO_4)_2$ and ethanol solutions of $[Cu\ en_2]Cl_2$ (see Table I), on the other hand, the λ_{max} and ε_{max} values are larger than those described above. In these cases, it is probable that the coordination of pyridine molecules or chloride ions to the bis(ethylenediamine)copper(II) ions takes place, giving the 5- or possibly 6-coordinated complexes, the tetragonalities of which are apparently much lower than those of the more or less solvated complex ions, as has been described above.[6] The spectrum of $[Cu\ en_2]Cl_2$ in concentrated lithium chloride shows, further, that chloro-complex formation also takes place to some extent in this medium.

In summing up all the data in Table I, we can conclude that the higher the tetragonality of the bis(ethylenediamine)copper(II) ion in a solution is, the shorter is its λ_{max} value. It is interesting to note that the powder reflection spectrum of $[Cu\ en_2](ClO_4)_2$ reported by Meek and Ehrhardt[7] shows the λ_{max} value of 525 mμ, which is still shorter than all the values in Table I; this indicates that the bis(ethylenediamine)copper(II) ion in this particular case is of the highest tetragonality, since the complex is in contact with only the perchlorate ions, which have only a negligible ability to coordinate.

3) In these solutions, and also in nitromethane, we can also expect that the dissociation of $[Cu\ en_2](ClO_4)_2$ into bis(ethylenediamine)copper(II) and perchlorate ions is hindered to some extent. However, it is quite certain that the bonding of a perchlorate ion above or below a planar complex ion is much weaker than that of a molecule of water, ethanol or acetone; therefore, we can assume that the tetragonality of the bis(ethylenediamine)copper(II) ions in an aqueous sodium (or magnesium) perchlorate solution or in nitromethane is, at any rate, much higher than that in water, ethanol or acetone (cf. the spectrum of solid $[Cu\ en_2](ClO_4)_2$ (see text)).

4) In the case of $[Cu\ glycine_2]$, for example, the λ_{max} and ε_{max} values in water are 630 mμ and 44, while in a 8 M solution of sodium perchlorate they are 602 mμ and 41 respectively.

5) A similar effect of sodium perchlorate on some nickel ammines has already been reported by C. K. Jørgensen, *Acta Chem. Scand.*, **11**, 399 (1957) and K. Sone and M. Kato, *Z. anorg. u. allgem. Chem.*, **301**, 277 (1959); in these cases, it was found also that the effect is intensified remarkably by heating. In the case of the bis(ethylenediamine)copper(II) ion, on the other hand, the effect of heating is not so large, and only comparatively small increases in λ_{max} and ε_{max} take place (the values in a 8 M solution of sodium perchlorate at 80°C are ca. 535 mμ and 65 respectively).

6) Cf. the spectra of $[Cu\ en_3]^{2+}$, $[Cu\ en_2NH_3]^{2+}$ and $[Cu\ en_2OH]^{+}$ reported by J. Bjerrum and E. J. Nielsen, *Acta Chem. Scand.*, **2**, 297 (1948) and H. B. Jonassen, R. E. Reeves and L. Segal, *J. Am. Chem. Soc.*, **77**, 2748 (1955).

The Heats of the Dilution of *cis*-Polybutadiene Solutions in Benzene and Toluene

By Akihiro KAGEMOTO, Sachio MURAKAMI and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received December 6, 1965)

In a previous paper,[1] we measured the heats of the dilution of the atactic polystyrene solution and found that the interaction parameter, χ_H, between the polymer and the solvent depends on the concentration. In order to confirm this fact for other polymer solutions, the heats of dilution of which have not been directly determined, we measured the heats of the dilution of *cis*-polybutadiene, using toluene and benzene as a solvent.

The calorimeter used in this study has been described in the previous paper.[1] The *cis*-polybutadiene sample, the molecular weight of which was about 200000, was supplied by Dr. Toshio Yoshimoto of the Bridgestone Tire Co., Ltd.

The heats of the dilution of *cis*-polybutadiene solution were measured over the concentration range from 0.36 to 0.05 in a volume fraction of polymer at 25.0±0.01°C for the benzene solution, and at 26.0±0.01°C for the toluene solution, by adding the solvent in successive 10- or 20-ml. portions to a solution of a known concentration. The data obtained are shown in Table I. The *cis*-polybutadiene - toluene system is exothermic, while the benzene system is endothermic.

As was shown in the previous paper,[1] the heat of dilution, $\Delta\overline{H}_d$, is related to the initial volume fraction of the polymer, ϕ_2, and the final ϕ'_2 value as follows:

1) A. Kagemoto, S. Murakami and R. Fujishiro, This Bulletin, **39**, 15 (1966).

either $$\Delta\overline{H}_d = RT\chi_H\phi_2\phi'_2\Delta n_1 \quad (1)$$

when the interaction parameter, χ_H, is not dependent on the concentration,

or $$\Delta\overline{H}_d/RT\phi_2\phi'_2\Delta n_1 = \chi_1+\chi_2(\phi_2+\phi'_2)/2 \quad (2)$$

when χ_H depends linearly on the concentration, in conformity with the equation that $\chi_H=\chi_1+\chi_2\phi_2$. In these equations, Δn_1 is the number of moles of the solvent added.

By using the experimental data presented in Table I and Eq. 1, the interaction parameter has been obtained for each dilution process of each system; these values are given in the last column of the same table.

According to Eq. 1, $\Delta\overline{H}_d$ must linearly vary

TABLE I. HEATS OF DILUTION OF *cis*-POLYBUTADIENE SOLUTION

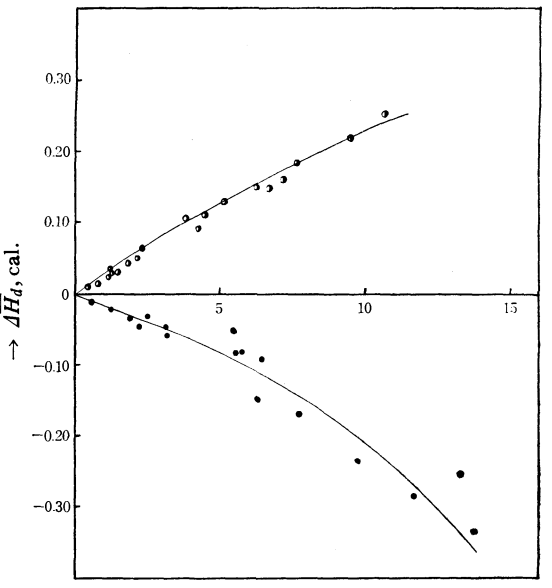

Fig. 1. $\Delta\overline{H}_d$ versus $\phi_2\phi_2'\Delta n_1$ data for *cis*-polybutadiene solution in benzene -◑- at 25°C and in toluene -●- at 26°C.
The curves are drawn according to Eq. 2 with the parameter of Table II.

TABLE II. VALUES OF INTERACTION PARAMETER $\chi_H=\chi_1+\chi_2\phi_2$

Solvent	χ_1	χ_2
Toluene	−0.019	−0.067
Benzene	0.039	−0.005

with the $\phi_2\phi'_2\Delta n_1$ value. However, as is shown in Fig. 1, those plots are not linear, indicating that χ_H depends on the concentration.

In order to obtain the dependence of the χ_H parameter on the concentration, a least-square analysis of the data were carried out according to Eq. 2; this gave the values of χ_1 and χ_2 summarized in Table II.

By using the values of χ_1 and χ_2 listed in Table II, the $\Delta\overline{H}_d-\phi_2\phi'_2\Delta n_1$ curve has been calculated for each system; this curve, shown by the full line in Fig. 2, is in good agreement with the experimental data for each system.

As is shown in Table II, the χ_H parameter in a good solvent (an exothermic system) is considerably dependent on the concentration, while in a poor solvent (an endothermic system) it depends hardly at all on the concentration.

Such a tendency was also seen in the polystyrene solution and explained by the use of the dilute solution theory.

The authors wish to thank Dr. Toshio Yoshimoto of the Bridgestone Tire Co., Ltd. for supplying the sample.

The Properties of Some Arjunolic Acid Derivatives

By Shin-ichi SASAKI, Hung Cheh CHIANG, Kazuo HABAGUCHI
Hong-Yen HSÜ and Koji NAKANISHI

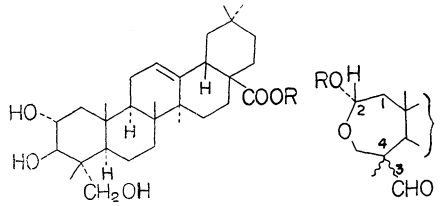
Department of Chemistry, Tohoku University, Katahira-cho, Sendai

(Received December 20, 1965)

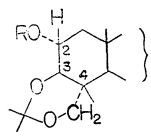
In connection with our investigations of South-East Asian plants,[1] the roots of *Psidium guaijava L.* ("banjiro" or "banzakuro") from Taiwan were studied because of the reputed cancerostatic activity of this Chinese herb. Since the ether extract was an intractable mixture, it was first methylated; the ester was then chromatographed and recrystallized. This ester eventually turned out to be methyl arjunolate,[2] the methyl ester of arjunolic acid (1).[3,4] Preliminary chemical and spectroscopic studies carried out prior to its identification, however, disclosed a few points worthy of comment; these points will be reported below.

Although the product obtained by the periodate oxidation of the ester 2 was analyzsed in the correct manner for a dialdehyde, it afforded only a mono-2, 4-dinitrophenylhydrazone, and its NMR spectrum showed only one aldehydic proton as a singlet (9.09 p. p. m.). Furthermore, the one-proton quartet (J 9.5 and 5 c. p. s.) that newly appeared at 5.12 p. p. m. in the oxidation product was shifted to 6.01 p. p. m. (J 9.1 and 5) in its acetate, a behavior which is characteristic of hemiacetals.[5] As has been mentioned above, the aldehyde proton signal is a singlet; therefore, the aldehyde group must be attached to a tertiary carbon atom. It follows that the structures of the oxidation product and its acetate should be 3 and 4 respectively, and that they are derived by means of hemiacetal formation between the primary hydroxyl group and the 2-aldehyde group. The C_2–H in Structures 3 and 4 is represented as β-axial in view of its 9.5- and 5-c. p. s. coupling constants.

The ester 2 afforded an acetonide 5 when reacted with acetone and cupric sulfate; the acetonide is formed between the 3-OH and 4-CH_2OH, as is evidenced by the appearance of a one-proton multiplet due to C_2-H at 5.5 p. p. m. in the NMR spectrum of the acetonide acetate 6.

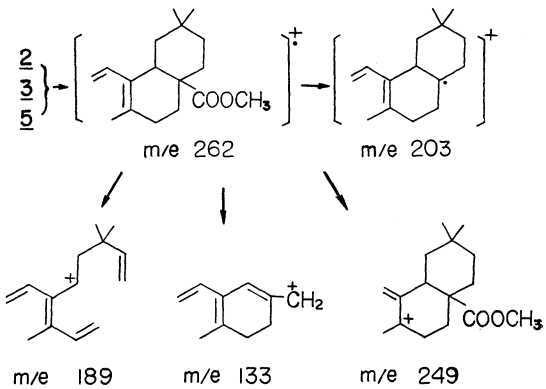


1 R=H 3 R=H } (C_{20} as COOMe)
2 R=Me 4 R=Ac }



5 R=H } (C_{20} as COOMe)
6 R=Ac }

The mass spectra of methyl arjunolate 2, the hemiacetal 3, and the acetonide 5 are very similar in the high mass range in that they are characterized by peaks at *m/e* 262, 249, 203, 189 and 133, all derived from a retro-Diels-Alder-type cleavage of the β-amyrin skeleton.[6]



Experimental

The mass spectra were measured with a Hitachi RMU-6D model; ionization energy: 70 eV.; ionizing chamber heater: 250°C; evaporation temperature: 200°C.

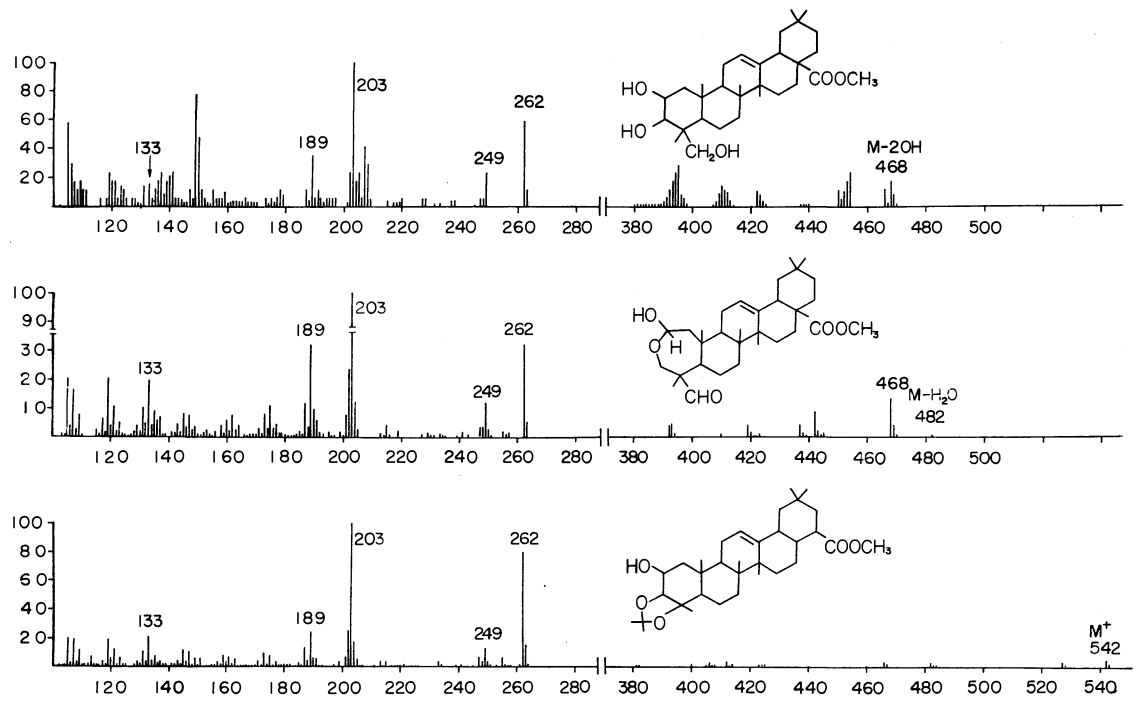

Fig. 1. Mass spectra of arjunolic acid derivatives.

The Extraction of Arjunolic Acid.—The roots (10 kg.) of pulverized *Psidium guaijava L.* were extracted continuously with ethanol to give 300 g. of a brown powder. After the powder had been extracted with petroleum ether, the residue was extracted with ether; when the ether extract was evaporated, 25 g. of a crude pale yellow residue was obtained. This was dissolved in methanol and treated with diazomethane; the solution was then passed through a column of silicic acid (1250 g., 100 mesh, Mallinckrodt) and eluted with chloroform to yield 2.5 g. of crude crystals. Several recrystallizations from acetone gave 2.0 g. of pure methyl arjunolate as white needles; m. p. 240—242°C, $[\alpha]_D$ 60.75° (*c* 1.0%, $CHCl_3$). ν_{max}^{KBr} 3425, 1730, 1460, 1385, 1365, 1040 cm^{-1}.

Found: C, 74.08; H, 10.01. Calcd. for $C_{31}H_{50}O_5$: C, 74.06; H, 10.03%.

The compound was identified as methyl arjunolate by a mixed melting point test and by a comparison of its IR spectrum with that of an authentic specimen.[2)]

The Periodate Oxidation of Methyl Arjunolate.—A solution of 100 mg. of the ester 2 in 20 ml. of ethanol was treated with 100 mg. of sodium periodate dissolved in 2 ml. of water; the mixture was then left in the dark for 24 hr. The crystalline precipitate was filtered and recrystallized several times from ethanol to give 60 mg. of needles; m. p. 200—201°C, $[\alpha]_D$ 191.8° (*c* 1.0% $CHCl_3$), ν_{max}^{KBr} 3530, 2720 1725 cm^{-1}.

Found: C, 74.50; H, 9.61. Calcd. for $C_{31}H_{48}O_5$; C, 74.36; H, 9.66%.

2, 4-*Dinitrophenylhydrazone;* m. p. 194—196°C.

Found: C, 65.54; H, 7.95; N, 8.08. Calcd. for $C_{37}H_{52}O_6N_4$: C, 65.59; H, 7.70; N, 8.23%.

The Acetate 4 (prepared by the treatment of 3 with acetic anhydride-pyridine): m. p. 197—198°C.

Found: C, 73.79; H, 9.31. Calcd. for $C_{33}H_{50}O_6$: C, 73.03; H, 9.31%.

The Acetonide 5.—The methyl ester 2 (200 mg.), dissolved in 40 ml. of anhydrous acetone, was treated with 1.8 g. of anhydrous cupric sulfate and the mixture was then stirred for 24 hr. at room temperature. The mixture was filtered, the filtrate was dried in vacuo, and the residual solid was dissolved in chloroform and chromatographed through silicic acid (100 mesh, Mallinckrodt) to yield the acetonide 5. The crude compound was recrystallized from ethanol and then from acetone to give 120 mg. of needles, m. p. 152—153.5°C.

Found: C, 74.45; H, 9.30. Calcd. for $C_{34}H_{54}O_5$: C, 75.23; H, 10.03%.

The Acetate 6: m. p. 197—200°C.

Found: C, 74.18; H, 9.77. Calcd. for $C_{36}H_{56}O_6$: C, 73.93; H, 9.65%.

We are grateful to the Toyo Rayon Company for the grant which enabled us to purchase the RMU-6D mass spectrometer.

The Preparation of Four Optically Active Isomers of 3-Methylmalic Acid

By Susumu TATSUMI, Masami IMAIDA and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 20, 1966)

3-Methylmalic acid contains two asymmetric centers and, hence, exists in two racemic forms — four optically active forms. Although there have been several reports[1-3] on the preparation of this hydroxy acid, these procedures all yield a mixture of the two isomeric racemates. Therefore, neither the two racemic forms nor their four optically active forms have yet been identified.

In the present work, the two racemic forms and four optically active forms were prepared. A mixture of isomeric racemates was synthesized from ethyl ethoxalyl propionate by Scherp's procedure,[2] and then it was separated into two racemic forms by means of the differential solubility of their barium salts in water. The less soluble salt yielded the racemic form with a m. p. of 115°C (I), while the more soluble one yielded the racemic form with a m. p. of 129°C (II). Then, their optical resolutions were performed by the usual method, using brucine as a resolving reagent. The values of the optical rotation of the optically active isomers were as follows:

(A) From the racemic form with the lower melting point (I):

(+)-isomer $[\alpha]_D^{20}$ +9.1° (*c* 3.7, water)

(−)-isomer $[\alpha]_D^{20}$ −8.9° (*c* 3.7, water)

(B) From the racemic form with the higher melting point (II):

(+)-isomer $[\alpha]_D^{20}$ +5.2° (*c* 3.2, water)

(−)-isomer $[\alpha]_D^{20}$ −5.3° (*c* 3.2, water)

The racemic form with the m. p. of 129°C (II) was assigned the threo form by the method of the nitrous acid deamination of DL-*threo*-3-methylaspartic acid, whose configuration had previously been proved by Baker et al.[4]

Experimental*

The Preparation of the Mixture of Isomeric Racemates.—The mixture of isomeric racemates was prepared from ethyl ethoxalylpropionate by the method of Scherp,[2] but using a Raney nickel catalyst in place of platinum oxide catalyst.

The Separation of the Mixture into Two Racemic Forms.—A very viscous colorless syrup of the mixture, weighing 148 g., was dissolved in 1000 ml. of water; the mixture was then adjusted to pH 8 with a 10% barium hydroxide solution. The resulting solution was stored overnight in a refrigerator. Then the salt which had precipitated was collected by filtration, washed several times with cold water, and dried in air at 80°C. Yield, 155 g. The salt was dissolved in 300 ml. of 6 N hydrochloric acid, and the resulting solution was then concentrated under reduced pressure. The residue was treated with a small amount of water, and the solution was again evaporated in vacuo to remove as much free hydrochloric acid as possible. This treatment was repeated several times to ensure the complete removal of the hydrochloric acid, and then the residue was extracted with six 30 ml. portions of acetone. The acetone extracts were combined and evaporated to a very viscous syrup. This was then dissolved in 100 ml. of ethyl acetate, and to the solution there was added 50 ml. of petroleum ether. This solution was stored in a refrigerator, and the precipitated crystalline product was collected by filtration. Yield, 65 g. The recrystallization of this product from ethyl acetate - petroleum ether (2 : 1) gave white crystals of I. Yield, 46 g. M. p. 113—115°C.

Found: C, 39.26; H, 5.51. Calcd. for $C_5H_8O_5$: C, 40.54; H, 5.44%.

The mother liquor of the barium salt of I was stored for a week, and a small amount of crystalline precipitate was filtered off. The clear solution was concentrated and decomposed with 120 ml. of concentrated hydrochloric acid, and then treated as has been described above. In this way, 28 g. of white crystals of II were obtained. M. p. 128—129°C.

Found: C, 39.81; H, 5.73. Calcd. for $C_5H_8O_5$: C, 40.54; H, 5.44%.

The Optical Resolution of I.—Thirty grams of I and 86 g. of brucine dihydrate were dissolved in 800 ml. of boiling water, and the resulting solution was allowed to stand overnight in an ice box. The crystals of the brucine salt which precipitated were collected by filtration; seven recrystallizations of this salt from ten parts of boiling water gave 25 g. of the pure brucine salt of I. This salt was suspended in 200 ml. of cold water and decomposed with 50 ml. of a N sodium hydroxide solution. The precipitated brucine was removed by filtration, and the alkaline filtrate was washed twice with 30 ml. portions of chloroform, neutralized with concentrated hydrochloric acid, and then evaporated to a syrup. To this a small amount of water was added, and the resulting solution was decolorized with charcoal and evaporated to dryness in order to remove the free hydrochloric acid. The residue was extracted several

* All the melting points given in this paper are uncorrected values.

times with 20 ml. of acetone. The acetone extracts were combined and again evaporated to a syrup. The syrupy product was dried over sulfuric acid in a vacuum desiccator. In this way, white crystals of (+)-I were obtained. Recrystallization from 10 ml. of ethyl acetate - petroleum ether (1 : 1) gave 3.6 g. of optically-pure (+)-I. m. p. 107°C, $[\alpha]_D^{20}$ +9.1° (*c* 3.7, water).

Found: C, 40.36; H, 5.51. Calcd. for $C_5H_8O_5$: C, 40.54; H, 5.44%.

The mother liquor of the brucine salt of (+)-I was concentrated to a paste. After it had been stored for a week in an ice box, the brucine salt of (−)-I was collected. Optically-pure (−)-I was obtained from this salt by the procedure described above. Yield, 1.3 g. M. p. 106—107°C, $[\alpha]_{20}^{D}$ −8.9° (*c* 3.7, water). Found: C, 40.40; H, 5.24%.

The Optical Resolution of II.—Twenty grams of II and 58 g. of brucine dihydrate were dissolved in 900 ml. of boiling water, and then the resulting solution was treated as described for the resolution of I. Thus, 2.7 g. of optically pure (−)-II crystallized out. M. p. 111°C; $[\alpha]_{20}^{D}$ −5.3° (*c* 3.2, water).

Found: C, 40.32; H, 5.50. Calcd. for $C_5H_8O_5$: C, 40.54; H, 5.44%.

From the mother liquor of the brucine salt of (−)-II, 1.1 g. of optically pure (+)-II were obtained. M. p. 110—111°C, $[\alpha]_D^{20}$ +5.2° (*c* 3.2 water). Found: C, 40.54; H, 5.39%.

The Deamination of DL-*threo*-3-Methylaspartic Acid with Nitrous Acid.—Five grams of DL-*threo*-3-methylaspartic acid[4] were dissolved in 50 ml. of N hydrochloric acid, and the resulting solution was cooled to about 5°C in an ice bath. A solution of 3.5 g. of sodium nitrite in 30 ml. of water was then added slowly, with a continuous vigorous stirring and with cooling. (The addition required about 30 min.). After the addition, the reaction mixture was allowed to stand at 5°C for 1 hr., and then at room temperature overnight. To the reaction mixture, 50 ml. of concentrated hydrochloric acid were added, and the solution was evaporated to dryness in vacuo. Water was added, and the evaporation repeated. The yellowish residue was extracted several times with boiling acetone, and the white residue was discarded. The combined acetone extracts were evaporated under reduced pressure, and the resulting syrup was dissolved in a small amount of water. After decoloration with charcaol, the solution was again evaporated to a syrup; it was then allowed to stand in a refrigerator. The crystalline product was collected by suction, and two recrystallizations from ethyl acetate gave white crystals of II. Yield, 2.4 g.; m. p. 129°C. Found: C, 40.77; H, 5.59. Calcd. for $C_5H_8O_5$: C, 40.54; H, 5.44%.

SHORT COMMUNICATIONS

Aluminum Chloride-Catalyzed Reactions of Organosilicon Compounds. A Rapid Redistribution Reaction of Chlorodisilanes

By Hideki SAKURAI, Kenji TOMINAGA and Makoto KUMADA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received May 11, 1966)

In recent years, considerable attention has been directed toward a study of the organopolysilanes.[1] An interesting example of this involves the reaction of organodisilanes with an electrophilic reagent.[2] During the course of an investigation of the reactivity of organopolysilanes toward electrophiles, we have found that methylchlorodisilanes readily undergo aluminum chloride-catalyzed redistribution reaction at room temperature, while the disproportionation of alkylchlorosilanes catalyzed by aluminum chloride has been reported to proceed slowly, even at much higher temperatures.[3,4]

$$(CH_3)_3SiSi(CH_3)_3 + Cl(CH_3)_2SiSi(CH_3)_2Cl \underset{\longleftarrow}{\overset{AlCl_3}{\longrightarrow}} 2(CH_3)_3SiSi(CH_3)_2Cl \quad (1)$$

When an equimolar mixture of hexamethyldisilane and 1, 2-dichlorotetramethyldisilane is stirred at room temperature in the presence of anhydrous aluminum chloride (0.05—0.25 mol./l.), the equilibrium is established between pentamethylchlorodisilane and its original components within 1.5 hr.[5]

As the equilibrium is established rapidly in favor of pentamethylchlorodisilane, the reaction can be applied in a preparative scale. In a typical experiment a mixture of 73.5 g. of hexamethyldisilane, 94.5 g. of tetramethyldichlorodisilane, and 5.5 g. of anhydrous aluminum chloride was stirred for about 2 hr. at room temperature. After 3 g. of acetone had been added to the mixture to deactivate the catalyst, the mixture was subjected to simple distillation under reduced pressure. The fractionation of the distillate gave 114 g. (68.5%) of pure pentamethylchlorodisilane.

In view of these finidings, it became of interest to investigate the aromatic substitution by a mixture of pentamethylchlorodisilane and aluminum chloride, since it is well known that halosilanes do not react with benzene in the presence of Lewis acid.[3,4]

Although an attempted silylation of benzene by a mixture of pentamethylchlorodisilane and aluminum chloride was unsuccessful, we have found that detrimethylsilylation was effected very rapidly by pentamethylchlorodisilane in the presence of a catalytic amount of aluminum chloride.

$$C_6H_5Si(CH_3)_3 + Cl\text{-}Si(CH_3)_2Si(CH_3)_3 \overset{AlCl_3}{\longrightarrow} C_6H_5Si(CH_3)_2Si(CH_3)_3 + Cl\text{-}Si(CH_3)_3 \quad (2)$$

Using competitive reaction conditions in benzene, we found that phenyltrimethylsilane underwent the reaction faster than *p*-chlorophenyltrimethylsilane and slower than *p*-methylphenyltrimethylsilane with pentamethylchlorodisilane.[6]

The order of substituent effects demonstrates the electrophilic nature of the reaction; it also confirms the present reaction to be a new class of aromatic electrophilic substitution.[7]

5) The apparent equilibrium constant, $K=[C_5H_{15}Si_2Cl]^2/[C_6H_{18}Si_2][C_4H_{12}Si_2Cl_2]$, was found to be 82.6 for the original mixture of 6.22 mmol. of hexamethyldisilane, 5.78 mmol. of tetramethyldichlorodisilane and 1 mmol. of aluminum chloride in 20 ml. of benzene. In chloroform, however, the reaction did not proceed even after one week at room temperature.

6) The apparent relative rates at an early stage of the reaction were found: $k_{p\text{-}CH_3}/k_H=2.0$ and $k_{p\text{-}Cl}/k_H=0.2$.

Novel Diphenylketene Derivatives of Dicyclopentadienyl-vanadium and -titanium

By Pang-bu HONG, Kenkichi SONOGASHIRA and Nobue HAGIHARA

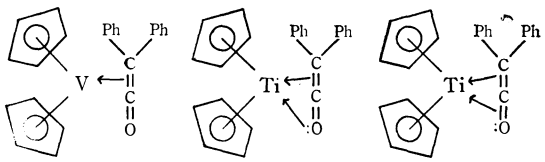
The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received May 18, 1966)

The interaction of cumulative carbon-carbon double bond systems with various organometallic compounds has been reported from this laboratory.[1] Because the comparison between the two kinds of interactions of ketene- and allene-systems with organometallic compounds is an interesting problem, we now wish to report on the isolation and on some properties of the diphenylketene derivatives of vanadium and titanium.

When a solution of diphenylketene (I) (3.7 g., 1.91 mmol.) and dicyclopentadienylvanadium (3.3 g., 1.82 mmol.) in toluene (20 ml.) was stirred under nitrogen at 60°C for 1 hr., the color of the reaction mixture changed from violet to dark green. After the mixture had then cooled to room temperature, dark green crystals separated. Recrystallization from toluene gave 5.5 g. (81% yield) of air-sensitive dark green crystals ((II); m. p. 159—163°C in a sealed tube under nitrogen). Found: C, 76.83; H, 5.30; mol. wt. (in benzene), 386. Calcd. for $C_{24}H_{20}OV$: C, 76.79; H, 5.37; mol. wt., 375. IR (KBr disk): 1618 and 1580 cm^{-1}, and no absorption in the region of 1620—2800 cm^{-1}.

II is paramagnetic; its electron paramagnetic resonance spectrum of a benzene solution shows a *g*-factor of 1.9976 and a ^{51}V hyperfine splitting of 45.5 gauss. This splitting and *g*-value are almost the same as those of the acetylene derivatives of dicyclopentadienylvanadium.[2] This fact suggests that the diphenylketene is bound to the metal as tightly as acetylene, although infrared data excludes such a cyclic structure as that of the acetylene derivatives. In view of the facts mentioned above, we postulate II as the most probable structure; in it the metal is coordinated through the C=C double bond in the ketene.



(II) (III-a) (III-b)

A similar reaction of I (1.4 g.) with dicyclopentadienyltitanium dicarbonyl (1.1 g.) in hexane has been found to form dicyclopentadienyl-diphenylketene-titanium (III) in a yield of 90%. III crystallizes as orange-yellow prisms from the reaction mixture, m. p. 215—217°C (decomp.), in a sealed tube under nitrogen. Found: C, 77.07; H, 5.49; O, 4.74; Ti, 13.6; mol.wt. 367 (vapor pressure osmometer, in benzene). Calcd. for $C_{24}H_{20}OTi$: C, 77.42; H, 5.41; O, 4.30; Ti, 13.0%; mol. wt. 372. IR (KBr disk): 1575 and 1555 cm^{-1}, and no absorption in the region of 1580—2800 cm^{-1}.

The NMR spectrum of III in methylene chloride or deuterochloroform shows that the relative intensity of π-cyclopentadienyl and phenyl protons is approximately 1 : 1. although the decomposition of the complex with the chlorinated solvents prevents precise measurements. To obtain the effective atomic number of krypton, the titanium atom must be supplied with 4 electrons from the π-complexed diphenylketene. Of the two most probable structures, a and b, the former, which involves the coordination of the diphenylketene group through the π-complexing C=C bond and the lone pair of the oxygen, is favored on the basis of a consideration of the steric requirement and its similarity with the cyanoamido complex.[3]

The reaction of II and III with such proton-donors as alcohol, hydrochloric acid, water and acetic acid were of considerable interest. These reagents decomposed the diphenylketene complexes, with the liberation of tetraphenylethane (IV). For example, when treated with glacial acetic acid, the III complex yielded IV, with a vigorous gas evolution, in a yield of 53%. Similarly, the vanadium complex, II, gave IV in a 25% yield, when treated with ethanol. The formation of IV in the above reactions suggests that the carbon-carbon double bond in the ketene is weakened by bonding to the metal.

Further work on the interaction of ketenes with organometallic π-compounds is in progress.

The Copolymerization of Vinyl Chloride and Ethylene by a Ziegler-Natta Catalyst

By Akira MISONO and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

and Kunikazu YAMADA

Central Research Laboratory, Sekisui Chemical Co., Shimamoto-cho, Mishima-gun, Osaka

(Received June 3, 1966)

Recently, Yamazaki et al. have reported the copolymerization of vinyl chloride with propylene by the use of the catalyst systems consisting of $Ti(n\text{-}OBu)_4$ and organoaluminum compounds.[1] In the course of the studies of the copolymerization of vinyl chloride with ethylene, the present authors have also found that the same catalyst systems can copolymerize these monomers in a manner quite different from the radical copolymerization which they previously reported.[2] This paper will deal with the copolymerization by the use of the $Ti(n\text{-}OBu)_4$-$AlEtCl_2$ catalyst system.

The reaction was carried out in a stainless-steel autoclave equipped with an agitating device. The resultant copolymer was treated and purified in the usual manner. The composition of the product was calculated from the elemental analyses data. The reduced specific viscosity of the tetrahydrofuran-soluble polymer was measured using a 0.5 g./100 ml. cyclohexanone solution at 30.0°C.

Typical copolymerization results, including the results of successive solvent extraction, are shown in Table I. The copolymerizates obtained by the use of the present catalyst system were considerably richer in ethylene than those obtained in the radical copolymerization using trialkylboron-peroxide systems.[2] The copolymerizate became richer in ethylene with an increase in the aluminum/titanium molar ratio. At aluminum/titanium molar ratios higher than 5, only polyethylene was obtained at any composition of the monomer mixture.

In order to investigate the composition distribution of the copolymerizate, successive solvent extraction, using tetrahydrofuran and monochlorobenzene, of the products obtained at aluminum/titanium molar ratios of 1.8, 2.5 and 3 were carried out. These results are shown in Table I. The copolymerizates being extracted not only according to the difference in molecular weight, but also according to the difference in composition, it was considered that the copolymerizates consisted of copolymers of different compositions. There may exist several active sites in the catalyst system, each with different reactivity ratios and each producing its own type of polymer.

The catalyst system was active for vinyl chloride homopolymerization, but it showed little activity for ethylene at aluminum/titanium molar ratios lower than 2.5. However, the catalyst changed its activity for each monomer at an aluminum/titanium molar ratio slightly higher than 2.5. From the infrared spectroscopy of the extracted fractions of the copolymerizates, particularly investigating the 900—700 cm^{-1} region where absorptions due to the methylene rocking mode of polyvinyl chloride (833 cm^{-1}), the vinyl chloride-ethylene random copolymer (750 cm^{-1}) and polyethylene (730 and 720 cm^{-1}) are observed, it was proved that a random copolymer with a broad composition distribution was obtained at aluminum/titanium molar ratios lower than 2.5, whereas, at an aluminum/titanium molar ratio of 3, a block copolymer rich in ethylene was formed, along with a random copolymer rich in vinyl chloride.

Detailed experimental results and a discussion of the reaction mechanism will be reported in the near future.

TABLE I. COPOLYMERIZATION RESULTS WITH USE OF $Ti(n\text{-}OBu)_4$-$AlEtCl_2$ CATALYST SYSTEM

Bismuth-Carbon Cleavage on Complex Formation

By Rokuro OKAWARA, Kiyoshi YASUDA and Masanobu INOUE

Department of Applied Chemistry, Osaka University, Higashinoda, Miyakojima, Osaka

(Received June 4, 1966)

Numerous investigations have been concerned with the preparation of triarylbismuths from diarylbismuth halides. Gilman et al.[1] have reported that the reaction of diphenylbismuth halides with hydrazine hydrate in refluxing alcohol gave triphenylbismuth and inorganic bismuth halides according to;

$$3Ph_2BiX \longrightarrow BiX_3 + 2Ph_3Bi \quad (1)$$

However, we have obtained monophenylbismuth compounds together with triphenylbismuth by the reactions of diphenylbismuth halides with pyridine at room temperature.

$$2Ph_2BiX \xrightarrow{py} PhBiX_2 \cdot 2py + Ph_3Bi \quad (2)$$

These compounds correspond to the hypothetical intermediate substances of the conversion reaction 1. Hartmann et al.[2] have assumed that analogous compounds are formed in the decomposition reactions of para-substituted phenylbismuth compounds.

Experimental.—Phenylbismuth Halides. — Ph_2BiX and $PhBiBr_2$ were prepared by the reaction[3] of Ph_3Bi and BiX_3 (X=Cl, Br), and purified by the recrystallization from dry benzene.

Phenylbismuth Dibromide Pyridine Adduct.—Method 1: A solution of 3 g. Ph_2BiBr in 50 ml. of dry pyridine was added dropwise to 150 ml. of petroleum ether. After filtering 0.2 gr. of white solid (A), m. p. 143—146°C, the filtrate was kept standing for a day at room temperature, and 1.1 gr. of pale yellow needle-like crystals (B) of $PhBiBr_2 \cdot 2py$ was obtained, m. p. 145—146°C. Yield (A+B) 62%.

Found: Bi, 34.72; C, 31.93; H, 2.33; N, 4.65; Br, 26.42. Calcd. for $C_6H_5BiBr_2 \cdot 2C_5H_5N$: Bi, 34.59; C, 31.81; H, 2.50; N, 4.64; Br, 26.46%.

Removal of the solvents under reduced pressure from the mother liquor gave 1.3 gr. of white solid, which was recrystallized from ethanol to give Ph_3Bi, m. p. 77—78°C. Yield 87%.

Method 2: On addition of a solution of $PhBiBr_2$ (1 g.) in 40 ml. of pyridine to 150 ml. of petroleum ether, a creamy precipitate of $PhBiBr_2 \cdot 2py$ (m. p. 145—146°C) was obtained almost quantitatively.

The infrared spectra and the mixed melting point showed that the complexes prepared by methods 1 and 2 were identical.

Phenylbismuth Dichloride Pyridine Adduct.—White needle crystals of $PhBiCl_2 \cdot 2py$ (m. p. 136—137°C) was prepared by the same procedure (method 1) used for the bromide. Yield 77%.

Found: Bi, 40.67; C, 37.83; H, 2.80; N, 5.46; Cl, 13.77. Calcd. for $C_6H_5BiCl_2 \cdot 2C_5H_5N$: Bi, 40.56; C, 37.30; H, 2.93; N, 5.44; Cl, 13.76%.

From the mother liquor a 95% yield of Ph_3Bi was obtained.

The Photochemical Reactions of Ethyl Benzoylformate in Solution

By Tamotsu TOMINAGA, Yoshinobu ODAIRA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received June 8, 1966)

In an earlier paper dealing with photoethyl oxallylation,[1] the present authors reported that the direct introduction of ethyl oxallyl radicals, generated by the photolysis of diethyl oxalate or ethyl phenyl oxalate, into several hydrogen-donating solvents was successful, and that ethoxycarbonyl derivatives, i. e., esters, were always found to be the second principal product in a series of the above reactions.

Concerning the formation of esters, it seems more likely that the esters would be formed by a recombination between ethoxycarbonyl and solvent radicals. However, as has been previously pointed out,[2] ethoxycarbonyl radicals decompose exothermically because of their remarkable unstability and give rise to only carbon dioxide and ethyl radicals (quantitatively).

Meanwhile, in our photoreactions of the above oxalates in a solvent, carbon monoxide was invariably isolated as a major gaseous product; the ratio of the formation of carbon monoxide to that of carbon dioxide was approximately 4.5. From the above results, it may be considered that the reaction path for ester formation involving free ethoxycarbonyl radicals produced through the photolysis of the oxalate is not very significant. Subsequently, it seems that the esters may be formed by the secondary photolysis of the corresponding α-keto esters.

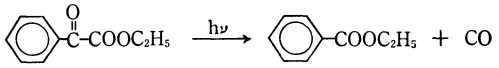
The photochemistry of α-keto esters in various media has been extensively studied recently by several investigators. Giving the photolysis of ethyl benzoylformate as an example, in an inert solvent such as benzene, ethyl benzoylformate is photodecarbonylated to afford benzaldehyde and acetaldehyde.[3] In alcoholic solvents at room temperature,[4,5] the formate is officiently photoreduced to the corresponding pinacol, while, on the other hand, at elevated temperature it undergoes intramolecular hydrogen abstraction, yielding acetaldehyde, the corresponding hydroxyketene, and the enol of phenylglyoxal. At any rate, the formation of esters from the α-keto esters by photodecarbonylation has not yet been reported.

In order to make sure of the feasibility of the formation of the ester from the α-keto ester, the photolysis of ethyl benzoylformate in solvents such as benzene and cyclohexane was undertaken.

The irradiation of a solution of ethyl benzoylformate (0.075 mole) in benzene (1.5 mole) with a light of approximately 3660 Å, provided by a 300 W. high-pressure mercury lamp through a suitable filter system, was carried out at 20°C for 7 days. As the photoproducts, ethyl benzoate (0.65 g.), ethyl mandelate (2.45 g.) and biphenyl (1.1 g.) were obtained, together with the products, such as benzaldehyde (0.5 g.) and acetaldehyde (0.1 g.), described above. Moreover, besides the above constituents, a small amount of a gaseous product consisting of carbon monoxide, carbon dioxide and ethane in the ratio of 19 : 6 : 1 was obtained.

In addition, the irradiation, at 20°C for 54 hr., of a solution of ethyl benzoylformate (0.1 mole) and cyclohexane (5.0 mole), using a 300 W. high-pressure mercury arc lamp, afforded the following various photoproducts: ethyl benzoate (1.0 g.), ethyl mandelate (1.6 g.), benzaldehyde (0.7 g.), biphenyl (0.4 g.), benzophenone (0.25 g.), ethyl cyclohexyl carboxylate (0.5 g.), and bicyclohexyl (1.8 g.), along with very small amounts of acetaldehyde, cyclohexyl methyl carbinol and cyclohexyl methyl ether. Most of the gaseous product obtained was composed of carbon monoxide. The conversion percentage of ethyl benzoylformate was 52%.

Although the present photochemical reaction is rather complex due to the many different radicals produced, the results show a plain demonstration of the possibility of ester formation from the α-keto ester by photodecarbonylation.



Details of this and further work will be reported shortly.

The Absolute Configuration of Pulegoneoxide

By Jun KATSUHARA

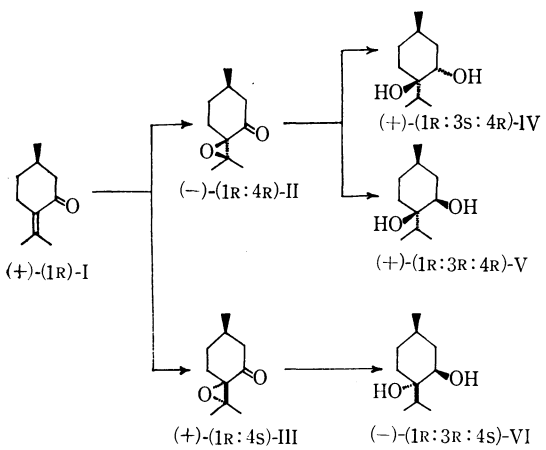
Sun Star Dentifrice Company, Akutagawa, Takatsuki, Osaka

(Received June 9, 1966)

Reusch and Johnson[1] recently reported on the configuration of diastereomeric pulegoneoxides and deduced that the (−)-pulegoneoxide which was derived from (+)-pulegone should be assigned the *cis* structure, and the (+)-pulegoneoxide, the *trans* structure, on the basis of IR, UV, NMR, and ORD data.

In contrast to the above deduction, Djerassi et al.[2] suggested that the assignment should be reversed in the light of his ORD investigations. The present paper will attempt to establish the absolute configuration of these pulegoneoxides by means of unequivocal chemical transformations of these oxides into diols with well-defined configurations.

(+)-(1R)-Pulegone (I) was oxidized with 30% hydrogen peroxide in a 30% sodium hydroxide solution to give a mixture of *cis*- and *trans*-pulegoneoxide, m. p. 43°C.



The fractional distillation, followed by the zone-melting purification, of the mixture afforded (−)-pulegoneoxide (II), m. p. 54°C, $[\alpha]_D^{20}$ −18.8° (ethanol), and (+)-*cis*-pulegoneoxide (III), m. p. 59°C; $[\alpha]_D^{20}$ +46.6° (methanol).

The (−)-diastereomer (II) was then reduced with lithium aluminum hydride in ether to give (+)-*trans*-4-hydroxyneomenthol (IV) in an 83% yield, m. p. 72°C; $[\alpha]_D^{20}$ +22.6° (chloroform), and (+)-*cis*-4-hydroxymenthol (V) in a 17% yield, m. p. 76°C; $[\alpha]_D^{20}$ +10.4° (chloroform).

These diols (IV and V) were identified as such by an IR-comparison with authentic (+)-(1R : 3s : 4R)-*trans*-4-hydroxyneomenthol[3] and (+)-(1R : 3R : 4R)-*cis*-4-hydroxy menthol[4] respectively.

The diastereomeric (+)-pulegoneoxide (III) was reduced with lithium aluminum hydride to give (−)-*trans*-4-hydroxyneoisomenthol (VI) in an almost quantitative yield, m. p. 76°C, $[\alpha]_D^{20}$ −22.0 (methanol). This was identified by a melting-point determination and by an IR comparison with authentic (−)-(1R : 3R : 4s)-*trans*-4-hydroxy-neoisomenthol.[4]

The results in the present study unambiguously settle the dispute about the absolute configuration of pulegoneoxides and support Djerassi et al.'s assignment based on the ORD investigations. The observed negative and positive Cotton effects of (−)-II and (+)-III respectively also suggest the reasonable applicability of the "reversed" Octant rule[2] to spiro [5, 2] systems. Further details will be reported elsewhere in the near future.

Studies on Amino-hexoses. XII. Crystalline Muramicitol and Its Use in a Study of the Lysozyme Action on the Cell Wall of Micrococcus Lysodeikticus

By Saburo HARA and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University, College of Science, Toyonaka, Osaka

(Received June 11, 1966)

It has been concluded that the egg white lysozyme splits the polysaccharide part of the bacterial cell wall and that the di- and tetra-saccharides released have muramic acid as their reducing ends.[1] One of the structure analyses of these oligo-saccharides consisted of the reduction of the saccharides with borohydride and the examination of the subsequent hydrolysis mixture on chromatograms. As a result of a lack of the authentic muramicitol, 2-amino-3-*O*-(D-1'-carboxyethyl)-2-deoxy-D-glucitol, however, the above conclusion was drawn from the facts that muramic acid disappeared or diminished and that a new ninhydrin positive compound appeared on the chromatograms.

In order to gain a straight and positive conclusion, we have now prepared crystalline muramicitol and used it as the reference standard in a study of lysozyme action on the cell wall of M. lysodeikticus. As is shown in Table I, egg white lysozyme splits *N*-acetyl-muramide linkages only, leaving *N*-acetyl-glucosaminide linkages intact; this seems somewhat peculiar, because the same enzyme splits *N*-acetyl-glucosaminide linkages in chitin,[2] glycol chitin and carboxymethyl chitin.[3]

TABLE I. THE COMPOSITION OF THE ACID HYDROLYSATES (μmol./g.)

	Intact cell wall	Lysozyme digest treated with sodium borohydride
Muramic acid	597	169
Glucosamine	628	649
Muramicitol	0	360
Glucosaminitol	0	0
Glutamic acid	740	731
Glycine	765	729
Alanine	1635	1615
Lysine	697	688
Ammonia	763	832

The Preparation of Muramicitol.—Muramic acid[4] (150 mg.) was dissolved in 5 ml. of water, and to this solution there was then added 50 mg. of sodium borohydride while it was being stirred at room temperature. After the mixture had stood for 2 hr., its pH was adjusted to 5.6 by adding Amberlite IR-120 (H^+ form). The solution separated from the resins was concentrated to dryness in vacuo. To the residue 10 ml. of dry methanol was added, and the solution was evaporated to dryness in order to remove the methyl borate formed. This process was repeated three times. The residue was dissolved in 0.5 ml. of water, and to this solution 10 ml. of methanol was added. After the mixture had stood in a refrigerator, 90 mg. of colorless crystals were obtained. The specimen melted at 196°C (uncorr.) ($[\alpha]_D^{26}$ +44.9 (*c*, 0.423, water)). Found: C, 42.29; H, 7.72; N, 5.33. Calcd. for $C_9H_{19}O_7N$: C, 42.68; H, 7.56; N, 5.53%. The muramicitol thus obtained showed no reducing power against a ferricyanide reagent.[5] The ninhydrin color reaction was very weak, and the molar extinction coefficient was about 6% that of muramic acid. In a Stein-Moore column,[6] the specimen eluted before aspartic acid at pH 3.25 (0.2 N citrate).

The Lysozyme Action on the M. Lysodeikticus Cell Wall.—A cell wall (4.4 mg.) isolated from M. lysodeikticus by the usual bead-shaking method[7] was incubated with 0.5 mg.- of crystalline egg white lysozyme for 24 hr. at 37°C in 1.5 ml. of a M/15 phosphate buffer of pH 7.0. After the incubation had ended, the pH of the solution was adjusted to 9.0 by adding 0.1 N sodium hydroxide; then the mixture was treated with sodium borohydride for 24 hr. at room temperature. After lyophilization and hydrolysis with 6 N hydrochloric acid for 16 hr. at 100°C, an appropriate amount of the hydrolysate was run on a Stein-Moore column using an automatic instrument (Hitachi KLA-3). In Table I the results are shown and compared with the hydrolysate of the intact cell wall.

No correction was made for the degradation during acid hydrolysis, and the data for the minor-constituent amino acids are omitted.

This investigation was supported by U. S. Public Health Service Grant AI-04586-04.

Dielectric Loss Measurement by Differential Thermal Analysis (DTA)

By Takasuke MATSUO, Hiroshi SUGA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 15, 1966)

Dielectrics with an imaginary part, ε'', of electric susceptibility absorb energy proportional to $\varepsilon'' E_0^2 \omega$ per unit of time per unit of volume from an applied electric field, $E_0 \sin \omega t$. This suggests the possibility of measuring the dielectric loss factor of substances by temperature measurements. In fact, we observed this effect by the DTA technique which we have been developing.

The construction of the main part of the DTA apparatus has been reported elsewhere.[1] Electrodes for applying the field are a pair of 2.0-by-0.7 cm^2 aluminum foils attached to the outer surface of the DTA-specimen glass tube. The electrodes are electrically insulated from the copper block by a thin sheet of polyethylene, which also serves to keep the electrodes in place. A fine copper lead is pressed to the electrode beneath the polyethylene sheet.

The alternating voltage source is a 6CL6-807 high-frequency amplifier driven by a commercial test oscillator. A suitable output voltage was obtained by adjusting the position of the output tap of the 807-plate tank coil. The terminal voltage, usually 10—100 V., was monitored by a valve voltmeter. This assemblage worked satisfactorily between 200 kc. and 20 Mc.

As examples, results on glycerol and cyclohexanol are presented below. The dielectric properties of the former were studied extensively by Davidson and Cole[2] and by others. Our results are illustrated in Fig. 1 as a maximum-loss temperature-vs.-frequency relation.

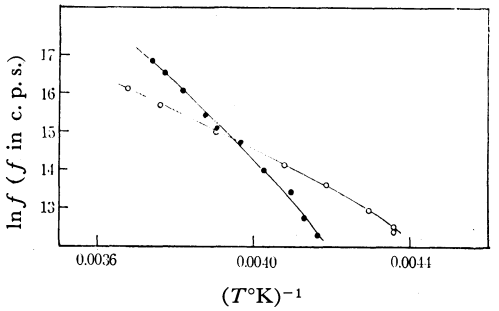

Fig. 1. Frequency vs. maximum-loss-temperature relation for glycerol and cyclohexanol.
—●— Glycerol —○— Cyclohexanol

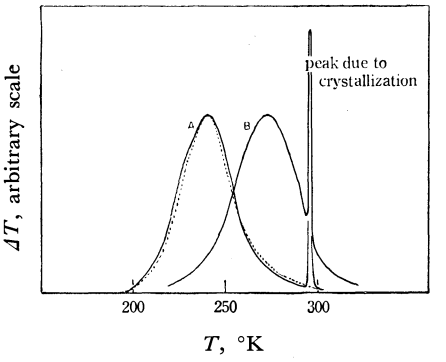

Fig. 2. ΔT vs. temperature plot for cyclohexanol.
A: At 0.81 Mc.
The broken line is the Debye type loss factor with $\tau = \tau_0 \exp(E/RT)$.
B: At 10.1 Mc.

The dielectric behavior of cyclohexanol has been reported on by several authors.[3] On cooling, the crystal takes a metastable form which shows a dielectric loss maximum. In Fig. 2, the ΔT value for this crystal is compared with a normalized Debye-type loss factor with a single $\tau = \tau_0 \exp(E/RT)$ ($\tau_0 = 1.38 \times 10^{-15}$ sec., $E = 9.78$ kcal./mol). The Arrhenius plot for the evaluation of τ_0 and E is given in Fig. 1. These values are in fair agreement with those given in the literature. An interesting feature of this crystal is seen in the ΔT curve for 10.1 Mc., in which the peak due to the crystallization is superposed on the higher-temperature side of the dielectric loss peak without breaking the continuity of the latter. This provides evidence that the mode of the rotational motion of the molecules does not change essentially upon crystallization.

Finally, it should be added here that recently the thermal method of detecting dielectric loss has been applied independently to barium titanate by Pilawski and Danielewicz.[4] Their method seems to be useful for substances with large ε'' values, while for those with smaller ε'' values, our method is more suitable.

The Crystal Structure of Ethylzinc *t*-Butoxide

By Yutaka MATSUI, Kazuhide KAMIYA and Masao NISHIKAWA

Research and Development Division, Takeda Chemical Industries, Ltd., Higashiyodogawa-ku, Osaka

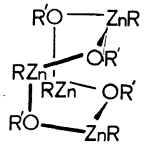
and Yujiro TOMIIE

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received June 15, 1966)

For several years one of the present authors has been sudying $ZnEt_2$ or its derivatives as catalysts for the polymerization of alkylene oxides; in these studies it has been assumed that RZnOR' plays an important role in $ZnEt_2$-alcohol-Al_2O_3 or RZnOR'-Al_2O_3 catalyst systems.[1]

Recently, Coates et al.[2] speculated about the structure of RZnOR' (I). This has prompted us to report our results, obtained through X-ray



(I)

analysis which had been carried out in this laboratory. Since there seems to be some discrepancy between their results and ours, we want to publish a short account of our results now.

Ethylzinc *t*-butoxide was prepared by mixing *t*-butanol and $ZnEt_2$ (molar ratio: 1/1) in dry hexane under nitrogen; single crystals, as colorless prisms, were thus obtained.

The unit cell is monoclinic, with parameters of $a=16.96$ Å, $b=11.02$ Å, $c=10.06$ Å, and $\beta=119°$. The assumption of $(C_6H_{14}OZn)_8$ in a unit cell leads to a reasonable calculated density of 1.35 gcm^{-3}. Systematic extinctions of F_{obs} (h, k, l) when $h+k$ is odd, lead to a *C*-centered lattice, that is, *C*2, *Cm* or *C*2/*m*. A total of 740 independent reflections was recorded photographically with a Weissenberg camera; from these reflections the three-dimensional Patterson function was computed. The results show that a molecule consists of four $EtZnOBu^t$ and that it is in a form resembling a cube, its eight corners being occupied by four zinc and four oxygen atoms.

There are various cubic models that have a different arrangement of atoms. The analysis of the Patterson function alone is not enough to determine the true structure among them. Calculation was carried out by the least-squares method on the assumption of various arrangements of zinc and oxygen atoms in the molecule. However, the temperature factors of the atoms, which were assumed to be oxygen, came to have minus values. Thus, oxygen atoms should not be fixed at any four of the eight corners of the model. The reflection data can be explained most clearly on the hypothesis that the electron density at the eight corners is similar; i. e., the *R*-value reaches a minimum (23%) when such is the case. The structure could not be explained without a consideration of some kind of disorder. In this case, the most possible space group would be *C*2/*m* (*pseudo* symmetry) and the molecules would occupy the special position of 2/*m* in the unit cell. The bond distances and bond angles in this molecule are illustrated in Fig. 1.

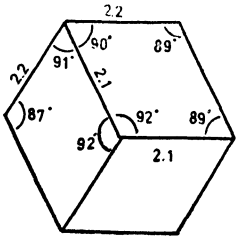


Fig. 1.

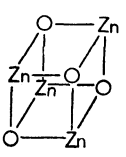
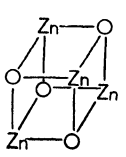
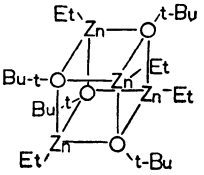
A disordered structure consisting of II and III is most probable, because bond distances between metals are usually above 2.5 Å, and the value of 2.15 Å obtained by our calculation is appropriate for Zn-O. In the disordered sturcture, it may be difficult to clarify the configuration of substituents. However, IV could presumably be assumed to be the structure of this molecule. At present, analysis is still under progress by means of the (F_o-F_c) synthesis to determine the configuration of ethyl and *t*-butoxyl groups.



(II)



(III)



(IV)

Coates has estimated that six probable forms of I would interconvert rapidly, in which case the time-average structure would be cubic. However, it has been shown from the present study that the molecule takes a form resembling a cube, consisting of not three-, but of four-coordinated zinc and oxygen atoms. There is thus no necessity for assuming the time-average structure of I.

The Energy of the Excimer Luminescence of Naphthalene under a Variety of Geometrical Configurations

By Tohru AZUMI* and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received August 24, 1965)

A four-electron ASMO treatment of the interaction of two naphthalene molecules to yield excimers of D_{2h}, C_2, or S_4 is developed, and the energies of these excimers are calculated as a function of the angle, α, between corresponding bonds of the two molecules. It is shown that excimers are stable at two configurations, $\alpha=0°$ and $\alpha=75°$; that the excimer with $\alpha=0°$ does not emit because of the forbidden character of the transition, and that the excimer with $\alpha=75°$ emits and is considered to play a predominant role in the observed excimer fluorescence.

A large number of compounds exhibit, in a concentrated solution, a broad and structureless fluorescence about 6000 cm^{-1} to the red of the normal structured fluorescence. This broad fluorescence band is ascribed to the dimeric species produced by the photoassociation of one ground-state molecule and one excited-state molecule; the term "excimer fluorescence" has been used to describe this phenomenon. Although quite a lot of experimental information is available, theoretical interpretations of excimer fluorescence are scarce. Azumi and McGlynn[1] have suggested that the excimer state may be satisfactorily represented by a linear combination of molecular exciton states and charge resonance states. On the basis of this model, the energy of the excimer luminescence was calculated, by Azumi, Armstrong, and McGlynn,[2] for excimers of naphthalene, anthracene, pyrene, and perylene at the highest possible symmetry of excimer configuration (i. e., D_{2h}). Similar calculations have also been given by Murrell and Tanaka[3] and by Konijnenberg[4]. The agreement between the calculated and the experimental excimer energies strongly supports the above-mentioned idea and the general scheme of the calculation. There are, however, some pitfalls in the calculations which have been presented in the past. The calculations given by these three sets of authors were all carried out for an excimer configuration which may not exist in reality. The excimer configuration for which the calculations were carried out is such that one of the molecules which constitute an excimer is exactly superposed, at some distance, over the other. In an excimer of such a high symmetry, the transition between the lowest excimer state and the dimeric ground state is dipole-forbidden. On the other hand, as has been illustrated by Birks, Dyson, and King,[5] the lifetime of the excimer fluorescence is quite short, indicating the allowed character of excimer luminescence. In some cases, an excimer luminescence of a long duration is observed; however, it has been clarified that this duration is due to triplet-triplet annihilation, and not to the inherent forbidden character of the excimer luminescence.[6-10] All these experimental evidences seem to reveal that excimer luminescence is essentially allowed, and that, consequently, the excimer has a symmetry lower than D_{2h}.

Various geometrical configurations of sandwich-type excimers (in which two molecular planes are parallel) were analyzed group-theoretically by Azumi and McGlynn.[11] It was shown that excimer luminescence should be forbidden not only for the D_{2h} configuration, but also for the C_{2h}, C'_{2h}, or S_2 configurations of the excimer. That is, if the corresponding bonds of the two molecules that constitute an excimer are aligned parallel, excimer luminescence is invariably forbidden. In order for excimer luminescence to be an allowed transition, as seems to be the case, there must be some angle between the corresponding bonds of the two molecules. These are schematically represented in Fig. 1 for the naphthalene excimer.

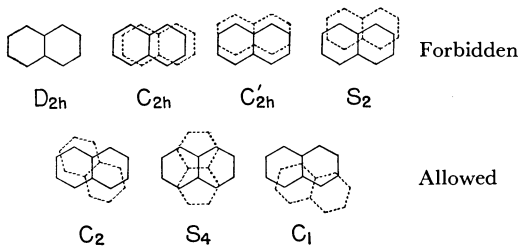

Fig. 1

This conclusion, arrived at group-theoretically, might, however, be hard to accept. First of all, it is against the intuition of chemists that a symmetrical configuration should be favored over an asymmetrical one. In addition, since in most aromatic crystals the two nearest molecules are aligned in the way of C_{2h} or S_2, there has been a suggestion that the excimer should have a similar configuration. It is, in this respect, desirable that some experimental or other kind of theoretical support of the above conclusion be obtained. Polarization measurements, conjoined with group theoretical analysis, would be most fruitful. Unfortunately, however, the polarization measurement of the excimer luminescence in a liquid solution is not possible because excimer formation is diffusion-controlled.[12] As a result, there has not been any experimental information thus far regarding the geometry of the excimer. Another way to approach this goal is to calculate the energy of the excimer luminescence for a variety of the geometrical configurations which give allowed dipole transitions and to see if there is any stable configuration among them. It is this which is effected in this paper.

In this paper, the effect of the angle, α, between the corresponding bonds of the two molecules is analyzed. Namely, excimers of D_{2h} ($\alpha=0°$), C_2 ($0°<\alpha<90°$), and S_4 ($\alpha=90°$) are considered, and the energy of the excimer luminescence is calculated as a function of the angle, α. (See Fig. 2.) Interest is focussed on the variation in energy with respect to the angle, α; in this respect, the separation of the two molecular planes is arbitrarily taken to be 3 Å.

Zeroth-order Dimeric Wave Functions

The general scheme of calculation is essentially identical with those given by Azumi, Armstrong, and McGlynn,[2] since the methods employed by these authors proved satisfactory. The highest-occupied and the lowest-vacant molecular orbitals of one ground state molecule (say, Molecule A) are designated, respectively, as ϕ_1 and ϕ_2, and the corresponding orbitals of the other molecule (say, Molecule B), as θ_1 and θ_2. ϕ_1 and ϕ_2 are orthogonal, as are also θ_1 and θ_2. It is assumed that orthogonality exists between ϕ_1 and θ_2 and between θ_1 and ϕ_2; the overlap between these orbitals is not exactly zero in our overlap approximation (see below), but it is surely very small and may well be neglected. The overlap integrals between ϕ_1 and θ_1 and between ϕ_2 and θ_2 are designated, respectively, as S_1 and S_2; namely, in the bracket notation:

$$S_1 = (\phi_1 \mid \theta_1) \tag{1}$$

$$S_2 = (\phi_2 \mid \theta_2) \tag{2}$$

The zeroth-order dimeric wave functions of interest are, then, expressed in terms of these four molecular orbitals. The wave function for the dimeric ground state is:

$$\psi_G = (1 - 2S_1^2 + S_1^4)^{-1/2} \mid \phi_1\bar{\phi}_1\theta_1\bar{\theta}_1 \mid \tag{3}$$

where:

$$\mid abcd \mid = (4!)^{-1/2} \sum_p (-1)^p \mathbf{P} a(1)b(2)c(3)d(4) \tag{4}$$

The excitation of one electron to a higher orbital produces two molecular exciton states, ψ_A and ψ_B, and two charge resonance states, ψ_C and ψ_D.

The C_2 Excimer.—When an excimer is of the C_2 symmetry, it may easily be shown group-theoretically that all of the four wave functions form bases for the irreducible representation of B. The normalized wave functions are:

$$\psi_A = \{2(1 - S_1^2)\}^{-1/2}\{ \mid \phi_1\bar{\phi}_1\theta_1\bar{\theta}_2 \mid + \mid \phi_1\bar{\phi}_1\theta_2\bar{\theta}_1 \mid \} \tag{5}$$

$$\psi_B = \{2(1 - S_1^2)\}^{-1/2}\{ \mid \phi_1\bar{\phi}_2\theta_1\bar{\theta}_1 \mid + \mid \phi_2\bar{\phi}_1\theta_1\bar{\theta}_1 \mid \} \tag{6}$$

$$\psi_C = \{2(1 - S_1^2)\}^{-1/2}\{ \mid \phi_1\bar{\theta}_2\theta_1\bar{\theta}_1 \mid + \mid \theta_2\bar{\phi}_1\theta_1\bar{\theta}_1 \mid \} \tag{7}$$

$$\psi_D = \{2(1 - S_1^2)\}^{-1/2}\{ \mid \phi_1\bar{\phi}_1\phi_2\bar{\theta}_1 \mid + \mid \phi_1\bar{\phi}_1\theta_1\bar{\phi}_2 \mid \} \tag{8}$$

The D_{2h} Excimer.—When an excimer is of the D_{2h} symmetry, namely, when $\alpha=0°$, the two

wave functions ψ_{I} and ψ_{II} fall into the B_{3g} representation, and the two wave functions ψ_{III} and ψ_{IV} into the B_{2u} representation. These are, in terms of Eqs. 5—8;

$$\psi_{I} = \{2(1 + S_1S_2)\}^{-1/2}(\psi_{A} - \psi_{B}) \quad (9)$$

$$\psi_{II} = \{2(1 + S_1S_2)\}^{-1/2}(\psi_{C} - \psi_{D}) \quad (10)$$

$$\psi_{III} = \{2(1 - S_1S_2)\}^{-1/2}(\psi_{A} + \psi_{B}) \quad (11)$$

$$\psi_{IV} = \{2(1 - S_1S_2)\}^{-1/2}(\psi_{C} + \psi_{D}) \quad (12)$$

The S_4 Excimer.—When an excimer is of the S_4 symmetry, namely, when $\alpha=90°$, the two wave functions $\psi_{A}\pm i\psi_{B}$ fall into the degenerate E representation, and are also $\psi_{C}\pm i\psi_{D}$. When the configuration interaction between these two E states is considered, only one wave function from each E state may be taken. These are:

$$\psi_{\alpha} = 2^{-1/2}(\psi_{A} + i\psi_{B}) \quad (13)$$

$$\psi_{\beta} = 2^{-1/2}(\psi_{C} + i\psi_{D}) \quad (14)$$

Hamiltonian Matrix Elements

The Hamiltonian of the system is expressed in atomic units as:

$$H = \sum H_c(\nu) + \sum_{\nu<\mu} 1/r_{\nu\mu} \quad (15)$$

where $1/r_{\nu\mu}$ is the electrostatic repulsion between π electrons, ν and μ, and where $H_C(\nu)$ represents the effect of the core on the ν electron. In expressing integrals over molecular orbitals, the following notational simplification is made: ϕ_1 and ϕ_2 are designated as 1 and 2 respectively, and θ_1 and θ_2, as 1′ and 2′ respectively. Further,

$$(ij \mid kl) = \iint i(\nu)j(\nu)(1/r_{\nu\mu})k(\mu)l(\mu)\mathrm{d}\tau_{\nu}\mathrm{d}\tau_{\mu} \quad (16)$$

$$H^{c}_{ij} = \int i(\nu)H_c(\nu)j(\nu)\mathrm{d}\tau_{\nu} \quad (17)$$

The energy of the ground state, E_0, is then expressed as:

$$\begin{aligned}E_0 = {} & (1-2S_1^2+S_1^4)^{-1}[2(11 \mid 11) \\ & + (4-2S_1^2)(11 \mid 1'1') - 8S_1(11 \mid 11') \\ & + (-2+6S_1^2)(11' \mid 11') + (4-4S_1^2)H^{c}_{11} \\ & + (-4S_1+4S_1^3)H^{c}_{11'}] \end{aligned} \quad (18)$$

The other matrix elements are obtained similarly.

The C_2 Excimer.—The hamiltonian matrix elements are:

$$\begin{aligned}H_{AA} = {} & H_{BB} \\ = {} & (1-S_1^2)^{-1}[(11 \mid 11)+(11 \mid 22)+2(11 \mid 1'1') \\ & +(2-S_1^2)(11 \mid 2'2')+(12 \mid 12) \\ & -2S_1(11 \mid 11')-2S_1(11' \mid 22)-(11' \mid 11') \\ & -2S_1(12 \mid 1'2)+(-1+2S_1^2)(12' \mid 12') \\ & +(3-S_1^2)H^{c}_{11}+(1-S_1^2)H^{c}_{22}-2S_1H^{c}_{11'}] \end{aligned} \quad (19)$$

$$\begin{aligned}H_{CC} = {} & H_{DD} \\ = {} & (1-S_1^2)^{-1}[(11 \mid 11)+(2-S_1^2)(11 \mid 22) \\ & +2(11 \mid 1'1')+(11 \mid 2'2') \\ & +(-1+2S_1^2)(12 \mid 12)-2S_1(11 \mid 11') \\ & -2S_1(11' \mid 22)-(11' \mid 11')-2S_1(12 \mid 1'2) \\ & +(12' \mid 12')+(3-S_1^2)H^{c}_{11}+(1-S_1^2)H^{c}_{22} \\ & -2S_1H^{c}_{11'}] \end{aligned} \quad (20)$$

$$\begin{aligned}H_{AB} = {} & (1-S_1^2)^{-1}[-S_1S_2(11 \mid 1'1') \\ & +(2-S_1^2)(12 \mid 1'2')-2S_2(11 \mid 11') \\ & -2S_1(11 \mid 22')+3S_1S_2(11' \mid 11') \\ & +(-1+3S_1^2)(11' \mid 22')-2S_1(12 \mid 12') \\ & +S_1^2(12' \mid 1'2)-2S_1S_2H^{c}_{11}+(3S_1^2S_2-S_2)H^{c}_{11'} \\ & +(-S_1+S_1^3)H^{c}_{22'}] \end{aligned} \quad (21)$$

$$\begin{aligned}H_{AC} = {} & H_{BD} \\ = {} & (1-S_1^2)^{-1}[-S_1(11 \mid 22)-S_1(11 \mid 1'1') \\ & -S_1(11 \mid 2'2')-S_1(12 \mid 12)-2(11 \mid 11') \\ & +(3S_1^2-1)(11' \mid 22)+3S_1(11' \mid 11') \\ & +2(12 \mid 1'2)-S_1(12' \mid 12')-2S_1H^{c}_{11} \\ & +(-S_1+S_1^3)H^{c}_{22}+(-1+3S_1^2)H^{c}_{11'}] \end{aligned} \quad (22)$$

$$\begin{aligned}H_{AD} = {} & H_{BC} \\ = {} & (1-S_1^2)^{-1}[S_2(11 \mid 11)+2S_2(11 \mid 1'1') \\ & -S_1(12 \mid 1'2')-2S_1S_2(11 \mid 11') \\ & +(3-S_1^2)(11 \mid 22')-S_2(11' \mid 11') \\ & -2S_1(11' \mid 22')+2S_1^2(12 \mid 12') \\ & -S_1(12' \mid 1'2)+(3S_2-S_1^2S_2)H^{c}_{11} \\ & -2S_1S_2H^{c}_{11}+(1-S_1^2)H^{c}_{22'}] \end{aligned} \quad (23)$$

$$\begin{aligned}H_{CD} = {} & (1-S_1^2)^{-1}[-S_1S_2(11 \mid 1'1')+S_1^2(12 \mid 1'2') \\ & -2S_2(11 \mid 11')-2S_1(11 \mid 22') \\ & +3S_1S_2(11' \mid 11')+(-1+3S_1^2)(11' \mid 22') \\ & -2S_1(12 \mid 12')+(2-S_1^2)(12' \mid 1'2) \\ & -2S_1S_2H^{c}_{11}+(-S_2+3S_1^2S_2)H^{c}_{11'} \\ & +(-S_1+S_1^3)H^{c}_{22'}] \end{aligned} \quad (24)$$

Overlap matrix elements are:

$$S_{AB} = S_{CD} = -S_1S_2 \quad (25)$$

$$S_{AC} = S_{BD} = -S_1 \quad (26)$$

$$S_{AD} = S_{BC} = S_2 \quad (27)$$

The D_{2h} Excimer.—Hamiltonian and overlap matrix elements are expressed as follows. For B_{3g} states:

$$H_{I\,I} = (1 + S_1S_2)^{-1}(H_{AA} - H_{AB}) \quad (28)$$

$$H_{II\,II} = (1 + S_1S_2)^{-1}(H_{CC} - H_{CD}) \quad (29)$$

$$H_{I\,II} = (1 + S_1S_2)^{-1}(H_{AC} - H_{AD}) \quad (30)$$

$$S_{I\,II} = -(1 + S_1S_2)^{-1}(S_1 + S_2) \quad (31)$$

For B_{2u} states:

$$H_{III\,III} = (1 - S_1S_2)^{-1}(H_{AA} + H_{AB}) \quad (32)$$

$$H_{IV\,IV} = (1 - S_1S_2)^{-1}(H_{CC} + H_{CD}) \quad (33)$$

$$H_{III\,IV} = (1 - S_1S_2)^{-1}(H_{AC} + H_{AD}) \quad (34)$$

$$S_{III\,IV} = -(1 - S_1S_2)^{-1}(S_1 - S_2) \quad (35)$$

The S_4 Excimer.—The Hamiltonian and overlap matrix elements are:

$$H_{\alpha\alpha} = H_{AA} \quad (36)$$

$$H_{\beta\beta} = H_{CC} \quad (37)$$

$$H_{\alpha\beta} = H_{AC} \quad (38)$$

$$S_{\alpha\beta} = -S_1 \quad (39)$$

MO Integrals in Terms of AO Integrals

As bases molecular orbitals, ϕ_1, ϕ_2, θ_1, and θ_2, simple Hückel molecular orbitals are used. The differential overlap within any one molecule is neglected, since this approximation has been proved to be rather successful. No simplification is made for an intermolecular overlap integral (i. e., the overlap between two atomic orbitals which belong to different molecules.).

Hereafter, r, s, t, and u refer to atomic orbitals. The numbering r, s, t, or u, which designates the atom position within a molecule, is common to both Molecule A and Molecule B, and corresponding atoms on different molecules have the same number. Only when it is necessary specifically to indicate that the r atom is in Molecule A (or Molecule B) is the atomic orbital designated as r_A (or r_B) instead of just r.

The integrals over molecular orbitals are expressed in terms of integrals over atomic orbitals in the following way:

Overlap Integrals.—S_1 and S_2 are expressed as:

$$S_1 = \sum_r \sum_t C_{r1}C_{t1}(r_A \mid t_B) \quad (40)$$

$$S_2 = \sum_r \sum_t C_{r2}C_{t2}(r_A \mid t_B) \quad (41)$$

Electron Repulsion Integrals.—Mulliken's approximation[13] is applied consistently; it is set as:

$$r(\nu)t(\nu) = (1/2)(r \mid t)[r(\nu)r(\nu) + t(\nu)t(\nu)] \quad (42)$$

The electron repulsion integral is, then, expressed as:

$$(ij \mid kl) = (1/4) \sum_r \sum_s \sum_t \sum_u C_{ri}C_{sj}C_{tk}C_{ul}$$
$$(r \mid s)(t \mid u)[\gamma_{rt} + \gamma_{ru} + \gamma_{st} + \gamma_{su}] \quad (43)$$

where:

$$\gamma_{rt} = (rr \mid tt)$$

is the atomic Coulomb repulsion integral.

Core Integrals.—The core integral over molecular orbitals, i and j, is expressed as[2]:

$$H^c_{ij} = \sum_r \sum_t C_{ri}C_{tj}(r \mid t)[-A_c - (1/2)\sum_{q \neq t}\{(q:rr) + (q:tt)\}] - 2(11 \mid ij) - 2(1'1' \mid ij) \quad (44)$$

where summation over q should be carried out over all the carbon atoms in both Molecule A and Molecule B. A_c is the experimental electron affinity of the carbon atom in its valence state, and has the value[14] of:

$$A_c = 0.69 \text{ eV}.$$

and $(q : rr)$ is the Coulomb penetration integral.[15]

The Evaluation of AO Integrals

As basis functions for atomic orbitals, carbon 2p Slater orbitals are used. The appropriate choice of orbital exponent, Z, is a difficult task, but, in this paper, $Z=3.18$ is taken, since satisfactory results were obtained by Azumi, Armstrong, and McGlynn[2] with this Z value.

The integrals over atomic orbitals were evaluated in the following way:

Overlap Integrals.—As has been mentioned above, the differential overlap within any one molecule is neglected; namely, for the *intramolecular* overlap integral:

$$(r_A \mid t_A) = \delta_{rt} \quad (45)$$

The *intermolecular* overlap integral was evaluated by the formulas presented by Parr and Crawford[15];

$$(r_A \mid t_B) = S_\pi \cos^2\theta + S_\sigma \sin^2\theta \quad (46)$$

where

$$S_\pi = 240^{-1}\exp(-\rho/2)[240 + 120\rho + 12\rho^2 - 4\rho^3 - \rho^4] \quad (47)$$

$$S_\sigma = 120^{-1}\exp(-\rho/2)[120 + 60\rho + 12\rho^2 + \rho^3] \quad (48)$$

where:

$$\rho \equiv ZR \quad (49)$$

and where R is the distance, in atomic units, between two atoms, r_A and t_B. Furthermore, (see Fig. 3):

$$\cos\theta = v/R, \quad \sin\theta = h/R \quad (50)$$

Coulomb Repulsion Integrals.—The *intramolecular* Coulomb repulsion integral, $\gamma_{r_At_A}$, was taken from the table presented by Pariser.[16] These values were calculated from the Slater orbitals, with the exception of the one-center integral and the nearest neighbor two-center integrals; the latter values were obtained semi-empirically from the benzene spectrum.

13) R. S. Mulliken, *J. Chim. Phys.*, **46**, 497 (1949).

14) R. S. Mulliken, *J. Chem. Phys.*, **2**, 782 (1934).

15) R. G. Parr and B. L. Crawford, ibid., **16**, 1049 (1948).

16) R. Pariser, ibid., **24**, 324 (1956).

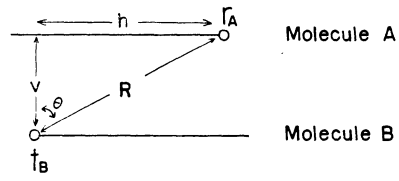

Fig. 3

Intermolecular Coulomb repulsion integrals were calculated, by the multiple expansion method proposed by Parr,[17] in atomic units[18];

$$\gamma_{r_A r_B} = R^{-1}[1 + (q/2R^2)(3\cos^2\theta - 1) + (3q^2/16R^4)(3 - 30\cos^2\theta + 35\cos^4\theta)] \quad (51)$$

where:

$$q = 24/Z^2 \quad (52)$$

Coulomb Penetration Integrals.—Since the penetration integral decreases very rapidly with the distance, some of the integrals may well be neglected, as is shown below.

The *intramolecular* Coulomb penetration integral, $(q_A : r_A r_A)$, is non-zero only when $q=r$ or q and r are adjacent. The integrals in these cases are evaluated by the formula given by Parr and Crawford[15]:

$$(q_A : r_A r_A) = (Z/3840)\exp(-\rho)[(4/7)\rho^5 + (67/7)\rho^4 + 86\rho^3 + 461\rho^2 + 1125(\rho+1)] \quad (53)$$

The *intermolecular* Coulomb penetration integral $(q_A : r_B r_B)$ is in all cases, neglected.

The Correction for Infinite Separation

The energies of the excited excimer states are obtained by solving secular equations of the form:

$$|\boldsymbol{H} - E\boldsymbol{S}| = 0 \quad (54)$$

where $\boldsymbol{H}$ and $\boldsymbol{S}$ represent, respectively, Hamiltonian and overlap matrices, the elements of which are given in Eqs. 19—39. It is convenient to calculate the energy with respect to the ground-state energy at $\alpha=0°$, E_0^0; for this purpose Eq. 54 is rewritten as:

$$|(\boldsymbol{H} - E_0^0\boldsymbol{S}) - E'\boldsymbol{S}| = 0 \quad (55)$$

where:

$$E' = E - E_0^0 \quad (56)$$

and where the calculated energy, E', is now the energy scaled from the ground state of the dimer of $\alpha=0°$.

The direct use of the theoretical Hamiltonian matrix elements reveals one significant difficulty. From the viewpoint of physical significance, $H_{AA}-E_0^0$ should converge on the ^1L_a excitation energy of the monomer at an infinite separation of the two molecules. As is evident from Eqs. 18 and 22, $H_{AA}-E_0^0$ equals (12|12) at an infinite separation. (12|12) is also the result of the theoretical evaluation of the ^1L_a monomer energy in a two-electron treatment; thus, H_{AA} extrapolates to a correct energy limit. However, the value of (12|12) is 0.491 eV., whereas ^1L_a is at 4.290 eV., and there exists great numerical discrepancy. This discrepancy, which may be due to the incompleteness of the simple four-electron treatment, needs to be calibrated. In this regard, the experimental ^1L_a monomer energy is obtained at an infinite separation. In other words, the monomer contribution is made as empirical as possible, while the dimerization effects are left in their fully theoretical form. This attitude is also adopted for charge resonance states. In sum, the $^1L_a-(12|12)$ term is added to all the diagonal terms of Eq. 55.

Results and Discussion

Calculations were carried out at intervals of five degrees in α. The lowest of the four excited states is the excimer state which is responsible for the excimer luminescence. The wave function of this state is expressed in the form of:

$$\psi = a\psi_A + b\psi_B + c\psi_C + d\psi_D \quad (57)$$

The energy of the excimer state, E', and the normalized mixing coefficients are summarized in Table I. The energy of the ground state scaled from that of $\alpha=0°$:

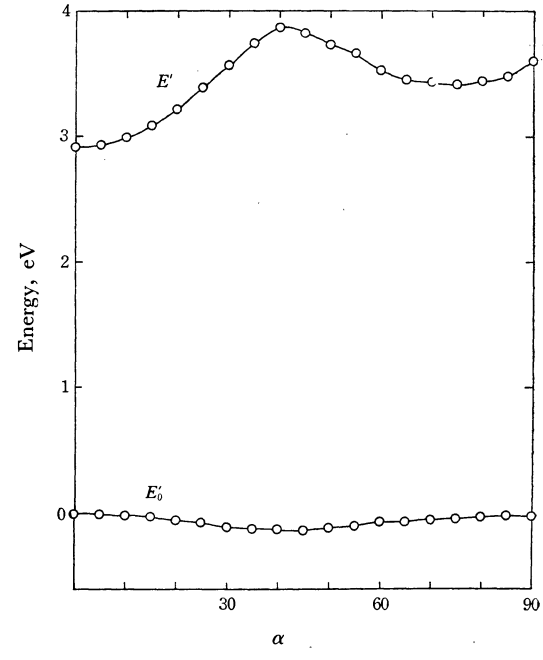

Fig. 4

17) R. G. Parr, ibid., **33**, 1184 (1960).
18) The unit of energy equals e^2/a_0, where e is the charge on an electron and a_0 is the Bohr radius.

$$E_0' = E_0 - E_0^0 \tag{58}$$

is also shown in Table I. The calculated energies are also plotted in Fig. 4 as a function of α. It seems reasonable to assume that the mutual repulsion of the two cores, a repulsion which is not included in the present calculation, is nearly independent of α. Figure 4 may then be considered to be the potential energy diagram expressed as a function of α. As may be seen in Fig. 4, there are two minima in the potential of the excited states, one at $\alpha=0°$ and one at $\alpha=75°$; consequently, the excimer is stable at these two configurations. We assume that when two molecules approach, by diffusion, to form an excimer, there is no specific orientation of the two molecules. If this assumption is true, various configurations (namely, various α values) of the excimer are formed, with nearly equal probabilities. They will immediately undergo relaxation according to the potential of Fig. 4. The potential barrier of 0.5 eV. between the two stable configurations is too high compared with the thermal kinetic energy of $1.5\boldsymbol{k}T=0.04$ eV., and the mutual transformation of the two is impossible at ordinary temperatures. It may well, then, be said that at an equilibrium state two kinds of excimers exist; the one with $\alpha=0°$ is hardly ever interpreted as being responsible for excimer fluorescence because of the forbidden character of the transition, while the one with $\alpha=75°$ may contribute to the observed excimer fluorescence.

The calculated energy of excimer fluorescence at $\alpha=75°$,

$$E' - E_0' = 3.46 \text{ eV}.$$

may seem to be too high compared with the observed energy (3.13 eV.)[19] of the naphthalene excimer fluorescence. However, to discuss this discrepancy is trivial, since, in the present calculations, the interplanar distance of 3 Å and the orbital exponent of $Z=3.18$ have been tentatively chosen rather arbitrarily. If smaller values of Z are used, as has been suggested[3,20] the calculated energy would surely become lower, and an agreement with the observed energy might well be obtained.

Concluding Remarks

It has been shown that there is considerable configuration interaction between molecular exciton states and charge resonance states. As may be seen in Table I, all of the four zeroth order states, the two molecular exciton states and the two charge resonance states, contribute to the excimer states in nearly equal measure. It has also been shown that the energy of the excited state varies significantly with the α value, and a stable configuration may be obtained at $\alpha\neq0°$. It has been suggested that these configurations should, in general, be included in the calculation of this sort.

A number of questions remain. We have excluded the configuration of $\alpha=0°$ as the one responsible for excimer luminescence. Whether or not we are justified in doing so is a difficult question. Group theoretically, the excimer state at $\alpha=0°$ is of the B_{3g} symmetry in the D_{2h} point group,[11] and the transition to the A_g ground state is forbidden. Further, different from, say,

the benzene fluorescence, there is no vibrational coupling to acquire an allowed transition moment in the excimer fluorescence, unless we consider hot bands, since the ground state is dissociative. These considerations favor our treatment; however, further investigations might be necessary. These will be the subject of ensuing publications.

In the present calculation we have considered only the excimer configurations in which two molecular planes are parallel and their principal axes coincide. This may actually seem rather a freakish situation. However, to treat excimers of random orientations is quite difficult, if not impossible; at any rate, it is beyond the limits of the present paper.

The present calculations are based upon the above-specified model, just one of many models we may think of; therefore, too much emphasis should not be placed upon our suggestion of the $\alpha=75°$ configuration. It is, however, of interest to add that our calculations on the radiative lifetime of the excimer fluorescence yield 6×10^{-6} sec. at $\alpha=75°$, which is in good agreement with the observed value[21] of $1.2-1.4\times10^{-6}$ sec. The details of the calculations will be published in the next paper.[22]

The authors wish to express their appreciation to Dr. Yoshito Amako for his fruitful discussions.

The numerical calculations were carried out on the NEAC 2230 at the Computation Center, Tohoku University; the invaluable help in the programming provided by the staff is greatly appreciated.

Appendix I

Table II presents the in-plane components of distance, h, between two carbon atoms which belong to different molecules (see Fig. 3). These values are required in evaluating integrals over atomic orbitals. The atom positions are indicated by numbers, and those in different molecules are indicated by primed numbers, as is shown in Fig. 1. Since the Hückel coefficients for molecular orbitals, ϕ_1 or ϕ_2, are zero for atoms 9 and 10, the summation over r in Eqs. 40—44 may be carried out only from 1 to 8. There are still $8\times8=64$ pairs of carbons whose distances are required, but only twenty of these need be obtained; these are shown in Table II in Å units. Any other pair is identical to one of the pairs given in the table by symmetry considerations.

Appendix II

The numerical results for intramolecular and intermolecular MO integrals are tabulated in Tables III and IV. All integrals except the overlap integrals are in eV. units.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1837—1842 (1966)

The Reaction Rate of the Alkaline Hydrolysis of Ethyl Acetate

By Hiroo TSUJIKAWA and Hakuai INOUE

Department of Chemical Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 11, 1965)

The reaction rate of the alkaline hydrolysis of ethyl acetate was studied by means of a continuous measurement of the electric conductivity change. The second-order rate constant decreased as the reaction proceeded. The decrease was evident when the initial concentrations of the ester and the base were close together. The initial rate constant at 25°C was measured as 0.1120 l./mol./sec. and the activation energy was 11.56 kcal./mol., values agreed well with those of previous studies. From the standpoint of the electronic theory of organic chemistry, Day and Ingold proposed a sequential reaction mechanism passing through an addition complex. The results of the approximate calculations to the pseudo-first-order reaction and the analog-computation of the exact models coincided with the experimental results. The difference in the activation energies of the forward and reverse reaction rates was calculated from the experimental data. At lower temperatures this reverse reaction rate was small, and the overall reaction rate was approximated as a pure second-order reaction. Other probable reasons for the rate constant decrease were also discussed.

The reaction rate of the alkaline hydrolysis of ethyl acetate has been well established to be a second-order reaction, and the mechanism has been discussed in detail.[1]

For the study of the performance of a flow-type stirred tank reactor, we carried out the hydrolysis reaction in it and analyzed the flow pattern in the reactor from the yield of the reaction. However, during the experiments, we found that the hydrolysis reaction could not satisfactorily be expressed as a second-order reaction. It was necessary to analyze the reaction rate more carefully. Therefore, we measured and analyzed the rate of the hydrolysis of ethyl acetate continuously. We will discuss the mechansim of the reaction kinetically.

Experimental

Apparatus.—The reaction was carried out in a batch-type reactor, and the electric conductivity of the reacting solution was measured with the time. The main apparatus is shown in Fig. 1. A 2-l. polyethylene beaker was used as the reaction vessel instead of a glass one, because in the case of a glass vessel some alkaline ions dissolved from the wall and so disturbed the exact measurement of the reaction rate.

During the reaction hydroxide ions are consumed and acetate ions are produced. This change in ion concentration results in a conductivity change in the solution, and by the measurement of this conductivity we could ascertain the degree of saponification.

The electrode used is shown in Fig. 2; it is set horizontally near the turbine so that the reactant flows thoroughly in it. The electrical circuits of the measuring system is shown in Fig. 3. A 0.8 V. a. c. current of

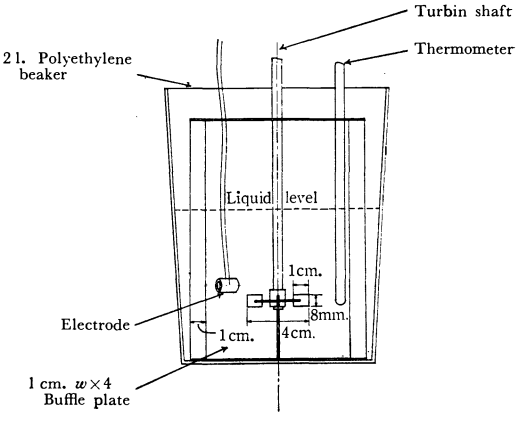

Fig. 1. The Experimental apparatus.

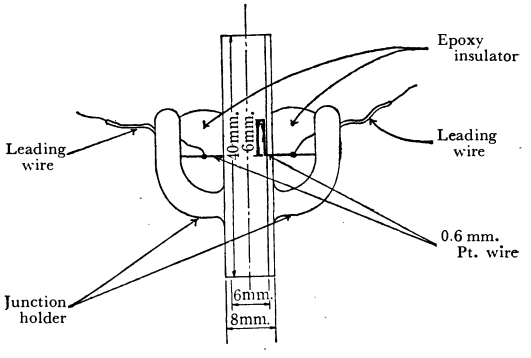

Fig. 2. The electrode.

1000 c/s is added at the electrode + a 5-ohm resistor in series. The voltage between the two sides of the resistor is amplified, converted into d. c., and recorded

1) M. L. Bender, *Chem. Revs.*, **60**, 53 (1960).

on a recording ammeter. Generally, the input-output characteristics of a diode are not linear, so the relation between the output current and the OH^-/CH_3COO^- ratio must be calibrated.[2] However, the negative feeding-back of the converted d. c. current to the intermediate part of the amplifier (the 15 kiloohm resistor and 10 microfarad condensor circuit of Fig. 3) forms a linear relationship between the current and the concentration ratio, as is shown in Fig. 4. By comparing the line in Fig. 4. with the conductivity of the reacting solution, in which the total concentration of OH^- and CH_3COO^- was about 0.02 N, we can calculate the degree of hydrolysis with the time.

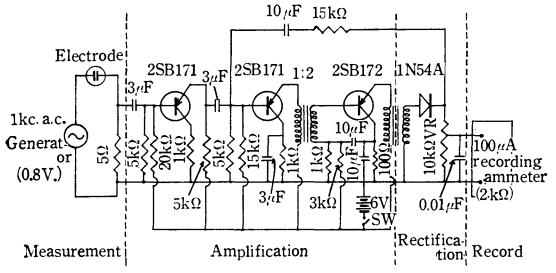

Fig. 3. The electric circuit for the electro-conductivity measurement.

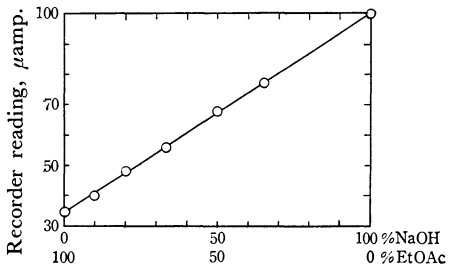

Fig. 4. The relationships between the ammeter reading and the reaction proceeding.

○ Total concentration of $Na^+ = 0.0200$ mol./l.
○ The ammeter was set 100 μamp. for 100% NaOH

Procedure.—A sodium hydroxide solution was prepared by dissolving sodium hydroxide (made by the Wako Pure Chemicals Co., Ltd., G. R. grade) in ion-exchange water with a relative resistance of more than 2×10^6 ohm-cm. The concentration was checked by an automatic titrater using a 0.1 N standard hydrochloric acid solution. Ethyl acetate (made by the Osaka Organic Chemicals Co., Ltd., G. R. grade) was used without any special processing; it yet gave a mean equilibrium conversion of 97%, which agrees with the theoretical equilirbium conversion.

To start the reaction, 994 ml. of a 0.02 N sodium hydroxide solution was poured into a beaker dipped in a water bath, and then vigorously stirred for more than 30 min., after which a definite volume of ethyl acetate was added to the solution under the stirring. The temperature of the mixture was kept constant during the reaction within a range of ±0.1°C.

Ethyl acetate dissolved into water within 10 sec., so the mixing time of the ester was negligible in comparison with the reacting time. During the reaction the conductivity of the solution was recorded continuously, and the degree of conversion was calculated. A small portion of the solution was sampled during the reaction and was acidified to stop the reaction rapidly; by the backtitration of the acid, the remaining hydroxide ions in the reacting system were determined. The concentration of hydroxide ions, as determined by this titration agreed well with that calculated from the conductivity measurements of the solution.

Results

Some results are shown in Fig. 5, where the concentration change is plotted as $(c_B - x_0)/(c_{A_0} - x)$ against the reaction time. The circled points in Fig. 5 stand for the experimental values, while the straight line in the figure shows the theoretical relation derived from the second order rate equation.

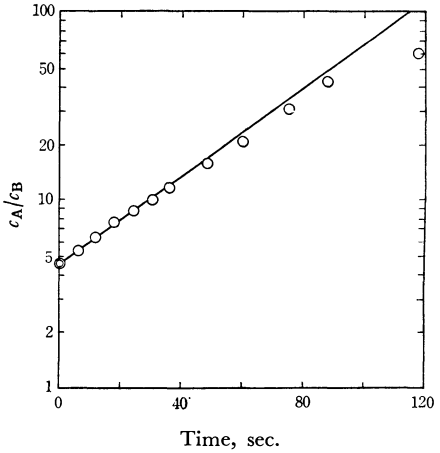

Fig. 5. Semi-logarithmic plot of experimental results.
Exptl. No. R-27 c_{A_0} 0.09897 N
Temp. 40.7°C c_{B_0} 0.02104 N
$k_{1\,obsd.}$ 0.337 l./mol. sec.

If the reaction is expressed as that of a complete second-order reaction, all the experimental values must be on the line. However the points obtained from the experiments deviate downwards from the linear relation. The deviation of the rate from the second-order rate equation becomes more remarkable as the initial concentrations of base and ester draw closer to each other.

Previous works on this kinetics did not analyze the rate in detail; usually only the mean initial rate constant has been obtained. The deviation from the second-order rate equation has never been analyzed in detail kinetically. Indeed, no such deviation has even been actually observed in the initial rate of the hydrolysis.

2) D. G. Flom and P. J. Elving, *Anal. Chem.*, **25**, 541 (1953).

We measured the initial rate constant by the addition of different amounts of the ester, and observed the rate constant independent of the concentration of the ester. These results coincided with those of previous works on the second-order rate equation. They are shown in Fig. 6, along with the inverse of the absolute temperature, $1/T$. The calculated activation energy of 11.56 kcal./mol. agrees well with those obtained in previous works; the rate constant at 25°C, 0.1125 l/N-sec., also agrees with them.[3-6]

Analysis and Discussion

The mechanism of the basic hydrolysis of ester has been discussed hitherto, and it is well known that the mechanism may be expressed by the following reaction scheme:

$$\underset{\text{(A)}}{H_3C\text{-}\overset{\overset{O}{\|}}{C}\text{-}OC_2H_5} + \underset{\text{(B)}}{OH^-} \underset{[II]\ k_2}{\overset{[I]\ k_1}{\rightleftarrows}} \underset{\text{(C)}}{H_3C\text{-}\overset{\overset{O^-}{|}}{C}\text{-}OH\,(OC_2H_5)} \underset{[IV]\ k_4}{\overset{[III]\ k_3}{\rightleftarrows}}$$

$$\underset{\text{(D)}}{H_3C\text{-}\overset{\overset{O}{\|}}{C}\text{-}OH} + \underset{\text{(E)}}{C_2H_5O^-} \xrightarrow{[V]\ k_5} \underset{\text{(F)}}{C_2H_5OH} + \underset{\text{(G)}}{CH_3COO^-}$$

This mechanism of the basic hydrolysis of esters was proposed by Day and Ingold.[7] and since analyzed by Bender,[8] Swarts,[9] and many other investigators.[1] However, these studies were mainly from the viewpoint of organic chemistry; no detailed kinetic analysis of the hydrolysis of ethyl acetate has ever been made. Usually the reaction has been considered to be a second-order form, but, according to the above mechanism, the second-order rate equation is applicable only when the concentration of the addition complex C is very small and when the reverse reaction rate is negligible in comparison with the forward reaction rate.

In general, the total reaction path may be expressed by the following mathematical equations:

$$\frac{dc_A}{d\theta} = \frac{dc_B}{d\theta} = -k_1c_Ac_B + k_2c_C \tag{1}$$

$$\frac{dc_C}{d\theta} = k_1c_Ac_B - (k_2+k_3)c_C + k_4c_Dc_E \tag{2}$$

$$\frac{dc_D}{d\theta} = \frac{dc_E}{d\theta} = k_3c_C - (k_4+k_5)c_Dc_E \tag{3}$$

$$\frac{dc_F}{d\theta} = \frac{dc_G}{d\theta} = k_5c_Dc_E \tag{4}$$

where c means the concentrations of chemical compounds or ions, and where the suffixes A, B, C, ···denote the compounds or ions shown above. The k's indicates the reaction rate constants; k_1 and k_2 are the rate constants for the forward and reverse reactions of $A+B \rightleftarrows C$, k_3 and k_4 are the rate constants of the forward and reverse reactions of $C \rightleftarrows D+E$, and k_5 is that of the $D+E \rightarrow F+G$ reaction. The reaction rates were assumed to be proportional to the concentrations of all the reacting compounds. θ denotes the time.

The deviation from the second-order rate form which we observed seems to give the key to the analysis of the mechanism of the reaction. As the reaction proceeds, the concentration of the ester and hydroxide ions become very small; the effect of the reverse reaction rate of the addition complex on the total rate will therefore become remarkable.

Of course, there are many possible causes of the deviation of the rate from the second-order form. The $CH_3COOC_2H_5+H_2O \rightleftarrows CH_3COOH+C_2H_5OH$ equilibrium suggests the reverse reaction of the products. However, the deviation of the rate could not be due to this effect for the following reasons. According to the effect of this reverse reaction, the overall reaction rate would be retarded by the addition of the reaction product. We measured the reaction rate in the presence of

sodium acetate or ethanol. The addition of the products actually retarded the overall reaction rate, but it is too small to illustrate the deviation from the second-order form. Experimentally the deviation is most remarkable when the concentrations of the ester and the base are close. We tried to estimate the rate constant of the reverse reaction by making an analysis using an analog computer, this gave a good coincidence with the experimental results, but we could not obtain the rate constant independent of the change in the ester concentration.

Moreover, the salt effect of the sodium acetate produced, the solvent effect of the ethanol produced, and other effects due to the decrease in the concentration of the reactants were discussed and checked by experiments, although we could not illustrate the deviation of the reaction rate satisfactorily.

To analyze the above reaction path, it is necessary to solve the mathematical equations, 1, 2, 3, and 4, but it would be meaningless to solve the whole system by assuming many rate constants arbitrarily. It seems to be more reasonable to assume the following approximations, which are based on the usual consideration of ionic reactions. First, the rate of the reaction IV is very slow and negligible compared to the rate of the reaction III. Second, the reaction V is regarded to be very rapid.

Therefore, the overall reaction may be expressed more simply as follows:

$$\frac{dc_A}{d\theta} = \frac{dc_B}{d\theta} = -k_1 c_A c_B + k_2 c_C \quad (1)$$

$$\frac{dc_C}{d\theta} = k_1 c_A c_B - (k_2+k_3) c_C \quad (2')$$

$$\frac{dc_F}{d\theta} = \frac{dc_G}{d\theta} = k_3 c_C$$

If the stationary state approximation is applied, the overall rate may be written:

$$\frac{dc_A}{d\theta} = -k_1\left(1 - \frac{1}{k_2+k_3}\right) c_A c_B$$

and expressed as a second-order rate equation such as was obtained experimentally at the initial stage of the reaction.

However, as the concentration of the reactants becomes small, the balance of the addition complex concentration is gradually broken and the process is not expressed by the approximation any more. This discussion does not necessarily depend on the assumption of the existence of a large amount of the addition complex, but it does depend on the relative scale of $k_1 c_A$, k_2, and k_3.

Without the stationary state approximation, Eqs. 1 and 2′ are not solved analytically because of their nonlinearity.

If $c_A \gg c_B$, then the change of c_A on the right hand of Eqs. 1 and 2′ can be neglected and the equations can be approximated as:

$$\frac{dc_B}{d\theta} = -k_1 c_{A_0} c_B + k_2 c_C \quad (1')$$

$$\frac{dc_C}{d\theta} = k_1 c_{A_0} c_B - (k_2+k_3) c_C \quad (2'')$$

The initial conditions are:

$$\theta = 0 \qquad c_B = c_{B_0} \qquad c_C = 0 \quad (5)$$

$$\frac{dc_B}{d\theta} = -\frac{dc_C}{d\theta} = -k_1 c_{A_0} c_{B_0}$$

The solutions are:

$$c_B = \frac{k_1 c_{A_0} c_{B_0} - (\alpha-\beta) c_{B_0}}{2\beta} e^{-(\alpha+\beta)\theta} + \frac{-k_1 c_{A_0} c_{B_0} + (\alpha+\beta) c_{B_0}}{2\beta} e^{-(\alpha+\beta)\theta} \quad (6)$$

$$c_C = \frac{k_1 c_{A_0} c_{B_0}}{2\beta}\left(e^{-(\alpha-\beta)\theta} - e^{-(\alpha+\beta)\theta}\right) \quad (7)$$

where:

$$\alpha = (k_1 c_{A_0} + k_2 + k_3)/2 \quad (8)$$

$$\beta = (\alpha^2 - k_1 c_{A_0} k_3)^{1/2} \quad (9)$$

Fig. 7, where the experimental results when c_A—c_B are plotted on semi-logarhythmic graph paper, shows that the whole process may be expressed by two straight lines, at the initial and final stages. These results coincide with Eqs. 7.

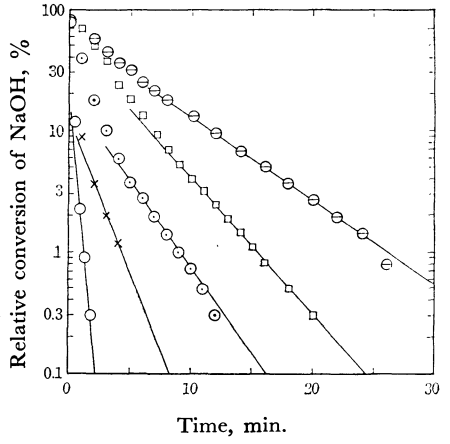

Fig. 7. Observation of $\alpha-\beta$ using the thermal rates of the reaction (temp. 30.5~30.7°C).

Initial ester concentration

⊖ 0.01985 mol./l. × 0.24211 mol./l.
□ 0.04959 mol./l. ○ 0.48422 mol./l.
⊙ 0.09897 mol./l.

Here let us survey the meaning of the time constants, $\alpha+\beta$ and $\alpha-\beta$. β has a rather complicated form, but noting $\alpha \gg k_1 k_3 c_{A_0}$ and using the Taylor expansion:

$$(1-x)^{1/2} = 1 - x/2 - x^2/8 + x^3/16 - x^4/128 + \cdots$$

β reduces to:

$$\beta \doteqdot \frac{k_1c_{A_0} + k_2 + k_3}{2} - \frac{k_1k_3c_{A_0}}{k_1c_{A_0} + k_2 + k_3} \quad (10)$$

Consequently:

$$\alpha+\beta \doteqdot k_1c_{A_0}+k_2+k_3 - \frac{k_1k_3c_{A_0}}{k_1c_{A_0}+k_2+k_3}$$

$$\doteqdot k_1c_{A_0}+k_2+k_3 \quad (11)$$

$$\alpha-\beta \doteqdot \frac{k_1k_3c_{A_0}}{k_1c_{A_0}+k_2+k_3} = \frac{1}{1/k_3+\frac{1}{k_1c_{A_0}}\left(1+\frac{k_2}{k_3}\right)} \quad (12)$$

If $k_3 \gg k_1c_{A_0}$ then:

$$\alpha-\beta \doteqdot \frac{k_1c_{A_0}}{1+k_2/k_3} \quad (13)$$

This is the time constant at the final stage of the reaction. The experimental measurements of $\alpha-\beta$ at 30°C are shown in Fig. 8. The k_2/k_3 values are calculated from Eqs. 11 at 30, 40, and 50°C and are shown in Fig. 9. The difference in the activation energies, k_2 and k_3, is obtained as 20 kcal./mol. from Fig. 9.

At lower temperatures, k_2/k_3 is small and the overall reaction rate is regarded as a second-order reaction, as uaual.[10]

The Confirmation of the Mechanism by an Analog Computer.—In order to confirm the above-mentioned mechanism at low concentrations of ester and base, Eqs. 1 and 2′ were solved directly by an analog computer. The boundary conditions were:

$$\theta=0 \qquad c_A=c_{A_0} \qquad c_B=c_{B_0} \qquad c_C=0 \quad (14)$$

The block diagram for the calculation is shown in Fig. 10. The "experimental chart reader" in Fig. 10 is used to read the results of the experiments into the computer and to compare them with the calculated results. An example of the calculation is shown in Fig. 11. In this calculation we must assume k_2 and k_3 respectively; the curve shown in Fig. 11 is an example. However, the main part of the curve is determined by the k_2/k_3 ratio, as may be understood from Eqs. 13; the absolute values of k_2 and k_3 in the reacting system could not be determined independently.

The calculated curve can be matched within a 3% error with such experiments.

Conclusion

It has been observed that the reaction rate of the basic hydrolysis of ethyl acetate is not expressed satisfactorily by a second-order rate equation, and it has been proved, from the kinetic analysis of the reaction rate, that the mechanism of the hydrolysis is the sequential reaction process through the addition complex. We have obtained k_1 and k_2/k_3 values for several temperatures. These results correspond well with the conclusion obtained in the general nucleophilic reaction of carboxylic acid derivatives,[1] though the difference between the activation energies for k_2 and k_3 is too large in comparison with the results obtained by the hydrolysis of ethyl benzoate.[11] This may be due to the approximation used to get $\alpha-\beta$ from the experimental data.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1842—1849 (1966)

Multiple Charge-transfer Bands of the Pyrene-Tetracyanoethylene Complex

By Haruo KURODA, Isao IKEMOTO and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 18, 1965)

The polarized absorption spectra of the single crystal of the pyrene-tetracyanoethylene complex have been observed by means of a microspectrophotometer. It is shown that two absorption bands, at 12700 cm^{-1} and 20000 cm^{-1} respectively, are polarized along the *c*-axis, the direction connecting the molecular center of the donor and that of the acceptor; hence, both have been assigned to the charge-transfer bands. The interactions of 32 possible charge-transfer states with the no-bond state are discussed in terms of the simple molecular orbital theory, and their contributions to the energy of the complex formation are compared with each other. It is revealed that the interactions of higher charge-transfer states are relatively important and can not be neglected compared with that of the lowest charge-transfer state, and that the appearance of the multiple charge-transfer bands is a natural consequence of such a configurational interaction. It is also suggested that the ratio of the intensities of the first and the second charge-transfer bands may be a parameter that offers information on the orientation of the donor molecule to the acceptor molecule. A probable model is proposed for the structure of the pyrene-tetracyanoethylene complex formed in the solution.

Some charge-transfer complexes show two or three charge-transfer bands in their absorption spectra. The appearance of such multiplet charge-transfer bands has been ascribed to the difference between the donor and acceptor orbitals associated with the charge transfer.[1-4] Briegleb, Czekalla and Reuss[5] have shown that the energy difference between the first charge-transfer band and the second one is approximately equal to the excitation energy of the donor cation in the cases of the chloranil complexes and the tetracyanoethylene (TCNE) complexes which involve polycyclic

aromatic hydrocarbons as the electron donor. Thus, the second charge-transfer bands in these cases can be assigned to the excitation associated with the charge transfer from the second highest occupied orbital of the donor to the lowest vacant orbital of the acceptor.

This interpretation, however, raises a question about the configuration of the complex. It is generally believed that a donor molecule takes an orientation relative to an acceptor molecule so as to give a maximum overlapping between the highest occupied orbital of the donor and the lowest vacant orbital of the acceptor. Such a structure is most favorable for the appearance of the first charge-transfer band, but it is not necessarily favorable for the second one since the symmetry of the second highest occupied orbital is usually different from that of the highest occupied orbital. In the case of the naphthalene-TCNE complex, for example, the first charge-transfer band should appear strongly when the molecules are stacked face-to-face, with their molecular centers directly over each other and with the central double bond of TCNE parallel to the long axis of naphthalene. However, the second charge-transfer band should be symmetry forbidden in this configuration. A similar situation may be expected also in the case of the pyrene-TCNE complex.

With these things in mind, Gott and Maish[6] suggested the presence of isomers which are different in the mutual orientations of the symmetry axes of the donor and acceptor. The presence of such orientational isomers has also been assumed by Zweig[7] as an explanation of the multiple charge-transfer bands of TCNE complexes of substituted benzenes.

In a previous paper,[8] we have shown, for several TCNE complexes, that the absorption bands corresponding to the first and second charge-transfer bands in the solution spectra appear in the absorption spectra of crystalline powders observed by means of the KBr pellet method. However, the possibility that the second absorption band found in a spectrum of crystalline powder is not a charge-transfer band, but a band associated with the excitation of the donor or acceptor, has not been conclusively ruled out. This point should be clarified by means of the observation of the polarized absorption spectra of the crystals.

In the present paper, the polarized absorption spectra of the crystal of the pyrene-TCNE complex will be shown in an attempt to prove that the multiple charge-transfer bands do really appear in the crystalline state as well as in the solution; then the interpretation of these bands will be discussed in detail in order to elucidate the general features of the multiple charge-transfer bands.

Experimental

Pyrene was purified by the successive application of recrystallization from a xylene solution, alumina column chromatography, and finally sublimation in vacuo. The purification of TCNE was accomplished by the sublimation in vacuo after the repetition of the recrystallization from a chlorobenzene solution. For the observation of the absorption spectrum of the complex crystal, minute single crystals of a lath shape, a few microns in width and in length and less than one micron thick, were prepared from a carbon tetrachloride solution.

The polarized absorption spectra were measured by means of a microspectrophotometer, a modification of the Olympus Model MSP-A-IV microspectrophotometer. An Xe-lamp of 500 W. was used as the light source. Although the technique of microspectrophotometry has been applied by other investigators to the observation of the spectra of organic crystals in the visible and ultraviolet regions, little has been done in the near infrared region because of the difficulty of finding a suitable detector. In the present experiment we have used a RCA 7102 photomultiplier tube as the detector in this region; it enables us to observe the absorption spectrum up to 1200 mμ.

Results and Discussion

(1) The Absorption Spectra and the Crystal Structure.—The visible absorption spectrum of a carbon tetrachloride solution of the pyrene-TCNE complex is shown in Fig. 1. The two broad bands at 13700 cm^{-1} and 19700 cm^{-1} are the first and the second charge-transfer bands respectively. The intensity ratio of these two bands remains constant over a wide temperature range. The oscillator strength of the first charge-transfer band is about 0.02.

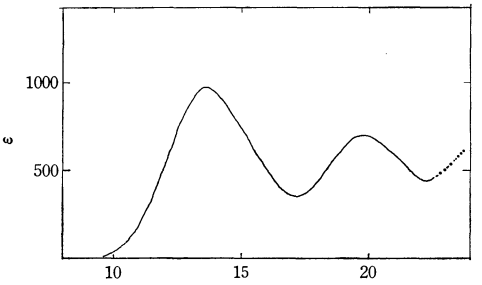

Fig. 1. The charge-transfer bands of pyrene-TCNE complex in carbon tetrachloride.

According to the results of the X-ray analysis of the crystal structure,[9] the crystal of the pyrene-TCNE complex has a monoclinic unit cell with

the lattice constants of $a=14.58$ Å, $b=7.34$ Å, $c=8.09$ Å and $\beta=92.4°$, and belongs to the $P2_1/a$ space group. Two pyrene and two TCNE molecules are contained in each unit cell. Pyrene and TCNE molecules are stacked alternately along the c-axis, their molecular planes parallel to each other so as to give a large overlap between their molecular orbitals. The crystals grown from a solution are either of lath-shape or are prisms elongated along the c-axis. In every case, the developed face is a (100) plane. Therefore, the b- and c-polarized spectra were observed in the direction perpendicular to the bc-plane with extremely thin crystals. The direction of the b-axis was determined by an examination with a polarizing microscope. The observed spectra are shown in Fig. 2.

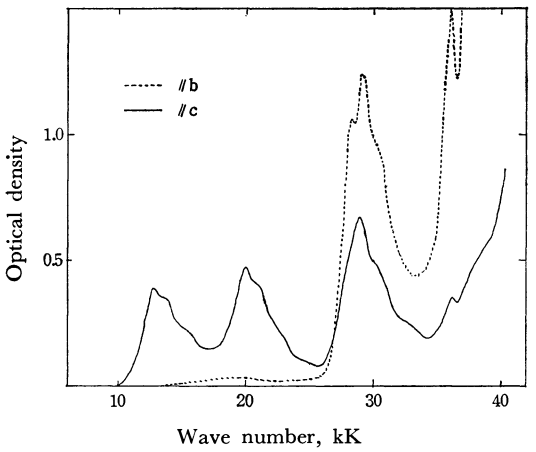

Fig. 2. The polarized absorption spectra of the crystal of pyrene-TCNE complex.

As can clearly be seen in Fig. 2, there are two absorption bands that are markedly polarized along the c-axis. The first band has the absorption maximum at 12700 cm^{-1}, and the second one, at 20000 cm^{-1}. No absorption band corresponding to the first one can be found in the b-polarized spectrum, but there is a very weak absorption with a maximum around 19000 cm^{-1}, which seems to correspond to the 20000 cm^{-1} band in the c-polarized spectrum. The third band in the c-polarized spectrum appears in the region of 25000 —35000 cm^{-1}, and the fourth begins from 35000 cm^{-1}. These bands are stronger in the b-polarized spectrum in contrast to the first and the second bands. Each band seems to have vibrational structures. The position of the peaks and the polarization ratio—the ratio of the integrated optical density of a band in the c-polarized spectrum to that in the b-polarized spectrum—are summarized in Table I.

The projection of the crystal structure along the a-axis onto the bc plane is shown in Fig. 3.

TABLE I. POLARIZATION RATIO AND POSITIONS OF PEAKS

Band	Polarization ratio of the band	Wave numbers of peaks cm^{-1}	
		b-polarized	c-polarized
I	>20		12700* 14000 15600
II	10	19500	20000* 21300
III	0.5	28900*	28400 29200* 31000
IV	0.2	>35000	>35000

* The maximum of the band.

It can readily be seen from this structure that, according to the oriented gas model, the short-axis polarized absorption of pyrene should be strongly polarized along the b-axis, while the long-axis polarized absorption may be exprected to show a polarization ratio of about unity. In any case, a large polarization ratio can hardly be expected for the local-excitation band. On the other hand, a charge-transfer excitation may be expected to be polarized along the c-axis, the direction connecting the centers of the pyrene and TCNE molecules stacked face-to-face. Thus, we can conclude that both the first and second absorption bands are charge-transfer bands, while the others are associated with the local excitations.

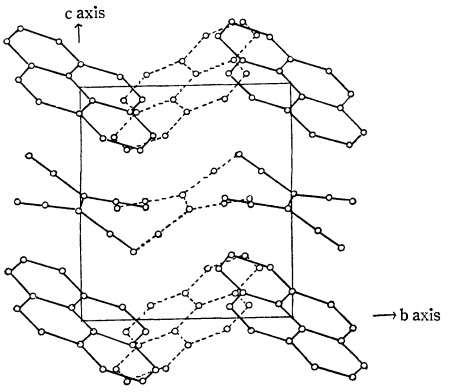

Fig. 3. The projection of the crystal structure of pyrene-TCNE complex along the a-axis on the bc plane.

The fact that the first band is exclusively polarized along the c-axis indicates that it is a pure charge-transfer band. The polarization ratio is a little lower for the second band. This could be due to mixing between the charge-transfer state and a local-excited state. Even if this is the case, however, the contribution of the local-excited state should

be quite small in order to give the observed polarization ratio. In the discussion below, therefore, we shall treat both of these absorption bands as pure charge-transfer bands, neglecting completely the interaction with any local excitation. The separation between the main peaks of the first and second charge-transfer bands is 7300 cm^{-1}, which approximately corresponds to the difference between the orbital energy of the highest occupied orbital and that of the second highest occupied orbital. It is most reasonable to presume that the first band is associated with a charge transfer from the highest occupied orbital of pyrene to the lowest vacant orbital of TCNE, and the second one, to that from the second highest occupied orbital. Interestingly, the integrated optical density is nearly the same for these two absorption bands in spite of the difference in the symmetry properties of these two molecular orbitals. The ratio of the integrated optical density of the first band to that of the second one is 0.94 in the c-polarized spectrum, and 1.3 in the solution spectrum. The significance of this ratio will be discussed later.

(2) Charge-transfer Interaction.—Since the experimental results described above indicate unambiguously that the first and second charge-transfer bands appear not only in the solution spectrum but also in the absorption spectrum of the crystal, where we can exclude the possibility of the presence of orientational isomers, the explanation for their appearance has to be found in the nature of the charge-transfer interaction between pyrene and TNCE, without assuming any orientational isomers. For the sake of simplicity, we shall consider here the interaction in a pair, a pyrene molecule and a TCNE molecule, stacked face-to-face as they are in the crystal, instead of the interaction in the crystalline state.

As is well known, the wave function of the ground state of a loosely-bounded molecular complex, or a weak complex, can be expressed as follows:

$$\Phi_N = a\phi_0(D\cdot A) + b\phi_1(D^+\cdot A^-) \qquad (1)$$

where $\phi_0(D\cdot A)$ and $\phi_1(D^+\cdot A^-)$ are the wave function of the no-bond structure and that of the dative structure respectively. Usually it is assumed that the wave function of the dative structure is satisfactorily expressed by the wave function of the lowest charge-transfer state where an electron has been transferred from the highest occupied orbital of the donor to the lowest vacant orbital of the acceptor, while the interactions of all the other, higher charge-transfer states are negligible. This approximation has been widely applied with success in the discussions of the charge-transfer bands, the dipole moment, and so on.[10] It can easily be seen, however, that the appearance of the second charge-transfer band can not be understood in terms of this approximation. We have to take into account the second chage-transfer state in which the donating orbital is the second highest occupied orbital of the donor. The energies of the Hückel orbitals of pyrene and TCNE are schematically shown in Fig. 4.* The molecular orbitals are numbered in the way shown in this figure.

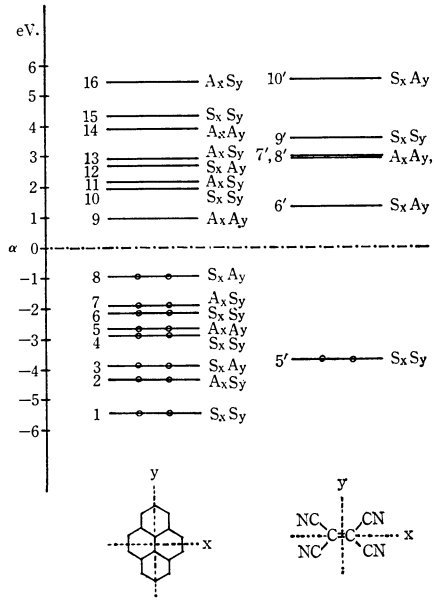

Fig. 4. The orbitals of pyrene and TCNE.

There can be a number of different charge-transfer states. In principle, all of them may interact with the no-bond state, and more or less contribute to the stabilization of the complex. The wave function of the ground state can be expressed generally as follows:

$$\Phi_N = a_0^0\phi_0(D\cdot A) + \sum_i\sum_j b_{ij}^0\phi_{ij}(D^+\cdot A^-) + \sum_k\sum_l c_{kl}^0\phi'_{kl}(D^-\cdot A^+) \qquad (2)$$

In Eq. 2, $\phi_{ij}(D^+\cdot A^-)$ is the wave function of a charge-transfer state where an electron has been transferred from the ith orbital of pyrene to the jth orbital of TCNE; $\phi'_{kl}(D^-\cdot A^+)$ is that of a state where an electron has been transferred from the lth orbital of TCNE to the kth orbital of pyrene, and a_0^0, b_{ij}^0 and c_{kl}^0 are the coefficients, generally $|a_0^0| \simeq 1$, $|b_{ij}^0| \ll 1$, $|c_{kl}^0| \ll 1$, for a weak complex such as pyrene-TCNE.

The energy of the ground state can be given by Eq. 3, using the approximation of the second-order perturbation theory:

10) See, for example, G. Briegleb, "Elektron-donator-acceptor-Komplexe" Springer-Varlay, Berlin, (**1961**).

* The value of β_{C-C} is assumed to be 2.16 eV.

$$W_N = W_0 - \{\sum_i\sum_j [H(0,ij) - W_0S(0,ij)]^2/(W_{ij} - W_0) + \sum_k\sum_l [H'(0,kl) - W_0S'(0,kl)]^2/(W'_{kl} - W_0)\} \quad (3)$$

where $H(0,ij) = \langle\phi_0|H|\phi_{ij}\rangle$, $H'(0,kl) = \langle\phi_0|H|\phi'_{kl}\rangle$, $S(0,ij) = \langle\phi_0 \mid \phi_{ij}\rangle$ and $S'(0,kl) = \langle\phi_0 \mid \phi'_{kl}\rangle$, and where W_0, W_{ij} and W'_{kl} are the energies of the ϕ_0,ϕ_{ij} and ϕ'_{kl} states respectively. If the wave functions of the complex are expressed in terms of the molecular orbitals of the donor and the acceptor, $S(0,ij)$ will be approximately equal to $\sqrt{2}\cdot S_{ij}$, where S_{ij} is the overlap integral between the donating and the accepting orbitals. Furthermore, it is possible to assume that $H(0,ij)$ is approximately proportional to $S(0,ij)$, and hence to S_{ij} also. Thus we can assume that $H(0,ij) - W_0S(0,ij) = -KS_{ij}$, where K is a constant. By using such approximations, Eq. 3 can be simplified to:

$$W_N = W_0 - K^2\{\sum_i\sum_j S^2_{ij}/(W_{ij} - W_0) + \sum_k\sum_l S'^2_{kl}/(W'_{kl} - W_0)\} \quad (4)$$

Therefore, the relative contribution of the interaction of a charge-transfer state, ϕ_{ij}, to the binding energy, $\Delta W = W_0 - W_N$, can be determined by comparing the values of $S^2_{ij}/(W_{ij} - W_0)$.

We have calculated S_{ij} as well as $S^2_{ij}/(W_{ij} - W_0)$ for a pair, a pyrene molecule and a TCNE molecule, stacked in the same way as they are in the crystal structure (Fig. 5). The distance between their molecular planes was taken to be 3.32 Å, the value determined by crystal structure analysis.

We have assumed the Hückel orbitals for the molecular orbitals of pyrene and TCNE, and the Slater functions with the orbital exponents of 1.64 and 2.13 a. u. for the 2p atomic orbitals of carbon and nitrogen respectively. It is known that a Slater function is not satisfactory for the tail of the atomic orbital, and it gives a markedly underestimated value in the calculation of an intermolecular integral.[11] In effect, the overlap integrals calculated in the present study will become nearly three times as large if the SCF atomic orbitals given by Roothaan, Clementi and Yoshimine[12] are used instead of the Slater orbitals. The use of a smaller orbital exponent has been recommended for the calculation of intermolecular integrals.[13] It can be shown, however, that the value of the overlap integral obtained by using SCF atomic orbitals is approximately proportional to the one obtained by using a Slater orbital for a given separation between the molecular planes of the donor and the acceptor which are stacked parallel to each other. Therefore, no essential difference is expected to occur in the estimation of the relative contributions of various charge-transfer states, even if SCF atomic orbitals are used, while the value of K is dependent on the atomic orbitals assumed. When Slater atomic orbitals are used, the value of K should be taken as 10—20 eV. in order to effect an agreement between the calculated binding energy and the observed one which is a few kcal./mol. The value of $W_{ij} - W_0$ was taken as equal to the energies of the first and second charge-transfer bands for the lowest charge-transfer state and the second one respectively. The values for the other states were estimated by using these values and the orbital energies.

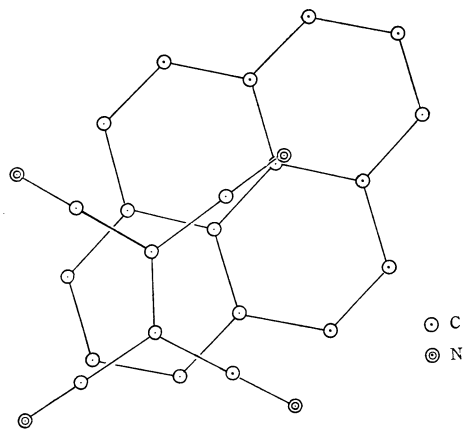

Fig. 5. The orientation of a pyrene molecule relative to the neighboring TCNE molecule in the crystal structure.

In Table II, the calculated values of S_{ij} and $S^2_{ij}/(W_{ij} - W_0)$ are given for 32 different charge-transfer states.* The charge-transfer states where the accepting orbitals are the 9′ orbital and the 10′ orbital of TCNE, and those where the donating orbitals are the 1′—4′ orbitals of TCNE, are omitted in this table because their contributions to ΔW are negligibly small. Generally, the lowest charge-transfer state is expected to play the most important role in the charge-transfer interaction. In the present case, this is the state where the donating orbital is the 8 orbital of pyrene and where the accepting one is the 6′ orbital of TCNE; we shall denote this state as [8→6′]. According to Table II, however, we have to give up such a preconception. The contribution of the lowest charge-transfer state to ΔW is by no means predominant in comparison with those of the other charge-transfer states. It can cover only 16 per cent of ΔW, while the contribution from the second charge-transfer state, [7→6′], is 19 per cent, and those

from the [5→6′] and [4→6′] states are both 14 per cent. It is thus revealed that the second charge-transfer state, as well as some of the much higher charge-transfer states, should be taken into account in discussions of the electronic states of the complex.

(3) **The Intensities of the Charge-transfer Bands.**—Corresponding to the expression of the wave function of the ground state given in Eq. 2, we can describe the wave function of a charge-transfer excited state associated with an electron transfer from the mth orbital of the donor to the nth orbital of the acceptor, as follows:

$$\Phi_E(mn) = a_0^{mn}\phi_0(D\cdot A) + b_{mn}^{mn}\phi_{mn}(D^+\cdot A^-) + \sum_{i\neq m}\sum_{j\neq n} b_{ij}^{mn}\phi_{ij}(D^+\cdot A^-) + \sum_k\sum_l c_{kl}^{mn}\phi'_{kl}(D^-\cdot A^+) \quad (5)$$

where $|a_0^{mn}|$, $|b_{ij}^{mn}|$ $(i\neq m,\ j\neq n)$, $|c_{kl}^{mn}| \ll 1$ and $|b_{mn}^{mn}| \simeq 1$. The transition moment of the charge-transfer excitation, $\Phi_E \leftarrow \Phi_N$, can then be approximately expressed by Eq. 6, neglecting all small terms and assuming that the dipole moment is zero in the no-bond state. The values of a_0^0 and b_{mn}^{mn} are taken as unity.

$$\mu(0, mn) = \langle\Phi_N|\mu|\Phi_E\rangle \simeq b_{mn}^0\langle\phi_{mn}|\mu|\phi_{mn}\rangle + \langle\phi_0|\mu|\phi_{mn}\rangle \quad (6)$$

where μ is the operator of the dipole moment. The dipole moment of the charge-transfer state, $\langle\phi_{mn}|\mu|\phi_{mn}\rangle$, is nearly the same for all the charge-transfer states; we shall denote it as μ_{CT}. We can also presume that the $\langle\phi_0|\mu|\phi_{mn}\rangle$ integral is roughly equal to $[S(0, mn)/2]\cdot\langle\phi_{mn}|\mu|\phi_{mn}\rangle$, according to Mulliken's approximation. Thus the following equations can be given for the transition moment:

$$\mu(0, mn) \simeq [b_{mn}^0 + S(0, mn)/2]\cdot\mu_{CT} \quad (7)$$

thus:

$$\mu(0, mn) \simeq [K/(W_{mn} - W_0) + 1/\sqrt{2}]\cdot S_{mn}\cdot\mu_{CT} \quad (8)$$

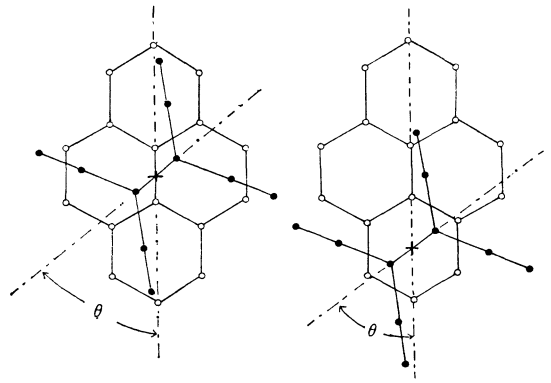
The ratio of the oscillator strength of the first charge-transfer band to that of the second one, f_1/f_2, can be roughly estimated by using Eq. 8. We obtained 0.8 for this ratio, assuming that $K \simeq 10$ eV. Since the observed value is 0.94 in the crystal spectrum and 1.3 in the solution spectrum, the agreement between the observed and the theoretical ratios seems satisfactory for such a rough approximation as we have made here.

We can predict that two charge-transfer bands associated with the charge-transfer states, [5→6′] and [4→6′], can be observed in the 25000—30000 cm^{-1} region with an oscillator strength comparable to the first charge-transfer band. The third band in the c-polarized spectrum could be due to these absorptions. The pyrene molecule has, however, ^1L_a and ^1L_b bands in this region. Therefore, we have to consider in this case the mixing of the local-excited states and the charge-transfer states. This problem will not be treated in this paper.

(4) **The Charge-transfer Bands and the Structure of the Complex.**—Hitherto we have assumed the orientation of the pyrene molecule to the TCNE molecule to be as it is in the crystal. However, the orientation could be different from this for the complex in solution. In the crystalline state, molecules would be arranged first of all in such a way that the crystal structure fulfills the condition of the closest packing. This leaves the possibility that molecules take an orientation

that is unfavorable for the charge-transfer interaction. On the other hand, molecules are supposed to take the most favorable orientation when they form a complex in a solution. It is worthwhile, therefore, to evaluate the binding energy associated with the charge-transfer interaction for various different orientations in order to ascertain the most stable structure.

Apparently the binding energy becomes quite small when the donor and acceptor molecules are not in close contact. We can safely ignore such a case, however, and can assume that the molecules are stacked face-to-face, so as to result in a large overlapping between their molecular orbitals. Then we have two variables; the one is the position of the symmetry center of TCNE relative to that of pyrene, and the other is the relative orientation of their molecular axes. We have made our calculation on the relative values of the binding energy, $\Delta W/K^2$, for the following two cases: [Model A], in which the symmetry centers are directly over each other (Fig. 6a), and [Model B], in which the relative positions of the centers are exactly the same as they are in the crystal structure (Fig. 6b). For each model, $\Delta W/K^2$ was evaluated by using Eq. 4 as a function of θ, the angle between the symmetry axes of the molecules, taking the 32 charge-transfer states into account. The results are shown in Fig. 7.



(a) Model A (b) Model B

Fig. 6. The models of pyrene-TCNE complex assumed for the calculation.

Interestingly, $\Delta W/K^2$ varies little with θ in either model. The difference between the largest value and the smallest one is less than 20 per cent of the mean value. This means that the rotation of the TCNE molecule around its symmetry axis perpendicular to the molecular plane would have a very low energy variation, less than 0.4 kcal./mol., as far as only the charge-transfer interactions are concerned. Therefore, we shall not be able to tell the value of θ for the most stable structure unless we have detailed information on other intermolecular interactions. This is a rather unexpected result, since we used to consider that the charge-transfer interaction would be the most strongly dependent on relative orientation of the molecules. Secondly, it may be seen in Fig. 7 that the value of $\Delta W/K^2$ is always larger in Model B than in Model A. This suggests that Model B is more acceptable for the stable structure than Model A.

The ratio of the oscillator strength of the first

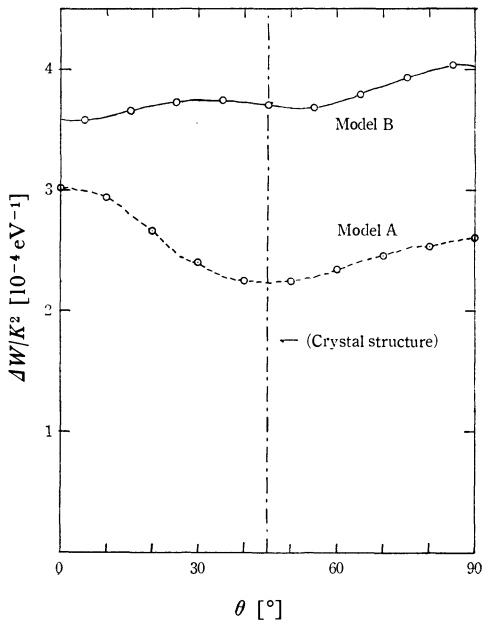


Fig. 7. The dependence of ΔW on the orientation of pyrene to TCNE.

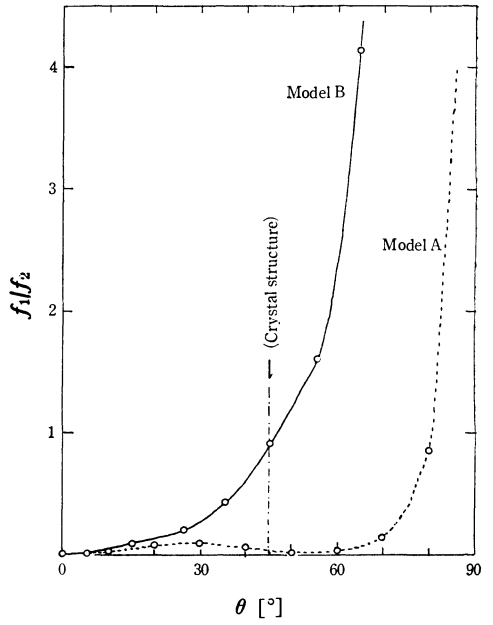

Fig. 8. The relation between the ratio of the oscillator strengths of the charge-transfer bands and orientation of pyrene to TCNE.

charge-transfer band to that of the second one may be theoretically estimated as a function of θ by means of Eq. 8. The results are shown in Fig. 8. It can be seen that the ratio varies markedly, depending on the θ value.

In the case of Model A, the f_1/f_2 ratio is very small except in the θ=80—90° region, where the magnitude of f_2 approaches zero. According to Eq. 8, the value of f_1 is smaller than 0.001 in this model; this is too small compared with the observed value, 0.02. On the other hand, f_1 and f_2 in Model B become comparable to each other in the θ=40—50° region, where the values of f_1 and f_2 are roughly estimated as 0.01, a value which is in agreement with the observed value. This structure corresponds to the one found in the crystal. Since the binding energy changes little with the θ value, we can not exclude the possibilities that the structures with different θ values co-exist, or that molecules rotate independently around their symmetry axes perpendicular to the molecular plane. In this case the oscillator strength, as well as the f_1/f_2 ratio, will be averaged over different values of θ. In Model A, the average f_1 value will be about 0.0005, and that of f_1/f_2, 0.06. Thus, it is impossible to explain the observed results with this model.

In Model B, however, the average value of f_1 is 0.01, and that of f_1/f_2, 0.9; these values are almost the same as those calculated for the orientation where the value of θ is fixed as 45°. The observed results can be explained well by means of this rotating model. Therefore, the following conclusions can be obtained from the results discussed above; (1) it is difficult to explain either the observed oscillator strengths of the charge-transfer bands or their ratio on the assumption of Model A, and (2) the oscillator strengths and their ratio can be reasonably explained using Model B if we assume either that θ=40—50°, or that the structures with different θ values co-exist with equal probability. In any case, it is Model B that seems more acceptable for the complex in solution.

Summary and Conclusion

We have shown, from the study of the polarized absorption spectra of the crystal of the pyrene-TCNE complex, that the first and second charge-transfer bands can be observed in the crystal spectra. A simple theoretical treatment has proved that the interactions of higher charge-transfer states make significant contributions to the stabilization of the complex. These interactions are by no means negligible; they thus should be taken into account in the discussions of the absorption spectra of the complex. If this has been done properly, the appearance of the multiple charge-transfer bands can be explained. We have pointed out the significance of the relative intensities of the first and the second charge-transfer bands for the purpose of ascertaining the structure of the complex.

We wish also to emphasize another important conclusion that has become clear in the present study. The structure of a charge-transfer complex has often been discussed by considering the symmetry properties of the highest occupied orbital of the donor and the lowest vacant orbital of the acceptor. However, this problem is not so simple. The interaction of the lowest charge-transfer state is not always predominant in the stabilization of the complex. When the interactions of the higher charge-transfer states are taken into account, however, the binding energy due to the charge-transfer interaction becomes rather insensitive to the change in the orientation of the molecular axes of the donor relative to those of the acceptor, provided that their molecular planes are parallel to each other and are in close contact. We can only predict the relative positions of the centers of the molecules in the case of the pyrene-TCNE complex. We have shown that the structure where the molecular centers are directly above each other is not likely to be the most stable structure because, in the first place, the binding energy will be relatively small in this case, and in the second place, the intensities of the observed charge-transfer bands can not be explained using this model. Thus, the relative positions of the centers as they are in the crystal seem to be acceptable also for the complex in solution. Although we have confined our discussion exclusively on the pyrene-TCNE complex, the general features of the conclusions, such as those on the origin of the multiple charge-transfer bands and on the nature of the charge-transfer interaction, can be extended to a number of the weak π-complexes that involve polycyclic aromatic compounds as the electron donors.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1850—1854 (1966)

The Activation of Titanium Dioxide as a Decontaminant for Radioactive Contamination

By Toshiko TAKAMI and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received November 19, 1965)

The decontamination efficiencies of treated and untreated titanium dioxide pastes were measured using ^{60}Co-contaminated surface of plastics, polyvinyl chloride. The titanium dioxides used were commercial titanium dioxide, hydrous titanium dioxide, titanium dioxide treated with sulfuric acid, and "Titanium Cake," an intermediate product of the titanium dioxide industry. Among these titanium dioxide decontaminants, titanium dioxide treated with sulfuric acid proved most effective in decontamination, even in neutral conditions, if activated properly. The optimum condition of activation was the 50% sulfuric acid treatment of commercial titanium dioxide at 50°C for 6 hr.

For the radioactive decontamination of a solid surface, we generally use radioactive decontaminants. These decomtaminants vary according to their purposes. In this connection, it is important to note that the residual contamination remaining even after a rough decontamination is often a matter of intense interest. Such a decontamination is often influenced by the nature and not by the amount of the decontaminant used. As for the decontaminants, such powdered substances as titanium dioxide,[1] alumina[1] and kaolin[2] are used. These substances are usually applied as pastes. Among these, titanium dioxide is comparatively effective and is widely used. However, little is known concerning its decontaminating action except for the facts that anatase is superior to rutile and the fresh precipitate is even more excellent.[1,3,4] However, it is troublesome to prepare a fresh precipitate from commercial titanium dioxide or a soluble titanium compound prior to each decontamination. It is, however, a usual practice in the preparation of an adsorbent to promote the adsorption capacity by the suitable treatment of its surface. Therefore, we desired to find a simple and effective method of activating a commercial titanium dioxide without complete dissolution, for the use as a decontaminant.

In the present investigation, the activation of titanium dioxide by sulfuric acid was undertaken for this purpose.

Experimental

Sample.—From the results of a preliminary experiment contaminating the solid surface of polyethylene, polystyrene and polyvinyl chloride, polyvinyl chloride was chosen as the test surface since it was comparatively more susceptible to contamination than the other specimens. A commercial product of polyvinyl chloride, 0.75 cm. thick and cut in a 2.5×2.5 cm. size, was used as the test piece. An aqueous solution of cobaltous chloride labeled with radioactive ^{60}Co was used as the contaminating solution, the concentration being 5.20×10^{-3} mol./l., and the specific activity, 19 c./mol. The titanium dioxide used as a decontaminant was a commercial product of the anatase type.

Experimental Procedure.—For the preparation of the contaminated sample, a test piece was soaked in a 0.5% solution of Epan 485 (a block copolymer composed of polyoxyethylene and polyoxypropylene, a Daiichi Kogyo Seiyaku product) to remove any oily contamination from the surface, rinsed with distilled water, and dried using filter paper. To contaminate the test piece, filter paper 2.0×2.0 cm. in size which had been soaked with 5 ml. of a radiaoactive $^{60}CoCl_2$ solution over a 24 hr. period, was placed on the sample for contamination. After an hour the filter paper was removed and the sample was immersed in water to rinse off the easily removable excess contaminant, the radioactivity was then measured using a Geiger-Müller counter (Aloka GP-1; window thickness: 1.4 mg./cm^2), with the sample placed 1 cm. below the counter tube. The amount of cobalt on the sample was calculated from this counting rate and the counting rate of a known amount of the cobaltous chloride, which was put in small droplets on a polyvinyl chloride sample and dried. Figure 1 shows the contamination remaining after such a treatment plotted against the time of washing. Here, the percentage of cobalt remaining on the surface was calculated from the counting rates observed for the test piece before and after the contamination. From this curve, it is difficult to distinguish between the contamination merely adhering to and that adsorbing on the solid surface. However, the initial, rapidly decreasing portion of the curve was

conveniently taken as due to the adhering contamination, and 1.5 minutes' washing was adopted for the preparation of a standard sample of the contamination. For further decontamination measurements, a 2 g. portion of titanium dioxide was mixed with 0.7 ml. of distilled water to make a paste, with which the sample was then put in close contact. After 5 min., the surface was rinsed with water for 30 sec. to remove the decontaminant, dried using filter paper, and the surface counting rate was measured. In these experiments, the pH of the paste was adjusted to 5.0—5.5 to avoid the co-operating action of hydrogen ions mentioned later. Also the mechanical action was not applied in order to study exclusively the chemical decontaminating action of the powder itself. In comparison with this, the decontamination experiment using distilled water without the powder was made in a shallow dish $2.4\times2.4\times0.3$ cm. in size. The sample was then similarly risned, and the amount of contamination was measured. Figure 2 shows the residual contaminations obtained with commercial titanium dioxide, hydrous titanium dioxide and distilled water without titanium dioxide, where the contaminations were plotted against the decontamination time. It may be seen in Fig. 2 that the residual contamination decreases rapidly in the initial one or two minutes, followed by a slow decrease in every case. Therefore, in the following experiments, the time of decontamination was properly chosen as 5 min., as has been mentioned above, after which the decrease in contamination was seen to be fairly slow. In discussing the effect of decontamination, the percentage of residual contamination,

$$\frac{\text{Residual contamination after 5 min.}}{\text{Initial contamination on standard sample}}\times 100$$

was used. All experiments were carrid out at room temperature (about 20°C).

Results

Decontamination by Commercial Titanium Dioxide and Hydrous Titanium Dioxide.— It is generally believed that freshly-precipitated titanium dioxide shows a strong decontamination power. Therefore, the hydrous titanium dioxide was prepared as follows.[5] About 24 g. of a commercial titanium dioxide was slowly dissolved in 60 ml. of concentrated sulfuric acid, stirred, and evaporated to dryness by heating it at 230°C for an hour. The product was then dissolved in 100 ml. of distilled water and filtered to remove any insoluble matter. The filtrate was neutralized with sodium hydroxide, and the precipitates formed were separated by decantation. It was then dried at 100°C for 24 hr., ground in a mortar, suspended in water, and heated to 70°C. The suspension was neutralized with hydrochloric acid, washed by repeated decantation using water, and dried. Thus, about 16 g. of neutral hydrous titanium dioxide was obtained.

Table I. Decontamination efficiency near neutral pH

Decontaminant	Initial contamination mol./4 cm² $\times 10^{10}$	Residual contamination mol./4 cm² $\times 10^{11}$	Residual contamination %
Water alone	1.11	3.31	29.8
Commercial titanium dioxide	1.92	3.95	20.5
Hydrous titanium dioxide	2.36	4.14	16.8
Titanium Cake A	1.88	4.76	25.3
Titanium Cake B	2.74	7.44	27.1

Table I shows the decontamination efficiency obtained for hydrous titanium dioxide, commercial titanium dioxide and water without titanium dioxide. It may be seen in this table that the addition of titanium dioxide to water evidently increases the decontamination efficiency and that the hydrous titanium dioxide shows a greater decontamination efficiency than the untreated one. The hydrous titanium dioxide reduced the remaining contamination to 50% of that obtained for the sample treated with distilled water alone. Therefore, hydrous titanium dioxide may be a better

5) W. B. Blumenthal, *Ceram. Age*, **51**, 320 (1948).

decontaminant than the untreated commercial product, which exhibits an 80% residual contamination, but it cannot be considered so effective a method of preparing a decontaminant, considering the concentrated sulfuric acid, the fairly high temperature and the exhaustive decantation required for the preparation of hydrous titanium dioxide.

Decontamination by Titanium Dioxide Treated with Sulfuric Acid.—We further attempted to prepare a more effective decontaminant by a more simple treatment of the commercial titanium dioxide powder, that is, by a mere surface treatment of titanium dioxide by sulfuric acid, without the total dissolution of the titanium dioxide.

Activation with Concentrated Sulfuric Acid.—About 20 g. of commercial titanium dioxide was treated with 20 ml. of concentrated sulfuric acid at 8, 20, 30, 50, 100 and 200°C for an hour, washed with water until it became neutral, and filtered. Table II shows the decontamination efficiencies for these samples. It may be seen in this table that the decontamination efficiency increased with the temperature of treatment, and that the maximum decontamination efficiency was attained above 50°C, regardless of the temperature. It was further confirmed that acid-treated titanium dioxide was more effective than hydrous titanium dioxide and, of course, than untreated titanium dioxide. In the above treatment, however, it was still troublesome to wash the treated sample with water alone, until it became neutral, although the time required for washing was remarkably shortened as compared with the case of the preparation of hydrous titanium dioxide mentioned above. Therefore, we further attempted to compare the difference in the decontamination efficiency of acid-activated (30°C, 1 hr.) titanium dioxide samples treated by the following three different methods of washing: washing until neutral with water alone; the addition of sodium hydroxide until the pH value of 2 was reached, followed by washing with water until neutral, and direct neutralization with sodium hydroxide. The results are shown in Table III.

TABLE II. EFFECT OF TEMPERATURE ON SULFURIC ACID TREATMENT OF TITANIUM DIOXIDE

Temp. °C	Initial contamination mol./4 cm² ×10¹⁰	Residual contamination mol./4 cm² ×10¹¹	Residual contamination %
8	6.74	9.99	17.4
20	2.21	2.58	11.7
30	2.78	3.30	11.0
50	1.44	1.30	9.0
100	8.07	7.38	9.1
200	7.25	7.21	9.8

TABLE III. EFFECT OF NEUTRALIZATION METHOD ON ACTIVATED TITANIUM DIOXIDE

Method	Initial contamination mol./4 cm² ×10¹⁰	Residual contamination mol./4 cm² ×10¹¹	Residual contamination %
Washing with water until neutral	2.78	3.30	11.0
Addition of NaOH until neutral	1.62	1.65	10.2
Addition of NaOH to pH 2 and washing with water	6.19	7.11	11.0

In this table, little difference in decontamination efficiency is seen amoung the treatments. From this, it may be concluded that direct neutralization by sodium hydroxide can be adopted to reduce remarkably the time of washing compared with mere washing with water. Therefore, the direct neutralization method was adopted in the following experiments.

Activation with Diluted Sulfuric Acid.—Attempt was then made to activate titanium dioxide with diluted sulfuric acid, since it is easier and desirable to use a diluted sulfuric acid than the concentrated one. The effects of the temperature and the time

TABLE IV. DECONTAMINATION EFFICIENCY OF ACTIVATED TITANIUM DIOXIDE UNDER VARIOUS CONDITIONS

Concn. of H_2SO_4 wt. %	Temp. °C	Time hr.	Initial contamination mol./4 cm² ×10¹⁰	Residual contamination mol./4 cm² ×10¹¹	Residual contamination %
15	50	6	2.45	2.88	13.0
15	50	24	1.52	1.90	12.5
30	50	6	2.44	3.12	13.1
30	50	24	2.76	3.92	10.7
40	50	6	3.48	3.77	10.9
40	50	24	3.26	3.26	10.0
50	50	6	1.15	1.07	9.3
50	30	1	2.86	5.25	18.4
50	30	3	1.61	1.97	12.2
50	30	6	1.60	1.91	11.9
50	30	24	0.937	1.04	11.1
75	30	1	5.60	6.99	13.9

of treatment on the decontamination efficiency under such conditions were examined. The results are shown in Table IV. From this table it may be seen that the temperature of treatment has a greater effect than the time of treatment above a 50% sulfuric acid activation. In the case of 30% sulfuric acid activation, the time of treatment is four times as long as that of the 50% sulfuric acid treatment needed to achieve the same decontamination efficiency. In the case of 15% acid activation, an even longer time is required.

Decontamination with "Titanium Cake."—The above experiments suggest that the so-called "Titanium Cake," that is, the wet intermediate product of the titanium dioxide industry, would be equally excellent as the acid-activated titanium dioxide in decontamination efficiency. Therefore, the decontamination efficiency was similarly examined with "Titanium Cake" with a pH value of about unity. The results are shown in Table I, where the pH of this paste was controlled with sodium hydroxide to 5.0—5.5. Contrary to the above expectations, "Titanium Cake" in a neutral-pH paste was little different in decontamination efficiency from distilled water alone, in spite of the wet nature of the "Titanium Cake."

Decontamination in an Acid Region.—It is further known that the decontamination efficiency of a decontaminant generally increases in an acid region, in addition to the action of the acid itself.[1] Therefore, the decontamination efficiencies of various titanium dioxide pastes were compared at a pH value of unity. The results are shown in

Table V. Decontamination efficiency in acid region

Decontaminant	Initial contamination mol./4 cm² $\times 10^{10}$	Residual contamination mol./4 cm² $\times 10^{11}$	Residual contamination %
Water alone	2.07	2.77	13.4
Commercial titanium dioxide	3.79	3.28	8.7
Activated titanium dioxide	9.14	2.90	3.2
Titanium Cake A	7.29	2.89	4.0
Titanium Cake B	8.80	5.00	5.7

Table V. Here, the pH values of "water alone" and commercial titanium dioxide were controlled with hydrochloric acid to unity, while acid-activated titanium dioxide was prepared under the optimum conditions of 50% sulfuric acid treatment at 50°C for 6 hr., followed by the addition of sodium hydroxide until a pH value of unity was reached, and the "Titanium Cake" with a pH value of unity was used without further control of the pH. These results confirm the view that the action of acid itself is remarkable in the decontamination, as can be seen from a comparison of the results of Tables IV and V. However, we can see a still further increase in the decontamination efficiency upon the addition of titanium dioxide; here again, acid-treated titanium dioxide proves to be best, as is to be expected.

Conclusion

It may be concluded from the results of the above investigation that an effective decontaminant for a surface of plastics contaminated with ^{60}Co is prepared by the surface treatment of titanium dioxide with sulfuric acid. The optimum conditions are treatment with 50% sulfuric acid at 50°C for 6 hr., but if we allow somewhat of a lowering of the decontamination efficiency, a 30% sulfuric acid treatment at 50°C for 24 hr. can also be recommended. These are more practicable conditions. The lowering of the temperature below 50°C resulted in a decrease in effect unrecoverable even by treatment over a prolonged time, this is in contrast to the decrease in efficiency produced by the lowering of the concentration of sulfuric acid which is recovered by a prolonged treatment. As for the pH dependence, it has been confirmed that the decontamination efficiency rises more remarkably in the acid region (pH unity) than near the neutral pH. "Titanium Cake," obtainable as a wet paste, is expected to be favorable for use as a decontaminant. The results of the measurements, however, show that in the neutral region, it is no more better than water without titanium dioxide, although it is nearly equal in its effect to acid-treated titanium dioxide in the acid region.

As for the titanium dioxide decontaminant, it is usually applied on a solid surface as a paste in 0.1 N hydrochloric acid. In this case the hydrogen ion and mechanical action during performance assist the decontaminating action, in addition tc the chemical action of titanium dioxide itself. However, it is not always allowable to lower the pH of the decontaminating solution and, further, to rub the surface effectively, because of the susceptibility to damage and the complicated shape of the solid surface. Also, the solid surface may often be scratched by rubbing, and thus, rendered to be liable to subsequent strong contamination. Consequencly, the titanium dioxide, even without such acid and mechanical actions, should have a good decontamination power in order to be effective under widely differing conditions of decontamination. In the present experiment, therefore, the mechanical effect of rubbing was avoided. The rubbing, if applied, would promote and make the decontamination efficiencies of almost all of the samples indistinguishable, but the subsequent contamination would become more marked. It

may be inferred, further, that the acid-treated titanium dioxide may be more highly recommended as a decontaminant than ordinary titanium dioxide, where a trace of residual radioactive contamination causes a serious problem, as in the case of skin contamination.

The authors are indebted to Mr. Tsutomu Seimiya of our laboratory for his assistance. They also thank Sakai Chemical Industry Co. Ltd., for titanium dioxide samples kindly given to them. The present study was made under the financial support of the Ministry of Education.

The Variation in Carbon-Halogen Bond Length with the Environment

By Arjun Singh RAJPUT and Suresh CHANDRA

Physics Department, University of Allahabad, Allahabad, India

(Received November 24, 1965)

The data on carbon-halogen bond lengths which have been obtained in recent years are summarized. It has been found that the interatomic distances corresponding to carbon-halogen bonds show a linear dependence on the number of adjacent atoms or bonds. Simple equations for these bond lengths are given to make it possible to estimate different carbon-halogen bond lengths empirically. It has been shown that this variation can be adequately explained on the basis of the hybridization effect. New values for the radii of the hybrid orbitals of carbon have been assigned and used to calculate the bond lengths in a variety of compounds. The agreement between calculated and experimental values is good.

As a result of the development of microwave spectroscopy for the study of the structure of the molecules, a large amount of information about interatomic distances in molecules has been accumulated. The accuracy of bond lengths determined experimentally depends upon the nature of the method used. The spectroscopic values for simple molecules are accurate to within ± 0.001 Å, while those for polyatomic molecules are somewhat less reliable. This accuracy has made it possible to derive relationships between bond lengths and various other bond properties. The dependence of the carbon-carbon and carbon-hydrogen bond lengths on the environment has been studied by many workers.[1-6] An analysis of these data has led to an empirical relationship for the C–C, C=C, C≡C and C–H bond lengths, which increase linearly with the increase in the number of adjacent bonds or atoms. This paper will deal with the carbon-chlorine, carbon-bromine and carbon-iodine bond lengths in simple polyatomic molecules. Recent experimental values for carbon-halogen bond lengths in polyatomic molecules seem to depend linearly on the environment. Simple empirical equations have been given to estimate the different carbon-halogen bond lengths. Many attempts[7-14] have been made to explain the variation in carbon-carbon and carbon-hydrogen bond lengths with the environment in terms of various descriptions of carbon atoms and their environment. It will be shown in this paper that the variation in carbon-halogen bond lengths can be explained on the basis of the hybridization effect. New values for the radii of the hybrid orbitals of carbon have been assigned, and these values have been used to calculate the bond lengths in a variety of compounds. It has been found that the calculated and the experimental values are in agreement.

A Summary of Carbon-Halogen Bond Lengths in Polyatomic Molecules.—The values of the bond lengths, the molecules from which they have been obtained, and the method by which they are determined are given in Table I. The quoted bond-length values may be supposed to be the best values available at the present time. Most of the

values have been obtained from microwave spectroscopic methods; they have been reported to be accurate to about ±0.005 Å. Some values not available from microwave spectroscopic methods involve larger experimental errors because they are not independent of some assumptions. Moreover, a small amount of uncertainity is also involved as a result of zero point vibrations, as the data pertain to the ground vibrational state and are not equilibrium bond lengths. A few values obtained from X-ray and electron diffraction data are accurate to only ±0.04 Å and require rectification by means of microwave spectroscopic methods.

It may be seen that the data of carbon-chlorine, carbon-bromine and carbon-iodine bond lengths confirm the earlier conclusions[4-6] that the bond lengths increase linearly with the increase in the number of adjacent bonds or atoms. This may easily be seen in Fig. 1, where the bond lengths

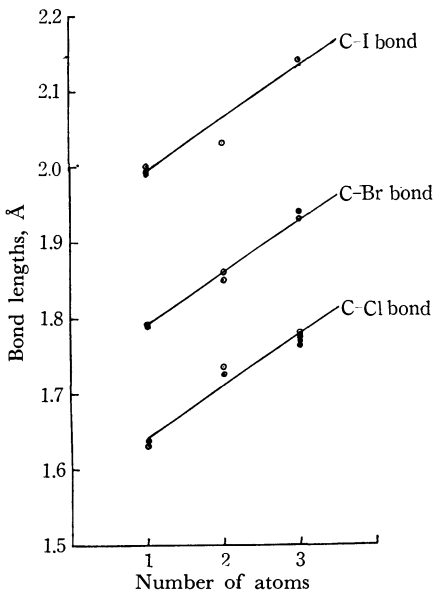

Fig. 1. A graph of carbon-chlorine, carbon-bromine and carbon-iodine bond lengths plotted against the number of adjacent atoms (or bonds).

are plotted against the number of adjacent bonds. In the figure all the bonds are equally well represented by lines with the slope of 0.070 n; i. e., all the lines are parallel. Most of the values for bond lengths lie within ±0.015 Å of the straight lines give by:

$$r(\text{C–Cl}) = 1.575 + 0.070\,n \quad (1)$$

$$r(\text{C–Br}) = 1.725 + 0.070\,n \quad (2)$$

$$r(\text{C–I}) = 1.925 + 0.070\,n \quad (3)$$

where n=1, 2 or 3.

Theory and Calculations

The properties of a bond depend upon the average number of electrons in it, their distribution among the molecular orbitals, and the concentration of the orbitals (as given by hybridization). Bond lengths are affected by changes in the hybridization of the orbitals forming the bond. Walsh[15] has pointed out that an increase in the s-character of the hybridization of carbon while passing from sp^3 to sp hybridization produces a stronger and shorter bond. Somayajulu[16] has shown that the strengths of the hybrid orbitals of carbon are in the order $sp > sp^2 > sp^3$; because stronger bonds are shorter, it is obvious that the radii of these orbitals will be in the order $sp^3 > sp^2 > sp$. Considering the CC "single bonds" it is evident from the accumulated structural data[6] that the best values for the lengths of the $\rangle$C-C$\langle$, $\rangle$C-C$\langle$ and ≡C-C≡ bonds are 1.534±0.005 Å, 1.472±0.005 Å and 1.378±0.005 Å respectively. If it is assumed that the $\rangle$C-C$\langle$, $\rangle$C-C$\langle$ and ≡C-C≡ bonds represent the tetrahedral (sp^3-sp^3) trigonal, (sp^2-sp^2) and digonal (sp-sp) bonds, we obtain for the radii of tetrahedral, trigonal and digonal carbon atoms the values of 0.767 Å, 0.736 Å and 0.689 Å respectively, which are very near to Lide's values (Ref. 14).

To account for the variation in carbon-chlorine, carbon-bromine and carbon-iodine bond lengths with the number of adjacent atoms or bonds, we have taken the covalent radii of chlorine, bromine and iodine to be 0.99, 1.14 and 1.33 Å respectively.[17] The values calculated for these bond lengths by the addition of the radii of hybrid orbitals of carbon and covalent radii of halogens and by applying of Schomaker-Stevensen correction[18] are given in Table I. Here the Schomaker-Stevensen coefficient has been given the value of 0.08.[17] It may be observed that in many instances the Schomaker-Stevensen correction gives a good agreement with the experimental values; in other instances, the additivity rule without this correction gives a better agreement. For example, the experimental values in ≡C-Cl, $\rangle$C-Br and ≡C-Br bands are fairly well reproduced by taking into account the Schomaker Stevensen correction, while in the case of $\rangle$C-Cl, $\rangle$C-Cl and $\rangle$C-Br bonds, the sum of the orbital radii gives a better agreement with the experimental values. It is not surprising that there are many exceptios to the Schomaker-Stevensen rule. In the case of carbon-iodine bonds, the Schomaker-Stevensen term becomes zero because the carbon and iodine have the same electronegativity value.

Discussion

It may be seen from the table that the bond lengths for a given bond environment in different molecules vary slightly. This slight variation in the carbon-chlorine and carbon-bromine bond lengths for a given bond environment in different molecules may be explained on the basis of the effect of an electronegative atom attached to the carbon atom which induces partial double-dond characters in other bonds formed by the carbon atom. It has been observed that the carbon-chlorine bond distance in $C_2H_2Cl_2$ is less than that in CH_3Cl, and that this bond distance in $CHCl_3$ is less than that in $C_2H_2Cl_2$. Brockway[19] has attributed this difference to the effect of the double-bond character of one carbon-chlorine bond induced by the partial ionic character of another carbon-chlorine bond formed by the same carbon atom. This effect of the induction of a double-bond character by the partial ionic character of another bond is much more important for fluorine-substituted molecules than for molecules containing chlorine, bromine or iodine. This is partially due to the well-known fact that the C–F bond has a larger ionic character than the other carbon-halogen bonds. This well-known shortening of carbon-fluorine bond lengths upon the addition of F-atoms is a different phenomenon and is often larger than the shortening of carbon-fluorine bond lengths with the number of adjacent atoms or bonds. Therefore, we have not included the carbon-fluorine bonds in this study.

We wish to express our most sincere gratitude to Professor Krishnaji for his kind supervision of the work. The financial assistance from the National Bureau of Standards, U. S. A., is also thankfully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1857—1861 (1966)

Molecular Vibrations and Structures of Polyalkyl Polysulfides. I. Polymethylene Disulfide

By Michiro HAYASHI, Yuji SHIRO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 4, 1965)

The polarized infrared spectra of oriented sheets of polymethylene disulfide were measured in the 4000—200 cm^{-1} region, and the fiber period was found to be 4.18 Å by X-ray diffraction. It was found that this polymer does not have the expected twofold symmetry axes intersecting the helical axis at right angles. The infrared active normal vibrations of two likely structural models were calculated by the use of a modified Urey-Bradley force field. The structure of polymethylene disulfide was concluded to be the GG'G conformation along the sequence of the $-S-CH_2-S-S-$ bonds of the 2_1 helical model.

Polyalkyl polysulfides $[(CH_2)_lS_m]_n$ are synthetic rubbers; one of them ($l=2$ and $m=4$) is commercially well known as Thiokol A. The present paper, the first of a series of reports on polyalkyl polysulfides, will deal with the molecular vibrations and the structure of polymethylene disulfide.

No studies have yet been reported on the molecular vibration and the structure of this substance. We therefore measured the polarized infrared spectra of an oriented sheet in the 4000—200 cm^{-1} region with a Perkin-Elmer 12C spectrometer. The fiber period of this substance was also measured by the X-ray diffraction method. The infrared active normal vibrations were calculated by the use of a modified Urey-Bradley force field, with the force constants transferred from the set obtained for simpler molecules with similar structures which we will report on separately.[1)]

Experimental

The sample was prepared by the reaction of dichloromethylene and an aqueous solution of sodium disulfide, using magnesium hydroxide as an emulsifying agent. About three times as much sodium disulfide as was really needed was used in order to prepare high-molecular-weight samples. The reaction products were purified by continuous extraction with absolute alcohol, so that impurities and lower-molecular-weight polymers were washed out. Solid sheets were prepared by

1) M. Hayashi, Y. Shiro and H. Murata, to be published.

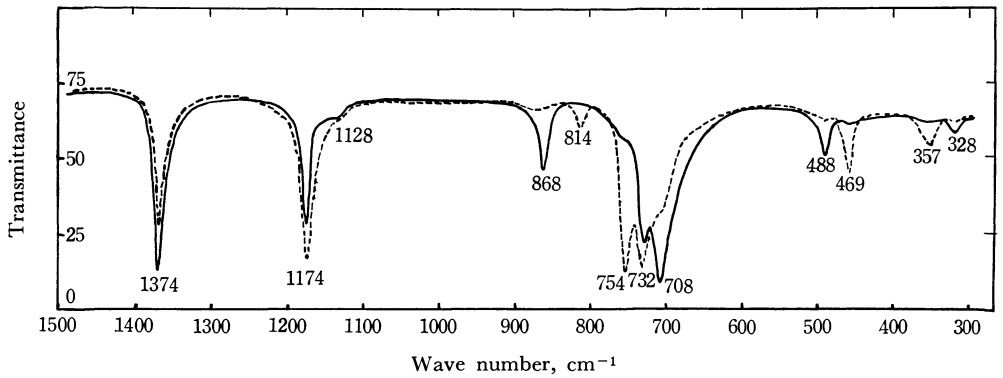

Fig. 1. Polarized infrared spectra of oriented film of polymethylene disulfide.
The solid curve was measured with the electric vector perpendicular and the broken curve with the electric vector parallel to the direction of orientation.

*1 The dichroism is shown as // and ∠ only for the infrared bands which exhibit clearly.
*2 The helical model is taken as 2_1.
*3 The helical model is taken as 4_1.
*4 Diagonal elements of potential energy distributions of the structural model GG'G are given in parentheses for mixed vibrations. (%)
*5 The phase differences are 180° for the B species of the GG'G form and 90° for the E species of the TGG form.
*6 The corresponding frequency is absent for GG'G since the phase difference is 180° for this case.

hot pressing, and then they were uniaxially oriented. The fiber period of the sample was determined to be 4.17 Å from the first and second horizontal layer lines on an X-ray rotation photograph. The orientation of the solid sheets was not, however, high enough for us to obtain more detailed information. The polarized infrared spectra were observed to be as shown in Fig. 1 and Table I.

Discussion

There are three internal rotation angles per chemical unit of polymethylene disulfide $[CH_2SS]_n$, one around the C–S bond and the other two around the C–S bonds. If we may assume that every chemical unit has the same structure, one set of these internal rotation angles is sufficient for specifying the structure of the entire helical polymer. Experimental data for simpler molecules, such as sulfur monochloride[2] and dimethyl disulfide[3], indicate that the only stable conformation for the S–S bond is the gauche form, with the internal rotation angle of 90°. On the other hand, for the C–S bonds, there are three stable forms, as evidenced by the experimental data for simpler molecules such as methyl ethyl sulfide.[4] These are the trans (the internal rotation angle of ca. 180°) and the two gauche conformations (ca. ±60°).

We will hereafter use symbols such as TGG for the models of the helical polymer, according to the system of notation used by Miyazawa et al.[5] For example, TGG implies that the internal rotation conformations along the series of –S–CH_2–S–S– bonds are trans, gauche and gauche. The two gauche conformations which are obtained by clockwise and counterclockwise 60° rotations from the cis form are denoted as G and G′ respectively, while the rotation around the S–S bond is conventionally fixed as G (the internal rotation angle of 90°) throughout the treatment.

As Table II shows, there are six different possible helical conformations. In the same table are shown the expected fiber periods, the twofold symmetry properties, the number of repeating units, and the number of helical turns per fiber period. Two conformations, TTG and GGG, may be discarded, however, since the expected fiber periods are too much longer than the experimental value of 4.17 Å.

The fiber period of the TG′G conformation is calculated to be much longer than the measured value and to be a highly distorted structure. Therefore, this conformation may well be discarded also. As for the molecular vibrations of this substance, it is expected that, in general, there are twenty-six or twenty-seven infrared active vibrations, which may be classified into two different groups (the groups belonging to the A and E species, or to the A and B species, respectively).[5]

There are fourteen pairs of degenerate vibrations belonging to the E species for the TGG structural model. For the G′G′G and GG′G models, there are thirteen non-degenerate B vibrations (with a phase difference of $\delta=180°$) since these models are 2_1 helices. The bands due to these E or B vibrations exhibit a perpendicular dichroism.

On the other hand, the thirteen vibrations due to the A species exhibit parallel dichroism. However, if the conformation has twofold symmetry axes intersecting the helical axis at right angles, the vibrations belonging to the A species may be classified into two groups, A_1 and A_2, and the vibrations belonging to the A_1 species become infrared-inactive. There will then be seven A_1 and six A_2 vibrations.

As for the S–S stretching mode, there are, in general, one A vibration and one pair of E vibrations. If twofold symmetry axes exist, this A vibration belongs to the A_1 species and, hence, is infrared-inactive.

As is shown in Fig. 1 and Table I, however, we have observed two infrared bands around 470 cm^{-1} which can easily be assigned to the S–S stretching mode on the basis of the assignments given to simpler molecules, and also on the basis of the normal vibration calculations (to be described later). Since we expect no other vibration in this region, the above assignments of the observed infrared bands are reliable. The band at 488 cm^{-1} exhibits a perpendicular dichroism; it may be assigned to the E vibrations. On the other hand, the band at 469 cm^{-1} exhibits a parallel dichroism; it may be assigned to the A vibration.

As for the C–S stretching modes, we have two A vibrations and two pairs of E vibrations. If twofold symmetry axes exist, one of the two A vibrations belongs to the A_1 species and, hence, becomes infrared-inactive. In the expected region, we have observed three bands, at 754, 732 708 cm^{-1}. The band at 708 cm^{-1} clearly exhibits a perpendicular dichroism, but the band at 754 cm^{-1} clearly exhibits a parallel dichroism. Therefore, we may assign them to the E and A vibrations respectively. The band at 732 cm^{-1} also exhibits a parallel dichroism, but this band appears also to have a perpendicular component which shows up as a shoulder of the band at 708 cm^{-1} when the electric vector is perpendicular to the direction of orientation. Therefore, we may assign the band at 732 cm^{-1} to the A vibration, which is overlapped by the E vibrations. This assignment is also supported by the results of the normal vibration calculations.

		(in md./Å)			
$\kappa(CH_2)$	0.0	$l(CH_2)$	−0.01	Y(CS)	0.054
Y(SS)	0.147	t	0.07	g	−0.05

p: CH bond streching interaction constant.
l: angle interaction constants between SCH.
Y: torsional constants.
t, g: trans and gauche angle interaction constants between SCH and CSS.

As for the SCS skeletal deformation mode, there is one A vibration, plus one pair of E vibrations. If twofold symmetry axes exist, this A vibration belongs to the A_1 species and, hence, becomes infrared-inactive. However, we have observed in the expected region the bands at 357 and 328 cm^{-1}, which exhibit a parallel and a perpendicular dichroism respectively.

The observation of the parallel bands due to the S–S stretching and SCS deformation vibrations indicates that the helical conformation of polymethylene disulfide does not have twofold symmetry axes intersecting the helical axis at right angles; we may therefore discard three structural models, TTG, GGG and G'G'G. Since TG'G has already been discarded, TGG and GG'G remain as the possible structural models for this substance. GG'G is a 2_1 helical model. Although TGG has two possibilities, 4_1 and 5_1, we think that the 4_1 helix is the most possible model because we have no example of 5_1 helices for other polymers. The values of the internal rotation angles were calculated so as to reproduce the measured fiber period. Two sets of values (195°, 70°, 90°, and 68°, −68°, 90°) were obtained for TGG and GG'G respectively on the assumption of the values of the bond lengths of r(C–S) = 1.81 Å and r(S–S) = 2.08 Å, and the valency angles of α(CSS) = 105° and α(SCS) = 109°28'.

We have also attempted to calculate the normal vibrations in order to confirm the assignments of the observed infrared bands, and also in order to examine whch structural model is more likely, TGG or GG'G.

For the calculation of the inverse kinetic energy matrix, values of r (C–H) = 1.09 Å and α(HCH) = 109°28' were used besides the molecular parameters described for TGG and GG'G structural models. For the potencial energy matrix, a modified Urey-Bradley force field was used. This force field includes the same modifications as those used for simpler molecules such as dithiamethyl methane.[1] The modification terms are: (1) the torsional terms with the force constants Y; (2) the C–H bond interaction terms with the force constants p; (3) the angle interaction terms between the SCH angles with the force constants l, and (4) the angle interaction terms between the HCS and CSS angles with the force constants t and g. The last terms are the same type of correction terms as the trans and gauche interaction terms of the $-CH_2-CH_2-$ groups. For pairs of H and S atoms in the trans and gauche forms in the $-H_2CSS-$ group, the force constants t and g are used respectively. The force constants were all transferred from the set obtained for such simpler molecules as dimethyl disulfide and dithiamethyl methane.[1] They are listed in Table III. The method developed by

Miyazawa et al.[5] was used for the calculation. The results are shown in Table I.

First, it was found that the calculated frequencies agree satisfactorily with the observed frequencies in the higher frequency region. Second, significant differences are seen between the calculated low frequncies for the two possible structural models. For the S–S stretching vibrations, the calculated frequencies are 510 and 514 cm^{-1} for TGG, but they are 475 and 485 cm^{-1} for GG'G, while the observed frequencies are 469 and 488 cm^{-1}. The frequency agreements are much better for the GG'G model in their absolute values and also in the splitting of the A and E components. The same conclusion may be drawn from the analysis of one of the skeletal deformation modes and the C–S stretching modes. For other vibrations, such as the CH_2 deformation and C–H stretching modes, we did not find any essential differences between the different structual models.

Therefore, we may conclude that the polymethylene disulfide chain most probably has the 2_1 helical conformation of the GG'G type.

The assignments of the observed infrared bands are shown in Table I, together with the potential energy distributions.

For such other polymers as polyoxymethylene, the structural model, GG'G, has not been taken into consideration because of the intrachain steric impact.[6] It should be noted, however, that the situation is somewhat different for the polymethylene disulfide chain. The GG'G model is possible for this polymer because of the long bond lengths, r(S–S) and r(S–C), which tend to relax such steric impact.

The authers wish to express their gratitude to Professor Masamichi Tsuboi, Dr. Akiko Y. Hirakawa and Dr. Yoshimasa Kyogoku of the University of Tokyo for the use of their infrared spectrometer, and Mr. Tohoru Chiba of the Toho Rayon Company for his X-ray diffraction analysis. We also wish to thank Professor Tatsuo Miyazawa of the Institute for Protein Research, Osaka University, for his encouragement and invaluable advice throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1861—1866 (1966)

Molecular Vibrations and Structures of Polyalkyl Polysulfides. II. Polyethylene Disulfide

By Michiro HAYASHI, Yuji SHIRO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 4, 1965)

The polarized infrared spectra of oriented sheets of polyethylene disulfide were measured in the 4000—200 cm^{-1} region; the fiber period was thus found to be 8.8 Å by X-ray diffraction. It is found that this polymer does not have twofold symmetry axes intersecting the helical axis at right angles. The infrared-active normal vibrations of the four likely structural models were calculated by the use of a modified Urey-Bradley force field. The structure of polyethylene disulfide was concluded to be the GGG'G conformation along the sequence of the $-S-CH_2-CH_2-S-S-$ bonds of the 3_1 helical model. This model is very similar to the structure of polymethylene disulfide reported in the previous paper. The above structure was then discussed in comparison with two models proposed previously (J. R. Katz, *Trans. Faraday Soc.*, **32**, 77 (1936); Y. Minoura, *J. Soc. Rubber Ind. Japan*, **28**, 399 (1955)).

In the previous paper,[1] we have reported on the molecular vibrations and the structure of polymethylene disulfide. As a continuation of the researches, we will deal with the molecular vibrations and the structure of polyethylene disulfide in the present paper. This is the second of a series of papers on polyalkyl polysulfides.

For polyethylene disulfide, Katz[2] reported the results of X-ray studies and proposed a structural model. Minoura,[3] in discussing the structure of this substance, found that the structural model proposed by Katz is not unique, but that several different structural models possibly have the measured fiber period.

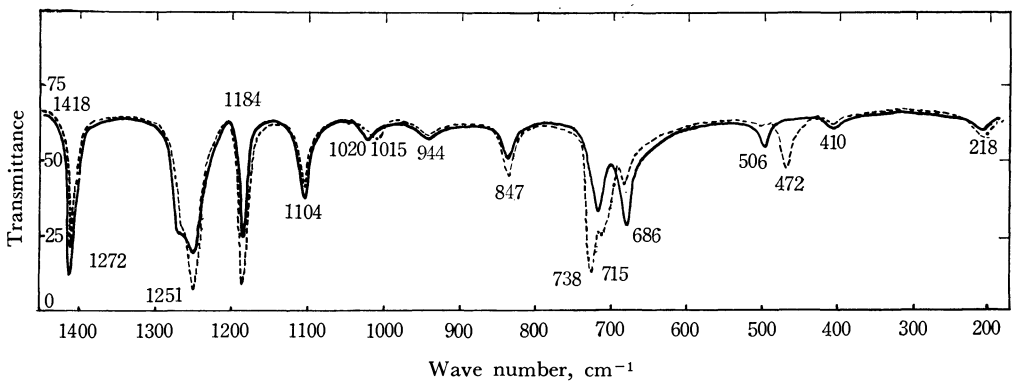

Fig. 1. Polarized infrared spectra of oriented film of polyethylene disulfide. The solid curve was measured with the electric vector perpendicular and the broken curve with the electric vector parallel to the direction of orientation.

We have measured the polarized infrared spectra of oriented sheets and have also remeasured the fiber period by X-ray diffraction. The infrared-active normal vibrations were calculated by the use of a modified Urey-Bradley force field, with the force constants transferred from the set obtained for simpler molecules with similar structures.[4]

Experimental

The sample used for the measurements was prepared by the reaction of 1, 2-dichloroethane and an aqueous solution of sodium disulfide, using magnesium hydroxide as an emulsifying agent. About a three-fold excess of sodium disulfide was used in order to obtain high-molecular-weight samples. The products were purified by continuous extraction with absolute alcohol; impurities and lower-molecular-weight polymers were thus washed out. The sheets were prepared by hot pressing and were subsequently uniaxially-oriented. The fiber period of the sample was measured as 8.8 Å on the X-ray rotation photograph; this value is in good agreement with the value reported previously.[2] The orientation of the solid sheets was not high enough for us to obtain more detailed information from the X-ray studies. The polarized infrared spectra of the oriented sheet were measured by a Perkin-Elmer 12C spectrometer; the results are shown in Fig. 1.

Discussion

There are four internal rotation angles per chemical unit of polyethylene disulfide $[-CH_2CH_2-SS-]_n$; one around the C–C bond, one around the S–S bond, and two around the two C–S bonds. As was described in the first paper of this series, the set of those four angles is sufficient to enable us to specify the structure of the entire helical polymer. As evidenced by the experimental data for simpler molecules,[5] there are three possible internal rotaion conformations around the C–C bond or the two C–S bonds, namely, the trans (180°) and the two gauche conformations (±60°), while the internal rotation angle around the S–S bond will be around 90°.

As in the previous paper, we will hereafter denote the structural models. For example, GTG'G is the structural model which consists of the gauche (60°), the trans (180°), the gauche prime (−60°) and the gauche (90°) internal rotation conformations along the sequence of the $-S-CH_2-CH_2-S-S-$ bonds. The angle around the S–S bond was fixed at 90° throughout the treatment.

As for molecular vibrations, it may be expected that, in general, there are twenty-two infrared active vibrations belonging to the A species. If the structural model has twofold symmetry axes intersecting the helical axis at right angles, these A vibrations can be classified into two groups (A_1 and A_2 species). We may expect a parallel dichroism for those vibrations, although the vibrations belonging to the A_1 species are infrared-inactive.

We have twenty-three pairs of degenerate vibrations belonging to the E species which exhibit a perpendicular dichroism. For 2_1 helical models, there are twenty-two B vibrations (with the phase difference of 180°) which give rise to perpendicular bands.

As for the S–S stretching mode, there is one A vibration and one pair of E vibrations. If twofold symmetry axes exist, the A vibration belongs to the A_1 species and, hence, becomes infrared-inactive. From the experimental data for such simpler molecules as dimethyl disulfide, we would expect, in the 500 cm^{-1} region, the bands due to

Y: torsion constants.
t, g: trans and gauche angle interaction constants for the CH_2-CH_2 groups.

the S-S stretching modes, but no other bands. As is shown in Fig. 1 and Table III, we have observed two infrared bands, at 506 and 472 cm^{-1}, which exhibit a perpendicular and a parallel dichroism respectively. This indicates that the molecular conformation of this substance does not have twofold symmetry axes intersecting the helical axis at right angles.

In Table I, we have listed seven possible structural models (without twofold symmetry axes) and the expected fiber periods. Of these structural models, we may discard two of them (TG'G'G and TG'GG) since their expected fiber periods are quite different from the observed values. The GG'G'G conformation is not a likely model either, since, for this conformation, the steric hindrance is very large.

Four structural models (TTGG, TGGG, GTG'G and GGG'G) remain as the 2_1, 3_1, 4_1 and 3_1 helical conformations respectively. The values of internal rotation angles were calculated so as to reproduce the measured fiber periods.

By the use of the bond length values of r(S-S)= 2.08 Å, r(C-S)=1.81 Å, and r(C-C)=1.54 Å, and the valency angles of α(CSS)=105° and α(SCC)= 112°, the sets of internal rotation angles, (165°, 170°, 52.6°, 90°), (166°, 63°, 52°, 90°), (73°, 196°, −73°, 90°) and (71°, 68,° −71°, 90°) were obtained for TTGG, TGGG GTG'G and GGG'G respectively. The first two structural models have trans and gauche C-S bonds, but the last two have gauche and gauche prime C-S bonds. As for the C-C bond, the first and third model are in the trans form, while the second and last are in the gauche form.

It is well-known that the CH_2 rocking frequencies of the $-CH_2CH_2-$ groups exhibit frequency differences characteristic of the conformation around the C-C bond. For example, in the case of 1, 2-dithiamethyl ethane, the frequency differences for the trans and gauche isomers are found to be 271 cm^{-1} and 118 cm^{-1} respectively. The difference for the trans isomer is always found to be much larger than for the gauche isomer.

For polyethylene disulfide, we may expect four infrared bands due to the CH_2 rocking modes, that is, two parallel bands belonging to the A species and two perpendicular bands belonging to the E species. Judging from the results of the normal vibration calculation, the bands belonging to the E species are possibly overlapped with the bands belonging to the A species for any

*1 The dichroism is shown as // and ∠ only for the infrared bands which exhibit clearly.
*2 The helical models are 2_1 for TTGG, 3_1 for TGGG and GGG'G.
*3 Diagonal elements of potential energy distributions of the structural model GGG'G are added in parentheses for mixed vibrrations. (%)
*4 This frequency is not existing since the phase difference is 180° for this model.

structural models, so that the dichroism of the band may not be expected to be high for the CH_2 rocking bands. In the region from 1050 to 700 cm^{-1}, we have observed seven infrared bands, at 1020, 1015, 944, 847, 738, 715 and 680 cm^{-1}. In the higher-frequency part of the region, we may also expect C–C stretching frequencies, while in the lower-frequency part of the region, we may also expect C–S stretching frequencies. Since we found C–C stretching frequncies around 1020 cm^{-1} for simpler molecules, such as 1, 2-ethanedithiol and 1, 2-dithiamethyl ethane, we may possibly assign the bands at 1020 and 1015 cm^{-1} to the C–C stretching frequencies. The band at 1020 cm^{-1} exhibits a highly perpendicular dichroism and so is assigned to the E species, whereas the band at 1015 cm^{-1} exhibits a highly parallel dichroism and is assigned to the A species.

We assign the band at 680 cm^{-1} to one of the C–S stretching frequencies, since this frequency is too low for the CH_2 rocking frequencies in comparison with the assignments given to simpler molecules. Since in no case are the C–S stretching frequencies higher than 750 cm^{-1}, we may assign the bands at 738 and 715 cm^{-1} to the C–S stretching frequencies also. We may assign the bands at 944 and 847 cm^{-1} to the overlapped CH_2 rocking frequencies. Their frequency difference is as great as 97 cm^{-1}, which is nearly equal to that for the gauche isomer of 1, 2-dithiamethyl ethane, This indicates that the conformation around the C–C bond of polyethylene disulfide is gauche; hence, the structural models TTGG and GTG'G may be eliminated from consideration.

We have calculated the infrared-active normal vibrations in order to confirm the assignments of the observed infrared bands, and also in order to examine which structural model is preferable, TGGG or GGG'G.

For the calculation of the inverse kinetic energy matrix, the bond length of $r(C–H)=109$ Å and the valency angle of $\alpha(HCH)=109°28'$ were used, besides the molecular parameters described above for TTGG, TGGG, GTG'G and GGG'G structural models. For the potential energy matrix, a modified Urey-Bradley force field was used. This force field includes the same modifications as were used for such simpler molecules as 1, 2-ethanedithiol and 1, 2-dithiamethyl ethane.[4] These modifications are: (1) torsional terms with the force constants Y, (2) C–H bond interaction terms with the force constants p, (3) angle interaction terms between the angles of one CH_2 group with the force constants, l, and (4) angle interaction terms between the angles of the CH_2–CH_2 group with the force constants t and g, which are usually called the trans and the gauche interaction terms.

The force constants were all transferred from the set obtained for simpler molecules. They are listed in Table II, while results are shown in Table III. The method developed by Miyazawa et al.[6] was used in the calculations.

First, from the calculation, it was found that the frequencies of the A and E vibrations due to the common vibrational modes, nearly coinciding except for the S–S stretching mode, some of the skeletal bending modes, and some of the torsional modes. Second, the calculated frequencies above 1000 cm^{-1} are not appreciably affected by the structural models, and the agreements between the observed and calculated frequencies are satisfactory for all structural models in this region. Third, the frequency differences of the two CH_2 rocking vibrations belonging to the same species exhibit behavior similar to that of simpler molecules; the trans conformation around the C–C bond produces a much larger frequency difference than that for the gauche conformation. From this reason too, as we have described before, we may discard the TTGG and GTG'G structural models from consideration.

Fourth, we found an appreciable frequency difference in the S–S stretching vibrations belonging to the A and E species for GTG'G and GGG'G, while the difference is very small for TTGG and TGGG. The observed S–S stretching frequencies and the difference in their A and E vibrations agree with the calculated frequencies of GTG'G and GGG'G much better than do the other models.

Furthermore, we found that the difference in the observed and the calculated frequencies of the CCS deformation vibration is much larger for the trans conformation of the C–C bond than that for the gauche conformation.

Therefore, we may conclude that the conformations of the –S–CH_2–CH_2–S–S– bond sequence are gauche, gacuhe, gauche prime and gauche; that is, the structural model of polyethylene disulfide is most probably the 3_1 helical model of the GGG'G type.

It may be seen in Table III that the calculated frequencies of two C–S stretching vibrations of both the A and E species do not agree very well with the observed frequencies. However, in previous papers on the vibrational assignments of such simpler molecules as 1, 2-dithiamethyl ethane, we have already pointed out that the calculated frequency differences of the two C–S stretching vibrations are much smaller than those of the observed values. We have concluded that this is due to imperfections in the force field; we therefore wish to modify the force field if sufficient observed data become available. In polyethylene disulfide

also, we see a similar situation. The assignments of the observed infrared bands are shown in Table III, together with the potential energy distributions.
